Structure
Radical scavenging activity

ABSTRACT

Polysaccharides of longan fruit pericarp (PLFP) were purified by gel filtration chromatography and methylated by methyl iodide. The structure of methylated PLFP was identified by gas chromatography/mass spectrometry. The results indicated that the percentages of methylated Ara, Glc and Gal increased gradually to a maximal value with increasing volume of methyl iodide. Methylation resulted in a decrease in the DPPH radical scavenging activity of PLFP, while the superoxide anion radical scavenging activity of PLFP decreased with increasing the degree of methylation. When the degree of methylation reached up to 47.4% or a higher value, a promoted effect on the generation of superoxide anion was observed. Furthermore, a high correlation coefficient between degree of methylation and superoxide anion radical scavenging activity of PLFP was determined, which indicated the important role of hydroxyl groups of monosaccharide units in the radical scavenging activity of PLFP.

1. Introduction

Longan (*Dimocarpus longan* Lour.) is an exotic subtropical fruit mainly planted in Southeast Asia, especially in China (Yang, Jiang, Wang, Zhao, & Sun, 2009). It is a desirable fruit gradually accepted by consumers over the world due to its sweet juicy mouthfeel and health benefits (Rangkadilok et al., 2007). In addition, the flesh, seed and pericarp of the fruit have been used as bioactive ingredients in traditional Chinese medicines for different treatments, such as improving women's health after childbirth and increasing the immunomodulatory capacity. Our previous work suggested that longan fruit pericarp tissue contained a large quantity of polysaccharides (Yang, Zhao et al., 2008). Thus, it is worthwhile to purify the polysaccharides from longan fruit pericarp and then evaluate their contribution to the pharmaceutical properties of the fruit.

In recent decades, plant polysaccharides have attracted a great deal of attention in the biomedical field due to their broad spectra of therapeutic properties and relatively low toxicity (Schepetkin & Quinn, 2006). A variety of bioactivities, such as antioxidation, immunomodulation, anti-tumour and hypoglycemic activity, have been confirmed for polysaccharides (Kardošová & Machová, 2006; Luk, Lai, Tam, & Koo, 2000). Plant polysaccharides have showed a strong antioxidant activity and can be explored as novel potential antioxidants (Tseng, Yang, & Mau, 2008). Some plant polysaccharides have been commercially developed into the important components of therapeutic drugs and skin care products (Deters, Dauer, Schnetz, Fartasch, & Hensel, 2001; Wang & Fang, 2002). It is well known that methylation of polysaccharides is a commonly used derivatization technique for the identification of polysaccharide structure (Kim, Reuhs, Michon, Kaiser, & Arumugham, 2006). It is also an effective method to modify the bioactivities and functions of natural products through partial derivatization of functional groups such as hydroxyl groups (Ouk, Thiebaud, Borredon, Legars, & Lecomte, 2002).

The antioxidant activity of polysaccharides of longan fruit pericarp (PLFP) and its structure has been investigated in a previous work (Yang et al., 2009). However, the relationship between PLFP structure and antioxidant activity is still unclear. In this study, PLFP was partially methylated to various extents. The DPPH and superoxide anion radical scavenging activities of the methylated PLFP were evaluated. The effect of methylation on the structure and radical scavenging activity of PLFP was also analysed.

2. Materials and methods

2.1. Plant materials

Fresh longan (*D.* longan Lour. cv. Shixia) fruit at the commercially mature stage were purchased from a local commercial market in Guangzhou, China. Fruit were selected for uniformity of shape and colour. The fruit pericarp was manually separated and collected.

2.2. Chemicals

Galactose, phenol and sulphuric acid were obtained from Guangzhou Reagent Co. (Guangzhou, China), while methyl iodide was purchased from Mingfeng Chemical Co. (Juzhou, China). 1,1′-Diphenyl-2-picrylhydrazyl (DPPH), nitroblue tetrazolium, riboflavin and methionine were purchased from Sigma Chemical Co. (St. Louis, MO, USA). All the other chemicals were of analytical grade.

2.3. Extraction and purification of PLFP

PLFP was extracted by hot-water following the method of Yang, Jiang, Zhao, Shi, and Wang (2008). Briefly, the lyophilised longan fruit pericarp tissues were pulverised. After passing through a 60-mesh stainless steel sieve, an aliquot (5 g) of the pericarp powder was extracted for 120 min with 100 ml of distilled water at 55 °C in a 150 ml conical flask. The extract was then filtered through a Whatman No. 1 paper (Whatman plc., Shanghai, China), and then concentrated to 25 ml at 65 °C using a vacuum rotary evaporator (BC-R203, Shanghai Biochemical Equipment Co., Shanghai, China). The proteins in the PLFP extract were removed by the Sevag reagent (Navarini et al., 1999), while protein content was estimated by Folin–Ciocalteu reagent using bovine serum albumin as standard (Lowry, Rosebrough, Farr, & Randall, 1951). After removal of the proteins from the PLFP extract, anhydrate ethanol (100 ml) was added and then maintained overnight at 4 °C to precipitate polysaccharides, which were finally obtained after centrifugation at 3860*g* for 15 min. The precipitated polysaccharides were collected and then dissolved in distilled water to a concentration of 2 mg/ml. The amount of polysaccharides was determined by the phenol-sulphuric acid method (Dubois, Gilles, Hamilton, Rebers, & Smith, 1956), by which the recovery of PLFP was expressed as mg galactose equivalents/g dry pericarp, while galactose was prepared in a serial of concentrations to make a standard curve for the PLFP calculation. Three milliliters of 2 mg/ml PLFP was loaded onto a Sephadex G-100 gel column (10 × 500 mm), and then eluted with 100 ml of distilled water at a flow rate of 0.5 ml/min. All the fractions were quantified for polysaccharide content and an elution profile was then drawn. The highest peak was collected and then lyophilised. It was subjected to methylation and radical scavenging activity analyses.

2.4. Methylation of PLFP

Methylation of PLFP was carried out by the method of Needs and Sevendran (1993) with minor modifications. The dried PLFP powder (10 mg) was dissolved in 5.0 ml of dimethyl sulfoxide at 60 °C before 200 mg of NaOH was added. The mixture was treated for 10 min using ultrasonic wave with an ultrasonic cleaner (KQ-300DE, Kunshan Ultrasonic Equipment Co., Kunshan, China, 40 kHz). After incubation for 1 h at 25 °C, methyl iodide at different volumes (0.1, 0.2, 0.4, 0.6 and 0.8 ml) were added to prepare partially methylated PLFP. The sample was kept for 1 h in the dark before 5.0 ml of distilled water was used to decompose the methyl iodide remained. The mixture was transferred into a dialysis bag with a molecular weight cut-off of 8000 Da, which was kept in distilled water. The water was changed every 6 h for four times. The methylated PLFP was concentrated at low pressure by a rotary evaporator (RE52AA, Yarong Instrument Co., Shanghai, China) and then freeze-dried.

2.5. Identification of PLFP structure

After hydrolysis of methylated PLFP (10 mg) with 10 ml of 2 M trifluoracetic acid, the methylated PLFP hydrolysate was dissolved in 5 ml of 0.2% (w/w) NaOH. Twenty milligrams of $NaBH_4$ was added to reduce the uronic acid. After 30 min of incubation at 40 °C, glacial acetic acid (100 μl) was added to terminate the reduction. The sample was dried at low pressure and then acetylated with 2 ml of acetic anhydride and 2 ml of pyridine. The reaction was maintained for 1 h at 100 °C. Two milliliters of distilled water was used to decompose the acetic anhydride remained. The acetylated derivatives were extracted with 4 ml of methylene chloride. A gas chromatography/mass spectrometer (GCMS-QP 2010, Shimadzu, Kyoto, Japan) was used to analyse the glycosidic linkage. The acetylated derivatives (1 μl) were loaded into a HP-1 capillary column. The split ratio was 50:1. The initial temperature of the column was 150 °C, which increased to 180 °C at 10 °C/min, then to 260 °C at 15 °C/min and finally held for 5 min at 260 °C. The injection temperature was 220 °C. The ion source of mass spectrometer was set at 200 °C. Helium was used as the carrier gas. Identification of monosaccharide derivatives was based on comparisons of their mass spectra with those recorded in the National Institute of Standards and Technology database. The contents of monosaccharide derivatives were quantified by the peak area normalisation method. The degree of methylation was calculated as the percentage sum of the methylated monosaccharides.

2.6. Assay of DPPH radical scavenging activity

The DPPH radical scavenging activity was measured by the method of Yang, Zhao, Shi, Yang, and Jiang (2008). The methylated PLFP was precisely weighted and dissolved in distilled water to obtain a final concentration of 100 μg/ml. Two milliliters of 0.2 mM DPPH in ethanol was added to 1 ml of the PLFP solution. The absorbance was measured at 517 nm after 20 min of incubation at 25 °C. Ethanol instead of DPPH was used for the control while distilled water instead of sample was used for the blank. The DPPH radical scavenging activity of the sample was calculated by the following equation:

$$\text{DPPH radical scavenging activity } (\%) = [1 - (A_{\text{sample}} - A_{\text{control}})/A_{\text{blank}}] \times 100$$

where A_{sample}, A_{control} and A_{blank} are the absorbances of sample, control and blank, respectively.

2.7. Assay of superoxide anion radical scavenging activity

Superoxide anion radical scavenging activity was determined by the method of Prasad et al. (2009) with some modifications. The methylated PLFP was dissolved in distilled water to obtain a final concentration of 100 μg/ml. One milliliter of 100 μg/ml methylated PLFP was mixed with 0.3 ml of 50 μM riboflavin, 0.3 ml of 0.13 M methionine and 0.3 ml of 510 μM nitroblue tetrazolium, and then 0.2 M phosphate buffer (pH 7.8) was added to obtain a final volume of 5 ml. The reaction solution was exposed to a fluorescent lamp with a power of 40 W for 20 min and the absorbance was then measured at 560 nm. The reaction mixture without sample was used as control. The superoxide anion radical scavenging activity (%) was calculated as (1 − absorbance of sample/absorbance of control) × 100.

2.8. Statistical analysis

Data were expressed as means ± standard deviations of three replicated determinations. One way of variance analysis was applied for determining significant difference at $P < 0.05$ between the results.

3. Results and discussion

3.1. Extraction and purification of PLFP

Hot water was used to extract the crude water-soluble polysaccharides from longan fruit pericarp. The crude water-soluble polysaccharide was determined to be 10.6 ± 0.7 mg galactose equivalents/g dry pericarp, which accounted for 93.3 ± 2.7% of the dry extract. In contrast, the protein content in the aqueous extract only accounted for 1.1 ± 0.1%, which was due to the removal by the Sevag reagent at the first step of purification. After the isolation and purification by the gel filtration chromatography, the major polysaccharide fraction was collected, which accounted for 65.4% (w/w) of the total PLFP (Yang et al., 2009).

3.2. Methylation of PLFP

Methyl iodide was used to form methoxyl group with glycoside units of PLFP molecular chain in this work. Table 1 shows the percentages of the methylated and unmethylated monosaccharide units. The structural analysis indicated that the purified PLFP without methylation contained 32.8% Ara, 17.6% Glc and 49.6% Gal. Due to the reduction by $NaBH_4$, the GalA residue was reduced to Gal and, thus, the percentage of Gal in this study represented the sum of Gal and GalA. The addition of 0.1 ml of methyl iodide led to the formation of methylated Ara (7.7%) and Gal (9%), but Glc did not change. Furthermore, the methylated Glc (3.8%) was formed when the volume of methyl iodide was up to 0.2 ml. By increasing the methyl iodide volume, the percentages of methylated Ara, Glc and Gal increased gradually. As shown in Table 1, when 0.6 ml of methyl iodide was used, the percentages of unaffected Ara, Glc and Gal were 5.3, 6.0 and 30.7%, respectively. However, a similar degree of methylation was observed when a larger amount of 0.8 ml of methyl iodide was used, with the percentage sum of unaffected Ara, Glc and Gal being 41.1%. This indicated that the degree of methylation had reached a maximum.

Hot water extraction is a commonly used method for polysaccharide extraction. The pectins and water-soluble hemicelluloses are easily prepared by this technique. In this work, the PLFP comprised of Ara, Glc, Gal and GalA, which belongs to the hemicellulose family. Natural polysaccharides have complex structures due to their heterogeneity comprising of different kinds of monosaccharide units and, thus, it is difficult to elucidate the relationship between structure and bioactivity (Yoshida, 2001). Methylation is an important sample preparation step for structural identification of complex polysaccharides (Jay, 1996). The general mechanism of polysaccharide methylation is based on the substitution of the proton from polysaccharide hydroxyl group with a methyl group. Two steps are involved: deprotonation of hydroxyl groups by NaOH and nucleophilic attachment of the alkoxyl ion to the methylation reagent. In complex polysaccharides, the reactivity of hydroxyl group relies on the intramolecular hydrogen bond interactions and steric effects (Ciucanu, 2006). This might explain the low methylation rate of Glc when 0.1 ml of methyl iodide was used in this work. From the methylation percentages obtained, Ara was more easily accessible to the methylation reagent, compared with Glc and Gal. The steric position of Ara in the PLFP chain might be responsible for this result.

3.3. DPPH radical scavenging activity

The DPPH radical scavenging activity of methylated PLFP and purified PLFP were determined to evaluate their antioxidant activities. As shown in Fig. 1, the DPPH radical scavenging activity of the purified PLFP was 22.1%, significantly ($P < 0.05$) higher than all the methylated PLFP samples. From the results obtained in this study, a high volume of methyl iodide represented a high degree of methylation for PLFP. By increasing the degree of methylation, the DPPH radical scavenging activity decreased. However, no further decrease was observed when the volume of methyl iodide increased in the range of 0.2–0.8 ml. The correlation coefficient between degree of methylation and DPPH radical scavenging activity was determined to be 0.72.

The DPPH radical scavenging activity is widely used to evaluate antioxidant ability in a relatively short time (Yuan et al., 2005). This method is based on the reduction of ethanolic $DPPH^-$ solution in the presence of a hydrogen donating antioxidant, leading to the formation of non-radical form DPPH–H. The polysaccharides have been proved to be able to reduce the stable DPPH radical to yellow diphenylpicrylhydrazine (Tsai, Song, Shih, & Yen, 2007), and the antioxidant activity of polysaccharides is highly related to their chemical structure (Rao & Muralikrishna, 2006). In this study, a good DPPH radical scavenging activity of purified PLFP was observed. As the hydroxyl group of the monosaccharide unit can donate proton to reduce the DPPH radical, the formation of a methoxyl group eliminates the hydrogen donating property of the monosaccharide unit. Therefore, the DPPH radical scavenging activity of PLFP decreased with enhanced methylation. Ara and Gal played important roles in the DPPH radical scavenging activity of PLFP. When 7.7% Ara and 9.0% Gal were methylated, a significant ($P < 0.05$) decrease in the DPPH radical scavenging activity was observed. With the further increase of the methylation degree, the DPPH radical scavenging activity of PLFP had no significant ($P > 0.05$) change. The highly reactive hydroxyl groups in the PLFP molecule are methylated more easily during the methylation reaction, compared with the other hydroxyl groups. When the volume of methyl iodide was 0.2 ml, it was hypothesised that most of the highly reactive hydroxyl groups were methylated. Therefore, further increase of the volume of methyl iodide could not decrease the DPPH radical scavenging activity of PLFP.

Table 1
Structural analyses of partially methylated PLFP and control*.

Monosaccharide units	Molar percentage					
	Control	Volume of methyl iodide				
		0.1 ml	0.2 ml	0.4 ml	0.6 ml	0.8 ml
Ara	32.8%	25.1%	18.4%	10.2%	5.3%	5.1%
Glc	17.6%	17.6%	13.8%	8.5%	6.0%	6.0%
Gal	49.6%	40.6%	37.5%	33.9%	30.7%	30.0%
Methylated Ara	0%	7.7%	14.4%	22.6%	27.5%	27.7%
Methylated Glc	0%	0%	3.8%	9.1%	11.6%	11.6%
Methylated Gal	0%	9%	12.1%	15.7%	18.9%	19.6%
Degree of methylation	0%	16.7%	30.3%	47.4%	58.0%	58.9%

* Control was the purified PLFP without methylation.

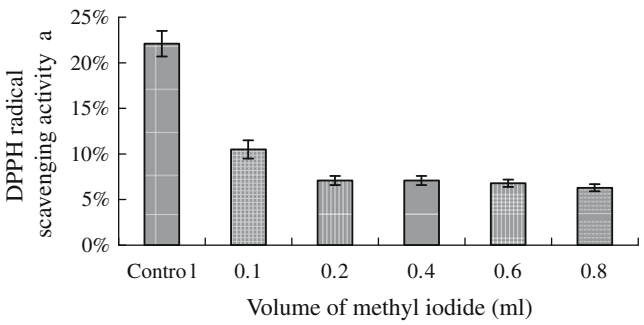

Fig. 1. DPPH radical scavenging activities of the methylated and purified PLFPs at 100 μg/ml.

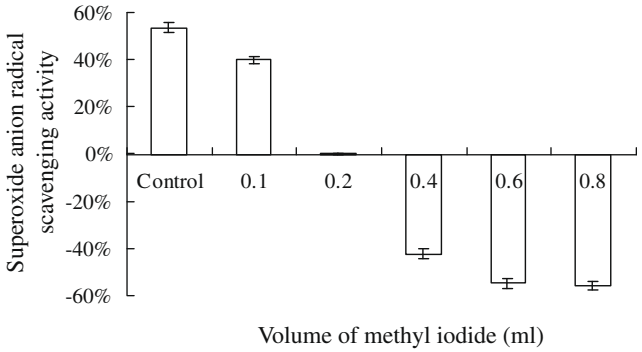

Fig. 2. Superoxide anion radical scavenging activities of the methylated and purified PLFPs at 100 μg/ml.

3.4. Superoxide anion radical scavenging activity

In this study, superoxide anion radical scavenging activity of the methylated PLFP and purified PLFP were measured to understand the effect of methylation (Fig. 2). The purified PLFP exhibited a superoxide anion radical scavenging activity of 53.6% and the activity decreased to 40% and 0.1% when 0.1 and 0.2 ml of methyl iodide were applied, respectively. The correlation coefficient between degree of methylation and superoxide anion scavenging activity was determined to be 0.98. Therefore, enhanced methylation led to a decrease in the superoxide anion scavenging activity of PLFP.

Superoxide anion radical ($O_2^{\cdot-}$) is one of reactive oxygen species (ROS) which are physiological metabolites (Jun et al., 2001). Many reports have indicated that exposure to ROS leads to damage to normal cell functions, such as enzyme inactivation, oxidative DNA damage (Halliwell, 1999) and induction of the aging process (Beckman & Ames, 1998). Polysaccharides can exert their capacities by scavenging ROS or preventing the generation of ROS. A nitroblue tetrazolium reduction system was used to determine the generation of superoxide anion radicals in this work. The general mechanism is the mixture of riboflavin and methionine can produce superoxide anion radicals, which reduce nitroblue tetrazolium from yellow to blue colour (Kang, 2008). From the results obtained in this work, an increase of degree of methylation would lead to a decrease of superoxide anion radical scavenging activity of PLFP, even promoting the generation of superoxide anion radicals when the volume of methyl iodide was in the range of 0.4–0.8 ml. It confirmed the importance of free hydroxyl groups of PLFP for its radical scavenging activity.

4. Conclusions

PLFP was purified by gel filtration chromatography and then methylated by different amounts of methyl iodide. In this study, no Glc unit was methylated while the percentage of methylated Ara and Gal were 7.7% and 9.0%, respectively, as 0.1 ml of methyl iodide was applied, and the percentages of methylated Ara, Glc and Gal increased gradually to the maximal point with increasing the methyl iodide amount, thereafter there was no further increase. The enhanced methylation resulted in the decreases in the scavenging activities of DPPH and superoxide anion radicals. As the effect of methylation on radical scavenging activity of PLFP was relatively complicated, further elucidation of the mechanism related to the group linkages of the PLFP should be conducted.

ABSTRACT

Effect of macerating enzymes on the polyphenol and polysaccharide composition of Merlot wines after 20 months of ageing was studied over three vintages (2004, 2005, 2006). Pectinase rich enzyme preparations, by degrading grape berry cell walls, led to a modification of the molecular weight distribution of polysaccharides released into the wines. Enzyme-treated wines contained more Rhamnogalacturonan II (RG-II) and less polysaccharides rich in arabinose and galactose (PRAGs) over the three vintages. The enzyme treatment also modified wine polyphenol composition. An increase of colour intensity, of derived pigments resistant to sulphite bleaching and of proanthocyanidins (condensed tannins) was observed, modulated by vintage effect. Principal Component Analysis of all the data indicated both vintage and enzyme effects. Beside the vintage effect separating the wine samples, the impact of enzyme treatment on wines was established for each year.

1. Introduction

Pectinase rich enzyme preparations obtained from *Aspergillus* sp. are commonly used in red wine-making to maximise the extraction of free-run juice during maceration, to aid in clarification and filtration, and to facilitate the processes (Canal-Llaubères, 1993). Pectinases act on the pectic substances which occur as the structural polysaccharides in the middle lamella and primary grape cell wall (Pinelo, Arnous, & Meyer, 2006). The polysaccharidic fraction of wines includes polysaccharides rich in arabinose and galactose (PRAGs) such as type II arabinogalactan-proteins (AGPs) and arabinans, Rhamnogalacturonans (RG-I and RG-II) coming from the pecto-cellulosic cell walls of grape berries (Doco & Brillouet, 1993; Pellerin et al., 1996; Pellerin, Vidal, Williams, & Brillouet, 1995; Vidal, Williams, Doco, Moutounet, & Pellerin, 2003), and mannoproteins (MPs) released by the yeasts during fermentation (Llaubères, Dubourdieu, & Villettaz, 1987; Waters, Wallace, Tate, & Williams, 1993). The structure and amounts of polysaccharides released in wines depend on the wine-making process and can be modified by enzyme treatment (Ayestaran, Guadalupe, & Leon, 2004; Doco, Williams, & Cheynier, 2007; Guadalupe, Palacios, & Ayestaran, 2007). Polysaccharides are one of the main groups of macromolecules of wine. They have been thoroughly studied because of their technological and sensory properties in wines. They play a role in the colloidal stability of wines through their ability to interact and aggregate with tannins. Polysaccharides do not prevent initial tannin aggregation but they influence particle size evolution (Riou, Vernhet, Doco, & Moutounet, 2002). RGII enhances tannin particle size, suggesting co-aggregation between RGII and tannins. It has been shown to decrease astringency in wine-like model solutions (Vidal et al., 2004) and is also known to inhibit hydrogen tartrate crystallisation (Gerbaud et al., 1996). The effect of enzymes on wine polysaccharide composition has been already studied (Doco et al., 2007): an increase of RG-II and a decrease of PRAGs were observed, along with a particular modification of AGPs, with loss of their terminal arabinose residues. Addition of macerating enzymes to the mash is also commonly performed to increase the extraction of phenolic compounds, and especially anthocyanins which are the red pigments of grapes, and thus to enhance wine colour intensity. However, studies on the effect of enzymes on wine colour and anthocyanin content have led to conflicting results (Sacchi, Bisson, & Adams, 2005): some publications have shown an increase of anthocyanins (Kelebek, Canbas,

doi:10.1016/j.foodchem.2009.04.130

Cabaroglu, & Selli, 2007; Revilla & Gonzalez-SanJose, 2003) or an increase of colour (Bakker, Bellworthy, Reader, & Watkins, 1999; Ducruet, An, Canal-Llauberes, & Glories, 1997), while others have reported a decrease of anthocyanins (Wightman, Price, Watson, & Wrolstad, 1997) or of colour (Bautista-Ortin, Martinez-Cutillas, Ros-Garcia, Lopez-Roca, & Gomez-Plaza, 2005). These discrepancies may be due to differences in grape polyphenol compositions, in their extraction rates into the wines, and in their reactions in wine, depending on many parameters, such as the cultivar, the maturity of grape berries, and the wine-making techniques. Indeed, the colour of red wine is not only due to anthocyanins extracted from the grape skins but also to various products formed during wine-making and ageing. In particular, tannins (i.e. proanthocyanidins, which are oligomers and polymers of flavan-3-ols such as catechins) that play a significant role in the taste of wines (Cheynier et al., 2006) and contribute to the colour stability of red wines as they react with anthocyanins to form derived pigments such as tannin–anthocyanin and anthocyanin–tannin adducts (Fulcrand, Atanasova, Salas, & Cheynier, 2004; Salas, Fulcrand, Meudec, & Cheynier, 2003). Tannin extraction is modulated by their interactions between them and with polysaccharides. In particular, it can be impeded by their adsorption on polysaccharides of the cell and vacuole walls (Renard, Baron, Guyot, & Drilleau, 2001). The effect of macerating enzymes on tannin concentration has been evaluated using a precipitation method (Romero-Cascales, Fernandez-Fernandez, Ros-Garcia, Lopez-Roca, & Gomez-Plaza, 2008), and from absorbance measurements at 280 nm performed directly on wines (Kelebek et al., 2007) or after fractionation of wine proanthocyanidins (Bautista-Ortin et al., 2005): an increased extraction of tannins was commonly observed. However, to our knowledge, no information is available on the effect of enzyme treatments on wine proanthocyanidin composition. Methods based on acid-catalysed cleavage in the presence of a nucleophilic agent (thiolysis, phloroglucinolysis), followed by HPLC analysis of the resulting depolymerisation products, have been developed to determine the quantitative and qualitative composition of wine proanthocyanidins. Their application has enabled the characterisation of seed (Prieur, Rigaud, Cheynier, & Moutounet, 1994), skin (Souquet, Cheynier, Brossaud, & Moutounet, 1996) and pulp (Mane et al., 2007) proanthocyanidins, thus making it possible to monitor their extraction into the wine (Morel-Salmi, Souquet, Bes, & Cheynier, 2006) and to establish relationships between tannin composition and astringency (Vidal, Francis et al., 2003). In this study, the effect of macerating enzymes on the polysaccharide and polyphenol composition and the colour of Merlot wines was determined over three vintages. Due to their importance in red wine quality, proanthocyanidin quantitative and qualitative compositions were determined by phloroglucinolysis.

2. Materials and methods

2.1. Grape materials

Raw materials for this study were grapes from *Vitis Vinifera* var. Merlot grown in an experimental parcel located near Bordeaux in Southern France and harvested at maturity (Table 1) over three vintages (2004, 2005 and 2006). Analyses at harvest [reducing sugars (RS) measured by a colorimetric method (OIV, 2005), total acidity (TA), weight of grape berries (W), pH, anthocyanins at pH 3.2 determined by Glories's method (Ribéreau-Gayon, Glories, Maujean, & Dubourdieu, 2004) (ApH3.2), absorbance at 280 nm (DO280)] were performed by SARCO (Laffort laboratory, France).

2.2. Preparation of trials

One hundred and seventy kilograms of grapes, representive sampling of the parcel, were destemmed and crushed, and distributed into 200 l stainless steel tanks. Bisulphite (6 g/hl) was first added. After homogenisation, different enzymatic preparations were added: enzyme A (Vinozym Vintage FCE, Novozymes, Denmark, a preparation of pectinases, mainly containing polygalacturonase purified from cinnamoyl esterase activity for red wine-making) was applied at 3.5 g/100 kg either alone or together with enzyme B (Vinoflow FCE, Novozymes, Denmark, a purified preparation of pectinases and beta-glucananses for red wine maturation) at 5 g/hl. Abbreviations used for trials are the following: control wine (control); enzyme A (A); enzymes A and B (AB), vintages: 2004 coded 04, 2005 coded 05, 2006 coded 06.

2.3. Wine-making

After 12 h of maceration at 12 °C, all fermentations were started by implanting Excellence SP (commercial yeast, Lamothe-Abiet, Bordeaux, France) at 20 g/hl and were carried out in 200 l stainless steel tanks equipped with temperature control enabling to regulate fermentation kinetics. Alcoholic fermentation started at 15 °C; the temperature was allowed to rise during fermentation and was then maintained at around 24–25 °C. When alcoholic fermentation was finished (11 days), the free-run juice of each trial was transferred to one 200 l tank. After devatting, the young wines were kept at 20–21 °C to favour malolactic fermentation using thermoregulation. Freeze dried bacteria culture was inoculated at 1 g/hl to induce malolactic fermentation. Wines were filtered after 6 months of ageing on clarifying 20×20 cm cellulose-Kieselguhr Seitz K200 plates prior to bottling. Wine samples were stored in the wine experimental cellar until analysis. All wines were analysed after the same period of ageing, i.e. 20 months after the end of alcoholic fermentation.

2.4. Preparation of total soluble polysaccharides of wines

The wine polysaccharides were isolated as previously described (Vidal, Williams et al., 2003). Wine (2.5 ml) was evaporated in centrifugal evaporator (EZ-2, Genevac®, Ipswich, UK). The residue was dissolved in 0.5 ml of water to obtain wine concentrated five times. Ethanol (2.66 ml, 95%) containing 0.5% HCl was added to obtain a final concentration of 80% ethanol. After one night at 4 °C, wine polysaccharides were precipitated and the supernatant was eliminated after centrifugation (10 min, 15,000 rpm). The pellet that corresponds to total wine colloids was dissolved in 1 ml of H_2O (Millipore). The oligosaccharides and salts contained in the total colloids were eliminated by retention on a column (4 ml) of an

ion exchange mixed resin (Mix Bed Resin AG 501-X8, Bio Rad); wine polysaccharides, not retained, were eluted by 2.5 bed volumes of H_2O. Total soluble polysaccharides were obtained after the freeze drying of water eluted materials.

2.5. Analysis of polysaccharides

The molecular weight distribution of the wine polysaccharides was determined by high-performance size-exclusion chromatography (HPSEC) using a system equipped with a 234-Gilson sampling injector (Roissy, France), a LC-10 AS Shimadzu pump (Kyoto, Japan). HPSEC elution was performed on two serial Shodex Ohpak KB-803 and KB-805 columns (0.8 × 30 cm; Showa Denkko, Japan) connected to a ERC-7512 refractometer (Erma, Japan) at 1 ml/min flow rate in 0.1 M $LiNO_3$. The apparent molecular weights were deduced from the calibration curve established with a pullulan calibration kit (P-400, M_W = 380,000 P-200, M_W = 186,000; P-100, M_W = 100,000; P-50, M_W = 48,000; P-20, M_W = 23,700; P-10, M_W = 12,200; P-5, M_W = 5800; Showa Denko K.K., Japan). The calibration equation was log $M_W = 28.321 - 1.04 \times tR$ (tR = column retention-time at peak maximum, and $r^2 = 0.997$). Neutral monosaccharides were released after hydrolysis of wine polysaccharides with 2 M trifluoroacetic acid (75 min at 120 °C) (Albersheim, Nevins, English, & Karr, 1967). They were then converted to the corresponding alditol acetate derivatives by reduction and acetylation and quantified by GC analysis (Harris, Henry, Blakeney, & Stone, 1984) using a fused silica DB-225 (210 °C) capillary column (30 m × 0.32 mm i.d., 0.25 μm film) with H_2 as the carrier gas on a Hewlett–Packard Model 5890 gas chromatograph. The different alditol acetates were identified on the basis of their retention time by comparison with standard monosaccharides. Neutral sugar amounts were calculated relative to the internal standard (myo-inositol). Polysaccharide composition of each wine was estimated from the concentration of individual glycosyl residues, determined by GC after hydrolysis, reduction, and acetylation, that are characteristic of the known wine polysaccharides as previously described (Vidal, Williams, O'Neill & Pellerin, 2001). The calculation of the wine polysaccharide concentrations takes account of the composition of characteristic monosaccharides as well as hydrolysis yield (Doco, Quellec, Moutounet, & Pellerin, 1999).

2.6. Sample preparation and analysis of wine polyphenols

2.6.1. Analysis of anthocyanins and tannin–anthocyanin dimer adducts

Anthocyanins and tannin–anthocyanin dimer adducts were analysed by direct injection of wines into the HPLC system. HPLC–DAD analyses were performed using a Waters 2690 system equipped with an autosampler system, a Waters 996 photodiode array detector, and a Millenium 32 chromatography manager software (Waters, Milford, MA). Separation was achieved on a reversed-phase Atlantis dC18 column (250 × 2.1 mm i.d., 5 μm packing) protected with a guard column of the same material (20 × 2.1 mm i.d., 3 μm packing) (Waters, Milford, MA). The elution conditions were as follows: 0.250 ml/min flow rate; oven temperature 30 °C; solvent A, water/formic acid (95/5 v/v); solvent B, acetonitrile/water/formic acid (80/15/5 v/v/v); elution began isocratically with 0% B during 5 min, then continued with linear gradients from 0% to 10% B in 20 min, from 10% to 20% B in 15 min, from 20% to 45% B in 15 min, from 45% to 60% B in 15 min, from 60% to 80% B in 5 min, followed by washing and re-equilibration of the column. The injection volume for all samples was 5 μl. A calibration curve was established using malvidin 3-*O*-glucoside from Extrasynthese (Genay, France) to quantify red pigments at 520 nm as equivalent malvidin 3-*O*-glucoside.

2.6.2. Analysis of tannins

Tannins were analysed by HPLC after acid-catalysed cleavage in the presence of excess phloroglucinol as previously described (Kennedy & Jones, 2001). The protocol was adapted for analysis of wine tannins as follows. Wine (4 ml) was evaporated in centrifugal evaporator (EZ-2, Genevac®, Ipswich, UK). The residue was dissolved in 4 ml of water/acetic acid (98/2 v/v) and 1 ml was applied on a C-18 solid phase extraction cartridge (Waters, Vac tC18 3cc) using the RapidTrace®SPE workstation (Caliper Life Sciences, Hopkinton, MA). Sugars and organic acids were eluted with 5 ml of water/acetic acid (98/2 v/v) and phenolic compounds recovered with 8 ml of methanol. Methyl paraben (2 g/l) was added as an internal standard. An eluent volume of 8 ml was evaporated to dryness under vacuum, redissolved in 200 μl of MeOH containing 0.2 N HCl, 50 g/l phloroglucinol, and 10 g/l ascorbic acid and heated for 20 min at 50 °C. Then, an equivalent volume of aqueous 200 mM sodium acetate was added to stop the reaction. Released terminal subunits and extension subunit-phloroglucinol adducts were analysed by HPLC using a Waters 2690 system with a reversed-phase Atlantis dC18 column (Waters, Milford, MA; 5 μm packing, 250 × 4.6 mm i.d.) protected by a guard column of the same material (20 × 4.6 mm i.d.; Waters, Milford, MA) and with a Securityguard™ cartridge C18 (Phenomenex, Torrance, CA; 4.0 × 3.0 mm i.d.). The mobile phase was a gradient of water/acetonitrile/formic acid (80/18/2 v/v/v; solvent B) in water/formic acid (98/2 v/v; solvent A), at a flow rate of 1 ml/min at 30 °C. Proportions of solvent B were as follows: 0–5 min with 0% B; 5–35 min, 0–10%; 35–70 min, 10–20%; 70–75 min, 20–100%; and 75–80 min, 100–0%. The injection volume for all samples was 10 μl. The proanthocyanidin units were detected by a Waters 996 photodiode array detector and quantified from peak areas at 280 nm using external calibration with known concentrations of flavan-3-ol monomers from Sigma (Saint Louis, MO) and flavan-3-ol-phloroglucinol adducts, purified in the laboratory. Each analysis was performed in triplicate. These analyses gave access to total proanthocyanidin content, their mean degree of polymerisation (mDP), and the percentage of each constitutive unit (i.e. catechin, epicatechin, epicatechin gallate (%gal), epigallocatechin (%egc). The mDP was calculated as the ratio between the summed molar concentrations of all released constitutive units and the summed molar concentrations of terminal constitutive units.

2.7. Spectrophotometric measurements

Absorbance measurements were made with a SAFAS® UV mc2 spectrophotometer (Monaco) and colour indices were deduced from these absorbance measurements as previously described (Atanasova, Fulcrand, Cheynier, & Moutounet, 2002; Glories, 1984; Somers & Evans, 1977). All the absorbance measurements were converted to a 10-mm light path cell and a dilution of 1 before calculating indices. Absorbance values at 420, 520, and 620 nm were measured, 30 min after addition of acetaldehyde, in a 1-mm light path cell. Hue (H) was calculated as A420/A520 and colour intensity corrected of bisulphite (CIcorr) as A420 + A52O + A620. Wine pigments corrected of bisulphite at wine pH (WPcorr) was defined as the absorbance at 520 nm, 30 min after addition of acetaldehyde. Colour due to derivatives resistant to sulphite bleaching was determined at 520 nm in a 1-mm light path cell, 30 min after addition of a metabisulphite solution, and sulphite bleaching resistant pigments (PR_{SO2}) was calculated. Total pigments at acidic pH ($P_{pH<1}$) was determined from absorbance at 520 nm with a 10-mm light path, 4 h after a 100-fold dilution in HCl 1 M. Total polyphenol index (TPI) was determined from absorbance at 280 nm with a 10-mm light path after a 100-fold dilution.

2.8. Statistical analysis

Data are expressed as the average of three measurements. ANalysis Of VAriance (ANOVA) and Principal Component Analysis (PCA) were carried out with the software XLSTAT (Addinsoft, Paris, France). The analytical data were centred and normalised before being treated by PCA.

3. Results and discussion

3.1. Effect of enzymes on wine polysaccharide profile

The polysaccharides isolated from Merlot wines have the same molecular weight distribution as previously described in Carignan (Doco et al., 1999) and Tempranillo (Guadalupe & Ayestaran, 2007) wines (Fig. 1). A first peak eluting between 14 and 16.5 min corresponds to mannoproteins (MPs) released from yeast during fermentation; a second peak eluting between 16.5 and 18 min corresponds mainly to a mixture of arabinogalactan-proteins (AGPs), arabinans, and few MPs; and a third peak eluting between 18 and 19.2 min corresponds mainly to Rhamnogalacturonan II (RG-II) with AGPs and MPs of lower molecular weight. Pectinase addition leads to a modification of the molecular weight distribution of wine polysaccharides (Fig. 1). A shift from higher to lower molecular weight polysaccharides is observed in enzyme-treated wines; the decrease in the second peak indicates that AGPs and arabinans have been partly degraded to lower molecular weight polysaccharides, while the increase of the third peak may reflect a release of both lower molecular weight polysaccharides and of RGII due to an extended cell wall degradation, as shown earlier (Doco et al., 2007). The enzyme effect on the AGP peak seems to be dependent of vintage. The decrease of the AGP peak in enzyme-treated wines was more pronounced in 2004 and 2006 (Fig. 1A and C, respectively) than in 2005 (Fig. 1B). This phenomenon may be due to a difference of maturity (Table 1) of grape berries between the three vintages.

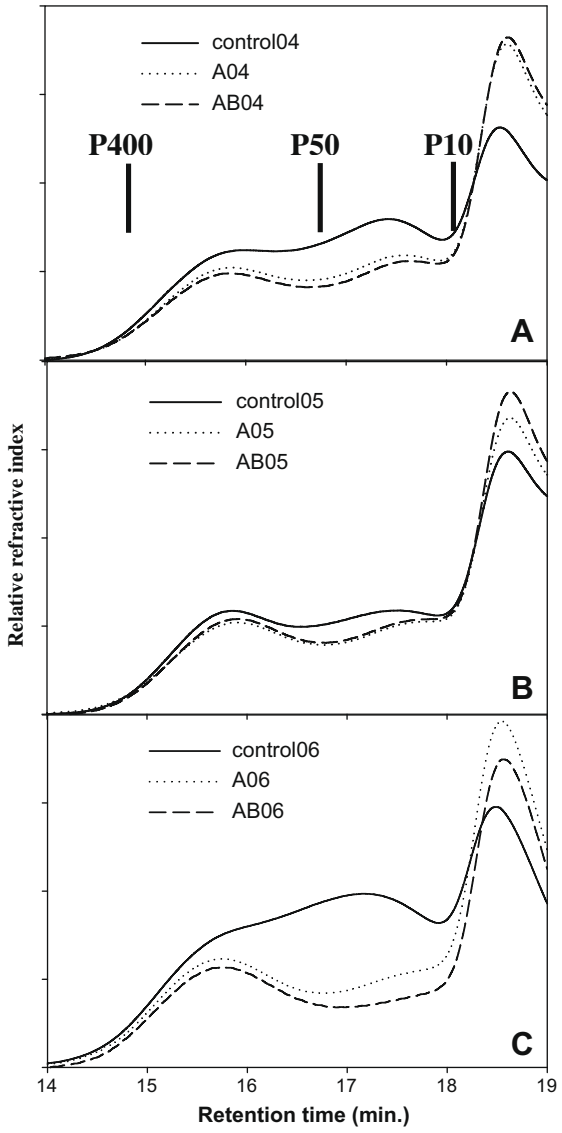

Fig. 1. Molecular weight distribution of polysaccharides isolated from 2004 wines (A), 2005 wines (B), 2006 wines (C).

3.2. Effect of enzymes on polysaccharide composition

Concentrations in MPs, PRAGs and RG-II were estimated from the concentration of individual glycosyl residues (mannose, arabinose, galactose, rhamnose, fucose, xylose, apiose, 2-*O*-methyl-fucose and 2-*O*-methyl-xylose) determined by GC after hydrolysis, reduction and acetylation. All the mannose is attributed to yeast MPs. PRAGs, representing mainly arabinogalactan–proteins and arabinans in wines, are estimated from the sum of galactose and arabinose residues. RG-II is calculated from the concentration of apiose, 2-*O*-methyl-fucose and 2-*O*-methyl-xylose. Fig. 2 presents the concentrations of MPs, PRAGs and RG-II in mg/l in wines. The data confirms the interpretation of molecular weight distribution profiles. The use of pectolytic enzymes modified the composition of the polysaccharides released from cell walls in wines as shown by a decrease of PRAG concentration and an increase of RG-II concentration. The loss of PRAGs was more pronounced in 2006 than in 2004 (Fig. 2A and C, respectively) and was not observed in 2005 (Fig. 2B). Again, this may be related to differences in grape maturity between the three vintages, as suggested above. As expected, no significant effect of pectolytic enzymes on MPs was observed.

3.3. Effect of enzymes on wine colour

Total polyphenol and wine colour indices (Table 2) were deduced from the absorbance measurements (Glories, 1984; Somers & Evans, 1977). Colour intensity was measured after addition of acetaldehyde to release anthocyanins eventually involved in bisulphite adducts (Atanasova et al., 2002). Large vintage differences were observed in the absorbance values. Thus, the total polyphenol and colour intensity values were higher in 2005 than in 2004 and 2006 at 20 months of ageing, suggesting that higher maturity was reached in this vintage. Indeed, monitoring of colour intensity and total polyphenol index during alcoholic fermentation (Fig. 3) shows a faster increase of these indices during the first days of fermentation in 2005 (Fig. 3B) than in 2004 and 2006 (Fig. 3A and C, respectively). In 2005, the extraction kinetics were identical in enzyme-treated wines and in the control wine. In contrast, in 2004 and 2006, TPI values were significantly higher in the treated wines than in the controls throughout fermentation. The total polyphenol index values after 20 months of ageing were also significantly higher in the enzyme-treated wines than in the control except for enzyme A in 2006. This suggests that the plant cell wall degradation induced by the enzyme treatment resulted in increased phenolic extraction from grapes and/or that changes in the wine polysaccharide composition enhanced the solubility and stability of phenolic compounds during wine ageing. The absorbance at 520 nm (WPcorr) and colour intensity (CIcorr) values were also higher in the enzyme-treated wines, after 20 months of ageing,

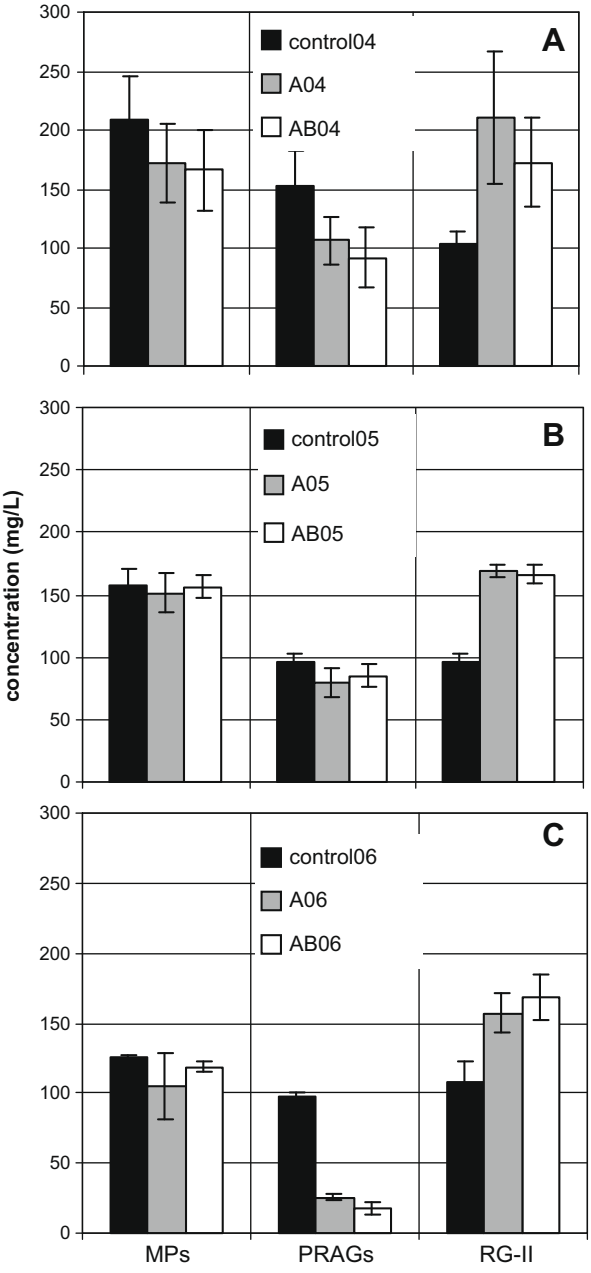

Fig. 2. Concentration (mg/l) of mannoproteins (MPs), polysaccharides rich in arabinose and galactose (PRAGs), and RhamnoGalacturonan II (RG-II) in 2004 wines (A), 2005 wines (B), 2006 wines (B).

for vintages 2004 and 2006, suggesting higher extraction of pigments from the grape berries and/or higher conversion of anthocyanins to derived pigments in wines obtained with enzymatic treatments. The latter hypothesis is confirmed by a higher level of sulphite bleaching resistant pigments (PR_{SO2}) in the treated wines than in the control wines, as genuine grape anthocyanins are bleached by sulphites while some derived pigments are not. This was not observed for the 2005 wines which showed higher values compared to the others. It seems that enzyme addition has no effect on Total Polyphenol Index (TPI) and Colour Intensity (CI) when using grapes with high initial values of these parameters, as above mentioned and shown by their monitoring of during alcoholic fermentation (Fig. 3B). Finally, the total pigment values measured in acidic conditions (ensuring conversion of all anthocyanins and derivatives to their flavylium pigment forms) were constant over the three vintages and little affected by the enzyme treatments. This indicates that the higher colour intensities measured in the 2005 wines are due to enhanced stabilisation of the pigments in the wines through formation of derived pigments or copigmentation rather than to a higher concentration of grape anthocyanins. Indeed, the sulphite bleaching resistant pigments contributed about 50% of the red colour in the 2005 wines and only 40% in the other two vintages, confirming that conversion of anthocyanin pigments occurred faster in the 2005 wines. The hue values were higher in the 2006 wines than in the other two series but were not modified by enzyme treatment.

3.4. Effect of enzymes on polyphenol composition

Tannin concentration (*T*) their qualitative composition (mDP, %gal, %egc), anthocyanin (ACN) concentration and tannin–anthocyanin adduct (TA) concentration are presented in Table 3. The enzyme-treated wines contained larger amounts of tannins than the control wines over the three vintages. Tannin composition was also qualitatively different in the treated wines. Their mDP were slightly higher than in the control wines. This may be due to easier extraction of higher molecular weight tannins as a results of the increased degradation of grape cell walls induced by enzyme addition. In all cases, tannins released into the wines are mainly tannins from skins as evidenced by the %egc. A slight but significant effect of enzymes on %gal was observed in 2004 and 2006. Inconsistent effects of enzyme treatments on the concentrations of anthocyanins and tannin–anthocyanin adducts measured by HPLC were observed (Table 3 ACN, TA). It should be emphasised that the concentration of native anthocyanins reflects both their extraction from the grape and their subsequent reactions in wine. The colour properties are not related to anthocyanin concentrations but depend, on one hand, on the nature and proportions of genuine anthocyanins and derivatives formed from them during wine-making, on the other hand on copigmentation phenomenon. Anthocyanin derivatives include TA adducts which are mostly colourless at wine pH but also other types of pigments that contribute colour in wine. The relative amounts of these various compounds depend on the concentrations of tannins and anthocyanins and on their molar ratio which are modified by enzyme treatment. The increase of colour intensity of enzyme-treated wines was not

related to a higher concentration of residual native anthocyanins in these wines. Thus, it is presumably due to other phenomena such as increased formation of derived pigments and enhanced copigmentation as a result of increased extraction of tannins (Fulcrand et al., 2004; Salas et al., 2003). It has been shown that the colour stability of malvidin 3-glucoside solutions was decreased in the presence of flavan-3-ol monomers but enhanced in the presence of procyanidin oligomers, especially as their the degree of polymerisation increased (Malien-Aubert, Dangles, & Amiot, 2002).

3.5. Vintage effect versus enzyme effect

Principal Component Analysis was performed on all the data generated from polysaccharide and polyphenol analysis and spectrophotometric measurements of the nine wines. The first and second Principal Components explained together 65.71% (PC1 36.43% and PC2 29.28%) of the total variance (Fig. 4). Projection of the wines on the first two PCs (Fig. 4A) shows a separation of the three vintages along the first two axes while control wines and enzyme-treated wines are separated along the second axis. PC1 is mainly associated positively with anthocyanins (ACN), hue (H), and tannins, and negatively with MPs, PRAGs, CIcorr, WPcorr, TPI, and PR_{SO2} (Fig. 4B). It contrasts 2006 wines, which show higher levels of free anthocyanins, H, and tannins, lower values of polysaccharides, and lower total polyphenol index, with the 2005 and, to a lesser extent, 2004 wines that exhibit higher values for total polyphenol and colour indices. Anthocyanin concentration is anti-correlated with CIcorr ($R = -0.76$), absorbance at 520 nm at wine pH

(WPcorr; $R = -0.74$) and PR_{SO2} ($R = -0.78$), these three values being highly correlated, again meaning that wine colour after 20 months of ageing is mostly due to derived pigments (Fulcrand et al., 2004; Salas et al., 2004). Total polyphenol index appears correlated with colour indices but not with anthocyanins or tannins and thus is mostly contributed by derived pigments. PC2 is associated positively with mDP, $P_{pH<1}$, T–A, %egc, and, to a lesser extent, to tannins and colour indices and negatively with PRAGs and MPs concentrations (Fig. 4B). TA and $P_{pH<1}$ are positively correlated ($R = +0.72$), suggesting that the T–A dimers can serve as markers of a large class of T–A adducts which represent the majority of pigments in wine acidified to pH < 1. These adducts, like anthocyanins, are coloured at acidic pH but do not contribute much to red colour at the wine pH. Within each vintage, the enzyme-treated wines are distinguished from the control wines along the second axis, on one hand, by their higher contents of RGII and lower levels of PRAGs, related to enzymatic degradation of plant cell walls, on the other hand, by their higher tannin content, higher values of mDP, indicating an increased extraction of tannins as a result of increased cell wall degradation. The 2004 wines are also distinguished from the other two vintages by their higher amounts of PRAGs and MPs.

In conclusion, the effect of enzyme treatment has been demonstrated for each vintage, especially with regards to RG-II and tannin concentrations. This effect is more or less marked depending on the vintage. In particular, the increase in colour and degradation of PRAGs was not observed in 2005, possibly due to differences in grape maturity. This should be investigated further. No effect on wine anthocyanin concentration was observed. However, in 2004 and 2006, higher colour indices in the enzyme-treated wines indicate that the enzyme treatment either resulted in higher anthocyanin extraction followed by their conversion to other pigments or favoured reaction mechanisms yielding derivatives that are pigmented in wine. Indeed, the enzyme treatment leads to an increase of pigments resistant to sulphite bleaching which contribute to wine colour. No effect was observed on the concentration of TA adducts which are mostly colourless at wine pH but appeared

correlated to the red colour measured under acidic conditions (pH < 1). Finally, changes in polysaccharide composition induced by enzyme treatments may impact the colloidal structure and the mouth-feel properties of phenolic compounds in wines, as shown earlier in model solutions.

Acknowledgments

We thank Frederic Veran (UMR SPO) for technical assistance and all the staff of the wine experimental cellar for assistance with the wine-making experiments.

ABSTRACT

The vinification technique called pre-fermentative cold maceration is used to enhance the anthocyans diffusion from the skins to the must, increasing the pigments extraction. For using this technique the application of low temperatures is needed. In this study, two different refrigerating methods (dry ice and cooling of grapes) have been assessed regarding the colour and the phenolic composition of the Syrah wines elaborated by applying pre-fermentative cold maceration. Results showed more intense and stable colours when grapes were previously refrigerated in cold-storage rooms, which showed higher values of chroma and more red-bluish hues. As regards phenolic composition, the cold maceration technique used yields to significant differences among the levels of phenolics, having higher levels of anthocyanins and some non-coloured phenols as flavonols in PR wines. Regarding the colour-composition relationships, it has been highlighted the importance of the co-pigments such as flavonols and cinnamic acids for classify the two groups of samples.

1. Introduction

Colour is one of the main characteristic defining the quality of wines. During the storage the red-bluish colour of young wines changes to red–orange hues and their astringency diminishes. These sensory changes are induced by the transformation of phenolic compounds along the vinification. At the first steps of the winemaking process the wine shows bluish hues and high colour intensity since monomeric anthocyanins are implicated in co-pigmentation reactions. Nevertheless, the co-pigmentation complexes trend to disappear in the next few months of ageing due to the transformation of monomeric anthocyanins into polymeric pigments. This conversion yields to the colour stabilization of wine which shows brownish hues and less intensity colour (Boulton, 2001; Hermosín, Sánchez-Palomo, & Vicario, 2005). Anthocyans are the pigments accounting for the colour of red wines, which are transferred to the wine during the maceration stage. The final colour of the wine depends on the extraction of phenolics from the must, which is determined by factors like the grape variety, as well as length and temperature of skin-contact, among others (Gómez & Heredia, 2004; Gómez-Plaza, Gil-Muñoz, López-Andreu, Martínez, & Fernández-Fernández, 2001).

Syrah has been described as an excellent and robust grape, easy to cultivate and little vulnerable to diseases. It is recommended to monitor the harvests, perform a long fermentation, watch carefully the temperature, and carry out the ageing in oak barrels in order to produce quality wines from this grape (Robinson, 1996). Syrah wines exhibit high acidity, high levels of tannins and colourants, and floral and fruity aroma, with characteristic scent of violet and cassis and smoked touches.

In the last years, a new trend aimed at implementing the production of high quality red wines has been observed, which is being possible thanks to important investments in technology and the application of novel procedures intended to enhance the extraction of grape components responsible for the colour of wine. In this sense, the pre-fermentative cold maceration, also known as cold soaking or cryomaceration, is being increasingly used by enologists worldwide in order to improve some important quality characteristics of wines such as colour and aroma. This technique consists in maintaining the crushed grapes at low temperatures (5–10 °C) for a variable period (from one to several weeks), and thus the beginning of the fermentation process is delayed. During this period the extraction of polyphenols from the skins to the must takes place in the absence of ethanol. Later on, the temperature is raised to 20–25 °C and the fermentation starts in contact with the skins. The removal of the skins is performed a few days later, when the alcoholic fermentation is practically finished.

The cold needed to achieve the required low temperature can be obtained in diverse manners. Some studies have revealed that the effects of the cold maceration over the final quality of the wine are different depending on the cryogenic and the temperature

used. In this sense, it is necessary to study comparatively refrigeration techniques employed to achieve the temperatures required for the pre-fermentative cold maceration. The most widely used technique is probably the addition of dry ice (solid carbon dioxide) which induces a thermal shock that cools down the must rapidly and inhibits the polyphenoloxidases enzymes. On the other hand, the saturation caused by the carbon dioxide produced by the sublimation of the dry ice displaces completely the oxygen present in the medium. Therefore, both the aroma compounds and the anthocyanic pigments become protected from oxidative reactions. Likewise, due to the freezing of the grape skins there are cellular breakdowns that favour the release and solubilisation of the pigments (Zamora, 2003, 2004). Other refrigeration method is cooling down (chilling) the grapes which will be used to produce the wine. This method consists in maintaining the grapes in a cold-storage room (below 4 °C) for 24 h prior crushing. In this case, the winery needs special equipments (cold-storage room) which are not habitual, and hence, this is not a usual process for vinification.

To gain insight into the etiology of colour it is necessary to relate the chromatic variables with the chemical compounds that account for it. Thus, there were initiatives where the anthocyanic pigments in solution (Gonnet, 1998, 1999, 2001; Heredia, Francia-Aricha, Rivas-Gonzalo, Vicario, & Santos-Buelga, 1998; Iñarrea, Negueruela, & Echavarri, 1992; Torskangerpoll & Andersen, 2005) or in the wine (Fernández de Simón, Hernández, Cadahía, Dueñas, & Estrella, 2003; Gómez-Cordovés & González-SanJosé, 1995; Gómez-Miguez, González-Manzano, Escribano-Bailon, Heredia, & Santos-Buelga, 2006) were studied.

The knowledge of the effects of the pre-fermentative cold maceration technique on the final quality of the wine is rather empirical; hence it is difficult to find related bibliography, and the scarce reports available are somewhat confusing. For instance, there are reports on the improvement of the colour and the phenolic content of wines through macerations with skins at around 15 °C (Gómez-Plaza, Gil-Muñoz, López-Andreu, & Martínez, 2000). Similarly, there are studies where the cold maceration is followed up with a raise in the temperature of fermentation to produce Syrah wines with higher colour intensity and varietal aromas (Reynolds, Cliff, Girard, & Kopp, 2001) in which authors recommend for this variety the use of temperatures of fermentation close to 30 °C along with a pre-fermentative cold maceration and a prolonged post-fermentative maceration.

The repercussion of the pre-fermentative cold maceration on the final colour and flavour of Syrah wines produced in Andalusia (southwest of Spain) have been already studied (Gómez & Heredia, 2004; Gómez-Míguez, González-Miret, & Heredia, 2007). The results revealed that the extraction of anthocyanins and other phenolic compounds was higher, and darker and less brown wines were obtained when the cold skin-contact process was applied.

Thus, the main objective of this study is to assess the influence of the application of two different refrigeration procedures for developing the pre-fermentative cold maceration on the colour and phenolic composition of Syrah wines. In this sense, the definition of chemical and colorimetric characteristics of the wines produced by pre-fermentative cold maceration, as well as the possible relationships between colour and chemical composition as a function of the technique of production have been assessed.

2. Materials and methods

2.1. Wine samples and vinification process

Six hundred and forty-four samples of musts and wines, corresponding to six different vinifications, were analysed. The wines were elaborated under different cold-maceration conditions, by using two different cooling techniques to achieve low temperatures: direct refrigeration (DR) of the crushed grapes (must and solid parts) by adding carbonic ice (three assays average: 10 days CM at 5–10 °C), and previous refrigeration (PR), that is the refrigeration of the grapes in a cold-storage room at 0° for 24 h prior crushing (three assays average: 10 days CM at 3–8 °C).

All wines were elaborated in triplicate. In order to avoid effects due to other factors different from the refrigeration technique, all the processes involving the winemaking were carried out under the same conditions for all the six assays, as detailed below.

Healthy grapes of *Vitis vinifera* cv. Syrah, grown in southwest Spain, were harvested at optimum maturity (average 13.3° Baumé). Grapes were manually harvested, placed in 20 kg plastic boxes and transported to an experimental wine-production centre. About 1500 kg of grapes per assay were processed. The grapes were destemmed and crushed and then transferred into 1000 l stainless steel tanks. The cold-maceration was carried out controlling the skin contact time (10 days) and temperature (below 10 °C) by using an industrial refrigeration system, consisted of a refrigeration unit (HITSA-TOPAIR, mod RAE-101, Madrid, Spain) for the recirculation of refrigerant liquid (water:glycerol at 2–7 °C) through cooling water jackets to keep low temperatures. The cold-maceration conditions for each assay were those indicated above. After the cold-maceration period was completed, the temperature of the tanks was left to rise up to 20 °C to allow starting the alcoholic fermentation, which was conducted at controlled temperature (21–23 °C). The fermentation caps were punched down once a day for 4 days during this phase. After this, the mash was drawn off to remove the skins and other solid parts, and the free-run musts were left to finish the fermentation under the same conditions. At the end of fermentation, which occurred after 25 days, the wine was racked and stored in 500 l stainless steel tanks.

The treatments were adjusted at the same levels for all the assays: 50 mg/l total sulphur dioxide, 7 g/l total acidity expressed as tartaric acid.

2.2. HPLC–DAD phenols analysis

High performance liquid chromatography was applied for the phenolic content determination by direct injection of the samples, previously filtered through a 0.45 μm Nylon filter, in an Agilent 1100 (Palo Alto, CA), equipped with a quaternary pump, an UV–Vis diode-array detector, an automatic injector, and the ChemStation software. All analyses were made in triplicate.

The *anthocyans* identification was performed following a modification of the method described in Gómez and Heredia (2004). Anthocyanins were separated on a Zorbax C18 column (250 × 4.6 mm, 5 μm particle size) maintained at 38 °C. Water–acetonitrile–formic acid (3:10:87) as solvent A, and water–acetonitrile–formic acid (50:10:40) as solvent B were used. The elution profile was as follows: 0–10 min 94% A–6% B; 10–15 min 70% A–30% B; 15–25 min 60% A–40% B; 25–35 min 55% A–45% B; 35–40 min 50% A–50% B; 40–42 min 40% A–60% B; 42–43 min 94% A–6% B. The flow-rate was 0.8 ml/min and the injection volume was 50 μl. UV–Vis spectra were recorded from 200 to 800 nm with a bandwidth of 2.0 nm. The quantification was made at 525 nm by comparing the areas and the retention times with malvidin 3-glucoside standard. The HPLC determination of the non-coloured phenolics was carried out as described in Hernanz et al. (2007). The wavelengths of detection were 280 nm (benzoic acids and tyrosol), 320 nm (cinnamic acids and their tartaric esters) and 360 nm (flavonols). The external calibration method was used for quantification, by comparing the areas with patrons of gallic, caffeic, *p*-coumaric, *m*-coumaric, protocatechuic, *p*-hydroxybenzoic and ferulic acids, catechin, epicatechin, tyrosol,

rutin, quercetin, kaempherol and quercetin-3-D-galactoside. For the identification of quercetin derivatives and the tartaric esters of the cinnamic acids their spectra were comparing to those from quercetin and the corresponding free acids, respectively.

2.3. Spectrophotometric colour measurement

Spectrophotometric measurement of the visible absorption spectrum (380–770 nm) at constant intervals ($\Delta\lambda$ = 2 nm) was made, using distiled water as reference. The spectra were integrated by the CromaLab® software (Heredia, Álvarez, González-Miret, & Ramírez, 2004), which takes into consideration the Commission Internationale de l'Éclairage (CIE) recommendations

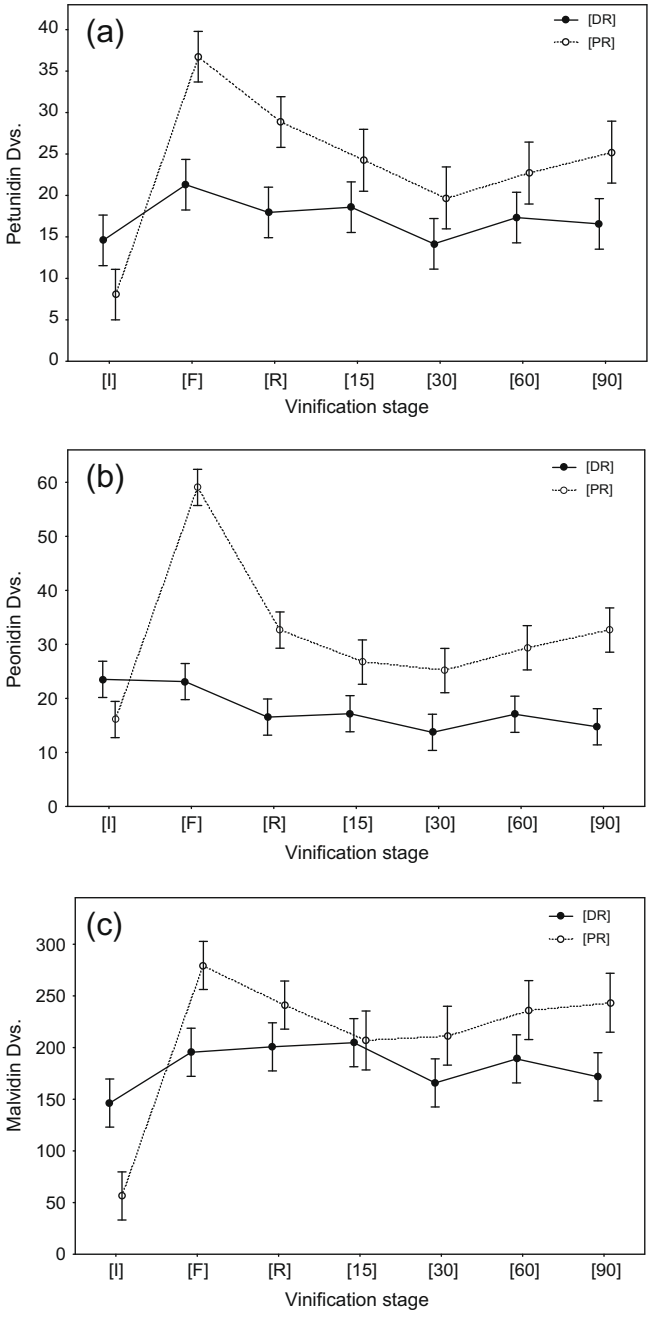

Fig. 1. Evolution of the major anthocyanidins occurring in the wine. (a) Petunidin derivatives, (b) peonidin derivatives, (c) malvidin derivatives.

(CIE, 2004). The colour coordinates of the uniform space CIE 1976-($L^*a^*b^*$) (CIELAB) were obtained considering the 10° Standard Observer and the Standard Illuminant D65 (Wyszecki & Stiles, 1982).

2.4. Statistical analysis

Analysis of variance (ANOVA/MANOVA), Principal Components Analysis (PA), and Stepwise Discriminant Analysis were applied in order to evaluate whether significant differences among the samples exist as well as to select the variable that most influence the differences between them. For the statistical treatment of the data the Statistica v.6.0 software (StatSoft Inc., 2001) was used.

3. Results and discussion

The colour of Syrah wines obtained by the application of different procedures of pre-fermentative cold maceration was objectively evaluated by tristimulus colorimetry. An exhaustive follow-up of the winemaking process allows us to acquire valuable information on the changes in pigments and colour of the wines.

The assessment of the changes in the levels of the pigments occurring along different stages is decisive to establish the points at which the different techniques have a greater impact in the quality of the wines. In this sense, the following stages were considered in the study: the initial point or grape crushing [I], the beginning of the fermentation [F], the skin removal [R], and 15, 30, 60 and 90 days after the removal of the skins. The mean values and the standard deviations of the colorimetric parameters, as well as the anthocyanic and phenolic composition for each type of chilling process are shown in Tables 1–3, respectively.

Regarding the colour, it can be observed that the chroma C^*_{ab} was higher in the wines obtained with previous refrigeration of the grapes and their lightness L^* was lower (darker wines). According to these results, higher anthocyanic and other phenolics contents were found in PR wines than in DR ones. Moreover, the analysis of variance (ANOVA) revealed significant differences among the levels of all the 3-glucoside anthocyanins as a function of the cold-maceration technique used, with high levels of significance in most of cases: $p < 0.001$ for delphinidin (Dp3g), cyanidin (Cy3g), petunidin (Pt3g) and peonidin (Pn3g); $p < 0.05$ for malvidin (Mv3g).

The evolutions of the compounds grouped by the anthocyanidin and the substituent were studied. When the major anthocyans

were grouped by the anthocyanidin (Fig. 1) a very higher increase of the concentration along the cold-skin maceration was observed in all cases for the wines produced with previous refrigeration (PR). During the fermentation stage, these levels diminished, although they were always above those corresponding to the wines obtained by direct refrigeration (DR), especially for peonidin derivatives. DR wines showed a certain trend to diminish the levels of the anthocyanins and its derivatives, whilst the PR wines showed a slight ascending trend.

In general, the assays corresponding to the PR technique led to higher levels of each individual monoglycoside. It is worth stressing the changes in Mv3g, the major monoglycoside by far. Thus, it was noticed that the levels reached in both cases were similar, although in the case of the direct application of cold (DR) the appearance of the maximum levels holds back up to the removal of the skins, which denotes a slower extraction when dry ice is employed.

Considering the evolution of the groups of anthocyans, regarding the substituent (Fig. 2), it is observed that the changes in the levels of monoglycosides (Fig. 2a) were much similar (except for the cryomaceration stage, where higher levels were obtained for PR wines), although some differences and maybe a higher stability was perceived in the PR wines. The changes in the levels of acetate derivatives of the anthocyans (Fig. 2b) were different and were clearer in the case of the coumarates (Fig. 2c), being their levels always higher when the previous refrigeration is used.

It could be expected that the use of carbonic ice (DR) affects the extraction of chemical components due to the breakage of the grape skins occurring during the freezing. Nevertheless, the PR wines showed higher levels (Tables 2 and 3) of anthocyanins and most of non-coloured phenols than the DR wines. It could be due to the local effect of the ice just in the mass being directly in contact with the carbonic ice, and so the increase of the extraction due to the effect of freezing is not in the whole mass. Moreover, this effect leads to more unspecific extractions which can induce reactions involving anthocyanins, yielding to less colour wines.

Considering the non-coloured phenolics, the flavonoids encompass different compounds such as the flavonols, which exhibit a great capacity to stabilize the colour of anthocyans by co-pigmentation phenomena (Gómez-Miguez et al., 2006). Differences

between the two methodologies were observed, having higher levels in the samples from previously refrigerated grapes (PR), as observed in Fig. 3a (total flavonols), and b (total phenols).

The definition of the colour by tristimulus colorimetry enables to establish objectively the chromatic characteristics of the wines and, above all, their variability. The colour points represented in the (a^*b^*)-colour diagram as well as their lightness are shown in Fig. 4a (DR wines) and b (PR wines). It can be noticed that practically all of samples are located in the fourth quadrant (positive a^*, negative b^*) of the (a^*b^*)-plane, corresponding to the purple or red-bluish colours region. The (a^*b^*)-colour diagram allows one to observe a clear trend in the evolution of colour. In general for both chilling techniques, during the pre-fermentative cold maceration a net rise in the chroma C^*_{ab} together to a decrease in the lightness L^* is observed, whilst the hue h_{ab} remains virtually constant. Along the active maceration (simultaneous to the alcoholic fermentation) and during the first stage after the removal of the skins slight changes in hue are noticed, although the values of chroma lie high. As the vinification proceeds, a reduction in the levels of chroma is observed, along with increase of hue towards 0°, i.e., towards the net red. Considering separately both techniques, after the pre-fermentative cold maceration the PR wines reached higher levels of chroma C^*_{ab} than the DR wines (48.1 and 35.4 CIELAB units, respectively), and lower lightness L^* values (63% and 76%, respectively). Comparing the final wines (after 90 days of stabilization) the PR wines kept the purple hues (nega-

tive h_{ab} values) while some DR wines changed towards higher hue values.

The capability of different groups of variables for discriminating between types of wines (regarding the refrigeration technique) has been studied, highlighting the repercussion on the most relevant chemical components over the colour that is pigments and co-pigments.

The inclusion of the chemical information yielded by the non-coloured phenols on the PCA model allows us to reach very good discriminations, both between musts and wines, as expected (Fig. 5a), as well as between chilling technique (Fig. 5b), which makes possible to state conclusions about the colour stabilization by co-pigmentation reactions. In the second case (regarding the technology), the differentiations is mainly due to the Factor 1, which includes different phenolics considered good co-pigments as cinnamic acids and specially several flavonols (Table 4). Since the PCA is a non-conditioned technique, the results are of great enological value because they demonstrate the advantages of the pre-refrigeration of the grapes over the direct refrigeration for achieving a better colour stabilization in red wines by means of co-pigmentation.

On the other hand, Stepwise Discriminant Analysis (SDA) is a conditioned technique, so the groups of samples are previously defined. Its objective is to find a model which better classify the samples into their corresponding group based on the information given by the variables included in the study or to find the variables which better classify the samples. In this study, these variables are those phenolics presenting the major influence on the differences marked by the refrigeration technique used for the pre-fermentative cold maceration. The classification functions obtained showed that it is necessary to include almost all the anthocyans for reaching a good discrimination (up to 95%, Table 5). Nevertheless, 100% of cases correctly classified is achieved by including only fourteen phenolics (Table 6), most of them flavonols and cinamic acids, which are considered as good co-pigments.

4. Conclusions

It can be concluded that regarding the cooling technique used for reaching the low temperatures needed for the pre-fermentative cold maceration process the refrigeration of the grapes before crushing leads to wines with higher concentrations of anthocyanins as well as other phenolics than those wines obtained by using dry ice. Furthermore, higher values of chroma and red-bluish hues are shown in these wines. Thus, the technique used for obtaining the low temperature influences the final chemical composition of the wine, especially regarding the phenolic compounds having high co-pigmentation power, which are of great interest on the stability of the colour of wines submitted to aging process.

ABSTRACT

Compared with those of major commercial leafy vegetables, leaves of sweet potato have higher contents of flavonoids and phenolic acids, which provide significant health benefits and may be used as natural colourants. We have analysed the expression of key flavonoid biosynthesis genes using RT-PCR and the accumulation of polyphenolic compounds using high-performance liquid chromatography coupled to a photodiode-array detector, during the development of leaves of sweet potato plants growing under either long day or short day photoperiods. A massive induction of flavonoid pathway gene expression, correlating with a dramatic increase in the content of an anthocyanin, catechins, flavonols, hydroxycinnamic acids and hydroxybenzoic acids, was observed during sweet potato leaf exposure to a long day photoperiod. These results provide further support for the protective role of flavonoids and phenolic acids against enhanced light exposure in plants.

1. Introduction

In recent years, there has been a global trend toward the use of natural phytochemicals present in natural resources—such as vegetables, fruits, oilseeds and herbs—as antioxidants and functional ingredients (Elliott, 1999; Kaur & Kapoor, 2001; Larson, 1988; Namiki, 1990). Sweet potato (*Ipomoea batatas* (L.) Lam.) ranks as the world's seventh most important crop. It is more tolerant to diseases, pests and high moisture than are many other leafy vegetables grown in the tropics or the Mediterranean region. As a crop, sweet potato is used both for food and as an industrial source of starch (Mano, Ogasawara, Sato, Higo, & Minobe, 2007), but its leaves have been largely neglected, except for occasional use as livestock feed.

Polyphenolic compounds are a large group of secondary metabolites widely distributed in plants, which can be divided into two major subgroups: flavonoids and phenolic acids. Flavonoids, perhaps the most important single group of phenolics in foods, comprise a group of over 4000 aromatic plant compounds, which include anthocyanins, proanthocyanidins, flavonols and catechins. Phenolic acids, on the other hand, include hydroxycinnamic acids (*e.g.* caffeic or ferulic acid conjugates, sinapic acid) and hydroxybenzoic acids (*e.g.* benzoic, gentisic or *p*-anisic acids) (Li et al., 2007).

Recent experimental work has revealed that, compared with major commercial leafy vegetables, such as brassicas and lettuce, sweet potato leaves have higher contents of flavonoids, mainly anthocyanins, and phenolic acids (Kaur & Kapoor, 2001), which have significant medicinal value for certain human diseases and may also be used as natural food colourants. These polyphenolics show various kinds of physiological functions—such as radical-scavenging, anti-mutagenic, anti-diabetes and anti-bacterial activities *in vitro* or *in vivo*—which may be important in maintaining and promoting human health (Mazza, Pomponi, Janiri, Bria, & Mazza, 2007).

Flavonoids fulfill many plant functions, including the production of yellow, red or blue pigmentation. Different flavonoid subclasses have been found to play protective roles in plant tissues and the biosynthesis of flavonoids often increases in response to external stress factors, such as drought, cold temperatures, wounding or excess UV light (Chalker-Scott, 1999; Winkel-Shirley, 2002). Indeed, in addition to coloured anthocyanin pigments, other

doi:10.1016/j.foodchem.2009.05.005

flavonoids and phenolic acids, especially sinapate esters and other hydroxylated or methoxylated cinnamic acid derivatives, have been found to play a role in photoprotection. These compounds accumulate mainly in the epidermal cells of plant tissues after light stress induction (Landry, Chapple, & Last, 1995; Winkel-Shirley, 2001). Flavonoids are synthesized via the general phenylpropanoid pathway, with the key steps of the main flavonoid pathway being well known (for review, see Holton & Cornish, 1995; Weisshaar & Jenkins, 1998; Winkel-Shirley, 2001).

The aim of the present study was to analyse the expression of key flavonoid pathway genes—chalcone synthase (*CHS*), chalcone flavanone isomerase (*CHI*), flavanone 3-hydroxylase (*F3H*), dihydroflavonol 4-reductase (*DFR*) and UDP-glucose flavonoid 3-O-glucosyl transferase (*UFGT*)—and the qualitative and quantitative composition of polyphenolic compounds in leaves of sweet potato plants exposed to long day (16 h light) or short day (8 h light) photoperiods. Flavonoids (anthocyanins, catechins and flavonols), as well as hydroxycinnamic and hydroxybenzoic acids, were identified and quantified in sweet potato leaves by high-performance liquid chromatography (HPLC), coupled to a photodiode-array detector. Results show induction of gene expression, indicating activation of the flavonoid pathway, and higher content of flavonoids and phenolic acids in leaves exposed to a long day photoperiod, suggesting a role for these compounds in the protection against enhanced light exposure in sweet potato plants. The study of plant polyphenolic compounds is an important scientific agenda for food and nutritional sciences, which may contribute to the improvement of conventional foods with added health benefits.

2. Materials and methods

2.1. Plant material

Sweet potato (*I. batatas* (L.) Lam.) was planted in sandy soil in 1 l pots with a layer of gravel at the bottom. Six replicate pots per cultivar were used, with one plant per pot. Plants were grown for 30 days under photosynthetic active radiation (PAR 400–700 nm) at 150 μmol m^{-2} s^{-1} and 22 °C, under either long day (16 h photoperiod) or short day (8 h photoperiod) conditions. Leaves of sweet potato plants were harvested at day 10 and day 30 from the two different photoperiod conditions, immediately frozen in liquid nitrogen and stored at −80 °C until used.

2.2. RT-PCR analysis of flavonoid pathway genes

Total plant RNA was extracted from plant material stored at −80 °C using the Tri-Reagent (Sigma–Aldrich) according to the manufacturer's instructions. The integrity of the isolated RNA was verified in a 1% (w/v) ethidium bromide-stained agarose gel, being judged by the sharpness of ribosomal RNA bands. No degradation was detected in any of the samples tested. Total RNA concentration and quality were determined spectrophotometrically by absorbance at 280 nm (A_{280}), 260 nm (A_{260}) and 230 nm (A_{230}) with a NanoDrop (UV-160A, Shimadzu, Kyoto, Japan). In all tested samples, the A_{260}/A_{230} ratios were greater than 1.8, indicating that only weak contamination by polysaccharide or polyphenol occurred. The A_{260}/A_{280} ratios ranged between 1.6 and 2, indicating little or no protein contamination.

cDNA was synthesized using the Superscript III First-Strand Synthesis System (Invitrogen). Transcriptional analysis of five key genes from the flavonoid pathway, encoding chalcone synthase (*CHS*), chalcone flavanone isomerase (*CHI*), flavanone 3-hydroxylase (*F3H*), dihydroflavonol 4-reductase (*DFR*) and UDP-glucose flavonoid 3-O-glucosyl transferase (*UFGT*), as well as of the housekeeping 18*S* ribosomal RNA gene, used as a loading control, was performed by semi-quantitative PCR using *Taq* DNA Polymerase with ThermoPol Buffer (Biolabs, New England) and the following gene-specific primer sets: 5′-TTCCGTGAAGCGCCTCATGATGTA-3′ and 5′-ACTTGTCCTCCACTTGGTCCAGAA-3′ (*CHS*), 5′-TCCCTT-TG AGAAGCTGACACGGAT-3′ and 5′-0TCCGACAGCGGCTTGTTCTCTAT T-3′ (*CHI*), 5′-ACGGCCACTTTCTGAGTAATGGGA-3′ and 5′-TACGATT TGCTGCTGCTCCTTTGC-3′ (*F3H*), 5′-AGCTTTGATGAAGCCAT-TGCA GGG-3′ and 5′-TCGCAGAGATCATCCAGATGCACA-3′ (*DFR*), 5′-ACCC ACGAGGAGTTCATCATG-3′ and 5′-AAGCAGGTGCACTAATT-CTTGG AA-3′ (*UFGT*), and 5′-CTGCCAGTAGTCATATGCTTGTC-3′ and 5′-GT GTAGCGCGCTGCGGCCC-3′ (18*S* ribosomal RNA gene). The correct PCR products were obtained with all primer sets when amplifying genomic DNA.

For all genes, the following PCR conditions were used: initial denaturation was performed at 94 °C for 2 min, followed by 25 cycles at 94 °C for 30 s, 55 °C for 45 s and 72 °C for 1 min. The final extension was performed at 72 °C for 10 min. PCR products were resolved by electrophoresis in 1% (w/v) ethidium bromide-stained agarose gels.

2.3. Preparation of sweet potato extracts

Leaves of sweet potato (0.3 g) were homogenised at room temperature with 3 ml of methanol (Merck) in a rotary mixer (Edmund Buhler Gmg H-Ks 15, Germany) at 45 °C angle and 220 rpm for 24 h and the mixture was then centrifuged at 1600*g* for 10 min. The supernatant was filtered though Whatman no. 4 filter paper and kept at 4 °C before analysis. The resulting extracts were used for different experimental analyses.

2.4. Colour analyses

A direct measurement of absorbance at 420, 520, and 620 nm in methanolic extracts was carried out using an Ultrospec 1100 pro-UV/visible spectrophotometer (GE Healthcare Life Sciences, England). The following variables were calculated: colour intensity (CI) as the sum of 420, 520, and 620 nm absorbances; proportions of yellow (Ye%), red (Rd%) and blue colour (Bl%) were calculated by dividing the absorbances at 420, 520 and 620 nm by the colour intensity (CI), respectively (Kelebek, Canbas, & Selli, 2008).

2.5. Determination of chlorophylls a and b

A direct measurement of absorbance at 652, 665, and 750 nm in methanolic extracts was carried out using an Ultrospec 1100 pro-UV/visible spectrophotometer (GE Healthcare Life Sciences, England). The following variables were calculated (in mg l^{-1}): Chl a = $(16.29 \times OD_{665}) - (8.54 \times OD_{652})$ and Chl b = $(30.66 \times OD_{652}) - (13.58 \times OD_{665})$. Each OD value was corrected for the absorbance at 750 nm (*e.g.* $OD_{665} = A_{665} - A_{750}$) (Porra, Thompson, & Kriedemann, 1989).

2.6. Determination of total phenolic compounds

Each methanol extract (0.2 ml) was mixed with 1.0 ml of Folin–Ciocalteau's reagent and 0.8 ml of saturated sodium carbonate solution (7.5%). After a 30 min incubation at room temperature, the absorbance was read at 765 nm against a blank in an Ultrospec 1100 pro-UV/visible spectrophotometer (GE Healthcare Life Sciences, England). A linear calibration curve of gallic acid, in the range 20–500 μg ml^{-1} with an r^2 value of 0.999, was constructed (data not shown), and the total phenolic content was expressed as gallic acid equivalents (GAE) in g/100 g of fresh material (Huang, Chang, & Shao, 2006).

2.7. Quantification of flavonoids and phenolic acids

Methanol extracts were filtered through a 0.45 μm filter. HPLC analyses of flavonoids and phenolic acids were conducted with a Dionex liquid chromatograph (USA) equipped with a model P580 solvent pump (USA), a ASI-100 autosampler (USA), a PDA-100 photodiode-array detector (USA) and Dionex Software. A Lochrospher 100 RP-18, with a reversed-phase column (25 cm × 4 mm, 5 μm; Merck, Darmstadt, Germany), was used throughout this study. Phenolic acids and flavonoids were detected at 280 and 360 nm, with the exception of anthocyanins, which were detected at 510 nm. The mobile phase was 5% formic acid and methanol in a linear gradient starting at 15% and reaching 35% in 15 min (then isocratic until 20 min), at a flow rate of 1 ml/min and an injection volume of 20 μl. Phenolic compounds were identified by comparison of their retention times with those of pure standards and quantified individually, based on standard curves of each flavonoid or phenolic acid type. Quantitation was performed with the linear calibration curves of standard compounds according to Jaakola, Määttä, Pirttilä, Törrönen, and Kärenlampi (2002) and Jaakola, Määttä-Riihinen, Kärenlampi, and Hohtola (2004).

2.8. Expression of data and statistical analysis

All data presented are means ± standard deviations. Significant differences between means ($p < 0.05$) were estimated by Student's *t*-tests using SPSS 16.0.

3. Results

3.1. Colour parameters and chlorophyll and total phenolic contents

While growing sweet potato plants in either short day or long day photoperiods, striking differences were observed between leaves of plants grown for 30 days under these two light conditions (Fig. 1). Leaves of plants growing under a long day photoperiod (16 h light/8 h dark) were slightly larger, with both the blade and the petiole displaying a reddish colour not evident in leaves growing under a short day photoperiod (8 h light/16 h dark). This prompted us to examine colour parameters, as well as the total phenolic and chlorophyll contents of sweet potato leaves exposed to the two light regimes.

Colour parameters were analysed by direct measurement of absorbance at 420, 520 and 620 nm in methanolic extracts. Results presented in Table 1 indicate higher colour intensity (CI) in leaves growing under a long day photoperiod when compared with leaves growing under a short day photoperiod. In particular, enhanced red colour in leaves that were exposed to long day, when compared with leaves exposed to short day conditions was observed. By contrast, yellow colour was reduced in leaves exposed to a long day photoperiod when compared with leaves exposed to a short day photoperiod. No differences in blue colour were observed between leaves exposed to the two different photoperiods, indicating a preponderant role for red and yellow colours in leaves under long and short day conditions, respectively (Table 1). Leaf colour was therefore clearly affected by the photoperiod regime in sweet potato.

Chlorophyll a and b contents were determined by direct measurements of absorbance at 652, 665 and 750 nm in methanolic extracts. Experimental results obtained show that the photoperiod had no effect on leaf chlorophyll content, but an overall reduction of approximately 63% (averages of 0.24–0.09 mg/100 g fw) in chlorophyll a and 61% (averages of 0.23–0.09 mg/100 g fw) in chlorophyll b contents was observed between days 10 and 30 of light exposure (Table 1). The reduction in chlorophyll content has a negative effect on plant photosynthetic efficiency, as the latter is dependent on the light harvesting properties of the chlorophylls (Demmig-Adams & Adams, 1992). Our results show that both chlorophylls decrease with time under both light treatments (Table 1).

Total phenolic content was estimated by the Folin–Ciocalteau colourimetric method, based on the procedure of Taga, Miller, and Pratt (1984), using gallic acid as a standard phenolic compound. As shown in Table 1, there is a large variation in the total phenolic content of the plant material analysed, ranging from 4.94 to 25.0 g GAE/100 g fresh weight for leaves exposed for 10 days to short day and 30 days to long day conditions, respectively. Higher amounts of total phenolic compounds were obtained in extracts of leaves exposed to a long day (8.63–25.0 GAE g/100 g), whereas leaves exposed to a short day photoperiod had a lower phenolic content (4.94–5.76 GAE g/100 g).

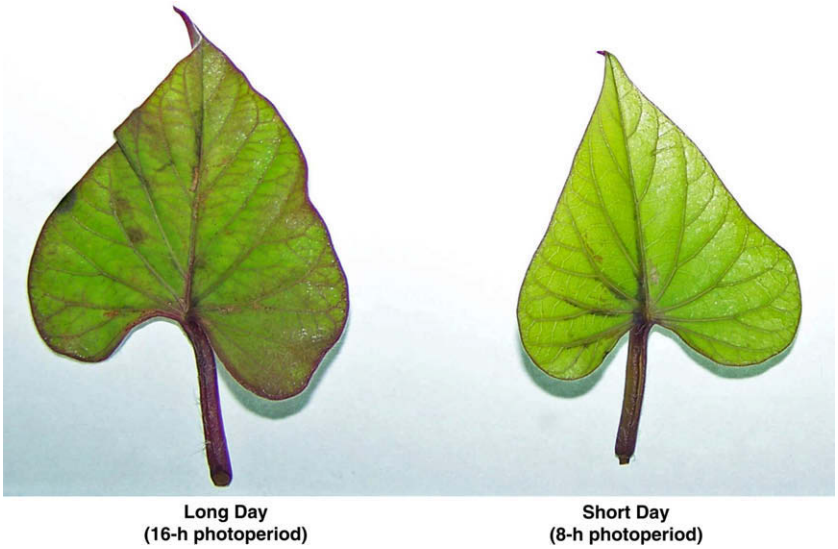

Fig. 1. Detached leaves from sweet potato plants 30 days after light exposure. Plants were grown in chambers with photosynthetic active radiation (PAR 400–700 nm) at 150 μmol m^{-2} s^{-1} and 22 °C under long day (16 h photoperiod) or short day (8 h photoperiod) conditions.

Table 1
Colour parameters (CI, Ye, Rd and Bl) and concentrations of chlorophylls a and b (mg/100 g fresh sample) and total phenolic compounds (g GAE/100 g fresh sample) in sweet potato leaves collected at days 10 and 30 of exposure to long day (16 h photoperiod) or short day (8 h photoperiod) conditions. Values are means ± SD of duplicate assays.

Means ± SD ($n = 2$). Different letters in the same rows are significantly different at $p < 0.05$.

3.2. Expression of flavonoid pathway genes

RT-PCR analysis was performed to analyse the expression of five key genes of the flavonoid pathway (Fig. 2A). Expression of one of these genes, *CHS*, coding for chalcone synthase, was undetectable in the plant material analysed (Fig. 2B). Regarding each of the other four flavonoid pathway genes, chalcone flavanone isomerase (*CHI*), flavanone 3-hydroxylase (*F3H*), dihydroflavonol 4-reductase (*DFR*) and UDP-glucose flavonoid 3-O-glucosyl transferase (*UFGT*), higher transcript levels were always detected in leaves of plants grown under a long day photoperiod, except for the *UFGT* gene after 10 days (Fig. 2B). In leaves of plants growing under short day conditions, it was not possible to detect expression of *CHI* and *DFR*, and only low levels of transcript were observed for the *F3H* and *UFGT* genes. With the exception of the *UFGT* gene, which was expressed at a low level at day 10 and undetectable at day 30 under a short day photoperiod, the number of days of light exposure did not apparently affect the expression of any of the flavonoid pathway genes studied (Fig. 2B). In summary, expression of the examined flavonoid pathway genes was largely higher in leaves of sweet po-

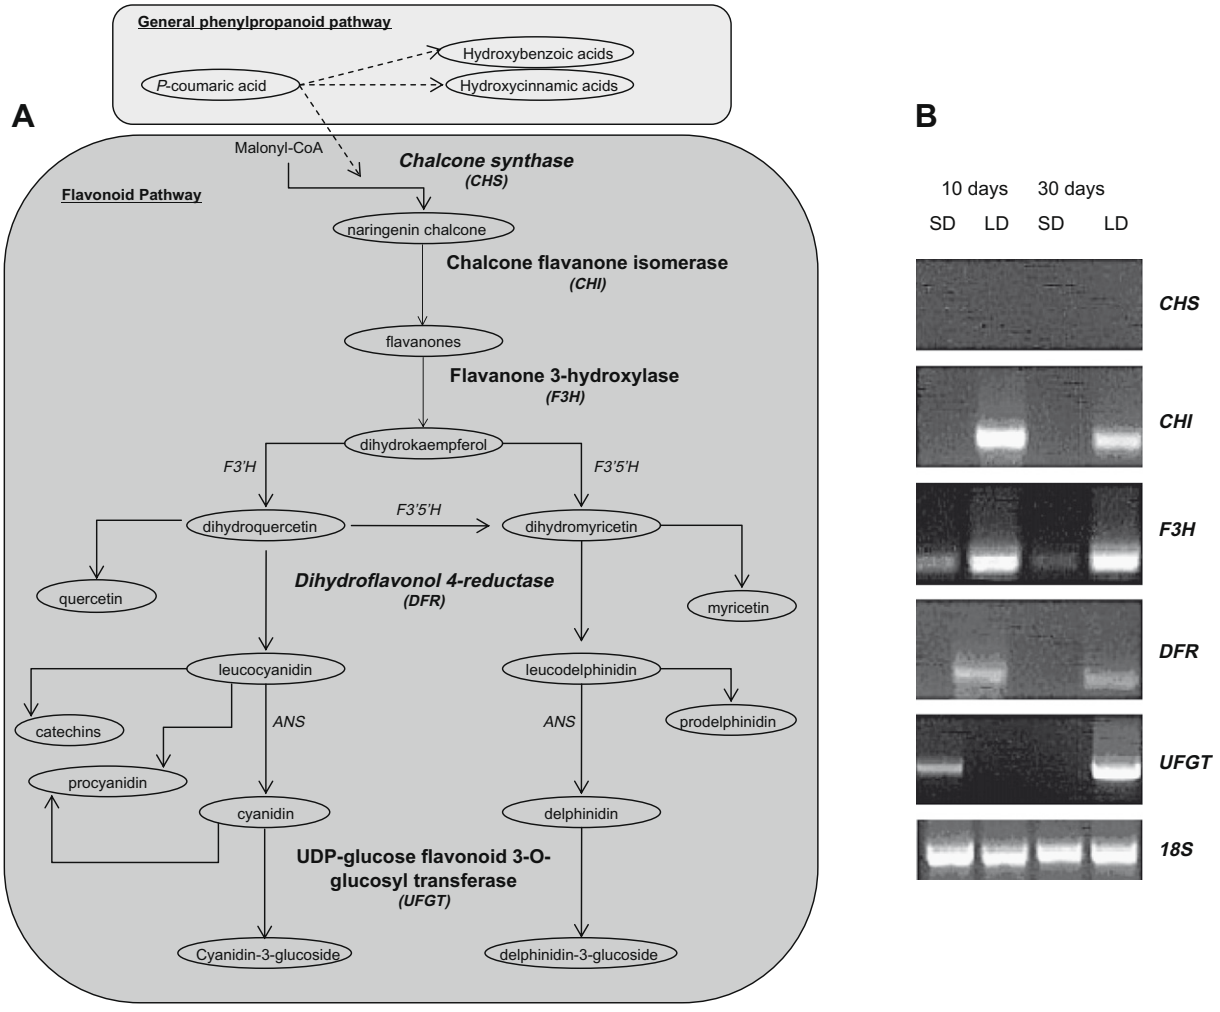

Fig. 2. (A) Schematic representation of the flavonoid pathway. Genes whose expression was determined are shown in bold. (B) RT-PCR analysis of the expression of five flavonoid pathway genes in sweet potato leaves collected at days 10 and 30 of exposure to long day (16 h photoperiod) or short day (8 h photoperiod) conditions. Amplification of 18*S* ribosomal RNA was used as a loading control. Results are representative of three independent experiments.

tato plants growing under long day than in leaves of plants growing under short day conditions, independently of the time of light exposure (10 or 30 days).

3.3. Flavonoid and phenolic acid composition

Anthocyanins, catechins, proanthocyanidins, flavonols, hydroxycinnamic acids and hydroxybenzoic acids from the sweet potato leaves under study were identified and quantified using high-performance liquid chromatography combined with a photodiode-array detector (HPLC–PDA). HPLC–PDA analyses, showing the separation of 13 flavonoids and phenolic acids from leaves of sweet potato plants after 10 and 30 days of growth under short day or long day photoperiods, are illustrated in Fig. 3. A good separation could be achieved in a short separation time of 30 min. The concentration of the identified components was calculated using the obtained calibration curves (data not shown).

Although typical anthocyanins are not abundant in green leaves, it was possible to detect delphinidin-3-glucoside (960 g g^{-1} fw) in leaf extracts of sweet potato plants grown for 30 days under a long day photoperiod (Table 2). High levels of delphinidin-3-glucoside detected under these growth conditions correlate with a higher expression of the *UFGT* gene (see Fig. 2B), which catalyses the conversion of delphinidin to delphinidin-3-glucoside (see Fig. 2A). These results are consistent with a redder colour of leaves under a long day photoperiod when compared with leaves of plants growing under short day conditions, which were mainly green (see Fig. 1). Higher transcript levels of the *CHI* and *F3H* flavonoid pathway genes were also observed in leaves of plants growing under a long day (see Fig. 2B), correlating with higher concentrations of the flavonol kaempferol in leaves under a long day as compared with leaves growing under a short day photoperiod (Table 2). These results provide further support to the protective role of flavonoids in plants growing under high photoperiod (Tawaha, Alali, Gharaibeh, Mohammad, & El-Elimat, 2007).

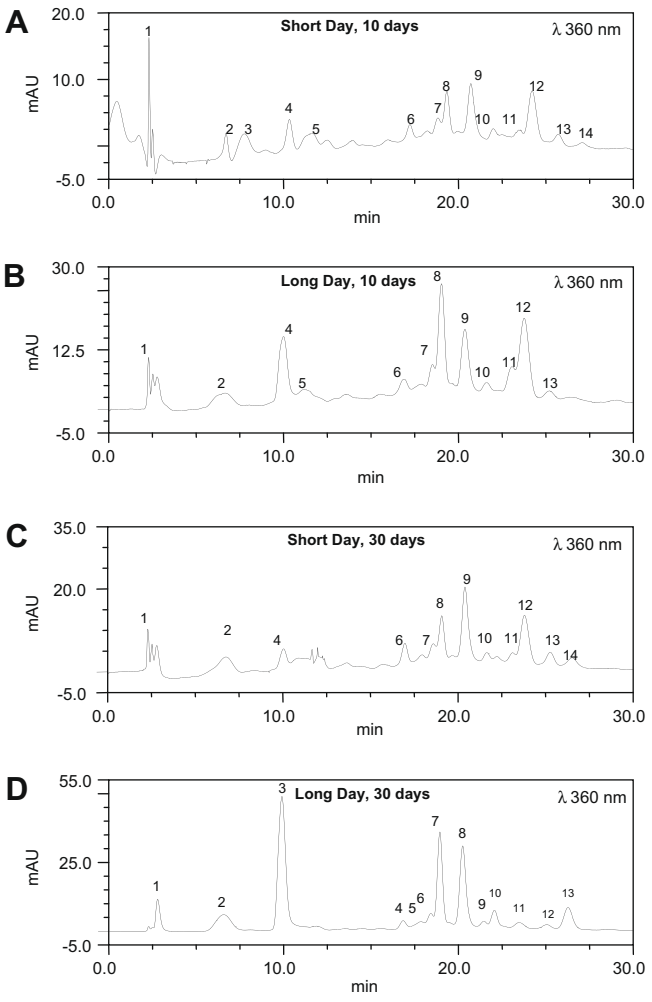

Fig. 3. HPLC chromatogram at 360 nm of different flavonoids and phenolic acids in sweet potato leaves collected at days 10 (A and B) and 30 (C and D) of exposure to long day (B and D) or short day (A and C) conditions. Peaks: 1 – gallic acid; 2 – gentisic acid; 3 – catechin; 4 – chlorogenic acid; 5 – caffeic acid; 6 – epicatechin; 7 – *p*-coumaric acid; 8 – sinapic acid; 9 – benzoic acid; 10 – anisic acid; 11 – kaempferol; 12 – myricetin; 13 – cinnamic acid; 14 – quercetin.

The flavonols (+)-catechin and (−)-epicatechin were also identified and quantified (Table 2). Again, the results obtained indicate higher amounts of total catechins (65.0 g g^{-1}) in leaves of sweet potato plants growing under a long day photoperiod for 30 days. The quantitative compositions of flavonols (quercetin, myricetin and kaempferol), hydroxycinnamic acids (*p*-coumaric, caffeic or ferulic acid conjugates and chlorogenic, sinapic and cinnamic acids) and hydroxybenzoic acids (benzoic, gentisic and *p*-anisic acids) were also consistently higher in leaves of plants growing under a long day photoperiod, with the exception of quercetin and myricetin that were not detected under this light regime.

Hydroxycinnamic acids, namely *p*-coumaric acid conjugates (415 g g^{-1}) and sinapic acid (480 g g^{-1}), were the major phenolic acids detected in sweet potato leaves exposed to a long day photoperiod for 30 days, as compared with those of plants growing under short day conditions for the same period of time (12.2 and 31.4 g g^{-1}, respectively). Similar results were obtained for hydroxybenzoic acids, namely benzoic (106 g g^{-1}), and *p*-anisic acids (48.0 g g^{-1}), which were present in higher amounts in leaves under a long day for 30 days than in leaves of plants exposed to a short day photoperiod for the same length of time (3.53 and 2.98 g g^{-1}, respectively). The levels of gentisic acid were also significantly higher (approximately fourfold) under long day than under short day conditions, but in this case no effect of exposure time was detected.

4. Discussion

Flavonoid compounds of fruits and vegetables have been considered as therapeutic agents due to their beneficial health effects, such as their supposed protection against certain cancers, cardiovascular diseases and aging (Ross & Kasum, 2002). Moreover, they have also been deemed a source of colours for food products, mainly anthocyanins (Espìn, Soler-Rivas, Wichers, & Garcìa-Viguera, 2000), alternative to synthetic dyes whose harmful effects upon human health have often been assumed and, in some cases, demonstrated. According to Mano et al. (2007), sweet potato accumulates flavonoid compounds in various tissues, such as flowers, leaves, stems and non-tuberous, as well as tuberous, roots. In the present study, attention was focused on sweet potato edible leaves and on the effects of different light treatments on their compositions in polyphenolic compounds.

Previous work has established that the antioxidant properties of some vegetables and fruits are partly due to low molecular weight phenolic compounds, particularly flavonoids, which are known to be potent antioxidants (Wang, Nair, Strasburg, Booren, & Gray, 1999). The total concentration of phenolic acid compounds in leaves of sweet potato reported in the present study is lower than that reported by Huang et al. (2006) for sweet potato tubers, but comparable to that reported for other edible plant leaves (Gins, Kolesnikov, Kononkov, Trishin, & Gins, 2000; Takenaka, Nagata, & Yoshida, 2000). These were found to be rich in chlorogenic acid,

caffeic or ferulic acid conjugates and quercetin. This is in agreement with our results, in which increases in hydroxycinnamic acids, such as chlorogenic acid and caffeic or ferulic acid conjugates, under a long day photoperiod correlated with an increase in total phenolic compounds.

The biosynthesis of flavonoid compounds is catalysed by several enzymes, namely *CHS*, *CHI*, *F3H*, *DFR* and *UFGT*. *CHS* is the first committed enzyme of flavonoid biosynthesis, while *DFR* is the first committed enzyme of anthocyanin biosynthesis (see Fig. 2A). Expression of the genes coding for these enzymes is regulated by environmental cues, particularly light and temperature (Owens et al., 2008). In the present study, expression of the *CHS* gene was undetectable, whereas *DFR* was expressed only in leaves of sweet potato plants exposed to a long day photoperiod. This may explain why chalcones and anthocyanins were not detected in methanolic extracts, except for leaves growing for 30 days under a long day photoperiod, where a large amount of delphinidin-3-glucoside was detected in parallel with high levels of expression of the *UFGT* gene. After 10 days, under a short day photoperiod, significant levels of the *UFGT* transcript were detected, but this did not correlate with detectable amounts of the anthocyanin. High amounts of delphinidin-3-glucoside could result in a non-proportional increase in flavonoid compounds, such as hydroxycinnamic and hydroxybenzoic acids, or even catechins and kaempferol. In fact, the major flavonoid compounds found in sweet potato leaves were hydroxycinnamic acids, mainly *p*-coumaric acid conjugates and sinapic acid, present in almost equal proportions and representing about 85% of the total pigment content.

Hydroxycinnamic acids are thought to have the ability to shield the underlying tissues from harmful UV radiation. Indeed, Burchard, Bilger, and Weissenböck (2000) detected an increase in hydroxycinnamic acid concentrations in grape (*Vitis vinifera*) leaves as a consequence of strong visible radiation whereas, in the same study, the flavonoid production was specifically enhanced by UV radiation. In the present work, the high levels of *p*-coumaric acid, a precursor of both the flavonoid pathway and the biosynthesis of other hydroxycinnamic acid conjugates, detected after 30 days of exposure of sweet potato leaves to a long day photoperiod, may explain the overall activation of flavonoid production, as well as the sharp increase in hydroxycinnamic acid contents.

The qualitative and quantitative compositions of flavonols and phenolic acids also differed within leaves of plants growing under different photoperiod regimes. Kaempferol, the major flavonol in the sweet potato leaves studied, was detected in higher amounts under long day exposure, whereas quercetin and myricetin were detected only under a short day photoperiod, probably because high levels of kaempferol, produced upstream in the metabolic pathway, prevent accumulation of these compounds.

Strikingly, sweet potato leaf colour was affected by the photoperiod. Leaves exposed to long day conditions displayed enhanced red colour compared with yellow/green leaves from plants under a short day light photoperiod. The detected higher expression of all examined flavonoid pathway genes, as well as larger amounts of catechins, flavonols, and particularly the anthocyanin delphinidin-3-glucoside, under a long day photoperiod, explains the redder colour of leaves growing under these light conditions.

In summary, the results obtained in the present study show that photoperiod regimes influence the accumulation of phenolic acids, anthocyanins and other flavonoids in sweet potato leaves by increasing the total contents of these compounds under long day conditions, and that this accumulation is correlated with up-regulation of key flavonoid pathway gene expression. The results suggest that flavonols and the anthocyanin delphinidin-3-glucoside, together with hydroxycinnamic and hydroxybenzoic acids, play a predominant role in the defence against increased light exposure in sweet potato leaves. A dramatic induction of the synthesis and accumulation of flavonoids has previously been observed in response to high (sun)light. Although flavonoids are increasingly recognised as playing important roles as antioxidants, further work is necessary to uncover the full potential of these compounds in the improvement of human health, as well as to identify their presence in various foods and elucidate environmental effects on their contents in plants.

5. Conclusion

To our knowledge, this is the first work reporting the quantification of individual polyphenolic compounds in leaves exposed to different light regimes of sweet potato. Results show that the increased light exposure imposed by a long day photoperiod induces the expression of at least four key flavonoid pathway genes (*CHI*, *F3H*, *DFR* and *UFGT*), which positively correlates with the accumulation of an anthocyanin, catechins and the flavonol kaempferol, as well as hydroxycinnamic and hydroxybenzoic acids, in sweet potato leaves, suggesting a protective role for these compounds in plant tissues under increased light exposure.

Indian honeys
Phenolics content
Antioxidant
Radical scavenging activity
DPPH
Proline

ABSTRACT

The study was intended to characterise the physicochemical and antioxidant properties of some commercial brands of Indian honeys. All the samples showed considerable variations with reference to their level of total phenolics, protein, radical scavenging activity, ascorbic acid equivalent antioxidant content (AEAC) and ferric reducing antioxidant potential (FRAP). Comparative studies of Indian honeys indicated the strong correlation between proline content and AEAC as well as 2,2-diphenyl-1-picryl-hydrazyl (DPPH) scavenging activity whereas phenol content was strongly correlated with FRAP values. Thus, overall antioxidant activity seems to be contributed by proline and phenol contents. Besides these major factors, colour pigments (ABS_{460}) were also found to contribute significantly to the overall observed antioxidant activity.

1. Introduction

Honey, produced by the honeybee, is a natural supersaturated sugar solution, which is mainly composed of a complex mixture of carbohydrates. Besides this, it also contains certain minor constituents viz., proteins, enzymes (invertase, glucose oxidase, catalase, phosphatases), amino and organic acids (gluconic acid, acetic acid, etc.), lipids, vitamins (ascorbic acid, niacin, pyridoxine etc.), volatile chemicals, phenolic acids, flavonoids, and carotenoid like substances and minerals (Blasa et al., 2006). The composition of honey depends on the plant species visited by the honeybees and the environmental, processing and storage conditions (Bertoncelj, Dobersek, Jamnik, & Golob, 2007; Guler, Bakan, Nisbet, & Yavuz, 2007). Blossom or nectar honey is derived from the nectaries of flowers and honeydew honey comes from the sugary excretion of some hemipterous insects on the host plant or from the exudates of the plants.

Honey has been traditionally used for different purposes and has a great potential to serve as a natural food antioxidant. In recent years much attention has been focused on the use of natural dietary antioxidants as an effective protection against oxidative damage. Enzymes in honey serve as antioxidants by promoting the removal of oxygen (Oszmianski & Lee, 1990). Honey consumption has been reported to be effective in increasing the total plasma antioxidant and reducing capacity in humans (Gheldof, Wang, & Engeseth, 2003).

The comparative physicochemical characterisation of different honeys from other regions of the world has been carried out extensively (Azeredo, Azeredo, De Souza, & Dutra, 2003; Finola, Lasagno, & Marioli, 2007; Guler et al., 2007; Ouchemoukh, Louaileche, & Schweizer, 2007). Although in India honey is produced and consumed on a large scale, there is a lack of information on the comparative biochemical properties of Indian honeys. Therefore, the objective of the current study was to investigate the physical, biochemical and antioxidant properties of Indian honeys and also to study their possible interdependence.

2. Materials and methods

2.1. Chemicals

Ascorbic acid, Folin–Ciocalteu's phenol reagent, gallic acid and L-proline were procured from Sigma Chemical Co. Ltd. (St. Louis, Mo., USA). Bovine serum albumin (10 mg/ml) was obtained from Bangalore Genei, Bangalore, India. Sodium chloride (NaCl) and trichloroacetic acid (TCA) were purchased from S.D. Fine-Chem. Ltd., Mumbai, India.

2.2. Honey samples

The present study was carried out using seven reputed commercial Indian honey brands. Fresh honey samples weighing 250 g, packed and sealed in glass bottles, were purchased from a

doi:10.1016/j.foodchem.2009.05.001

local market, and stored at 4 °C. The samples were analysed at the earliest in such a way that none of the samples exceeded the storage period beyond six months. The honey samples were kept at ambient temperature (26 ± 2 °C) overnight before the analyses were performed.

2.3. Physical analysis

2.3.1. Viscosity

Viscosity is the measure of the internal friction of a fluid. The viscosity measurements were performed at ambient temperature, using a Brookfield disc-type viscometer (model RVDVI+, Brookfield Engineering Labs, INC. Stoughton, MA 02072, USA). All the commercial honey samples were non-crystalline liquid honeys and any air bubbles which could interfere in the viscosity analysis were removed. The spindle type and spindle speed (shear rate in rpm) were S-6 and 50 rpm, respectively. A 35 ml aliquot of honey sample was withdrawn in a Falcon tube and used to measure the viscosity. The measurement was repeated thrice for each sample and the mean viscosity (cP) was calculated.

2.3.2. Water activity

A small aliquot of honey sample weighing approximately 1 g was used for determining water activity (a_w) using a water activity meter. This measures the water activity of the sample based on its equilibrium relative humidity (ERH). The relationship between a_w and ERH is a_w = ERH (in percentage)/100 (AqualabCX2T, Decagon Devices, USA) (Chirife, Zamora, & Motto, 2006). The measurements were performed in triplicates for each sample and the mean was determined.

2.3.3. Moisture content

The moisture content was determined based on the refractometric method. In general, the refractive index increases with the increase in the solid content. The refractive indices of honey samples were measured at ambient temperature using an Atago hand refractometer and the readings were further corrected for a standard temperature of 20 °C by adding the correction factor of 0.00023/°C. Moisture content was determined in triplicate and the% moisture content values corresponding to the corrected refractive index values were calculated using Wedmore's table (AOAC, 1990).

2.3.4. pH

The pH was measured using a pH meter (Elico ph analyser, Elico Pvt Ltd., Mumbai) for a 10% (w/v) solution of honey prepared in milli Q water.

2.3.5. Ash content

The ash content was determined by placing 2–3 g of honey samples in a crucible in a muffle furnace and heating at 640 °C for 6 h. Measurements of ash were done in triplicate and the mean was expressed in g% (AOAC, 1990).

2.3.6. Electrical conductivity

The measurement of electrical conductivity is based on the determination of the electrical resistance. The electrical conductivity was measured using a conductivity bridge (type CLOI/02A) for a 20% (w/v) solution of honey suspended in milli Q water (Bogdanov et al., 1997). The electrical conductivity of the milli Q water was < 10 μS/cm. Each sample was analysed in triplicate and the mean was expressed in mS/cm.

2.3.7. Total soluble solids (TSS) and total solids (TS)

The total soluble solids of the honey samples were measured by refractometry using a Atago hand held refractometer and the results were expressed in °Brix. All the measurements were done at ambient temperature and the readings were corrected for a standard temperature of 20 °C by adding the correction factor of 0.00023/°C (AOAC, 1990). The total solid content (%) in the honey samples was calculated by using the formula: TS (%) = 100 - moisture content (Amin, Safwat, & El-Iraki, 1999).

2.3.8. Colour measurement

For colour analyses a 30 ml aliquot of honey sample was packed and sealed in high-density polyethylene packets. The colour of the honey samples was measured based on reflectance measurement using a Minolta CM-3600D Spectrophotometer (Konica Minolta Sensing, Inc., Osaka, Japan). The reflectance of the whole visible spectrum (360–780 nm) was recorded at a wavelength interval of 10 nm. An illuminant C and 2° viewing angle were used as the standard light source and observer, respectively. The instrument was first calibrated with a black and white standard and then the reflectance was measured. The CIE colour parameters used were L^*(Lightness: L^* = 100 for white and 0 for black), a^*(redness/greenness axis: positive a^* is red and negative a^* is green), b^*(yellowness/blueness axis: positive b^* is yellow and negative b^* is blue), C^*(chroma or saturation index), and H^*(Hue). These parameters were analysed using JAYPAK 4808 software (Quality Control System, Version 1.2).

2.3.9. Colour intensity: ABS_{450}

The net absorbance of the honey samples was determined by the method of Beretta, Granata, Ferrero, Orioli, and Facino (2005). The honey samples were diluted to 50% (w/v) with warm (45–50 °C) milli Q water and the solution was filtered through a 0.45 μm filter. There was a complete absence of coarse particles in the honey solutions as all the commercial samples were non-crystalline liquid honeys. The absorbance was measured using a spectrophotometer at 450 and 720 nm and the difference in absorbance was expressed as mAU (Beretta et al., 2005).

2.4. Biochemical analysis

2.4.1. Reducing sugar and total sugar

The total reducing sugar was determined using 3,5-dinitrosalicylic acid (DNSA). In principle the reducing sugar reduces DNSA to 3- amino- 5-nitrosalicylic acid resulting in the formation of reddish–orangeish colouration which is measured spectrophotometrically at 540 nm (Khalil et al., 2001). The honey solution (0.1 g/ml) was diluted 100 fold with milli Q water. A 1 ml aliquot of this diluted solution was mixed with equal amounts of the DNSA solution and incubated in a boiling water bath for 10 min. The mixture was allowed to cool to ambient temperature, mixed with 7.5 ml of milli Q water and the absorbance was measured at 540 nm using a spectrophotometer. A glucose solution of known concentration was used as a standard. The estimation of total sugar content was performed following the inversion of sucrose (a non-reducing sugar) to a reducing sugar and subsequently measuring its concentration as discussed before (Sawhney & Singh, 2000). Briefly, the honey solution (0.1 g/ml) was diluted 33 fold with milli Q water and to 1 ml of the diluted solution, concentrated hydrochloric acid was added to obtain a final concentration of 2 N. The mixture was incubated at 68 °C for 8 min for the complete inversion of sucrose to a reducing sugar. The acid hydrolysed solution was cooled to ambient temperature and neutralised by the addition of sodium hydroxide. The total volume was adjusted to 2 ml with milli Q water. From this, a 500 μl aliquot was withdrawn for quantifying the total sugar content in terms of reducing sugar as per the method described above. Measurements were performed in triplicate. The sucrose concentration (%) in honey samples was calculated using the equation: sucrose (%) = (total sugar−total reducing sugar) × 0.95 (Amin et al., 1999).

2.4.2. Total protein content

The total protein content was determined by Lowry's method of protein estimation which is based on the formation of a copper–protein complex and the reduction of phosphomolybdate and phosphotungstate present in Folin–Ciocalteau reagent to hetero polymolybdenum blue and tungsten blue, respectively. Bovine serum albumin (0–100 μg/ml) was used as a standard for preparing the calibration curve.

2.4.3. Total phenolic content

The total phenolic content was determined by the Folin–Ciocalteu method (Singleton, Orthofer, & Lamuela-Raventos, 1999). Thirty microlitre of honey solution (0.1 g/ml) was mixed with 2.37 ml of milli Q water and 150 μl of 0.2 N Folin–Ciocalteu reagent. The solution was thoroughly mixed by vortexing and incubated for 2 min at ambient temperature. Four hundred and fifty microlitre of sodium carbonate solution (0.2 g/ml) was added to the reaction mixture and further incubated for 2 h at ambient temperature. The absorbance was measured at 765 nm using a spectrophotometer. The total phenolic content was determined by comparing with a standard curve prepared using gallic acid (0–200 mg/l). The mean of at least three readings was calculated and expressed as mg of gallic acid equivalents (mg GAE)/100 g of honey.

2.5. Analysis of antioxidant activities

2.5.1. Antioxidant content

The antioxidant content in terms of ascorbic acid equivalent antioxidant content (AEAC) was determined using the method of Meda, Lamien, Romito, Millogo, and Nacoulma (2005). The honey sample was dissolved in methanol to a final concentration of 0.03 g/ml. A 0.75 ml aliquot of the methanolic honey solution was mixed with 1.5 ml of 0.02 mg/ml of DPPH solution prepared in methanol. The mixture was incubated at room temperature for 15 min and the absorbance was measured at 517 nm using a spectrophotometer. The blank used was 0.75 ml of methanolic honey solution mixed with 1.5 ml of methanol. Ascorbic acid standard solutions (0–10 μg/ml) prepared in milli Q water were used to plot the calibration curve. Measurements were performed in triplicate and the mean value was expressed as mg of ascorbic acid equivalent antioxidant content (AEAC) per 100 g of honey.

2.5.2. DPPH radical scavenging activity

The DPPH (2,2-diphenyl-1-picryl-hydrazyl) radical scavenging effect (H/e^- transferring ability) of honey samples was measured as per the method described by Chen, Lin, and Hsieh (2007). The DPPH was dissolved in absolute ethanol to a 0.2 mM concentration. A 100 μl aliquot of honey solution (0.1 g/ml) was diluted to 500 μl with 70% ethanol, and vigorously mixed with 400 μl of DPPH solution by vortexing. The mixture was incubated at room temperature for 15 min and the absorbance of the solution (T_1) was measured at 517 nm. Sample blank (B_1) consisted of 600 μl of 70% ethanol and 400 μl of DPPH whereas DPPH blank (B_2) contained 100 μl of honey sample, 500 μl of 70% ethanol and 400 μl of absolute ethanol. The DPPH scavenging activity was calculated using the following formula:

$$\text{DPPH scavenging activity } (\%) = [1 - \{(T_1 - B_2)/B_1\}] \times 100$$

Where T_1, B_1, and B_2 are the absorbencies of the sample, sample blank and DPPH blank, respectively.

2.5.3. Ferric reducing/antioxidant power (FRAP) assay

The reducing power of the ethanolic extracts of honey was determined according to the method of Oyaizu (1986). A 1 ml aliquot of ethanolic honey extract (10% v/v) was mixed with 2.5 ml of phosphate buffer (0.2 M, pH 6.6) and 2.5 ml of potassium ferri-cyanide (1%). The mixture was incubated at 50 °C for 20 min. After this, 2.5 ml of 10% trichloroacetic acid was mixed by vortexing. The mixture was centrifuged at 3000 rpm for 10 min. A 2.5 ml aliquot of the supernatant was mixed with an equal amount of milli Q water and 0.5 ml of 0.1% $FeCl_3$. The absorbance was measured at 700 nm using a spectrophotometer. Precipitation or flocculation was never observed. Assays were performed in triplicate. Ascorbic acid (1.0 mg/ml) was used as a reference standard. The increase in absorbance provided an indication of higher reducing power of the samples being analysed.

3. Results and discussion

3.1. Physical analysis

3.1.1. Ash content and electrical conductivity

The percentage ash content is an indicator of the mineral content. It is considered as a quality criterion indicating the possible botanical origin of honey. Its value in the analysed samples ranged from 0.03 to 0.43 g% (Table 1). For most of the honeydew honeys from Romania, ash values ranged from 1.17 to 1.23, whereas, for floral honeys (acacia, sun-flower and lime), it ranged from 0.03 to 0.40 (Al et al., 2009). Generally, the ash content of blossom honey is $\leqslant$0.6% as compared to honeydew honey or blends of honeydew and blossom honeys where this value is $\geqslant$1.2% (Ouchemoukh et al., 2007). Thus based on this criterion, the analysed Indian honeys could be similar to the blossom honeys and the ash content values are comparable to the blossom honeys of Romania as mentioned above and also with Algerian honeys, for which the reported values are in the range of 0.06–0.54% (Ouchemoukh et al., 2007). The variability in the ash content of honeys could be due to harvesting processes, beekeeping techniques and the material collected by the bees during the foraging on the flora

Table 1
Comparative physical parameters of analysed honeys.

Honey	a_w[a]	Moisture (%)	Viscosity (cP)	TS[b] (%)	TSS[c] (°Brix)	RI[d]	Ash (%)	EC[e] (mS/cm)	pH

[e] Electrical conductivity.

(Finola et al., 2007). The electrical conductivity (mS/cm) in honey samples varied in the range of 0.33–0.94. A linear relationship is known to exist between the ash content and the electrical conductivity which is expressed as $C = 0.14 + 1.74\,A$, where C is the electrical conductivity and A is the ash content (Bogdanov et al., 2000). The coefficient of correlation between electrical conductivity and ash was found to be 0.98, which indicated a strong positive correlation between the two parameters. Similarly, a correlation value of 0.92 has been found to exist between the electrical conductivity and ash content for some Algerian honeys (Ouchemoukh et al., 2007).

3.1.2. pH

All the Indian honeys analysed were found to be acidic in character. Their pH values ranged from 3.7 to 4.4 (Table 1). In general, honey is acidic in nature irrespective of its variable geographical origin. The pH values of Algerian, Brazilian, Spanish and Turkish honeys have been found to vary between 3.49 to 4.53, 3.10 to 4.05, 3.63 to 5.01 and 3.67 to 4.57, respectively (Azeredo et al., 2003; Kayacier & Karaman, 2008; Ouchemoukh et al., 2007).

3.1.3. Moisture content

The moisture content (%) in the investigated samples ranged from 17.2 to 21.6. Except for sample V, all other tested Indian honeys had moisture contents below 20%, which is the maximum prescribed limit for the moisture content as per the Codex standard for honey (Codex Alimentarius, 2001). The moisture level of the analysed samples was consistent with the previous reported values for some Indian honeys for which the corresponding values ranged from 18.7% to 21.8% (Singh & Bath, 1997). The moisture content of honeys of different origins show varietal differences and it may range from 13% to 29% (Kayacier & Karaman, 2008). A higher moisture content could lead to undesirable honey fermentation during storage caused by the action of osmotolerant yeasts resulting in the formation of ethyl alcohol and carbon dioxide. The alcohol can be further oxidised to acetic acid and water resulting in a sour taste (Chirife et al., 2006). The moisture content of honey depends on various factors such as harvesting season, degree of maturity reached in the hive and climatic factors (Finola et al., 2007).

3.1.4. Water activity and viscosity

The water activity of the honey samples varied from 0.57 to 0.70 (Table 1). Our results are quite similar to those of Greek honeys for which the a_w values ranged from 0.53 to 0.67 (Lazaridou, Biliaderis, Bacandritsos, & Sabatini, 2004). The water activity is an important factor, which governs the food stability by preventing or limiting microbial growth. The osmotolerant yeasts are able to grow at a minimal water activity of 0.6 (Chirife et al., 2006). The honey sample IV, which had the lowest moisture content was found to have the highest water activity. Such observations are occasionally observed in certain honey samples probably due to the variation in the constituents and/or levels of individual sugar components (Abramovič, Jamnik, Burkan, & Kač, 2008). Viscosity is known to be affected by the water content and in our study an inverse correlation was found between the water activity and viscosity, with a correlation value of −0.9308. The viscosity of the samples ranged from 1140 to 8500 cP. All the analysed Indian honey samples were Newtonian with reference to their rheological behaviour and satisfactorily followed an Arrhenius model within a temperature range from 5 to 40 °C (Saxena et al., 2009, unpublished data).

3.1.5. Colour characteristics

The colour characteristics are presented in Table 2. Honey samples having an L value >50 are lighter honeys, whereas, samples having an L value ⩽50 are dark honeys. Therefore, based on this classification, the studied Indian honeys can be regarded as dark honeys because the L values of the samples ranged from 26.3 to 36.8. The 'a' values varied from 0.12 to 4.9; 'b' values ranged from 0.7 to 14.4; 'C' values ranged from 3.1 to 14.7 and 'H' value ranged from 44.7 to 89.4. Thus it is apparent that all the samples being darker had red and yellow components. The colour intensity (ABS_{450}) is supposed to be related to pigments (carotenoids, flavonoids etc.), which are also known to have antioxidant properties (Frankel, Robinson, & Berenbaum, 1998). The ABS_{450} values for the samples ranged from 524 to 1678 mAU (Table 2). The reported ABS_{450} values for some Italian and Slovenian honeys are in the range of 25 to 3413 mAU and 70 to 495 mAU, respectively (Beretta et al., 2005; Bertoncelj et al., 2007).

3.2. Biochemical analysis

3.2.1. Sugar

The total sugar and the total reducing sugar content in the honey samples ranged from 45.3% to 66.7% and 43.3% to 65%, respectively (Table 3). The data indicated that the majority of soluble sugars in honey samples are reducing sugars. The sucrose content (%) in the samples ranged from 0.4 to 8.8. Except for sample number VII, all other samples had sucrose levels below 5% which is the maximum prescribed limit as per the Codex standard (Codex Alimentarius, 2001). A higher sucrose content observed in one sample could be attributed to reasons such as overfeeding of honeybees with sucrose syrup, adulteration, or an early harvest of honey, wherein sucrose has not been fully transformed into glucose and fructose (Anklam, 1998; Azeredo et al., 2003; Guler et al., 2007). Some unifloral honeys like Banskia, Citrus, Hedysarum,

VI	36.8 ± 0.3	0.1 ± 0.08	13.2 ± 0.1	13.3 ± 0.12	89.5 ± 0.4	1338 ± 0.7
VII	36.3 ± 0.3	2.7 ± 1.9	14.4 ± 0.7	14.7 ± 1.01	79.6 ± 7.1	796 ± 3.5

Medicago and Robinia contain up to 10% sucrose, whereas, up to 15% sucrose has been reported for Lavandula honeys (Bogdanov et al., 2000). Reducing sugars, which include mainly glucose and fructose, are the major constituents of honey (Küçük et al., 2007). A lime honey from Romania had 42.49% of combined glucose and fructose content (Al et al., 2009). Overheating of honey samples during processing or storage for very long periods could lead to the conversion of sugars to hydroxy methyl furfural (HMF). A low level of HMF is an indicator of the freshness of honey. In a parallel study, the HMF content of honey samples has been determined. In many of the samples the HMF content was found to be more than internationally recommended limit of 80 mg/kg (Saxena et al., 2009, unpublished data).

3.2.2. The protein content

In the current study the protein content (μg/g of honey) in the Indian honeys ranged from 480 to 2293, which was determined using the bovine serum albumin (BSA) as standard (R^2 = 0.9931). The protein content in Indian honeys was comparable to that found in Brazilian honeys where it varied from 199 to 2236 μg/g (Azeredo et al., 2003). Relatively higher protein levels ranging from 3700 to 9400 μg/g have been reported in Algerian honeys (Ouchemoukh et al., 2007). The protein content in honeys can be attributed to the presence of enzymes, some of which are introduced by bees themselves, and others are thought to be derived from the nectar. The protein content of honey is normally less than 5 mg/g (Anklam, 1998). The level of protein is dependent on the type of flora and thus it is variable. Proline is the predominant amino acid found in honey. The proline content in the honey samples was found to vary from 133 to 674 mg/kg (Saxena et al., 2009, unpublished data).

3.2.3. The total phenolic content

The total phenolic content (mg GAE/100 g of honey) of Indian honeys was found in the range of 47 to 98, which was determined using gallic acid as standard (R^2 = 0.9988). A similar level of phenolic content was also observed for Romanian honeydew honeys for which the phenolic content varied from 23.0 to 125.0 mg GAE/100 g (Al et al., 2009). For Algerian and Slovenian honeys, the phenolic content ranged from 64 to 1304 and 448 to 2414 mg GAE/100 g, respectively (Bertoncelj et al., 2007; Ouchemoukh et al., 2007). The concentration and type of polyphenolic substances in honey is variable and depends on the floral origin of honey (Küçük et al., 2007).

3.2.4. Antioxidant activity

Due to the lack of a specific official analytical approach for determination of antioxidant property of honey, different antioxidant assays have been used to evaluate the antioxidant properties of Indian honeys (Bertoncelj et al., 2007). Commonly used antioxidant assays are the FRAP (Ferric reducing antioxidant power) assay, percentage DPPH (1,1-diphenyl-2-picrylhydrazyl) scavenging activity, and ascorbic acid equivalent antioxidant content (AEAC). These methods are in wide use for assessing the antioxidant activity of different plant extracts (Chen et al., 2007).

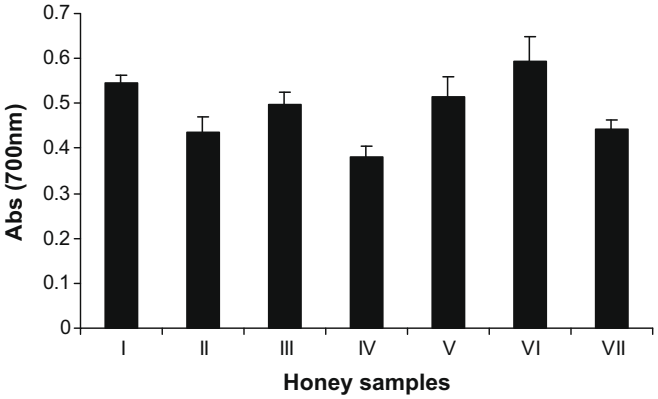

Fig. 1. Ferric reducing antioxidant power (FRAP) of the honey samples. The absorbance value at 700 nm for 1 mg/ml conc. of ascorbic acid (used as standard) was 1.543.

3.2.5. DPPH scavenging activity

DPPH is a stable nitrogen centred radical and has been widely used to test the free radical scavenging ability of various samples. The higher the DPPH scavenging activity, the higher the antioxidant activity of the sample. The presence of an odd electron is responsible for the strong absorption maxima at 517 nm for DPPH, which results in a purple colour. The decolourisation of DPPH occurs from purple to yellow when the unpaired electron of DPPH forms a pair with a hydrogen donated by a free radical scavenging antioxidant, thus converting DPPH into its reduced form. The DPPH radical scavenging effect of Indian honeys is presented in Table 4. The percentage DPPH scavenging activity ranged from 44 to 71. Five Indian honeys showed scavenging activity greater than 50% except for two samples whose scavenging activities were below 50%.

3.2.6. Ascorbic acid equivalent antioxidant content (AEAC)

Using the standard curve of ascorbic acid (R^2 = 0.9826), it was found that the ascorbic acid equivalent antioxidant content (mg AEAC/100 g of honey) of the analysed Indian honeys ranged from 15 to 30. The AEAC values for the multifloral Burkina Fasan honeys ranged from 10.20 to 37.87 mg AEAC/100 g (Meda et al., 2005). Thus our AEAC results are similar to those reported for multifloral Burkina Fasan honeys.

3.2.7. FRAP assay

The FRAP assay of all the Indian honeys tested are displayed in Fig. 1. The absorbance values in FRAP assay varied from 0.38 to 0.59. A relatively higher absorbance value indicated more reduction of ferric ions to ferrous ions. Samples having a higher reducing

Table 4
DPPH scavenging activity, ascorbic acid equivalent antioxidant content (AEAC), phenol content, and protein content of tested honeys.

Honey	DPPH scavenging activity (% ± SD)[a]	AEAC[b] (mg/100 g ± SD)	Phenol content (mg GAE/100 g ± SD)	Protein content (μg/g ± SD)
I	64 ± 0.7	24.4 ± 0.8	98 ± 1.2	1789 ± 5.5

Table 5
Correlation matrix showing the interrelation amongst ascorbic acid equivalent antioxidant content, DPPH scavenging, FRAP, proline, phenol, and ABS_{450}.

	AEAC	DPPH scavenging	FRAP	Proline	Protein	Phenol	ABS_{450}
AEAC	1	0.97	0.82	0.94	0.95	0.84	0.74
DPPH scavenging	0.97	1	0.84	0.96	0.88	0.80	0.72
FRAP	0.82	0.84	1	0.73	0.64	0.90	0.83
Proline	0.94	0.96	0.73	1	0.92	0.78	0.77
Protein	0.95	0.88	0.64	0.92	1	0.77	0.67
Phenol	0.83	0.80	0.9	0.78	0.77	1	0.90
ABS_{450}	0.74	0.72	0.83	0.77	0.67	0.90	1

power had a higher absorbance value at 700 nm. Similar observations have also been observed for Turkish honeys (Küçük et al., 2007).

3.3. Correlation amongst the biochemical parameters and antioxidant properties

The correlation matrix (Table 5) showed a significant correlation between the biochemical and antioxidant parameters. The correlation values between ABS_{450} and FRAP, ABS_{450} and AEAC and ABS_{450} and percentage DPPH scavenging were 0.83, 0.74 and 0.72, respectively. Thus the colour pigments may have a role in the observed antioxidant activities of the honey samples. A strong correlation value of 0.90 was obtained between the ABS_{450} and phenolic content and 0.83 between the ABS_{450} and FRAP values. Almost similar values were obtained between ABS_{450} and phenolic content (=0.90) and between ABS_{450} and FRAP values (=0.85) for Slovenian honeys (Bertoncelj et al., 2007). A good correlation was observed between the ABS_{450} and percentage DPPH scavenging activity, FRAP and AEAC values indicating probable involvement of pigments conferring antioxidant property to honey.

There are reports indicating the role of amino acids in exhibiting antioxidant properties. In our study, the best interrelation was observed between the proline content and the DPPH scavenging activity for which the correlation value was 0.96 followed by a correlation value of 0.94 between proline content and AEAC. Previous work by Meda et al. (2005) has shown that the level of proline is a major factor responsible for radical scavenging activity as evident from their higher correlation values ($R = 0.75$) compared to that between radical scavenging activity and total phenolics ($R = 0.5$). Thus the percentage of total proline content in honey samples might be a critical factor responsible for their observed antioxidant activity. Protein can also work as an effective antioxidant as reported by Sivapriya and Srinivas (2007). The seminal work of Rice-Evans, Miller, and Paganga (1996), has very clearly indicated that not all plant products bear the same phenolic composition and not all phenolics posses the same antioxidant capacity. Therefore, it is not the quantity but the quality of polyphenols, which serves as the major determinant of the antioxidant capacity of food. This may explain the possible moderate correlation observed between the total phenol content and the antioxidant capacity of the analysed Indian honeys ($R = 0.80$ between phenol and DPPH scavenging activity; $R = 0.83$ between phenol and AEAC). The FRAP values correlated well with the phenolic content with a correlation value of 0.9. Previous studies on honey indicate that the presence of compounds such as polyphenols and flavonoids may function as potential natural antioxidants (Beretta et al., 2005; Blasa et al., 2006). The antioxidant activity of phenolics is mainly due to their redox properties. It can be summarised that the overall antioxidant property in the studied Indian honeys can be attributed to various contributing factors such as proline, phenolics, colour pigments and proteins though the relevance of proline appears prominent as shown by the correlation value.

4. Conclusion

All the seven commercial Indian honeys demonstrated antioxidant activities, which may have therapeutic potential. Though honey has a significant amount of phenols it is felt that the antioxidant property of honey is mainly due to its proline content as evidenced by the significant correlation observed between the antioxidant activity and proline content.

Viscosity
Fatty acid
Oil uptake

ABSTRACT

The fatty acid compositions of seven edible vegetable oils were investigated and correlated with their rheological behaviours and the amount of absorbed oils to fried products. All oil samples showed constant viscosity as a function of shear rate, exhibiting Newtonian behaviours. The highest viscosity was observed in hazelnut oil, followed by olive, canola, corn, soybean, sunflower, and grapeseed oils. In addition, a high correlation (R^2 = 0.94) demonstrated that the flow behaviours of vegetable oils were positively governed by their major components (18:1 and 18:2 fatty acids). It was also shown that a more rapid change in viscosity with temperature was observed in the oils containing more double bonds (R^2 = 0.71). Furthermore, even though the overall tendency was that the potato strips fried in the oils with high viscosity appeared to cause more oil uptake, a significant effect of oil types on oil uptake was not observed.

1. Introduction

Frying has been widely used for food industrial and household purposes as a typical way to prepare for foods. Frying is a very complex process where a variety of chemical and physical phenomena take place such as starch retrogradation, Maillard reactions, surface porosity, oil degradation, and etc. (Mellema, 2003). Specially, in terms of heat and mass transfer, heat is transferred from hot oils to foods and water is evaporated from the surface of the foods. Consequently, the pores caused by water evaporation are occupied by oils, thus causing a significant increase in the oil content of the product. Therefore, it seems that frying belongs to a dehydration process (Budzaki & Seruga, 2005).

Frying provides good sensory properties such as crisp texture, brownish colour, and juicy taste. Nonetheless, a negative aspect of fried foods has recently come to the attention of consumers since such products may contain undesirable components such as acrylamide, trans/saturated fatty acids, and a high amount of oil, even up to 50% of the total weight (Funami, Funami, Tawada, & Nakao, 1999). Specifically, since trans fatty acids are widely reported to be a causative factor in health problems such as coronary heart disease (Van de Vijver et al., 2000; Willett & Ascherio, 1994), non-hydrogenated vegetable oils have been receiving great attractions, consequently causing a dramatic increase in its use as an edible frying medium. This comprehensive trend is also supported by the new food guide pyramid of the United States Department of Agriculture (Goldie, 2005), which recommends to consume vegetable oils high in mono- or polyunsaturated fats and low in saturated fats. Therefore, a variety of natural oils from vegetable sources have been used, which include soybean, corn, palm, sunflower, canola, olive oils, and etc.

Basically, frying is the immersion and cooking of foods in hot oils. Therefore, the first step to understand the frying process would be to characterise the quality of the frying oils being used. Thus, a number of previous studies on vegetable oils have been found where a focus was mainly placed on their chemical (Abdulkarim, Long, Lai, Muhammad, & Ghazali, 2007; Dobarganes, Márquez-Ruiz, & Velasco, 2000) and rheological (Erhan, Asadauskas, & Adhvaryu, 2002; Wan Nik, Ani, Masjuki, & Eng Giap, 2005) properties. However, detailed correlations between such properties have not yet been analysed and only limited sources of vegetable oils have been utilised in preceding studies.

In addition, few reports are available on the amount of absorbed oils to foods depending on the type of vegetable oils, even though the oil uptake is a critical issue in a frying process. A couple of studies demonstrated that oil uptake was related to the oxidative degradation of vegetable oils (Dobarganes et al., 2000; Tseng, Moreira, & Sun, 1996). However, to our knowledge, there was only a report in 2007 (Kita, Lisinska, & Golubowska, 2007) in which the oil uptake and texture of foods fried in sunflower, soybean, peanut, rapeseed, olive, palm, and modified oils were compared as a function of frying temperature. Unfortunately, this study did not provide detailed information on the effect of the oil type on the oil uptake.

Therefore, in this study, the flow behaviours of seven vegetable oils were investigated and then correlated with their fatty acid composition. Also, the effect of the type of vegetable oils on the oil uptake of fried potato strips was investigated.

2. Materials and methods

2.1. Experimental materials

Seven edible vegetable oils (canola, corn, grapeseed, hazelnut, olive, soybean, and sunflower oils) were purchased from a commercial source. All chemicals used in this study were of analytical grade.

2.2. Measurement of fatty acid composition

Fatty acid composition of fresh vegetable oils was investigated by using GC–MS (6890N, Agilent Technologies, DE, USA). After each oil sample was methylated with boron trifluoride (Seiichi, Akiko, Yasue, & Chiemi, 2007), the fatty acid methyl esters were injected into a capillary DB-23 column (0.25 mm ID × 60 m × 0.25 μm film thickness, J & W Scientific, CA, USA). Oven temperature was programmed to be 100 °C for 1 min and then raised to 195 °C (15 °C/min), to 210 °C (1 °C/min), and to 240 °C (10 °C/min), which was held for 10 min. Helium was used as carrier gas. Fatty acid composition was expressed as percentage of the total peak area of all the fatty acids in the oil sample.

2.3. Rheological measurement

The flow behaviours of vegetable oils were measured by using a controlled-stress rheometer (Rheostress RS1, Thermo Hakke, Germany) with parallel plates (35 mm diameter). Shear rates in the range of 10–1000 s^{-1} under steady shear conditions were applied to oil samples of which resulting shear stress was measured at 25 °C. Also, in order to investigate the effect of temperature on oil viscosity, the oils were sheared at a constant shear rate of 100 s^{-1} over temperatures ranging from 20 to 70 °C and their viscosity was then measured.

2.4. Frying experiments

Potatoes were hand-peeled and cut into strips (0.9 × 0.9 × 5 cm) using a rectangular-shaped mould and knife. The potato strips were fried at 170 °C for 1 min in each oil by using a deep fryer (T-Fal, Serie F18-R, France). They were then placed in a strainer, allowing for the excessive oil to drain off and air-cooled at ambient conditions. Frying experiments were run in triplicate and fresh oil was used for each batch.

2.5. Oil content analysis

Total oil content in fried potato strips was determined using the soxhlet extraction method (AOAC, 2000).

2.6. Statistical analysis

All experiments were carried out in triplicate and a randomized complete block design was applied to statistically analyse the experimental results using the SAS system (SAS Institute Inc., Cary, NC, USA), followed by Duncan's multiple range test. The rheological curves reported were the mean values of three measurements.

3. Results and discussion

The fatty acid compositions of seven different vegetable oils were analysed as shown in Table 1. For all of the oils tested in this study, the percent amount of total saturated and unsaturated fatty acids ranged from 12% to 22% and from 78% to 88%, respectively. Specially, canola and hazelnut oils contained a great amount of unsaturated fatty acids, relatively compared to the other oil samples. The predominant component of olive, canola, and hazelnut oils was oleic acid (18:1) whilst the others were rich in linoleic acid (18:2). The presence of linolenic acid was found in soybean (7.8%) and canola (13.0%) oils which were relatively higher than other vegetable oils. These results are in great agreement with a previous study (Shahidi, 2004).

The flow behaviours of vegetable oils were characterised by steady shear measurements at 25 °C. All of the oil samples showed the similar flow pattern which could be characterised by straight lines as shown in Fig. 1, indicating that the shear stress is directly proportional to the shear rate. Therefore, the characteristics of this type of flow were adequately described by the equation given below

$$\sigma = \eta \cdot \dot{\gamma}$$

where σ is shear stress, $\dot{\gamma}$ is shear rate, and η is viscosity. Since viscosity is given by the slope of the shear stress vs. shear rate curve, the viscosity of all oil samples appeared to remain constant regardless of the shear rates tested. It was previously recognised that fresh vegetable oils showed Newtonian flow behaviours because of their long chain molecules (Maskan, 2003; Santos et al., 2004). However, the values of viscosity (that is, the slope of each curve) varied distinctly depending on the type of oil samples. The highest viscosity was observed in hazelnut oil, followed by olive, canola, corn, soybean, sunflower, and grapeseed oils (Table 2).

The dependence of viscosity on the type of vegetable oils was investigated by correlating the oil viscosity with fatty acid composition. First, an effort was made to investigate how the degree of

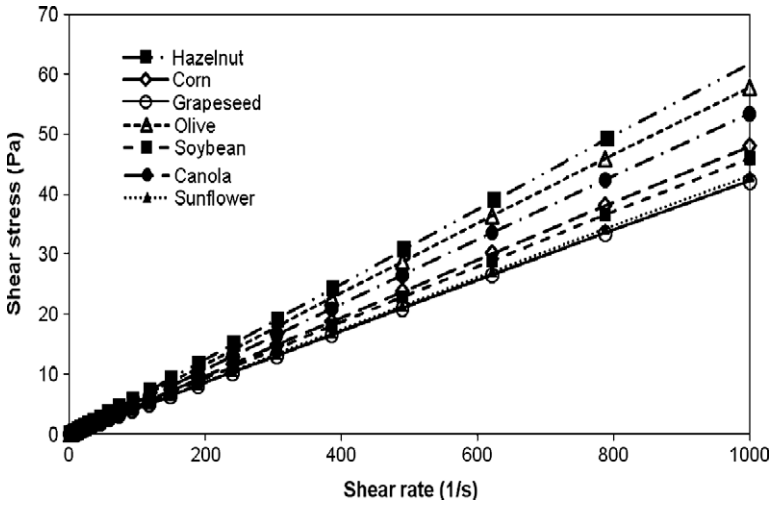

Fig. 1. Curves of shear stress vs. shear rate of edible vegetable oils at 25 °C.

unsaturation affected oil viscosity. Unfortunately, any positive correlation was not observed between viscosity and total saturated (or unsaturated) fatty acids (R^2 = 0.01). However, when the viscosities of the vegetable oils were plotted against either 18:1 or 18:2 fatty acids, it was interesting to note that there were highly positive correlations between them (R^2 = 0.94) as shown in Fig. 2. This relatively good fit demonstrated that the major components of the vegetable oils (18:1 and 18:2 fatty acids) appeared to make a great contribution to their flow behaviours. Especially, a decrease in the oil viscosity was distinctly observed with increasing portion of 18:2 fatty acids and a decreasing portion of 18:1 fatty acids, which indicated more double bonds in the chain, as shown in Table 1. Since each double bond with a *cis* configuration form causes a kink in the straight chain (Abramovic & Klofutar, 1998), the presence of double bond does not allow fatty acid molecules to stack closely together, consequently interfering with packing in the crystalline state. Thus, fatty acids with more double bonds do not have a rigid and fixed structure, being loosely packed and more fluid-like.

Furthermore, the flow behaviours of vegetable oils were investigated as a function of the temperature ranging from 20 to 70 °C. As can be seen in Fig. 3, all of the oil samples exhibited the same viscosity pattern over temperature, which was a non-linear decrease in viscosity with increasing temperature. This temperature effect on oil viscosity has been attributed to decreased intermolecular interactions by great thermal molecular movement (Santos, Santos, & Souza, 2005a). A favourably good agreement was found when the results were compared with other studies (Caristi, Bellocco, Gargiulli, Toscano, & Leuzzi, 2006; Maskan, 2003; Santos, Santos, & Souza, 2005b). In addition, the effect of temperature on the oil viscosity was evaluated by means of the Arrhenius temperature model, which describes the exponential decrease of the viscosity over temperature

$$\eta = A \cdot \mathrm{EXP}(E_a/RT)$$

where η is the oil viscosity, A is the pre-exponential factor, E_a is the activation energy, R is the gas constant, and T is the absolute temperature.

As also presented in Table 2, the calculated values of the activation energy and constant of the vegetable oils were ranged from 24.6 to 26.9 kJ/mol and from 1.18×10^{-6} to 2.23×10^{-6} Pa·s, respectively. The highest value of the activation energy was observed in olive oil, followed by hazelnut, corn, canola, soybean,

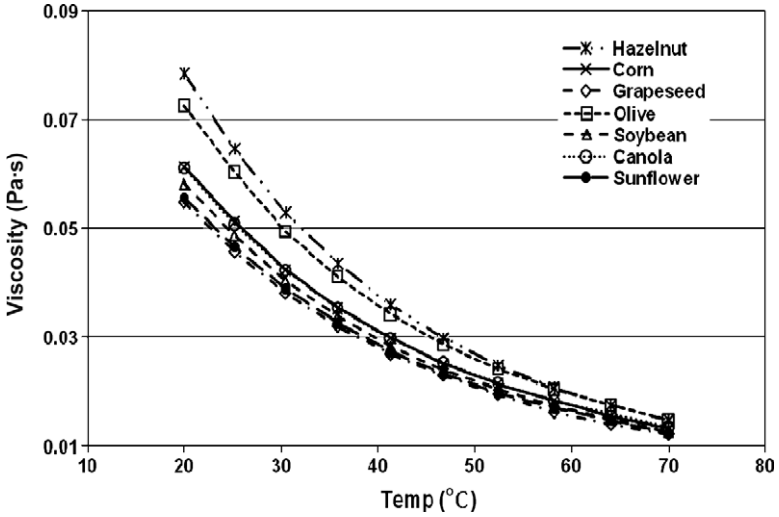

Fig. 3. Effect of temperature on the flow behaviours of vegetable oils.

grapeseed, and sunflower oils. Since the activation energy indicates the sensitivity of a material to temperature changes (Steffe, 1996), the statistical results demonstrated that the flow behaviours of corn, canola, olive, and hazelnut oils were highly dependent on temperature change, compared to the other oil samples. Also, when the activation energy value of each oil sample was plotted against the content of 18:2 fatty acid (data not shown), there was a reasonable correlation ($R^2 = 0.71$) suggesting that the oils containing more double bonds exhibited less activation energy.

In addition, another effort was made to investigate whether there is any correlation between the viscosity of vegetable oils and the oil uptake of fried foods that are cooked in the oils. For doing so, potato strips were fried in five different vegetable oils (olive, canola, soybean, corn, grape oils) and the amount of absorbed oil to the potato samples were analysed. It is generally recognised that the higher viscosity of frying oils, the greater oil content of fried foods (Dana & Saguy, 2006). This would be explained by the fact that high viscosity can allow the oils to be accumulated more easily on the surface of fried foods and enter inside during the cooling period (Maskan, 2003). Therefore, before this frying experiment started, the potato samples fried in olive or canola oils would be expected to have greater oil uptake due to their high viscosity. However, significant differences amongst the samples could not be detected as presented in Table 3. It indicates that viscosity might not be the only factor to affect the oil content. Another possible explanation would be that a more substantial difference in the viscosity amongst the oils might be needed to cause a significant change in the oil uptake. Nonetheless, an overall increase in the oil content by high viscosity could be observed from the mean values of the oil content. Table 3 showed that the highest mean value was observed in the samples fried in olive oil, followed by canola, corn, soybean, and grapeseed oils. Kita et al. (2007) reported the oil pickup of potato crisps, depending on the type of oils that were sunflower, soybean, peanut, rapeseed, olive, palm, and modified oils. Even though this study did not clearly explain the oil uptake difference amongst the used oils, it demonstrated that the samples fried in olive oil contained the highest oil content, which could be favourably compared to our results.

Table 3
Oil uptake of the potato strips fried in different vegetable oils (means with different letters in the same column are significantly different at the 5% level).

Vegetable oils	Oil content (%)
Grapeseed	5.21a
Soybean	5.30a
Corn	5.30a
Canola	5.39a
Olive	5.57a

4. Conclusions

As a principal and essential frying component, edible vegetable oils were characterised in terms of their fatty acid composition, flow behaviours, and oil uptake. The results demonstrated that there was a high correlation between oil viscosity and fatty acid composition, suggesting that the oils with more double bonds appeared to have lower viscosity due to their loosely-packed structure. Also, their flow behaviours over temperature could be well characterised by the Arrhenius model. Unexpectedly, the contribution of oil type to oil uptake of fried foods was not statistically effective. Thus, as long as fresh vegetable oils are used for frying applications, it seems that the effect of the oil type on the oil uptake of fried foods can be disregarded. However, since the quality stability of oils over time could vary depending on the oil type, further research would be necessary to investigate how pertinent quality parameters of the oils and their consequent oil uptake patterns are changed by frying conditions (time and temperature) and repeated use.

Porcine plasma protein hydrolysate

ABSTRACT

Antioxidant activity and functional properties of porcine blood plasma protein hydrolysates (PPH) prepared with Alcalase at 6.2%, 12.7% and 17.6% of degree of hydrolysis (DH) were investigated. The PPH showed stronger radical-scavenging ability and possessed stronger Cu^{2+}-chelation ability and a reducing power compared to non-hydrolysed plasma protein ($P < 0.05$). The antioxidant activity of PPH, indicated by thiobarbituric acid-reactive substance (TBARS) values in a liposome-oxidising system, increased with increasing DH ($P < 0.05$). The Alcalase hydrolysis increased protein solubility from its original 68.46–81.79% (non-hydrolysed) to 82.95–94.94% (hydrolysed) over a broad pH range (3.0–8.0). However, hydrolysis decreased surface hydrophobicity and suppressed emulsifying and foaming capacity of the plasma protein. To identify antioxidant peptide, PPH was subjected to ultrafiltration, ion-exchange chromatography and reverse-phase high performance liquid chromatography (RP-HPLC), and the amino acid sequences of isolated peptides were determined by liquid chromatography/tendem mass spectrometry (LC–MS/MS). The peptide with the strongest antioxidant activity had the amino acid sequence of His-Asn-Gly-Asn. The results indicated that PPH could be used as a novel antioxidant but may be of limited utility as an emulsifying or foaming agent.

1. Introduction

Functional properties of proteins can be modified by physical, chemical and enzymatic treatments through changing the protein structure. Enzymatic treatment is a particularly attractive technique to modify proteins due to the milder process conditions required, the relative ease to control the reaction, and minimal formation of by-products (Mannheim & Cheryan, 1992). Selective enzymatic hydrolysis under controlled conditions has been used to improve the solubility and enhance the emulsifying and foaming properties of wheat gluten (Agyare, Xiong, & Addo, 2008) and fish protein (Shahidi, Han, & Synowiecki, 1995).

The cleavage of peptide bonds leads to an increase in the concentration of free amino and carboxyl groups, which increases solubility. Hydrolysis also disrupts the protein tertiary structure and reduces the molecular weight of the protein and, consequently, alters the functional properties of proteins (Adler-Nissen, 1986; Kristinsson & Rasco, 2000). However, extensive hydrolysis could have a negative impact on the functional properties (Kristinsson & Rasco, 2000).

In addition to their functionalities, protein hydrolysates, such as hydrolysed wheat protein (Liyana-Pathiranaa & Shahidi, 2007), zein protein (Kong & Xiong, 2006), and porcine haemoglobin (Chang, Wu, & Chiang, 2007), have been shown to possess antioxidant activity. A typical enzymatic protein hydrolysate is a mixture of proteoses, peptones, peptides, and free amino acids (Chang et al., 2007). The levels and compositions of free amino acids and peptides were reported to determine the antioxidant activities of protein hydrolysates (Wu, Chen, & Shiau, 2003). The type of proteases used and the degree of hydrolysis also affect the antioxidant activity (Kong & Xiong, 2006).

Many antioxidative peptides also have been identified from a variety of food proteins, such as royal jelly protein (Guo, Kouzuma, & Yonekura, 2009) and egg yolk (Park, Jung, Nam, Shahidi, & Kim, 2001). Marcuse (1962) reported that several amino acids, such as Tyr, Met, His, Lys, Gly and Trp, are generally accepted as antioxidants despite their prooxidative effects in some cases. Kawashima, Itoh, Miyoshi, and Chibata (1979) noted that some di- and tri-peptides containing aromatic amino acid residues, as well as peptides containing Tyr, Pro and His, showed strong antioxidant activity.

Animal blood, collected from packing plants, is a valuable protein source from which bioactive peptides can be produced. Presently, the utilisation of porcine serum protein is limited. The production of protein hydrolysates with antioxidant activity and improved functional properties would be of economical interest as well as processing significance. Unlike bovine plasma protein and its hydrolysates, which are restricted or banned from food uses due to the concern with potential transfer of animal diseases,

plasma protein from wholesome swine is considered safe for human consumption.

In this study, the antioxidant activity of porcine plasma protein hydrolysates (PPH) prepared by Alcalase-hydrolysis was evaluated. The surface hydrophobicity, solubility, and emulsifying and foaming properties in relation to the degree of hydrolysis were examined. Meanwhile, the antioxidative peptides were isolated from the hydrolysate, and their amino acid sequences were determined.

2. Materials and methods

2.1. Materials and chemicals

Porcine plasma protein was obtained from Beidahuang Meat Corporation (Harbin, Heilongjiang, China). The dry porcine plasma protein powder contained 70% protein as determined by the Kjeldahl method of determination (AOAC, 2000). Alcalase 2.4 L (6×10^4 u/g) was obtained from Novozymes (Bagsvaerd, Denmark). Testing chemicals, including 3-(2-pyridyl)-5,6-bis(4-phenyl-sulphonic acid)-1,2,4-triazine (ferrozine), 2,4,6-tris(2-pyridyl)-S-triazine (TPTZ), 1,1-diphenyl-2-picrylhydrazyl (DPPH), Soybean L-α-phosphatidylcholine, and 1-anilino-8-naphthalene-sulphonate (ANS) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). All other chemicals and reagents used were of analytical grade.

2.2. Preparation of porcine plasma protein hydrolysates (PPH)

Porcine plasma protein solution (40 mg protein/mL) was heat pretreated (90 °C, 5 min) and then hydrolysed with Alcalase at 55 °C. The enzyme to substrate ratio (E/S) was 2:100 (g/g). The pH of the porcine plasma protein solution was adjusted to the optimal values for Alcalase (pH 8.0) before hydrolysis was initiated, and it was readjusted to the optimal value every 15 min during hydrolysis with 1 M NaOH. The hydrolysates were produced by varying the hydrolysed time to 0.5, 2 and 5 h, which yielded 6.2%, 12.7%, and 17.6% of degrees of hydrolysis (DH), respectively.

After hydrolysis, the pH of the solution was brought to 7.0, and the solution was then heated at 95 °C for 5 min to inactivate the enzyme. The hydrolysates were freeze-dried (LGJ-1 Freeze-Dryer, Shanghai, China), pulverised, placed in sealed bags, and stored at 4 °C until use. DH of hydrolysed protein was determined using a pH-stat method (Adler-Nissen, 1986).

2.3. Determination of antioxidant activities

2.3.1. Thiobarbituric acid-reactive substances (TBARS)

The antioxidant activity of PPH was initially assessed by means of TBARS analysis in an oxidising liposome system. Liposomes were prepared from soybean phosphatidylcholine according to the method of Decker and Hultin (1990). A series of mixed solutions of 5 mL of liposome with 1 mL of PPH (40 mg protein/mL) at 6.2%, 12.7%, and 17.6% of DH were prepared. The control solution was prepared by mixing 1 mL of water instead of 1 mL of protein solution (40 mg protein/mL) with 5 mL of liposome. Oxidation was initiated by adding 0.1 mL of 50 mM $FeCl_3$ and 0.1 mL of 10 mM sodium ascorbate into the liposome/protein solution and continued for 60 min in a 37 °C water bath. The concentrations of TBARS (secondary products from lipid oxidation), with or without the presence of PPH, were determined according to the method which outlined by Kong and Xiong (2006).

2.3.2. 2,2-Diphenyl-1-picryhydrazyl (DPPH) radical scavenging activity

The DPPH radical scavenging activity was determined according to the method of Yen and Hsieh (1995) with slight modification. Aliquots (4.0 mL) of the DPPH radical solution (1×10^{-4} M, in methanol) were each incubated with 1.0 mL of PPH (40 mg protein/mL in distilled water) at room temperature for 30 min in the dark. The absorbance of reacted solutions was measured at 517 nm.

2.3.3. Reducing power

The reducing power of PPH was measured using the ferric reducing/antioxidant power (FRAP) assay (Benzie & Strain, 1996). Absorbance (593 nm) of samples was taken at 30 s intervals for up to 8 min. Sample FRAP values were calculated based on a $FeSO_4$ standard curve (prepared with 100–1000 μM $FeSO_4{\cdot}7H_2O$), and were expressed as $FeSO_4$ equivalent (μM).

2.3.4. Metal chelating activity

The metal chelating effect was determined as previously described (Kong & Xiong, 2006).

2.4. Surface hydrophobicity

The determination of superficial hydrophobicity followed the method described by Akita and Nakai (1990) using 1-anilino-8-naphthalene-sulphonate (ANS) as the fluorescence probe. Fluorescence intensity (FI) was measured with a fluorometer (F-4500 model, Hicathi, Tokyo, Japan) at an excitation wavelength of 374 nm and an emission wavelength of 485 nm. After drawing a graph of the fluorescence as a function of protein concentration, the inclination was calculated and considered as the hydrophobicity.

2.5. Determination of functional properties

2.5.1. Solubility

To determine protein solubility, 200 mg of PPH samples were dispersed in a buffer solution (0.02 M sodium phosphate and 0.01 M citric acid), in pH 3.0–8.0. The mixtures were stirred at room temperature for 30 min and centrifuged at 7500g for 15 min. Protein contents in the supernatants were determined using the Biuret method (Gornall, Bardawill, & David, 1949). Total protein content in PPH samples was determined after solubilisation of the samples in 0.5 M NaOH. Protein solubility was calculated as follows:

$$\text{Solubility } (\%) = (A/B) \times 100$$

where A is protein content in supernatant and B is total protein content in sample.

2.5.2. Emulsifying properties

The emulsifying properties were determined according to the method of Pearce and Kinsella (1978) with a slight modification. Vegetable oil (10 mL) and 30 mL of 0.2% PPH solution were mixed in a buffer solution (0.02 M sodium phosphate and 0.01 M citric acid, pH 3.0–8.0) and homogenised at 20,000 rpm for 1 min using a homogenizer (IKA T18 basic, IKA-Werke GmbH & Co., Staufen, Germany). An aliquot of the emulsion (50 μL) was pipetted from the bottom of the container at 0 and 10 min after homogenisation and mixed with 5 mL of 0.1% sodium dodecyl sulphate (SDS) solution. Absorbance at 500 nm was measured using a spectrophotometer (UT-1800, Pgeneral, Beijing, China), using 0.1% SDS solution as the blank. The emulsifying activity index (EAI) and the emulsion stability index (ESI) was calculated as follows:

$$\text{EAI}(\text{m}^2/\text{g}) = (2 \times 2.303 \times A_{500})/[0.25 \times \text{Protein weight}(\text{g})]$$

where A_{500} represents the absorbance at 500 nm.

$$\mathrm{ESI(min)} = A_0 \times \Delta t / \Delta A$$

where $\Delta A = A_0 - A_{10}$ and $\Delta t = 10$ min, A_{10} and A_0 represent the absorbance after 10 min and time zero, respectively, at 500 nm.

2.5.3. Foaming properties

Foaming capacity and foaming stability of PPH were determined according to the method of Sathe and Salunkhe (1981) with a slight modification. Protein solutions (20 mL of 0.5%), prepared in a buffer (0.02 M sodium phosphate and 0.01 M citric acid, pH 3.0–8.0), were homogenised at 16000 rpm for 2 min using a homogenizer (IKA T18 basic, IKA-Werke GmbH & Co., Staufen, Germany). The whipped sample was immediately transferred into a 25 mL cylinder and the total volume was read after 30 s. The foaming capacity (FC) was calculated according to the following equation:

Foaming capacity (%) = $[(A - B)/B] \times 100$where A is the volume after whipping (mL); B is the volume before whipping (mL).

The whipped sample was allowed to stand at 20 °C for 3 min and the volume of whipped sample was then recorded. Foam stability (FS) was calculated as follows:

Foam stability (%) = $[(A - B)/B] \times 100$where A is the volume after standing (mL); B is the volume before whipping (mL).

2.6. Isolation of antioxidant peptides

PPH with DH of 17.6%, which exhibited the strong antioxidant activity, was fractionated by ultrafiltration (Amicon Stirred Cell 8400, Millipore, USA) with membranes having three different molecular weight cut-offs (3*k*, 6*k* and 10*k*). Four fractions (<3*k*, 3–6*k*, 6–10*k*, and > 10*k*) were separated, lyophilised and then stored at −20 °C until use. The antioxidant activity of these four fractions was determined by reducing power and DPPH radical scavenging activity.

The <3*k* fraction that exhibited high antioxidant activity was dissolved in 20 mM sodium acetate buffer (pH 4.0) and fractionated by ion-exchange chromatography on a SP Sepharose Fast Flow column (2 × 25 cm; GE Healthcare Bio-Sciences AB, Sweden) equilibrated and eluted with a linear gradient of NaCl concentrations from 0 to 1 M. Fractions of 3 mL were collected at a flow rate of 1 mL/min, and the eluted peaks were detected by ultraviolet (UV) absorbance at 280 nm. The fractions showing the highest antioxidant activity were pooled and lyophilised. The antioxidant fraction was dissolved in distilled water and separated by reversed-phase high performance liquid chromatography (RP-HPLC) on an octadecylsilyl ODS column (5 μm, 4.6 × 250 mm; Phenomenex, Macelesfield, United Kingdom) using a linear gradient of acetonitrile containing 0.05% trifluoroacetic acid (TFA) at a flow rate of 0.5 mL/min. The eluted peaks were detected by UV absorbance at 215 nm. Fraction which showed the highest antioxidative activity was further purified by RP-HPLC on an ODS column using a linear gradient of acetonitrile containing 0.05% TFA at a flow rate of 0.75 mL/min. The eluted peaks were detected by UV absorbance at 215 nm.

2.7. Peptide sequence analysis

Molecular mass and peptide sequence of purified fraction was determined using an ultra performance LC–MS/MS (ACQUITY TQD, Waters, New Castle, Delaware, USA). The amino acid sequence of antioxidant activity peptide was obtained over the m/z range 50–1500 and was identified using the SEQUEST sequencing algorithm.

2.8. Statistical analysis

All the experiments were carried out in triplicate. Data were analyzed using the General Linear Models procedure of Statistix 8.1 software package (Analytical Software, St. Paul, MN) for microcomputer. Analysis of variance (ANOVA) was done to determine the significance of the main effects. Significant differences ($P < 0.05$) between means were identified using Tukey procedures.

3. Result and discussion

3.1. Effect of DH on antioxidant activity of PPH

3.1.1. TBARS, DPPH radical scavenging activity and reducing power

The PPH prepared by Alcalase exhibited significant inhibition of TBARS formation, and the inhibition was more pronounced at increasing DH (Table 1). TBARS were lowered by 25.4%, 28.8% and 38.6% at 6.2, 12.7 and 17.6 of DH, respectively, compared to the non-hydrolysed plasma protein. The effect of PPH to inhibit TBARS formation in the liposome system suggested that lipid peroxides generated in the oxidising liposome system were readily decomposed into malondialdehyde or other secondary, TBA-reactive compounds. DPPH radical scavenging activity and reducing power of PPH with different DHs are also depicted in Table 1. As the DHs increased DPPH radical scavenging activity significantly increased ($P < 0.05$), which presented 21.72%, 31.3%, 45.4% and 76.8% scavenging activity corresponding to 0%, 6.2%, 12.7% and 17.6% of DH, respectively. The reducing power (4 min FRAP value) of PPH correlated well with DPPH radical scavenging activity, and it presented 3.0-fold increase for 17.6% of DH sample compared to non-hydrolysed plasma protein.

The ability of PPH to chemically inhibit lipid oxidation as demonstrated in the present study may be attributed, in part, to protein structural changes. Non-hydrolysed plasma protein, because of its compact structure, had a minimal antioxidant activity. Disruption of the native protein structure by enzyme hydrolysis resulted in the opening and exposure of active amino acid residues and patches capable of reacting with oxidants (Kong & Xiong, 2006). Fragmentation of plasma proteins would contribute to the antioxidant activity as well. Hirose and Miyashita (1999) postulated that besides acting as a free radical scavenger, a protein hydrolysate

				Cu^{2+}	Fe^{2+}
DH: 0%	2.05 ± 0.01[a]	456.4 ± 1.4d	21.43 ± 0.09[d]	15.82 ± 0.58[d]	5.62 ± 0.30[c]
DH: 6.2%	1.53 ± 0.01[b]	713.1 ± 8.8[c]	31.16 ± 0.93[c]	23.23 ± 0.99[c]	6.80 ± 0.62[c]
DH: 12.7%	1.48 ± 0.01[c]	1303.4 ± 8.2[b]	45.14 ± 1.51[b]	31.98 ± 1.53[b]	9.67 ± 0.30[b]
DH: 17.6%	1.37 ± 0.01[d]	1407.9 ± 9.9[a]	76.53 ± 1.51[a]	44.45 ± 2.01[a]	12.03 ± 0.52[a]

[a–d] Means in the same row with different superscript letters differ significantly ($P < 0.05$).

could serve as a protecting membrane surrounding lipid droplets against oxidation initiators. Presumably, by converting to more amphoteric and structurally flexible short peptides, hydrolysate fragments could readily diffuse to the water–oil interface, where they would adsorb or loosely bind to the phospholipids membrane in the liposome where oxidation occurs.

DPPH is a stable free radical that shows maximal absorbance at 517 nm in ethanol. When DPPH encounters a proton-donating substance (H^+), the radical is scavenged by changing colour from purple to yellow and the absorbance is reduced. In our DPPH test, the protein hydrolysates reduced the DPPH radical to a yellow-coloured compound, apparently due to the DPPH radical accepting an electron or hydrogen to become a stable diamagnetic molecule. Wu et al. (2003) reported that for mackerel protein hydrolysate, its DPPH scavenging activity was improved gradually with increasing hydrolysis time. Qian, Jung, and Kim (2008) noted that antioxidant peptide from bullfrog skin protein inhibited lipid peroxidation more efficiently than α-tocopherol.

The strong reducing power of PPH may be attributed to the increased availability of hydrogen ions (protons and electrons) due to peptide cleavages. Cumby, Zhong, Naczk, and Shahidi (2008) reported that for canola protein hydrolysate, the reducing power increased with increasing DH. It is known that Alcalase acts as an endo peptidase, thus cleaving peptide bonds at the interior of the polypeptide chain. Therefore, Alcalase mainly produces small- and medium-sized oligopeptides or polypeptides, some of which were antioxidative.

3.1.2. Metal chelating activity

Metal chelating activity of PPH with different DHs is shown in Table 1. The Cu^{2+} chelating activity increased markedly with increasing DH ($P < 0.05$), which presented 24.23%, 31.98% and 44.45% chelating activity for 6.2%, 12.7% and 17.6% of DH, respectively. In contrast, the Fe^{2+} chelating activity of hydrolysates, which was relatively low (5.62% at 0 DH), increased slightly with DH.

Transition metals may act as catalysts that promote the generation of the first few radicals, which initiate the oxidative chain reactions. Chelating agents may reduce the availability of transition metals and inhibit the radical-mediated oxidative chain reactions in biological or food systems, and consequently improve human health, and food quality, stability, and safety. Transition metal ions react very quickly with peroxides by acting as one-electron donors to form alkoxyl radical (Gordon, 2001). The chelating activity of peptides in PPH suppressed lipid oxidation. Presumably, peptide cleavages led to an enhanced metal ion binding due to an increased concentration of carboxylic groups and amino groups in branches of the acidic and basic amino acids, thus removing prooxidative free metal ions from the hydroxyl radical system. The direct relationship between soluble protein/peptide concentration and the increase in the chelating capability supported this premise. Kong and Xiong (2006) reported that hydrolysed zein possessed far stronger Cu^{2+} binding activity than Fe^{2+} binding. Haga, Fujinaga, and Kuboi (2005) also noted a far weaker Fe^{2+} binding than Cu^{2+} binding (875 fold difference) by dehydrin, a protein found in higher plants and yeast.

3.2. Surface hydrophobicity

Changes in surface hydrophobicity as a result of proteolysis influence the functional properties, especially the interfacial properties, of the hydrolysates. As is shown in Fig. 1a, the surface hydrophobicity of PPH with different DHs was significantly affected by pH; the highest value was reached at pH 3.0, and higher DH had lower surface hydrophobicity ($P < 0.05$). At pH 7.0, the hydrophobicity of 0%, 6.2%, 12.7% and 17.6% of DH were 64.83%, 26.34%, 6.38% and 4.53% (photons), respectively. Due to shortening of peptide chains, proteolysis is accompanied by gain or loss in hydrophobicity, depending mainly on the nature of the hydrolysed protein and molecular weight size of the formed peptides (Calderon de la Barca, Ruiz-Salazar, & Jara-Marini, 2000). In our present work, enzymatic hydrolysis by Alcalase was accompanied by a decrease of surface hydrophobicity. The possible reason is that peptides released from the native structure of porcine plasma protein reveal great flexibility, which helped them to adopt a conformation with hydrophilic groups more exposed outward.

3.3. Effect of DH on functional properties of PPH

3.3.1. Solubility

The solubility of PPH in the pH range of 3.0–8.0 is shown in Fig. 1b. All hydrolysates were soluble over a wide pH range with more than 78% solubility, significantly higher than that of non-hydrolysed plasma protein ($P < 0.05$). At pH 7.0, the solubility of PPH of 0%, 6.2%, 12.7% and 17.6% DH were 77.5%, 89.2%, 90.3% and 91.7%, respectively. Because smaller peptides resulting from

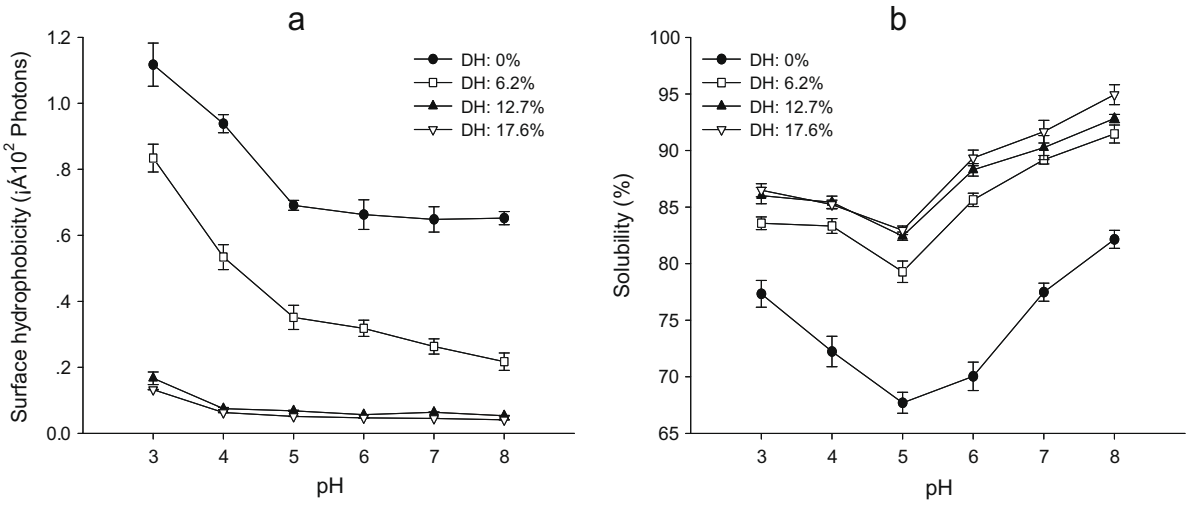

Fig. 1. Surface hydrophobicity (a) and solubility (b) of porcine PPH prepared using Alcalase with different degree of hydrolysis as influenced by pHs. Results are the means from three replicates.

hydrolysis are more polar than polypeptides in non-hydrolysed proteins, they can form stronger hydrogen bonds with water and thereby being more soluble in aqueous solutions.

3.3.2. Emulsifying and foaming properties

The EAI and ESI of hydrolysates are shown in Fig. 2a and b. Both EAI and ESI decreased ($P < 0.05$) with increasing DH. The peptides with low molecular weights probably had a reduced amphiphilicity required for producing a good emulsion. Turgeon, Gauthier, and Paquin (1991) also showed that hydrolysis resulted in a drastic loss of emulsifying properties. Although small peptides diffuse rapidly toward the interface, they are less efficient in stabilizing emulsions because they may not readily agglomerate to produce a fat globule membrane due to charge repulsions.

Foams are biphasic colloidal systems with a continuous liquid or aqueous phase and a dispersed gas or air phase. A degradation of FC and FS ($P < 0.05$) with increasing DH was observed in the present study (Fig. 2c and d), which corresponded to the decrease of emulsifying properties. Klompong, Benjukal, Kantachote, and Shahidi (2007) reported reduced foaming properties for capelin protein hydrolysates at high DHs. A foam stability reduction occurs since more microscopic peptides do not have the strength needed to maintain the stable foam (Shahidi et al., 1995). The molecular properties that are relevant for foaming are similar to those required for emulsification.

When determining the effect of pH on emulsifying and foaming properties, the lowest EAI, ESI, FC and FS were found at pH 5.0, with coincided with the minimal protein solubility. Since the lowest solubility occurred at pH 5.0 (the PI of porcine plasma protein), peptides could not move rapidly to the interface. Protein solubility makes an important contribution to the emulsifying and foaming behaviour of protein. The pH of the dispersing medium dramatically influences foaming properties, especially foam stability.

3.4. Isolation of antioxidant peptides and determination of amino acid sequences

The antioxidant activity of four ultrafiltration fractions with different molecular weights (<3*k*, 3–6*k*, 6–10*k*, and >10*k*) was shown in Table 2. The <3*k* fraction exhibited the highest reducing power and DPPH radical scavenging activity ($P < 0.05$). Guo et al. (2009) reported that the low molecular weight fraction

Table 2
Antioxidant activity of peptide fractions (40 mg/mL) of hydrolysate (DH of 17.6%) with different molecule weight.

Fraction (*k*)	Reducing power (μM)	DPPH radical scavenging activity (%)
>10	557.3 ± 16.3[d]	31.11 ± 1.07[d]
6–10	664.9 ± 22.4[c]	41.30 ± 1.23[c]
3–6	866.6 ± 12.5[b]	50.38 ± 2.06[b]
<3	1206.4 ± 31.5[a]	70.07 ± 1.86[a]

(<1*k*) from the protease N hydrolysate of royal jelly proteins had the greatest antioxidant activity. Park et al. (2001) also noted that <5*k* hydrolysate from egg yolk protein had the highest antioxidant activity.

To identify the antioxidant peptides derived from PPH, the <3*k* antioxidant hydrolysate, which had the highest antioxidant activity, was separated by ion-exchange chromatography into six fractions (A, B, C, D, E, and F) (Fig. 3). Fraction *E* was found to

(b) The MS/MS spectrum of active fraction E_{3b} separated from ultra performance liquid chromatography.

possess strong antioxidant activity. This fraction was further separated by RP-HPLC using 0.05% TFA-acetonitrile system and fractionated to four fractions (E_1, E_2, E_3, and E_4) (Fig. 4a). Subfraction E_3 possessed the highest antioxidant activity. Subfraction E_3 was further separated by RP-HPLC using the same solvent system. Two fractions (E_{3a} and E_{3b}) were obtained, and E_{3b} had the higher antioxidant activity (Fig. 4b). The reducing power of fraction E_{3b}, E_3 and E were 236.4, 194.8 and 183.7 μM, respectively, at protein concentration of 1 mg/mL.

Consequently, the E_{3b} fraction was analyzed for amino acid sequencing and the result is shown in Fig. 5. This antioxidative peptide had an amino acid sequence of His-Asn-Gly-Asn, and the molecular weight was 441 (Fig. 5a and b). Rajapakse, Mendis, Jung, Je, and Kim (2005) noted that the peptide isolated from fermented mussel sauce contained Gly, Phe and His, and it exhibited the highest radical scavenging activity and metal chelating activity. In the free radical-mediated lipid peroxidation system, antioxidant activity of peptide or protein is dependent on molecular size and chemical properties such as hydrophobicity and electron transferring ability of amino acid residues in the sequence. Guo et al. (2009) also reported 29 antioxidative peptides that were isolated from royal jelly proteins hydrolysate, and found that some small peptides with 2–4 amino acid residues (Phe-Lys, Ala-Leu, Arg-Tyr, Tyr-Tyr, and Lys-Asn-Tyr-Pro) had strong antioxidant activity. Our result indicated that the antioxidant activity of the peptides isolated from PPH depends on their special amino acid sequences.

4. Conclusions

The hydrolysis by Alcalase enhanced the antioxidant activity of hydrolysates from porcine plasma protein in a liposome model system. The antioxidant activity increased with increasing DH. Further analyses suggested the possible involvement of multiple reactions and processes leading to the inhibition of lipid oxidation, i.e., the

ability to donate hydrogen, to stabilize or terminate radicals, and to sequester prooxidative metal ions. The antioxidant activity of the peptides isolated from PPH depends on their special amino acid sequences. However, hydrolysis had enormously negative effects on the functional properties, notably emulsifying and foaming capacity of the plasma protein. Therefore, PPH could be used as a potential antioxidant but may not be suitable as a functional food ingredient.

ABSTRACT

Decalepis hamiltonii, a climbing shrub, grows in the forests of peninsular India and is consumed for its health promoting properties. The hepatoprotective activity of the aqueous extract of the roots of *D. hamiltonii* with known antioxidant constituents was studied against carbon tetrachloride (CCl_4)-induced oxidative stress and liver injury in rats. Pretreatment of rats with aqueous extract of the roots of *D. hamiltonii*, single (50, 100 and 200 mg/kg b.w.) and multiple doses (50 and 100 mg/kg b.w. for 7 days) significantly prevented the CCl_4 (1 ml/kg b.w.) induced hepatic damage as indicated by the serum marker enzymes (AST, ALT, ALP, and LDH). Parallel to these changes, the root extract also prevented CCl_4-induced oxidative stress in the rat liver by inhibiting lipid peroxidation and protein carbonylation, and restoring the levels of antioxidant enzymes (SOD, CAT, GPx, GR, and GST) and glutathione. The biochemical changes were consistent with histopathological observations suggesting marked hepatoprotective effect of the root extract in a dose dependent manner. Protective effect of the aqueous extract of the roots of *D. hamiltonii* against CCl_4-induced acute hepatotoxicity could be attributed to the antioxidant constituents.

1. Introduction

Liver damage is a widespread pathology which in most cases involves oxidative stress and is characterised by a progressive evolution from steatosis to chronic hepatitis, fibrosis, cirrhosis, and hepatocellular carcinoma. Various xenobiotics are known to cause hepatotoxicity one among them is carbon tetrachloride (CCl_4) (Kodavanti, Joshi, Young, Meydrech, & Mehendale, 1989). Reductive dehalogenation of CCl_4 by the P450 enzyme system to the highly reactive trichloromethyl radical initiates the process of lipid peroxidation which is considered to be the most important mechanism in the pathogenesis of liver damage induced by CCl_4 (Demirdag et al., 2004). Trichloromethyl radical can even react with sulfhydryl groups of glutathione (GSH) and protein thiols. In addition, CCl_4 also alters the antioxidant profile of the liver including the antioxidant enzymes like superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), glutathione reductase (GR), and glutathione transferase (GST) (Sheweita, El-Gabar, & Bastawy, 2001).

Steroids, vaccines, and antiviral drugs, have been used as therapies for liver pathologies, have potential adverse side-effects, especially if administered chronically or sub-chronically. Therefore, herbal products and traditional medicines with better effectiveness and safe profiles are needed as a substitute for chemical therapeutics. As oxidative stress plays a central role in liver pathologies and their progression, the use of antioxidants have been proposed as therapeutic agents, as well as drug co-adjuvants, to counteract liver damage. A number of studies have shown that the plant extracts having antioxidant activity protect against CCl_4 hepatotoxicity by inhibiting lipid peroxidation and enhancing antioxidant enzyme activity (Shahjahan, Sabitha, Jainu, & Devi, 2004; Sheweita et al., 2001).

Decalepis hamiltonii (Wight and Arn.) (family: Asclepiadaceae), a climbing shrub, grows in the forests of peninsular India. Its tuberous roots are consumed as pickles and juice for its health promoting properties in southern India. The roots are also used in folk medicine and ayurvedic (the ancient Indian traditional system of medicine) preparations as general vitaliser and blood purifier (Nayar, Shetty, Mary, & Yoganarshimhan, 1978). We have earlier shown that the roots of *D. hamiltonii* possess potent antioxidant properties, which could be associated with their health benefits (Srivastava, Shereen, Harish, & Shivanandappa, 2006). Our recent work has shown that the aqueous extract of the roots of *D. hamiltonii* is a cocktail of antioxidants (activity guided purification) namely, 4-hydroxyisophthalic acid, ellagic acid, 14-aminotetradecanoic acid, 4-(1-hydroxy-1-methylethyl)-1-methyl-1, 2-cyclohexane diol, 2-hydroxymethyl-3-methoxybenzaldehyde, 2,4,8 trihydroxybicyclo [3.2.1]octan-3-one; out of these five are novel antioxidants (Srivastava, Harish, & Shivanandappa, 2006;

Srivastava, Rao, & Shivanandappa, 2007). We have also reported that the methanolic extract contains several antioxidant compounds (Harish, Divakar, Srivastava, & Shivanandappa, 2005). The present study investigates the hepatoprotective potential of *D. hamiltonii* aqueous extract pretreatment against CCl_4-induced liver toxicity in rats.

2. Materials and methods

2.1. Chemicals

Nicotinamide adenine dinucleotide phosphate reduced (NADPH), 1-chloro-2,4-dinitrobenzene (CDNB), thiobarbituric acid (TBA), glutathione (GSH), oxidised glutathione (GSSG), glutathione reductase (GR), cumene hydroperoxide (CHP), pryogallol, bovine serum albumin (BSA), 2,4-dinitrophenyl hydrazine (DNPH), tetraethoxypropane were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Trichloroacetic acid (TCA), hydrogen peroxide (H_2O_2), 5,5′dithiobis(2-nitrobenzoic acid) (DTNB) and other chemicals were purchased from Sisco Research Laboratories, Mumbai, India. All the chemicals used were of highest purity grade available.

2.2. Preparation of the root powder and extraction

Roots of *D. hamiltonii* were washed with water, followed by crushing with a roller to separate the inner woody core from the outer fleshy layer. The fleshy portions were pooled, dried at 40 °C in a hot air oven and fine powdered. The powder was used for extraction.

The aqueous extract was prepared by homogenising the root powder in warm water (50 °C) and allowed to stand for 24 h, filtered with Whatman paper No. 1 and the filtrate was lyophilised and weighed (17% of root powder). To quantify/characterise the extract composition total polyphenolic content was measured. The aqueous extract had a total polyphenolic content of 13.8 mg/g extract. Aqueous extract of *D. hamiltonii* (DHA) was chosen for this study as it shows highest antioxidant activity among the different solvent extracts (Srivastava et al., 2006).

2.3. Animals and treatments

Sixty day old adult male Wistar rats (180–200 g) were divided into groups of eight each. Appropriate guidelines of the local animal ethics committee were followed for the animal experiments. In a 90 days dietary study on rats it was established that the root extract of *D. hamiltonii* is safe to the mammalian system at the highest dose used in this study. Based on the preliminary experiments the hepatoprotective dose of the aqueous extract of *D. hamiltonii* was decided. In single dose pretreatment (oral) experiment, administration of aqueous extract of the roots of *D. hamiltonii* at 50, 100 and 200 mg/kg b.w. was followed, after 1 h, by oral administration of CCl_4 (1/2 LD_{50}-1 ml/kg b.w.). In multiple dose pretreatment experiment, aqueous extract of the roots of *D. hamiltonii* was administered for seven consecutive days at 50 and 100 mg/kg b.w. followed by a single oral dose of CCl_4 (1 ml/kg b.w.) on the 7th day. Animals were sacrificed by anesthesia 16 h after CCl_4 administration, the liver perfused with saline were dissected out and processed immediately for biochemical assays.

2.4. Experimental groupings

Single dose: Group I – control; Group II – CCl_4 (sunflower oil was used as the vehicle); Group III – *D. hamiltonii* aqueous extract (DHA) 50 mg/kg b.w. + CCl_4; Group IV – DHA 100 mg/kg b.w. + CCl_4; Group V – DHA 200 mg/kg b.w. + CCl_4; Group VI – DHA 200 mg/kg b.w.

Multiple dose: Group I – Control; Group II – CCl_4; Group III – DHA 50 mg/kg b.w. + CCl_4; Group IV – DHA 100 mg/kg b.w. + CCl_4; Group V – DHA 100 mg/kg b.w.

2.5. Serum enzymes

Blood samples were collected in tubes, allowed to clot and the serum was collected by centrifugation at 2000*g* for 10 min and stored at 4 °C for biochemical analysis. Serum transaminases (alanine transaminase (ALT) and aspartate transaminase (AST)) were determined by the method of Reitman and Frankel (Reitman & Frankel, 1957). The reaction mixture containing the substrates (L-alanine (200 mM) or L-aspartate (200 mM) with α-ketoglutarate) and enzyme in phosphate buffer (0.1 M, pH 7.4) was incubated for 30 min and 60 min for ALT and AST, respectively. After incubation, DNPH (1 mM) was added and kept for another 30 min at room temperature. The colour was developed by the addition of NaOH (0.4 M) and read at 505 nm in a spectrophotometer. Lactate dehydrogenase (LDH) activity was assayed by the method of Kornberg (1955). The reaction mixture consisted of NADH (0.02 M), sodium pyruvate (0.01 M) in sodium phosphate buffer (0.1 M, pH 7.4). The change in the absorbance was recorded at 340 nm at 30 s interval for 3 min. Alkaline phosphatase (ALP) activity was assayed by the method of Walter and Schutt (1974) with *p*-nitrophenyl phosphate (1.25 mM) as the substrate. The enzyme activity was calculated using the extinction coefficient, $1.85 \times 10^{-3}\ M^{-1}\ cm^{-1}$ for *p*-nitrophenol.

2.6. Lipid peroxidation

Lipid peroxidation (LPO) in the tissue homogenate was measured by estimating the formation of thiobarbituric acid reactive substances (TBARS) (Ohkawa, Ohishi, & Yagi, 1979). Tissue homogenate (10% w/v in 50 mM phosphate buffer, pH 7.4) was boiled in TCA (10%) and TBA (0.34%) for 15 min, cooled and centrifuged. Absorbance of the supernatant was read at 535 nm. TBARS was calculated using tetraethoxypropane as the standard.

2.7. Antioxidant enzymes

Liver tissue was homogenised (10% w/v) in ice-cold 50 mM phosphate buffer (pH 7.4), centrifuged at 10,000*g* for 20 min at 4 °C and the supernatant was used to assay the enzyme activities. Superoxide dismutase (SOD) activity was measured using pyrogallol (2 mM) autoxidation in Tris buffer (Marklund & Marklund, 1974). Catalase (CAT) activity was measured using H_2O_2 (3%) as the substrate in phosphate buffer (Aebi, 1974). Glutathione peroxidase (GPx) activity was measured by the indirect assay method using glutathione reductase. Cumene hydroperoxide (1 mM) and glutathione (0.25 mM) were used as substrates and oxidation of NADPH by glutathione reductase (0.25 U) in tris buffer (0.05 M, pH 7.4) was monitored at 340 nm (Mannervik, 1985). Glutathione reductase (GR) activity was estimated using oxidised glutathione (0.5 mM) and NADPH (2 mM) in potassium phosphate buffer (0.1 M, pH 7.4) (Calberg & Mannervik, 1985). Glutathione-S-transferase (GST) activity was assayed by the method of Warholm, Guthenberg, Bahr, and Mannervik (1985) in phosphate buffer (0.1 M, pH 7.6) containing glutathione (0.5 mM) and CDNB (0.5 mM) and change in the absorbance at 344 nm was monitored in a UV–visible spectrophotometer.

2.8. Glutathione

A 10% (w/v) liver homogenate was prepared in 5% (w/v) trichloroacetic acid, centrifuged at 2000*g* for 10 min and the

glutathione (GSH) content in the deproteinised supernatant was estimated by Ellman's reagent with a standard curve (Ellman, 1959).

2.9. Protein carbonyls

Liver homogenate (10% w/v) was prepared in 20 mM Tris–HCl buffer, pH 7.4 with 0.14 M NaCl, centrifuged at 10,000*g* for 10 min at 4 °C. Supernatant (1.0 ml) was precipitated with an equal volume of 20% TCA and centrifuged. The pellet was resuspended in 1.0 ml of DNPH (10 mM in 2 M HCl) and allowed to stand at room temperature for 60 min with occasional vortexing. 0.5 ml of 20% TCA was added to the reaction mixture and centrifuged, the pellet obtained was washed three times with acetone and 1.0 ml of 2% of SDS (in 20 mM Tris–HCl, 0.1 M NaCl, pH 7.4) was added to solublise the pellet. The absorbance of the solution was read at 360 nm and the carbonyl content was calculated using a molar extinction coefficient of 22,000 M^{-1} cm^{-1} (Levine et al., 1990).

Protein content was estimated by the method of Lowry, Rosenbrough, Farr, and Randall (1951) with bovine serum albumin as the standard.

2.10. Histopathological examination

Pieces of liver from the left lobe were fixed in Bouin's fluid for 24 h and processed for paraffin embedding. Sections (6 μm thick) were stained with hematoxylin and eosin and imaged with Olympus photomicroscope.

2.11. Statistics

Data were expressed as mean ± SE ($n = 8$) and significant difference between the groups was statistically analysed by Duncan's multiple range test (Statistica Software, 1999). A difference was considered significant at $p < 0.05$.

3. Results

The food consumption and body weights of the DHA treated rats were comparable to the control group.

3.1. Serum enzymes

Levels of the serum marker enzymes of hepatic damage, AST, ALT, LDH, and ALP increased significantly in CCl_4 treated rats compared to the control group. In single dose experiment, DHA at 100 and 200 mg/kg b.w. prevented the liver damage as judged by the restored enzyme levels (Fig. 1). Multiple pretreatment of DHA at a lower dose (50 mg/kg b.w.) was more effective than that of single administration (Fig. 2).

3.2. Lipid peroxidation

The effect of DHA on CCl_4-induced lipid peroxidation in the liver is shown in Tables 1 and 2. CCl_4 increased the hepatic TBARS concentration significantly which was inhibited by DHA pretreatment. Single dose pretreatment with the highest dose of DHA (200 mg/kg b.w.) was most effective in inhibiting the hepatic lipid peroxidation.

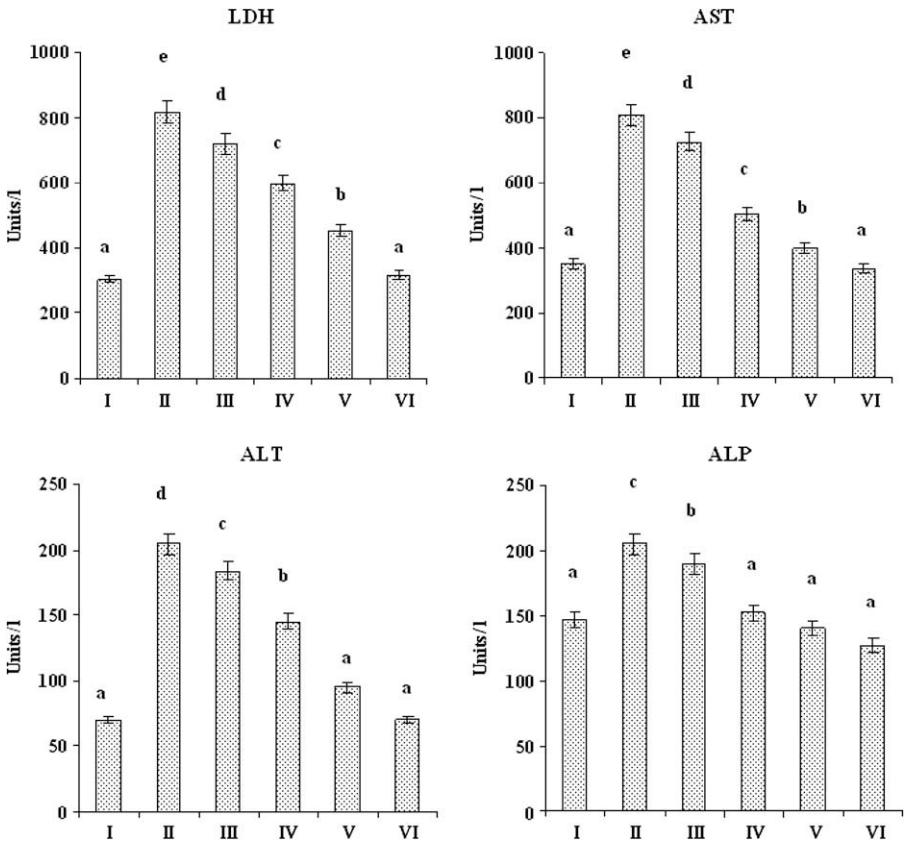

Fig. 1. Protective effect of the aqueous extract of the roots of *D. hamiltonii* (pretreatment-single dose) on CCl_4 hepatotoxicity: serum enzymes. Group I – control; Group II – CCl_4; Group III – DHA 50 mg/kg b.w. + CCl_4; Group IV – DHA 100 mg/kg b.w. + CCl_4; Group V – DHA 200 mg/kg b.w. + CCl_4; Group VI – DHA 200 mg/kg b.w. LDH, lactate dehydrogenase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; ALP, alkaline phosphatase. Each bar represents the mean ± SE, $n = 8$; bars with different alphabets differ significantly at $p < 0.05$ level (DMRT).

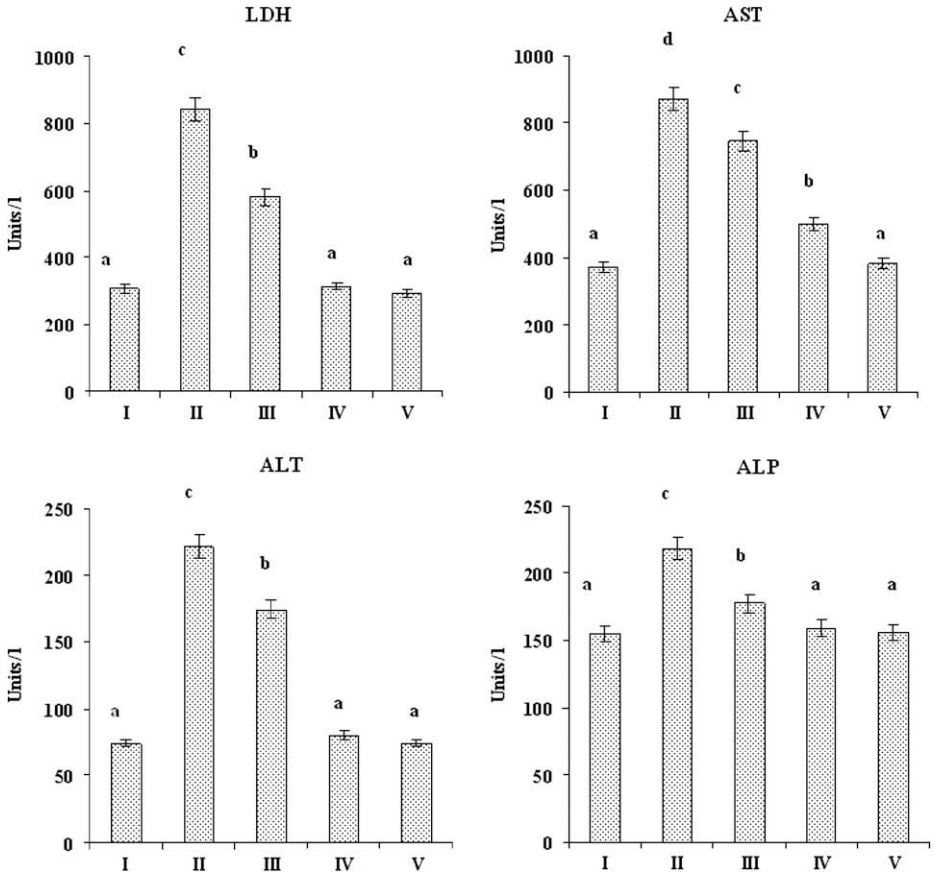

Fig. 2. Protective effect of the aqueous extract of the roots of *D. hamiltonii* (pretreatment-multiple dose) on CCl_4 hepatotoxicity: serum enzymes. Group I – control; Group II – CCl_4; Group III – DHA 50 mg/kg b.w. + CCl_4; Group IV – DHA 100 mg/kg b.w. + CCl_4; Group V – DHA 100 mg/kg b.w. LDH, lactate dehydrogenase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; ALP, alkaline phosphatase. Each bar represents the mean ± SE, $n = 8$; bars with different alphabets differ significantly at $p < 0.05$ level (DMRT).

3.3. Antioxidant enzymes

The hepatic antioxidant enzyme activities were decreased in the liver of rats administered with CCl_4. Activities of SOD, CAT, GPx, GR and GST were restored by DHA pretreatment. Multiple dose pretreatment of the root extract was more effective in the restoration of biochemical changes than a single dose at a given DHA dose. Further, DHA multiple dose pretreatment, by itself, significantly boosted the antioxidant enzyme activities (except SOD) in the liver (Tables 1 and 2).

3.4. Glutathione

Administration of CCl_4 decreased the hepatic GSH level which was restored to normal level by DHA at higher doses in both single and multiple pretreatments (Tables 1 and 2). Pretreatment of DHA

Table 1

alone raised the hepatic GSH levels which was significant with multiple dose pretreatment.

3.5. Protein carbonyls

CCl_4 treatment increased the protein carbonyl content in the rat liver. DHA pretreatment prevented CCl_4-induced protein carbonyl formation in dose dependent manner except for the lowest dose in single dose experiment (Tables 1 and 2).

3.6. Histopathology

Histopathological examination of the liver of CCl_4 administered rats revealed degenerative changes such as vacuolisation and pyc-

notic nuclei in the parenchymal cells in the centrilobular areas which were significantly reduced with DHA pretreatment at higher doses. Histological picture of the liver of rats pretreated with DHA did not reveal degenerative signs and was comparable to that of control (Plates 1 and 2).

4. Discussion

Hepatotoxicity induced by CCl_4 is the most commonly used model system for the screening of hepatoprotective activity of plant extracts/ drugs. Administering CCl_4 to rats markedly increases serum AST, ALT, ALP, and LDH levels which reflects the severity of liver injury (Lin, Yao, Lin, & Lin, 1996). In this study, significant increase in AST, ALT, ALP, and LDH in the serum were observed after administration of CCl_4, as reported earlier. The leakage of large quantities of enzymes into the blood stream was associated with centrilobular necrosis and ballooning degeneration of the liver. However, the increased levels of these enzymes were significantly decreased by pretreatment with *D. hamiltonii* aqueous extract, implying that the extract prevented the liver damage which was further confirmed by the reduced amount of histopathological injuries.

Lipid peroxidation has been implicated in the pathogenesis of hepatic injury by the free radical derivatives of CCl_4 and is responsible for cell membrane damage and consequent release of marker enzymes of heptotoxicity (Danni et al., 1991). In the present study, significantly elevated levels of TBARS, products of membrane lipid peroxidation, observed in CCl_4 administered rats indicated hepatic damage. Pretreatment of *D. hamiltonii* extract prevented lipid peroxidation which could be attributed to the radical scavenging antioxidant constituents (Srivastava et al., 2006).

GSH is the major non-enzymatic antioxidant and regulator of intracellular redox homeostasis, ubiquitously present in all cell types (Meister & Anderson, 1983). Mechanistic studies on CCl_4-induced studies reveal that GSH conjugation plays a critical role in eliminating the toxic metabolites, which are the major cause of liver pathology (Lee, Shimoji, Hossain, Sunakawa, & Aniya, 2008). CCl_4 administration leads to a significant decrease in the glutathione level which can be an important factor in the CCl_4 toxicity. The mechanism of hepatoprotection by *D. hamiltonii* extract against CCl_4 toxicity might be due to restoration of the GSH level. Multiple dose pretreatments of *D. hamiltonii, per se*, increased the levels of GSH which may possibly be due to enhancing of GSH synthesising enzyme activities such as γ-glutamylcysteine synthetase (γ-GCS) and GSH synthetase; this needs further investigation.

One of the major consequences of oxidative stress is irreversible protein modification, such as generation of carbonyls or loss of thiol residues (Berlett & Stadman, 2001). As CCl_4 toxicity is mediated by free radical metabolites, in CCl_4 intoxicated rats a significant increase in the protein carbonyl content was observed

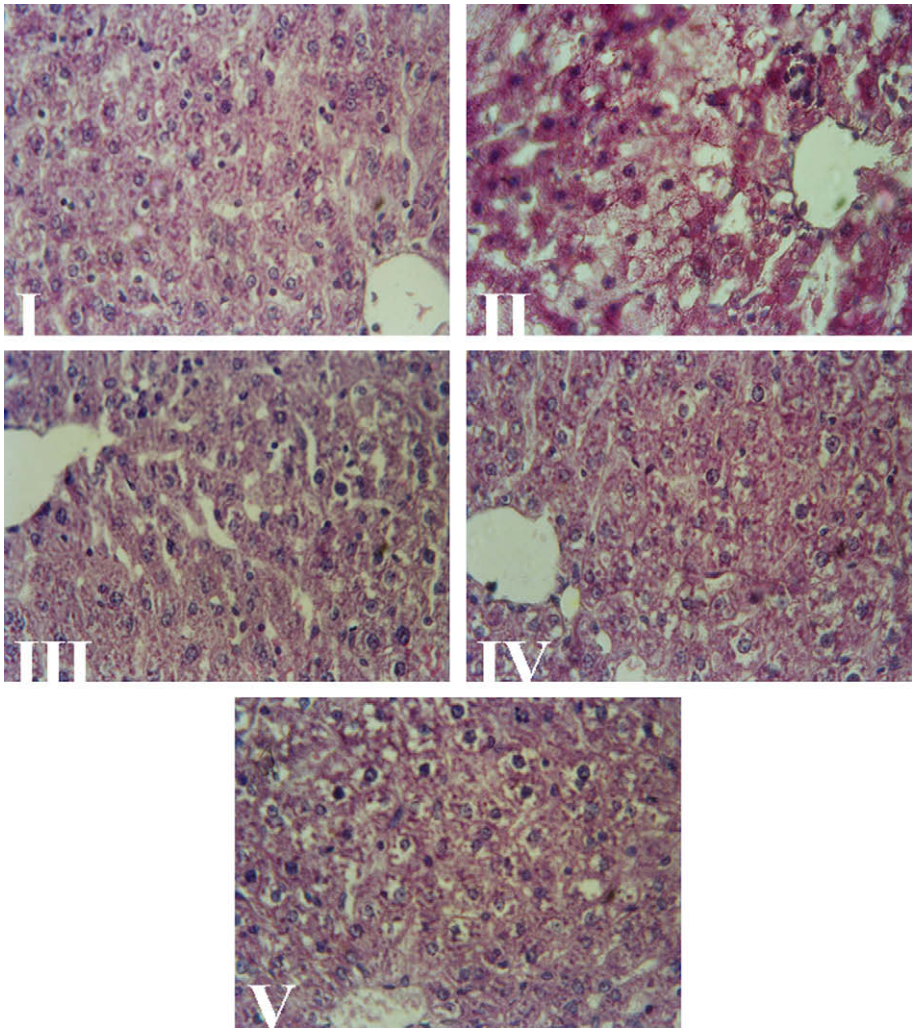

Plate 2. Hepatoprotective effect of *D. hamiltonii* aqueous extract pretreatment (multiple dose) on CCl_4-induced liver damage. H and E staining, magnification, ×400. Group I – Control; Group II – CCl_4; Group III – DHA 50 mg/kg b.w. + CCl_4; Group IV – DHA 100 mg/kg b.w. + CCl_4; Group V – DHA 100 mg/kg b.w.

which was restored to normalcy by *D. hamiltonii* extract pretreatment. The antioxidant activity of *D. hamiltonii* extract and its GSH status elevating effect could be responsible for this observation.

Among the cellular antioxidants, SOD, CAT, GST, GPx, and GR have received extensive studies. SOD catalyses the dismutation of superoxide anion to H_2O_2 and O_2. Because H_2O_2 is still harmful to cells, catalase and GPx further catalyse the decomposition of H_2O_2 to water. In the reaction catalysed by GPx, GSH is oxidised to GSSG, which can then be reduced back to GSH by GR. GSH is also a cofactor for GST, a phase II enzyme, primarily involved in the detoxification of electrophilic xenobiotics via catalysing the formation of GSH-electrophile conjugate (Hayes, Flanagan, & Jowsey, 2005). Thus, the coordinate actions of various cellular antioxidants in mammalian cells are critical for effectively detoxifying free radicals. CCl_4 administration to rats declined antioxidant capacity of the rat liver as evinced in decreased activity of the antioxidant enzymes, which is in agreement with earlier reports (Shahjahan et al., 2004). *D. hamiltonii* extract pretreatment prevented the reduction in the antioxidant enzyme activities and consequent oxidative damage to the liver. In fact, the multiple dose pretreatment of *D. hamiltonii* extract alone significantly boosted the antioxidant enzyme activities. Similar studies have shown a positive effect of different classes of polyphenols on antioxidant enzyme activities *in vivo* (Molina, Sanchez-Reus, Iglesias, & Benedi, 2003; Scharf, Prustomersky, Knasmuller, Schulte-Hermann, & Huber, 2003).

In conclusion, the *D. hamiltonii* aqueous extract effectively prevented CCl_4-induced hepatotoxicity which explains its health promoting property. Our previous study with ethanol, an inducer of oxidative stress, also shows hepatoprotective effect of *D. hamiltonii* extract (Srivastava & Shivanandappa, 2006). Even though ethanol and CCl_4 have different mechanisms of toxicity *D. hamiltonii* aqueous extract could protect the rat liver. The hepatoprotective activity of *D. hamiltonii* extract could be a result of free radical scavenging activity or boosting the antioxidant capacity of the liver. The bioactive antioxidant principles of the aqueous extract that have been identified (Srivastava et al., 2006) could be responsible for the observed hepatoprotective effect. Further studies with the individual antioxidant compounds isolated from *D. hamiltonii* root extract on hepatocytes are underway which will enable us to understand the exact mechanism of hepatoprotective action by *D. hamiltonii*.

ABSTRACT

Recent studies have evidenced volatile biomarkers in ruminant tissues that distinguish between exclusive pasture and exclusive concentrate diets. As ruminants usually alternate these diets, we set out to monitor the persistence of volatile tracers of pasture diet in perirenal fat and caudal subcutaneous fat in lambs ($n = 28$) fed on pasture and then fattened at increasing levels with concentrate: Four groups of lambs ($n = 7$) were stall-finished to achieve a final weight gain of 0, 4, 8, and 12 kg, respectively. Thirty nine pasture diet tracers including terpenes, 2,3-octanedione and toluene were found that distinguish between the four different diets in both tissues. According to their clearance rates monitored in the adipose tissues of lambs fattened with different amounts of concentrate, different types of persistence were evidenced. Most of the compounds exhibited a "short" persistence, e.g. 2,3-octanedione and terpenes, while some displayed a "medium" or "long" persistence. Finally, performing discriminant analysis on ratios of tracers from the two adipose tissues enabled the correct differentiation of the four different diets.

1. Introduction

There is an increasing demand from consumers, commercial entities and bodies operating product certification systems for the development of robust analytical tools to authenticate ruminant feeding based on meat products. Numerous studies have found the analysis of the volatile fraction of dairy (Engel et al., 2007) and meat products (Engel & Ratel, 2007; Sebastian, Viallon-Fernandez, Berge, & Berdague, 2003; Vasta & Priolo, 2006) to allow the construction of robust models for animal diet authentication. These studies were conducted on samples from animals fed exclusively either pasture or concentrate. However, ruminants are usually fed diets in which pasture and concentrate periods alternate. Some authors (Aurousseau, Bauchart, Faure, et al., 2007; Aurousseau, Bauchart, Galot, et al., 2007; Larick & Turner, 1990; Larick et al., 1987; Noziere et al., 2006) have studied the variations in levels of diet biomarkers in meat or milk samples from animals fed with alternating diets consisting of an exclusive pasture feeding period followed by a concentrate-finishing period of variable duration. Monitoring the level of carotenoids (Noziere et al., 2006) or fatty acids (Aurousseau, Bauchart, Faure, et al., 2007; Aurousseau, Bauchart, Galot, et al., 2007) allowed only the differentiation of diets exhibiting marked differences in the concentrate-finishing levels. By analysing the volatile fraction of beef samples, Larick et al. (1987) showed that volatile compounds could segregate diets into graduated concentrate-finishing durations. However, the list of the feeding tracers identified differs from other literature reports and may not be reliable, given the harsh operating conditions used by these authors. Recent developments in volatile compound analysis such as instrumental drift correction (Arvanitoyannis & Van Houwelingen-Koukaliaroglou, 2003; Deport, Ratel, Berdague, & Engel, 2006) and gentle operating conditions limiting the occurrence of artefacts caused by heat (Vasta, Ratel, & Engel, 2007) identified dozens of relevant discriminant compounds with identifiable metabolic origins.

The objective of this three-step study was to determine the persistence of volatile tracers of pasture diet in adipose tissues of lambs initially fed on pasture and stall-fattened to achieve a final weight gain of 0 kg (P), 4 kg (PC4), 8 kg (PC8), or 12 kg (PC12). Two adipose tissues, the perirenal fat (PRF) and the caudal subcutaneous fat (CSCF), were analysed in each animal, as we had previously found in preliminary study that the parallel analysis of volatile diet tracers from the two tissues improved the power of differentiation between exclusive pasture and exclusive concentrate diets (Sivadier, Ratel, Bouvier, & Engel, 2008). The aim of the first step was to identify the volatile pasture diet tracers by comparing the volatile compound composition in the two tissues of lambs fed on pasture and then fattened for either 0 or 12 kg with concentrate. The second step aimed at characterising the persistence rates of these tracers by determining their relative abundances in adipose tissues of lambs stall-finished for a final weight gain of 0, 4, 8, or 12 kg. The third step

doi:10.1016/j.foodchem.2009.02.088

aimed at assessing the relevance of these findings concerning the persistence of the pasture diet tracers for distinguishing between different concentrate fattening degrees in grazing lambs on the basis of conventional GC–MS analysis of their adipose tissues.

2. Materials and methods

2.1. Animal products

A herd of 28 male INRA401 lambs born at the INRA research centre (Theix, France) during a 6-week period were divided, after a 45-day weaning period, into four groups of seven lambs each. The first group (P) was fed exclusively at pasture (consisting predominantly of Graminaceae) with no other additional feed. The animals were slaughtered according to the conventional EU procedures at the targeted weight of 40 kg, corresponding to a mean age of 186 days. The other three groups were initially fed at pasture until they reached the target weights of 28 kg (PC12), 32 kg (PC8), and 36 kg (PC4). Each of these three groups was installed in a large stall where they were offered a pelleted concentrate diet consisted of (w/w) 30% hay and 70% commercial concentrate containing barley (20%), wheat bran (15%), wheat (15%) and sugar beet (15%) as main constituents (THIVAT Nutrition Animale, Saint-germain-de-salles, France). The animals were all slaughtered at the target weight of 40 kg weight, corresponding to a mean age of 163 days.

Perirenal and subcutaneous fats were chosen for the study according to a preliminary work (Sivadier et al., 2008), in which it was established that the simultaneous data treatment of the volatile fraction of these two adipose tissues improved diet authentication. In addition, Vezinhet, Prud'hon, and Benevent (1974) reported different growth rates: perirenal fat is developed early in the lamb's life, while subcutaneous fat starts growing in the post-natal period. Diet information may thus have different implications in both tissues.

2.2. Preparation of samples

At 1 h *postmortem* a sample of each adipose tissue was excised from the lamb carcass: perirenal fat (PRF) was adipose tissue directly covering the left kidney, and caudal subcutaneous fat (CSCF) was tissue 10 cm from the tail. The adipose samples were trimmed free of all traces of muscle and immediately immersed in liquid nitrogen, wrapped in aluminium foil, vacuum packed and stored at −80 °C until the next preparation step.

Two days before the analysis each adipose tissue was immersed in liquid nitrogen, cut into small cubes (less than 0.1 g) and ground in liquid nitrogen with a crushing machine (Dangoumeau, Prolabo, Nogent-sur-Marne, France) to a fine homogeneous powder. Three grams of powder were then placed in glass vials (Wheaton Science Products) under a nitrogen flow and heated for 15 min at 70 °C in a 100–800 oven (Memmert, Schwabach, Germany). A mean of 1.2 g of liquid lipid phase was obtained, placed in glass vials sealed under nitrogen flow, and stored at −20 °C until analysis. Just before analysis, the frozen extracts were thawed for 7.5 min at 70 °C.

2.3. Addition of the standards

The comprehensive combinatory standard correction (CCSC) was used to correct instrument drifts, according to Deport et al. (2006). As previously stated by Engel and Ratel (2007), six standards were chosen according to various criteria including: (i) boiling point compatibility with the experimental conditions, (ii) stability, (iii) absence in samples before analysis, (iv) purity of commercially available solutions, (v) relative specificity of mass spectrometry fragmentation and (vi) safeness. The standards used were 2-methyl-pentane (S1; purity 99.5%), fluoro-benzene (S2; purity 99.7%), 1-bromo-butane (S3; purity 99.7%), bromo-benzene (S4; purity 99.5%), 1-fluoro-naphthalene (S5; purity 99.0%) and 1-phenyl-nonane (S6; purity 99.8%) (Sigma–Aldrich Chimie, Saint-Quentin-Fallavier, France). A mixture of the six standards was made and co-analysed with the lipid liquid extract at a final concentration of approx. 50 ppm for each standard (w/w).

2.4. Dynamic headspace–gas chromatography–mass spectrometry (DH–GC–MS) analysis

A plug of glass wool (0.2 g) (VWR International, Fontenay-sous-Bois, France) was introduced into a glass extraction cartridge (diameter 28 mm, length 100 mm, Ets. Maillière, Aubière, France). A 1 g aliquot of sample was placed on the glass wool and 10 µl of the mixture of standards was added on a second plug of 0.1 g of glass wool placed on the sample. The volatile fraction was extracted by dynamic headspace using a purge-and-trap device (3100 Sample Concentrator, Tekmar, Cincinnati, OH, USA). After a pre-purge of 5 min and a preheat of 15 min, the headspace of the sample was purged for 30 min under a 65 ml min^{-1} helium flow (He U quality, purity 99.995%, Messer, St.-Georges-d'Espéranche, France). The temperature of the sample during the DH extraction step was set at 70 °C. The volatiles were trapped by adsorption on a porous-polymer adsorbent Tenax trap column (Tenax TA, straight, 12″ × 30.5 cm, 24 cm of adsorbent, Supelco, Bellefonte, PA, USA) maintained at 36 °C. After a dry purge at 36 °C for 5 min, the volatile compounds were desorbed for 10 min at 230 °C under a helium flow (He N55, purity 99.9995%, Messer). Extracted compounds were then transferred to the head of a capillary column after cryoconcentration at −150 °C. After desorption, the Tenax trap was further heated for 30 min at 230 °C.

The compounds condensed at the head of the column were analysed by GC (model 6890, Hewlett–Packard, PA, USA); the interface was heated at 225 °C for 2 min followed by injection of the compounds in splitless mode into the non-polar phase of the capillary column (SPB5, 60 m × 0.32 mm × 1 µm, Sigma–Aldrich, St. Louis, MO, USA). The oven temperature was held at 40 °C for 5 min, and then increased to 230 °C with a gradient of 3 °C.min^{-1}, and maintained at this temperature for 10 min. The GC column was connected to a mass spectrometer (model 5973A, Hewlett–Packard). The temperature of the transfer line was set at 230 °C. The temperature was fixed at 180 °C in the MS source and at 150 °C in the MS quadrupole. The electron impact energy was set at 70 eV and data were collected in the range of *m/z* 33 to 230 at a scan range of 6.85 scans per second. Tentative identification of volatiles was based on: (i) mass spectra by comparison with MS spectra database including NBS 75 K, Wiley 275L or Masslib (MSP Kofel, Zollikofen, Switzerland) and (ii) comparison of retention indices (RI) with published RI values (Kondjoyan & Berdague, 1996) or with those of our internal data bank. The peak area of the tentatively identified compounds was integrated from the specific ion for each of the molecules to avoid co-elution problems. The integrations were performed with the Enhanced ChemStation software (version D.01.02.16, Hewlett–Packard).

2.5. Data treatment

Data were processed using the Statistica Software release 8.0 package (Statsoft, Maisons-Alfort, France) and the R software version 2.1.4. R development Core Team (2006). R: A language and environment for statistical computing. R Foundation for Statistical Computing, Vienna, Austria. ISBN 3-900051-07-0, URL http://www.R-project.org.

DH–GC–MS raw data were processed with CCSC according to Engel and Ratel (2007). The mixture of the six selected standards was analysed together with the sample, and the abundance of each compound specific ion was normalised by the sum of the abundances of the specific ion of standards, selected among the $\sum_{p=1}^{6} C_6^p$ possible sums where p represents the number of standards in a given sum, enabling the best product discrimination.

To determine which compounds distinguished between the exclusive pasture diet (P) and the alternate pasture then 12 kg concentrate-finishing diet (PC12), a one-way analysis of variance (ANOVA) was performed according to the model: CCSC pre-treated abundance of compound specific ion: type of feeding, $p < 0.05$. Principal component analyses (PCA) were performed on the CCSC pre-treated abundances of the discriminant compound specific ions to visualise the structure of the data.

To monitor the persistence of specific tracers of the four types of diet in PRF and CSCF, the compounds that discriminated between P and PC12 were filtered by one-way ANOVA (model: CCSC pre-treated abundance of compound specific ion: type of feeding, $p < 0.05$) according to the four modalities: P, PC4, PC8, and PC12. A Newman–Keuls mean comparison test was then performed on the resulting dataset to determine which compound distinguished between the four diets with increasing concentrate quantities.

To establish the possibility of distinguishing between the four types of diet on the basis of the volatile compounds from the lipid liquid extracts of the two adipose tissues, the most robust volatile tracers were obtained by filtering previous datasets of PRF and CSCF with a one-way ANOVA (with same factor) followed by a leave-one-out cross validation procedure ($p < 0.05$). A PCA was then performed on the filtered tracers from each adipose tissue and from the two pooled together in the same dataset ($n = 35$), to visualise the structure of the data. A Newman–Keuls mean comparison test was performed on the coordinates of the observations on the first principal component to assess its significance in the differentiation of the four diets. The gain in discriminative power obtained by processing the two adipose tissue volatile tracers in parallel was assessed by performing a discriminant analysis (DA) carried out on the previous datasets. The Wilk's λ values, which give the quality of differentiation of the four diets, were determined for the combinations of three tracers (triplets) from one or the two adipose tissues, built up according to the "best subset" algorithm. The optimisation of the differentiation of the four diets was obtained via ratios of tracer abundances. On the basis of the tracers from the two tissues previously selected ($n = 35$), the A_{35}^2 possible ratios were calculated and filtered by a one-way ANOVA (model: ratio of CCSC pre-treated abundances of compound specific ions: type of feeding, $p < 0.05$) followed by a leave-one-out cross validation procedure. Among the selected ratios, when several involved the same compound in the same tissue, only the one with the best Fisher F was selected. After processing the data with a PCA a Newman–Keuls mean comparison test was performed on the coordinates of the observations on the two principal components of the first map to assess their significance in the differentiation of the four diets.

3. Results and discussion

3.1. Identification of pasture diet tracers in the adipose tissues

A list of 125 volatile compounds known as potential tracers of pasture or concentrate feeding diets (Engel & Ratel, 2007; Maruri & Larick, 1992; Sebastian et al., 2003; Sivadier et al., 2008; Vasta & Priolo, 2006) were semi-quantified in perirenal fat (PRF) and caudal subcutaneous fat (CSCF) of P- and PC12-lambs. The compounds distinguishing between P and PC12 diets were selected by one-way

Table 1
Compounds identified as lamb pasture feeding tracers in PRF and CSCF tissues.

LRI[a]	Compounds[b] ($n = 54$)	PRF[c] ($n = 41$)	CSCF[c] ($n = 36$)	Ref.[d]

ANOVA ($p < 0.05$). Forty-one and 36 compounds were selected in the PRF and CSCF, respectively. Twenty-three were common to the two tissues studied (Table 1). The fact that some compounds were found to be discriminant in one tissue but not in the other (18 in PRF, and 14 in CSCF) supports the informative complementarity of the two tissues and the usefulness of studying them in parallel. The first map of the PCA performed on discriminant compounds of the two tissues is shown in Fig. 1. It reveals a clear differentiation between the two diets, confirming that the volatile fraction of these two tissues allows the authentication of the lamb diets.

Among the compounds distinguishing between P and PC12 diets in the two tissues ($n = 54$), 28 compounds had been determined as pasture diet tracers by several previous studies (Engel & Ratel, 2007; Sebastian et al., 2003; Sivadier et al., 2008; Vasta & Priolo, 2006). The common determination of these 28 pasture diet tracers in fat tissues of lambs raised with different husbandry practises (e.g. animal breed, type of pasture & concentrate, lamb growth rate...) validate the relevance of these compounds for a robust authentication of fats of pasture fed lambs (Table 1).

3.1.1. 2,3-Octanedione

This compound is the most widely recognised pasture diet tracer in the literature (Sivadier et al., 2008; Vasta & Priolo, 2006). According to Young, Berdague, Viallon, Rousset-Akrim, and Theriez (1997), it originates from the oxidation of linoleic acid by the action of the enzyme lipoxygenase, which is present in leafy plants but absent in seeds, except for soybeans. Three other ketones (1-octen-3-one, (E,E)-3,5-octadien-2-one, and acetophenone) were identified as tracers in several previous studies (Sivadier et al., 2008; Vasta & Priolo, 2006).

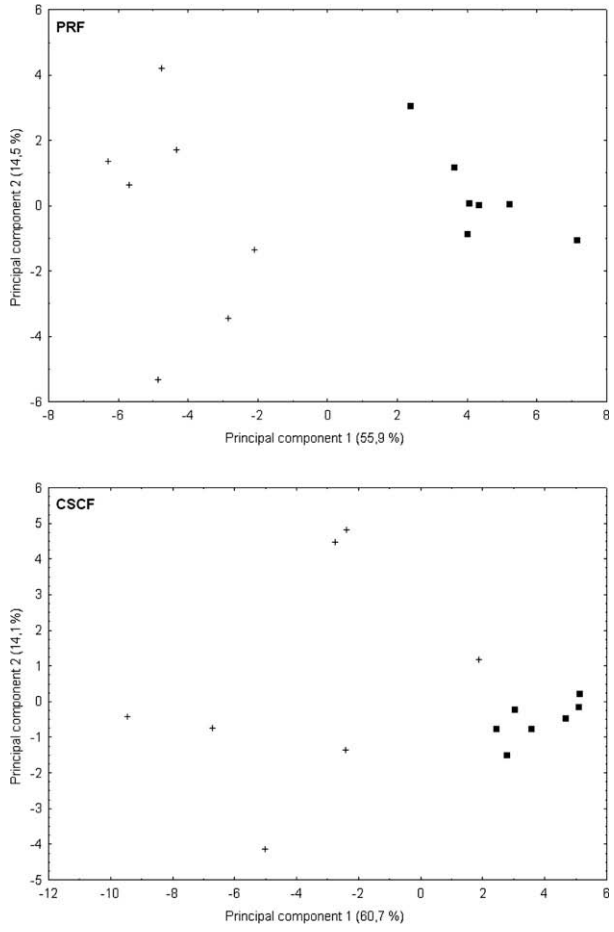

Fig. 1. Differentiation of concentrate- and pasture fed lambs based on GC–MS analysis of their adipose tissues: exclusive pasture (+/cross) and alternating pasture and fattening for 12 kg with concentrate (■/solid square). First map of normed PCAs carried out from the CCSC pre-treated abundances of the volatile compounds determined affected by the two types of diet by one-way ANOVA ($p < 0.05$). Forty-one compounds were selected in perirenal fat (PRF), and 36 in caudal subcutaneous fat (CSCF).

3.1.2. Alkanes

Similarly, six alkanes (3-methyl-nonane, 2,3,7-trimethyl-decane, tetradecane, pentadecane, hexadecane, and heptadecane) were identified as reliable pasture diet tracers (Engel & Ratel, 2007; Larick et al., 1987; Sebastian et al., 2003; Sivadier et al., 2008). As regards the four non-branched alkanes (C_{14}—C_{17}), their relation with the pasture diet could be explained by the higher amounts of long chain polyunsaturated fatty acids in the tissues of pasture fed lambs in comparison with concentrate fed lamb tissues (Aurousseau, Bauchart, Faure, et al., 2007; Aurousseau, Bauchart, Galot, et al., 2007). According to Watanabe and Sato (1971), these saturated alkanes may derive from decarboxylation and splitting of carbon–carbon chains.

3.1.3. Benzene compounds

Benzaldehyde, 1,3,5-trimethyl-benzene, and toluene were detected in higher amounts in adipose tissues of pasture fed lambs than in tissues of lambs fed with any of the three concentrate-finishing diets. According to Rios, Fernandez-Garcia, Minguez-Mosquera, and Oerez-Galvez (2008), the toluene may arise from the degradation of carotenoids supplied by pasture. These three compounds are also atmosphere pollutants which are known to be retained by green plants (Binnie, Cape, Mackie, & Leith, 2002).

3.1.4. Terpens

Mainly originating from green herbages (Body, 1977), terpenes are commonly detected in adipose tissues of pasture fed lambs (Priolo et al., 2004; Sivadier et al., 2008). They are generally too specific to some plant species to be used as generic tracers of a pasture diet (Engel & Ratel, 2007). However, p-cymen, α-copaene, β-caryophyllene, and trans-cadina-1(6),4-diene are identified as recurrent pasture diet tracers in the literature (Engel & Ratel, 2007; Sivadier et al., 2008; Vasta & Priolo, 2006) and can be considered as generic pasture diet tracers.

3.1.5. Aldehydes

2-Butenal, pentanal, (E)-2-pentenal, (Z)-4-heptenal, and 2,4-heptadienal were found to be characteristic of the pasture diet by some previous studies (Engel & Ratel, 2007; Sebastian et al., 2003; Sivadier et al., 2008). In contrast with Brown, Melton, Riemann, and Backus (1979), who proposed that some aliphatic aldehydes (e.g. pentanal) were related to the pasture feeding, Vasta and Priolo (2006) showed there was no consensus for relating these compounds to a given diet. Because they originate from lipid oxidation, their occurrence may be favoured by many factors other than the type of feeding, such as the temperature used for volatile compound extraction.

3.1.6. (E)-2-Octene

This compound, derived from α-linolenic acid according to Elmore et al. (2004), was determined as a pasture diet tracer in both this study and the literature (Engel & Ratel, 2007; Maruri & Larick, 1992; Sivadier et al., 2008).

To our knowledge, there is no evidence indicating the metabolic origin of methional, dimethyl-sulfone, 2-methyl-furane, and (E)- and (Z)-4-octene. Nevertheless, these compounds were also identified as pasture diet tracers in previous data (Engel & Ratel, 2007; Sivadier et al., 2008; Vasta & Priolo, 2006).

Among the compounds that were not found to distinguish between diets P and PC12, some were recurrently identified as pasture diet tracers in the literature (Engel & Ratel, 2007; Maruri & Larick, 1992; Sebastian et al., 2003). These compounds are: 1-methyl-cyclohexane, hexane, (Z)-2-octene, heptanal, m-cymen, and 3 alkyl-benzenes (2-ethyl-1,3-dimethyl-benzene, 1,2,3,4- and 1,2,4,5-tetramethyl-benzene). These discrepancies with the literature may be explained by differences between the rearing protocol used by the previous and the present studies. The PC12 diet consisted in pasture feeding for approximately 80 days after weaning, followed by concentrate feeding for about the same duration, while the exclusive concentrate feeding periods in the previous studies (Engel & Ratel, 2007; Maruri & Larick, 1992; Sebastian et al., 2003) were 101, 113, and 175 days after weaning. Hence we can assume that using the PC12 diet, the duration of the period where concentrate is given may be too short to significantly decrease the level of these compounds. Accordingly, we can assume that these compounds are particularly persistent pasture diet tracers. Concerning the other compounds found discriminant in previous studies but not in the present work, these may

[a] Compounds found to distinguish between the four types of diet. The amounts of the compounds in the volatile fraction of the tissues are expressed in percentages of their amount in the exclusive pasture diet (P).

[b] Adipose tissues: PRF = perirenal fat, and CSCF = caudal subcutaneous fat.

[c] Diets: P = exclusive pasture; PC4, PC8, PC12 = alternating pasture and fattening for 4 kg, 8 kg, and 12 kg, respectively with concentrate. For each tissue and each compound, values with different letters (A and B) within a same row were found significantly different ($p < 0.05$) according to a Newman–Keuls mean comparison test.

[d] Persistence degree resulting from the Newman–Keuls mean comparison test.

be too specific to experimental features to be considered as generic.

3.2. Persistence of pasture diet tracers in adipose tissues

The 54 compounds found to distinguish between the P and PC12 diets were semi-quantified in the adipose tissues of the lambs fed with the PC4 and PC8 diets. The compounds distinguishing between the four diets were determined by ANOVA ($p < 0.05$). Thirty-two and 22 compounds were selected as feeding tracers in the PRF and CSCF, respectively, with 15 in common (Table 2). Thirty-three of these 39 pasture feeding tracers decreased significantly when animals are finished with concentrate. This decrement confirms first that these compounds are pasture diet tracers, and second that the switch to concentrate diet results in a more or less fast decrease in the abundance of these tracers in lamb adipose tissues. These data are in agreement with the study performed by Larick et al. (1987) which showed a decrease of pasture diet tracers in fat tissue of beef finished with concentrate.

Twenty-four compounds in PRF and 13 in CSCF were shown to distinguish between P and each of the other alternating diets and can so be considered as pasture diet tracers with "short" persistence (see Table 2). Similarly, most of the volatile pasture diet tracers evidenced in beef fat by Larick et al. (1987) were shown to decrease significantly whatever the duration of the concentrate-finishing diet. The short persistence pointed out for 2,3-octanedione in both studies suggests an interspecific genericity. Four compounds in PRF and 5 in CSCF distinguished between P diet and pasture diets followed by a concentrate fattening for a final weight gain greater than or equal to 8 kg (PC8 and PC12). The latter compounds were considered as tracers with "medium" persistence. Similarly, 2-undecanone in PRF and 2,3-butanedione in CSCF that distinguish between the P and PC12 diets were considered as exhibiting a "long" persistence. Most of the pasture tracers which were commonly identified in PRF and CSCF exhibited the same persistence degree in the two tissues suggesting that the mechanisms responsible for the decrement of these compounds are common to PRF and CSCF. Finally, the results presented in Table 2 also confirm the different content in pasture diet tracers of both tissues which was previously evidenced by Sivadier et al. (2008).

All tracers that were alkenes or terpenes exhibited the same persistence, suggesting similar clearance mechanisms within the same chemical family. Considering the terpenes, the prompt variations in amounts of these compounds in response to a pasture-concentrate switch is consistent with previous work on ground beef (Larick et al., 1987). In contrast, other compounds exhibited different persistence within a given chemical family, suggesting that chemical family is not, in most cases, the only factor explaining the persistence of these tracers. The between-diet variation exhibited for linear *n*-alkanes suggest that the chain length of the compounds could be one of the other factors to consider. A systematic short persistence was found for tetra-, penta- and hexadecane in agreement with the result found by Larick et al. (1987) for hexa-, hepta- and octadecane. In contrast, a systematic higher amount in the 4 kg fattening (PC4) has been pointed out for decane, undecane, dodecane and tridecane. These C10—C13 linear alkanes may be suitable for segregating the four feeding situations together with pasture diet tracers with short, medium and long persistence.

3.3. Differentiation of four lamb diets varying in concentrate finishing duration

To determine the relevance of analysing the volatile fraction of the two adipose tissues to distinguish between the four types of diet, the most discriminative tracers listed in Table 2 were selected by a leave-one-out procedure ($p < 0.05$). A PCA was performed on

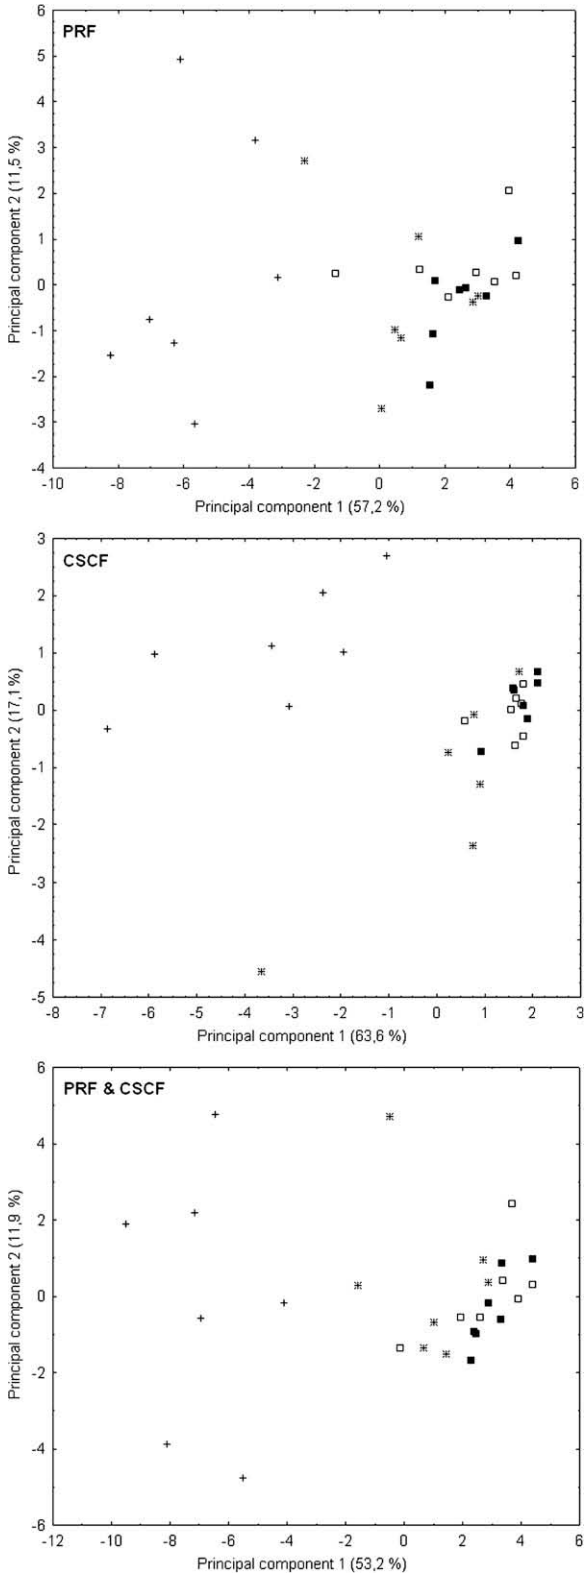

Fig. 2. Differentiation of pasture fed lambs fattened for various weight gain with concentrate based on GC–MS analysis of their adipose tissues: exclusive pasture (+/cross) and alternating pasture and fattening with concentrate for a final gain of weight of 4 kg (⁎/star), 8 kg (□/open square), or 12 kg (■/solid square). First map of normed PCAs carried out from the CCSC pre-treated abundances of the volatile compounds determined distinguishing between the four types of diet by one-way ANOVA followed by a leave-one-out cross validation procedure ($p < 0.05$). Twenty-five compounds were selected in perirenal fat (PRF) and 10 in caudal subcutaneous fat (CSCF). The pooled datasets thus comprised 35 compounds.

the resulting compounds selected in PRF ($n = 25$) and CSCF ($n = 10$) tissues, respectively. Whatever the tissue, the first maps (Fig. 2) show a clear segregation between the pasture and the three other diets. The Newman–Keuls mean comparison test performed on the coordinates of the observations on the first principal component confirmed that only the exclusive pasture diet was significantly differentiated from the three other concentrate-finishing diets in the two adipose tissues (data not shown). This may be explained in part by the fact that most of the tracers involved in the PCA had a "short" persistence.

To assess the usefulness of the combined analysis of PRF and CSCF, the tracers from the two tissues were pooled together in the same dataset ($n = 35$), and a PCA was run on these data (Fig. 2). The Newman–Keuls mean comparison test on the coordinates of the observations on the first principal component revealed a clear segregation of P, PC4, and the two other diets (data not shown). This improvement of the segregation compared with single tissue data confirms previous report showing that the parallel treatment of the data from different adipose tissues improves diet authentication (Sivadier et al., 2008).

The complementarity of PRF and CSCF tissues for differentiating the four diets was assessed by carrying out discriminant analyses (DA) on tracers either from one, or from the two adipose tissues. The tracers ($n = 35$) were combined into all possible triplets, and their Wilk's λ values, which indicate the quality of the distinction between the four diets, were calculated. The 120 most discriminative combinations (i.e. showing the lowest Wilk's λ values) formed by triplets involving tracers from PRF, CSCF and the two adipose tissues were considered. Fig. 3 shows that CSCF exhibits tracers which were less discriminant than PRF, and that the combination of the two datasets resulted in an improvement in the animal diet discrimination. However, this improvement was not sufficient to distinguish between PC8 and PC12 even in the most highly discriminant models (data not shown).

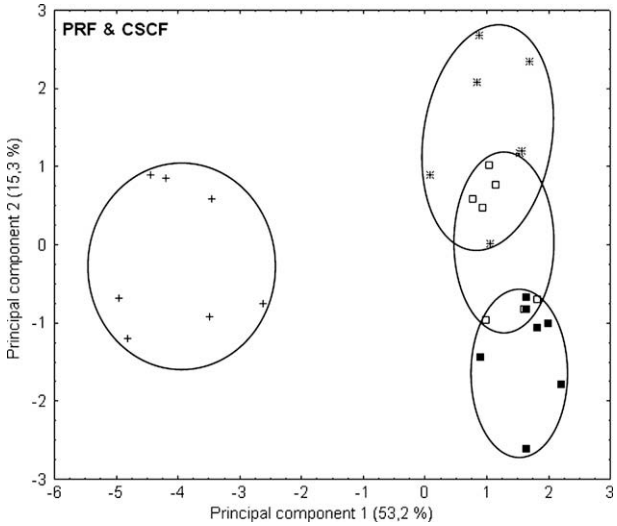

Fig. 4. Differentiation of pasture fed lambs fattened for various weight gain with concentrate based on GC–MS analysis of their adipose tissues: exclusive pasture (+/cross) and alternating pasture and fattening for 4 kg (✳/star), 8 kg (□/open square), or 12 kg (■/solid square) with concentrate. First map of normed PCA carried out from 11 selected ratios. To illustrate the differences in diets, the projection of lambs were clustered into ellipses.

To maximise the discrimination, the abundances of the 35 discriminative compounds from the two adipose tissues were built up into ratios according to Engel et al. (2007). All possible ratios ($n = 1225$) were then filtered by ANOVA ($p < 0.05$) followed by

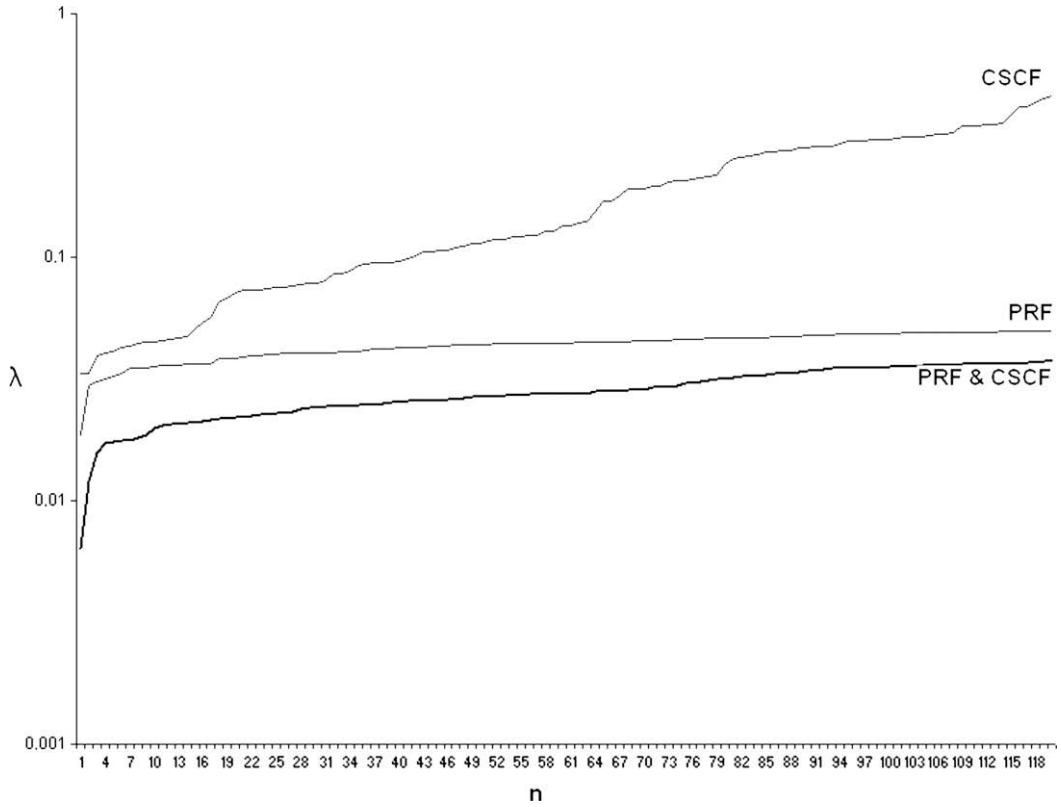

Fig. 3. Comparison of the quality of the diet differentiation by parallel analysis of the adipose tissues. Diagram of Wilk's λ values (λ) calculated for each triplet ($n = 120$) composed by diet tracers from one or the two adipose tissues (PRF = perirenal fat, and CSCF = caudal subcutaneous fat), after a discriminant analysis (DA).

leave-one-out cross validation procedure. 271 discriminant ratios were finally selected. Among the ratios involving the same compound from the same tissue (numerator or denominator), the ratio that exhibited the best Fisher *F* was selected. A PCA (Fig. 4) was carried out on the dataset formed by the 11 selected ratios. The first plane of the PCA revealed a strong segregation of the pasture diet and the three other diets displayed by the first principal component, while the second one segregated the three diets. Newman–Keuls test performed on the coordinates of the observations on both axes of the PCA confirmed that by considering the first and second principal components of the PCA, the four diets were significantly differentiated.

4. Conclusions

In the present study, DH–GC–MS technique and instrumental drift correction were used to extract the relevant information contained in the volatile fraction of the perirenal fat (PRF) and the caudal subcutaneous fat (CSCF) of lambs fed four different diets. The compounds distinguishing between the diets exhibited all the possible degrees of persistence, with most tracers exhibiting a "short" persistence. Only the combined treatment of the diet tracers from the two adipose tissues allowed efficient segregation of the four types of diet. To authenticate the feeding history of grazing ruminants, it is essential to determine the persistence of pasture diet tracers in their tissues, but it is also important to assess the latency rates of these tracers. This will be the subject of a further study.

Acknowledgement

The lambs used in this experiment were produced at the Herbivore Research Unit (INRA, UR1213, Theix, France) facilities; the authors acknowledge the active contribution of M. Bernard, J.C. Bonnefoy, C. Coustet, R. Jailler and S. Prache to the raising and the slaughtering of the animals.

Ischemia-reperfusion
EGCG

ABSTRACT

Quercetin-3-rhamnoglucoside (rutin) has a wide spectrum of biochemical and pharmacological activities. Orally administered compounds are absorbed in the intestine. Although absorption of rutin from the jejunum of the rat was good, binding of rutin to the intestinal wall components may limit its absorption from the small intestine. The physiological importance of an orally administered compound depends on its interaction with target tissues. Since there is limited information on the importance of rutin *in vivo*, we focused on the protective effect of rutin on intestinal injury. The intestinal mucosa is extremely sensitive to reactive oxygen species. We used a rat mesenteric ischemia-reperfusion (I/R) injury model as a model of oxidative injury and investigated the antioxidant activities of rutin *in vivo*. We found that rutin, which has combined antioxidant activity from radical-scavenging, xanthine oxidase inhibition and chain-breaking effects, exhibits a protective effect on I/R injury in the rat small intestine.

1. Introduction

Common buckwheat is recognised as a healthy food in many countries, such as China, Nepal and Japan, because it is rich in flavonoids, vitamins, amino acids and other substances. One of the most important components of buckwheat is quercetin-3-rhamnoglucoside (rutin), a flavonol glycoside compound. This natural substance has a wide spectrum of biochemical activities, including antioxidant, antiviral, antitumor, antiinflammatory and antiallergic activities, and is a stimulant of the immune system (Watanabe, 1998). Moreover, rutin is commercially prepared and used as dietary supplements. Orally administered compounds are absorbed in the intestine. It has been reported that absorption of rutin from the jejunum of the rat was good and that rutin is mainly absorbed in its unmetabolized form (Spencer, Chowrimootoo, Choudhury, Debnam, & Srai et al., 1999). However, it has also been reported that binding of rutin to the intestinal wall components may greatly limit its absorption from the small intestine (Carbonaro & Grant, 2005). The physiological importance of an orally administered compound depends on its interaction with target tissues. Thus, we focused on the effect of rutin on the jejunum.

The interest in using rutin in cosmetic and pharmaceutical formulations is to enhance their antioxidant and vasoprotective properties for promoting relief of symptoms of lymphatic and venous insufficiency and for reducing capillary fragility (Calabrò, Tommasini, Donato, Stancanelli, & Raneri et al., 2005). Production of reactive oxygen species (ROS) in tissue contributes to the development of various chronic diseases, such as cancer, neurodegenerative diseases and cardiovascular diseases (Benzie, 2000). Administration of antioxidants to patients may therefore help in removing ROS and thus improving their clinical outcome. Dietary antioxidants can improve the activities of cellular antioxidant defence systems including enzymes, such as superoxide dismutase and glutathione peroxidase, and help to prevent oxidation damage to cellular components. There has been considerable public and scientific interest in therapeutic use of natural antioxidants. In addition to buckwheat, rutin is found in fruits and vegetables, such as kale, apple and orange juice (Careri, Elviri, Mangia, & Musci, 2000; Paganga, Miller, & Rice-Evans, 1999). In order to evaluate *in vitro* antioxidant activities of various compounds, a screening procedure such as *in vitro* radical-scavenging assay is widely used. However, there is little information on the importance of dietary flavonoids, including rutin, as antioxidants *in vivo*, or evidence for such activity *in vivo*.

The intestinal mucosa is extremely sensitive to ROS (Kong, Blennerhassett, Heel, McCauley, & Hall, 1998). Since there is limited information on the importance of rutin as an antioxidant *in vivo*, we focused on the protective effect of rutin on intestinal oxidative injury. It is well known that ROS are responsible for intestinal isachemia-reperfusion (I/R) injury (Adam, Crespy, Levrat-Verny, Leenhardt, & Leuillet et al., 2002). Intestinal I/R is a common clinical problem in the settings of severe burns, circulatory shock and strangulation ileus. Furthermore, intestinal I/R injury is a serious medical problem often necessitating surgical intervention. In this study, we used a rat mesenteric I/R injury model as a model of oxi-

dative injury and investigated the antioxidant activities of rutin *in vivo*.

2. Materials and methods

2.1. Chemicals

Rutin, (−)-epigallocatechin gallate (EGCG), thiobarbituric acid (TBA), 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile) (MeO-AMVN), luminol, hydrogen peroxide, diethylenetriamine-N,N,N′,N″,N″-pentaacetic acid (DTPA) and iron (II) sulphate heptahydrate were purchased from Wako (Osaka, Japan). Xanthine oxidase was purchased from Nacalai Tesque (Kyoto, Japan). Hypoxanthine was purchased from Sigma (St. Louis, MO). 4,4-Difluoro-5-(4-phenyl-1,3-butadienyl)-4-bora-3a,4a,-diaza-s-indacene-3-propionic acid saccinimidyl ester (BODIPY) was purchased from Invitrogen (Carlsbad, CA). All other reagents were of the highest grade available and used without further purification.

2.2. Animals

Male Wistar rats, aged 6 weeks (180–200 g in weight), were obtained from Japan Laboratory Animals (Tokyo, Japan). The housing conditions were the same as those described previously (Itagaki, Kurokawa, Nakata, Saito, & Oikawa et al., 2009). The rats were housed for at least 1 week at 23 ± 3 °C and 50 ± 10% relative humidity and were maintained on a 12-h light/dark cycle. During the acclimatisation, the rats were allowed free access to food and water. The experimental protocols were reviewed and approved by the Hokkaido University Animal Care Committee in accordance with the "Guide for the Care and Use of Laboratory Animals".

2.3. Measurement of superoxide anion-scavenging activity

Superoxide anion-scavenging activity was measured by the chemiluminescent superoxide anion probe method, using a superoxide anion-2-methyl-6-methoxyphenylethynylimidazopyrazynone (MPEC) reaction kit (ATTO Corp., Osaka, Japan) according to the manufacturer's instructions (Itagaki et al., 2009).

2.4. Measurement of hydroxyl radical-scavenging activity

The method is based on the generation of HO· by Fenton reaction and the determination of HO· by chemiluminescence (Hirayama & Yida, 1997). For the Fenton reaction, H_2O_2 solution (1 mM) was prepared by diluting hydrogen peroxide solution with 25 mM imidazole-nitrite solution (pH 7.0); ferrous sulphate solution (1 mM) was prepared by dissolving $FeSO_4 \cdot 7H_2O$ in distilled water and DTPA solution (1 mM) was prepared in distilled water. As a chemiluminescent reagent, luminol solution (1 mM) was prepared by dissolving luminol in 200 mM borate buffer (pH 9.5). The reaction solution was composed of 0.16 mM ferrous sulphate, 0.16 mM DTPA, 0.25 mM hydrogen peroxide, and 0.16 mM luminal, with or without tested compounds (final concentrations of 0.001, 0.01, 0.1, 1 and 10 mM, respectively). The ferrous iron (Fe^{II})–H_2O_2–luminol chemiluminescence signal profile was obtained by the multilabel counter, Wallac 1420 ARVOse. The results are expressed as inhibition, representing the percentage of inhibition of luminol chemiluminescence with respect to that occurring in a control:

$$\text{Inhibition rate} = [(AUC_{control} - AUC_{sample})/AUC_{control}] \times 100$$

where $AUC_{control}$ and AUC_{sample} represent the area under the curve (AUC) of luminol chemiluminescence kinetics in the control and samples, respectively.

2.5. Measurement of radical chain-breaking activity

The assay was carried out as described in a previous report (Itagaki et al., 2009).

2.6. Intestinal I/R model

Surgical procedures and tissue sampling were carried out as described in a previous report (Itagaki et al., 2009).

2.7. TBA analysis

The amount of lipid peroxide in the intestine was determined as that of malondialdehyde (MDA) (Itagaki et al., 2009).

2.8. Evaluation of changes in vascular permeability

Extravasation of Evans blue dye into tissue was used as an index of increased vascular permeability. Evans blue dye (20 mg/kg) was injected (1 ml/kg) through the jugular vein 5 min prior to reperfusion. Sixty min after reperfusion, fragments of the loop were cut and Evans blue dye was extracted using 4 ml of formamide (24 h at 37 °C).

2.9. Data analysis

Nonlinear regression analysis was performed by using Origin® (version 6.1J). Student's *t*-test was used to determine the significance of differences between two group means. Statistical significance among means of more than two groups was determined by one-way analysis of variance (ANOVA). A value of $p < 0.05$ was considered significant.

3. Results and discussion

ROS are continuously generated by metabolism in the body and exert physiological actions (Gate, Paul, Ba, Tew, & Tapiero, 1999). Although the action of ROS is normally limited by the antioxidant defence system of the body, an excess of ROS induces oxidative damage in vulnerable targets, such as membrane unsaturated fatty acids, protein thiols, and DNA bases (Ceconi, Boraso, Cargnoni, & Ferrari, 2003). Since oxidative stress is an imbalance between ROS production and antioxidant defence, the antioxidant capacity in patients is likely to be compromised. Much interest has been shown in the discovery of new antioxidants in recent years, due to their potential applications in the treatment of ROS-induced diseases. For the prevention of these diseases, an approach focusing on the health aspects of natural antioxidants should be beneficial. However, there is not much available experimental evidence of their physiological functions, in comparison with experimental evidence of the physiological functions of pharmaceutical drugs.

In this study, we compared the antioxidative activities of rutin with those of EGCG, a well-known antioxidative flavonoid. In the first part of this study, the antioxidant activities of rutin were evaluated using an *in vitro* system. The superoxide radical anion appears to play a central role, since other ROS are formed in reaction sequences starting with the superoxide radical anion. Xanthine/xanthine oxidase is also a main source of ROS (Chambers, Parks, Patterson, Roy, & McCord et al., 1985). Moreover, the intestinal mucosa is one of the richest sources of xanthine oxidase. In this study, we therefore used a xanthine/xanthine oxidase system to generate superoxide anions. EGCG and rutin inhibited the light emission induced by xanthine oxidase in a concentration-dependent manner. IC_{50} values of EGCG and rutin for light emission induced by xanthine oxidase are listed in Table 1. EGCG and rutin

prevented the light emission induced by xanthine oxidase. Highly reactive free radicals, such as peroxyl radicals involved in auto-oxidation of lipoproteins and of biological membranes, are responsible for microvascular damage. Since hydroxyl radical production plays a significant role in the initiation of lipid peroxidation, we investigated the hydroxyl radical-scavenging activities of EGCG and rutin. The results showed that EGCG and rutin both exhibit hydroxyl radical-scavenging activities (Table 1). Since the influence of free radical-mediated oxidation is amplified, because it is proceeded by a chain mechanism, the role of chain-breaking activity is important as well as radical-scavenger activity (Riley, 1994). Recently, Beretta, Aldini, Facino, Russell, & Krinsky et al., (2006) reported a method that enables specific measurements of chain-breaking activities of tested compounds, using BODIPY, and showed that EGCG acts as a chain-breaking antioxidant, as well as a radical-scavenger. We therefore investigated the chain-breaking activity of rutin using BODIPY. EGCG and rutin inhibited BODIPY oxidation, and the TAP values of these compounds increased in a concentration-dependent manner (Table 2).

Evidence supporting an antioxidant function for flavonoids is usually derived from *in vitro* assays. However, evidence that flavonoids, including rutin, act directly or indirectly as antioxidants *in vivo* is limited. Antioxidant studies using laboratory animals should be carried out to obtain a mechanistic basis and safety profiles before they can be applied to humans for intervention trials. As a model of ROS-induced diseases, we selected intestinal I/R injury (Adam et al., 2002; Kong et al., 1998). We confirmed *in vivo* antioxidant activities of EGCG and rutin, using a rat I/R injury model. Lipid peroxidation is an integral process in the oxidation of unsaturated fatty acids via a radical chain reaction, and overproduction of lipid peroxide contributes to small intestinal injury. The increase in the amount of lipid peroxide after I/R was significantly inhibited by treatment with EGCG and rutin (Fig. 1). Since vascular permeability has been shown to be significantly higher in rats with I/R than in sham-operated rats, elevated vascular permeability is also one of the indicators of I/R injury (Pompermayer, Amaral, Fagundes, Vieira, & Cunha et al., 2007). We therefore investigated the effects of these compounds on increased vascular permeability, as assessed by reduction in the level of Evans blue dye. Elevation of vascular permeability by intestinal I/R was attenuated by treatment with EGCG and rutin (Fig. 2). I/R injury occurs clinically during abdominal aortic aneurysm surgery, small bowel transplantation, cardiopulmonary bypass, strangulated hernias and neonatal necrotizing enterocolitis. Moreover, reperfusion of ischemic vascular beds may lead to recruitment and activation of leukocytes, release of mediators of the inflammatory process and further injury to the affected vascular bed and remote sites (Lefer & Lefer, 1996). Thus, strategies that limit the damage induced by the reperfusion process may be useful in the treatment of ischemic disorders in various organs (Willerson, 1997). The protective effect of rutin on intestinal I/R injury may be relevant to human health.

As stated above, I/R injury is considered to be a major clinical problem and occurs in many kinds of tissues, including the stomach, pancreas, and cardiac and skeletal muscle (Harris, Leiderer, Peer, & Messmer, 1996; Reiter & Tan, 2003). In addition to I/R injury, ROS are thought to play an important role in many diseases (Benzie, 2000; Gate et al., 1999). The doses of rutin, with clinically

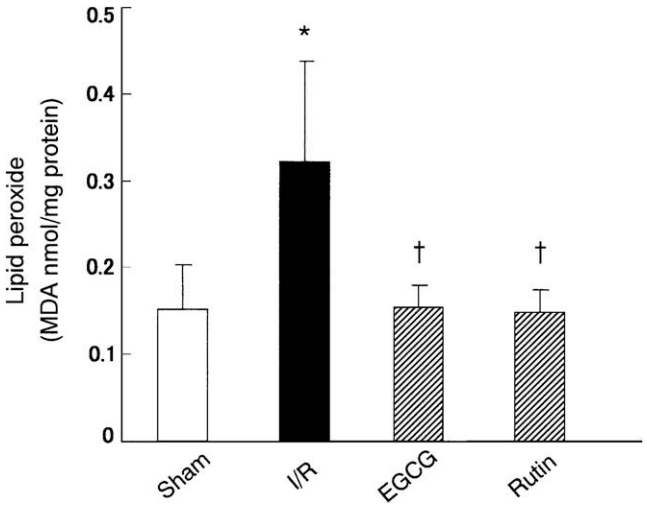

Fig. 1. Effects of EGCG and rutin (1 mM) on the amount of lipid peroxide in the small intestine after I/R. Each value is the mean with S.D. of 3 rats (I/R + rutin), 4 rats (I/R + EGCG) or 11 rats (sham, I/R). $^{*}P < 0.05$, significantly different from nonischemia control animals. $^{\dagger}P < 0.05$, significantly different from animals not treated with compounds (I/R animals). *Abbreviations:* MDA, malondialdehyde; I/R, ischemia-reperfusion; EGCG, (−)-epigallocatechin gallate.

Table 1
IC_{50} values of EGCG and rutin on xanthine oxidase-induced light emission and superoxide anion-scavenging activity

	Xanthine oxidase-induced light emission	Superoxide anion-scavenging activity
	IC_{50} (M)	
EGCG	9.13 ± 0.70	0.80 ± 0.02
Rutin	71.7 ± 11.1	10.6 ± 1.59

Each value represents the mean with S.D. of three independent experiments.
Abbreviation: EGCG, (−)-epigallocatechin gallate.

Table 2
Antioxidant activities of EGCG and rutin determined by the TAP assay.

Concentration (mM)	EGCG	Rutin
	TAP value (%)	
0.0001	0.95 ± 6.82	15.6 ± 16.1
0.001	35.9 ± 8.90	35.1 ± 5.01
0.01	78.9 ± 3.68	62.0 ± 3.42
0.1	85.8 ± 3.68	81.7 ± 2.01
1	78.6 ± 4.18	84.5 ± 0.31

Each value represents the mean with S.D. of three independent experiments.
Abbreviations: EGCG, (−)-epigallocatechin gallate; TAP, total antioxidant performance.

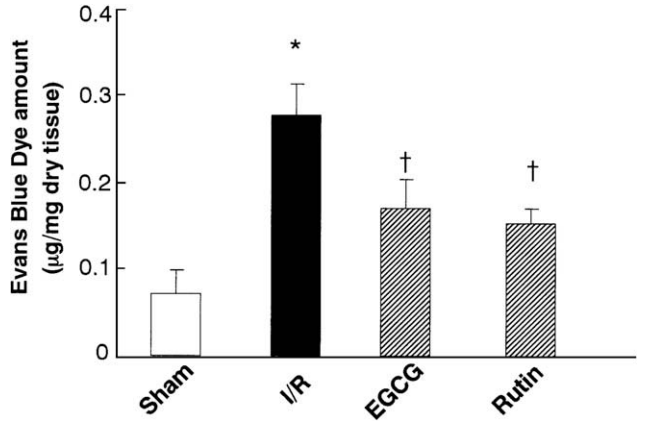

Fig. 2. Effects of EGCG and rutin (1 mM) on changes in vascular permeability in the small intestine. Each value is the mean with S.D. of 4 rats (I/R + rutin), 5 rats (sham) or 6 rats (I/R, I/R + EGCG). $^{*}P < 0.05$, significantly different from nonischemia control animals. $^{\dagger}P < 0.05$, significantly different from animals not treated with compounds (I/R animals). *Abbreviations:* I/R, ischemia-reperfusion; EGCG, (−)-epigallocatechin gallate.

clearly demonstrated effects, have been reported to be between 180 and 350 mg (Schilcher, Patz, & Schimmel, 1990). Thus, the intake of 100 g of buckwheat flour or bran in food would cover ~10% of the therapeutic doses. These are well below the therapeutic doses but could meet the demands of preventive nutrition and post-therapeutic nutritional treatment, especially with the consideration that, besides buckwheat, other foods and/or beverages could also be consumed as natural nutritional sources of rutin. A recommended daily intake of rutin has not been established. Further studies are needed to establish the recommended daily doses of rutin and food sources of dietary rutin.

For the prevention of ROS-induced diseases, an approach focusing on the health aspects of functional foods should be beneficial (Swinbanks & O'Brien, 1993). In order to develop new functional foods, it is important to select a suitable ingredient that has a scientific background. The results of this study should provide a scientific background of the usefulness of rutin as a functional food ingredient.

In summary, we have found that rutin, which has combined antioxidant activity from radical-scavenging, xanthine oxidase inhibition and chain-breaking effects, exhibits a protective effect on I/R injury in the rat small intestine. Rutin might be useful for prevention of oxidative injury in humans and for *in vivo* studies.

ABSTRACT

In West Africa, *Alchornea cordifolia*, *Baphia nitida*, *Cassia occidentalis* and *Boerhavia diffusa* leaves are used in food and drinks, as well as in traditional medicine, to treat rheumatic ailments which incur oxidative stress. First, these plants were evaluated for their antioxidant properties through a scavenger effect on reactive oxygen species (ROS), such as hydrogen peroxide and hypochlorous acid. All of them showed dose-dependent antioxidant activity. The values obtained were comparable to those of antioxidant pharmacological substances: N-acetylcysteine and Mesna. Second, rates of total phenolic, flavonoid and proanthocyanidin contents were evaluated. The highest rates were to be found in the most active extracts, indicating that antioxidant activity could be influenced by these phytochemical groups.

The results of our study confirm the traditional use of these plants in inflammatory diseases, and demonstrate that they could contribute, through their phenolic contents, to attenuating tissue damage due to ROS. These plants can also be beneficial for health as a source of antioxidants when they are included in food and drinks.

1. Introduction

In West Africa, numerous plants are included in food or drinks and are also successfully used in traditional medicine, e.g. *Alchornea cordifolia* (Schumach. & Thonn.) Müll. Arg. (Euphorbiaceae), *Baphia nitida* Lodd. (Fabaceae), *Cassia occidentalis* L. (Fabaceae) and *Boerhavia diffusa* L. (Nyctaginaceae) leaves. On the one hand, *A. cordifolia* and *C. occidentalis* leaves are used as decoctions in water instead of coffee and as a drink mixed with pineapple fruit juice (Motte, 1980). *B. diffusa* leaves, mixed with *Afromomum melegueta* fruits and *Zingiber officinale* rhizomes, are included in foodstuffs, as well as *B. nitida* leaves, which are used alone (Chastanet, Fauvelle-Aymar, & Juhé-Beaulaton, 2002). On the other hand, all these plants prevent or cure several illnesses, including those with severe inflammatory components, such as bronchial asthma and rheumatic ailments (Adjanohoun & Ake Assi, 1979). On the pharmacological level, they share anti-inflammatory properties (Mavar-Manga, Brkic, Marie, & Quetin-Leclercq, 2004). In addition, many scientific works report evidence of their effectiveness in antimicrobial (Agrawal, Srivastava, Srivastava, & Srivastava, 2004), antispasmodic (Borrelli et al., 2005), diuretic (Mishra & Singh, 1980), and immuno-modulating (Pandey, Maurya, Singh, Sathiamoorthy, & Naik, 2005) treatments. Our study, which is the first of its kind, aims at investigating the capacity of all four plants to scavenge reactive oxygen species (ROS) and at determining the compounds responsible for this effect.

Activation of neutrophils or macrophages, through inflammatory substances is known to generate ROS (Roos, 1991), such as hydrogen peroxide (H_2O_2), and hypochlorous acid (HOCl). At low rates, ROS act as signalling molecules in various intracellular processes and are produced continuously in most tissues. Antioxidants within the human body tend to limit oxidant rate. Any excessive increase in their production in the course of oxidant stress is particularly preponderant, on the one hand, in illnesses such as chronic inflammatory diseases (Sahinoglu, Stevens, Bhatt, & Blake, 1996), rheumatoid arthritis (Afonso, Campy, Mitrovic, & Collin, 2007) or pulmonary diseases (Chabot, Mitchell, Guteridge, & Evans, 1998) and, on the other hand, in others such as atherosclerosis, brain and heart ischemia, cancer, neurodegenerative diseases and acute kidney failure (Yoshioka & Ichikawa, 1989). ROS are associated with cell damage as they react with different macromolecules, such as membrane proteins, lipids and DNA. Therapeutic action aimed at correcting oxidant–antioxidant imbalance is a clinical challenge,

doi:10.1016/j.foodchem.2009.04.117

and has increasingly been the object of research work. Several articles have reported that polyphenols, such as flavonoids and proanthocyanidins, which are widely distributed in the vegetable kingdom, show antioxidant properties (Hatano et al., 1989). Previous phytochemical works have indicated the presence of flavonoids and phenolic acids, such as ellagic acid and two glycosides of quercetol, in *A. cordifolia* leaves (Ogungbamila & Samuelsson, 1990) and the presence of cinnamoyl derivatives, quercetin, kaempferol and their glycosides, in *B. diffusa* leaves (Ferreres et al., 2005). No polyphenolic compounds had previously been isolated and identified in *B. nitida* and *C. occidentalis* leaves.

The aim of this study was therefore to determine the antioxidant activity of the four studied plant leaves versus ROS and to correlate this activity with the total phenolic, flavonoid and proanthocyanidin contents of each plant. This could explain, at least partly, their traditional anti-inflammatory uses.

2. Materials and methods

2.1. Chemicals and instruments

All chemicals were purchased from Sigma Chemical Co. (USA) and from Merck (France). Thin-layer chromatography (TLC) was performed on Merck silica gel F_{254} plates. Natural standard products (gallic acid, cyanidin and hyperoside, ellagic acid, quercetin, kaempferol and hyperin) were obtained from Extrasynthèse (France). All absorbances were measured with a Kontron Uvikon 869 spectrophotometer.

2.2. Plant material

Fresh leaves of *A. cordifolia*, *B. nitida*, *C. occidentalis* and *B. diffusa* were harvested at the Floristic National Center of Abidjan and verified by an expert botanist (Prof. Aké Assi, Department of Botany, University of Abidjan) to be identical to samples from the Herbarium at the centre (Table 1). Voucher specimens were deposited in the Botanical Department of the Centre National de Floristique at the Cocody University of Abidjan (Côte d'Ivoire). The leaves were collected and dried in darkness in a 25 °C air-conditioned room. These conditions were the most appropriate in order to protect the polyphenolic content of each plant.

2.3. Preparation of ethyl acetate and aqueous extracts

2.3.1. Ethyl acetate extract

The dried leaves were powdered (50 g) and macerated for 24 h at room temperature in 500 ml of methanol/acetone/water (70:70:30 v/v/v); then the filtrates were low pressure-concentrated at 30 °C to remove the methanol and acetone phases. The remaining water was extracted three times with ethyl acetate. The ethyl acetate phases obtained were evaporated to dryness and conserved at 4 °C (Table 2). This powder was dissolved in the appropriate solvents for further studies.

2.3.2. Aqueous extract

The fine powder (50 g) of dried leaves were macerated for 48 h at room temperature in 500 ml of distilled water. The aqueous extracts obtained were lyophilised and conserved at 4 °C, and aliquots of lyophilised powder were dissolved in the appropriate solvents for chemical and pharmacological studies (Table 2).

Table 2
Yields in percent of dry matter after extraction.

Plant	Aqueous extract	Ethyl acetate extract
Alchornea cordifolia	7.0	8.3
Baphia nitida	8.4	11.5
Cassia occidentalis	12.0	40.3
Boerhavia diffusa	6.6	6.3

2.4. Phenolic content

2.4.1. General

The extracts were tested by thin-layer chromatography (TLC) and colorimetric methods to determine the presence of flavonoids, proanthocyanidins and total phenolics. All measurements were made three times. The results were expressed in mg/mg of dry extract and compared with standards treated under the same conditions.

2.4.2. Thin-layer chromatography (TLC) analysis

TLC of phenolic extracts was performed on Merck 5554 Silicagel F_{254} aluminium sheets. Proanthocyanidins were analysed with toluene/acetone/formic acid, 3:3:1 (v/v). Detection: visible, UV alone (550 nm), anisaldehyde/H_2SO_4 (anisaldehyde, 0.2 ml/MeOH, 85 ml/AcOH, 10 ml/H_2SO_4, 5 ml) then 3–4 min at 105 °C. Flavonoids were analysed with ethyl acetate/formic acid/water, 8:1:1 (v/v). Detection: visible, UV alone (365), aminoethyl-diphenyl borinate in MeOH with 3% PEG 300 (visible and UV).

2.4.3. Determination of total phenolic content

Total phenolics were quantified by the colorimetric method adapted from Singleton, Joseph, and Rossi (1965), using Folin–Ciocalteu reagent (7 ml distilled H_2O, 0.5 ml Folin–Ciocalteu reagent); 0.5 ml of each aqueous extract solution was added. After 3 min, 2 ml of 20% Na_2CO_3 were added and the whole heated to 100 °C for 1 min in a water bath. Absorbance was measured at a wavelength of 680 nm and compared with a standard of gallic acid.

2.4.4. Determination of proanthocyanidin content

The method used in experimentation was similar to that of Porter, Hrtich, and Chan (1986). The results were compared with those obtained with a standard of cyanidin.

2.4.5. Determination of flavonoid content

Total flavonoid contents were determined with the aluminium chloride ($AlCl_3$, $6H_2O$) method used by Lamaison and Carnat (1991). A volume of 1 ml of methanolic extract solution was added to 1 ml of 2% methanolic aluminium chloride. Absorbance was measured 10 min later at a wavelength of 394 nm and compared with a standard of hyperoside.

2.5. Pharmacological activities

2.5.1. General

The aqueous and ethyl acetate extracts were both dissolved in phosphate buffered saline (PBS) 0.5 M, pH 7.4. The concentrations

Table 1
Plants and parts used for analysis.

Family	Plant	Aspect (m)	Part used	Herbarium no.
Euphorbiaceae	*Alchornea cordifolia*	Shrub (5–12)	Leaf	183
Fabaceae	*Baphia nitida*	Three (3–8)	Leaf	257
	Cassia occidentalis	Herb (1)	Leaf	317
Nyctaginaceae	*Boerhavia diffusa*	Herb (1)	Leaf	386

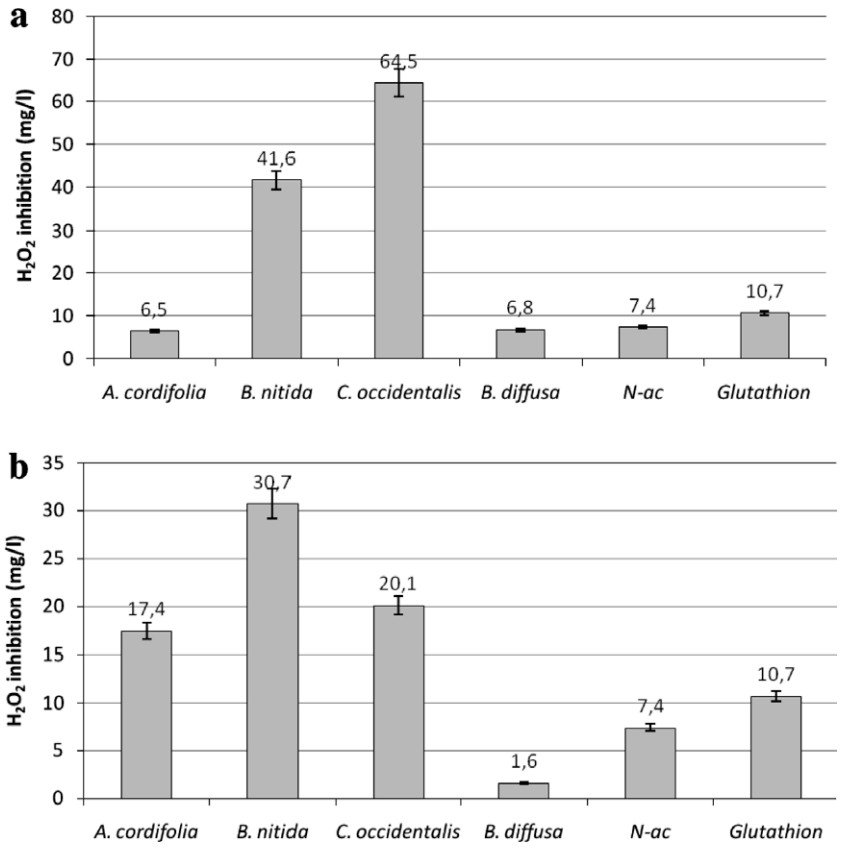

Fig. 1. Scavenger activities of plant extracts. Inhibitory concentrations (IC_{50}) of aqueous (a) and ethyl acetate (b) extracts towards H_2O_2. Histograms represent 3–4 experiments. Values are means ± S.E.M. ($p < 0.5$).

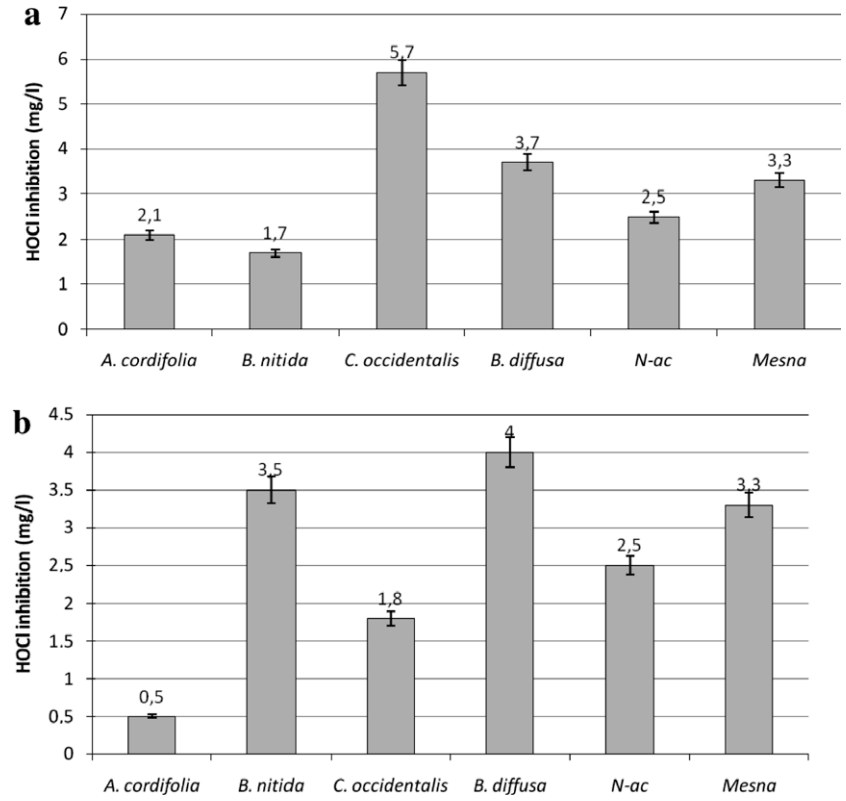

Fig. 2. Scavenger activities of plant extracts. Inhibitory concentrations (IC_{50}) of aqueous (a) and ethyl acetate (b) extracts towards HOCl. Histograms represent 3–4 experiments. Values are means ± S.E.M. ($p < 0.5$).

inhibiting 50% activity (IC_{50}) of extracts were obtained with a computer programme graphpad (prism 4, Mo, USA). They were uniformly expressed as the corresponding dry matter weight. All experiments were carried out three times.

2.5.2. Scavenging of hypochlorous acid (HOCl)

The amount of HOCl was measured by taurine chlorination (Weiss, Klein, Slivka, & Wei, 1982). Sample aliquots contained 100 µl of sodium hypochlorite (600 mM), 100 µl taurine (150 mM) and 100 µl of each extract solution from each plant in a final volume of 1 ml PBS pH 7.4. Absorbance was measured at a wavelength of 350 nm against a reference aliquot after adding 10 µl of potassium iodide (2 M).

The percentage of HOCl production inhibited by each plant extract was then calculated and results expressed in IC_{50} values.

2.5.3. Scavenging of hydrogen peroxide (H_2O_2)

H_2O_2 was measured according to Pick and Keisari (1980). Sample aliquots contained 100 µl of H_2O_2 (120 mM), 100 µl of each plant extract (in ranging concentrations) and the total volume of each vial was completed to 1 ml by adding phosphate buffered saline (PBS), pH 7.4. After 15 min at 37 °C, 1 ml of phenol red (0.2 mg/ml) containing horseradish peroxidase (17 U/ml), was added to induce the oxidation of phenol red by H_2O_2. After 15 min at 37 °C, 50 µl of NaOH (1 N) were added and the amount of H_2O_2 was determined by measuring absorbance at a wavelength of 610 nm against a reference aliquot. H_2O_2 concentrations were derived from a standard curve, using reagent grade H_2O_2. The percentage of H_2O_2 production inhibited by each plant extract was then calculated and results expressed in IC_{50} values.

2.6. Statistical analysis

Results were expressed as means ± S.E.M. and values were compared using the Wilcoxon test. Differences were considered to be statistically significant when $p < 0.05$.

3. Results

Assessment was made of the antioxidant activities of two extracts from each plant: an aqueous extract and an ethyl acetate extract. *In vitro* assays were performed in the two scavenging systems of H_2O_2 and HOCl (Figs. 1 and 2). Activity evaluation of plant

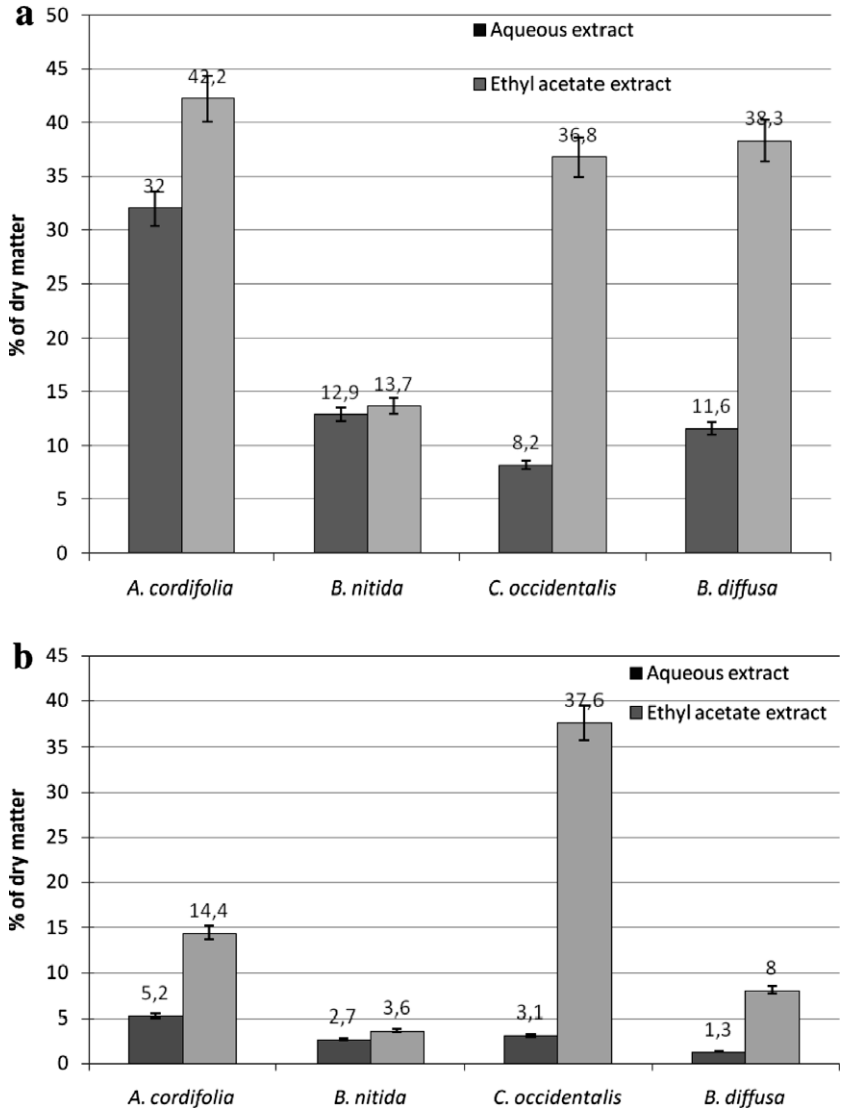

Fig. 3. Phenolic contents of aqueous and ethyl acetate extracts: total phenols (a) and flavonoids (b). Histograms represent 3–4 experiments. Values are means ± S.E.M. ($p < 0.5$).

extracts towards H_2O_2 and HOCl showed the capacity of the four plants to scavenge these ROS in a dose-dependent manner.

Activities towards H_2O_2, (Fig. 1) indicate that the ethyl acetate and aqueous extracts of *B. diffusa* (IC_{50} values of 1.6 and 6.8 mg/l, respectively), as well as the aqueous extract of *A. cordifolia* (IC_{50} values of 6.5 mg/l), had the best antioxidant activities of the tested extracts and were superior to N-acetylcysteine and Mesna reference substances (IC_{50} values of 7.4 and 10.7 mg/ml, respectively).

Activities towards HOCl (Fig. 2) reveal that aqueous extracts of *A. cordifolia* and *B. nitida* (IC_{50} values of 2.1 and 1.7 mg/l, respectively) and ethyl acetate extracts of *A. cordifolia* and *C. occidentalis* (IC_{50} values of 0.5 and 1.8 mg/l, respectively) had strong antioxidant activities, superior to those of N-acetylcysteine and Mesna reference substances (IC_{50} values of 2.5 and 3.3 mg/l, respectively).

Chromatographic analysis on thin-layer silica gel revealed the presence of flavonoids and the absence of proanthocyanidins in the four plants. As previously indicated, ellagic acid, quercetin and hyperin were identified in *A. cordifolia*, and quercetin and kaempferol in *B. diffusa*, when compared with authentic samples. Numerous other flavonoids were present in all four plant extracts. Proportions of total phenolics and flavonoids were measured for each plant according to the methods of Singleton et al. (1965) and Lamaison and Carnat (1991), respectively. Fig. 3a and b shows the concentrations of total phenolics and flavonoids: the former vary from 8.2% to 42.2% of dry extracts and the latter from 1.3% to 37.6%. For all four plants, concentrations are higher in the ethyl acetate extracts than in the aqueous ones.

4. Discussion

The IC_{50} values versus ROS (H_2O_2 and HOCl) observed in extracts from all four plants are comparable with those of pharmacological substances such as N-acetylcysteine and Mesna (Gressier, Cabanis, & Lebègue, 1994) which were previously reported to be effective ROS scavengers in therapeutics (Göksel, Levent, Özer, Feriha, & Nursal, 2006). The most efficient species are *A. cordifolia* and *B. diffusa* as they present the lowest IC_{50} values, between three and ten times lower than those of the other two plants. These data are very interesting as this is the first time they have been obtained for these plants whose strong antioxidant properties are therefore confirmed through a different experimental protocol.

Comparison of total phenolic and flavonoid contents with antioxidant activities shows a good correlation in the case of *A. cordifolia*, *B. nitida* and *B. diffusa* ethyl acetate and aqueous extracts. The antioxidant activity of *C. occidentalis* seems to be due to the high flavonoid content of the ethyl acetate extract (Figs. 2 and 3).

These scavenger activities of the studied plants could, at least partly, justify their traditional anti-inflammatory use, as phenolics, including flavonoids, are known for their antioxidant properties, which could be partially involved in anti-inflammatory mechanisms (Sala et al., 2003). First they act as antioxidants against free radicals which can attract various inflammatory mediators contributing to a general inflammatory response and tissue damage (Nijveldt et al., 2001). Second, the anti-inflammatory activity of flavonoids may be due to a decrease in the activation of the Nuclear Factor κB by ROS, such as HOCl and H_2O_2, which induce the transcription of inflammatory cytokines and cyclo-oxygenase-2 implicated in inflammatory mechanisms *in vivo* (Schinella, Tournier, Prieto, Mordujovich de Buschiazzo, & Ríos, 2002).

These results confirm those obtained by other authors, following different experimental protocols. The work undertaken on *A. cordifolia* (Mavar-Manga et al., 2004) and *B. nitida* (Onwukaeme, 1995) showed that flavonoid concentration was correlated to anti-inflammatory activity. Antioxidant activity, following yet another protocol, was assessed in *B. diffusa* (Devaki, Shivashangari, Ravikumar, & Govindaraju, 2005) through its protective effect against the intoxication of hepatocytes *via* carbon tetrachloride and ethanol in rats and mice. Oxygen species have been reported to have an important role in inflammatory processes after intoxication by ethanol, carrageenan and carbon tetrachloride (Yoshikawa, Tanaka, & Kondo, 1983). *B. diffusa* reduced oedema on mouse paw induced by carrageenan (Mugdal, 1975) confirming its antioxidant action. Jafri, Jalis Subhani, Javed, and Singh (1999) reported that *C. occidentalis* leaves could protect rat liver against intoxication induced by ethanol. This protective action could be due to an antioxidant effect of *C. occidentalis* revealed in our tests.

In conclusion, our study assesses, for the first time, the antioxidant activity of *A. cordifolia*, *B. nitida*, *C. occidentalis* and *B. diffusa* against ROS and its correlation with their phenolic and flavonoid contents. According to these results it is probable that the anti-inflammatory effects of the four plants, which have been confirmed in certain experimental models, could be at least partly related to their antioxidant activities. All of these results confirm the beneficial effects of these plants in traditional medicine, and as sources of antioxidants in food and drinks.

Acknowledgements

The authors wish to thank Professor Aké-Assi Laurent for identifying the plant species.

ABSTRACT

The potential of laccase-generated tetramethoxy azobismethylene quinone (TMAMQ) for measuring antioxidant activity of a wide range of structurally diverse molecules present in food and humans was investigated for the first time. All the tested antioxidants including simple phenolics, polyphenols and vitamins quenched TMAMQ. The antioxidant activity of phenolics and polyphenolics depended on the position and number of hydroxyl groups on the benzene ring. Equally interesting was the ability of amino acids like cysteine, tryptophan and methionine as well as peptides (glutathione) and proteins (albumin) to quench TMAMQ, demonstrating the great potential of TMAMQ for analysis of antioxidant activity of serum samples. Further, TMAMQ is promising is a more reliable tool for measuring antioxidant activity of amino acids when considering conflicting reports on antioxidant activity of some of the amino acids. The extracts from various food samples showed varying antioxidant activity with highest for spinach (4.36 mg methanol extract/mmol TMAMQ) followed by kiwi (13.95 mg methanol extract/mmol TMAMQ) and lettuce (40 mg methanol extract/mmol TMAMQ). The use of the laccase generated TMAMQ can be exploited for the development of laccase based biosensors for complex and coloured samples thereby facilitating online monitoring of antioxidants in food, cosmetic and health industries.

1. Introduction

The human body is exposed to a large variety of reactive species (free radicals) from both endogenous and exogenous sources. Endogenous free radical species (superoxide, nitric oxide and hydrogen peroxide) are products of normal cellular function. These cellular functions include mitochondrial respiration (Serrano, Goni, & Saura-Calixto, 2007), activated phagocytes, arachidonic acid metabolism, ovulation and fertilization (Magalhaes, Segundo, Reis, & Lima, 2008; Singh, Sharad, & Kapur, 2004). Exogenous sources of free radicals include pollutants such as car exhaust, industrial contaminants encompassing many types of nitrogen reactive species, drugs and xenobiotics (toxins, pesticides, herbicides etc.) (Kohen & Nyska, 2002; Valko et al., 2007). Cell damage caused by free radicals has been implicated in the pathogenesis of at least 50 diseases conditions (Dalle-Donne, Rossi, Colombo, Giustarini, & Milzani, 2006; Halliwell, 1994). Similarly, in food, for example the oxidation of lipids by free radicals has historically been a major problem for food processing industries responsible for the formation of off-flavours and undesirable chemical compounds which may be detrimental to health (Jadhav, Nimbalkar, Kulkarni, & Madhavi, 1996).

To protect the cells and organs against free radicals, biological systems have evolved a highly sophisticated and complex antioxidant protection system. These antioxidants therefore constitute the body's first line of defence against free radical damage. The antioxidants include biologically built-in mechanism of neutralizing free radicals for example glutathione peroxidase, catalase, and superoxide dismutases, glutathione and albumin (Singh et al., 2004; Valko, Rhodes, Moncol, Izakovic, & Mazur, 2006). The exogenous sources of antioxidants are mainly of dietary origin including vitamin C, tocopherols, carotenoids, flavonoids (Singh et al., 2004; Valko et al., 2006). Endogenous and exogenous antioxidants function interactively and synergistically to neutralize free radicals. When the availability of antioxidants is limited, cell damage and food oxidation occurs. Strangely, despite the well recognised importance of antioxidants for human health and food preservation, currently there is no nutritional standard index available related to antioxidants for food labelling because of the lack of standardised methods (Ou, Huang, Hampsch-Woodill, Flanagan, & Deemer, 2002). However, recently determining antioxidant capacity has become a very active research topic as recently demonstrated by international efforts to standardise assay methods (Prior, Wu, & Schaich, 2005).

Recently, we have discovered that laccase oxidised syringaldazine was a reliable tool for measuring antioxidant activity of vitamin C and vitamin E (Nugroho Prasetyo et al., 2009). The performance of laccase oxidised syringaldazine was comparable to the commercially available 2,2-diphenyl-l-picrylhydrazyl (DPPH) radical.

Syringaldazine is a yellowish compound which is converted to tetramethoxy azobismethylene quinone (TMAMQ) with maximum absorbance at 530 nm (deep purple colour) upon oxidation by laccases (Harkin, Larsen, & Obstharkin, 1974; Holm, Nielsen, & Eriksen, 1998). It is a well known laccase substrate which is also used to detect peroxidase activities. The reaction of laccase with syringaldazine first generates a free radical and loss of the second electron can either proceed enzymatically or by disproportionation forming a deep purple coloured quinone (TMAMQ – Fig. 1) which is not prone to polymerisation under appropriate conditions (Kuznetsova & Romakh, 1996; Thurston, 1994). Further, electrochemical and pulse radiolysis studies of the oxidation of syringaldazine confirmed a reversible two-electron-two-proton transfer leading to the formation of a deep purple compound (Hapiot, Pinson, Neta, & Rolando, 1993).

Syringaldazine can also be oxidised by chlorine and is currently used for the colorimetric determination of chlorine in water (Bauer & Rupe, 1971; Cooper, Roscher, & Slifker, 1982). This work, is the first to explore the ability of laccase generated TMAMQ to measure the antioxidant activity of a wide variety of structurally different antioxidants relevant to both the food industry and human health. The study is also extended to investigate the ability of laccase generated TMAMQ to measure antioxidant activity of crude extracts of known important dietary sources. This knowledge will allow the development of laccase based biosensors for complex thereby facilitating online monitoring of antioxidants in food, cosmetic and health industries.

2. Materials and methods

2.1. Chemicals and enzyme

All the used antioxidants molecules were of analytical grade. The phenolics were purchased from Sigma–Aldrich, Steinheim, Germany while the flavonoids were purchased from Carl Roth GmbH, Karlsruhe Germany. All the other chemicals were purchased from Merck, Darmstadt, Germany. The *Trametes hirsuta* laccase was produced and purified as previously described by Almansa, Kandelbauer, Pereira, Cavaco, and Guebitz (2004). Food samples of onion (*Allium cepa*), green and fermented tea (*Camellia sinensis*), *kiwi* (*Actinidia arguta*), apple (*Malus domestica*), carrot (*Daucus carota subsp. sativus*), roasted coffee (*Coffea robusta*), lettuce (*Lactuca sativa*), spinach (*Spinacea oleracea*), pumpkin seed (*Curcubita maxima*), tomato (*Solanum lycopersicum*) and garlic (*Allium sativum*) were purchased from local markets in Graz, Austria.

2.2. Laccase activity assay

The activity of laccase was determined spectrophotometrically by monitoring the oxidation of 2,2′-Azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) (ε_{436} = 29,300 M^{-1} cm^{-1}) as a substrate at 436 nm in 50 mM sodium succinate buffer at pH 4.5 and 30 °C (Nugroho Prasetyo et al., 2009). The spectrophotometric measurements were done by recording the absorbance in the time scan mode for 2 min using a Hitachi U-2001 UV–vis spectrophotometer.

2.3. Generation of TMAMQ

TMAMQ stock solutions were prepared by incubating syringaldazine (0.17 mM) with 50 μl of laccase (20 nkat ml^{-1}) in 50 mM sodium succinate buffer at pH 4.5. The reaction mixture (1 ml) was incubated at 30 °C for 10 min while shaking at 140 rpm in a thermomixer (Eppendorf AG, Germany). The oxidation process was monitored at 530 nm using a Hitachi U-2001 UV–vis spectrophotometer in disposable cuvettes of 1 cm pathway. To this stock solution of laccase generated TMAMQ, methanol was added to a final concentration of 80% (v/v) to stop laccase activity and to stabilize the TMAMQ (Nugroho Prasetyo et al., 2009).

2.4. Determination of antioxidant activity of pure molecules

Different concentrations of pure antioxidant molecules dissolved in methanol (0–20 μM) were added to 800 μl of TMAMQ dissolved in 80% methanol (final absorbance of 0.8) in order to obtain a dose response curve. The mixture was thoroughly mixed and incubated at 30 °C while shaking in a thermomixer (Eppendorf AG, Germany) at 140 rpm until full completion of the reaction as evidenced by no further decrease in absorbance. The degree of decoloration of the solution indicates the scavenging efficiency of the added antioxidant sample. The stoichiometrical reduction of TMAMQ (μM of TMAMQ reduced by 1 μM antioxidant) was then calculated from a dose response curve of added antioxidant.

2.5. Preparation of food samples and extraction of antioxidants

2.5.1. Recovery of simple phenolic compounds

Food samples were purchased fresh from local markets, and the edible parts blended using a blender GT800 (Uetendorf, Switzerland) and then freeze-dried. The procedure followed for extraction of antioxidants was as previously described by Saura-Calixto, Serrano, and Goni (2007) with slight modifications. The first extraction procedure involved suspending 0.5 g of freeze dried food sample in 20 ml of 98% methanol/water (50:50 v/v) in a 250 ml Erlenmeyer flask and incubating at 25 °C while mixing at 150 rpm for 1 h. The mixture was then centrifuged at 2500 g for 20 min and the supernatant recovered. The residue was then washed with 20 ml of 98% acetone/water (70:30 v/v) and centrifugation repeated as described above to maximally recover remaining antioxidants as recommended by previous researchers (Perez-Jimenez et al., 2008). The antioxidant activity of the different extracts was determined separately after adjusting pH to 7 using NaOH to stabilize the extracts (Perez-Jimenez et al., 2008).

2.5.2. Recovery of hydrolysed tannins

The residues arising from methanol extracts were mixed with 20 ml of methanol and 2 ml of concentrated sulphuric acid. Sam-

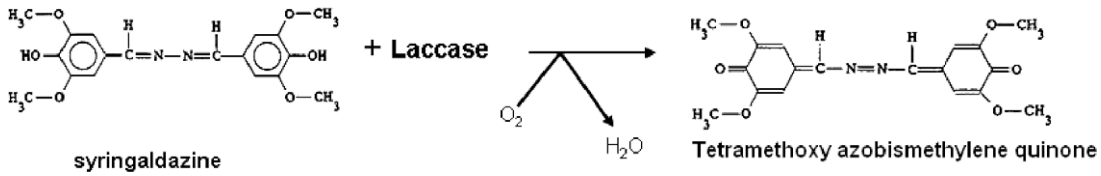

Fig. 1. Laccase oxidation of syringaldazine results in the formation of a water molecule and tetramethoxy azobismethylene quinone (TMAMQ).

ples were then incubated at 85 °C for 20 h in a shaking water bath. The samples were then centrifuged at 2500*g* for 20 min and supernatants recovered; subsequently the pH of supernatant was adjusted to 7 using NaOH. This fraction contained hydrolysable tannins and other phenolics linked to carbohydrates and proteins (Hartzfeld, Forkner, Hunter, & Hagerman, 2002).

2.5.3. Recovery of condensed tannins

The remaining residues from the two extraction processes were further treated with 37% HCl/98% butanol/$FeCl_3$ (5:95, v/v) at 100 °C for 3 h. Samples were centrifuged as described above and the supernatants recovered. The precipitates were further washed twice with 37% HCl/98% butanol (5:95 v/v) (Porter, 1989). The samples were then centrifuged at 2500*g* for 20 min and supernatants recovered. The pH of the antioxidant fractions from this extraction step corresponding to condensed tannins were adjusted to 7 as described above.

2.5.4. Determination of antioxidant capacity of food samples

The different extracts obtained above were incubated separately with the TMAMQ as described above for pure antioxidants. The extracts were mixed in varying amounts to obtain a dose response curve. The mixture was thoroughly mixed and incubated at 30 °C while shaking at 140 rpm until full completion of the reaction as evidenced by no further decrease in absorbance. The stochiometrical reduction of TMAMQ was then calculated from the decrease in absorbance as described above.

2.5.5. Antioxidant activity of oils

Extra-virgin olive oil and maize oil produced by Warenhandels-AG, Salzburg, Austria and Unilever, Wien, Austria respectively were used directly without any modification. Total antioxidant capacity was determined directly after diluting aliquots in ethyl acetate (Espin, Soler-Rivas, & Wichers, 2000). The mixture was thoroughly mixed and incubated at 30 °C while shaking at 140 rpm until full completion of the reaction as evidenced by no further decrease in absorbance. The stoichiometrical reduction of TMAMQ was then calculated from the dose response curve as described above.

2.5.6. Measurement of total phenols

The phenol content of the extracts was determined according to the Folin–Ciocalteu procedure (Singleton & Rossi, 1965). Briefly, test sample (100 μl) was mixed with 100 μl of Folin–Ciocalteau reagent and swirled. Subsequently, 500 μl of nanopure water, 50–100 μl of sample, and 100 μl of Folin–Ciocalteu reagent were added to a 2 ml eppendorf reaction tube. The contents were mixed and allowed to stand for 5–8 min at 25 °C. Thereafter, 1 ml of a 7% sodium carbonate solution was added, followed by the addition of nanopure water. Solutions were mixed and allowed to stand at 30 °C again for 2 h. Total phenolic content was determined using TECAN Infinite M200 plate reader (Tecan Austria GmbH, Grödig, Austria) at 650 nm wavelength. Total phenolic content was determined as gallic acid equivalents (GAE) expressed as milligrams per litre of gallic acid per milligram of extract (Peschel et al., 2006).

3. Results and discussion

In a first stage, the antioxidant scavenging activity of different pure molecules (phenolics, amino acids, peptides, proteins and vitamins) was investigated followed by the antioxidant activity of food extracts.

3.1. Antioxidant activity of phenolics

Among phenolic compounds, phenolic acids, flavonoids and tannins are regarded as the main dietary antioxidants (Pellegrini et al., 2007; Sikora, Cieslik, & Topolska, 2008) and were therefore selected. The antioxidant activity of simple phenolics increased with increasing number of hydroxyl groups in the order (guaiacol [0.01 μM] < pyrogallol [5.79 μM]) (Table 1). A similar trend was also observed with hydroxybenzoic acids in the order 4-hydroxybenzoic acid [no activity] < 2,5-hydroxybenzoic [0.63 μM] < gallic acid [3.91 μM] (Table 1). Substitution of the 3- and 5-hydroxyl group in gallic acid with methoxy groups as in syringic acid reduced the antioxidant activity from 3.91 μM to 1.03 μM, respectively. However the presence of the two methoxy groups in syringic acid adjacent to the OH group enhanced antioxidant activity as compared with vanillic acid (Table 1).

The antioxidant activity of hydroxycinnamic acids also increased with increasing number of hydroxyl groups (Table 1). Like the monohydroxy benzoic acid (4-hydroxybenzoic acid), p-coumaric acid showed no antioxidant activity in terms of hydrogen donating capacity towards TMAMQ. However, the presence of another hydroxyl group for example in caffeic acid as compared with p-coumaric showed an antioxidant activity of 2.47 μM (Table 1). The antioxidant behaviour of hydroxybenzoic acids and hydroxycinnamic acids in the presence of TMAMQ is consistent with previous observation (Rice-Evans, Miller, & Paganga, 1996; Villano, Fernandez-Pachon, Moya, Troncoso, & Garcia-Parrilla, 2007) when these respective antioxidants were incubated with ABTS and *N,N-*

Table 1
Amount of TMAMQ quenched by 1 μM of the phenolics tested.

Phenolics	Number of OH	Amount of TMAMQ (μM) reduced by 1 μM of phenolics
Simple phenolics		
Guaiacol	1	0.01 ± 0.004
Catechol	2	2.57 ± 0.30
Pyrogallol	3	5.78 ± 0.14
Hydroxybenzoic acids		
4-hydroxybenzoic acid	1	–
2,5-hydroxybenzoic acid	2	0.63 ± 0.02
Gallic acid	3	3.91 ± 0.02
Vannilic acid	1	0.67 ± 0.03
Syringic acid	1	1.03 ± 0.04
Hydroxycinnamic acids		
ρ-coumaric	1	–
Cafeic acid	2	2.47 ± 0.31
Eugenol	1	0.2 4 ± 0.15
Ferulic acid	1	1.23 ± 0.12
Sinapic acid	1	3.58 ± 0.22

(–) no antioxidant activity detected.

diphenyl-picryl hydrazyl (DPPH) radicals. The introduction of methoxyl groups at *meta* and *para* positions in hydroxybenzoic acids increased the antioxidant activity when comparing vannilic acid (0.67 μM) and syringic acid (1.03 μM). A similar trend was also observed for hydroxycinnamates when comparing caffeic acid (2.47 μM) to sinapic acid (3.58 μM). However, substitution of the 3-hydroxyl group only of caffeic acid by a methoxy group (ferulic acid) considerably decreased the antioxidant activity of hydroxycinnamates (Table 1). The antioxidant activity of the tested hydroxycinnamic acids was in the order sinapic acid > cafeic acid > ferulic acid > p-coumaric acid (Table 1).

In agreement with previous studies using other assay procedures, the antioxidant activity of phenolic antioxidants depended on the number and positions of the hydroxyl groups in relation to the carboxyl functional group and presence of methoxyl groups (Balasundram, Sundram, & Samman, 2006; Monach, Williamson, Morand, Scalbert, & Rémésy, 2005; Robards, Prenzler, Tucker, Swatsitang, & Glover, 1999) For example, the increase in antioxidant activity of phenolics with increasing degree of hydroxylation and the decrease in antioxidant activity with substitution of the hydroxyl groups at the 3- and 5-position with methoxyl groups as in syringic acid has also been reported by Rice-Evans and her co-workers (Rice-Evans et al., 1996). Further, in this study just as in previous studies (Andreasen, Landbo, Christensen, Hansen, & Meyer, 2001), generally the hydroxycinnamic acids exhibited higher antioxidant activity compared to the corresponding hydroxybenzoic acids. The high antioxidant activity of hydroxycinnamic acids has been attributed to the presence of CH=CH–COOH group, which ensures greater H-donating ability and radical stabilisation than the –COOH group in the hydroxybenzoic acids (Rice-Evans, Miller, & Paganga, 1997). However, comparing ferulic acid and eugenol which basically share similar functional groups, the presence of $CH_2CH{=}CH_2$ negatively influenced the antioxidant activity of the later (Table 1).

3.2. Antioxidant activity of polyphenols

The antioxidant activity of anthocyanins, flavonols, flavones and flavan-3-ols was investigated (Table 2). Among the anthocyanins tested, delphinidin chloride reduced 5.40 μM TMAMQ, pelargonidin chloride reduced 3.68 μM TMAMQ and paeonidin chloride reduced 2.89 μM of TMAMQ. Cyanin chloride and oenin chloride each reduced 0.88 μM and 0.94, respectively. malvidin chloride (1 μM) showed the highest antioxidant activity reducing 13.01 μM of TMAMQ although in previous studies its antioxidant activity was similar to that of peonidin. This result is consistent with results obtained with hydroxbenzoic and hydroxycinnamic acids when comparing antioxidants with one methoxyl group and two methoxyl groups demonstrating the advantage of this method over the DPPH and ABTS methods. Increase in methoxyl groups enhances the electron donating ability of the antioxidant. The B-ring hydroxyl configuration has been reported to be the most significant determinant for radical scavenging ability of flavonoids (Balasundram et al., 2006; Burda & Oleszek, 2001; Cao, Sofic, & Prior, 1996). The antioxidant activity of quercetin (4.80 μM), a flanovol was more than twice that of rutin hydrate (2.01 μM) a flavone, similar to that reported by (Lien, Ren, Bui, & Wang, 1999; Silva et al., 2002). This also adds evidence to the premise that flavonols are more effective free radical scavengers than flavones (Lien et al., 1999; Rice-Evans et al., 1996) and that glycosylation of flavonoids reduces their antioxidant activity when compared to the corresponding aglycones. Although quercetin has an identical number of hydroxyl groups in the same positions as catechin, the 2,3-double bond in the C ring and the 4-oxo group maybe responsible for enhancing the antioxidant activity of the later. Epigallocatechin gallate had an antioxidant activity three times that of catechin (Table 2) which shows the contribution of gallic units on the former.

Generally the antioxidant activity responses of polyphenols and phenolics were in good agreement with the proposed structure-activity relationship as summarised by previous reports (Balasundram et al., 2006; Heim, Tagliaferro, & Bobilya, 2002; Rice-Evans et al., 1997).

3.3. Antioxidant activity of endogenous antioxidants and free amino acids

Of the 21 free amino acids tested, only cysteine, tryptophan, serine, arginine, methionine and glycine quenched TMAMQ as shown in Table 3. A higher antioxidant activity (0.47) was obtained with cysteine (containing a free –SH group) followed by tryptophan (0.16), an aromatic containing amino acid. Many contradictory results are found in the literature when comparing the antioxidant activity of amino acids. For example, Trianitis and co-workers (Triantis, Yannakopoulou, Nikokavoura, Dimotikali, & Papadopoulos, 2007) using the luminal-sodium hypochlorite chemiluminescence observed antioxidant activity with 13 of the amino acids listed in Table 3 while another previous report (Perez-Jimenez & Saura-Calixto, 2006) using ORAC and ABTS recorded antioxidant activity for tyrosine, trypotophan and arginine. Interestingly, Meucci and Mele (1997) using ABTS and Triantis et al. (2007) using DPPH reported antioxidant activity only for a few amino acids. In another report,

Table 2
Amount of TMAMQ quenched by 1 μM of the polyphenolics tested.

Antioxidants	Position and number of free –OH substituents	Amount of TMAMQ (μM) reduced by 1 μmol antioxidant
Anthocyanidins

Vitamin E	13×10^{-1}
β-carotene	5×10^{-2}

Ahmad, Al-Hakim, Adel, and Shehata (1983) found that lysine, arginine, glutamic acid, methionine, and hydroxyproline had high antioxidant activity. From structural point of view lysine and glutamic acid may not be antioxidants and this was confirmed by TMAMQ. This may indicate the superiority of TMAMQ as a more reliable tool to measure antioxidant activity of serum amino acids and proteins. Nevertheless, despite this controversy, the antioxidant activities of cysteine, tryptophan, methionine just as observed with TMAMQ are well established (Hernandez-Ledesma, Davalos, Bartolome, & Amigo, 2005; Levine, Mosoni, Berlett, & Satdtman, 1996; Masella, Di Benedetto, Vari, Filesi, & Giovannini, 2005; Pastore, Federici, Bertini, & Piemonte, 2003).

The antioxidant activities of cysteine, methionine and glycine when discussed in connection with the observed antioxidant activity of glutathione and serum albumin justify its already known role as a major antioxidant source in humans. Further, the observed antioxidant activity of cysteine, glutathione and albumin strengthens the crucial role of sulphydryl groups as source of antioxidants in proteins or peptides. For example glutathione is a tripeptide composed of cysteine, glutamic acid and glycine which is viewed as the principal non-protein thiol involved in the antioxidant cellular defence (Masella et al., 2005; Pastore et al., 2003). Albumin which also showed antioxidant activity with TMAMQ is believed to contribute 70% of the free radical-trapping activity of serum (Bourdon & Blache, 2001) and its antioxidant activity is attributed to cysteine residues (Oettl & Stauber, 2007).

Another widely reported human endogenous antioxidant is uric acid which also quenched TMAMQ (Table 3). Uric acid is reported as a selective antioxidant responsible for quenching hydroxyl radicals and hypochlorous acid (Genestra, 2007; Kohen & Nyska, 2002).

3.4. Antioxidant activity of vitamins and other compounds

The antioxidant activity of vitamin E was almost similar to that of ascorbic acid (Table 3) as determined in a previous study (Nugroho Prasetyo et al., 2009). The antioxidant activity of β-carotene was weak compared to Vitamin C and E (Table 3). Similarly low antioxidant activity of β-carotene was also reported using DPPH radical (Jimenez-Escrig, Jimenez-Jimenez, Sanchez-Moreno, & Saura-Calixto, 2000; Lee, Ozcelik, & Min, 2006). This may be attributed to antioxidant mechanisms of carotenoids which have been known to quench singlet oxygen radicals primarily by physical mechanism in which the excess energy of the singlet oxygen is transferred to the carotenoid's electron rich structure. The excited carotenoid then enters into its ground state by losing the extra energy as heat (Sies & Wilhelm, 2004). This means that the electron/hydrogen transfer mechanism is not the major route justifying the low antioxidant values. Equally interestingly was oleuropein which gives extra-virgin olive oil its bitter, pungent taste, which was also able to quench 0.82 μM TMAMQ confirming earlier reports that it is a powerful antioxidant (Tripoli et al., 2005).

3.5. Total phenolic content and antioxidant activity of extracts of food samples

The antioxidant activity of common fruits and vegetables found in Austrian food markets (Graz) was investigated. The different antioxidants in the food samples were extracted sequentially using different solvents (methanol, acetone, acidified methanol and butanol). The antioxidant activity as well as the total phenols of each solvent extract was analysed separately as summarised in Table 4 and Fig. 2, respectively. The different solvents extracted different antioxidants as reflected by the different antioxidants activities obtained with the different fractions (Table 4). The antioxidant activity of the methanol extract of spinach was the highest (4.36 mg extract/mmol TMAMQ) followed by kiwi (13.95 mg extract/mmol TMAMQ) and lettuce (40 mg extract/mmol TMAMQ), respectively. The rank order of the antioxidant activity of the methanol extracts of spinach, kiwi and lettuce reflected the total phenols content of the respective fractions in that order (Fig. 2). This antioxidant activity rank order agrees well with the Oxygen Radical Absorbance Capacity (ORAC) method which ranked spinach > white onion > tomato > carrot (Ou et al., 2002). Other previous reports (Cao et al., 1996; Kaur & Kapoor, 2001; Prior & Cao, 2000) also consistently reported high antioxidant activity of the same food samples using the ORAC assay. In other similar studies, (Perez-Jimenez et al., 2008) also observed that efficient extraction of antioxidants required the use solvents with different polarities. The different solvents extracted different antioxidants as reflected by the different antioxidants activities obtained with the different fractions. The antioxidant capacities of kiwi have been previously attributed to high levels of vitamin C present in the fruit (Chun et al., 2005; Halvorsen et al., 2002; Wang, Cao, & Prior, 1996) and could explain the antioxidant activity of the methanol extract. Although methanol extracts exhibited the highest concentration of phenolics in the other samples (Fig. 2), in pumpkin seeds the total phenolics were highest in hydrolysed tannins fractions. Surprisingly the acetone fraction of the pumpkin seeds showed the highest antioxidant activity of 13.44 mg extract per 1 mmol TMAMQ (Table 4). The data also show that different solvents are required for the extraction of different antioxidants contained in various food samples (Table 4).

The hydrolysed tannins and condensed tannins fractions of garlic acid also showed a high antioxidant activity when compared to the antioxidant activity of other fractions (Table 4). The antioxidant activity of tomato fractions and kiwi were generally high for all the fractions (Table 4). High levels of carotenoids especially lycopene in tomato and tocopherols in all chlorophyll containing tissues for example lettuce and spinach have been shown to contribute significantly to their antioxidant activity (Piironen, Syvaeoja, Salminen, & Koivistoinen, 1986). The antioxidant activity of all extracts from ap-

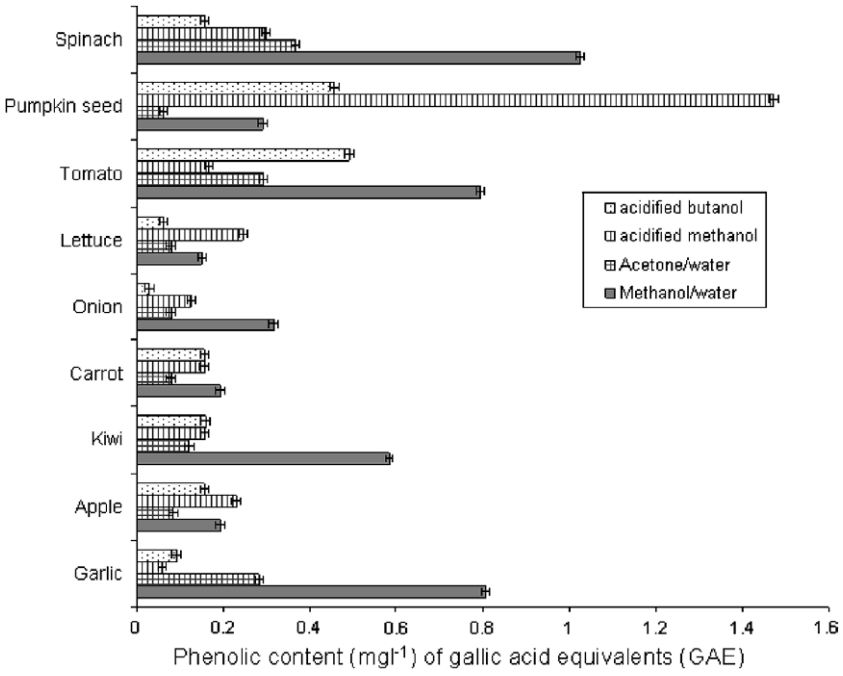

Fig. 2. Total phenol content in the different food extracts.

ples was generally low (Table 4) which probably can be justified by earlier reports that the major source of antioxidants in apples are found in the peel which is believed to contain about 7-times higher antioxidants than the pulp (Sikora et al., 2008).

3.6. Antioxidant activity of beverages and oils

The water extracts obtained from green, fermented teas and coffee were very active in quenching TMAMQ (Table 4) as compared to food samples in Table 4. The antioxidant activity of teas is mainly attributed to catechins namely; epigallocatechin gallate, epigallocatechin, gallic acid, epicatechin and catechin (Balasundram et al., 2006; Sikora et al., 2008). The antioxidant activity of green tea (0.59 g/mmol) was twice as effective as that of fermented tea (1.15 mg/mmol (Table 4). The decrease in antioxidant activity in fermented tea is attributed to changes occurring during the fermentation process where the flavanols in green tea leaves (mainly catechins and their gallic esters) undergo an oxidative polymerization by polyphenol oxidases, turning the leaves black (Daglia, Papetti, Gregotti, Berte, & Gazzani, 2000; Richelle, Tavazzi, & Offord, 2001; Wei, Zhou, Cai, Yang, & Liu, 2006). The antioxidant activity of coffee was lower as compared to that of green tea (Table 4). Coffee processing like in teas leads to the modification and loss of some polyphenolic antioxidants during roasting (Daglia et al., 2000; Tubaro, Micossi, & Ursini, 1996). Extra virgin olive oil quenched TMAMQ and its activity of 20.32 ml may partly be attributed to the presence oleuropein already shown above to quench TMAMQ as well as other phenolics described by earlier researchers as a powerful antioxidants both *in vivo* and *in vitro* (Tripoli et al., 2005). Maize oil also showed antioxidant activity (Table 4). Different oils have different antioxidants-contributing compounds as described by Pennington (2002).

Although generally the rank order of antioxidant activity of most of the known pure antioxidants and food samples investigated in

this work agree with previous studies using different approaches (ORAC, DPPH, ABTS), the actual values obtained vary. There may be several underlying factors among which are effects of solvents. Solvents have been shown to influence the reaction of antioxidants (Dangles, Dufoura, & Fargeixa, 2000) as well as the reaction mechanism favouring hydrogen atom transfer in apolar solvents and electron transfer mechanisms in polar solvents (Perez-Jimenez & Saura-Calixto, 2006; Saito & Kawabata, 2004). There is therefore a need to investigate the effects of solvents as well as other reaction conditions which might influence accurate measurement of antioxidant activity of given samples using TMAMQ.

4. Conclusions

All known different classes of antioxidants molecules tested (dietary and endogenous) were able to quench TMAMQ. This observation demonstrates the great potential application of TMAMQ for antioxidant activity measurement in both food, cosmetic and health industries. The TMAMQ seem to be more reliable than both DPPH and ABTS method when considering antioxidant activity of amino acids and this may well extend to antioxidant activity of serum proteins. Adding to this interesting observation, the extensive information accrued in the development of laccase based biosensors for phenolics detection in wine, beer, tea and vegetable extracts (Franzoi, Dupont, Spinelli, & Vieira, 2009; Gamella, Campuzano, Reviejo, & Pingarron, 2008; Jarosz-Wilkolazka, Ruzgas, & Gorton, 2004, 2005; Merle et al., 2008; Portaccio et al., 2006; Roy, Abraham, Abhijith, Kumar, & Thakur, 2005; Shleev et al., 2006) makes the development of an automated method for antioxidant activity determination feasible. In this case the immobilized laccase on the biosensor can be designed in such a way that laccase oxidises immobilized syringaldazine to TMAMQ which is further reduced to syringaldazine upon addition of a sample containing antioxidants molecules. The resulting oxygen consumption can be easily monitored (Nugroho Prasetyo et al., 2009) and converted into electrochemical signals.

Rice starch
Molecular simulation

ABSTRACT

The objective of this study was to develop a new method to measure the degree of amylose retrogradation in rice starch using size-exclusion high performance liquid chromatography (SE-HPLC). This developed method is based on the change in molecule size related to the retention time of amylose. Results showed that SE-HPLC was able to provide accurate data to evaluate the amylose retrogradation by comparing with other well-established methods. The principle of the measurement was further studied in molecular level by molecular dynamic (MD) simulation. It indicated that amylose molecules were transformed from disordering configuration to ordering one due to the increase in Van der Waals (Vdw) and hydrogen forces, and decrease in bonded interaction during the short-term storage.

1. Introduction

Amylopectin and amylose, as major rice starch components, have different roles in starch retrogradation. Much evidence suggests that the changes in amylopectin properties are responsible for all long-term rheological and structural deteriorations (Miles, Morris, Orford, & Ring, 1985). Amylose, however, is related to the short-term change completing in a few hours (Khanna & Tester, 2006; Ring et al., 1987). Amylose crystallite is especially considered as a nucleus for amylopectin recrystallization, resulting in acceleration of the whole retrogradation process (Gudmundsson & Eliasson, 1990). It is therefore of importance to determine amylose retrogradation during the short-term storage of rice starch.

It is known that many methods have been applied in the measurement of starch retrogradation (Karim, Norziah, & Seow, 2000). Bao, Shen, and Jin (2007) evaluated the short-term retrogradation of rice starch by using near-infrared spectroscopy; whereas the direct determination was not reported in their work. X-ray diffraction studies clearly showed that the development of crystallinity occurred in an aging starch gel (Miles, Morris, & Ring, 1985; Miles et al., 1985). Nevertheless, the sensitivity of this method was too low to detect the minor extent of recrystallization during a rapid storage (Smits, Ruhnau, Vliegenthart, & van Soest, 1998). Differential scanning calorimetry (DSC) was apparently used for measuring retrogradation of starch and proved to be a valuable tool to quantify the crystallinity of amylopectin rather than amylose recrystallite since this recrystallite was transformed at much higher temperature (120–160 °C), at which the pans would be leaked before the transition occurred (Eerlingen, Jacobs, & Delcour, 1994; Russell, 1987). Enzymatic method (EN), based on measuring the resistance of starch to enzymatic hydrolysis, was performed to determine retrogradation degree; but this retrogradation is related to the amylose recrystallite as well as the retrograded amylopectin (Eerlingen, Crombez, & Delcour, 1993; Tsuge, Hishida, Iwasaki, Watanabe, & Goshima, 1990). Size-exclusion high performance liquid chromatography (SE-HPLC) has been used in the estimation of molecular weight (M_w) of starch components, according to the different retention time (T_R) for its components (Dias, Fernandes, Mota, Teixeira, & Yelshin, 2008). However, to the best of our knowledge, no other literatures related to this topic were found to exam amylose retrogradation by analysing the change in T_R.

The research presented here had two objectives. The first objective was to evaluate the possibility of measuring amylose retrogradation in rice starch using SE-HPLC method. The second objective was to clarify the principle of this method in molecular level by molecular dynamic (MD) simulation.

2. Materials and methods

2.1. Materials

Rice starch (amylose content 29.7%, proteins content $\leqslant$ 0.2%, lipids content $\leqslant$ 0.1%) was isolated and purified from various milled fresh grains (Shandong Province, China) according to previously described protocols (Takeda, Hizukuri, & Juliano, 1986). α-Amylase from *Bacillus subtilis* was kindly provided from Genencor Biotechnology Inc. (Wuxi, China). All other chemicals and reagents were of analytical grade unless otherwise stated.

2.2. Preparation of the different aging samples

Rice starch (1.0 g) was dispersed in water (2 mL) and shook by a blender. The blend was heated at 100 °C for 20 min in a vacuum oven before the mixture was stored at 4 °C for the required time (0, 1, 3, 5, 7, 14, and 24 h) to accelerate the aging process. The resulting gelatinized and retrograded samples were dried at 40 °C in a vacuum oven until the water was evaporated to get dry powders.

2.3. SE-HPLC

A serial of dried powders (0.1 g) was dispersed in NaOH (0.5 mol/L, 2 mL) and mildly shook. The volume of this suspension was later diluted to 100 mL before incubation at 45 °C for 2 h. The resultant solution (about 2 mL) was centrifuged at 10,000*g* for 15 min and filtered with a 0.2 μm filter. From each supernatant, a volume of 10 μL (w/w, 0.1%) was injected for HPLC analysis. The HPLC system comprised a Waters 2410 pump equipped with auto-sampler and differential refractive index detector (Waters, Model 410, Milford, MA). An ultrahydrogel linear column (7.8 mm × 300 mm, Waters Corporation) and detector were maintained at 37 °C. The mobile phase was sodium acetate-acetic acid buffer (0.05 mol/L, pH 5.0) containing sodium nitrate (w/w, 0.02%) at a flow rate of 0.9 mL/min. The final retention time (T_R) of samples was collected and analysed by the following described Eq. (1) to perform a calculation of retrogradation degree

$$R(t) = \frac{A \cdot (T_t - T_0)}{(T_\infty - T_0)} \cdot 100\% \quad (1)$$

where $R(t)$ represents the recrystalline fraction of amylose (%) developed at time t, T_t is retention time of the sample stored for t hours, T_0 is the retention time of the gelatinized sample, T_∞ is limiting retention time of 24 h storage sample, and A is the amylose area (%) occupied of the peaks.

2.4. Differential scanning calorimetry

Thermal analysis was performed by using a Pris 1 DSC (Pekin-Elmer Inc., USA) under ultrahigh-purity nitrogen atmosphere. The equipment was calibrated with indium and tin standards. The prepared sample of 3.0 mg and distilled water (6 μL) were together added into an aluminum pan. The sealed sample were equilibrated at 25 °C for 8 h and then heated from 25 to 100 °C at a constant rate of 8 °C/min to analyse the enthalpy change (ΔH) in phase transition. An aluminum pan containing 6 μL of distilled water was meantime used as a reference. The final retrogradation degree of samples was calculated as following Eq. (2) (Baik, Kim, Cheon, Ha, & Kim, 1997)

$$X(t) = \frac{\Delta H_t - \Delta H_0}{\Delta H_\infty - \Delta H_0} \quad (2)$$

where $X(t)$ represents the crystalline fraction (%) developed at time t, ΔH_0 is enthalpy change (J/g) at time zero (the gelatinized sample), ΔH_t is enthalpy change at time t, and ΔH_∞ is limiting enthalpy change (4 weeks for all samples).

2.5. Enzymatic measurement

The degree of starch retrogradation was measured with the method previously described by Tsuge et al. (1990) with minor modifcation. Basically, 20 mg of starch was dispersed by water (3 mL), acetate buffer (0.1 mol/L, 2 mL), and α-amylase solution (8 unit, 2 mL). This suspension was incubated at 37 °C for 20 min before terminated this enzymatic reaction by NaOH (4 mol/L, 5 mL). The pH of the resultant solution was adjusted to neutrality with HCl (4 mol/L). The total volume was made up to 100 mL with water. From each sample, 10 mL of the digested solution was collected and mixed with I_2-KI solution (w/w, 0.2:2%, 5 mL) in a volumetric flask. The resulting solution was again made up to 100 mL with water and kept at 25 °C for 20 min. The absorbance of each samples was measured at 625 nm in calculation of degree of retrogradation (DR, %)

$$DR\ (\%) = \frac{100 \cdot (b - c)}{(a - c)} \quad (3)$$

where a represents the absorbance of total starch fraction, b is the absorbance of starch fraction to be tested, and c is the absorbance of the complete digestion of starch.

2.6. Molecular dynamic (MD) simulation

Amylose fraction and waters' interactions were simulated in a required periodic box (56 × 38 × 38 Å) by using MD module of HYPERCHEM 8.0 software (Hypercube Inc., Waterloo, Canada). In brief, the proposed model of amylose fraction was comprised eighteen polymeric glucose units in a rather stiff left-handed helix and dissolved in the water (60%, w/w) (Fig. 1). By imposing a restraint on a gradient of 0.01 × 4.186 8 kJ/(mol Å), this model of the interaction was energetically optimised using the AMBER force field. The resulting configuration was directly performed at a step size of 0.001 ps under 100 °C (373 K) for 2 ps. This optimised model was further simulated for 2 ps at a lower temperature of 4 °C (277 K) to analyse the changes of the structures and energies during the process of temperature decreasing. Some important parameters including molecular volume, solvent-accessible surface (grid), bonded interaction, and non-bonded interaction were collected and analysed.

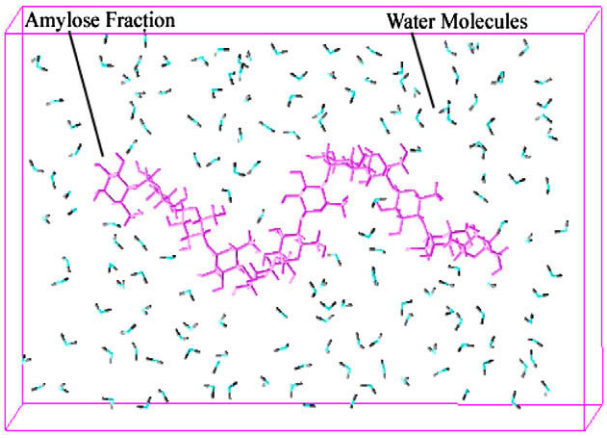

Fig. 1. The interaction model of amylose fraction and water (60%, w/w).

2.7. Statistic analysis

Statistical analysis was performed by using ORIGIN 7.5 (OriginLab. Inc., USA). Data were expressed as means of triplicate and analysed by a one-way analysis of variance (ANOVA). Treatment means were considered significantly different at $P \leqslant 0.05$.

3. Results and discussion

3.1. SE-HPLC analysis

Data obtained from SE-HPLC for rice starch samples with different storage time are summarised in Table 1. Rice starch displayed two elution profiles: the former one corresponding to the amylopectin (T_R around 13 min) and the second assigned to amylose fractions (T_R around 16 min). These profiles correspond to the results of previous studies (Suortti, Gorenstein, & Roger, 1998). Retention time (T_R) of amylopectin was not obviously affected by the storage time increasing from 0 h to 24 h. This can be attributed to the larger molecular size of amylopectin as retention time will not be affected by the molecular size that exceeds the separation range of ultrahydrogel (1×10^4–1×10^6 Da). Nevertheless, the aging treatment did significantly increase T_R of amylose but not affect area of amylose fraction compared to that of gelatinized starch ($P \leqslant 0.05$). This increase in T_R was corresponding to the structure change of amylose molecules during the short-term storage. It has been proposed that gelatinized amylose was transformed from disordering to an ordering one by hydrogen bond increasing (Miles et al., 1985; Tang & Copeland, 2007). The ordering amylose molecules, therefore, could be probable easily incorporated into the core of hydrogel, resulting in the increase of retention time. Upon this potential principle, we proposed the SE-HPLC method that can be used to evaluate the degree of amylose retrogradation in rice starch.

3.2. Comparison of different methods for determination of amylose retrogradation degree of rice starch

As shown in Table 2, there is significant difference in the degree of retrogradation of rice starch between SE-HPLC and DSC ($P \leqslant 0.05$). This significance is mainly ascribed to the different principles of both methods. DSC has been reported to be sensitive to the amylopectin fraction of the gels but not to the major proportion of amylose crystallite (Russell, 1987); whereas SE-HPLC is directly related to conformational changes of amylose molecules in a molecular level. The degree of retrogradation determined by SE-HPLC, however, showed a good accordance with that by enzymatic measurement. The similar accordance was shown between SE-HPLC and EN–DSC (the value determined by EN minus the value from DSC), which is suitable for the evaluation of the degree of amylose retrogradation. The relative coefficient ($R = 0.98$) between the two methods further showed a good linearity. These results strongly indicate that the SE-HPLC is able to be used to measure the amylose retrogradation in rice starch. Nevertheless, a major disadvantage of enzymatic measurement is associated with other food constituents (Tsuge et al., 1990). This disadvantage is not for the SE-HPLC determination in this work since we have removed the protein contained in starch and dispersed rice starch by NaOH solution. The dispersion presented could disrupt amylose–lipid complex formation and exclude the potential effect of this complex on the determination before the injection of samples.

3.3. Volume and surface values analysis

An optimised model of the amylose fraction/waters' interaction was achieved in the MD runs and a stable configuration in the equilibrium state was yielded at different temperature (100 or 4 °C). As can be seen in Table 3, the volume of amylose fraction as well as the solvent-accessible surface obviously decreases during the aging process of decreasing the simulation temperature ($P \leqslant 0.05$). This decrease in molecule size was related to the ordering of amylose fraction, which was often achieved at a lower energy (Ogura & Yamamoto, 1995). This ordering conformation indicates that the more retention time taken for the retrograded rice amylose is required to get through hydrogel column in SE-HPLC system. In addition, some main forces that may cause the change of molecular size were analysed by the final single point energies. Van der Waals (Vdw) and hydrogen bond energies ("-" in Table 3 means the force orientation) increased significantly ($P \leqslant 0.05$), but not for electro-

Table 1
Main parameters of SE-HPLC for rice starch samples in the treatment of different storage time.

Storage time (h)	Peak 1		Peak 2	
	Area (%)	Retention time (min)	Area (%)	Retention time (min)

static energy during the aging process. It suggests that the ordering structure formation at lower temperature was mainly ascribed to the change of Vdw attraction and hydrogen bond force. This finding was partially in agreement with the results of that Vdw attraction was the dominant driving force in the formation of ordering polymer (Xie & Soh, 2005). In general, the more negative the force energy was, the more thermodynamically favourable was the formation of the ordering structure (Yousef, Zughul, & Badwan, 2007). Especially, the change in bonded interaction was exothermal judged from the negative enthalpy change (−1.99 ± 0.14 kJ mol^{-1}), although the change was found less significant in comparison to the non-bonded interaction energy including Vdw attraction, hydrogen bond, and electrostatic force. This result indicates that the bonded interaction also accelerates the deformation of amylose molecules during the aging process.

4. Conclusions

This work clarified that the degree of amylose retrogradation is abele to be measured by a SE-HPLC method. Compared to other well-known methods, SE-HPLC method was proved to be an effective measurement of amylose retrogradation during the short-term storage of rice starch. The principle of this method could be studied in molecular level by MD simulation. It indicates that amylose recrystallization was induced by Vdw attraction, hydrogen bond force, and bonded interaction, resulting in the transformation of amylose molecule to the final ordering configuration. This study as well suggested the theoretical calculation provided a good reference for practical guidance.

Analytical Methods

Flow injection analysis of BHA by NiHCF modified electrode

Amperometric determination
Flow injection analysis

ABSTRACT

Flow injection method is described for the determination of the antioxidant *tert*-butylhydroxy anisole (BHA) based on its catalytic oxidation at a nickel hexacyanoferrate (NiHCF) surface modified graphite wax composite electrode fabricated using a new approach. The electrochemical characteristics of the modified electrode were studied using cyclic voltammetry. The voltammetric response of BHA at the modified electrode showed current densities remarkably higher than the bare graphite electrode and occurred at a reduced over voltage of 200 mV. Linear calibration graphs were obtained in the range of 1.2×10^{-6}–1.07×10^{-3} M. A detection limit of 6×10^{-7} M was obtained with a correlation coefficient of 0.9983 based on S/N = 3. Reliable results were obtained by applying the proposed flow injection method to determine BHA spiked in dehydrated potato flakes. Results suggest that the developed method can be effectively employed for the determination of BHA from food samples.

1. Introduction

Antioxidants have extensive use in the food industry, being added to a wide variety of foods in order to improve their stability and especially to prevent rancidity in products containing lipids or fats. They also find their use in food packaging, animal feed, cosmetics, pharmaceutical preparation, in rubber and petroleum products. Lipid oxidation can be retarded by oxygen removal or by using antioxidants. The latter are mostly phenolic compounds, such as *tert*-butylhydroxyanisole (BHA), propyl gallate (PG) and BHT (Hudson, 1990) that provide the best results in combination with a chelating agent. Recently, people have found that these artificial antioxidants may cause loss of nourishment and even produce toxic substances to harm human health. The concentration of these additives present in a particular food is limited by legislation in many countries (Furia, 1980). The most widespread trend is to reduce the use of these compounds. As the potential harmful effects of these compounds on health have been extensively discussed (Grice, 1988; Witschi, 1986). It has become important to determine their contents in those materials that are used by people. It is reported that it is more effective to use a mixture of two or more antioxidants rather than a single compound in practical use (Robards & Dilli, 1987).

Several methods, usually involving separation steps, have been proposed for the determination of phenolic antioxidants. In the past few years, few electroanalytical methods have been described. Generally, chromatographic methods are often used for the analysis of these compounds (Delgado-Zamarren, Gonzalez-Maza, Sanchez-Perez, & Carabias Martınez, 2007; Lee, Lin, Li, & Tsai, 2006). Determination of BHA by preconcentration on a carbon paste electrode has been reported (Wang & Freiha, 1983). HPLC methods with an electrochemical detector have been reported for the determination of BHA (Andrikopoulos, Brueschweiler, Feber, & Taeschleer, 1991). Even though they appear to be sensitive tool for the determination of phenolic antioxidants, these methods are time consuming. Chemically modified electrodes pave way for the reliable and time effective determination of these compounds with greater sensitivity.

The use of conventional electrodes for electrochemical detection has a number of limitations. The limitations are low sensitivity and reproducibility, slow electron transfer reaction, low stability over a wide range of solution composition, surface fouling and high overpotential. The use of mediators showing electrocatalytic activity to modify electrode surfaces constitutes an interesting approach to fabricate sensing surfaces for analytical purposes. In operation, the redox active sites shuttle electrons between the analyte and the electrodes with significant reduction in activation overpotential. A further advantage of the chemically modified electrodes is that they are less prone to surface fouling and oxide formation compared to inert substrate electrodes. A wide variety of compounds have been used as electron transfer mediators for modification of electrode surfaces with various procedures. Metal hexacyanoferrates show interesting redox chemistry that is accompanied by changes in their electrochromic behaviour and have been potentially applied in solid-state batteries, electrode materials, electroanalytical, ion exchange and electrocatalytic purposes (Chen, 1996a, 1996b; Honda & Hayashi, 1987; Kubota & Tamamushi, 1995; Lin & Bocarsly, 1991).

doi:10.1016/j.foodchem.2009.04.104

The modification of electrode surfaces with metal hexacyanoferrate is possible in different ways such as electrodeposition, adsorption, entrapping into a polymer matrice, electroless deposition, mechanically attaching the insoluble metal-hexacyanoferrate or by the reaction between metal hexacyanoferrate with self-assembled monolayer of an organosulfur compound on a gold electrode (Cai, Ju, & Chen, 1995; Gao, Wang, Li, & Zhao, 1991; Golabi & Noor Mohammadi, 1998; Mortimer, 1997; Pournaghi-Azar & Razmi-Nerbin, 1998; Reddy, Dostal, & Scholz, 1996; Xu, Wang, & Chen, 2000). The electrochemical deposition process that leads to the formation of the metal hexacyanoferrate (MHCF) on the electrode surface needs to be carefully controlled and hence it is pertinent to develop a simple and reliable method to fabricate stable MHCFs in short time. Most of the research activities use Au (Cox, Jaworski, & Kulesza, 1991), Pt, or Glassy Carbon (Lin & Bocarsly, 1991) as matrices for the preparation of modified electrodes in electroanalytical studies. These matrices may be replaced by a low cost and better anchoring functionalized surfaces because in this case the attachment of some transition metals, on these surfaces may be performed using a simple chemical method.

Very few reports are available for the determination of BHA using modified electrodes. A nickel pthalocyanin modified carbon paste electrode and a polymer coated glassy carbon electrode for the amperometric determination of BHA were reported (Ruiz, Blazquez, & Pingarron, 1995; Ruiz, Calvo, & Pingarron, 1994;). The simultaneous determination of BHA and TBHQ (tert-butylhydroquinone) at a polypyrrole electrode modified with a nickel pthalocyanin complex is also reported (De La Fuente, Acuna, Vazquez, Tascon, & Batenero, 1999). Our previous works include the use of Silver Hexacyanoferrate, Manganese Hexacyanoferrate modified graphite electrode used for the amperometric determination of BHA (Jayasri & Sriman Narayanan, 2006, 2007). Another new technique was adopted for the fabrication of cobalt hexacyanoferrate electrode using an amine adsorbed graphite powder as the substrate, which was used for the amperometric determination of BHA (Richard Prabakar & Sriman Narayanan, 2006). A similar modification procedure is adopted in the present work for the fabrication of a Nickel Hexacyanoferrate surface modified graphite wax composite electrode (GWCE). The modified electrode was found to have excellent mediation properties and was able to catalyze BHA oxidation effectively.

The present paper describes a method involving the coordination of nickel on a amine adsorbed graphite surface as an electrode matrix and the chemical derivatization of nickel anchored on the electrode to nickel hexacyanoferrate (NiHCF) film. The modification was achieved by adsorbing p-phenylenediamine onto graphite, which was used for making a graphite wax composite electrode. The electrode served as the base over which Ni^{2+} ions were coordinated to the adsorbed amine. It was followed by derivatization of the metal to its stable hexacyanoferrate thin film on the electrode surface. The NiHCF film was effectively used for the amperometric determination of BHA as it was found to have excellent catalytic activity over the oxidation of BHA. Differential pulse voltammetry (DPV) and flow injection technique were effectively used for the determination of the analyte from commercially available potato chips samples spiked with BHA. An amperometric method for the determination of Hydrazine from industrial wastewater samples using the electrode has been reported by us (Richard Prabakar & Sriman Narayanan, 2008).

2. Experimental

2.1. Chemicals and reagents

Graphite powder (1–2 μm) was purchased from Aldrich chemicals, Germany. All other reagents were of analytical grade. All aqueous solutions were prepared using doubly distilled water. Studies on effect of pH were carried out by adjusting the pH using 0.1 M HCl and 0.1 M NaOH solutions. *p*-Phenylenediamine solution (PPD) (10 mM) and $NiCl_2$ solution (0.01 M) were prepared by dissolving appropriate quantity in dry DMF and dry ethanol, respectively. All measurements were done after carefully degassing the solutions with pure nitrogen.

2.2. Flow injection procedure

A custom-built single channel flow cell was used in this work. A solution of 0.1 M $NaNO_3$ in phosphate buffer (pH 7.0) was used as the carrier (C) at a flow rate of 4.0 mL min^{-1}. The solution contained in the sample loop was injected and transported by the carrier stream after the baseline had reached a steady state value.

2.3. Treatment of commercial food sample

BHA spiked in commercially available potato chips (containing no BHA as the preservative) was analysed. The commercial sample was powdered in a mortar and pestle. 1 g of the powdered sample was weighed and spiked with a calculated amount of BHA. About 1 g of the spiked sample was placed in a centrifuge tube. To this 5 mL of 10% methanol solution was added and mechanically shaken for 20 min. The supernatant was collected after centrifuging. This extraction was repeated three times with 5 mL aliquots of 10% methanol solution and the supernatants were added together and concentrated to one third of its volume. The resulting extract was then diluted to the required concentration using the carrier solution (C). The same extract solution was used for differential pulse voltammetric determination and flow injection technique. Similar procedure was extended for other potato chips samples.

2.4. Apparatus

Electrochemical measurements were done using an Electrochemical workstation [CH Instruments (660B)] interfaced to an IBM personal computer with standard three-electrode configuration. The surface modified NiHCF graphite wax composite electrode was used as the working electrode. A platinum wire served as the counter with standard calomel electrode as the reference. Solutions were deoxygenated by bubbling high-purity nitrogen for 5 min prior to electrochemical experiments and all experiments were carried out at 25 °C.

FIA was done using a high pressure Michlins peristaltic pump PP10 (India) and a Rheodyne (Cotati, CA) model 7725 injection valve equipped with a 20 μL loop, coupled to a custom built radial flow cell with a platinum wire counter electrode and a Ag/AgCl ($E_{Ag/AgCl}$ = 0.1939 V vs. SHE) reference electrode connected to Electrochemical workstation CH Instruments (660B) controlled by an IBM personal computer for data acquisition. The reference electrode was filled with 3 M KCl solution. Working electrode was a 3 mm diameter NiHCF graphite paraffin wax composite electrode. The measurements made were converted to the standard calomel electrode values.

2.5. Electrode preparation

The fabrication of the surface modified NiHCF electrode involves four main steps as reported in our previous work (Richard Prabakar & Sriman Narayanan, 2008). In short, a graphite wax composite electrode was prepared using the p-phenylenediamine adsorbed graphite powder. An optimised composition was followed for the preparation of the electrode. The electrode was polished and surface was dipped in $NiCl_2$/EtOH to coordinate the metal cation (Ni^{2+}) to the adsorbed amine. The irreversibly bound metal

cation was then derivatized to its stable insoluble hexacyanoferrate form by cycling in potassium ferrocyanide solution. A stable thin layer was formed on the electrode surface.

3. Results and discussion

3.1. Electrochemical response of the modified electrode

The ions have a considerable role in the electrochemical behaviour of the modified electrode. In order to maintain the electro neutrality of the modified film during the electrochemical process, ions usually enter or leave the immobilized film. So ions have a considerable effect on the electrochemical behaviour of the modified electrode may be indicative of some characteristics of the film, depending on the nature or size of the alkali metal cations in the solution. The effect of different electrolytes on the electrochemical behaviour of the film was investigated by changing the cation and anion in the electrolyte solution. From our previous investigation it was found that 0.1 M $NaNO_3$ produced well defined and resolved peaks. Hence 0.1 M $NaNO_3$ was chosen as the background electrolyte for further electrochemical studies (Richard Prabakar & Sriman Narayanan, 2008).

The cyclic voltammogram obtained for NiHCF film in 0.1 M $NaNO_3$ (pH 7.0) displayed a single and well-defined redox couple (with peak potentials: E_{pa} – 0.330 V, E_{pc} – 0.286 V) in this electrolyte solution. The ratio of I_{pa}/I_{pc} remains almost equal to unity, as expected for a surface-type behaviour. The peak potentials are almost unchanged, and the peak potential separation is at least 25 mV at scan rate of 25 mV s^{-1}. The formal potential for the redox peak appeared at a potential of 0.312 V, at a scan rate of 50 mV s^{-1}. Generally, in this potential range only hexacyanoferrate is electroactive and not the metal cation as the latter requires a less positive potential for electrochemical transformation. Hence the redox peak is attributed to the hexacyanoferrate (II/III) system. It is interesting to note that the value obtained is appreciably lower when compared to previous reports (Pournaghi-Azar & Razmi-Nerbin, 1998).

3.2. Electrocatalytic behaviour of the NiHCF modified electrode

Fig. 1 shows the cyclic voltammograms of the bare and NiHCF modified electrodes in the absence and presence of BHA. As seen in Fig. 1. BHA at the bare graphite electrode is electroactive in this electrolytic solution at a higher overpotential (curve d). The NiHCF modified wax composite electrode in the blank solution (pH 7.0, 0.1 M $NaNO_3$) exhibits a well-behaved redox reaction at 330 mV (curve a). Upon the addition of 1×10^{-4} M BHA, an enhancement in the anodic peak current was observed (curve b). The anodic peak current observed increases with increasing BHA concentration in the solution. The increase in current on the addition of BHA is mainly due to the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ system. The iron in the NiHCF system gets electrochemically oxidised from Fe^{2+} to Fe^{3+}. The oxidised iron centre catalytically oxidises BHA to Tertiary butyl quinone thereby getting converted to the ferro form. This process repeat in a cyclic fashion producing the large anodic current increase.

As seen in Fig. 2a the cyclic voltammogram of the NiHCF modified electrode at various scan rates in the presence of 2.5×10^{-5} M BHA reveal that the catalytic effect of the NiHCF film appeared even at high scan rates of up to 100mV s^{-1} due to a considerable catalytic reaction rate. It can also be noted from Fig. 2a that with increasing scan rate, the peak potential for the catalytic oxidation of BHA shifts to more positive potentials, suggesting a kinetic limitation in the reaction between the redox sites of the NiHCF film and BHA. However, the oxidation current for BHA increased linearly with the square root of the scan rate (inset b), suggesting that

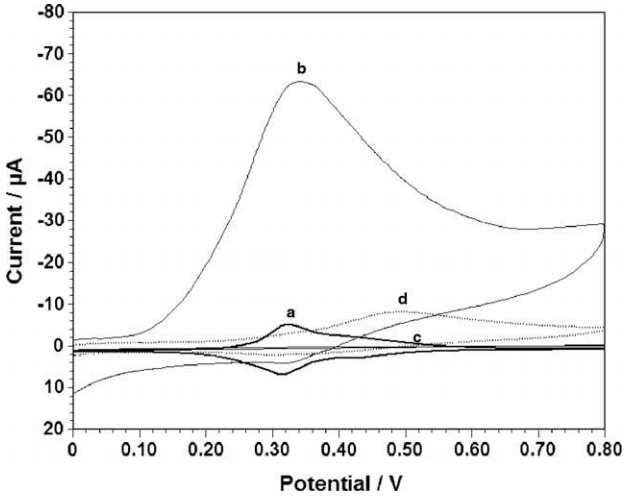

Fig. 1. Cyclic voltammogram in 0.1 M $NaNO_3$ for (a) NiHCF surface modified GWCE, (b) with 2.5×10^{-4} M of BHA at the modified electrode, (c) unmodified GWCE electrode and (d) with 2.5×10^{-4} M of BHA; scan rate 50 mV s^{-1}.

the reaction is mass transfer controlled. Also, a plot of the scan rate–normalised current ($I/v^{1/2}$) versus scan rate (inset c), exhibits linearity typical of an EC_{cat} process.

The influence of pH on the NiHCF modified electrode in the presence of analyte was studied in the pH range of 2–9. As observed in Fig. 2d, a maximum current response was observed at pH 7.0; the reason could be that at low pH, oxidation of BHA could be hindered by the production of H^+ ions. Since H^+ ions are one of the products formed during oxidation of BHA leading to a common ion effect. At pH greater than 7.0, a decrease in catalytic effect was observed. This decrease in alkaline range is also observed for other Prussian blue analogues (Pournaghi-Azar & Datangoo, 2002). The possible reason could be due to the hydrolysis of Fe^{2+} of $[Fe(CN)_6]^{4-}$ to $Fe(OH)_2$. Therefore pH 7.0 was selected as the optimum pH value for this work.

The cyclic voltammetric results lead to the conclusion that the oxidation of BHA at the NiHCF modified electrode could be due to diffusion of BHA to the electrode surface in the solution.

3.3. Hydrodynamic study

Hydrodynamic voltammetry was performed with the NiHCF modified electrode to study the response in dynamic conditions and also to optimise its operational potential for amperometric studies. The resulting steady state current was measured by increasing the potential of the working electrode in steps under stirred condition. The plot of current versus applied potential of the (a) bare electrode and (b) modified electrode in the presence of 1.5×10^{-5} M of BHA is shown in Fig. 3. The current starts to increase from 0.26 V and attains a maximum at 0.37 V. So an operational potential for amperometric studies could be chosen from a range starting from 0.37 V. A potential of 0.4 V was chosen as the operational potential for flow injection analysis studies.

3.4. Flow injection analysis

The NiHCF electrode showed excellent and strong mediation properties that enabled the determination of BHA at low potential. Fig. 4a shows the flow injection response of the NiHCF electrode to BHA at three different concentrations. As shown in the figure three successive additions of 2.98×10^{-5}, 3.96×10^{-5} and 4.95×10^{-5} M of BHA showed a well defined and near constant response. The modified electrode offered a sharp rise in current with every

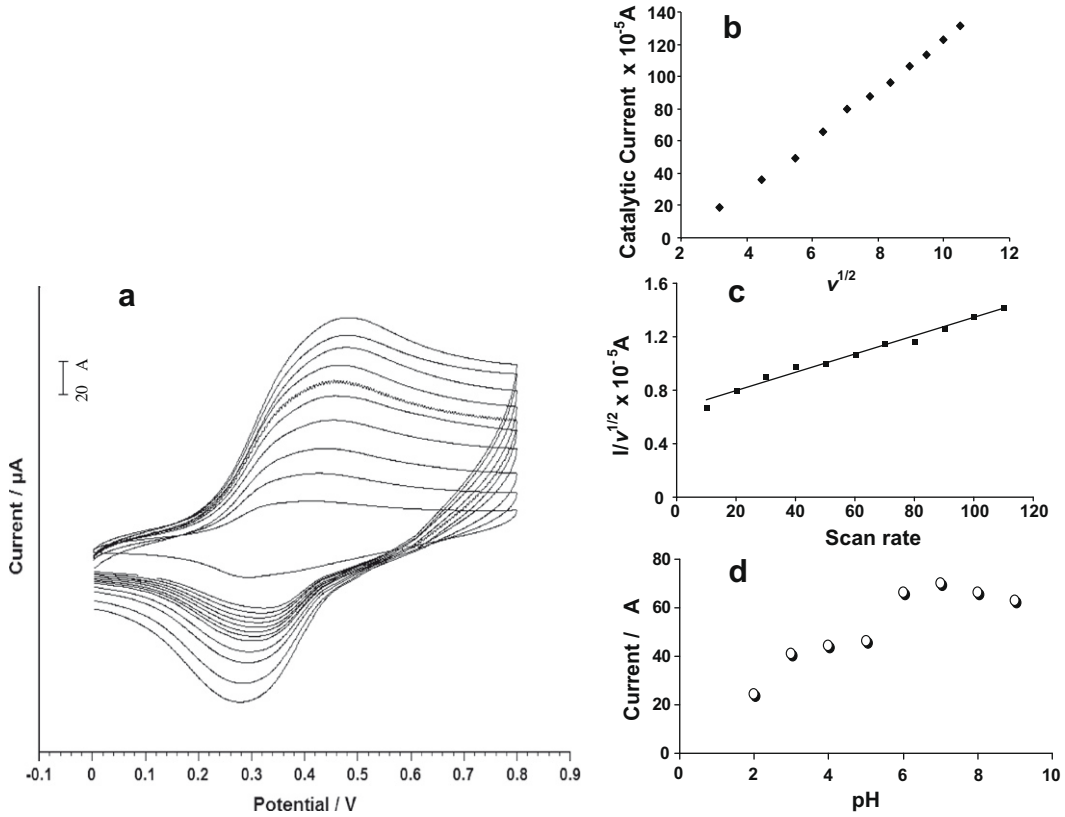

Fig. 2. (a) Dependence of the cyclic voltammetric response at a NiHCF surface modified graphite wax composite electrode on scan rate in 0.1 M $NaNO_3$ (pH 7.0, phosphate buffer solution) solution containing 2.5×10^{-5} M BHA. Scan rate: 10–150 mV s^{-1} with increments of 10 mV s^{-1}, respectively. (b) Variation of the catalytic current with the square root of scan rate. (c) Plot of normalised current vs. scan rate, (d) effect of pH on catalytic current of the NiHCF surface modified GWCE with 4.95×10^{-5} M of BHA; in 0.1 M $NaNO_3$.

addition of BHA. The signal appeared in a response time of less than 4 s. Fig. 4b shows the amperometric response of the modified electrode to equivalent concentrations of BHA recovered from potato chips spiked with BHA. Comparing the results, both appear synonymous with respect to sensitivity and results also confirmed that the detection limits were appreciably low. The NiHCF electrode also offered a highly invariable response over a long period of time. At a fixed potential of 0.4 V the catalytic current observed was also linearly dependent on the BHA concentration in the range 1.2×10^{-6}–1.07×10^{-3} M. Fig. 4c shows that the anodic peak current was linearly dependent on the BHA concentration, with a correlation coefficient better than 0.996 and the detection limit was 6×10^{-7} M.

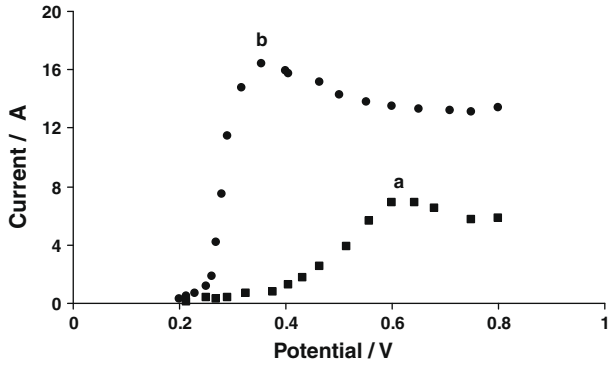

Fig. 3. Hydrodynamic voltammograms of: (a) unmodified GWCE and (b) NiHCF surface modified GWCE for 2×10^{-5} M BHA in 0.1 M $NaNO_3$; pH 7.0 (PBS); stirring rate 300 rpm.

The influence of flow rate of carrier solution was studied. On increasing the flow rate, the response of the sensor decreases and at flow rates higher than 4.0 mL min^{-1}, the response of the modified electrode to 2.48×10^{-5} M of BHA concentration is almost constant (figure not included). Therefore, a flow rate of 4.0 mL min^{-1} was used in all subsequent experiments.

3.5. Precision, linearity and detection limit

Under the selected conditions given above, the response of the NiHCF modified electrode to BHA concentration was linear over the range 1.2×10^{-6}–1.07×10^{-3} M, with a detection limit of 6×10^{-7} M (S/N = 3). The regression equation was I/mV = 1.6913 + 4.972 [BHA/10^{-6} M]. The correlation coefficient was 0.9965. These results further show that the NiHCF modified electrode, compared with the bare graphite electrode, offered a better sensitivity for BHA. It was also found that the NiHCF modified electrode showed good long-term stability in a flow stream. For evaluating the reproducibility of the NiHCF electrode a series of replicate additions of BHA of the same concentration was done and its chrono amperometric response was analysed. A relative standard deviation (RSD) of 2.4% was observed for 30 repetitive injections of 4×10^{-6} M BHA.

To determine the intra- and inter-day precision of this method, a series of seven repetitive injections of BHA containing 4×10^{-6} M were analysed on different days. For repeatability, the relative standard derivations (RSDs) of the peak current were 2.5%. Such good precision reflects the excellent antifouling surface of NiHCF surface modified GWCE. For reproducibility, the RSDs for the peak current (2.8%) show that the proposed method was both stable and reproducible.

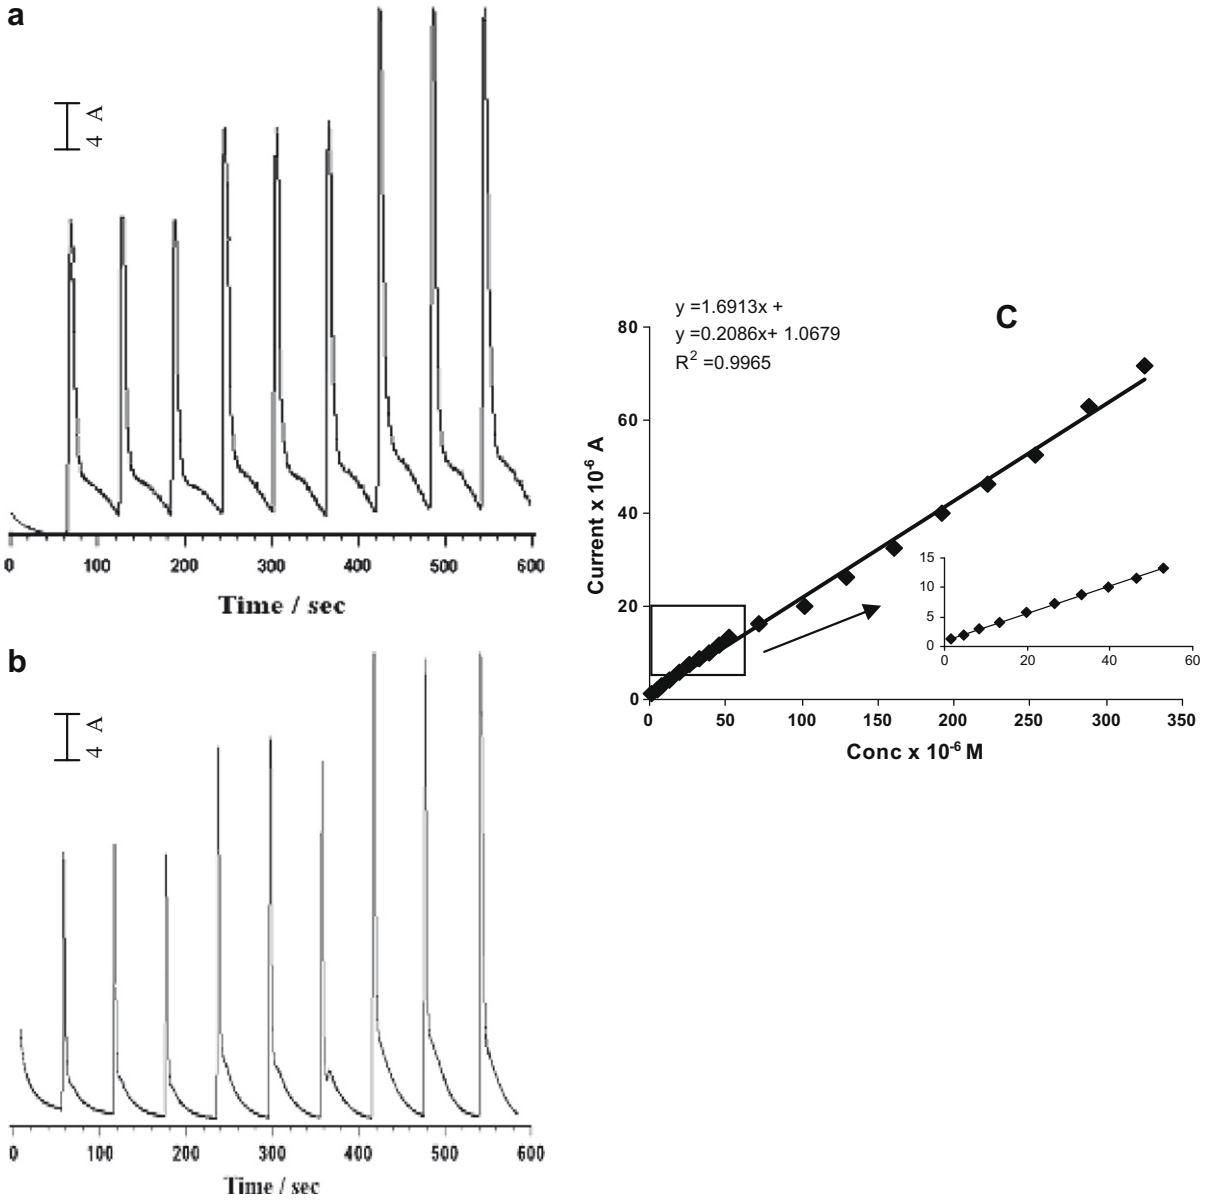

Fig. 4. (a) Flow injection response of the NiHCF modified GWCE at 0.4 V in 0.1 M $NaNO_3$ (pH, 7.0 phosphate buffer) for three replicate additions of 2.98×10^{-5} M, 3.96×10^{-5} M and 4.95×10^{-5} M of BHA from standard sample. (b) Flow injection response of the NiHCF modified GWCE at 0.4 V in 0.1 M $NaNO_3$ (pH, 7.0 phosphate buffer) for three replicate additions of 2.98×10^{-5} M, 3.96×10^{-5} M and 4.95×10^{-5} M of BHA recovered from spiked potato chips sample flow rate 4.0 mL min^{-1}. (c) Calibration plot for variation of catalytic current vs. BHA concentration.

3.6. Interferences

Different substances commonly present in commercial antioxidant mixtures (Citric acid, Propyl gallate (PG), BHT, ascorbic acid and propylene glycol) were tested during the chrono amperometric measurements at the modified electrode (at 0.4 V) in order to check their interference with the BHA signals. A concentration of 200:1 (interferent:BHA) was the maximum ratio tested. Under the experimental conditions described for the determination of BHA at a concentration of 5 μM, citric acid, BHT and propylene glycol showed no significant effect on response even at a interferents to analyte ratio of 1:200, 1:100 and 1:160, respectively.

It was found that ascorbic acid and propyl gallate interfered with BHA determination even with interferents to analyte ratio 0.7:1 and 1:1, respectively. However, in practise, ascorbic acid will be easily cleaned up by the extraction procedure described in the experimental section, because it is water-soluble (hence, its general use in beverages and solid food products). However the interference from propyl gallate could not be eliminated. Further research on improving the selectivity of the modified electrode is in progress.

3.7. Model sample analysis

Model sample analysis was done to evaluate the applicability of the NiHCF modified electrodes utility .The studies were carried out by spiking a known amount of BHA in commercially available potato chips. BHA was extracted as discussed in Section 2.3. Differential pulse voltammetry (DPV) was employed for the determination. Fig. 5 shows the differential pulse voltammetric response of the modified electrode response to increasing additions of BHA. Table. 1 shows the results obtained and the values obtained are an average of five replicate measurements. The

samples analysed were potato chips obtained from local market containing no added BHA.

4. Conclusion

The results above demonstrated that the NiHCF film was firmly immobilized to the electrode surface and the new approach for fabrication of NiHCF electrode onto an amine adsorbed graphite composite electrode appeared to be stable. The NiHCF electrode effectively catalyzes the oxidation of BHA via a surface layer mediated transfer. The NiHCF modified electrode is stable for long periods that enable it as an effective and rapid sensor for the determination of BHA. Low detection limit and high catalytic effect with lack of electrode surface fouling by the oxidised products of BHA. Hydrodynamic and flow injection analysis show that the NiHCF modified electrode as a definite candidate for the determination of BHA in flow systems and also as a promising tool that can be employed for the routine analysis of BHA from food samples.

ABSTRACT

A headspace solid-phase microextraction gas chromatography mass spectrometric procedure (HS-SPME-GC–MS) was developed and applied in order to determine 22 volatile compounds (including alcohols, esters, aldehydes and terpenes) in different *orujo* spirit samples from the Geographic Denomination "*Orujo de Galicia/Augardente de Galicia*". The *orujo* samples considered in this study were elaborated from *Albariño* variety grapes grown in the *Rías Baixas* restricted geographical area, and *Albariño* variety grapes grown in other geographical areas of Galicia (NW Spain) using two of the traditional distillation techniques: alembic and steam distillation. HS-SPME adequate results were obtained using a 65 μm carbowax-divinylbencene fibre during a headspace extraction at 40 °C with constant magnetic stirring for 15 min, and after a 5 min period of pre-equilibrium time. Desorption was performed directly in the gas chromatograph injector port for 5 min at 250 °C using the splitless mode. The applied method was demonstrated to be sensible, accurate, precise, and linear over more than one order of magnitude. Multivariate chemometric techniques (such as cluster analysis, principal component analysis and linear discriminant analysis) were used to characterise the *orujo* samples according to the geographical origin of the grapes and the distillation system employed in their elaboration on the basis of the chemical information provided for their volatile composition data.

1. Introduction

The alcoholic beverage *orujo* is produced in Galicia (NW Spain) by distillation of fermented grape pomace. Galicia is the only region in Spain which could obtain a geographic denomination for *orujo* alcoholic distillates, in the same category as French *marcs*, Italian *grappas*, Portuguese *bagaceiras* and Greek *tsipouros* (European Regulation, EEC, 1989). This beverage has come to be a product of an important economic interest for producers and not merely as a complementary activity to wine elaboration.

The resulting *orujo* distillates undergo strict quality controls established by the Directive Council of the Geographic Denomination "*Orujo de Galicia/Augardente de Galicia*" (DOG, 1993). This Council defined the origin of the raw material, the authorised grape varieties, the geographical production areas, and several other characteristics which are necessary in order to be classified as a quality product under the brand "*Orujo de Galicia*". Among these, the concentration limits of different volatile compounds in the distilled spirit (ethanol, methanol, the total content of higher alcohols, ethyl acetate, and acetaldehyde) must be determined to ensure the product meets these standards.

More than 300 different compounds are present in *orujo* distillates, mainly alcohols, esters, carboxylic acids, aldehydes and acetals. These compounds produce key notes which characterise the flavour and aroma of these beverages. There are many factors in the production of distillates which influence the sensorial characteristics appreciated in the final commercial products: the raw material, the different distillation systems and the distillate maturation in wood (when this takes place) (Silva, Macedo, & Malcata, 2000). In the case of an unaged distillate, this set of compounds is composed of the volatile substances present in the grapes and of the ones formed either during fermentation or generated during distillation (Silva & Malcata, 1999; Silva, Malcata, & De Revel, 1996). Some of these compounds are present in relatively large amounts and can be determined by direct gas chromatography. Other compounds are present at much lower concentrations. Therefore, the determination of these constituents often requires the use of sophisticated preconcentration procedures before gas chromatography.

Chemometric pattern recognition techniques have been widely applied in food chemistry (Brown, Bear, & Blank, 1992; Forina & Lanteri, 1984) to elucidate the chemical information provided for

doi:10.1016/j.foodchem.2009.04.105

the different multicomponent analytical techniques. Since the pioneering works done by Kwan, Kowalski, and Skogerboe (1979) and Kwan and Kowalski (1980) on the classification of wines of *Vitis vinifera* cv. Pinot Noir from France and the United States, a number of examples reported in previous studies demonstrate the useful combination of chemical analysis and chemometrics to solve different problems in a variety of food products. These include the characterisation of the geographic classification of olives (Pinheiro & Esteves da Silva, 2005), ciders (Alonso-Salces, Guyot, et al., 2004; Alonso-Salces, Herrero, et al., 2004), coffees (Rocha, Maeztu, Barros, Cid, & Coimbra, 2003; Zambonin, Balest, De Benedetto, & Palmisano, 2005) and wines (Jurado et al., 2008; Martí, Busto, & Guasch, 2004), etc.

In this work, a headspace solid-phase microextraction (HS-SPME) and gas chromatography-selective ion monitoring/mass spectrometry (GC-SIM/MS) procedure was applied in order to determine 22 volatile compounds (alcohols, esters, aldehydes and terpenes) in *orujo* spirit samples from the Geographic Denomination "*Orujo de Galicia/Augardente de Galicia*". Using the chemical information obtained and applying multivariate chemometrical tools–such as cluster analysis, principal component analysis and linear discriminant analysis–the *orujo* samples were characterised according to their geographical and botanical origins, and also to the distillation system employed in their elaboration.

2. Experimental

2.1. Orujo samples

Thirty commercial *orujo* spirit samples that were provided by the Directive Council of the Geographic Denomination "*Orujo de Galicia/Augardente de Galicia*" in order to guarantee their geographical origin and authenticity were used in this study. All samples were *orujo* monovarietal spirits (2004 vintage) obtained from the distillation of *Albariño* variety grapes. Nine of the samples were obtained from the alembic distillation of grapes grown in the *Rías Baixas* restricted geographical area (for identification purposes, these were coded as class 1). The remaining twenty one samples were obtained using steam distillation: 11 of them (coded as class 2) from grapes grown in the *Rías Baixas* restricted geographical area and the other 10 (coded as class 3) from grapes grown any place in Galicia other than the *Rías Baixas* area. All samples were collected in 400 mL glass bottles and stored at 4 °C before analysis.

2.2. Reagents

All volatile compound standards such as alcohols: 1-propanol, 2-methyl-1-propanol, 3-methyl-1-butanol, 2-phenylethanol, 3-octanol (used as an internal standard); esters: ethyl hexanoate, ethyl lactate, ethyl octanoate, ethyl decanoate, diethyl succinate, 2-phenyl ethyl acetate, ethyl dodecanoate, ethyl tetradecanoate; acids: acetic, hexanoic, octanoic, decanoic; aldehydes: benzaldehyde; and terpenes: linalool, α-terpineol, citronellol, nerol, geraniol, were supplied by Aldrich Flavor and Fragrances (Alcobendas, Madrid, Spain). The sodium chloride, used to control the ionic strength, was supplied by Panreac (Barcelona, Spain). Absolute ethanol (Panreac, Barcelona, Spain) and ultra-pure Milli-Q water (Millipore Co., Bedford, USA) were used as solvents. All solvents and reagents used were analytical grade.

Stock standard solutions of 10^3 or 10^4 mg $L^{-1}$of each component were prepared by dissolving the pure standards in 40% (v/v) ethanol. Then they were stored at 4 °C. Working standard solutions of each compound were prepared daily by mixing an aliquot of each individual solution and diluting them with ultrapure water to obtain a final ethanol content of 10% (v/v).

2.3. Apparatus and methods

2.3.1. Analytical determinations

Twenty two volatile compounds such as alcohols: 1-propanol, 2-methyl-1-propanol, 3-methyl-1-butanol, 2-phenylethanol, 3-octanol (used as an internal standard); esters: ethyl hexanoate, ethyl lactate, ethyl octanoate, ethyl decanoate, diethyl succinate, 2-phenyl ethyl acetate, ethyl dodecanoate, ethyl tetradecanoate; acids: acetic, hexanoic, octanoic, decanoic; aldehydes: benzaldehyde; and terpenes: linalool, α-terpineol, citronellol, nerol, geraniol were analysed using HS-SPME-GC–MS All determinations were carried out in triplicate and the average values were calculated.

2.3.2. HS-SPME

A manual fibre-holder and two types of fibres–100 μm polydimethylsiloxane (PDMS) and 65 μm carbowax-divinylbenzene (CW-DVB)–were obtained from Supelco (Bellefonte, PA, USA). In all cases, the fibres were conditioned before use by inserting them into the GC injector port for 1 h at 250 °C (PDMS) and for 30 min at 220 °C (CW-DVB). Between injections, the fibres were desorbed for 10 min at 250 °C in split mode in order to prevent any contamination. Due the high ethanol content of the *orujo* spirits (40% v/v) a dilution to 10% ethanol before solid-phase microextraction was necessary. The SPME process was carried out by introducing 6 mL of diluted *orujo* spirit into a 12 mL PTFE coated septum-closed vial; 1.5 g of sodium chloride and 20 mg L^{-1} of the internal standard (3-octanol) were added. SPME extractions were performed by inserting the fibre in the headspace for 15 min at 40 °C using continuous magnetic stirring of the liquid phase at 1100 rpm. Before the extraction, the sample with 25% (w/v) of NaCl was maintained at 40 °C for 5 min in order to establish equilibrium between headspace and sample. After each extraction, the fibre was inserted into the GC injector port using a 0.75 mm i.d. liner (in order to improve the GC resolution). Desorption time and temperature were 5 min and 250 °C, respectively. All experiments and sample measurements were carried out in triplicate and the average values were calculated.

2.3.3. GC–MS

Chromatographic analysis were performed using an Agilent 6890 gas chromatograph equipped with a mass spectrometric detector (MSD) model 5973 N (Agilent Technologies Deutschland Gmbh, Waldbronn, Germany). The capillary column used was a HP-Innowax (30 m × 0.25 mm i.d., film thickness 0.25 μm) from Agilent Technologies. The gas chromatographic operation conditions were as follows. The injector temperature was 250 °C; the carrier gas employed was Helium (purity 99.9995%) at a constant flow rate of 1 mL min^{-1}. The oven temperature program was 5 min at 40 °C, then 1.5 °C min^{-1} up to 80 °C, and finally 5 °C min^{-1} up to 200 °C. This final temperature was maintained for 0.5 min. The injection was made in splitless mode for 2 min at a temperature of 250 °C and using a SPME inlet guide and pre-drilled Thermogreen LB-2 septa from Supelco (Bellefonte, PA, USA).

The mass spectrometer was operated in electron impact mode with the following conditions. The source temperature was 230 °C; the quadrupole temperature selected was 150 °C and the relative electron multiplier voltage (EM) applied was 400 V with a resulting voltage of 1553 V. In order to improve the detection limits, the selected ion monitoring (SIM) mode was used. The data acquisition was carried out with the HP-Chemstation software version D.00.00.38 (Agilent Technologies). The compounds were identified using the NIST98 version 2.0 mass spectra library. Each compound was further confirmed by comparing its mass spectra,

linear retention index (LRI), and retention times with those obtained for the standards.

2.3.4. Data analysis and chemometrical procedures

A matrix ($X_{30\times22}$) with the chemical data was constructed. The rows of this matrix were the different *orujo* samples (objects) and the columns were the 22 variables (features) measured for each object. Therefore, each *orujo* sample could be represented in the 22-multidimensional space by a data vector (an assembly of 22 features). Data vectors belonging to the different categories were analysed using chemometrical procedures (Latorre, Peña, Garcia, & Herrero, 2000; Padin et al., 2001; Rodriguez et al., 2006). Cluster analysis (CA) and principal component analysis (PCA) were applied to obtain visualisation in a reduced dimension of the structure of the data. The linear discriminant analysis (LDA) was focused in order to develop a classification model to differentiate samples in function of classes 1, 2 or 3. The statistical and chemometrical analysis were performed by means of the following statistical software packages: Statgraphics (Statgraphics plus 5.1, 2000), Parvus (Forina, Lanteri, Armanino, Casolino, & Casale, 2007) and SPSS (SPSS for windows v. 15.0, 2006).

3. Results and discussion

3.1. HS-SPME extraction

Two fibre coatings, PDMS and CW-DVB, were used in order to determine which coating was more appropriate for the determination of flavor volatiles present in *orujo* spirits. Considering the peak areas, CW-DVB fibre provided the best results except for terpenes where the performance of both fibres was similar.

In order to optimise the SPME method, some parameters controlling the performance of the extraction were taken into account. The variables studied and the ranges considered were sample volume (6–10 mL), extraction temperature (30–50 °C), amount of NaCl to control the ionic strength (25–30% w/v), extraction time (5–25 min), pre-equilibrium time (0–10 min), desorption temperature (150–250 °C) and desorption time (1–5 min). The best conditions were as follows: 6 mL of the *orujo* sample diluted to 10% ethanol and 25% of NaCl were placed into a 12 mL PTFE coated septum-closed vial. SPME extractions were performed by inserting the fibre in the headspace for 15 min at 40 °C using continuous magnetic stirring of the liquid phase at 1100 rpm. Before the extraction, the sample with 25% (w/v) of NaCl was maintained at 40 °C for 5 min in order to establish equilibrium between headspace and sample. Desorption time and temperature were 5 min and 250 °C, respectively. The optimisation of the extraction procedure has been described in detail in previous work (Peña, Barciela, Herrero, & Garcia-Martín, 2008).

3.2. Performance of the method

The performance characteristic of the method such as linearity, precision, recovery and limit of detection and quantification, were tested. The results demonstrated that the proposed method is sensible (with detection limits between 0.0045 and 0.2399 mg L^{-1}), precise (with coefficients of variation in the range 0.99–8.18%) and linear over more than one order of magnitude. The developed method presented recoveries comprised between 76.0% and 112.4%.

3.3. Volatile profiles of orujo samples

The results of the HS-SPME-GC–MS determination for the 22 volatile compounds in *orujo* samples are summarised in Table 1. Mean, standard deviation, maximum and minimum values for each feature are presented. Alcohols constitute the group of compounds with the highest concentration in distilled beverages and they are responsible for their flavouring aromas. The level of these compounds depends on the grape variety, fermentation conditions and distillation technique. The predominant alcohol in *orujo* spirits was 3-methyl-1-butanol (isoamyl alcohol) with a mean value of 448.8 mg L^{-1}. This alcohol together with 2-methyl-1-butanol quantitatively accounts for the most of the higher alcohols and they may be considered predictors of sensory character in distilled products. Other alcohols like 2-methyl-1-propanol and 1-propanol are present in *orujo* spirits at high mean concentrations (170.5 and 146.7 mg L^{-1}, respectively). Another alcohol studied: 2-phenyl ethanol (mean value found in *orujo* samples 5.019 mg L^{-1}) is an aromatic alcohol that introduces a pleasant rose like aroma to

distillates. The distillation technique plays an important role in the content of this alcohol.

Fatty acid esters are probably the group of compounds that contribute the most to the distillates aroma and quality. Ethyl esters are produced during the fermentation. They gain access to the spirits and increase during ageing. Grape variety is an important factor in determining the concentration of ethyl esters in these beverages (Milicevic, Banovic, Kovacevic-Ganic, & Gracin, 2002). The results obtained for these compounds in the analysed samples showed values in the range from 3.283 mg L^{-1} for ethyl hexanoate to 35.71 mg L^{-1} for ethyl dodecanoate.

Acetic acid esters, like 2-phenyl ethyl acetate, isoamyl acetate and hexyl acetate, are responsible for the flowery and fruity aroma of distillates while ethyl acetate, ethyl lactate and diethyl succinate derive mainly from bacterial spoilage of the distillate marc. The concentration obtained for 2-phenyl ethyl acetate, ethyl lactate and diethyl succinate was 0.327, 103.0 and 6.862 mg L^{-1}, respectively. The low value of ethyl lactate means that the maintenance of the pomace was satisfactory and no undesirable lactic and acetic fermentations took place.

Long chain fatty acids (such as hexanoic, octanoic and decanoic acids) are a group of compounds that affect the flavor to a lesser extent than the ones previous described. The concentration obtained for these acids was 3.598 mg L^{-1}, 7.906 and 8.321 mg L^{-1} for hexanoic, octanoic and decanoic acids, respectively. Other volatile carboxylic acids, such as acetic, showed a mean concentration of 128.0 mg L^{-1}. Benzaldehyde was also analysed because the formation of this compound is associated with microbial development during the ensilage of grape pomace. The mean concentration obtained for the samples measured was 1.732 mg L^{-1}.

Terpenes are another very important chemical group which has an important effect on flavor and aroma. These compounds are present in the grapes and can be used for varietal differentiation of wines and other related products. Five terpenic alcohols were identified in *orujo* samples: linalool, α-terpineol, citronellol, nerol and geraniol. The mean concentrations were 1.622 mg L^{-1} and 0.075 mg L^{-1} for linalool and nerol, respectively. There was only one sample in which nerol was not detected; thus, it is obvious that the spirits produced from *Albariño* grape pomace are characterised for their intense aromas.

In spite of certain differences in the mean values, there are no significant differences in the volatile levels of the *orujo* samples according to the distillation technique employed or to the geographical origin of the grapes. The examination of the box-whisker plots constructed for each individual variable showed an overlap between ranges of concentration. When measured alone, none of the variables, were able to discriminate between different classes of *orujo*. Therefore, a multivariate approach must be evaluated.

3.4. Data reduction and visualisation

When a multivariate data set is analysed, the first approach is the search for natural groupings in the samples. For this goal two unsupervised chemometric procedures were applied: principal component analysis (PCA) and cluster analysis (CA).

3.4.1. Principal component analysis

Principal component analysis was used to provide a partial visualisation of data in a reduced-dimension plot. The principal components or eigenvectors are orthogonal and they are a linear combination of the original variables (Jolliffe, 2002). PCA was performed on the autoscaled data to avoid the effect of different size variables. The study of loadings for the variables in the first two principal components (Fig. 1) shows that fatty acids, ethyl lactate and diethyl succinate, were the dominant features in the first principal component which represented 29.10% of the total variability.

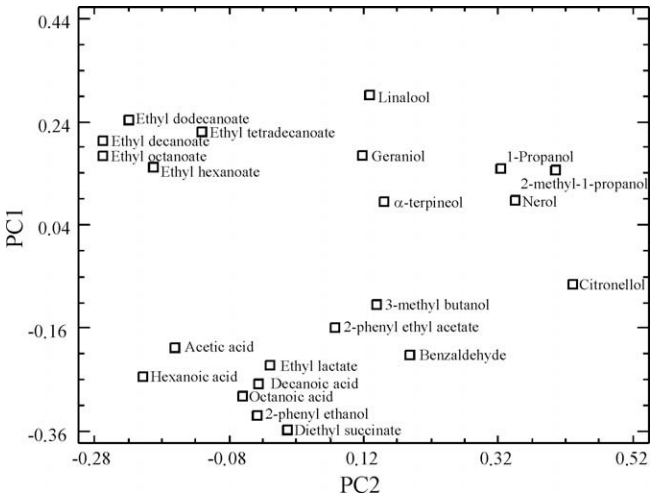

Fig. 1. Loadings of the variables in the first two principal components.

1-propanol, 2-methyl-1-propanol, citronellol and nerol (positive part of PC2) and fatty acid ethyl esters (negative part) dominate the second principal component which accounted for 17.41% of the total data variance. Chemically, the first principal component or eigenvector can be interpreted in relation to compounds that do not have a significant influence in the flavor of *orujo* samples (fatty acids); some of them are related to the bacterial spoilage of these beverages (ethyl lactate and diethyl succinate). Major contributions to the second principal component are from analytes related to the grape variety, fermentation conditions and distillation procedure such as alcohols, terpenes and fatty acids ethyl esters. When the score analysis of *orujo* samples on the space formed by the first three principal components (62.1% of total variability accounted) was carried out, a natural separation between the three classes of *orujo* samples considered was detected. As can be seen in Fig. 2, *orujo* samples of class 1 formed a separated group in the positive part of PC1. Samples of class 3 formed another group in the negative part of the first principal component. Samples from class 2 are located in a point between the two previous classes. Since the score plot of Fig. 2 provides a reduced vision in three dimensions of the sample 22-dimensional space, it can be concluded that the three classes of *orujo* are distributed in different areas in the high dimensional space considered.

3.4.2. Cluster analysis

Cluster analysis (CA) is an unsupervised chemometric technique that reveals the natural groupings existing between samples char-

Table 2
Classification of *orujo* samples using LDA in validation set.

Category	1	2	3	% Correct classification
1	9	0	0	100
2	0	10	1	90.9
3	0	1	9	90.0

acterised by the values of a set of measured variables. CA is commonly applied together with PCA to study the structure of a data set before applying other multivariate pattern recognition procedures with classification purposes. In the present work, CA was applied to the autoscaled data to avoid the variable size; the similarities between samples were calculated on the basis of the Euclidean distance, whereas Ward's method was used as a linkage procedure to establish the clusters (Massart & Kaufman, 1993). The results achieved are presented in a graphic mode as a dendrogram (see Fig. 3). At a distance level of 75, three clusters (coded a-c) can be identified. From the left, the first cluster (cluster a) is a group made of class 1 samples. The second cluster (b) is mainly formed by samples from class 2, even though four class 3 samples were also present. The last cluster (c) includes the other remaining samples of class 3 plus one sample coded as 2. This chemometric technique demonstrated (as well as PCA) that there exists a certain overlap between categories 2 and 3. The two unsupervised displaying procedures used, PCA and CA, produced consistent results for the study of latent structures in the *orujo* samples data set. It can be concluded that the volatile compounds data may provide enough information to develop classification systems to differentiate different kinds of *orujo* samples of class 1, 2, and 3.

3.5. Pattern recognition analysis: linear discriminate analysis

In this section, volatile data of the *orujo* samples were processed by a chemometrical pattern recognition procedure in order to develop a classification rule to relate the volatile compounds content of the analysed *orujo* samples with the geographical origin of the grapes and the distillation procedure employed in their elaboration. Linear discriminant analysis (LDA) was applied to search for optimal linear boundaries between categories in the 22-dimensional space. The discriminant functions are established to achieve the highest discrimination among the given categories, maximising the ratio between-class variance to within-class variance in any particular data set to guarantee the maximal class separability (Vandeginste et al., 1998). LDA was operated over the autoscaled data matrix $X_{30\times22}$ to characterise *orujo* samples in the established categories 1, 2 and 3. In order to validate the classification rule developed for this study, a test set was constructed on the basis of the leave-one-out algorithm (Miller & Miller, 1988).

In Fig. 4, a plot of the samples in the space defined by the two discriminant functions was shown. There is a clear trend for the samples to cluster among themselves. As can be seen in Table 2, all samples in the validation set for class 1 were correctly classified in the appropriate group. The successful classification for classes 2 and 3 were lower but acceptable (one sample misclassified in each class). The average percentage of correct classification was 93.33%. These results are concordant with those provide by visualisation techniques in which a certain overlap between class 2 and 3 was pointed out.

4. Conclusions

An HS-SPME-GC–MS method has been used to determine the concentration of 22 volatile compounds of *orujo* spirits from the Geographic Denomination "*Orujo de Galicia/Augardente de Galicia*". Samples were obtained from the alembic or steam distillation of grape pomace from *Albariño* variety grapes grown in the *Rías Baixas* restricted geographical area or in other zones of Galicia. In spite of certain differences in the mean values, there are no significant differences in the volatile levels of the *orujo* samples according to the distillation technique employed or to the geographical origin of the grapes. Therefore a multivariate approach has been evaluated. PCA and CA show that the three classes of *orujo* considered naturally appear separated; thus, the available volatile compounds data may provide enough information to develop classification systems to differentiate different kinds of *orujo* samples. A lineal model (LDA) was constructed and recognition abilities in the range 90–100% were obtained.

In conclusion, this study shows that the combination of chemical information obtained in a single analysis and chemometrical analysis was able to differentiate *orujo* spirits elaborated with different distillation procedures and with grapes produced in different geographical areas.

Acknowledgments

We express our gratitude to *orujo*-producers and to the *Consello Regulador das Denominacións Xeográficas dos Augardentes e Licores Tradicionais de Galicia* (Certification Council of CBO) for providing *orujo* samples with guaranteed origin.

Staphylococcal enterotoxin B
Colloidal gold

ABSTRACT

The lateral flow assay (LFA), a rapid, sensitive, and reproducible technique, was successfully applied to detect staphylococcal enterotoxin B (SEB). The assay was based on a double-antibody sandwich format on a porous nitrocellulose membrane. When SEB-containing samples were applied to the LFA-device, the toxin initially reacted with polyclonal antibody (Pab)-coated colloidal gold particles and then reacted with the fixed Pab on the membrane. These reactions resulted in a red line at the detection zone, with intensity proportional to the SEB concentration (under 100 ng/ml). With this method, 1 ng/ml of SEB can be detected in less than 5 min and was highly reproducible. Signal can be amplified to 10 pg/ml by silver enhancement. This assay also showed no cross-reaction with other SEs, such as SEA, SEC, SED and SEE. The assay was significantly faster than the ELISA or real-time PCR assay and should facilitate early and rapid SEB detection in clinical and food samples.

1. Introduction

Staphylococci are gram-positive bacteria with the appearance of immobile, grape-like clusters. Recently, *Staphylococci* are becoming increasingly resistant to antibiotics and cause a wide range of diseases. They can cause illness directly by infection, or indirectly through their products, such as the toxins that are responsible for food poisoning and toxic shock syndrome (TSS) (Balaban & Rasooly, 2000). The low molecular weight staphylococcal enterotoxins (SEs, 27–30 kDa) produced by different strains of *Staphylococcus aureus* are the main cause of gastroenteritis resulting from the ingestion of contaminated foods. In addition, hospital-acquired infection causes thousands of deaths every year (Altekruse, Cohen, & Swerdlow, 1997). Many *S. aureus* strains produce one or more serotypes of specific exotoxins, including SEs A to E (SEA to SEE), SE-like toxins (SEls); and TSS toxin-1 (Bohach, Dinges, Mitchell, Ohlendorf, & Schlievert, 1997; Bohach, Fast, Nelson, & Schlievert, 1990; Dinges, Orwin, & Schlievert, 2000; Marrack & Kappler, 1990; McCormick, Yarwood, & Schlievert, 2001). These toxins are responsible for specific acute clinical syndromes such as TSS (due to both TSS toxin-1 SEs and SEls), food poisoning (due to SEs), and staphylococcal scarlet fever (a mild form of TSS) (Holtfreter & Broker, 2005; Muller-Alouf, Carnoy, Simonet, & Alouf, 2001; Proft & Fraser, 2003). According to previous studies, little as 100 ng of SEB may make a person ill with symptoms of classic food poisoning (nausea, vomiting and/or diarrhoea) (Evenson, Hinds, Berstein, & Bergdoll, 1988), and the inhalation exposure of SEB could cause a clinically ill in only a few hours (Franz et al., 1997).

It is also well-known that several countries considered SEB as an attractive choice for a biological aerosol weapon to contaminate food or water supplies due to its inherent stability, high morbidity rate, high intoxication effect, and ease of dissemination (Poli, Rivera, & Neal, 2002; Ulrich, Sidell, Taylor, Wilhlmsen, & Franz, 1997). It is currently listed as a restricted (B-list) agent by the Center for Disease Control and Prevention (CDC) (Ferguson, 1997) and is considered by NATO to be a significant threat as a potential biological aerosol weapon. Therefore, the development of a highly sensitive and specific detection method to monitor the toxin in the nares, blood, serum, urine or tissues of individuals would be desirable. Many investigators have reported highly sensitive SEB immunoassay methods, such as enzymatic bionanotransduction and enzyme-linked immunosorbent assays (ELISA). The detection limit of SEB of the former was 10 ng/ml in 4 h assay time (Branen, Hass, Maki, & Branen, 2007), and the latter were 2.8 ng/ml (Chan et al., 2003) and 3.9 ng/ml (Sapsford, Francis, Sun, Kostov, & Rasooly, 2009) respectively. However, these assays are either time consuming (including overnight incubations and complex assay procedures), require special equipment (ELISA reader), or are labor-intensive (require training to perform the analysis).

The lateral flow assay (LFA), also called the immunochromatographic assay or the strip assay, has been under development for several years, such as for antibodies (Peng et al., 2007; Smits, Abdoel, Solera, Clavijo, & Diaz, 2003), allergens (Schubert-Ullrich et al., 2009; Tsay, Williams, Mitchell, & Chapman, 2002) and for antigens (Chiao, Shyu, Hu, Chiang, & Tang, 2004; Diederen & Peeters, 2006; Shyu, Shyu, Liu, & Tang, 2002). This technique is based on an

doi:10.1016/j.foodchem.2009.04.106

immunochromatographic procedure that utilises antigen–antibody properties and enables rapid detection of the analyte. It includes several benefits, such as a user-friendly format, rapid results, long-term stability over a wide range of weather conditions, and relatively low manufacturing costs. These characteristics render it ideally suited for on site testing by untrained personnel.

Recent studies have used monoclonal antibodies based on this assay to detect ricin (Shyu et al., 2002) and sulfonamides (Wang et al., 2007) and a polyclonal antibody (Pab) to detect botulinum neurotoxin (Chiao, Wey, Shyu, & Tang, 2008; Chiao et al., 2004). In this research, we used a Pab to develop a rapid and sensitive sandwich immunochromatographic assay that can detect SEB contamination in food or clinical samples.

2. Materials and methods

2.1. Materials

Purified SEB toxin (Sigma–Aldrich, St. Louis, MO, USA) was stored at −20 °C until use. The thawed toxin was diluted in phosphate-buffered saline (PBS) and stored at 4 °C. Other SE toxins (A–E) were purchased from Denka Seiken Co., Ltd. (reversed passive latex agglutination (RPLA) kit; Tokyo, Japan) and stored at 4 °C according to the manufacturer's recommendations.

Anti-SEB IgG was purified from anti-SEB sera with a thiophilic gel (T-gel), which is an IgG specific immunosorbent (Pierce, Rockford, IL, USA). The anti-SEB sera were obtained from SEB immunized rabbits (New Zealand), and the sera titers were determined by ELISA. High-flow nitrocellulose (NC) membranes (AE 98), glass fiber conjugated pad (AccuFlow™ G), sample application pad (#12-S) and reagent adsorption pad (470 Zuschnitte/Cuts) were all purchased from Schleicher & Schuell GmbH (Dassel, Germany). Goat anti-rabbit IgG and silver enhancer reagent were obtained from Sigma.

2.2. Preparation of colloidal gold probes

Colloidal gold probes, measuring 25 nm (Fig. 1), were prepared with sodium citrate by using a modified citrate reduction method (Grabar, Freeman, Hommer, & Natan, 1995). Briefly, an aqueous chloroauric acid solution (200 ml of 0.01% $HAuCl_4$, Sigma) was boiled with vigorous stirring, followed by the rapid addition of 2 ml of 1% sodium citrate to the solution. Boiling was continued for 10 min; the heat source was then removed and stirring was continued for an additional 15 min. After the solution reached room temperature (RT), the probes were filtered through a 0.8 μm Gelman membrane (Voigt Global Distribution Inc., Lawrence, Kansas, USA). The size of the colloidal gold particles was analysed by transmission electron microscopy (TEM) (H-600; Hitachi Instrument Co., Tokyo, Japan); the particles can be stored at 4 °C for several weeks in a dark glass bottle.

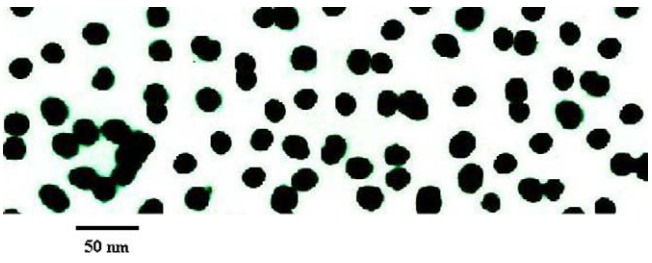

Fig. 1. TEM image of colloidal gold particles. Colloidal gold particle are examined by TEM imaging. The probe size is approximately 25 nm (100,000×), suggesting that the generated gold probes are suitable for conjugation of antibodies.

2.3. Conjugation of antibody to colloidal gold nanoparticles

The pH value of the colloidal gold solution (1%, w/v) was adjusted to 8.5 with NaOH. T-gel purified anti-SEB IgG (0.2 ml; 2 mg/ml; in 5 mM potassium carbonate buffer; pH 8.5) was added to 40 ml pH-adjusted colloid gold solution. The mixture was gently mixed for 30 min and then centrifuged for 30 min (4 °C, 1550*g*; 8178 swing-out rotor, Labofuge 400R; Heraeus Instruments). After centrifugation, the colloid gold pellets were suspended in 20 mM Tris/HCl, pH 8.2 containing 1% BSA and adjusted the optical density to 5.0 at O.D.520. The anti-SEB IgG-coated colloidal gold nanoparticles were ready for use without further preparation.

2.4. Preparation of immunochromatographic test strips

The schematic description and composition of the immunochromatographic test device has been described previously (Biagini et al., 2006; Chiao et al., 2008; Fong et al., 2000; Shyu et al., 2002). Briefly, goat anti-rabbit IgG and rabbit anti-SEB IgG were separately sprayed onto a NC membrane AE 98, using a Biodot dispensing apparatus (Biodot XYZ 3000 1414) to form a control region (C) and a test region (T). The membrane was then mounted in a plastic cassette with an additional reagent adsorbent filter, colloidal gold conjugate pad, and a sample application pad (Fig. 2). This test device was prepared as follows: 2 μl of goat anti-rabbit IgG (0.5 mg/ml, Sigma) and 2 μl of rabbit anti-SEB IgG (1 μg/ml in K_2CO_3, pH 8.5) were separately applied near one end (top) of the strip membrane; the membrane was then dried for 1 h at RT to fix the antibodies. Any remaining active sites on the membrane were blocked by incubation with 1% (w/v) low-melting-point polyvinyl alcohol (in 20 mM Tris/HCl, pH 7.4) for 30 min at RT. The membrane was washed once with water, dried, and immersed in a 5% sucrose solution to assist free mobility of the labeled reagent and dried again. Sucrose can protect the colloidal gold probe from irreversibly adsorbing to the membrane surface when dried. The membrane was then adhered to an adhesive paper plate (2.44 × 11.81 in., Adhesives Research Inc., Taiwan).

On the other hand, the SEB IgG-coated colloidal gold nanoparticles were sprayed onto the sliced conjugated pad (1 × 10 cm, 50 μl/cm) by Biodot AirJet dispensing apparatus (Biodot XYZ 3000 1414). The pad was then kept in a 37 °C incubator for 2 h until fully dried. After that the pad was adhered to the adhesive plate at the bottom end of the sucrose-coated membrane. Finally, a sample application pad (2 × 10 cm) and a reagent adsorption pad

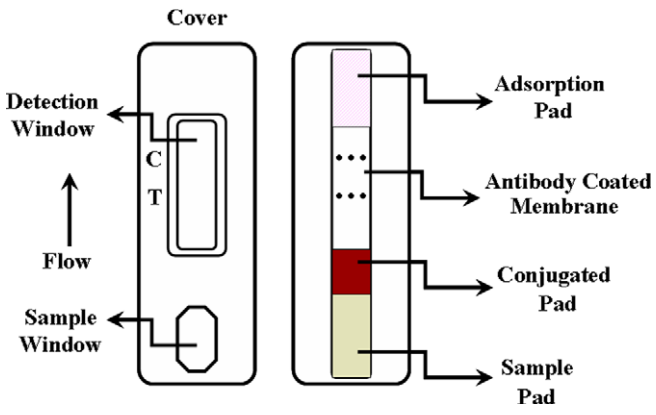

Fig. 2. The schematic description of immunochromatographic test device in a plastic cassette. The device is assembled with a nitrocellulose membrane, a sample pad, a conjugate pad and an adsorption pad. Sample and conjugate pad provide equivalent mixture of the liquid sample and serve as a reservoir for the assay reagents. The adsorption pad adsorbs extra liquid and ensures sufficient flow-through.

(1.2 × 10 cm) were adhered onto the plate to complete the fabrication of the device. The plate was then cut into 5-mm wide strips (by Biodot CM4000) and then mounted in a plastic cassette.

2.5. ELISA for determination of anti-SEB titer

Three rabbits were immunized with the SEB toxin (150 μg toxin/rabbit/boost) to induce anti-SEB Pab. Vaccination was carried out by intramuscular injection every 2 weeks. Whole blood was collected from each rabbit after three boosts, stored overnight at 4 °C, and then purified by further centrifugation (4 °C, 500*g*; 8178 swing-out rotor, Labofuge 400R; Heraeus Instruments, Hanau, Germany) to remove blood cells. Purified sera were stored at 4 °C. For ELISA analysis, all the sera were serially diluted 40,000- to 160,000-fold, with PBS.

2.6. Sensitivity and specificity test

Toxin samples (volume, 80 μl) containing an appropriate amount of SEB (1000–0.1 ng/ml) were applied onto the strip at sample window for the sensitivity assay. To help the sample to migrate, a half volume (40 μl) of tracing buffer (PBS) was applied. With the aim of detecting the very low levels of toxin content, a silver enhancement process was applied to intensify the binding signal of the colloidal gold: following the strip assay, the tested strips were washed once with PBS containing 0.1% (w/v) tween 20 and twice with distilled water, the washed strips were then soaked in a silver enhancer reagent (Sigma) for 5 min and fixed with sodium thiosulfate at room temperature.

For the specificity test, samples containing different enterotoxins (SEA, SEB, SEC, SED, and SEE) were assayed using the SEB test strip by the methods described above.

2.7. Practicability of the SEB test strip with simulated samples

For the purpose of evaluating the practicability of the SEB test strip in natural conditions, three different matrices were used as toxin diluents to mimic actual samples. The samples were prepared by diluting SEB (1 μg/ml) in a stock solution with the appropriate volume of human serum (1:5 in PBS), urine (1:1 in PBS), and cow milk powder (2% w/v in PBS). The serum required dilution because it was too viscous to flow through the membrane, while the urine required dilution because it was a weak acid and would interfere with the antigen–antibody reaction, and the milk need to be diluted because the milk particles and lipid would have blocked the pores of the membrane. Control samples were prepared by directly diluting the various matrices with PBS. All mimic samples were assayed on SEB test strips.

3. Results

3.1. Sensitivity of SEB test strip

Different concentrations of SEB toxin were assayed by the SEB test strip. Results were determined by the appearance of (positive result) or absence of (negative result) a red line in the test area, respectively, under the condition that a red line could be visualised at the control zone. Analyses were completed in less than 5 min, and the detection limit of SEB was 1 ng/ml (Fig. 3). All the results were highly reproducible throughout the assay. The intensity of the red color is proportional to the SEB concentration (under 100 ng/ml). However, in the absence of SEB (buffer only), no immunogold was bound to the solid-phase test antibody; hence no red signal can be visualised in this region. In the case of silver enhancement, the strong binding between silver molecules and colloidal gold particles developed a dark line at the place of the colloidal gold particles. By using silver enhancement, 10 pg/ml of the SEB toxin could be detected (Fig. 4). False positive results were not obtained in any of the assays performed.

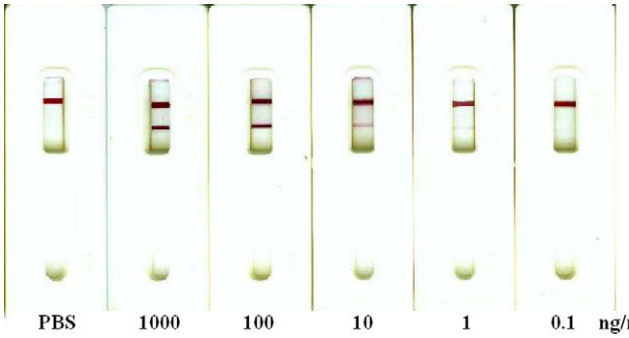

Fig. 3. Immunochromatographic assay of SEB. A series of dilutions (1000–0.1 ng/ml) of SEB was prepared in PBS. The detection limit of SEB toxin was 1 ng/ml. False positive was not detected in the absence of SEB.

3.2. Cross-reactivity of SEB test strip

The cross-reactivity of SEA, SEC, SED, and SEE on the SEB strip was examined. Samples of five different SEs (A through E) were each diluted in PBS buffer. When 100 ng/ml of each toxin was tested, only SEB produced a red band in the test region (Fig. 5), which suggests a clear specificity of the strips.

3.3. Detection of SEB in various matrices

Simulated samples (SEB toxin diluted in human urine, serum and cow milk powder) were also assayed by the SEB test strips. The results showed that SEB diluted in urine (Fig. 6a) or milk powder (Fig. 6b) provides better detection sensitivity than SEB diluted in serum (Fig. 6c). The detection limit of SEB in the simulated urine and milk samples was 10 ng/ml, which was 1-fold less sensitive than the detection limit of SEB in PBS; however, it was more sensitive than that of SEB in serum (100 ng/ml).

4. Discussion

The *Staphylococcus* toxin SEB poses a serious threat to the food industry and human health. Unfortunately, there is no effective

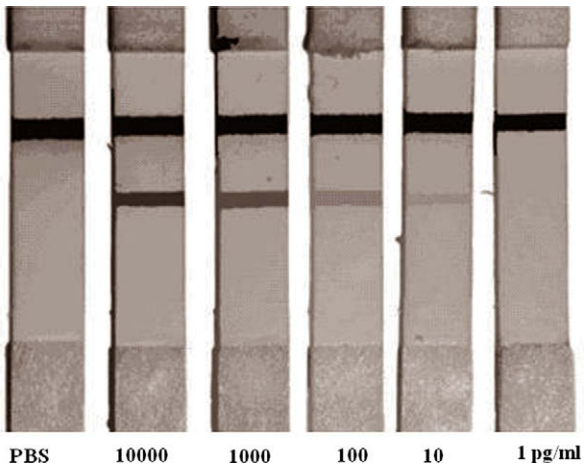

Fig. 4. Silver enhancement of immunochromatographic detection of SEB. The tested membranes were immersed in silver enhancer solution to amplify detection limitation. Sensitivity of the SEB strip can be intensified to 10 pg/ml after the silver enhancement.

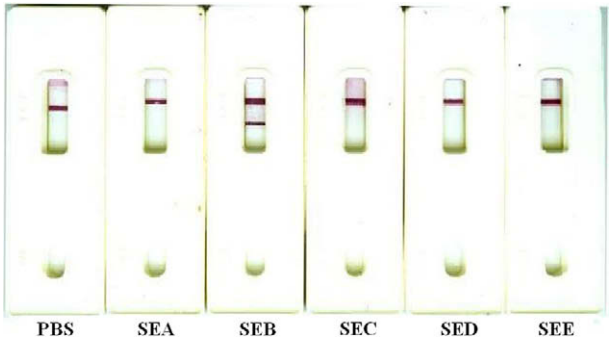

Fig. 5. Cross-reactivity assay of SEB test strip. Samples containing SE toxins (SEA–SEE, 100 ng/ml each) were applied to SEB test strip, while only SEB produced a red band in the test region. Non-specific binding was not visualised in the absence of SEB.

vaccine or specific anti-toxin to treat SEB poisoning. Therefore, a simple and rapid method to screen for SEB toxin would provide an important tool to protect the food supply.

In this paper, a SEB immunochromatographic assay was developed that utilises colored colloidal gold nanoparticles as a tracer which provides clear evidence of SEB identification. The criterion for reactivity was judged by the formation of red lines at both the test and control areas within 5 min but no longer than 10 min after sample addition. Formation of a red line at the control position other than the test position was classified as a negative result, while the absence of a red line at the control position was treated as an invalid result, and thus need to be reanalysed. The detection limit of the SEB toxin in the SEB strips was 1 ng/ml, and it could be enhanced to 10 pg/ml with the silver enhancer reagent. In contrast, since the Pab-based SEB test strips had no cross-reaction with other SEs (SEA, SEC, SED, and SEE) even when 1 μg/ml of the toxins was tested, suggesting that these SEB strips have high specificity for SEB.

In Fig. 3, there seems no difference in staining intensity observed between 1000 and 100 ng, previous studies explained this phenomenon: Chan et al. (2003) found that when using LFA to detect heart-type fatty acid-binding protein, the linear range of the detection was laid between 2.8–125 ng/ml, which suggested the staining intensity may reach an equilibrium value in LFA if the antibody exceeds a certain amount. Qian and Bau (2003) also established a mathematical model explained when the target analyte concentration is low, the signal level increases nearly linearly as the target analyte concentration increases; however, once the target analyte concentration exceeds a certain value, the signal reaches a plateau.

In strip analyses, the purified IgGs from the immunized rabbits were applied onto the devices. We could not measure the amount of specific anti-SEB IgG contained in the T-gel-purified IgG because the purified IgG was total IgG rather than specific IgG. Nevertheless, we obtained good detection specificity and sensitivity in the SEB strip test by using this total IgG as a reagent. On the other hand, previous studies (Chiao et al., 2004; Sharma, Eblen, Bull, Burr, & Whiting, 2005) discovered that in LFA, some components in urine, serum or milk may interfere the antigen–antibody reaction and result in a weak signal. In our study of SEB, although the signal intensity in simulated tests was not as sensitive as that in PBS only, the strips are still with sufficient sensitivity to detect SEB in food.

There are several steps in the immunochromatographic assay procedure. First, two antibodies are immobilized on the membrane: a suitable concentration of antibody (e.g., 1 μg/ml) against the test antigen, and an antibody against the IgG of the animal spe-

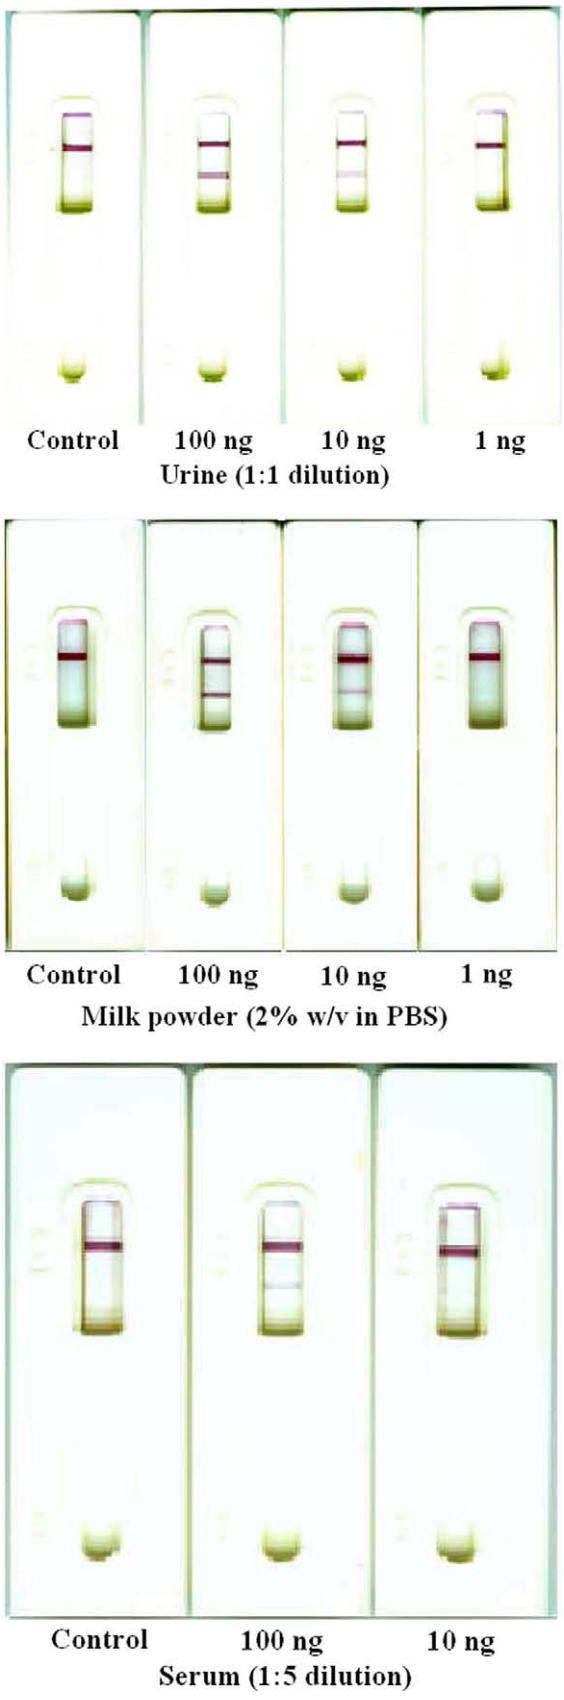

Fig. 6. Detection of SEB in various matrices. Simulated samples were assayed by SEB test strip. All the SEB samples were diluted in the control reagents that diluted in PBS (urine, 1:1 dilution (a); milk powder, 2% w/v (b); serum, 1:5 dilutions (c)). Simulated samples in urine and milk powder have same detection limit (10 ng/ml), while in serum, detection sensitivity has ten times less (100 ng/ml).

cies from which the pathogen antibody is derived. The antibodies are strongly adsorbed by the membrane and remain attached to the surface throughout the procedure. Second, any remaining sites on the membrane still capable of binding protein are blocked by other chemicals, such as polyvinyl alcohol, to reduce the nonspecific binding of antibody or antigen to the membrane. Third, when samples containing the toxin antigen are added to the device, the liquid mixture migrates along the NC membrane. As a result, the sample reacts with the two antibodies bound on the membrane and forms a visible line(s). The color intensity is proportional to the concentration of the pathogen. To avoid nonspecific binding and to prevent undesired cross-reactivity of the antibodies with the test line, all the procedures require conscientious development and optimisation of various capture lines.

The strip assay described above exhibits potential as a general assay method for the detection of the SEB toxin in biological fluids. The detection of the SEB toxin by the device requires approximately 5 min; this is much quicker than the time required for ELISA or radioimmunoassay; further, the results also can be read directly by the naked eye. Therefore, the strip assay is a highly specific, easy to operate, low cost, and sensitive assay for the rapid and reproducible detection of the SEB toxin.

In summary, we have successfully developed a polyclonal-based strip test kit that can rapidly detect SEB without cross-reaction with antibodies against other SEs. The results imply that the strip assay is sufficiently sensitive to support the detection of SEB contamination in clinical or food samples.

ABSTRACT

Brevetoxin B (PbTx-2) was covalently linked to carrier protein bovine serum albumin and human gamma globulin. A monoclonal antibody against PbTx-2, which showed high cross-reactivity values with PbTx-1, PbTx-3 and PbTx-9 (more than 89%) was obtained from ascites and some characteristics of monoclonal antibody were studied. An direct competitive enzyme-linked immunosorbent assay (ELISA) for detection of PbTxs was developed, which showed an IC50 value of 5.3 ng mL^{-1} with a detection limit of 0.6 ng $well^{-1}$. The recoveries of PbTxs from cockle (88.4%–102.3%) and oyster (89.4%–104.3%) demonstrated that the matrices of cockle and oyster where PbTxs are found do not interfere with the assay. The newly developed competitive ELISA appears to be a reliable and useful method for mass monitoring of PbTxs in mollusk.

1. Introduction

Brevetoxins (PbTxs) are potent marine neurotoxins produced by the planktonic red tide dinoflagellate *Karenia brevis* and are accumulated in filter-feeding molluscan shellfish by dietary transfer. They are lipid-soluble polycyclic polyether compounds and are the only molecules known to activate voltage sensitive sodium channels in mammals through a specific interaction with site 5 of the alpha subunit of the sodium channel (Dechraoui, Naar, Pauillac, & Legrand, 1999). Human ingestion of toxic shellfish causes neurotoxic shellfish poisoning (NSP). Although PbTxs can be used as powerful tools in neuroscience research (Naar, Branaaa, Bottein-Dechraoui, Chinain, & Pauillac, 2001), their detrimental effects on human health and negative impact on seafood industries have mainly raised global awareness. Therefore it is very important to develop a precise, sensitive, reproducible and specific detection method as an alternative to the conventional mouse intraperitoneal (i.p.) bioassay (Lewis, 1995), solid-phase extraction (SPE) assay, receptor binding assay (RBA), radioimmuno-assay (RIA), and liquid chromatography–mass spectrometry (LC–MS) (Twiner et al., 2007), competitive electro-chemiluminescence-based immunoassay (Poli et al., 2007), cell based assay (Fairey, Bottein Dechraoui, Sheets, & Ramsdell, 2001) and in vitro assays (Plakas et al., 2008).

Immunological methods based on antibodies are simple, sensitive, economical and high throughput procedure for quantifying biologically relevant compounds, but require a continuous supply of well-defined specific antibodies. To date, Polyclonal and monoclonal antibodies to PbTx-2-type brevetoxins (Naar et al., 2001) and polyclonal antisera to PbTxs have been raised in animals such as mice (Trainer & Baden, 1990), goats (Melinek, Rein, Schultz, & Baden, 1994; Poli, Rein, & Baden, 1995; Trainer & Baden, 1991), and rabbits (Levine & Shimizu, 1992). Although they exhibit high affinity, but usually available in only limited supply and require batch standardisation and continual supply of antigen for booster injections. On the other hand, the antigens (PbTxs) are very expensive, so it is restricted to detect this kind of compounds by polyclonal antisera.

It is one of the key steps to generate a hybridoma cell line, which permanent secreting high affinity monoclonal antibody (mAb) against PbTxs, for the establishment of a precise, sensitive, and specific immunoenzymatic assay for PbTxs. Since PbTxs are small molecules, haptens must be synthesised and coupled to carrier proteins to induce antibody production. In this study, we aimed at obtaining mAbs against PbTxs and developing mAb-based enzyme-linked immunosorbent assay (ELISA) with better performance using a larger number of haptens as competitors.

2. Materials and methods

2.1. Materials

PbTx-1, PbTx-2, PbTx-3, PbTx-9, ciguatoxin-1 (the purity ⩾ 98% by HPLC), okadaic acid, microcystin LR and dinophysistoxin (the purity ⩾ 95% by HPLC) were obtained from Sigma Chemicals Co. (St. Louis, MO, USA). Agarose, complete and incomplete Freund/s adjuvant, polythylene glycol-4000 (PEG), RPMI 1640, foetal bovine serum (FBS), horseradish peroxidase-conjugated goat anti-mice IgG (HRP–IgG), bovine serum albumin (BSA), human gamma globulin (HGG), HT and HAT were purchased from Express China. All other reagents were of analytical grade. The ELISA was carried out in 96-well polystyrene microtiter plates (Stripwell plate 2592, Costar, Changchun, China). Well absorbencies were read with a MK3 microplate reader (Thermo, Shanghai, China).

2.2. Animals

Female Balb/C mice, 6- to 7-week old and 9- to 10-week old, being immunized and using to produce ascites, respectively, were obtained from Changchun Institute of Biological Products, Jilin province China.

2.3. Buffers and solutions

The buffers used regularly were coating buffer, 50 mmol L^{-1} carbonate buffer (pH 9.5); phosphate buffered saline (PBS), 10 mmol L^{-1} sodium phosphate buffer (pH 7.4) containing 140 mmol L^{-1} NaCl; dilution buffer, PBS containing 0.1% (w/v) gelatin; washing buffer (PBST), 10 mmol L^{-1} sodium phosphate buffer (pH 7.4) containing 140 mmol L^{-1} NaCl and 0.05% (v/v) Tween 20; and TMB solution, 70 μL of 0.65% H_2O_2, 250 μL of 10 mg mL^{-1} 3,3/5,5/-tetramethylbenzidine (TMB) in dimethylsulfoxide (DMSO) per 25 mL of phosphate citrate buffer, pH 5.4.

2.4. Preparation of PbTx–protein conjugates

Conjugates were prepared according to a modified method of Naar et al. (2001). Briefly, A 10-fold molar excess of succinic anhydride solubilised in 10 mL of anhydrous pyridine was added to 8 mg of crystalline PbTx-2. After incubation (6 h at 65 °C) the solvent was evaporated under a stream of nitrogen and the residue was reacted with a 10-fold molar excess of tributylamine and isobutyl chlorocarbonate as 1/10th dilutions in dry peroxide-free dioxan for 30 min at room temperature. Then the carrier protein HGG and BSA (the same hapten/carrier molar ratio) were added at room temperature and incubated for more than 30 min, that were used for immunisation (PbTx–HGG) and antibody screening (PbTx–BSA) respectively. Conjugates were recovered by acetone precipitation, resuspended in 1 mL distilled water, filter sterilised (0.22 μm), dispensed into sterile tubes then freeze-dried overnight and stored at −20 °C until use.

2.5. Conjugate analysis

The conjugates were analysed using a modification of the methods of Kamps, Carlin, and Shefield (1993). Briefly, TAE was employed for electrophoresis buffer and the mixture solution of 0.04% bromophenoland blue and 6.67% sucrose was used as loading buffer. Each sample (5 μg $μL^{-1}$) 1 μL mixed with an equal volume of loading buffer was applied to the gel and samples were separated at 230 V for 30–40 min. The gel was fixed with 20% trichloroacetic acid for 30 min, stained with Coomassie blue R-250 for more than 2 h and destained with ethanol–acetic acid (250 mL 95% ethanol + 80 mL acetic acid, distilled water to 1000 mL) with several changes until be satisfied. The pictures of the gels were taken by ultraviolet irradiation (UVI) gel auto imaging system.

2.6. Immunization

Immunogen (PbTx–HGG 100 μg, in 0.1 mL PBS, pH 7.4) and freunds complete adjuvant (0.1 mL) was injected (female Balb/C mice, 6- to 7-week old) at multiple subcutaneously (s.c.) sites as the first immunization. The subsequent injections were intraperitoneally (i.p.) with 50 μg of immunogen (0.1 mL) and the same volume Freunds incomplete adjuvant at the 3rd, 5th, 7th, and 9th week, respectively. After the third immunization, at the 10th day of each injection, the animals were bled by tail–tip cut method, and the serum was tested for its ability to bind to PbTx–BSA or the carrier protein HGG and BSA. The animals, whose serum titres (serum antibody titres) bind to PbTx–BSA were 4 × 103 or higher were selected to be spleen donors for hybridoma production, and received intravenous injection (i.v.) boosts of 20 μg immunogen conjugate in PBS (pH 7.0). Four days after the final boost, spleens were removed from immunized mice.

2.7. Hybridoma screening and generation

The immunized mice spleen cells were mixed with myeloma cells (SP2/0) at a 5–10:1 (spleen: myeloma) ratio in the presence of polyethylene glycol (PEG), mol. wt 4000, and plated into 96-well tissue culture plates filled with RPMI + 20% FBS/HAT medium at 37 °C in an atmosphere of 5% CO_2. Specific antibody-secreting hybridoma were screened by ELISA employing PbTx–BSA as target antigen, BSA and HGG as non-relevant control antigens. Hybridoma showing significant PbTx-specific inhibition were cloned three times by limiting dilution. One clone was chosen for further study.

2.8. Ascites produce and mAb affinity determination

Hybridoma (2×10^6 cells for each mice) were injected into abdomens of the 9- to 10-week old Balb/C mice for seven days after liquid olefin was injected. The ascites were obtained through the needle of a 20 mL injector about seven days later. The mAb was purified from ascites using the method of Zhou et al. (2006). MAb subtyping was performed by an ELISA commercial kit "mouse monoclonal antibody isotyping reagents" (Sigma), and the operational procedure based on its manufacturer's instructions. The affinity of mAb for PbTxs was measured by a competitive enzyme immunoassay according to the method of Dong and Wang (2002).

2.9. Protocol of direct competitive ELISA

A direct competition ELISA format was utilised to measure PbTx-2 binding and cross-reactivity (CR) to related compounds PbTx-1, PbTx-3, PbTx-9, ciguatoxin-1, okadaic acid, microcystin LR and dinophysistoxin. Indirect ELISA was carried out as follows: (1) 200 μL of coating antigen PbTx–BSA diluted with the coating buffer at 0.5 μg mL^{-1} was added into a microtiter plate and incubated overnight at 4 °C. (2) Plates were washed three times using 300 μL $well^{-1}$ of PBST (10 mM PBS containing 0.05% Tween 20, pH 7.4) and then followed by incubation with 50 μL $well^{-1}$ of standard analyte (for inhibition assay) in 0.01 M PBS at different dilutions or sample solution or blank together with the mAb (1:8000 with the dilution buffer solution, 50 μL $well^{-1}$) for 30 min at 37 °C. (3) After washing three times, 100 μL of HRP–IgG (working concentration recommend 1:4000) was then added to each well and incubated for 30 min at 37 °C. (4) The plates were washed

again, and 100 μL well^{-1} of TMB solution was added. (5) After incubation for 15 min at 37 °C, the reaction was stopped by adding 50 μL of 2 M H_2SO_4 well^{-1}. (6) The absorbance was measured at 450 nm and recorded. Standard curves were obtained by plotting absorbance against the logarithm of analyte concentration.

2.10. Spiking of mollusk extracts

Non-toxic cockle *Austrovenus stuchibuli* and oyster *Crassostrea virginica* were purchased from a local supermarket. The tissue was thoroughly disrupted in dimethyl sulfoxide (50% w/v) and then centrifuged at 1500 g for 15 min. The supernatant was passed sequentially through a 100 mm nylon mesh, Whatman No. 1 filter and then finally through a Whatman GF/B filter yielding a slightly opalescent yellowcolored extract. Standard analyte of PbTx-2, PbTx-1, PbTx-3 and PbTx-9 was incorporated respectively at the required concentrations using vortexing. Recoveries were determined at concentrations of 4, 40 and 400 ng/g of whole shellfish meat ($n = 5$) by the use of non-toxic cockle or oyster homogenates spiked with standard analytes.

In order to see if the under- or overestimation in recoveries can be rationalised by the matrix effect of the extract of the mollusks, unspiked cockles or oysters were extracted with 10 mL of dimethyl sulfoxide as described above and standard analyte of PbTx-2, PbTx-1, PbTx-3 and PbTx-9 was spiked respectively into the extract to obtain standard curves. The standard curve in the buffer was also obtained.

3. Results and discussion

3.1. Analysis of the conjugates

Conjugates were prepared according to the procedure described in Section 2. In nondenaturing agarose gel electrophoresis, the more negative charged protein migrates further in the gel towards the anode (+) than the more positive charged protein. The coupling of protein with protein modifier and haptens will induce the changes of the protein charge, therefore the migration of carrier protein, treated protein and hapten-carrier protein will be different. Fig. 1 illustrates the results of nondenaturing agarose gel electrophoresis for conjugates. The net charge of PbTx–HGG (lane 3) becomes more negative than that of treated HGG (lane 2) and untreated HGG (line 1), so it migrates to a greater extent towards the anode (+), and the migration of PbTx–HGG and treated HGG became decentralized. The conjugate band migrations were different from those of treated proteins and carrier proteins alone. The net charge of PbTx–BSA (lane 6) becomes more negative, so PbTx–BSA migrates to a greater extent towards the anode (+) than that of treated BSA and untreated BSA, and the migration of PbTx–BSA and treated BSA became decentralized. The results indicated that PbTx was coupled with BSA and HGG successfully.

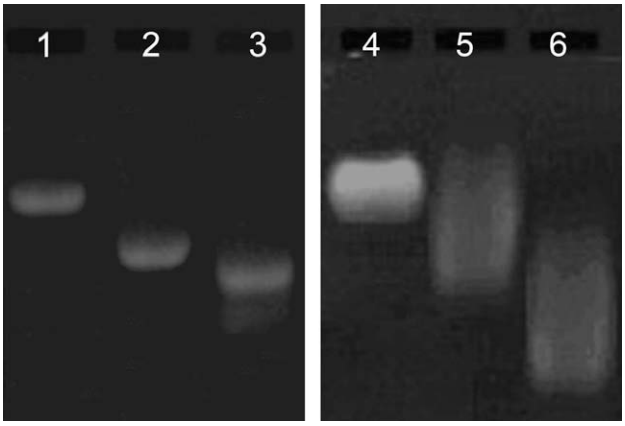

Fig. 1. Analysis of PbTx–HGG and PbTx–BSA conjugations by non-denaturing agarose gel electrophoresis. Lane 1. HGG, lane 2: treated HGG (the procedure was performed according to Section 2, only PbTxs was not added), lane 3: PbTx–HGG conjugates, lane 4: BSA, lane 5: treated BSA (the procedure was performed according to Section 2, only PbTxs was not added), lane 6. PbTx–BSA conjugates.

3.2. Antisera titres of immunized mice and screening of hybridoma

Like most other marine toxins, PbTx, as hapten, has no immunogenicity and must be conjugated to a protein carrier to add immunogenicity. A previous study indicated that the titres of produced antibody for the hapten changed according to the carrier protein used in the conjugation and different mice (Kentaro, Yonekazu, & Tamao, 1999). In the present study, six mice were immunized by PbTx–HGG. Table 1 shows the results of serum titres of immunized mice. There are four mice whose serum titres were 4×10^3 higher. No. 6 mouse was selected to be spleen donors for hybridoma production. Hybridoma supernatants were screened by ELISA for binding to target and control antigens in parallel, then positive clones were checked for PbTx-2 reactivity by competitive inhibition ELISA. A screened hybridoma cell line designated 2C4, was established after being subcloned for 3 cycles by "limiting dilution".

3.3. The characteristics of mAb

The hybridoma cells were expanded and injected into Balb/C mouse abdomen. The mAb was obtained from ascites and purified by the caprylic/ammonium sulphate precipitation (CA–AS) method. The protein concentration of ascites was 24.5 mg mL^{-1}, calculated as following equation (Liu, Cai, Wang, & Li, 1999): Concentration (mg mL^{-1}) = $1.45 \times OD_{280} - 0.74 \times OD_{260}$. Here OD_{280} is the absorption value of ascites at 280 nm, OD_{260} is the absorption value of ascites at 260 nm. The ELISA titres of ascites and purified mAb were 3.2×10^5 and 6.4×10^5, respectively. The mAb secreted by 2C4 belongs to the IgG1 class.

The average affinity of mAb was 0.82×10^9 M^{-1} calculated as following equation (Dong & Wang, 2002):

$$Ka = \frac{n-1}{2(n[Ab'] - [Ab])} \quad (1)$$

Here n is the concentration time of two different concentration plate coating antigens in one group, [Ab'] and [Ab] are the mAb concentrations (ng L^{-1}) correspond to 50% of maximum absorption values of two different concentration plate coating antigens.

The CR was calculated according to the following equation:

$$CR\% = \frac{\text{standard}IC_{50}}{\text{cross-reactant}IC_{50}} \quad (2)$$

Table 1
Titres of antisera from the immunized mice by indirect ELISA[a].

Mouse no.	Titers of antiserum		
PbTx–HGG[b]	PbTx–BSA[c]	BSA[c]	HGG[c]
1	1:8000	Negative	1:16000
2	1:400	1:200	1:8000
3	1:16000	Negative	1:64000
4	1:8000	Negative	1:32000
5	1:4000	1:400	1:1600
6	1:32000	Negative	1:64000

[a] The titrations by indirect ELISA were performed for the serum of mice after the fourth booster.
[b] As immunogen.
[c] As plate-coating antigen.

IC50 is PbTx concentration reducing the ELISA maximum response to 50%. CR (%) of PbTx-2 was defined as 100%. The CR of the mAb with some other marine toxins is shown in Table 2. The mAb showed high CR values with PbTx-1, PbTx-3 and PbTx-9, low CR values with ciguatoxin-1 and okadaic acid, and no significant CR values with microcystin LR and dinophysistoxin in the direct competitive ELISA. Therefore the mAb secreted by 2C4 is class-selective and has potential to be used for broad spectrum assay of PbTx-1, PbTx-2, PbTx-3 and PbTx-9. It is expensive and time consuming to produce the brevetoxin antiserum, which depends on the continual supply of animals and brevetoxins, and it is difficult to get the uniform antiserum due to the individual difference of animals. The uniform mAb can be readily obtained which dose not need brevetoxins.

Table 2
Specificity of the mAb to different marine toxins in the competitive ELISA[a] using PbTx–BSA as coating antigen.

Compound	IC_{50} (ng mL^{-1})[b]	CR (%)
PbTx-2	6.4	100.00
PbTx-1	6.57	97.45
PbTx-3	5.31	120.63
PbTx-9	7.15	89.56
Ciguatoxin-1	175.82	3.64
Okadaic acid	216.22	2.96
Microcystin LR	#[c]	<0.1
Dinophysistoxin	#[c]	<0.1

[a] Antigen coating solution was made in PBS at 500 ng mL^{-1} and final ascites dilution was 1:64,000 in PBS-T.
[b] Data represent the means of five experiments.
[c] The IC_{50} cannot be evaluated.

3.4. Extraction recovery

In order to understand the under- and overestimation in recovery values, unspiked cockles or oysters were extracted with 10 mL of dimethyl sulfoxide and standard analyte of PbTx-2, PbTx-1, PbTx-3 and PbTx-9 was spiked respectively into the extract to obtain standard curves. The standard curves obtained in the matrix extract are presented in Fig. 2. No remarkable matrix extract intersecting appears in standard curves of buffer, cockle and oyster matrix extract.

Recoveries of PbTx-2, PbTx-1, PbTx-3 and PbTx-9 extracted from tissue homogenates spiked at three dose levels are shown in Table 3. Recoveries of PbTx-2, PbTx-1, PbTx-3 and PbTx-9 were 98.7%–104.3%, 92.9%–101.2%, 95.4%–103.2% and 88.4%–99.3%, respectively and the recoveries of analytes from cockle (88.4%–102.3%) and oyster (89.4%–104.3%) were very similar, which is consistent with the corresponding standard curves in the matrix extract intersecting the standard curve in the buffer (Fig. 2). The results demonstrated that the matrices of cockle and oyster where PbTxs are found do not interfere remarkably with the assay. The optimised ELISA detection limit was calculated by taking the mean absorbance value of 10 blank wells plus 2 times standard deviations of the mean. The detection limit was found to be

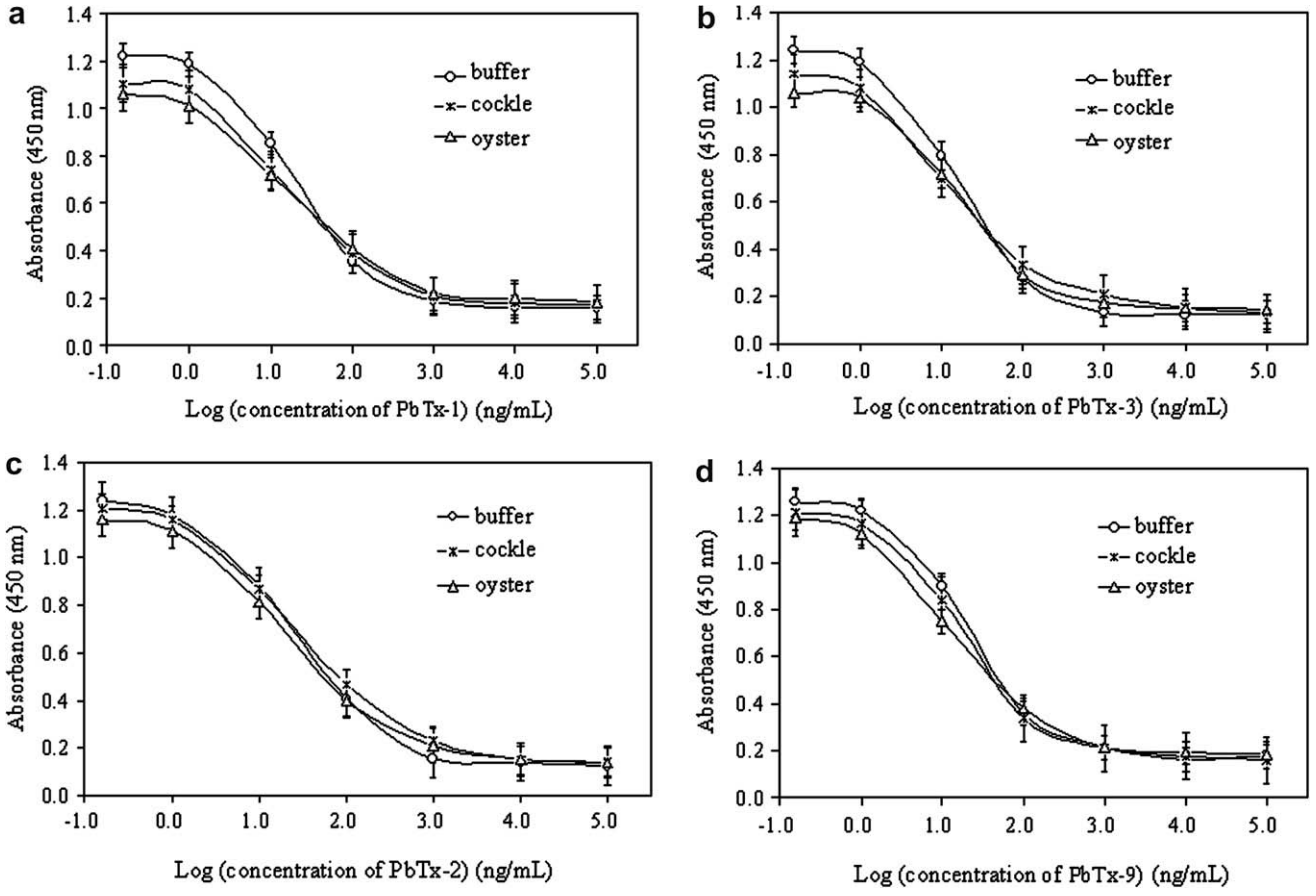

Fig. 2. Direct competition ELISA curves for PbTxs in matrix extract of cockle and oyster. Standard curve (a) PbTx-2 in extract by direct competition ELISA, (b) PbTx-1 in extract by direct competition ELISA, (c) PbTx-3 in extract by direct competition ELISA, (d) PbTx-9 in extract by direct competition ELISA. The details of assay protocol were described in text.

Table 3
Rcoveries of toxins from spiked homogenates of whole meat of shellfish[a].

Toxin	Concentration (ng/g)	Recovery (%) of toxins from	
		Cockle	Oyster
PbTx-2	4	102.1 ± 1.3	98.7 ± 2.4
	40	99.7 ± 0.8	104.3 ± 0.3
	400	101.3 ± 0.6	102.2 ± 2.7
PbTx-1	4	98.4 ± 1.3	92.9 ± 3.2
	40	101.2 ± 2.1	99.5 ± 2.2
	400	97.8 ± 0.7	95.4 ± 3.4
PbTx-3	4	95.4 ± 1.6	103.2 ± 3.1
	40	99.3 ± 2.5	101.8 ± 2.3
	400	102.3 ± 0.9	98.5 ± 4.1
PbTx-9	4	88.4 ± 3.1	92.3 ± 3.3
	40	98.6 ± 0.4	89.4 ± 2.9
	400	99.3 ± 1.2	96.2 ± 0.8

Results are mean ± SD (n = 5).
[a] Assay conditions were described in the text.

0.6 ng well^{-1}, close to the sensitivity of immunochromatographic assay (Zhou et al., 2009), higher than electrochemi-luminescence-based competitive displacement immunoassay (Poli et al., 2007) and lower than ELISA (Naar et al., 2001). The assay could be accomplished within 1.5 h, less than that of other immunoassays (Naar et al., 2001; Twiner et al., 2007).

4. Conclusions

We produced a monoclonal antibody which shows high-affinity against PbTxs, and developed monoclonal antibody-based competitive ELISA for detection of PbTxs. The IC50 value of the optimised direct competitive ELISA was 5.3 ng mL^{-1} with a detection limit of 0.6 ng well^{-1}. The antibody showed high CR with PbTx-1, PbTx-3 and PbTx-9, negligible CR with ciguatoxin-1 and okadaic acid, and no signigcant CR with microcystin LR and dinophysistoxin. Recoveries of PbTxs from spiked cockle and oyster ranged 88.4%–102.3% and 89.4%–104.3%, respectively. The newly developed competitive ELISA seems to be a useful method for monitoring PbTxs in mollusk.

Urine

ABSTRACT

Carboxylic acid haptens were synthesised, for Hesperetin (**Hesp**) and Naringenin (**Nar**). They had a spacer arm (4 or 6 carbons long) on the C7 position. Haptens were coupled to bovine serum albumin. Polyclonal antibodies were generated. Enzyme-linked immunosorbent assays (ELISAs) were developed. Owing to sensitivity, one antibody for each flavanone was retained, namely anti-**h4-Hesp** and anti-**h4-Nar**. For **Hesp** and Nar, IC_{50} of the standard curves were 1.29 pmol/well and 0.72 pmol/well, respectively. Intra-assay and inter-assay variations were 10.24% and 10.53%, respectively for **Hesp** and 10.03% and 10.79%, respectively for **Nar**. Anti-**h4-Hesp** was highly specific when **anti-h4-Nar** showed cross-reactions with liquiritigenin and eriodictyol, which were significantly reduced in heterologous assay conditions. Assays were validated by comparisons with HPLC Coularray. Measurements were done on diet, plasma and urine samples from mice fed on diets enriched with **Hesp** or **Nar** and on a range of diluted mice urine samples.

1. Introduction

Hesperetin (**Hesp**) and Naringenin (**Nar**) belong to the flavanone family, which is one category of flavonoids. All flavonoids have a C6–C3–C6 backbone. There has been considerable interest in the flavonoid content of foods since the early 1980s when a link was established between a diet rich in fruits and vegetables and a reduced risk of chronic diseases (Steinmetz & Potter, 1991a, 1991b). Among other compounds, a high intake of **Hesp** and/or **Nar** was shown to be associated with a reduced risk of several chronic diseases (Knekt et al., 2002). This includes vascular risk in humans for which various mechanisms have been proposed like increased nitric oxide production (Liu, Xu, & Cheng, 2008), significant decrease of triacylglycerol, total cholesterol and phospholipid levels in serum (Huong, Takahashi, & Ide, 2006), and significant increase in high density lipoprotein (HDL) in plasma (Jeon et al., 2007). **Hesp** and **Nar** also display anti-atherogenic effects (Lee et al., 2003). **Nar** has been shown to present oestrogenic effects (Bovee, Schoonen, Hamers, Bento, & Peijnenburg, 2008) although essentially via non genomic pathways (Koohi, Walther, & Ivell, 2007). **Hesp** and **Nar** were also shown to exhibit anti-oestrogenic effects in MCF-7 and fibroblasts co-culture through anti-aromatase effects (van Meeuwen, Korthagen, de Jong, Piersma, & van den Berg, 2007). Several studies are in accordance and show a preventive effect of **Nar** against lung cancer (Hsiao et al., 2007; Malaveille et al., 1996).

Hesp and **Nar** are commonly conjugated in plants with a variety of groups like glycoside, malonyl or acetyl. Their concentrations in citrus fruits are exceptionally high, reaching 180–320 mg/L for

hesperidin (**Hesp**-glycoside) in orange juice (Gil-Izquierdo, Riquelme, Porras, & Ferreres, 2004) and 26 mg **Nar** (equivalent aglycones)/100 g fresh grapefruit (Harnly et al., 2006) while in strawberries or tomatoes, **Nar** concentrations (equivalent aglycones) are about 1.8 or 2 mg/100 g fresh fruit.

Numerous methods have been reported for the determination of flavonoids. They rely essentially on chromatographic separation associated with various detection methods allowing the concomitant determination of several compounds in one run (Sakakibara, Honda, Nakagawa, Ashida, & Kanazawa, 2003). Generally, quantification in vegetal foodstuffs is achieved after the hydrolysis of the glycosylated flavonoids to allow comparison with commercially available aglycone standards and to reduce the number of compounds to analyse. The hydrolysis procedure included refluxing the samples in an acidified methanolic solution but this hydrolysis procedure may also lead to the degradation of the aglycones (Merken, Merken, & Beecher, 2001). In biological fluids, flavonoids are not present as native forms or aglycones but as conjugated derivatives resulting from the intestinal and hepatic conjugation process (namely glucuronidation, sulfatation, methylation). Thus quantification of flavonoids in plasma and urine is achieved after enzymatic hydrolysis of conjugates (Morand, Manach, Donovan, & Remesy, 2001) followed by a chromatographic analysis coupled to diode array detection (Radtke, Linseisen, & Wolfram, 2002), coulometric detection (Manach, 2003), photo-diode array electrospray mass spectrometry (Franke et al., 2002), UV detection (Kanaze, Kokkalou, Georgarakis, & Niopas, 2004) or MS–MS detection (Grace, Mistry, Carter, Leathem, & Teale, 2007). All these techniques induce rather high costs and require high physicochemical skills. Detection in biological fluids enables the determination of the flavonoid bioavailability and the correlation of the ingested amounts with the registered effects. They may prove that when the plasma concentrations increase, the effect is higher. Such an approach can also exhibit the high inter-individual variation of plasma concentrations, thus explaining the large variety of effects registered in consumers. Naringin, namely the **Nar**-glycoside from food, is first deglycosylated into **Nar** by the β-glycosidases of enterocytes. Then colonic bacteria are able to metabolize **Nar** into various compounds including **Nar** aglycone phloroglucinol, 3-(4-hydroxyphenyl)-propionic acid, and 3-phenylpropionic acid depending on the human subject and on the quality of gut microflora (Rechner et al., 2004). Then, in rat and human plasmas, flavanones are present as glucuronide and sulphate conjugates (Felgines et al., 2000; Manach, Morand, Gil-Izquierdo, Bouteloup-Demange, & Remesy, 2003). In addition, **Hesp** and probably **Nar** as well, can bind with human serum albumin to form a polyphenol–protein complex in molecular association ranging from 0.3 to 7 (Xie, Xu, & Wang, 2005). This can influence **Hesp** availability at the cellular level. Rat liver microsomes are also able to convert flavanones into flavones and hydroxy-quinones having different activities compared to their parent compounds (Nikolic & van Breemen, 2004). Therefore, plasma bioavailability of **Nar** and **Hesp** results from complex processes.

In this context and to further explore the biological effects of these compounds it appeared relevant to develop easy-to-use methods and limited cost methodologies for biological fluid analysis. This can help to correlate an ingested quantity of glycosylated compounds with circulating forms and biological effects, and demonstrate a dose dependant effect based on circulating concentrations rather than on ingested amount. Therefore this paper relates the chemical synthesis of new haptens of **Nar** and **Hesp**, and the production of specific antibodies and their use in quantitative ELISA for measuring **Nar** and **Hesp** concentrations in diets and in animal fluids.

2. Materials and methods

2.1. Chemicals

Hesp (4′-methoxy-3′,5,7-trihydroxyflavanone) and **Nar** (4′,5,7-trihydroxyflavanone) were purchased from Sigma–Aldrich Chemical Co. (Saint Quentin Fallavier, France). Ethyl 4-bromobutyrate, ethyl 6-bromohexanoate, and potassium *tert*-butoxide were obtained from Alfa Aesar (Bischheim, France). Dimethylformamide (DMF) was dried by distillation over CaO and stored over 4 Å molecular sieves. All moisture-sensitive reactions were performed under argon atmosphere in oven-dried or flame-dried glassware. Biological reagents were purchased from Sigma–Aldrich (Saint Quentin Fallavier, France) except for the secondary antibody, i.e. goat anti-rabbit IgG-horseradish peroxidase purchased from DAKO (Trappes, France) and the enzyme used to hydrolyse the samples, i.e. β-D-glucuronoside glucuronosohydrolase-arylsulfate sulfohydrolase from *Helix pomatia* which was purchased from Roche Diagnostic (Mannheim, Germany).

2.2. Instruments

Melting points were determined with a Stuart Scientific melting point SMP3 apparatus and were uncorrected. ^{1}H and ^{13}C NMR spectra were recorded with a Bruker AC-300 FT (^{1}H: 300 MHz, ^{13}C: 75 MHz) or with a Bruker AC 250 (^{1}H: 250 MHz, ^{13}C: 63 MHz). The spectra were calibrated using the frequency of the deuterated solvent (the lock frequency). The chemical shifts (δ) and coupling constants (J) are, respectively expressed in ppm and Hz. IR spectra were recorded with a Perkin–Elmer paragon 1000 FT-IR spectrophotometer. Thin-layer chromatography (TLC) was performed using Merck TLC plates, (0.25 mm, particle size 15 μm, pore size 60 Å). Merck silica gel 60 (70–230 mesh, 0.063–0.200 mm) was used for flash chromatography. The spots were visualised with a UV lamp. Mass spectra of **Hesp** and **Nar** haptens were acquired on a QStar Elite mass spectrometer (Applied Biosystems). The instrument was equipped with an ESI source and the spectra were recorded in the positive mode. The electrospray needle was maintained at 4500 V and operated at room temperature. Samples were introduced by injection through a 10 μL sample loop into a 200 μL/min flow of methanol from the LC pump.

Optical densities (OD) of microtitration plates were read on a Dynex MRX II microtitration plate reader at 490 nm. The plates were NUNC Maxisorp® 96 wells microtitration plates.

2.3. Chemical synthesis

2.3.1. Ethyl 4-{[5-hydroxy-2-(4-hydroxyphenyl)-4-oxo-3,4-dihydro-2H-chromen-7-yl]oxy} butanoate (**5**)

Typical procedure. **Nar** (4′,5,7-trihydroxyflavanone, 2.72 g, 10 mmol) was dissolved in acetone (30 mL), K_2CO_3 (2.76 g, 20 mmol) and ethyl 4-bromobutyrate (2.93 g, 15 mmol) were then added. The mixture was refluxed for 5 h and then allowed to cool to room temperature. The reaction mixture was filtered, and the filtrate was evaporated to dryness to give a yellow oil (5.8 g). Flash chromatography using dichloromethane: methanol (97:3) as an eluent gave the desired compound (**6**) as a pale yellow oil (R_f = 0.15, 3.0 g, 78%).

^{1}H NMR ($CDCl_3$, 300 MHz): δ1.24 (t, J = 7.1 Hz, 3H, CH_3), 2.08 (quintuplet, J = 6.8 Hz, 2H, CH_2), 2.48 (t, J = 6.8 Hz, 2H, CH_2), 2.69 (dd, J = 17, 3 Hz, 1H, H-3b), 3.06 (dd, J = 17, 13 Hz, 1H, H-3a), 3.98 (t, J = 6.8 Hz, 2H, CH_2), 4.12 (q, J = 7.1 Hz, 2H, CH_2), 5.27 (dd, J = 13, 3 Hz, 1H, H-2), 5.97 (d, J = 2.3 Hz, 1H, H_{ar}, 6), 6.01 (d, J = 2.3 Hz, 1H, H_{ar}, 8), 6.86 (d, J = 8.7 Hz, 2H, H_{ar}, 3′,5′), 7.27 (d, J = 8.7 Hz, 2H, H_{ar}, 2′,8′).

Table 1
Experimental conditions for synthesis of haptens 1–4.

Hapten	Step 1		Step 2	
	Conditions	Yield (%)	Conditions	Yield (%)
For Nar				
1	K_2CO_3 (3 eq), acetone, reflux	78	1 M LiOH, MeOH	45
3	K_2CO_3 (3 eq), DMF, 70 °C[a]	76	1 M LiOH, MeOH	34
For Hesp				
2	*t*-BuOK (2 eq), DMF, 70 °C[b]	80	1 M LiOH, MeOH	29
4	*t*-BuOK (2 eq), DMF, 70 °C[b]	65	1 M LiOH, acetonitrile	30

[a] Low yield of reaction in acetone and in *i*-propanol (ambient temperature, reflux).
[b] No reaction in conditions used for Naringenin haptens.

^{13}C NMR ($CDCl_3$, 75 MHz): δ196.3 (C=O), 173.4 (COOEt), 167.2 (CQ), 164.0 (CQ), 163.0 (CQ), 156.8 (CQ), 129.9 (CQ), 127.9 (CH_{ar}, 2′,6′), 115.7 (CH_{ar}, 3′,5′), 103.1 (CQ), 95.5 (CH_{ar}, 6), 94.6 (CH_{ar}, 8), 79.0 (CH-2), 67.3 (CH_2O), 60.8 (CH_2CH_3), 43.0 (CH_2-3), 30.7 (CH_2C=O), 24.3 (CH_2), 14.2 (CH_3).

The compounds (**6**), (**7**), and (**8**) were prepared as described for (**5**). The conditions used for each reaction are summarised in Table 1.

*2.3.2. Ethyl 4-{[5-hydroxy-2-(4-hydroxyphenyl)-4-oxo-3,4-dihydro-2H-chromen-7-yl]oxy} hexanoate (**7**)*

Nar (4′,5,7-trihydroxyflavanone, 2.72 g, 10 mmol) was reacted with ethyl 6-bromohexanoate (3.35 g, 15 mmol) as described for (**6**) except for the solvent used (see Table 1). The purification by flash chromatography using dichloromethane:methanol (95:5) as an eluent gave the target compound (**8**) as a yellow oil (R_f = 0.3, 3.16 g, 78%).

^{1}H NMR ($CDCl_3$, 300 MHz): δ1.24 (t, J = 7.1 Hz, 3H, CH_3), 1.47 (quintuplet, J = 7 Hz, 2H, CH_2), 1.66 (quintuplet, J = 7.0 Hz, 2H, CH_2), 1.87 (quintuplet, J = 7.0 Hz, 2H, CH_2), 2.32 (t, J = 7.0 Hz, 2H, CH_2), 2.76 (dd, J = 17, 3 Hz, 1H, H-3b), 3.08 (dd, J = 17, 12.8 Hz, 1H, H-3a), 3.95 (t, J = 7.0 Hz, 2H, CH_2), 4.12 (q, J = 7.1 Hz, 2H, CH_2), 5.33 (dd, J = 12.8, 3 Hz, 1H, H-2), 6.01 (m, 2H, H_{ar}, 6, 8), 6.89 (d, J = 8.7 Hz, 2H, H_{ar}, 3′, 5′), 7.30 (d, J = 8.7 Hz, 2H, H_{ar}, 2′,8′).

^{13}C NMR ($CDCl_3$, 75 MHz): δ196.1 (C=O), 173.7 (COOEt), 167.4 (CQ), 164.0 (CQ), 162.9 (CQ), 156.8 (CQ), 129.9 (CQ), 127.9 (CH_{ar}, 2′,6′), 115.7 (CH_{ar}, 3′,5′), 103.0 (CQ), 95.5 (CH_{ar}, 6), 94.5 (CH_{ar}, 8), 79.0 (CH-2), 68.1 (CH_2O), 60.3 (CH_2CH_3), 43.1 (CH_2-3), 34.1 (CH_2C=O), 32.4 (CH_2), 27.6 (CH_2), 24.1 (CH_2), 14.2 (CH_3).

*2.3.3. Ethyl 4-{[5-hydroxy-2-(3-hydroxy-4-methoxyphenyl)-4-oxo-3,4-dihydro-2H-chromen-7-yl] oxy}butanoate (**6**)*

Hesp (4′-methoxy-3′,5,7-trihydroxyflavanone, 2 g, 6.6 mmol) was reacted with ethyl 4-bromobutyrate (1.95 g, 10 mmol) under the conditions described in Table 1. The cooled reaction mixture was poured onto ice and the pH was adjusted to 2 with 10% HCl. The EtOAc/H_2O work-up gave the target compound (**5**) as an oil (2.1 g, 80%) which was used without further purification.

^{1}H NMR ($CDCl_3$, 250 MHz): δ1.23 (t, J = 7.1 Hz, 3H, CH_3), 2.01 (quintuplet, J = 6.8 Hz, 2H, CH_2), 2.46 (t, J = 7.3, 2H, CH_2COOEt), 2.74 (dd, J = 17, 3 Hz, 1H, H-3b), 3.09 (dd, J = 17, 12.8 Hz, 1H, H-3a), 3.88 (s, 1H, OCH_3), 4.04 (t, J = 6.3 Hz, 2H, CH_2O), 4.12 (q, J = 7.1 Hz, 2H, CH_2), 5.30 (dd, J = 12.8, 3 Hz, 1H, H-2), 6.04 (m, 2H, H_{ar}, 6, 8), 6.90 (m, 2H, H_{ar}, 5′, 6′), 7.02 (d, J = 1.9 Hz, 1H, H_{ar}, 2′).

^{13}C NMR ($CDCl_3$, 63 MHz): δ196.5 (C=O), 174.8 (COO), 167.1 (CQ), 163.7(CQ), 163.0 (CQ), 147.9 (CQ), 146.4 (CQ), 131.5 (CQ), 117.6 (CH_{ar}, 6′), 113.2 (CH_{ar}, 2′), 111.1 (CH_{ar}, 5′), 102.7 (CQ), 94.8 (CH_{ar}, 6), 93.0 (CH_{ar}, 8), 79.0 (CH-2), 67.1 (CH_2O), 60.3 (CH_2CH_3), 55.0 (OCH_3), 42.6 (CH_2-3), 29.8 (CH_2C=O), 24.1 (CH_2), 14.2 (CH_3).

*2.3.4. Ethyl 4-{[5-hydroxy-2-(3-hydroxy-4-methoxyphenyl)-4-oxo-3,4-dihydro-2H-chromen-7-yl]oxy}hexanoate (**8**)*

Hesp (4′-methoxy-3′,5,7-trihydroxyflavanone, 3.02 g, 10 mmol) was reacted with ethyl 6-bromohexanoate (3.35 g, 15 mmol) as described above. The purification by flash chromatography using diethyl ether:pentane (8:2) gave the target compound (**7**) as a yellow solid (2.8 g, 65%).

^{1}H NMR ($CDCl_3$, 300 MHz): δ1.27 (t, J = 7.2 Hz, 3H, CH_3), 1.48 (quintuplet, J = 7.2 Hz, 2H, CH_2), 1.75 (m, 4H, CH_2CH_2), 2.34 (t, J = 7.3, 2H, CH_2COOH), 2.79 (dd, J = 17, 3 Hz, 1H, H-3b), 3.08 (dd, J = 17, 12.8 Hz, 1H, H-3a), 3.93 (s, 1H, OCH_3), 3.98 (t, J = 6.4 Hz, 2H, CH_2O), 4.16 (q, J = 7.2 Hz, 2H, CH_2), 5.34 (dd, J = 12.8, 3 Hz, 1H, H-2), 6.04 (d, J = 2.3 Hz, 1H H_{ar}, 6), 6.06 (d, J = 2.3 Hz, 1H H_{ar}, 8), 6.90 (d, 1H, J = 8.3 Hz, H_{ar}, 5′), 6.94 (dd, J = 8.3, 1.9 Hz, 1H, H_{ar}, 6′), 7.06 (d, J = 1.9 Hz, 1H, H_{ar}, 2′), 12.02 (s, OH).

^{13}C NMR ($CDCl_3$, 63 MHz): δ196.3 (C=O), 174.0 (COO), 167.8 (CQ), 164.4 (CQ), 163.2 (CQ), 147.4 (CQ), 146.3 (CQ), 131.9 (CQ), 118.5 (CH_{ar}, 6′), 113.1 (CH_{ar}, 2′), 111.0 (CH_{ar}, 5′), 103.4 (CQ), 95.8 (CH_{ar}, 6), 94.9 (CH_{ar}, 8), 79.3 (CH-2), 68.6 (CH_2O), 60.7 (CH_2CH_3), 56.4 (OCH_3), 43.5 (CH_2-3), 34.5 (CH_2C=O), 28.9 (CH_2), 25.9 (CH_2), 24.9 (CH_2), 14.6 (CH_3).

*2.3.5. 4-{[5-Hydroxy-2-(4-hydroxyphenyl)-4-oxo-3,4-dihydro-2H-chromen-7-yl]oxy}butanoic acid (**1**) or **h4-Nar***

An ice-cooled 1 M LiOH solution (10 mL) was added dropwise to a solution of (**6**) (1.22 g, 3.15 mmol) in methanol (10 mL) at 0 °C and the mixture was allowed to reach room temperature. After stirring for 2 h the pH was adjusted to pH 2–3 with 10% HCl. The aqueous phase was extracted with ethyl acetate (3 × 40 mL). The combined organic extracts were washed with water (50 mL) and brine (50 mL), dried ($MgSO_4$) and concentrated under reduced pressure. Flash chromatography using diethyl ether:pentane (8:2) as an eluent gave the desired compound (**2**) as white crystals (R_f = 0.24, 0.4 g, 45%, m.p. 172 °C).

^{1}H NMR (CD_3OD, 300 MHz): δ2.06 (quintuplet, J = 6.8 Hz, 2H, CH_2),2.48 (t, J = 8.0 Hz, 2H, CH_2), 2.73 (dd, J = 17, 3 Hz, 1H, H-3b), 3.17 (dd, J = 17, 13 Hz, 1H, H-3a), 4.06 (t, J = 7.4 Hz, 2H, CH_2), 5.38 (dd, J = 13, 3 Hz, 1H, H-2), 6.06 (m, 2H, H_{ar}, 6, 8), 6.82 (d, J = 8.6 Hz, 2H, H_{ar}, 3′,5′), 7.33 (d, J = 8.6 Hz, 2H, H_{ar}, 2′,8′).

^{13}C NMR (CD_3OD, 63 MHz): δ197.9 (C=O), 174.4 (COOH), 168.3 (CQ), 165.2 (CQ), 165.0 (CQ), 164.5 (CQ), 130.9 (CQ), 129.3 (CH_{ar}, 2′,6′), 116.4 (CH_{ar}, 3′,5′), 116.3 (CQ), 96.1 (CH_{ar}, 6), 95.2 (CH_{ar}, 8), 80.3 (CH-2), 68.6 (CH_2O), 43.8 and 43.7 (CH_2-3), 30.6 (CH_2C=O), 25.4 (CH_2).

*2.3.6. 6-{[5-Hydroxy-2-(4-hydroxyphenyl)-4-oxo-3,4-dihydro-2H-chromen-7-yl]oxy}hexanoic acid (**3**) or **h6-Nar***

According to the procedure described above for compound (**2**), the intermediate (**8**) (2.2 g, 5.3 mmol) was treated with an ice-cooled 1 M LiOH solution (16 mL). Flash chromatography using diethyl ether: pentane (85:15) as an eluent gave a beige solid (R_f = 0.23) which was purified again by recrystallization from methanol to afford the desired compound (**3**) as white crystals (0.7 g, 34%, m.p. 144 °C).

^{1}H NMR ($(CD_3)_2CO$, 250 MHz): δ1.51 (quintuplet, J = 7.0 Hz, 2H, CH_2), 1.67 (quintuplet, J = 7.0 Hz, 2H, CH_2), 1.80 (quintuplet, J = 7.0 Hz, 2H, CH_2), 2.32 (t, J = 7.3, 2H, CH_2COOH), 2.75 (dd, J = 17, 3 Hz, 1H, H-3b), 3.20 (dd, J = 17, 13 Hz, 1H, H-3a), 4.07 (t, J = 6.4 Hz, 2H, CH_2), 4.97 (dd, J = 13, 3 Hz, 1H, H-2), 6.04 (m, 2H, H_{ar}, 6, 8), 6.90 (d, J = 8.5 Hz, 2H, H_{ar}, 3′,5′), 7.39 (d, J = 8.5 Hz, 2H, H_{ar}, 2′,8′), 12.13 (br s, OH).

2.4. Preparation of the conjugates

The haptens (**h4-Hesp**, **h6-Hesp**, **h4-Nar** and **h6-Nar**) were coupled to bovine serum albumin (BSA) for injection into rabbits and to swine Thyr for coating. The conjugation procedure was derived from that described in Riggle (1991) and Szurdoki, Szekacs, Le, and Hammock (2002). Briefly, tributylamine (17.3 μl, 0.072 mmol), isobutyl chloroformate (4.7 μl, 0.036 mmol) and hapten (0.036 mmol) were added to 1 mL of DMF at 4 °C and stirred in an ice bath for 30 min. The resulting activated hapten solution in DMF was added dropwise to the protein solution (BSA: 6.1 mg, 0.069 μmol or Thyr: 48.24 mg, 0.087 μmol) in 5 mL of a borate buffer (borate-boric buffer 0.2 M, pH 8.7). The mixture was stirred for 6 h at room temperature, dialysed against phosphate buffer saline (PBS: 0.01 M, pH 7.4, 0.9% NaCl) and then against distilled water. The hapten–protein conjugates were lyophilised and stored at −20 °C.

2.5. Matrix assisted laser desorption–ionisation mass spectrometry (MALDI-MS)

The mass spectra of the hapten-BSA conjugates were recorded in the linear mode with a Bruker Reflex III mass spectrometer equipped with a UV laser (337 nm). Samples (10 μM aqueous solutions) were mixed (1/1 v/v) with matrix solutions (sinapinic acid or α-cyano-4-hydroxy-cinnamic acid, 10 mM in water/acetonitrile containing 0.1% trifluoroacetic acid) and 1 μl of the mixture was applied on a stainless steel target and left to dry at room temperature. Spectra were acquired in the external calibration mode using BSA as a reference. The hapten/carrier protein ratio of each conjugate was estimated by measuring the change in molecular weight due to covalent hapten attachment through the lysine ε-amino groups of BSA: hapten number = $(MW_{conjugate} - MW_{BSA})/MW_{hapten}$. For **h4-Nar** MW was considered as 340, for **h6-Nar** MW = 368, for **h4-Hesp** MW = 370, and for **h6-Hesp** MW = 398.

2.6. Immunisation of the rabbits

Immunisation was performed on germ- and pathogen-free New Zealand rabbits from Millegen (Labège, France). Rabbits were ear-sampled before immunization to collect pre-immunserum. During the immunization procedure performed subcutaneously at multiple points, 500 μg of hapten–BSA conjugates were injected at each injection. The first three injections were performed at one-week intervals. Two additional injections then followed after a three-week interval. Fifty millilitre were collected one week after the last injection. After blood clotting at 4 °C for 24 h, serum was centrifuged at 3000*g* for 10 min at 4 °C. Sera were stored at −20 °C in small aliquots. For each hapten–BSA conjugate, two rabbits were injected and only one serum was retained based on a cross-test (direct binding of the antibody onto the coated conjugate) checking for antibody titre. Titres of all antisera obtained against h4- or h6-**Hesp** and Nar were compared using the homologous coupled molecule (Thyr-**h-Hesp** was used with anti-**h-Hesp** and Thyr-**h-Nar** was used with the anti-**h-Nar**, the immobilized antigens exhibiting an homologous length of the spacer arm). OD were compared for a 1/10,000 2nd antibody dilution at 490 nm.

2.7. Validation of the assays

2.7.1. Origin of the samples

Mice blood samples were collected between 02:30 pm and 03:00 pm on animals starved from 08:00 pm the day before and fed a single meal the following morning at 08:30 am. The diet was a semi-synthetic diet enriched with 0.02%, 0.05% and 0.1% hesperidin or 0.02% naringin. 24 h-urine samples were collected from mice fed for 18 weeks on a diet enriched either with 0.02% hesperidin or 0.02% naringin.

2.7.2. Hydrolysis of flavanone glucuronides

Hesp and **Nar**-glucuro and sulfo-conjugates contained in the food matrix and in the plasma, respectively, were hydrolysed using β-glucuronidase aryl-sulfatase from *Helix pomatia* (Roche

Table 2
Optimal conditions for each assay procedure.

Antisera		Anti-**h4-Hesp**	Anti-**h4-Nar**
Coating flavanone-Thyr (μg mL^{-1})		0.8	0.8
Specific antibody dilution		1/20,000	1/20,000
2nd antibody dilution		1/10,000	1/10,000
Standard curve limit (ng mL^{-1})		125–0.06	125–0.06
IC_{50} ng mL^{-1}		*1.95*	*0.98*
Detection limit (ng mL^{-1})		0.24	0.12
Slope		0.0805 ± 0.009	0.0778 ± 0.08
Intra-assay variation (%) n = 22	High (1000 ng mL^{-1})	9.06	10.01
	Low (5 ng mL^{-1})	11.42	10.03
Inter-assay variation (%) n = 10	High (1000 ng mL^{-1})	10.87	9.24
	Low (5 ng mL^{-1})	10.18	12.33

IC_{50}: Concentration of the analyte required for 50% inhibition of the antibody binding to the coating antigen.

Diagnostic). The hydrolysis recovery ratio was monitored as described in Bennetau-Pelissero et al. (2003).

2.7.3. Flavanone extraction from plasma

Free flavanone aglycones were extracted using a liquid–liquid extraction with acidified ethyl acetate (1% HCl). After evaporation to dryness, the extracts were stored at −20 °C until assay. In addition, three external standards of extraction, i.e. control plasma containing either **Hesp** or **Nar** in known quantities were run in parallel to the sample extraction to check the extraction recovery.

2.7.4. Extraction procedure for mice diets

The extraction procedure for diet samples was as described by Bennetau-Pelissero et al. (2003) and implied a re-suspension of 1 g of finely grounded diet into 100 mL of distilled water with vigorous shaking and sonications. The procedure then included

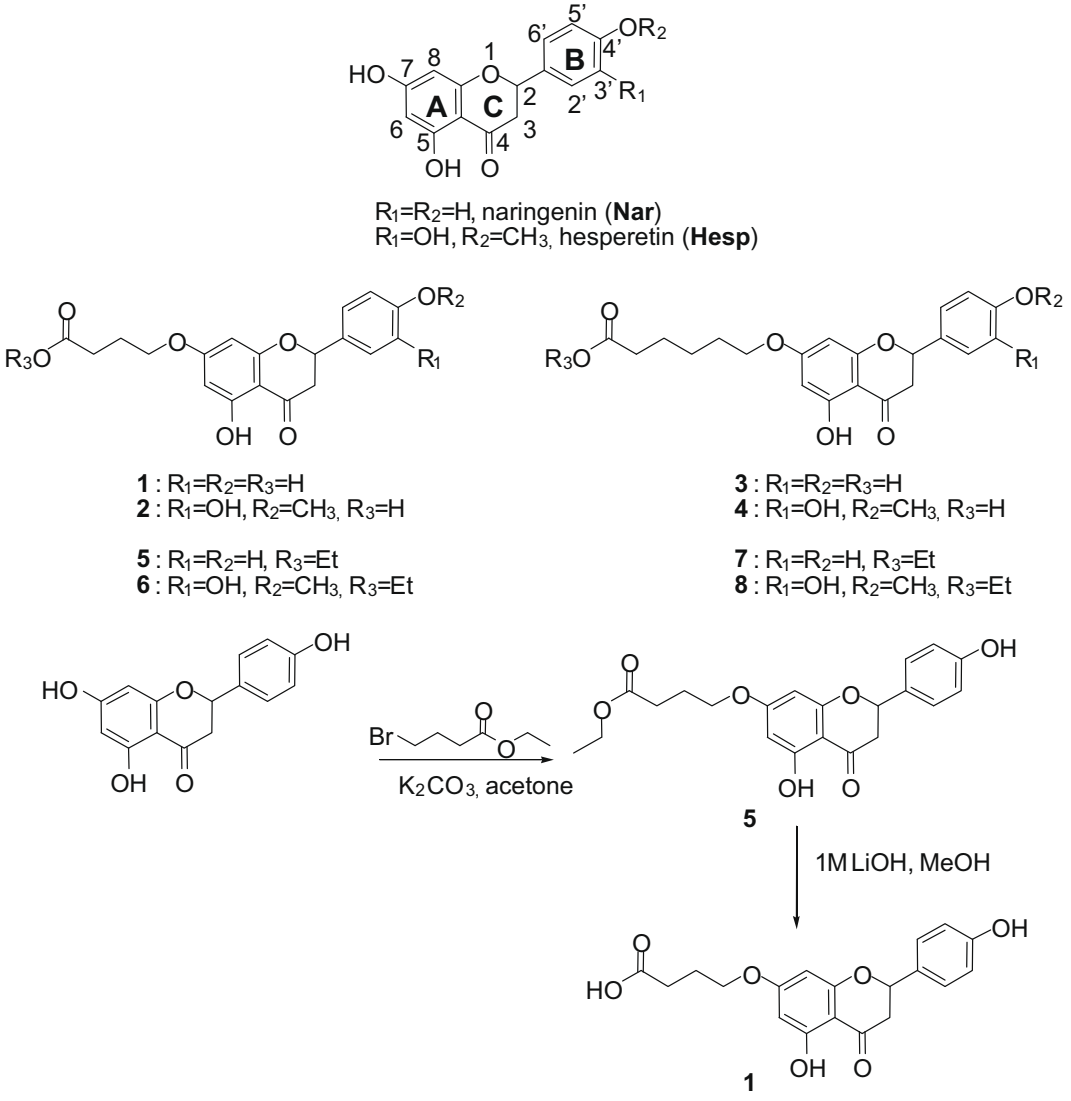

Fig. 1. Structure and synthesis of Naringenin and Hesperetin haptens.

an enzymatic hydrolysis with β-glucuronidase-aryl sulfatase (from Roche) before ethyl acetate extraction. This enzyme was demonstrated to hydrolyse glycosides. The recovery was monitored as previously described.

2.7.5. Assay procedure

Coating of the wells was performed overnight at 4 °C with the homologous hapten (with the corresponding spacer arm) coupled to Thyr (i.e. Thyr-**h**-**Hesp** and Thyr-**h**-**Nar** for **Hesp** and **Nar**, respectively) (200 μL/well). The conjugates were dissolved in a carbonate buffer (0.05 M, pH 9.6). Wells were then saturated at 37 °C for 30 min with PBS–Tween–PS–DMSO (PBS containing 1 mg mL^{-1} BSA, 0.05% Tween 20 and 1% DMSO) in order to avoid further unspecific binding. Then, plates were washed three times with PBS–Tween–DMSO (PBS, 0.05% Tween 20, 1% DMSO). Twelve serial dilutions (1 in 2) from 125 to 0.06 ng mL^{-1} of the appropriate analyte in PBS–Tween–PS–DMSO were prepared for the standard curves (100 μL/well). Specific antibodies in PBS–Tween–PS–DMSO were then added (100 μL/well). The competition incubation lasted for 2 h at 37 °C. The plates were washed three times with PBS–Tween–DMSO. The secondary antibody (goat anti-rabbit IgG coupled to horseradish peroxidase from Dako) was added as 200 μL/well in PBS–Tween–PS–DMSO. The incubation was performed at 37 °C for 30 min. Peroxidase activity was revealed by adding 200 μL/well of substrate solution (0.005 M *o*-phenylenediamine, 0.00025% H_2O_2 in citrate-phosphate buffer (0.15 M, pH 5.0)). The enzymatic reaction lasted for 30 min at room temperature and was stopped with 4 M H_2SO_4 (50 μL/well). ODs were read at 490 nm. The standard curves were expressed as log[flavanone] = f((Bi − Blank)/(Bo − Blank))* 100, where Bi is the OD of the sample or of the standard wells, Bo is the positive control, i.e. the ODmax obtained by making the antibody to react on the coating without any competitor added. Blanks are the negative controls obtained in wells regularly coated but without adding the primary antibody. The assays demonstrated that anti-h4-haptens gave the best results in homologous conditions. For these haptens and antibodies, the best assay conditions allowing the best sensitivity, are presented in Table 2. This is also shown in Fig. 2A.

2.7.6. Cross-reactivity tests

The cross-reactivity of an antibody is defined as its ability to react with a molecule distinct from the one it was initially raised against. The cross-reactivities of the antibodies were tested using a competitive procedure. Following the previously optimised

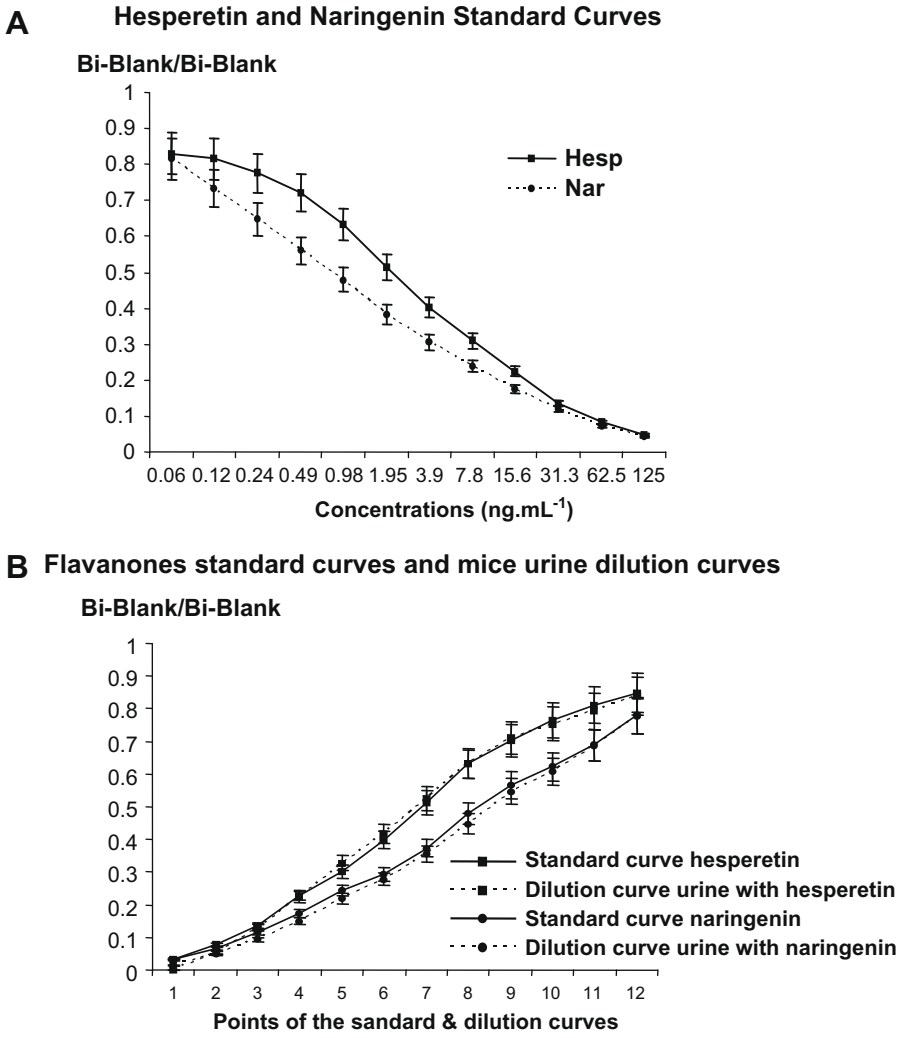

Fig. 2. In both figures points are the mean of duplicates. The equation of the competitive assay is Log [**Nar** or **Hesp** concentrations] = f(Bi − NC)/(Bo − NC) * 100, where Bi is the optical density of the sample or the standard, NC is the negative control obtained without the antibody, Bo is the total binding without any competitor. Analyte-antibody combinations are listed in Table 2. (A) Standard curves obtained with the two antibodies. (B) Standard curves obtained with each of the two antibodies and urine dilution curves. One urine sample contained 6979.35 ng mL^{-1} Hesperetin, after enzymatic hydrolysis and the other contained 10364.00 ng mL^{-1} Naringenin, after the same hydrolysis.

Table 3
Specificity tests.[a]

Compounds tested	Anti-**h4-Hesp**	Anti-**h4-Nar**	
	on h4-**Hesp-Thyr**	on **h4-Nar–Thyr**	on **h6-Nar–Thyr**
Genistein	0.007	0.375	
Daidzein	0.004	0.062	
Naringenin	0.5	100	
Hesperetin	100	1.5	
Naringin	<0.001	<0.001	
Hesperidin	<0.001	<0.001	
8-Prenyl Naringenin	0.031	8	
Isosakuranetin	4	0.025	
Eriodictyol	1	26.7	15
Liquiritigenin	0.03	50	31
Chrysin	0.0156	0.0019	
(−)-Homoeriodictyol	1.5	3	
Flavanone	0.12	0.25	
Luteolin	0.0156	0.1	

[a] Expressed as percentages of cross reaction in comparison to the homologous standard curves.

conditions (Table 2), the antibodies were challenged with **h4-Hesp** or **h4-Nar** coupled to Thyr as the coating and to serial dilutions of other compounds diluted in PBS–Tween–PS–DMSO as competitors. Eight concentrations of the various competitors were tested (from 50 μg mL^{-1} to 0.003 μg mL^{-1}) with a 4-fold decrease between each concentration. Other cross-reactivity tests were performed with the anti-**h4-Nar** in attempt to obtain lower cross-reactivity. These tests reside in heterologous competition between the free competitors and Thyr-**h6-Nar** as the immobilized coating. For these tests the antibody was at a concentration of 1/400,000 with a coating at 0.5 μg mL^{-1}, a secondary antibody dilution of 1/10,000 and a peroxidase revelation of 10 min at 37 °C.

2.8. Validation tests

The assays for **Hesp** and **Nar** were undertaken on plasma samples from mice fed on semi-synthetic diets based on 73% wheat starch, 15% casein, 6% mineral mixture (AIN 93 M), 1% vitamin mixture (93VX), and 5% corn oil. These semi-synthetic diets were enriched or not with hesperidin (**Hesp**-glycoside, 0.02%) or naringin (**Nar**-glycoside, 0.02%). To check for the absence of cross-reactions with **Hesp** and **Nar** metabolites, serial dilutions of urine samples collected on mice fed with the corresponding semi-synthetic diet were compared to the **Hesp** and **Nar** standard curves (Fig. 2B). Data obtained using the new ELISA techniques on plasmas were compared to values obtained on the same samples by the HPLC method coupled to coularray detector (Table 4).

2.9. HPLC analysis

HPLC analysis was performed using a system consisting of two pumps (Model 580, ESA, Chelmsford, USA) for high pressure gradients, a temperature-controlled autosampler (Gilson, Villiers-le-Bel, France), a 150 × 4.6 mm Hypersil BDS C18–5μ column (Touzard et Matignon, Les Ulis, France), a thermostatic chamber and an eight-channel Coularray detector (model 5600, Eurosep, Cergy, France). Mobile phases consisted of a 30 mmol/L NaH_3PO_4 buffer (pH 3) containing 20% acetonitrile (A) or 40% acetonitrile (B). Separation was achieved using a gradient elution (35 °C, 0.8 mL/min): 0–3 min: 100% A, 3–30 min: linear gradient from 100%A to 100%B, 30–35 min: 100%B, 35.01–45 min: 100%A. Potentials were set at 25–350–480–550–650–750–850 mV (with Pd as the reference). **Hesp** and **Nar** were quantified using the sums of the areas obtained on the electrodes 2, 3 and 4, 5, 6, respectively.

3. Results and discussion

3.1. Immunogen design

Specificity and selectivity of an antibody is crucial for immunologic assays since the comparison to a standard curve is only relevant if the compound detected in the sample is the same. Otherwise the assay is only semi-quantitative. **Hesp** and **Nar** are small molecules and, thus, are not immunogenic. Design and preparation of the corresponding haptens and the hapten-protein conjugates are necessary for efficient antibody generation. Previous studies, demonstrated that the hapten chemical structure has a relevant influence on the process of antigen–antibody recognition and thus on the specificity and the sensitivity of an immunoassay (Bennetau-Pelissero et al., 2000; Le Houerou et al., 2000). **Hesp** and **Nar** have a common chemical structure and differ by functional groups present on the B ring (Fig. 1). The high hydroxylation degree of the flavanone skeleton offers the opportunity for easy introduction of an *O*-carboxyalkyl spacer arm. So, the linkers bearing a carboxylic function required for covalent coupling to carrier proteins were introduced at the C7-OH position (ring A) in order to exhibit the flavanone skeleton and the specific recognising sites to allow the best discrimination between **Hesp** and **Nar**. The linker length variation (4 carbon atoms for haptens **1** and **2**, and 6 carbon atoms for haptens **3** and **4**, Fig. 1) for both compounds was expected to improve the specificity of the immunoassay in heterologous combination of the coating and the immunizing haptens. Our previous experience led to us developing polyclonal antibodies, as they previously demonstrated to be more specific than monoclonal when used against small molecules. Indeed, within the flavonoid

[b] HPLC was performed with a coulometric detection (Coularray).

family all molecules are strongly structurally related. Therefore specific recognition of this kind of molecule needs the recognition of different combined epitopes on the molecule by different IgG. This can be achieved using polyclonal antibodies. In this case, the specificity results from the combination of different IgG towards different portions of the antigen used at a concentration avoiding cross-reactivities with one particular epitope rather than another. Each combination is unique and is characteristic of each individual rabbit.

3.2. Synthetic work

The C7-hydroxyl group of **Hesp** and **Nar**, which was selected as the site for linker attachment, is the most reactive hydroxyl functions available. For this reason, it can be easily region selectively alkylated without using any protective group. Thus, all haptens were prepared in the same two steps. The synthesis of hapten **1** is outlined in Fig. 1 and the experimental conditions for all haptens **1–4** are summarised in Table 1. In the first step, the corresponding ethyl esters **5–8** were obtained in good yields with a classic Williamson ether synthesis. A stronger base was needed in the case of **Hesp** derivatives. In the saponification step the yields were lower. Ester hydrolysis was not completed. For **Hesp** derivatives, the formation of transesterification products was observed and for hapten **4**, the yield of the reaction was improved by using acetonitrile.

3.3. Analysis of the BSA conjugates

Haptens (**1**), (**2**), (**3**) and (**4**) were then reacted with a carrier protein, i.e. BSA, to produce immunogenic constructions in order to obtain anti-**Hesp** and anti-**Nar** antibodies. The molecular ratios of haptens to protein were estimated by MALDI-MS. The hapten-protein ratios in all cases were nearly the same: approximately 10 haptens per carrier protein. This density was considered to be sufficient to obtain a good antibody quality (Malaitsev & Azhipa, 1993).

3.4. Immunization tests

In Table 2 it appears that the titres of the antibodies were rather similar since they were both used at the same dilution (1/20,000). This means that the immunization protocol was suitable for the generation of antibodies to flavonoids, to be used in ELISA tests.

3.5. ELISA tests

The optimal conditions of the two ELISAs are shown in Table 2. Before ELISAs, the recovery ratios registered in parallel to all tested samples, showed recovery between 98% and 100%. For each conjugate of **Hesp** and **Nar**, two antibodies were generated, selected for their relative sensitivity and the best were used thereafter. The standard sigmoid curves obtained for the best antibodies (anti-**h4-Hesp** and anti-**h4-Nar**) and the conditions are presented in Fig. 2A. Anti-**h4-Nar** allows the best sensitivity (IC_{50} at 0.98 ng mL^{-1}), and anti-h4-Hesp exhibits an IC_{50} at 1.96 ng mL^{-1}. For **Hesp** and **Nar**, the best detection limits were 0.24 and 0.12 ng mL^{-1}, respectively. This is correlated to a weaker specificity for anti-**h4-Nar**. This is in accordance with literature (Avrameas, 1992). It must be noted that the sensitivity reached here was obtained with a Thyr-h-flavanone complex characterised by a ratio of 20 molecules of h-flavanone for 1 molecule of Thyr. In previous works (Bennetau-Pelissero et al., 2000, 2003; Le Houerou et al., 2000), it was shown that the sensitivity of an assay can be improved by reducing this coupling ratio. The present ELISAs present a good sensitivity and compare favourably with other analytical techniques. Indeed, Felgines et al. (2000) had a detection limit of 820 ng mL^{-1}, using HPLC coupled to UV detection (320 nm). In parallel, Harnly et al. (2006) had detection limits of 6 g mL^{-1} and 5 g mL^{-1} of **Hesp** and **Nar**, respectively using HPLC coupled to UV diode array detection. Kanaze, Kokkalou, Georgarakis, and Niopas (2004) obtained detection limits of 10 ng mL^{-1} for both **Hesp** and **Nar** using HPLC coupled to UV detection (288 nm). Only Franke, et al. (2002) reported better sensitivity using LC–MS with detection limits of 1.75 ng mL^{-1} and 0.05 ng mL^{-1} in urine and 0.2 ng mL^{-1} and 0.05 ng mL^{-1} in plasma for **Hesp** and **Nar**, respectively.

Intra and inter-assay variation coefficients were determined for both antibodies using either high (1000 ng mL^{-1}) or low concentrated solutions (5 ng mL^{-1}). Inter-plate variations were calculated as variation coefficients of measurements carried out on 11 microtitration plates. Intra-assay variations were calculated as the variation coefficients obtained on 22 values of the same sample. These variations were always below 11% (Table 2). Therefore these assays appeared to be as reliable as other physicochemical techniques (Felgines et al., 2000; Franke et al., 2002; Kanaze et al., 2004).

3.6. Cross-reactivity of the antibodies

The two antisera, anti-**h4-Hesp** and anti-**h4-Nar**, were tested against various other flavonoids for cross-reactivities (Table 3). For anti-**h4-Hesp**, only isosakuranetin presents a cross-reaction of 4%. There were no other significant cross-reactions. Isosakuranetin differs from **Hesp** because it lacks a hydroxyl group at the C3′ position. These structures are therefore rather similar and this could explain the low cross-reaction registered here. On the other hand, for anti-**h4-Nar** some significant cross-reactions were registered for liquiritigenin and eriodictyol (50% and 26.4% respectively). Cross-reactions with liquiritigenin may find their origin in the bounding between BSA and **h4-Nar**. Most likely, BSA produces steric hindrance towards the C5 position that lies in the vicinity of the C—O-linker. Since liquiritigenin differs from **Nar** by the occurrence of a hydroxyl group at the C5 position, it is likely that the antibodies cannot discriminate very well between the two molecules for this reason. One solution would be to harvest the polyclonal antibody using liquiritigenin but this would affect its titre and therefore its sensitivity. Fortunately, liquiritigenin occurs only in licorice and in specific medicinal herbs used in Chinese traditional medicine and it will be easy to avoid it on a regular basis. Eriodictyol, a major flavanone from lemon, presents an additional hydroxyl group at the C3′ position when compared to **Nar**. The observed cross-reaction seems hard to explain since previous works showed that polyclonal antibodies were quite powerful at discriminating molecules in such configuration. Again, the antibody can be harvested with eriodictyol at the expense of a loss of sensitivity. Another way to reduce cross-reactions is to perform heterologous competition using a coating molecule having another affinity with the antibody. Tests were performed with anti-**h4-Nar** on an immobilized Thyr-**h6-Nar**. Cross-tests previously showed that the affinity of the anti-**h4-Nar** was higher for Thyr-**h6-Nar** than for Thyr-**h4-Nar**. In these conditions cross-reactivities were reduced from 50% to 31% and from 26.4% to 15% for liquiritigenin and eriodictyol, respectively (Table 3). These cross-reactions can give fairly good assay results, considering that eriodictyol concentration in grapefruit is much lower than that of **Nar**. Therefore, the dilution needed to assay these types of samples or biological fluids will reduce the risk of miss-quantification.

3.7. Validation of the assays

Validation was undertaken on mouse and Human plasmas enriched with known quantities of **Hesp** and **Nar** (data not shown) as well as on specifically enriched semi-synthetic diets. A semi-

synthetic diet was enriched with 200 μg/g of Hesperidin, i.e. after hydrolysis, enriched with 96.7 μg/g equivalent Hesperetin. When treated in triplicates as previously described, our assay detected 96.22 ± 15.29 μg/g where 15.29 was the standard deviation. Another semi-synthetic diet was enriched with 200 μg/g of Naringin, i.e. after hydrolysis, enriched with 93.9 μg/g equivalent Naringenin. When treated in triplicates as mentioned in the technical section, our assay measured 102.90 ± 16.34 μg/g where 16.34 was the standard deviation. The results obtained were therefore in accordance with the expected data, and the lower specificity of the Naringenin assay could be seen when comparing the accuracy of the results obtained with the two assays.

Then several mouse plasmas were tested to check for the ability of the assay to detect **Hesp** and **Nar** in natural biological fluid samples. Data obtained on plasma from mice fed with a diet enriched with 0.02%, 0.05% or 0.1% hesperidin are presented in Table 4. There were three plasmas for each treatment and each determination was done in duplicate. As shown in Table 4, the flavanone concentrations in the plasma were strictly correlated with their concentration in the diet. Some interindividual variations were observed, as in the case of previously published results (Felgines et al., 2000; Franke et al., 2002). However there was a twofold increase between each group of Hesp plasma concentrations in agreement with the hesperidin proportions in the diets. Moreover, ELISA values were in close agreement with HPLC-Coularray values. It was possible to get highly concentrated urine samples from mice fed either with a 0.02% hesperidin or a 0.02% naringin-enriched diet. Urine sample were enzymatically hydrolysed and dilution curves were compared to draw a parallel between the corresponding standard curve and the biological fluid. The agreement was found to be excellent as shown in Fig. 2B. This demonstrated that the cross-reactions of the antibody with other urine constituents including **Hesp** and **Nar** metabolites were negligible and that the antibodies could be used for assays in biological fluids.

In conclusion, although **Hesp** and **Nar** are closely related molecules, it appeared here that the specificity obtained in similar conditions was not identical. **Hesp** is well-discriminated, and as demonstrated by the good concordance between the urine dilution curve and the **Hesp** standard curve, the cross-reactions with the parent compounds likely to be present in biological samples are very low. Fortunately, because eriodictyol and liquiritigenin are likely not to be present in large amounts in grapefruits and in biological fluids from subjects having had this food matrix, the cross-reactions observed with anti-**h-Nar** do not reduce the interest of the assay. Once again the good agreement between the urine dilution curve and the **Nar** standard curve shows the interest of the assay for biological samples. Using heterologous competition, it was demonstrated that the specificity of the Nar assay could be improved.

Acknowledgements

This work was funded by the PNRA (ANR program on food) through the AGRUVASC project and by the Aquitaine Region. We gratefully thank Russell Wallace and Zoé Tebby for careful reading of the manuscript.

Olive oil authentication
DNA-based markers
qRT-PCR

ABSTRACT

Olive oil authentication using DNA-based markers is becoming very important. qRT-PCR was an efficient tool in investigating the utility of PCR primers for olive oil authentication allowing to discard primers with low PCR efficiency. It also allows investigating of the relative effectiveness among four DNA isolation methods and therefore qRT-PCR would be useful for further optimisation of the DNA extraction protocols. The number of target molecules for the amplification of 80 bp amplicons was higher than that of 200 bp. Therefore the amplicon size should be optimised for olive oil authentication since the higher the number of templates the greater the probability of successful amplification. On conclusion, qRT-PCR is a useful tool in the development of molecular markers for olive oil authentication and it should be used for the optimisation of critical parameters such as the amplicon size and the DNA extraction method.

1. Introduction

Olive (*Olea europaea* L. subsp. *europaea* var. *europaea*) is one of the most ancient crops of the Mediterranean basin. The main use of this crop is the production of olive oil but its drupes can also be consumed as table olives. Olive oil has been traditionally very important in all the Mediterranean area but its consumption is increasing throughout the world due to its importance in the diet and its beneficial effect on health.

Food authenticity and traceability have become very important in the last years to allow consumers to perform informed choices about the foods they buy and eat. There are several ways in which food can be misdescribed including the substitution of one ingredient by a similar but cheaper one and over-declaring a quantitative ingredient. Accordingly, olive oil authentication has become very important.

Several Protected Denomination of Origin (PDO) olive oil regions have been established by legislation to ensure both producer's profits and consumer's rights. In this context, it is mainly the identification of the olive cultivar used for the oil production which is of importance for authentication (Luykx & van Ruth, 2008) since the contribution of cultivars is known for each designation.

The authenticity of olive oil has been addressed using different techniques such as proton transfer reaction mass spectrometry (PTR-MS), nuclear magnetic resonance spectroscopy (NMR) or high performance liquid chromatography (HPLC) among others (Luykx & van Ruth, 2008). However, the chemical composition of olive oil may differ among seasons and growing areas. Besides, investigations concerning the origin and authenticity of olive oil through the chemical analysis of different oil's components have shown that no single known parameter could detect the presence of hazelnut and almond oils in olive oil, in percentages lower than or equal to 5% (Christopoulou, Lazaraki, Komaitis, & Kaselimis, 2004). Consequently chemical analyses *per se* are not sufficient to assure olive oil authenticity.

This has promoted a growing interest towards the application of DNA-based markers since it is independent from environmental conditions. Thus, specific protocols for DNA isolation from olive oil have been developed (Breton, Claux, Metton, Skorski, & Berville, 2004; Busconi et al., 2003; Consolandi et al., 2008; De la Torre, Bautista, Cánovas, & Claros, 2004). Besides, different types of DNA markers including RAPDs (Belaj, Trujillo, de la Rosa, Rallo, & Gimenez, 2001; Doveri, O'Sullivan, & Lee, 2006), AFLPs (Belaj, Rallo, Trujillo, & Baldoni, 2004), SCARs (Busconi et al., 2003; De la Torre et al., 2004; Doveri, O'Sullivan, & Lee, 2006), SNPs (Doveri, O'Sullivan, & Lee, 2006) and microsatellites (Breton et al., 2004; Diaz, De la Rosa, Martin, & Rallo, 2006) have been applied to cultivar identification or olive oil traceability. A summary of PCR-based methods applied in the authentication of olive plant origin has been recently reviewed (Mafra, Ferreira, & Oliveira, 2008).

Whatever the DNA isolation method, tiny amounts of degraded DNA are obtained when isolating DNA from oil samples. Because of their low detection limits, PCR and the adapted kinetic qRT-PCR (real-time quantitative PCR) have been used extensively for the

doi:10.1016/j.foodchem.2009.05.012

detection and quantification of nucleic acids (Freeman, Walker, & Vrana, 1999). However, the usefulness of the PCR technique for traceability purposes depends on the quality and quantity of the isolated DNA. At the detection limits of an assay, mathematical models (Taberlet et al., 1996) and experimental evidence (Morrison, Weis, & Wittwer, 1998) have shown that nucleic acids are detected inconsistently and quantified imprecisely. Considering the tiny amounts of DNA isolate from olive oil, the DNA isolation method needs optimisation in order to obtain enough DNA quantity (Breton et al., 2004). Consequently, comparison between different DNA isolation methods is crucial in order to be successful in olive oil authentication.

Besides, there are other factors that may affect the application of the DNA technology for olive oil authentication. DNA technology should rely on amplification products smaller than 200 bp in food products where a high degradation of DNA may occur (Hupfer, Hotzel, Sachse, & Engel, 1998; Unseld, Beyermann, Brandt, & Hiesel, 1995), but the size of the amplifiable DNA has not been considered for olive oil authentication.

Finally, olive is an allogamous wind-pollinated species and therefore DNA isolated from olive oil represents a composite profile of the maternal alleles juxtaposed with alleles contributed by the pollen donors (Doveri, O'Sullivan, & Lee, 2006). Cytoplasmic DNA is maternally inherited and thus it is not affected by the pollen donors. Therefore, the isolation of this DNA type from olive oil should be addressed as a first step towards its use in olive oil traceability.

The aim of this present work was to use qRT-PCR as a tool in the development of molecular markers for olive oil authentication and to identify critical aspects which should be optimised for this purpose.

2. Material and methods

2.1. DNA isolation

DNA from the olive cultivar 'Picual' was isolated from young leaves following the method described by Belaj et al., 2001. Isolation of DNA from one commercial 'Picual' monovarietal oil was carried out by using four different protocols.

2.1.1. CTAB based method (Doyle, 1991)

To 1 ml of a homogenised oil sample, 500 μl of pre-warmed (60 °C) CTAB extraction buffer (2% CTAB, 1.4 M NaCl, 50 μM DTT, 20 mM EDTA, 100 mM Tris–HCl, pH 8.0) were added, mixed and incubated for 30 min at 60 °C. After addition and mixing of 500 μl of cold chloroform (C):isoamyl alcohol (I) (24:1) the mixture was centrifuged at 20,000*g* for 30 min, 4 °C, and the upper phase was transferred to a new tube. This step was performed once again to obtain a clearer supernatant. For DNA precipitation, 1 volume of cold isopropanol was added, mixed smoothly by inverting the tube and kept at −20 °C overnight. The supernatant was discarded after centrifugation (30 min, 4 °C, 20,000*g*). The pellet was then washed with 500 μl of 70% v/v ethanol/water, centrifuged (30 min, 4 °C, 20,000*g*) and dried.

2.1.2. Hexane method (Consolandi et al., 2008)

One millilitre of oil sample and 500 μl of hexane were pipetted into a 2 ml microcentrifuge tube, vortexed vigorously for 5 min and centrifuged (15 min, 4 °C, 20,000*g*). The oily supernatant was transferred to a fresh 2 ml tube and mixed with 400 μl lysis buffer (50 mM Tris pH 8.5, 1 mM EDTA, 0.5% v/v Tween 20) and 2 μl of 10 mg/ml Proteinase K. The same reagents were also added to the centrifugation pellet. Both samples were incubated at 48 °C for 2 h and centrifuged (30 min, 4 °C, 20,000*g*). The oily upper phase and the two aqueous phases were each transferred to a new microtube, avoiding contact with the oil–water interphase and sediment, and then heated to 95 °C to inactivate Proteinase K. The DNA was precipitated by mixing samples with 500 μl of cold absolute isopropanol, incubating them at −20 °C overnight, followed by centrifugation (30 min, 4 °C, 20,000*g*) and discarding of liquid phases. The residue of each tube was washed with 500 μl of 70% ethanol, centrifuged (30 min, 4 °C, 20,000*g*) and dried at 36 °C for 15 min.

2.1.3. CTAB–hexane method

The extraction was carried out in a 2 ml microtube by adding 500 μl of pre-warmed CTAB extraction buffer to a mixture of 500 μl of hexane and 1 ml of olive oil. The sample was shaken vigorously, incubated at 60 °C for 30 min and centrifuged (30 min, 4 °C, 20,000*g*) and aqueous phase was then transferred to a new tube. Precipitation and washing of DNA was completed as described in the CTAB based method.

2.1.4. CTAB–hexane–chloroform method

This method is a modification of the previous one, but, in this case, half the volumes of oil (500 μl), CTAB lysis buffer (250 μl) and hexane (250 μl) were mixed in a 2 ml microtube and incubated at 60 °C for 30 min. Cold C:I (24:1) was then added (500 μl), the mixture centrifuged (30 min, 4 °C, 20,000*g*) and 1 ml of the upper part of the solution was transferred to new tube and mixed with a volume of chloroform:isoamyl alcohol (24:1). After centrifugation (30 min, 4 °C, 20,000*g*), the aqueous phase was transferred to a microtube. Prior to precipitation and washing of DNA performed as in the CTAB base method, 10–20 μg/ml linear acrylamide (Ambion) were added to the sample to improve DNA recovery.

Dried DNA pellets obtained by each method were resuspended in 25 μl of 0.1 × TE buffer/ml of oil. Four independent extractions of 1 ml of oil, or eight extractions of 500 μl of oil (CTAB–hexane–chloroform method), were carried out for each oil sample. DNA of the replicates was pooled in a single tube for PCR reactions.

2.2. Oligonucleotide primers

In order to asses the quantity and length of the different types of DNA extracted from all the samples, primers pairs for amplification of specific cytoplasmic and nuclear DNA fragments of (approximately) 80 and 200 bp were designed from *O. europaea* sequences available in GenBank (Table 1). The PCR primers were designed using the Primer Express software (Applied Biosystems, Foster City, CA, USA), in accordance with the criteria required for qRT-PCR primer design. The primers were synthesised by TAGN (Gateshead, United Kingdom).

2.3. Quantitative real-time PCR (qRT-PCR) amplification

For qRT-PCR amplification 2.5 μl of DNA was added to 7.5 μl of milliQ water, 12.5 μl of 2X SYBR Green™ Master Mix (Applied Biosystems), 2.5 μl of a mixture of 2 μM of each (forward and reverse) primer, for each primer pair. Three duplicate reactions were used for each sample, and each set included template controls containing water to check for contamination in the reaction components. The qRT-PCR amplifications were conducted using an ABI PRISM® 7000 Sequence Detection System (Applied Biosystems, Foster City, CA, USA), with thermocycling initiated by 10 min of initial denaturation at 94 °C followed by 40 cycles (94 °C for 15 s; 60 °C for 60 s) with a single fluorescent reading (SYBR Green I chemistry) at the end of each cycle. After the amplification, a dissociation protocol was performed to estimate the melting point (T_m) curves. The threshold cycle (Ct) was calculated by the ABI PRISM 7000 software after removing the effect of background (β_0).

Table 1
Sequences of primers pairs for specific amplification of chloroplastic and nuclear DNA fragments, size of amplicons, and source sequence used for designing them.

Primer	Forward 5′–3′	Reverse 5′–3′	Size (bp)[a]	SCF	GenBank accesion
C4-80	GGTGTTATTCCCGTGGCTTCAG	ACGGAATCATCCCCAAAGATCTC	80	0.96	AJ001766
C4-200	AAAGGGCGATGCTACCATATTGA	GGGATTCGCAGATCTTCCAGAC	182	2.19	AJ001766
N3-80	GTTCGCCAAAAGGACCGACAT	GCCAGACATGGTGCAGCAGTT	83	1	AJ416321
N3-200	TACACCACGGTCATGCAAGTCC	TGGCGAACAGAAGACCGATAATG	193	2.33	AJ416321

[a] SCF: size calibration factor = A_{si}/A_{sref}, where A_{si} is the number of base pairs of the amplicon *i*, and A_{sref} is the number of base pairs of amplicon N3-80.

2.4. Estimation of the PCR efficiencies

Concentration gradients of genomic leaf DNA obtained as described above, were used for generating the calibration curves. Each dilution reaction was set up in triplicate. The Ct values were plotted *vs* the concentrations (logarithmic value) of the input DNA, and parameters of the linear regression curves were used for calculating the efficiencies of each primer according to the equation $E = 10^{-1/b}$, where b is the slope of the curve.

2.5. Initial fluorescence (F_0) calculation

Initial fluorescence (F_0) was calculated according to the equation: $F_t = \beta_0 + F_0 \times E^{Ct}$ since F_0 is a good estimator of the input number of molecules for each amplicon type (Rutledge, 2004), where F_t is threshold fluorescence value, β_0 is the background, E is the efficiency of the primer, and Ct is the threshold cycle. As the amount of SYBR Green I dye bound to double stranded DNA is dependent on amplicon size, in order to compare fluorescence of amplicons differing in the number of base pairs, F_0 was corrected by a size calibration factor (SCF), $F_0^* = F_0/\text{SCF}$ being SCF = A_{si}/A_{sref}, where A_{si} is the number of base pairs of the amplicon *i*, and A_{sref} is the number of base pairs of amplicon N3-80 (Table 1), set as reference.

3. Results and discussion

3.1. Utility of qRT-PCR in the development of molecular markers for olive oil authentication

A great effort has been conducted during the last decade towards the identification of olive cultivars using molecular markers. At present SSR are the markers of choice for cultivar identification (De la Rosa, James, & Tobutt, 2002; Diaz et al., 2006; Diaz et al., 2007). Previous works on olive oil authentication have suggested the use of microsatellite markers for DNA tracking due to their small size (200–300 bp) (Pasqualone, Montemurro, Caponio, & Blanco, 2004). At first sight, SSRs developed for cultivar identification would seem to be the obvious choice when their amplicon size is adequate. Despite their utility for cultivar identification, primer pairs showing a good performance when tested on DNA isolated from leafs might not be suitable if the PCR efficiency is too low for producing detectable amounts of amplicons from very small input DNA.

To demonstrate this we used the primers developed to amplify the locus EMO3 used for cultivar identification (De la Rosa et al., 2002). The performance of EMO3 primers was assessed using qRT-PCR and DNA extracted from 'Picual' young leaves and 'Picual' monovarietal oil (Fig. 1). The amplification using leaf-extracted DNA was allowed to reach the exponential phase of the PCR reaction. However, the amplification conducted with oil-extracted DNA did not yield a detectable amplification since it could not reach the exponential phase (Fig. 1). Thus, EMO3 primers are not suitable for olive oil authentication due to their low PCR efficiency when using DNA extracted from oil. Furthermore small changes in the PCR efficiency might eventually allow the exponential phase to be reached and thus to obtain a detectable signal which would lead to haphazard detection and thus to false negatives when using conventional PCR.

To further demonstrate the effect of the PCR efficiency on the applicability of primers for olive oil traceability we designed a new set of primers using as a template the same sequence used to design EMO3 primers (AJ416321). These primers were named N3-200 (Table 1) and they amplify a PCR product of equivalent size to that of EMO3 (around 200 bp).

The results obtained with this primer pair are also shown in Fig. 1. The assay efficiency using this new set of primers is much higher as seen from the greater slope of the logarithmic transformation of the increase in the fluorescent signal (ΔRn). As a consequence, the amplification derived from leaf-extracted DNA is detected much earlier (around eight cycles before than when using EMO3). Furthermore, this difference in amplification efficiency can explain differences in detection of amplification of this locus for samples of oil-DNA. A detectable amplification was produced when using N3-200 primers whereas this was not the case when using EMO3 primers (Fig. 1).

Since qRT-PCR allows inspection into the PCR efficiency, it is a very useful tool in determining the utility for olive oil authentication of primers developed for other purposes. The higher the assay efficiency, the greater the slope of the logarithmic transformation of the increase in the fluorescent signal (ΔRn). Thus it is possible to overcome low PCR efficiencies by designing new primers for the same locus.

3.2. Utility of qRT-PCR to optimise the amplicon size

When degradation of DNA is expected, amplification products smaller than 200 bp have been proposed for food authentication (Hupfer et al., 1998; Unseld et al., 1995).

DNA isolated with the CTAB and the hexane methods (set as reference protocols within the framework of the European Project Oliv-Track) was used to investigate whether the size of amplicons might be optimised for olive oil authentication.

The relative quantity of target molecules for the amplification of either 200 or 80 bp amplicons was determined using qRT-PCR. To do this, primer pairs yielding an amplicon size of around 200 or 80 bp were designed for amplifying each specific locus (AJ001766 or AJ416321, Table 1). Thus, N3-80 and N3-200 were used for nuclear DNA while C4-80 and C4-200 were used for chloroplastidial DNA (Table 1). As explained in the materials and methods section, a corrected $F_0^* = F_0/\text{SCF}$ was calculated to perform direct comparisons among amplicons differing in size (Table 2).

Fig. 2 shows the quantity of input molecules as estimated from F_0^* for each DNA type and isolation method considered (CTAB and hexane). It clearly indicates that independently of the isolation method used or the DNA type considered, the quantity of templates for the amplification of PCR products around 80 bp is much higher than that of 200 bp.

Indeed, the ratio F_0^*N3-80/F_0^*N3-200 = 9.96 (see Table 2 for F_0^* values), which means that the number of input molecules for the amplification of PCR products around 80 bp is tenfold higher than that of 200 bp for nuclear DNA when using the Hexane method. This ratio is 5.40 when considering chloroplastic DNA. For the CTAB

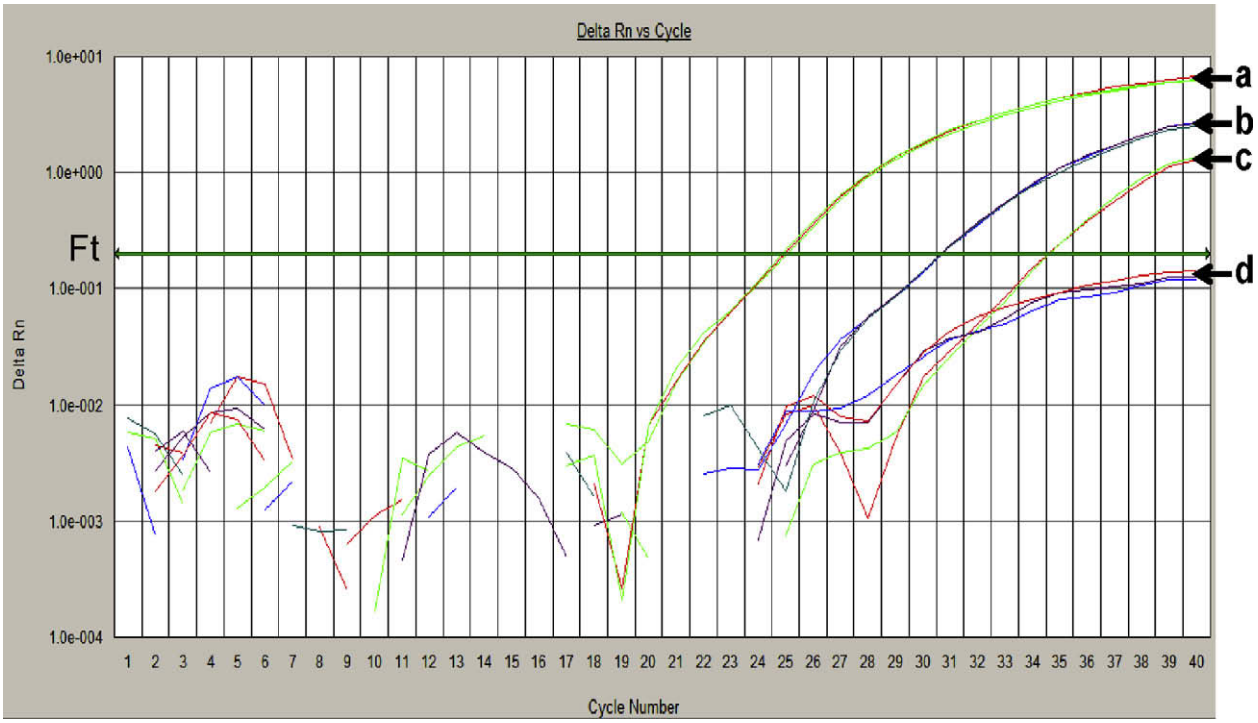

Fig. 1. Real-time PCR with DNA samples from cultivar 'Picual' using two set of primers designed on the basis of the sequence AJ416321. (a) Amplification with primers N3-200 using leaf-extracted DNA; (b) EMO3 amplification using leaf-extracted DNA; (c) N3-200 amplification using oil-extracted DNA; (d) EMO3 amplification using oil-extracted DNA. Values of fluorescence (delta Rn = ΔRn) are logarithmic. Note that for the same amount of input DNA, the EMO3 primers were allowed to reach the threshold fluorescence (Ft) when using leaf-extracted DNA but not in the case of oil-extracted DNA due to low assay efficiency. On the contrary, in the case of N3-200 primers the threshold limit is reached in both cases.

method, these ratios were 3.23 and 4.84 for nuclear and chloroplastic DNA, respectively.

Although it is known that DNA degradation takes place during olive oil extraction its influence on olive oil authentication has been neglected so far. Previous works on olive oil authentication using DNA-based markers have suggested that microsatellites may constitute a good possibility for DNA tracking due to their small size (200–300 bp) (Pasqualone et al., 2004). However, our results show that the quantity of templates for the amplification of PCR products around 80 bp is much higher than that of 200 bp whatever the extraction protocol, suggesting that the determination of optimal amplicon size should be considered for olive oil authentication.

Table 2
Quantity of template molecules in DNA extracted from 'Picual' commercial oil as estimated from corrected fluorescence (F_0^*) for each isolation method and primer pair.

DNA isolation method[a]	Primer pair	F_0^*[b]	±SE
CTAB	N3-80	3.36E−11	5.33E−12
CTAB	C4-80	1.37E−10	1.95E−12
CTAB	N3-200	1.04E−11	2.14E−12
CTAB	C4-200	2.83E−11	9.83E−12
Hexane	N3-80	2.47E−10	5.68E−11
Hexane	C4-80	2.58E−10	1.53E−11
Hexane	N3-200	2.48E−11	4.06E−12
Hexane	C4-200	4.78E−11	1.17E−11
CTAB + hexane	N3-80	5.19E−12	1.59E−12
CTAB + hexane	C4-80	1.22E−11	2.73E−12
CTAB + hexane + chloroform	N3-80	3.20E−10	2.69E−11
CTAB + hexane + chloroform	C4-80	2.62E−09	5.29E−11

[a] The methods are abbreviated as follows in the text: CTAB = CTAB; hexane = Hex; CTAB + hexane = CHex; CTAB + hexane + chloroform = CHex–Chl.

[b] F_0^*: corrected fluorescence. $F_0^* = F_0/SCF$ (SCF = size calibration factor, see Table 1).

3.3. Utility of qRT-PCR to compare between DNA isolation methods

The third task of this work was to compare the relative performance of four different protocols for DNA isolation from olive oil. The methods used are abbreviated as follows: CTAB + hexane = CHex; CTAB = CTAB; hexane = Hex; CTAB + hexane + chloroform = CHex–Chl.

The comparison among the methods used in this work is shown in Fig. 3 for both chloroplastic and nuclear DNA. It is clear that the

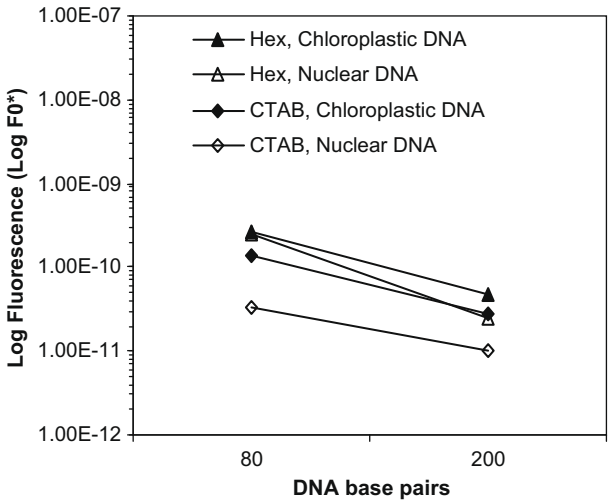

Fig. 2. Comparison between amplifiable DNA of sizes of 80 and 200 bp using qRT-PCR. Quantity of input molecules as estimated from F_0^* (shown in logarithmic scale) for each DNA type and isolation method (only hexane = Hex and CTAB methods were used).

worse method is CHex independently of the DNA type used. Besides, this figure allows a ranking to be established considering the quantity of DNA isolated as follows: CHex–Chl > Hex > CTAB > - CHex independently of the DNA type with but one exception since both CHex–Chl and Hex were almost equally efficient in isolating nuclear DNA (F_0^*N3-80$_{CHex-Chl}$/F_0^*N3-80$_{Hex}$ = 1.3, data from Table 2).

The CHex method had the poorest performance but the modifications proposed for the CHex–Chl allowed increasing the DNA obtained up to 61.7 and 214.7 times for nuclear and chloroplastic DNA, respectively (ratios of F_0^* values shown in Table 2).

The CHex–Chl method is based upon the CHex method with two modifications, the use of chloroform and the addition of nuclear acrylamide in order to improve DNA recovery. Therefore, either one or both modifications allowed to substantially improve the results obtained using the CHex method. The former method was the best for the isolation of both DNA types with one exception since the Hex protocol was almost equally efficient for nuclear DNA isolation. The Hex method was recently reported as the best protocol for nuclear DNA isolation (Martins-Lopes, Gomes, Santos, & Guedes-Pinto, 2008) but the differences found in our work indicate that further work is needed to optimise the isolation protocols and that qRT-PCR will be a useful tool for this purpose.

Regarding the DNA type, the quantity of chloroplastic DNA was higher than that of nuclear DNA for all the methods but Hex, where the ratio F_0^*C4-80$_{Hex}$/F_0^*N3-80$_{Hex}$ was 1.04 (F_0^* values from Table 2). For the other methods the ratio of chloroplastidial *vs* nuclear DNA was higher than 2 and as high as 8.19 in CHex-CHl (considering amplicon sizes of 80 bp).

Although not included in this work, it would be expected that similar results would be obtained when using mitochondrial DNA. Therefore, we think that more attention should be paid to cytoplasmic DNA (either mitochondrial or chloroplastic) for olive oil authentication since it is maternally inherited which offers several advantages over nuclear DNA. The use of this type of DNA would circumvent one of the limitations for olive oil authentication, the contribution of pollinators. Olive is a diploid species and most cultivars are considered self-incompatible, being that the flowers are wind pollinated. As a consequence the embryo of the seeds contains genetic information not only from the maternal parent but also from the pollen donor. Since olive oil is produced by crushing whole fruits, paternal DNA may hamper the traceability when using markers based on nuclear DNA (Doveri, O'Sullivan, & Lee, 2006).

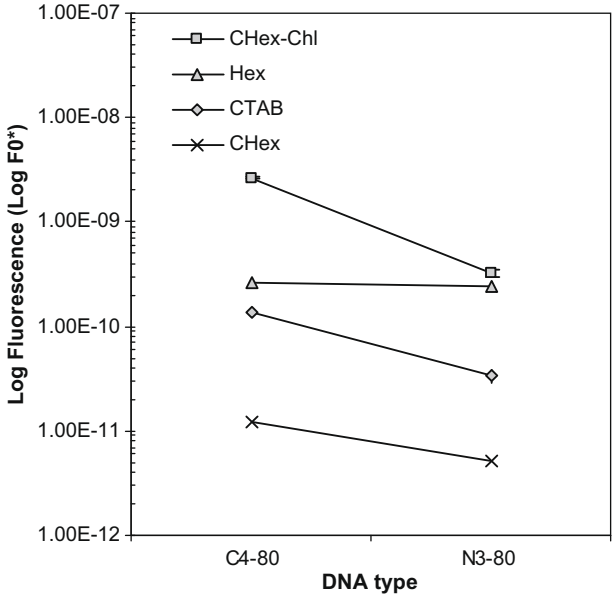

Fig. 3. Comparison among DNA isolation methods and DNA types (C = chloroplastic; N = nuclear) using qRT-PCR. Quantity of input molecules as estimated from F_0^* (shown in logarithmic scale) for each DNA type and isolation method (the methods used are abbreviated as follows: CTAB + hexane = CHex; CTAB = CTAB; hexane = Hex; CTAB + hexane + chloroform = CHex–Chl).

The higher quantity of cpDNA isolated from olive oil and the avoidance of the effect of the pollen donor on traceability cytoplasmic DNA (either mitochondrial or chloroplastic) should not be discarded for olive oil authentication, despite its use for the protection of PDOs (Luykx & van Ruth, 2008) would be more difficult at present.

Chloroplast polymorphism using microsatellites and PCR–RFLP has been reported (Besnard & Berville, 2002). The possibilities of developing new molecular markers to identify olive cultivars using cpDNA has been stated (Intrieri, Muleo, & Buiatti, 2007) but at present it is not known whether cpDNA is polymorphic enough to be used for unique cultivar identification.

The level of cpDNA variation differs among species. For instance, in tomato no variation in the plastome between an European and a Latin American tomato cultivar (Kahlau, Aspinall, Gray, & Bock, 2006) was found. In cucumber, the comparison of the cpDNA sequence between a frost-tolerant and a frost-sensitive genotype indicated that both sequences were identical with the exception of three polymorphic sites (Chung, Gordon, & Staub, 2007). On the contrary, the perennial species *Trifolium pratense* exhibits extremely high degrees of chloroplast DNA variation (Milligan, 1991).

Mitochondrial variation has been reported in olive (Besnard, Khadari, Baradat, & Berville, 2002). A higher degree of variation is usually reported for mitochondria than for chloroplast. For instance, 454 SNPs (single nucleotide polymorphisms) where detected for mitochondria between two genotypes of sugar beet, mostly in the non-coding regions (Satoh et al., 2004). Therefore, the applicability of citoplasmic DNA to olive oil authentication will depend on the degree of variation between olive cultivars which cannot be hypothesised *a priori*.

Recent advances in the sequencing technologies may allow the rapid sequencing of the chloroplast from different cultivars in the near future. This would allow the potential of cpDNA for cultivar determination to be evaluated.

4. Conclusions

The detection of frauds, either due to the mixtures with oils of other species such as hazelnut, or to the certification of PDOs would need quantitative tools. At its best, conventional PCR remains a semi-quantitative technique, and therefore, it is not optimal for authentication purposes when quantification is needed. The use of real-time chemistries allows for the detection of PCR amplification during the early phases of the reaction, providing a distinct advantage over detection of amplification at the final phase or end-point of the PCR reaction. qRT-PCR is a useful tool in the development of molecular markers for olive oil authentication since it allows inspecting the PCR efficiency. Besides qRT-PCR should be used for the optimisation of the amplicon size and the DNA isolation procedure which are critical aspects in olive oil authentication. The potential of cpDNA for olive oil authentication should be addressed in the future.

DFT calculation

ABSTRACT

Nutmeg (*Myristica fragans* and *Myristica argentea*) is a spice widely used in food. Argenteane is a dilignan which has been isolated from nutmeg mace (the lace-like seed membrane of nutmeg). On the basis of the experimental measurements of the lipid peroxidation inhibition, argenteane appeared to be an antioxidant as powerful as vitamin E. The present joint experimental and theoretical study helped to understand the mechanism of action of this compound. The density functional theory (DFT) calculations of the O–H bond dissociation enthalpies (BDEs) correlated with the capacity to scavenge free radicals. We demonstrated that the central moiety is able to release one or two H atom(s) to the free radicals. This mechanism was confirmed by (i) the BDE calculations and (ii) the free radical-scavenging capacity measurements of two lignans and 3,3′-dimethoxy-1,1′-biphenyl-4,4′-diol (i.e., the argenteane central moiety). In addition to this active part, two lipophilic chains participate in the molecule's capacity to react with the oxidative species generated in the membrane vicinity.

1. Introduction

The present paper reports on the biological properties of a natural lignan derivative (argenteane), which was isolated for the first time by our group (Filleur, Pouget, Allais, Kaouadji, & Chulia, 2002). Argenteane ((*bis*-*erythro*-5,5′-*bis*[1-(4-hydroxy-3-methoxyphenyl)-4-(3,4-methylenedioxyphenyl)-2,3-dimethylbutane])) is actually a dilignan (Fig. 1), the first of this type described in the plant kingdom. It has been isolated from nutmeg, together with other lignans (Filleur et al., 2002).

Nutmeg is the seed of the fruit of *Myristica*. The most common species is *Myristica fragans* but other species are used including *Myristica argentea* and *Myristica malabarica*, which are known to be less tasty but are still used in Indonesian diets. It is wrapped in a red or orange lace-like membrane, i.e., the mace. Both nutmeg and mace are spices with similar tastes. The former is sweeter while the latter is known to release more delicate flavors. Mace is also preferred in some dishes for the orange colour that is released (saffron-like colour). Nutmeg is a tropical fruit; it is native to Banda, a Mollucca island of Indonesia. Over the ages it has been cultivated in other regions (e.g., Malaysia and Grenada) but preferentially on volcanic soil. Nutmeg is used as thin slices or more generally as a powder. It is used in numerous recipes, including a lot of desserts (e.g. fruit cakes, muffins, pies) but in main courses as well (e.g., potato dishes, sauces). Nutmeg is also added to beverages (e.g., tea, mulled wine) and it is an ingredient of some curry powders.

Lignans constitute a group of polyphenolic compounds (Harworth, 1942) whose skeleton results from the establishment of a connection between β carbons of the lateral chains of two 1-phenyl propane moieties (Fig. 1). Six different groups of lignans are described: dibenzylbutanes which are just formed from the 8–8′ connexion, and the other five groups containing cyclised compounds (i.e., monofuranic lignans 9-*O*-9′, 7-*O*-9′ and 7-*O*-7′, butyrolactones, arylnaphthalenes, dibenzocycloctanes, furanofuranic lignans). Lignan derivatives obtained from nutmeg essentially belong to the dibenzylbutane group, with either a guaiacyl or piperonyl moieties on the aromatic rings.

Numerous studies have reported on the beneficial effects of diets rich in lignan derivatives. As isoflavonoids, they are phytooestrogens and thereby may prevent breast cancer (Le Bail, Champavier, Chulia, & Habrioux, 2000). As a lot of phenolic compounds, lignans also exhibit antioxidant properties (Filleur, Pouget, Duroux, Simon, & Chulia, 2001).

The present study is a joint theoretical and experimental study of the antioxidant property of argenteane (**1**) and two other derivatives derived from nutmeg (*meso*-dihydroguaiaretic acid (**2**) and *erythro*-austrobailignan-6 (**3**)) (Fig. 1). The antioxidant capacity is measured by the capacity, (i), to scavenge the stable free radical DPPH (2,2-diphenyl-1-picrylhydrazyl), and (ii), to inhibit lipid peroxidation. In order to gain a better understanding of these activities and to draw up a structure-activity relationship, the experimental results are then supported by theoretical calculations

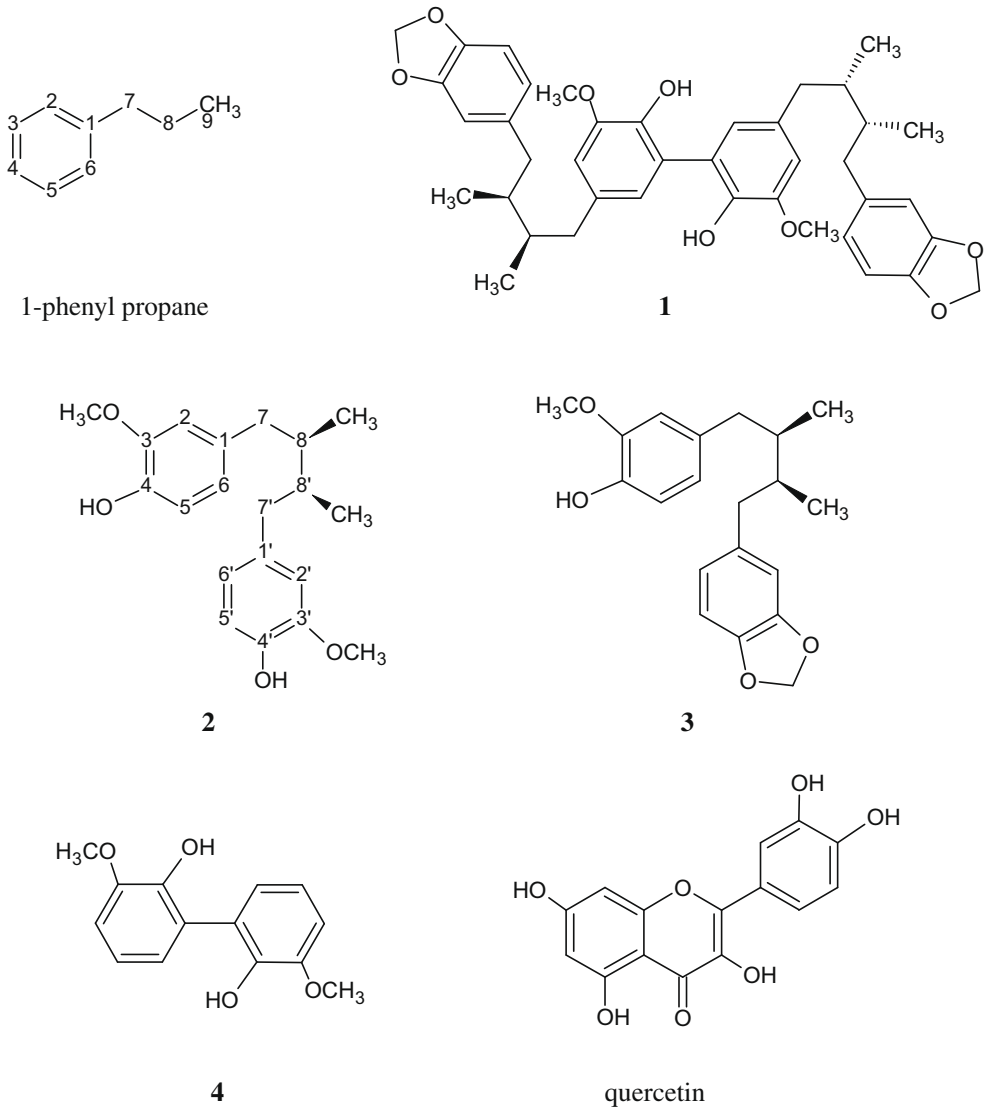

Fig. 1. Molecular structures of **1** (the dilignan, argenteane), **2** (*meso*-dihydroguaiaretic acid) and **3** (*erythro*-austrobailignan-6), **4** (3,3′-dimethoxy-1,1′-biphenyl-4,4′-diol) and quercetin.

at the DFT (density functional theory) level. We first detail the conformational features of **1**–**3**, which are described for the first time. Then we focus on the redox properties of those compounds and especially on their capacity to lose and to transfer a hydrogen to the free radicals involved in oxidative stress. Compounds **1**–**3** are compared to each other, to reference antioxidants (i.e., vitamin E and quercetin) and finally to the central moiety of **1** (i.e., compound **4**). Compound **4** was synthesised for the present study and its antioxidant capacity was evaluated. Again the quantum calculations help to establish the structure-activity relationship and finally to propose the mechanism of action of this new and effective lipid peroxidation inhibitor (as compared to quercetin and vitamin E).

2. Material and methods

2.1. Extraction and purification of argenteane

In order to reduce the number of steps for the isolation and purification of **1**, as compared to the previous reports (Filleur et al., 2002), a new processing method was developed here. Powdered mace of *M. argentea* Warb. (1 kg) was extracted with petroleum ether (10 l), thus yielding 675 g of extract. This extract was defatted by freezing and by partition against *n*-hexane and methanol (1:1). The defatted extract became a red viscous oil (340 g) that was afterwards dried under vacuum. In order to concentrate **1**, a Sephadex LH-20 column (45 × 800 mm) was used with methanol as the eluant. The subsequent extract (60 g) enriched in **1** was obtained. Compound **1** was isolated and purified by three successive MPLC (medium-pressure liquid chromatography) procedures: (i), silica gel column (Polygoprep (Ø 20–60 μm, 26 × 460 mm) eluted with *n*-hexane/$CHCl_3$ (100:0–50:50, 8 ml/min, 1200 ml), (ii), C-18 column (LiChroprep RP-18, Ø 18–25 μm, 15 × 230 mm) using methanol/water (90:10–100:0, 3 ml/min, 500 ml) as the eluant, and (iii), the same C-18 column using methanol/water (90:10–93:7, 3 ml/min, 400 ml) as the eluant. The different chromatographic steps were monitored by UV-detection at 254 nm. Pure compound **1** (60 mg) was thus obtained from 1 kg of *M. argentea* Warb. mace. The structure was confirmed by NMR, in agreement with the literature (Filleur et al., 2002).

Compounds **2** and **3** were obtained and identified following the procedure described by Filleur et al. (2002).

2.2. Enzymatic synthesis of compound **4**

Compound **4** (3,3′-dimethoxy-1,1′-biphenyl-4,4′-diol) was synthesised by a method derived from that previously described by Simmons, Minard, and Bollag (1988). Guaiacol (4 mM) was enzymatically oxidised by horseradish peroxidase (2 U/ml) in a citrate–phosphate buffer (pH 5.5) containing hydrogen peroxide (2 mM). The reaction was achieved at room temperature in 30 min. Enzyme activity was stopped by acidification of the reaction mixture with acetic acid. Separation of **4** was performed by MPLC, using three successive different systems: (i), C-18 column (LiChroprep RP-18, Ø 18–25 μm, 15 × 230 mm) using methanol/water (60:40–90:10, 3 ml/min, 600 ml) as the eluant, (ii), a silica gel column (Polygoprep Ø 20–60 μm, 15 × 230 mm) using *n*-hexane/ethyl acetate as the mobile phase (70:30–0:100, 3 ml/min, 500 ml), and (iii), a C-18 column using methanol/water (50:50–90:10, 3 ml/min, 550 ml) as the eluant. Purification was achieved on a Sephadex LH-20 column (15 × 600 mm) with methanol as the eluant.

^{1}H NMR and ^{13}C NMR spectra were measured in $(CD_3)_2CO$ on a Bruker DPX 400 MHz Avance spectrometer, using tetramethylsilane as an internal standard. Complete proton and carbon assignments were based on 1D and 2D (COSY, HMQC, HMBC) NMR experiments.

^{1}H NMR (400 MHz, acetone-d6) 6.94 (2H, dd, J = 7.5, 2.0 Hz, H-4, H-4′), 6.87 (2H, dd, J = 7.8, 2.0 Hz, H-6, H-6′), 6.83 (2H, br t, J = 7.6 Hz, H-5, H-5′), 3,87 (6H, s, H-7, H-7′). ^{13}C NMR (100 MHz, acetone-d6) 148.8 (C-3, C-3′), 144.9 (C-2, C-2′), 126.6 (C-1, C-1′), 124.4 (C-6, C-6′), 119.8 (C-5, C-5′), 111.3 (C-4, C-4′), 56.4 (OCH_3, C-7, C-7′) confirmed the molecular structure of **4** (Fig. 1).

2.3. DPPH free radical-scavenging capacity

Because of its paramagnetic properties, DPPH exhibits a characteristic ESR (electron spin resonance) signal. The ESR spectra were obtained with a Bruker model ESP300E spectrometer, using microsampling pipettes at room temperature under the following conditions: modulation frequency of 100 kHz, microwave frequency of 9.78 GHz, microwave power of 2 mW, modulation amplitude of 1.97 G, and time constant of 10.24 ms. The ESR spectra were recorded 3 min after sample preparation.

Mixtures that contained 50 μl of compound, dissolved in methanol at different concentrations, and 50 μl of DPPH ethanol solution (5×10^{-4}M) were tested. *Inhibition* was calculated as follows:

$$\text{Inhibition} = [ref - compound]/[ref - bg],$$

where *ref* and *compound* are the values of the double integrals for the ESR spectrum of the reference (DPPH + solvent) and the tested solution (DPPH + solvent + compound), respectively; *bg* represents the background signal (solvent). Each data point is the result of the average of three independent measurements. The IC_{50} value was calculated from the plot of inhibition against concentration.

2.4. Preparation of large unilamellar vesicles (LUV)

PLPC prepared from Sigma–Aldrich (St. Louis, MO) in chloroform was evaporated under vacuum in a round-bottomed flask to produce thin PLPC film. Multilamellar vesicles (MLV) were produced by vortexing the thin film after hydration with distillated water. MLVs were passed through 0.1 micron double-layer polycarbonate membrane using a Lipex™ extruder (Northern Lipids Inc., Burnaby, Canada) to produce LUV. The preparation resulted in a 250 mM PLPC LUV in water solution. Particle size ranged from 90 to 110 nm, determined using an N4 Plus submicron particle size analyser (Beckman-Coulter Inc., Fullerton, CA).

The tested compounds of various concentrations (10 μl in methanol) were added to 1 ml of LUVs mixture prior to the lipid peroxidation initiation. Oxidative stress was generated by γ-irradiation (400 Gy, Oris experimental irradiator; Oris Industries, Gif-sur-Yvette, France) of the liposomal mixture, which produces $OH^{\cdot}$ from the solvent. The oxidative stress effect was determined following the formation of conjugated dienes at 233 nm (Shimadzu UV-2401PC; Shimadzu, Kyoto, Japan).

2.5. Theoretical methodology

Over the past decade, the theoretical description of phenolic compounds has been achieved by using semi-empirical and DFT methods (Fiorucci, Golebiowski, Cabrol-Bass, & Antonczak, 2007; Lemaska et al., 2001; Leopoldini, Marino, Russo, & Toscano, 2004a; Leopoldini, Pitarch, Russo, & Toscano, 2004b; Lucarini, Pedulli, & Guerra, 2004; Priyadarsini et al., 2003; Russo, Toscano, & Uccella, 2000; Trouillas et al., 2004; Wright, Jonhson, & DiLabio, 2001; Zhang, Sun, & Chen, 2001; Zhang, Sun, & Wang, 2003). While the former method only gives good trends, the latter has given very good agreement with experimentation. In particular the description of redox properties may be reproduced by using hybrid functionals. The B3P86 functional has given very good BDE values for phenolic compounds. Indeed the theoretical O–H BDE of phenol obtained with this very functional is around 87 kcal/mol (Trouillas, Marsal, Siri, Lazzaroni, & Duroux, 2006), while the experimental value is 87 ± 1 kcal/mol (Wayner et al., 1995). A similar accuracy was obtained for catechol (Trouillas et al., 2006). Afterwards the use of B3P86 was successfully extrapolated to larger phenolic compounds to establish structure-activity relationships (Kozlowski et al., 2007a, 2007b; Trouillas et al., 2008). The use of other functionals, e.g., B3LYP has also given a reliable comparative description of polyphenols but the phenol BDE is shifted by about 4 kcal/mol, compared to the experimental value. The use of the 6-31+G(d,p) basis set is sufficient to reach a perfect agreement between the experimental and theoretical BDE of phenol (Trouillas et al., 2006), in order to describe the energies of molecules and corresponding radicals.

In the case of antioxidant polyphenols and due to the importance of electron delocalisation effects, calculations have to be performed over the entire molecules at the same level. In order to find the best conformation, we explored the potential energy surfaces at the B3P86/6-31G(d) level. Afterwards most stable geometries and energies were re-calculated at the B3P86/6-31+G(d,p) level. Both B3P86/6-31+G(d,p)//B3P86/6-31G(d) and B3P86/6-31+G(d,p) schemes gave very similar results (difference lower than 0.5 kcal/mol), indicating that the description of geometries can be carried out by using the 6-31G(d) basis set. This approximation was used for all the different structures since it is very accurate and since a PCM-B3P86/6-31+G(d,p) optimisation for compound **1** and the corresponding radical is not feasible. Indeed, the use of diffuse functions makes the convergence procedure a tricky problem for such a system.

The geometries and energies of the phenoxyl radicals ($ArO^{\cdot}$), obtained after the H abstraction from an OH group, were achieved starting from the optimised structure of the parent molecule. Following Pople, Gill, and Handy (1995), we decided to use an unrestricted approach for these open-shell systems. Compared to a restricted open-shell scheme, an unrestricted calculation allows more flexibility, e.g., this helps to describe the spin polarisation. Unrestricted DFT calculations may induce spin contamination since the unrestricted determinants are not eigenfunctions of $\langle S^2 \rangle$ operator. Nonetheless in our case spin contamination appeared to be weak.

For the four compounds (**1**–**4**) and the corresponding radicals, the most stable conformer exhibits a stabilising H-bonding interac-

tion between the OH group and the *ortho*-OCH_3 group. The vibrational frequencies have been evaluated and all conformations have been checked to have no imaginary frequency.

BDEs were calculated at 298 K using the sum of electronic and thermal enthalpies, which is the total electronic energy + ZPE + $E_{vibration}$ + $E_{rotation}$ + $E_{translation}$ + RT. Frequencies were calculated at the B3P86/6-31G(d) level (in which geometries have been optimised), using a scale factor of 0.9557 (Merrick, Moran, & Radom, 2007).

The solvent effects were implicitly taken into account by using a PCM (polarisable continuum model) method, since using a box of explicit solvent molecules is not feasible with such compounds. The effects of explicit water molecules in the surrounding of the OH group of phenol were investigated (Guerra, Amorati, & Pedulli, 2004), and confirmed that the use of PCM gives a relatively good description of BDEs. We also tested the use of a hybrid model (i.e., one or two molecules surrounding the OH groups + PCM) for quercetin (Kozlowski et al., 2007a), a bigger system than phenol. We observed only a slight difference in BDE as compared to a pure PCM calculation, while computational time was dramatically increased. Thus, in the present paper, calculations were performed with IEFPCM (Integral Equation Formalism PCM) and UA0 radii, well-adapted for phenol BDE description (data not shown).

All calculations were achieved in Gaussian 03 and implemented methods (Frisch, Trucks, Schlegel, et al., 2004).

The antioxidant (e.g., free radical-scavenging) capacity of phenolic compounds (ArOH) is strongly related to their redox properties, either H atom or electron transfer. The reactivity of those antioxidants usually follows one of those two reactions:

$$\text{HAT (H atom transfer)}: \text{ArOH} + R^{\cdot} \rightarrow \text{ArO}^{\cdot} + \text{RH} \quad (1)$$

$$\text{ET (electron transfer)}: \text{ArOH} + R^{\cdot} \rightarrow \text{ArOH}^{+\cdot} + R^{-} \rightarrow \text{ArO}^{\cdot} + RH \quad (2)$$

where R· is any radical implicated in oxidative stress, including DPPH·, ·OH, $O_2^{\cdot -}$, ROO· or NO·.

Reaction (1) is the homolytic dissociation of the O–H bond, and this is in relation to the BDE of the OH groups. Reaction (2) is a heterolytic dissociation in relation to the ionisation potential (IP) of ArOH and by the enthalpy of the $ArOH^{+\cdot}$ cation formation. Actually there exists a third mechanism, so-called sequential proton-loss-electron-transfer (SPLET), in which the proton is first lost, thereby allowing electron transfer (Zhang & Ji, 2006).

Different studies have demonstrated a very good agreement between BDEs and the free radical-scavenging capacity of phenolic compounds, thus indicating that reaction (1) is predominant for polyphenols (Fiorucci et al., 2007; Lemaska et al., 2001; Leopoldini et al., 2004a, 2004b; Lucarini et al., 2004; Priyadarsini et al., 2003; Russo et al., 2000; Trouillas et al., 2004; Wright et al., 2001; Zhang et al., 2001, 2003). We calculated the BDE (i.e., $H^{298K}(\text{ArOH}) - H^{298K}(\text{ArO}^{\cdot}) - H^{298K}(H)$) of each group for compounds **1**–**4**, in order to evaluate the capacity of each group to release one or two H atoms. BDE is a chemical descriptor related to the first mechanism. We also calculated ΔH and ΔG of reactions between **1**–**4** and free radicals (i.e., from reactants ArOH and $R^{\cdot}$ to final products $ArO^{\cdot}$ and RH). Let us insist on the fact that ΔH and ΔG are the same for the three mechanisms, as they are taken in their entirety (from initial to final products), i.e., $\Delta H = H^{298K}(\text{ArO}^{\cdot}) + H^{298K}(\text{RH}) - H^{298K}(\text{ArOH}) + H^{298K}(R)$. Those values give a global description of the free radical-scavenging action, whatever the mechanism involved, that is ΔH and ΔG take into account the different contributions, even if competition exists between the three mechanisms. Here we focus on two radicals $R^{\cdot}$ = DPPH and ROO·; the former is used to estimate the capacity of compounds to be oxidised, while the latter is involved in the lipid peroxidation process.

3. Results and discussion

3.1. Argenteane: a dimer issued from oxidation of lignan

Argenteane (**1**) is a dilignan formed in nutmeg. This is a natural dimer of the lignan compound **3**. Dimers, trimers and other oligomers of polyphenols are known to be formed in plants and they are called procyanidins or condensed tannins in the case of flavonoids. Numerous oligomers of catechin exist and they are classified in different sub-groups, depending on the carbon atoms involved in the covalent C–C bond formation. The presence of other types of dimers including quercetin and phenolic acid dimers, is reported as well (Ngoc Ly et al., 2005; Ralph, Quideau, Grabber, & Hatfield, 1994; Sang et al., 2002).

The natural dimerisation of **3** to form **1** can be explained by the capacity of the guaiacyl moiety (in **3**) to undergo enzymatically catalysed oxidation. The guaiacyl as well as the catechol moieties are known to bind to the active site of such oxidative enzymes (e.g., laccases) thus losing an H atom. Following the loss of one electron and one proton in the active site, a radical is formed from **3** and exhibits a strong spin density on carbon atom C5 (Fig. 2); this makes C–C bond formation easier.

3.2. Conformational analysis

The potential energy surface was first studied for compound **2**, following in particular the two torsion angles τ_1 = C1–C7–C8–C8′ and τ_2 = C8–C8′–C7′–C1′. Two conformers (**2a** and **2b**) were obtained, corresponding to ($\tau_1 = -168°$; $\tau_2 = 169°$) and ($\tau_1 = -170°$; $\tau_2 = 55°$), respectively. The guaiacyl moiety was computed so that a H-bonding existed between the H atom of the OH group and the O atom of the OCH_3 group. Conformations of **3** (**3a** and **3b**) were directly deduced from those of **2**, except that one of the guaiacyl moieties was turned to a piperonyl moiety (Fig. 1). We demonstrated that conformer **2a** (**3a**) is more stable than **2b** (**3b**) by

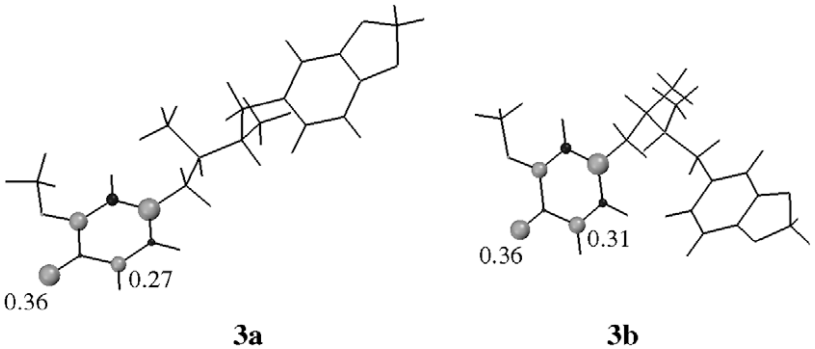

Fig. 2. Spin density distribution of the radicals obtained after H abstraction from **3**.

about 1 kcal/mol. Nevertheless this difference is too small to definitely exclude the latter.

As quoted above in text, the B3P86 functional has appeared to be relevant to evaluate phenol-BDE. Concerning the conformational analysis, no significant differences have been observed when changing the functional (data not shown). In this paper the energy difference between both conformers of **2** (**2a** and **2b**) was thoroughly evaluated. The effect of the Hartree–Fock (HF) weight included in the exchange part was especially investigated. In addition to the hybrid functional B3P86 (using 20% of HF), the two functionals BP86 (i.e., pure DFT functional with 0% HF) and BHandHP86 (i.e., 50% HF) were used to compute energies of **2**. The difference in energy between both conformers (**2a** and **2b**) was very similar with the three functionals and was lower than 1 kcal/mol. This result helped to state that, (i), B3P86 is relevant to estimate the properties of compounds **1**–**4**, and (ii), both conformers probably co-exist in solutions.

In a second step, two conformations of **4** were obtained after analysis of the potential energy curve corresponding to the variation of the torsion angle τ = C2–C1–C1′–C2′. The two conformations **4a** and **4b** correspond to $\tau = 135°$ and $-59°$. The H bond between the OH and OCH_3 groups was also favoured. In addition, for the latter conformer (**4b**), H bonding exists between the two hydroxyl groups. Both conformers possess exactly the same energy.

The conformations of **1** were then found by calculating the energies and conformations of all the different combinations of τ, τ_1 and τ_2. Some of the combinations led to dramatic steric interactions, and we finally obtained three different conformations **1a**–**1c**.

Conformers **1b** and **1c** exhibit H-bonding between the two OH groups of the central 3,3′-dimethoxy-1,1′-biphenyl-4,4′-diol moiety (as for **4b**). On the contrary, conformer **1a** does not possess this H bond, and exhibits a relatively planar shape. The three different conformers have very similar relative stability, since they possess energies lower than 0.5 kcal/mol, thus having the same Boltzmann's population and thus co-existing in solution. This conclusion may be a little bit different if the biosynthesis is oriented and favours one conformer rather than another, but to the best of our knowledge the active site of enzymes involved in dimer biosynthesis is only specific to the moiety where the oxidative process will occur, and not to rest of the molecule. Indeed such dimerisation occurs in different phenolic compounds regardless of the system size (e.g., phenolic acid (Ralph et al., 1994), catechin (Sang et al., 2002), quercetin (Ngoc Ly et al., 2005; Zhou, Kikandi, & Sadik, 2007), silybin (Gazak, Sedmera, Marzorati, Riva, & Kren, 2008)). Thus the dimer biosynthesis probably cannot influence one of the three conformers.

We studied the three conformers and the antioxidant activity is *a priori* an average of them, which is especially true for a redox action that does not require any stereospecific interaction, as for free radical-scavenging activity in solution.

3.3. Antioxidant properties of compounds *1*–*3*

In order to estimate the capacity of **1** and other two lignan derivatives from nutmeg to act as antioxidants we studied their capacity to scavenge the DPPH free radical and to inhibit the liposomal lipid peroxidation process. The former test directly gives the capacity to scavenge a free radical, usually by the HAT mechanism (Goupy, Dufour, Loonis, & Dangles, 2003). This test has been widely used over the past decades to give a quick and reliable estimation of the free radical-scavenging capacity. The latter directly gives the capacity of the molecule to react in the vicinity of the membrane in which an oxidative stress is generated. This test gives a better estimation of the actual antioxidant capacity that may occur in a stressed organism. Nonetheless both tests often correlate (Trouillas et al., 2008).

Table 1
Antioxidant capacity of **1**–**4** and two reference antioxidants, vitamin E and quercetin.

Compound	DPPH scavenging IC_{50} (μM)	Lipid peroxidation inhibition IC_{50} (μM)
1	70 ± 2	0.68 ± 0.04
2	46 ± 2	0.41 ± 0.01
3	103 ± 4	0.82 ± 0.04
4	70 ± 4	2.70 ± 0.05
Vitamin E	58 ± 1	0.60 ± 0.05
Quercetin	24 ± 2	0.24 ± 0.01

As we can see in Table 1, compound **2** is twice as effective a free radical scavenger (i.e. lower IC_{50} of about 46 μM) as compared to **3** ($IC_{50} \sim 103$ μM). Compound **1** exhibits an intermediate activity with an IC_{50} of 70 μM. The DPPH free radical-scavenging capacity of these three compounds is in the same range as that of vitamin E, but less active than quercetin. Quercetin is known to have a strong redox capacity (strong capacity to release an electron or an H atom) (Fiorucci et al., 2007; Leopoldini et al., 2004a, 2004b; Trouillas et al., 2006). Let us also note that guaiacol is much less active than **3** (IC_{50}(Guaiacol) = 300 μM, data from Kozlowski et al. (2007b) obtained under the same conditions as in the present paper). The same conclusions can be made for lipid peroxidation inhibition: (i), compound **2** is twice as active as **3** (IC_{50} = 0.41 and 0.82 μM, respectively), (ii), compound **1** is an intermediate inhibitor (IC_{50} = 0.68 μM), (iii), vitamin E is in the same range (IC_{50} = 0.60 μM) and (iv), quercetin is more active (IC_{50} = 0.24 μM).

3.4. Bond dissociation enthalpy

The BDEs of **1** and other derivatives are reported in Table 2. Two different values were obtained depending on the initial conformation. Concerning conformation without H bonding between the two OH groups (i.e., **1a**) the BDE was about 83.5 kcal/mol. In the absence of this H bond (i.e., **1b** and **1c**) the value is ~3 kcal/mol lower. This difference comes from the better stabilising effects that exist in the radical obtained after H abstraction from **1b** and **1c**. First the spin density is more delocalised for the radical derived from those two conformers, thus allowing a lower spin density on the oxygen atom (from which the H atom has been removed) (Fig. 3). Second the H bonding between the OH group of one ring and the O atom of the other ring is stronger in the radical (1.55 Å) than in the parent molecule (1.74 Å) (Figs. 3 and 4). Both stabilising effects are closely inter-linked since we obtained a non-zero spin density on the H atom involved in the H bond. As the three conformers may co-exist in a solution in which nothing favours one conformer over another, the BDE value can be seen as the mean value of the three values (i.e., 81.8 kcal/mol).

The OH BDE values obtained for compounds **2** and **3** are very similar to each other, whatever the conformer. That is, the intrinsic redox property of those two compounds does not explain their difference in activity. No differences in conformation and in electron delocalisation were noticed either. Thus the difference in the DPPH free radical-scavenging capacity was only due to the presence of two OH groups in **2**, rather than one in **3**. In conclusion, **2** scavenges twice as many radicals as **3**, by HAT mechanism. This helps and confirms the importance of the BDE parameter in order to explain the free radical-scavenging capacity of phenolic compounds.

Compound **3** is the monomer of **1**, nonetheless the chemical surrounding of the OH group is very different in both cases, and actually the BDE of **1** is lower than that of **3** by about 4 kcal/mol (gas phase calculation) and such a difference is sufficient to change the free radical-scavenging capacity and to make **1** a better antioxidant than its monomer (i.e., DPPH scavenging IC_{50} = 70 and

Table 2
BDEs (kcal/mol) of compounds **1**–**4** and of corresponding ArO· radicals (to form bi-radicals isomerised to quinones). The BDEs of quercetin at the same level, i.e., B3P86/6-31+G(d,p) are 80.0, 92.1, 90.3, 82.4 and 79.7 kcal/mol for the 3OH, 5OH, 7OH, 3′OH and 4′OH groups, respectively.

	Gas		Solvent	
	BDE	Bi-radical BDE	BDE	Bi-radical BDE
1a	83.5	83.8		
1b	81.0	92.8		
1c	80.9	91.7		
2a	85.5	107.7	81.9	
2b	85.9	106.0	82.3

	82.0[a]			

[a] B3P86/6-31+G(d,p) calculations (in this case the scale factor is 0.9588 (Merrick et al., 2007)).

103 μM, for **1** and **3**, respectively; lipid peroxidation inhibition IC_{50} = 0.68 and 0.82 μM, for **1** and **3**, respectively).

Moreover, in the case of **1**, a second HAT mechanism can occur on the second OH group to form a quinone. For conformer **1a** (without H bonding) the BDE of the second HAT is exactly the same as for the first, while for the other two conformers **1b** and **1c** (with H bond) the second BDE is much higher (by more than 10 kcal/mol). The higher BDE obtained in the latter case comes from the loss of the stabilising H bonding in the phenoxy radical. As a consequence of this high BDE, contrary to **2**, compound **1** cannot be twice as active as **3** as a free radical scavenger. This theoretical observation is accurately confirmed by experimental data from which we observed that IC_{50} values of **1** are between those of **2** and **3** (i.e., compound **1** with two OH groups is more active than **3** but less active than **2**).

From the calculation of ΔH and ΔG (Table 3), the conclusions are relatively similar to those drawn from BDE analysis, in terms of the comparative study between **1**, **2** and **3**. From the general point of view it must be noted that the entropic effects are negligible in the gas phase calculations but are a little bit more significant when taking the solvent effect into account.

The DPPH free radical-scavenging reaction with the different compounds is neither spontaneous (ΔG positive) nor exothermic (ΔH positive). Nevertheless the ΔH and ΔG values are relatively small indicating that the reaction is relatively neutral. The equilibrium may be shifted by secondary reactions (e.g., dimerisation) as suggested by different authors (Sang et al., 2002).

Concerning peroxy radical inhibition, the reaction is more favourable, i.e., spontaneous as well as exothermic.

3.5. Comparison between *1* and *4*

In the present study we synthesised compound **4**, which is the central moiety of compound **1**, which is the part of the molecule from which the HAT mechanism can occur. Compound **4** was evaluated for its DPPH free radical-scavenging capacity as well as for its capacity to inhibit lipid peroxidation. Like compound **1**, compound

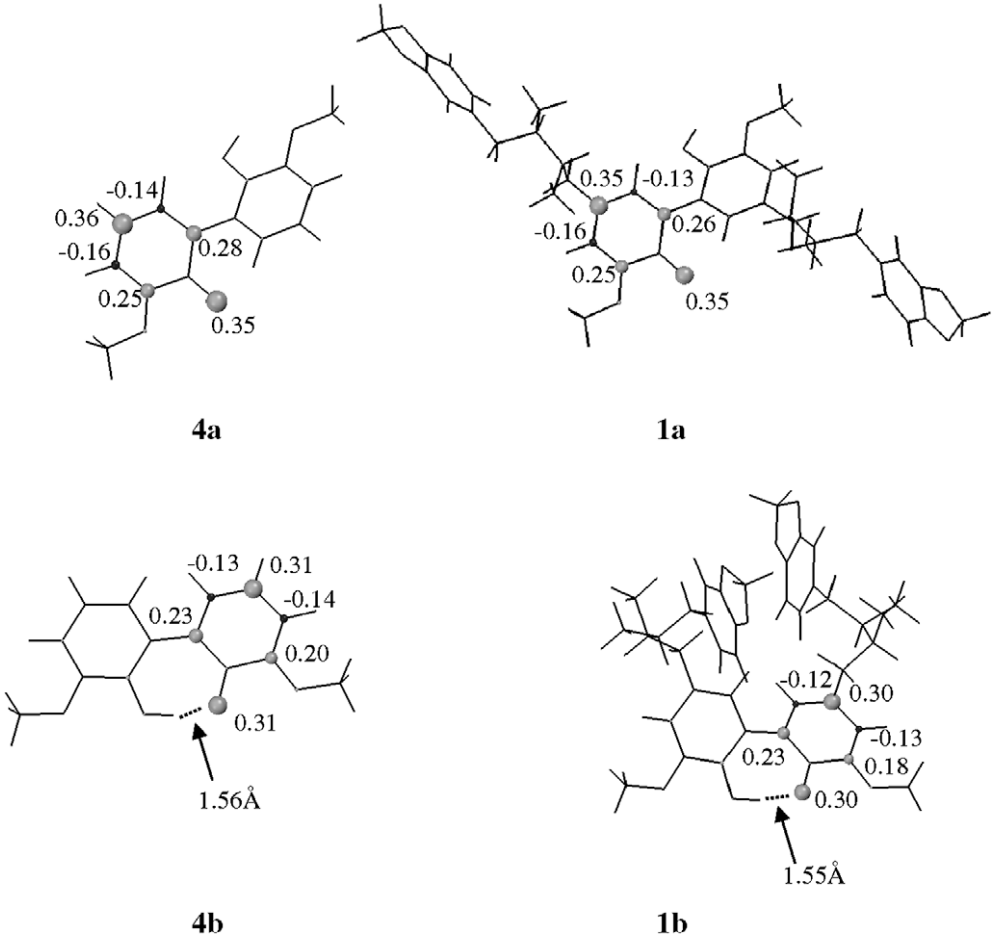

Fig. 3. Spin density distribution of the radicals obtained after H abstraction from (top) **4a** and **1a**, and (bottom) **4b** and **1b**.

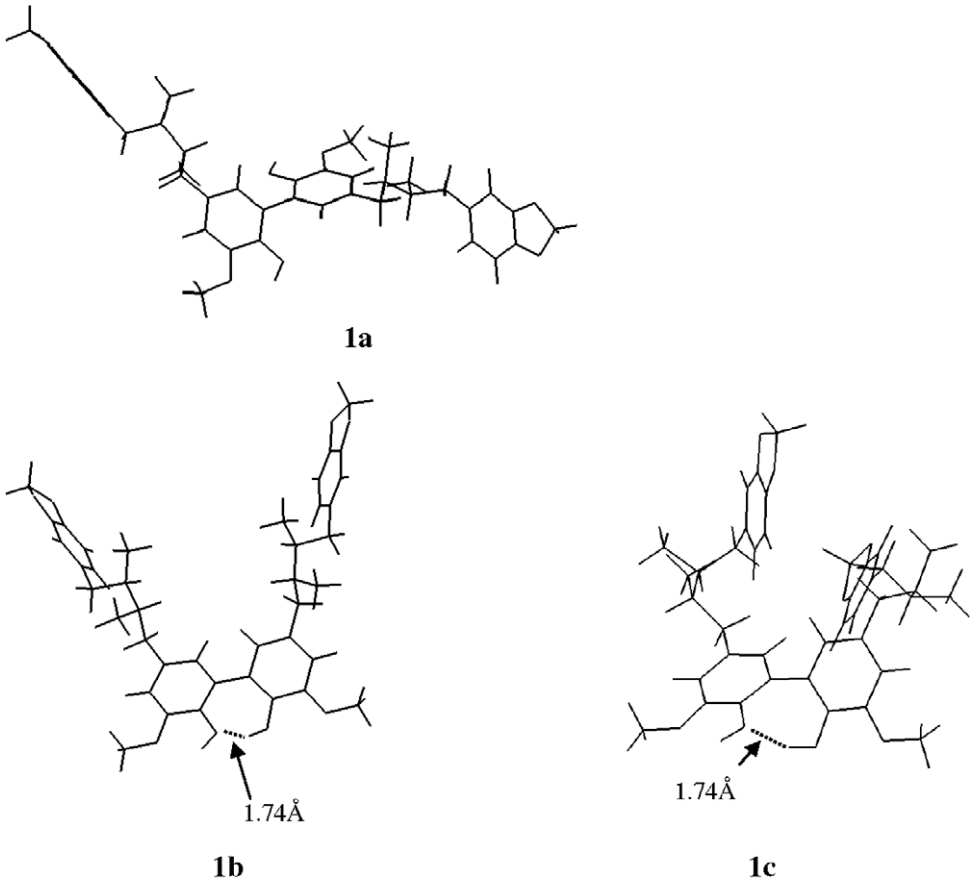

Fig. 4. Geometries of the three most stable conformers of **1**.

4 exists as different rotamers without or with H bonding interaction (i.e., **4a** and **4b**, respectively). As for **1b** and **1c**, the conformer with the H bond (**4b**) exhibits a BDE lower than its counterpart (i.e., conformer **4a** without H bond), by about 3 kcal/mol. Nonetheless, the calculations show that **4** has BDEs higher than **1**, by about 1–1.5 kcal/mol. This significant difference remains very small and should be attributed to a small but better capacity to delocalise spin density and to stabilise the ArO· radical by H-bonding (see the case of the conformers with H bonds).

In both cases (compounds **1** and **4**), as the different conformers (three and two conformers, respectively) may co-exist in a solution in which nothing favours one conformer over another, the BDE value is the mean value of the three or two values, respectively (i.e., 81.8 and 83.6 kcal/mol in the gas phase for **1** and **4**, respectively).

Table 3
ΔH and ΔG (kcal/mol) for the oxidative reaction between the different compounds and the DPPH and $CH_3OO^{\cdot}$ radicals. Calculations of conformations, enthalpies and Gibbs free energies of both radicals are performed at the B3P86/6-31+G(d,p) as for the different compounds and corresponding radicals.

	Gas				Solvent			
	DPPH		ROO·		DPPH		ROO·	
	ΔH	ΔG	ΔH	ΔG	ΔH	ΔG	ΔH	ΔG
1a	4.2	2.3	−0.6	−1.8				
1b	1.7	0.7	−3.0	−3.4				
1c	1.5	1.6	−3.2	−2.4				
2a	6.2	6.1	1.4	2.1	2.3	6.1	−6.6	−6.0
2b	6.5	6.2	1.8	2.1	2.8	6.9	−6.1	−5.2
3a	6.2	5.8	1.5	1.8	2.4	6.3	−6.5	−5.8
3b	6.5	6.1	1.8	2.1	2.2	8.3	−6.7	−3.9
4a	5.7	5.4	0.9	1.4	3.4	7.2	−5.5	−4.9
4b	2.9	2.7	−1.8	−1.3	2.5	6.3	−6.4	−5.8

The DPPH free radical-scavenging capacities of **1** and **4** are very similar (Table 1), so the difference in BDE is not enough to induce a difference in this activity. Let us confirm that this is also the case when we look at the ΔG and ΔH values. The reaction is neither spontaneous nor exothermic, as for **1**. Thus one can definitely conclude that the sheer free radical-scavenging capacities of **1** and **4** are equivalent; in other words, the free radical-scavenging capacity of **1** comes from the capacity of the central moiety (**4**) to release one or two H atoms. The influence of the rest of the molecule is very weak in this case.

Concerning the capacity of lipid peroxidation inhibition, the activity of **4** is dramatically decreased compared to **1**. This result cannot be explained by the sheer redox capacity, otherwise the behaviour would have been similar to the DPPH scavenging. The only parameter that may explain this difference in activity comes from the lower lipophilicity of **4** compared to **1** (log P = 3.0 and 10.6, respectively).

Argenteane (**1**) appears to be a powerful antioxidant, especially as a lipid peroxidation inhibitor since it is as effective as vitamin E. This activity comes from (i), a reliable HAT capacity of the two central OH groups, and (ii), an adapted lipophilicity.

It is well-known that vitamin E acts as an antioxidant directly from the membrane in which it is incorporated (Bisby & Parker, 1995). It is difficult to confirm that **1** is also inserted in the membrane; nonetheless here we confirmed the important role of its lipophilicity, thus concluding that **1** is at least relatively close to the membrane, closer than a more polar compound with the same redox capacity like compound **4**. So **1** acts either as a component of the membrane or accumulated in the very vicinity of the mem-

brane. In both cases, **1** has the capacity to accumulate in a relatively thin region, which increases its potential activity. Indeed as far as it could be accumulated in a relatively narrow region, its concentration is virtually (or artificially) increased. Thus, even if **1** is present in a relatively low concentration in the diet, its role as a protective agent against oxidative stress may be considered as powerful.

It must be stressed that the redox property of this compound could be improved by replacing the two piperonyl moieties with two guaiacyl moieties, or better still with two catechol moieties. Such a change is feasible with a conventional synthesis procedure (Nakai et al., 2003), nevertheless the lipophilic property would consequently be decreased for those two hypothetical compounds, thus reducing the capacity to act in the vicinity of the membrane. Argenteane seems to exhibit the perfect compromise between good redox capacity (for an effective free radical-scavenging capacity) and good lipophily (for a good interaction with membranes).

Acknowledgments

The authors thank the "Conseil Régional du Limousin" for financial support, IDRIS (Institut du Développement et des Ressources Informatiques Scientifiques, Orsay, Paris) and CALI (CAlcul en LImousin) for computing facilities. The authors are grateful to Daovy Allais and Sylvie Gautier for fruitful discussions that help to improve the quality of this work. The authors also thank Fabrice Collin and Monique Gardès-Albert for help and discussion concerning the lipid peroxidation experiments.

Nitrophenolates

ABSTRACT

A mix of nitrophenolates was applied to pepper plants in the irrigation system along the growth cycle. Fruits were labelled at fruit set to study the evolution of fruit growth and ripening based on fruit size and colour. In addition, at 3-day intervals, samples were taken in which the evolution of fruit weight, colour, nutritive (sugars and organic acids) and bioactive compounds (total phenolics, carotenoids, and ascorbic acid) was evaluated. Pepper fruit growth followed a simple sigmoid curve reaching its maximum size at 49 days after fruit set, although nitrophenolate treatments led to significant increases in fruit weight due to higher length, diameter, and pericarp thickness, without affecting the normal ripening process, since colour and carotenoid evolution was similar for both control and treated fruits. Glucose, fructose, ascorbic acid, citric acid, total antioxidant activity (TAA) and total phenolics increased during pepper development, and their levels were significantly enhanced by nitrophenolate applications. Thus, this treatment induced beneficial effects in terms of the improvement of fruit quality, and especially its nutritive and antioxidant constituents. Finally, it is advisable to consume peppers at the full red stage in order to achieve the maximum health-beneficial effects by consumers.

1. Introduction

Nowadays, agricultural practices are focused on the optimisation of nutrient management through a better control of plant water and nutrient requirements to improve plant health and crop yield. In this sense, the use of organic agriculture in peppers has demonstrated that quality was similar with respect to conventional or intensive practices, and thus avoiding the use of chemical fertilisers, lowering production costs and reducing grown water pollution (del Amor, 2006). Accordingly, natural compounds such as nitrophenolates (NPLs), have been shown to increase yield in sugar beet (Cerny & Ondrisik, 2003), cotton (Djanaguiraman, Sheeba, Devi, & Bangarusamy, 2005) and tomato (Djanaguiraman, Pandiyan, & Devi, 2005; Serrano et al., 2005), in which their effect were due to an increase in auxin concentration.

Peppers are fruits with a high importance in human diet due to their versatility to be consumed as fresh vegetable in salads, cooked meals or dehydrated for spices. Traditionally, commercial growers have harvested peppers at the mature green stage when pericarp becomes thick and the fruit has reached its maximum size. However, in recent years, there has been an increasing interest in picking peppers at the red colour with improved flavour, nutritional aspects and high acceptation by consumers (Frank, Nelson, Simonne, Behe, & Simonne, 2005). In fact, mature red peppers are considered one of the richest sources of natural pigments (carotenoids), and is thus used as a food colourant in the form of ground powder (Hornero-Méndez, Costa-García, & Mínguez-Mosquera, 2002). Apart from carotenoids, pepper fruit at the red stage is rich in vitamin C and phenolic compounds such as phenolics acids, flavonoids, hydroxycinnamates and flavones (Marín, Ferreres, Tomás-Barberán, & Gil, 2004). Moreover, fresh pepper is considered to be one of the vegetables with the highest content of vitamin C within the plant kingdom. Additionally, it is well known that phenolic compounds contribute to fruit sensory and nutritive quality in terms of modifying colour, taste, aroma and flavour, and also providing health-beneficial effects (Tomás-Barberán & Espín, 2001).

Literature exists on the evolution of physicochemical parameters during pepper fruit growth and development, such as weight, colour, firmness, total soluble solids, and acidity (Martínez, Curros, Bermúdez, Carballo, & Franco, 2007; Tadesse, Hewett, Nichols, & Fischer, 2002). In addition, differences in bioactive compounds, such as ascorbic acid, total phenolics, carotenoids and antioxidant activity, between mature green and red stages at harvest have been reported, although contradictory results were obtained probably due to varietal differences (Fox, Del Pozo, Lee, Sargent, & Talcott,

2005; Howard, Talcott, Brenes, & Villalon, 2000; Matterska & Perucka, 2005; Navarro, Flores, Garrido, & Martínez, 2006). However, as far as we are aware, no detailed information is available about the evolution of nutritive and antioxidant constituents along the whole growth and ripening process of peppers on plant, and there are no scientific reports about the effect of nitrophenolates on these issues. Therefore, the aim of this paper was to investigate the changes in nutritive compounds (glucose, fructose, sucrose and organic acids) and antioxidant constituents (total phenolics, total carotenoids, and ascorbic acid) during pepper development and ripening on plants and how this can be affected by the application of nitrophenolates. Moreover, total antioxidant activity (TAA) is analysed in two separate fractions (hydrophilic and lipophillic, H-TAA and L-TAA) and their relation with the antioxidant compounds is provided.

2. Material and methods

2.1. Plant material and experimental design

The experiment was carried out in a commercial plastic glasshouse located at Pilar de la Horadada (Alicante, Spain) in two consecutive growing cycles (2005 and 2006). Pepper plants (*Capsicum annum* L. cv. Herminio) were sowed in December and the production cycles finished on September next year under conventional cultural practices and fertilisation. The experiment was designed at totally random choosing 6 rows (six replicates) of 90 plants in each (540 plants/treatment) for the following treatments: Nitrophenolates (NPLs) were added to the irrigation system (1 l/ha), and control (no treatment). Treatments consisted of a mixture of Na-*p*-nitrophenolate (0.3%), Na-*o*-nitrophenolate (0.3%) and Na-nitroguaiacol (0.1%) and were applied at 2 week intervals from the development of first floral bunch (1st week March) to end of July.

After the fruit set (beginning June), for each row 10 fruits were marked at random to evaluate the fruit growth (diameter and length, mm) and maturation on plant (external colour). Taking into account these data, 6 samples of 5 similar fruits to those labelled on plant (one sample per row) were taken at 3-day intervals and transferred to the laboratory for further analytical determinations.

2.2. Growth parameters

For each sampling date, length (mm), diameter (mm), pericarp thickness (mm), weight (g) and colour (L*, a* and b* parameters using the Hunter Lab System in a Minolta colourimeter CR200, Minolta Camera Co., Japan) were individually measured in each fruit. Data are the mean ± SE of two consecutive years.

2.3. Samples preparation

For chemical determinations 6 sub-samples of 5 peppers were made by homogenising with liquid N_2 either the entire fruit pericarp (for smaller fruits) or taking a ring of the equatorial zone without placentary tissue, and the following parameters were quantified in duplicate in each of these sub-samples (data are the mean ± SE of the two years on a fresh weight basis).

2.4. Total acidity, total antioxidant activity, total phenolic compounds, sugars and organic acids

Total acidity was determined using 1 ml of the juice obtained from pepper samples diluted in 25 ml of distilled H_2O. The pH of the juice was recorded and then titratable acidity was calculated by potentiometric titration with 0.1 N NaOH up to pH 8.1. Results were the mean ± SE expressed as g of citric acid equivalent per 100 g^{-1}.

TAA was quantified according to Arnao, Cano, and Acosta (2001), which enables the determination of TAA due to both hydrophilic and lipophilic compounds in the same extraction. Briefly, for each sub-sample, five grams of tissue were homogenised in 5 ml of 50 mM phosphate buffer pH 7.8 and 3 ml of ethyl acetate, and then centrifuged at 10,000*g* for 15 min at 4 °C. The upper fraction was used for total antioxidant activity due to lipophilic compounds (L-TAA) and the lower for total antioxidant activity due to hydrophilic compounds (H-TAA). In both cases, TAA was determined using the enzymatic system composed of the chromophore 2,2′-azino-bis-(3-ethylbenzothiazoline-6-sulphonic acid) diammonium salt (ABTS), the horse radish peroxidase enzyme (HRP) and its oxidant substrate (hydrogen peroxide), in which $ABTS^{\bullet+}$ radicals are generated and monitored at 730 nm. The decrease in absorbance after adding the pepper extract was proportional to the TAA of the sample. A calibration curve was performed with Trolox ((R)-(+)-6-hydroxy-2,5,7,8-tetramethyl-croman-2-carboxylic acid) (0–20 nmol) from Sigma (Madrid, Spain), and results are expressed as mg of Trolox equivalent 100 g^{-1}.

Phenolic extraction for each sub-sample was performed using water:methanol (2:8) containing 2 mM NaF (to inactivate polyphenol oxidase activity and prevent phenolic degradation) as described by Tomás-Barberán et al. (2001) and quantified using the Folin–Ciocalteu reagent and results were expressed as mg gallic acid equivalent 100 g^{-1}. Sugars and organic acids were extracted with 50 mM phosphate buffer pH 7, according to a previous report (Serrano, Guillén, Martínez-Romero, Castillo, & Valero, 2005), and quantified by HPLC, using 0.1% phosphoric acid running isocratically with a flow rate of 0.5 ml min^{-1} through a Supelco column (Supelcogel C-610H, 30 cm × 7.8 mm, Supelco Park, Bellefonte, USA). Organic acids were detected by absorbance at 210 nm and expressed as g 100 g^{-1} for citric acid, and mg 100 g^{-1} for the remaining organic acids using a standard curve of pure L-ascorbic, citric, malic, oxalic and succinic acids (Sigma, Poole, Dorset, UK). The detection of sugars was obtained by a refractive index detector and results were expressed as g 100^{-1} using a standard curve of pure sugars (glucose, fructose and sucrose) purchased from Sigma.

2.5. Total carotenoids

Total carotenoids were extracted according to Mínguez-Mosquera and Hornero-Méndez (1993). Briefly, 5 g of flesh tissue were extracted with acetone and shaken with diethyl ether and 10% NaCl to separate out the two phases. The lipophilic phase was washed with Na_2SO_4 (2%), saponified with 10% KOH in methanol, and the pigments were subsequently extracted with diethyl ether, evaporated and then made up to 25 ml with acetone. Total carotenoids were estimated by taking the absorbance at 450 nm according to Deepa, Kaur, George, Singh, and Kapoor (2007) in a UNICAM Helios-α spectrophotometer (Cambridge, UK), and expressed as mg of β-carotene equivalent 100 g^{-1}, taking into account the $\varepsilon^{1\%}_{cm} = 2560$.

2.6. Statistical analysis

Data for the analytical determinations were subjected to analysis of variance (ANOVA). Sources of variation were sampling dates and treatment. Mean comparisons were performed using HSD the Tukey's test to examine if differences were significant at $p < 0.05$ (Table 1). To know which compounds contribute to TAA, linear regressions were performed amongst the functional compounds taking into account data from all sampling dates (from both control to treated fruits). All analyses were performed with SPSS software package v. 12.0 for Windows (2001).

3. Results

3.1. Pepper fruit growth and maturation

The growth of pepper fruit exhibited a single-sigmoid pattern, with the maximum growth rate being found between 25 and 40 days after fruit set (DAFS). However, differences were obtained depending on treatment (Fig. 1), since those plants treated with NPLs yielded fruits with significantly higher fruit weight than controls. The maximum fruit weight was reached after 46 and 49 DAFS, with final values of ≈343 and ≈317 g, for treated and control peppers, respectively. These differences were attributed to the higher length, diameter and pericarp thickness found in the treated (134.68 ± 1.86, 93.66 ± 1.06 and 7.86 ± 0.01 mm, respectively) than in control fruits (128.22 ± 0.92, 88.39 ± 1.03 and 6.75 ± 0.13 mm, respectively), taken into account data from the last 6 sampling dates. With respect to colour (Fig. 1), its evolution was similar in both control and treated fruits. The colour a* parameter varied very little from fruit set to day 36 and increased sharply from 39 to 57 DAFS, due to colour changes from green to red, which occurred in the last phase of fruit growth, when the fruit was near its maximum weight. The carotenoid pigments were analysed from 28 DAFS when peppers were still at the green stage to a weight of ca. 100 g, and their behaviour was similar to colour evolution. Thus, a significant increase was obtained at the later growth phase and maturation without differences irrespective of treatment, with a final concentration of ≈50 mg 100 g^{-1} (Fig. 1).

3.2. Sugars, acidity and organic acids

Glucose and fructose were found to be the major sugars by HPLC, the concentrations being higher for fructose than glucose. The concentrations of both sugars increased along the fast growth phase and especially during the maturation process. Moreover, those peppers from treated plants reached significantly higher levels of both glucose and fructose than control fruits (Fig. 2). Thus, final levels of glucose and fructose were 3.25 ± 0.13 and 3.59 ± 0.12 g 100 g^{-1}, respectively, in treated fruits and 2.42 ± 0.07 and 2.79 ± 0.14 g 100 g^{-1}, respectively, in control peppers. Sucrose occurred at low levels (<0.5%) and was not affected by treatment or the growth period (data not shown). On the other hand, total acidity increased continuously as did the growth cycle, and treated peppers also showed higher levels of acidity than controls, with final values of 0.33 ± 0.01 and 0.40 ± 0.02 g 100 g^{-1}, respectively (Fig. 3). The main organic acid contributing to pepper acidity was citric acid, which evolved in a similar way to total acidity (Fig. 3), and was also at higher concentrations in pepper from NPLs-treated plants, than in those from control ones. It is interesting to point out the ascorbic acid results due to its role as vitamin C. Thus, ascorbic acid significantly increased along the growth cycle reaching final concentrations of 132 ± 4 mg 100 g^{-1} in control fruits, although the contents were significantly higher (155 ± 3 mg 100 g^{-1}, over a 18% greater) in pepper from NPLs-treated plants (Fig. 3). Other organic acids such as succinic, malic, oxalic and fumaric acids were also detected in pepper fruits although at much lower concentrations, ranging from 20 to 120 mg 100 g^{-1}, with slight but not significant increases along the growth cycle and were not affected by treatment either (data not shown).

3.3. Total antioxidant activity and phenolics

Total antioxidant activity was evaluated in both hydrophilic (H-TAA) and lipophilic (L-TAA) fractions. As can been seen in Fig. 4, H-TAA was significantly higher (ca. 10-fold) than L-TAA along the fruit growth and maturation. H-TAA increased sharply from 18 to 31 DAFS (from ≈40 to 200 mg 100 g^{-1}) coinciding with the fast growth phase, the enhancement being found at a much lower rate from this time. The NPLs treatment affected H-TAA, since it was

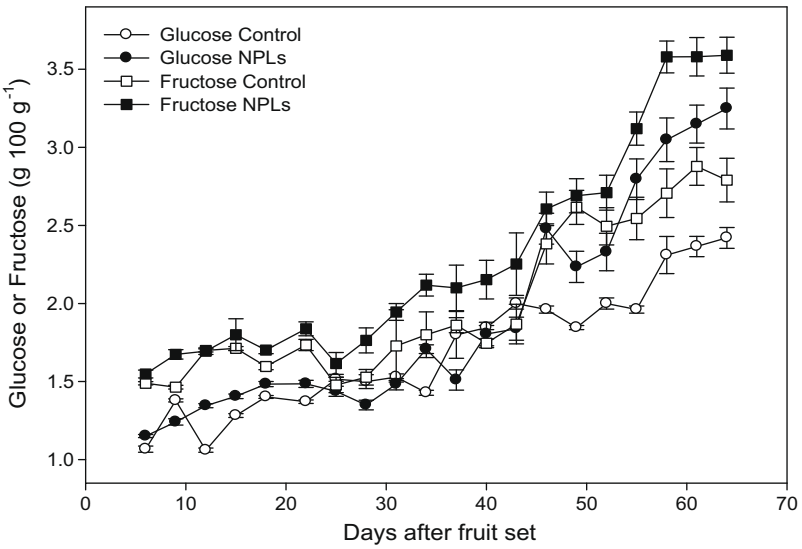

Fig. 2. Evolution of glucose and fructose along the growth and ripening of pepper from control and nitrophenolates (NPLs)-treated plants.

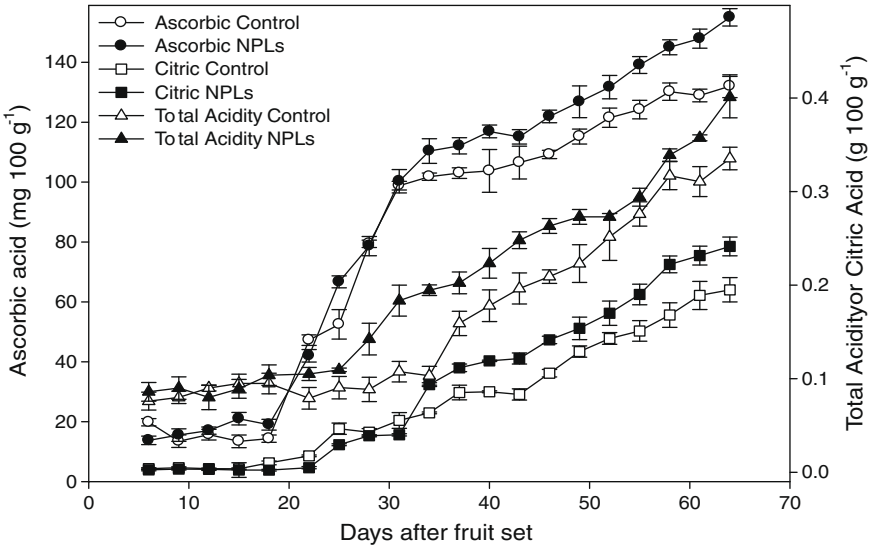

Fig. 3. Evolution of total acidity, and citric and ascorbic acids along the growth and ripening of pepper from control and nitrophenolates (NPLs)-treated plants.

significantly higher in treated peppers than in controls, with final values of 303 ± 12 and 246 ± 5 mg 100 g^{-1}, respectively. Contrarily, L-TAA was not affected by NPLs treatment, although it increased also along pepper growth and maturation, from levels of ≈7 mg 100 g^{-1} at early phases of development to final values of ≈28 mg 100 g^{-1} at full ripe stage. The phenolic content evolved in a similar way to H-TAA and was increased also by NPLs treatment. The final levels were 173 ± 3 and 142 ± 3 mg 100 g^{-1} for treated and control fruits, respectively (Fig. 4).

3.4. Correlations

To know which bioactive compounds are contributing to TAA in pepper, linear regressions were performed with data from either control or treated peppers (Table 2). Results revealed that the total phenolics and ascorbic acid were highly correlated (r^2 = 0.92–0.99) to H-TAA, whilst total carotenoids were highly correlated (r^2 = 0.81–0.97) to L-TAA and colour a* (r^2 = 0.81–0.97). In addition, colour a* parameter was also correlated to L-TAA in both control (r^2 = 0.78) and treated peppers (r^2 = 0.84).

4. Discussion

The current intensive agriculture is focused on obtaining vegetable crops with elevated yield and high quality fruits. However, there is a goal for producers to increase crop inputs for those commodities that have an elevated efficacy under intensive cultural practices, using greenhouses with an optimum control in irrigation, fertilisation, temperature, illumination, weed control, etc. However, there are few studies on the changes in nutritive and bioactive compounds with functional properties along the fruit development on plant and any report on the effect of NPLs on the behaviour of the above compounds. In this paper, we have demonstrated that glucose, fructose, ascorbic acid, citric acid, both H- and L-TAA, total phenolics and total carotenoids increased during pepper development, although their levels were significantly en-

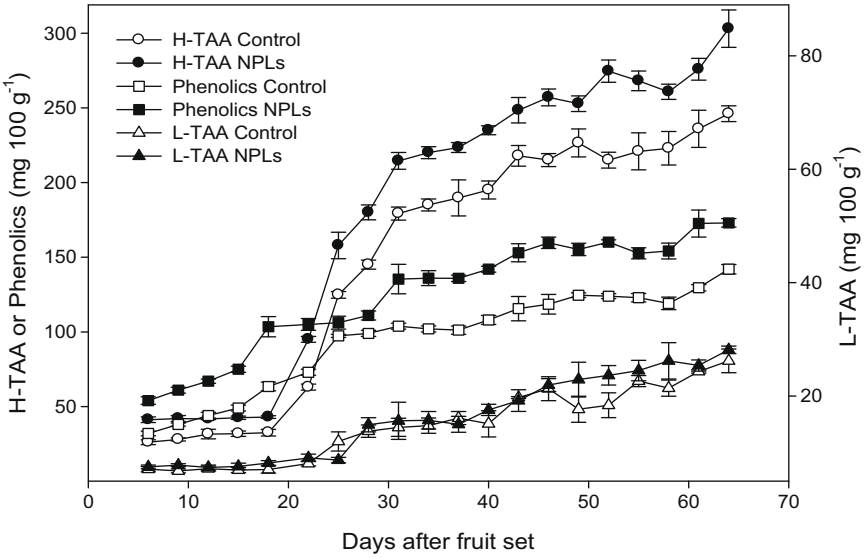

Fig. 4. Evolution of total phenolics and total antioxidant activity in the hydrophilic (H-TAA) or lipophilic (L-TAA) fraction along the growth and ripening of pepper from control and nitrophenolates (NPLs)-treated plants.

Table 2
Linear regressions between bioactive compounds and H-TAA (hydrophilic total antioxidant activity), L-TAA (lipophilic total antioxidant activity) or colour a^* in peppers from control and nitrophenolates (NPLs) treated plants.

	Control	Treated
H-TAA vs. phenolics	$y = 2.36x - 74.67$ $r^2 = 0.942$	$y = 2.41x - 119.97$ $r^2 = 0.921$
H-TAA vs. ascorbic acid	$y = 1.85x + 1.66$ $r^2 = 0.976$	$y = 1.87x + 16.01$ $r^2 = 0.985$
L-TAA vs. carotenoids	$y = 0.24x + 13.68$ $r^2 = 0.813$	$y = 0.30x + 14.08$ $r^2 = 0.937$
Colour a^* vs. carotenoids	$y = 1.17x - 19.20$ $r^2 = 0.973$	$y = 1.18x - 20.02$ $r^2 = 0.971$
L-TAA vs. colour a^*	$y = 0.32x + 15.29$ $r^2 = 0.777$	$y = 0.37x + 16.86$ $r^2 = 0.840$

hanced by NPLs application in the irrigation system, with the exception of L-TAA and total carotenoids.

Pepper fruit (*Capsicum annum* L. cv. Herminio) growth followed a simple sigmoid curve reaching its maximum size around 49 DAFS under our experimental conditions (summer time), although NPLs led to significant increases in fruit weight due to higher length, diameter, and pericarp thickness. Then, NPLs treatment improved fruit quality, since pepper fruit with high sizes are more appreciated by consumers and reach higher prices than smaller fruits at markets. The colour changes from green to red started when fruit had almost reached their final size, at 39 DAFS, and reached the full colour red (end of ripening) at day 55 of development. It is noticeable that NPLs did not modify the normal colour evolution of pepper fruit on plant. This pattern of fruit development (growth and colour changes) has been found in other pepper cultivars, although the time necessary to reach final size and full colour depended on cultivar and growth conditions. Thus, in cultivar 'New ace' final growth and colour changes occurred after 50 days of fruit set (Yahia, Contreras-Padilla, & González-Aguilar, 2001), whilst in 'Domino' cultivar, 56 days were needed (Hornero-Méndez et al., 2002), both cultivars being grown in greenhouse under controlled hydroponic conditions and receiving standard cultural practices. The colour change from green to red has been associated to ripening in sweet pepper, and it is well known that the red colour is due to carotenoid pigments (Mínguez-Mosquera & Hornero-Méndez, 1993; Pretel, Serrano, Amorós, Riquelme, & Romojaro, 1995), which is in agreement with the correlation found between colour a^* evolution and total carotenoid concentration reported herein. The main carotenoid compounds in pepper fruit have been found to be capsanthin followed by *cis*-capsanthin, β-carotene and zeaxanthin (Marín et al., 2004; Mínguez-Mosquera & Hornero-Méndez, 1993). The total carotenoid concentration in 'Herminio' pepper was within the range reported for other cultivars such as 'Vergasa' (Marín et al., 2004) and 'Robusta' (Fox et al., 2005), although higher carotenoid contents have been reported in 'Agridulce' and 'Bola' varieties (Mínguez-Mosquera & Hornero-Méndez, 1993).

The content of glucose and fructose started to accumulate at higher rates when fruit was approaching its final size (from 49 DAFS), although those peppers treated with NPLs exhibited a higher increase in these sugars. In addition, sucrose occurred at a very low concentration and did not change throughout the development process. This behaviour in sugar profile, evolution and final concentration has been reported for other pepper cultivars, since increases in both glucose and fructose were shown from green to red ripe stages in 'Mazurka' and 'Evident' cultivars (Lunning et al., 1994). However, in those peppers that are generally consumed at green stage, such as 'Padrón' the concentrations of sugars are 3–4-fold lower (López-Hernández, Oruña-Concha, Simal-Lozano, Vázquez-Blanco, & González-Castro, 1996). With respect to acidity, this parameter increased along the growth and maturation periods, although peppers from NPLs-treated plants showed higher acidity than controls. This acidity behaviour was further confirmed by the evolution of individual organic acids by HPLC. The main organic acid was citric acid followed by succinic, malic, oxalic and fumaric acids. These increases in soluble sugars and acidity have also been found during physiological ripening in many cultivars of both hot and sweet pepper, being correlated to colour changes (Behera, Pal, Sen, & Singh, 2004; Orowski, Grzeszczuk, & Jadczak, 2004; Tadesse et al., 2002). Moreover, NPLs application led to higher sugar and organic acid concentration in pepper pericarp as compared to pepper from control plants, which could be attributed to a higher net photosynthesis in NPLs-treated plants, and in turn, to higher levels of photo-assimilates to partitioning between plant sinks. In fact, NPLs increased photosynthesis in the cotton plant (Gou & Oosterhuis, 1995) and tomato plant growth by increasing the activity of antioxidant enzymes such as superoxidedismutase, catalase and peroxidase and the auxin contents (Djanaguiraman, Pandiyan,

et al., 2005). Accordingly, some bio-fertilizers applied to pepper plants to increase fruit weight and total yield also increased total soluble solids and acidity (Ghoname & Shafeek, 2005). In addition, the foliar application of Biozyme®, which contains phytohormones and micronutrients, induced also significantly higher levels of non-structural carbohydrates such as glucose and fructose (Belakbir et al., 1996). In a comparative study combining instrumental and sensory evaluation of flavour in fresh peppers, a close relationship between sweetness and concentration of glucose and fructose in pepper for red ripe stage has been reported, whilst the perceived sourness increased from the green to red maturation stages mainly due to an increased concentration of citric acid (Lunning et al., 1994). In this sense, the application of NPLs would induce an extra benefit related to consumer's acceptability, since red peppers with high contents of both sugars and acidity are more appreciated (Frank et al., 2005).

Fresh sweet peppers have exceptionally high ascorbic acid content, since a 100 g serving supply twice the current RDA (recommended daily administration) of 60 mg day^{-1}. In fact, concentrations ranging from 15 to 250 mg 100 g^{-1} of ascorbic acid have been found depending on cultivar, fruit ripening stage and growing conditions (Deepa, Kaur, Singh, & Kapoor, 2006; Fox et al., 2005; Howard et al., 2000; Jiménez, Romojaro, Gómez, Llanos, & Sevilla, 2003; Marín et al., 2004; Özden & Bayindirli, 2002). In the 'Herminio' cultivar, ascorbic acid concentration increased as did the developmental process, the enhancement being higher in NPLs-treated fruits, with final concentrations being considered as relatively high when compared to other pepper cultivars. According to our results, increases in ascorbic acid content have been reported to occur along the ripening process of both, hot and sweet pepper fruit and then, red fruit have higher vitamin C content than green ones (Behera et al., 2004; Jiménez et al., 2003; Marín et al., 2004; Navarro et al., 2006; Orowski et al., 2004; Pérez-López, del Amor, Serrano-Martínez, Fortea, & Núñez-Delicado, 2007). However, in bell pepper cultivars either maintenance or even a 2-fold decrease in ascorbic acid concentration from mature green to full red stages have been reported (Fox et al., 2005; Yahia et al., 2001).

In recent years phenolic compounds have attracted the interest of researchers because they show antioxidant activity and can protect the human body from free radicals, and have a certain role in the prevention of some diseases, including cancer, cardiovascular disease and neurodegenerative disorders (Ferrari & Torres, 2003; Kaur & Kapoor, 2001). Phenolic concentration was accumulated along the developmental stages of pepper fruit, and NPLs application led to higher total phenolic concentration. This evolution in phenolics does not seem to be a general behaviour during pepper fruit maturation, since decreases or increases in total phenolics have been associated with changes from green to red stage depending on cultivar (Conforti, Statti, & Menichini, 2007; Marín et al., 2004). Sweet pepper contains a very rich polyphenols pattern, since it has been identified to contain 5 hydroxycinamic acids and 23 flavonoids as the major phenolics compounds (Marín et al., 2004). Accordingly, in hot peppers flavonoids have been also identified as the main phenolics compounds, although capsaicinoids, such as capsaicin and dihydrocapsaicin, were also important (Hornero-Méndez et al., 2002).

Total antioxidant activity (TAA) is an important parameter in establishing the health functionality of a vegetable product and there are many methods for its measurement (Kaur & Kapoor, 2001). With the used method, we were able to measure TAA in two fractions, and the results showed that TAA was 10-fold higher in the hydrophilic fraction (H-TAA) than in the lipophilic one (L-TAA), according to previous reports in cv. 'Orlando', a California type pepper (Navarro et al., 2006) and in bell pepper 'Robusta' cultivar (Fox et al., 2005), indicating that the main compounds responsible for antioxidant properties of pepper fruits are water soluble compounds. In fact, the behaviour of total phenolics and ascorbic acid along the growth and maturation stages showed a similar pattern than that obtained for H-TAA, these compounds being highly correlated to H-TAA, which could be the responsible for this H-TAA. However, discrepancies exist in understanding the relationship between TTA and total phenols, since weak correlations between both parameters were found in several pepper cultivars at red stage (Belakbir et al., 1996; Deepa et al., 2006). Finally, L-TAA was correlated with colour a^* evolution and total carotenoids, which would be the main lipophilic compounds with antioxidant activity.

In conclusion, NPLs treatment induced beneficial effects during the growth cycle and maturation of sweet pepper in two ways. Firstly, NPLs yielded bigger fruits with higher contents of sugars (glucose and fructose) and organic acids, without affecting the normal ripening process on plant as showed by colour and carotenoid evolution. Secondly, this pre-harvest treatment also increased the bioactive compounds with functional properties, such as total phenolics and ascorbic acid, which were the main compounds contributing to TAA. In addition, since sugars, organic acids, total phenolics, carotenoids, and vitamin C increased along with the fruit ripening on plant, it should be advisable to harvest the peppers at the full red stage, in order to achieve the maximum benefit of their consumption in terms of nutritive and functional properties.

Tomato fruit
Tomato seed oil
Fatty acids
Heavy metal
Micronutrient

ABSTRACT

In this study, oils, micronutrients and heavy metal contents of tomato seeds and tomato (*Lycopersicon esculentum*) fruits from different Turkish resources were determined. The tomato seed oil contains more than 84% unsaturated fatty acids, such as oleic acid, linoleic acid and linolenic acid. The fatty acid composition of tomato seed oil was similar to that of soybean oil. Under supercritical conditions, partial thermal degradation occurs on the double bonds of unsaturated aliphatic carbons chains in fatty acids. Linoleic acid was the major unsaturated fatty acid in tomato seed oil. The concentrations of metals (Pb, Cd, Fe, Cu, Zn, Na, K, Ca and Mg) were determined in tomato samples.

1. Introduction

Tomato (*Lycopersicon esculentum*) is one of the world's major vegetables with a worldwide production of 126 million tons in 2005 (FAOSTAT, 2007). It is an excellent source of many nutrients and secondary metabolites that are important for human health: mineral matter, vitamins C and E, β-carotene, lycopene, flavonoids, organic acids, phenolics and chlorophyll (Giovanelli & Paradiso, 2002).

Tomato fruits contain several anti-oxidants such as vitamin C, provitaminic A carotenes, phenolic compounds, flavonoids and phenolic acids. Consumption of its components, β-carotene and lycopene, has been related epidemiologically to a lower incidence of cardiovascular disease and of prostate, gastrointestinal and epithelial cell cancer (Rao & Rao, 2007).

Heavy metal and nutritive contents of tomatoes depend on growing conditions (Miteva, Maneva, Hristova, & Bojinova, 2001). Heavy metal and nutritive contents of tomatoes grown using conventional and organic methods were determined (Rossi et al., 2008). Compared to crops grown using conventional and organic methods, organic tomatoes contained more salicylic acid but less vitamin C and lycopene. Organic tomatoes had higher Cd and Pb levels but a lower Cu content. Organic fruits had slightly higher protein content than conventionally cultivated fruits, but the difference was minimal and consequently the nutritive significance was poor (Rossi et al., 2008).

Several unit operations such as drying, grinding, squeezing and filtrating were used to obtain tomato seed oil from tomato seeds. Tomato seed oil was extracted with supercritical carbon dioxide in a semibatch-flow extraction apparatus. The effect of milling of seeds and solvent flow rate on the extraction behaviour was studied. The extraction rate increased as solvent flow rate increased (Roy, Goto, & Hirose, 2003; Roy, Goto, Hirose, Navaro, & Hortacsu, 1994). Supercritical fluid extraction is generally carried out by mechanically stirring or in a rocking batch reactor at the critical temperature and pressure of the solvent. The yield of soluble material increases with increasing pressure (Paul & Wise, 1971).

2. Materials and methods

2.1. Sampling

The samples of tomato (*L. esculentum*) seeds, tomato peels and industrial tomato wastes were supplied from different Turkish resources. Only tomato seeds were used for oil analyses. Whole tomato fruits were used for determination of mineral matter and phenolic compounds. The tomatoes were washed in distilled water before each experiment.

2.2. Supercritical acetone extraction of tomato seeds

Tomato seed oil was extracted with supercritical acetone in a batch pressure vessel (autoclave) within the temperature range 513–518 K and the pressure range 6.0–6.5 MPa. In addition, tomato seed oil was extracted with simple Soxhelet acetone solid–liquid extraction.

2.2.1. Fractionation of supercritical acetone extract

The deionised water was added into the acetone extract (1/1, v/v); and extracted with equal portions of petroleum ether (b.p. 413–433 K). Petroleum ether solubles were saponified for 3.5 h at 338 K using 0.5 N of methanolic potassium hydroxide to liberate the fatty acids present as their esters or acylglycerols. The unsaponifiables present in the mixture were then extracted 3–4 times with equal portions of petroleum ether. Upon removal of petroleum ether the unsaponifiables were obtained. The solution of saponifiables was diluted with an equal volume of water, then acidified to pH 3–4 by addition of 1.5 N hydrochloric acid. The fatty acids present in the solution were extracted using diethyl ether. After evaporation of ether, the acids were weighed. The fatty acids were methylated with diazomethane according to the method of Schelenk and Gellerman (1960).

2.3. Fatty acid analysis

The methyl esters of the fatty acids were analysed by gas chromatography (Hewlett–Packard 5790) on a 12 m 0.2 mm capillary column coated with Carbowax PEG 20 (Demirbas, 2009). The physico-chemical properties such as saponification value, acid value, iodine value and peroxide value of the tomato seed oils were determined.

2.3.1. Physico-chemical properties

The physico-chemical properties such as saponification value, acid value, iodine value and peroxide value of the tomato seed oils were determined by AOCS Tentative Methods (AOAC, 1990). All tests were performed in triplicate.

2.4. Mineral matter analysis

Mineral matter contents were determined according to earlier methods (Demirbas, 2000, 2001, 2002; Tuzen, Ozdemir, & Demirbas, 1998). Digestion of tomato seed samples was performed using an oxi-acidic mixture of HNO_3:H_2SO_4:H_2O_2 (4:1:1) (12 ml 97 for 2–4 g sample) and heating at 348 K for 3 h. After cooling, 20 ml-demineralised water was added, then the digest was again heated up to 423 K for 4 h and brought to a volume of 25 ml with demineralised water (Tuzen et al., 1998).

Cd levels in the samples were determined using a GBC 3000 graphite furnace for AAS. Determination of metal ion (Cu^{+2}, Fe^{+2}, Zn^{+2}) content was carried out with a GBC 905 model AAS using flame atomisation. For the determination of Pb and Cd contents, euterium and Smith-Hieftje background correction have been used (Demirbas, 2002). The wavelength and slit values, in nm, used for the determination of Pb, Cd, Fe, Cu and Zn were: 283.3 and 0.5, 228.8 and 0.5, 248.3 and 0.2, 324.7 and 0.5 and 213.9 and 0.5, 108 respectively. A flame photometer (Biotechnical Instruments, Model 8T 624D) was used for determinations of Na and K (Demirbas, 2005). For determination of Ca and Mg, the resulting digest solution was titrated with 0.01 M EDTA solution. The standard-addition procedure was used in all determinations.

2.5. Determination of phenolic substances

To obtain total phenolic substances from the supercritical acetone extract, 10 g of the extract obtained from tomato fruits were extracted four times with 250 ml of a 5% heated solution of NaOH at 343 K. 200-ml of the caustic solution was extracted twice with 25-ml of pentane to remove hydrocarbons. After addition of a 15% HCl solution to adjust the pH of the solution to 6, a 5% solution of $NaHCO_3$ was added to the solution until PH8.3 was obtained. As a result of this the precipitate dissolved (Morrison and Boyd, 1983). The clear solution was extracted four times with equal volumes of diethyl ether and then the ethereal layer, containing the phenols, was washed with distilled water and dried overnight with $MgSO_4$. The pH was measured using a glass electrode (Jenway 3010 model pH metre).

2.5.1. Antioxidative activity of phenolic substances

The antioxidative activity of total phenolic substances was determined using the nitric oxide method. The antioxidative activity of the isolated phenolics was determined by the ferric thiocyanate method (Nagatsu et al., 2004).

2.6. Statistical analysis

All analytical determinations were performed in triplicate and the mean values were reported. Results presented are means ± standard deviations of triplicate values. The percentages of fatty acid were compared by analysis of variance (ANOVA) taking $p < 0.05$ as the minimum criterion for statistical significance. Comparisons between means were performed with Tukey's test.

3. Results and discussion

3.1. Fatty acid analysis results

The percentage yields of supercritical acetone extractions are present in Table 1. The extract yield slightly increased with increasing temperature.

The chemical compositions of fatty acids of tomato seed oil and methyl esters from Soxhelet acetone extraction and supercritical acetone extraction are presented in Table 2. Mrystic (14:0), palmitic (16:0), stearic (18:0), arachidic (20:0), myristoleic (14:1), palmitoleic (16:1), oleic (9c-18:1), linoleic (9c, 12c-18:2) and gadoleic (20:1) fatty acids were observed in the oil samples. Unsaturated fatty acid as myristoleic acid, palmitoleic acid, oleic acid, linoleic acid, linolenic (9c, 12c, 15c-18:3) acid and gadoleic (9c-20:1) reach as high as 75.8%. In both extractions, palmitic acid was the major saturated fatty acid, followed by stearic acid. Linoleic acid was the major unsaturated fatty acid followed by oleic acid. The fatty acid composition of tomato seed oil was similar to that of soybean oil (Demirbas, 1998).

Table 1
Yields of supercritical acetone extraction (wt.% of dry tomato seed).

Runs	Temperature (K)	Total extract	Oil fraction	Unsaponifiables
1	513	39.1	35.3	3.8
2	515	40.7	36.4	4.3
3	518	41.8	36.9	4.9

Table 2
Chemical compositions of fatty acids in tomato seed oil and methyl esters by Soxhelet extraction (SAE) and supercritical acetone extraction (SCAE).

Fatty acid	Tomato seed oil (%)	Methyl esters from SAE and SCAE	
		SAE (%)	SCAE (%)
Myristic (14:0)	1.1	0.6	2.0
Palmitic (16:0)	18.1	16.4	22.6
Stearic (18:0)	4.0	3.5	5.2
Arachidic (20:0)	1.0	0.8	1.6
Myristoleic (14:1)	0.2	0.3	0.1
Palmitoleic (16:1)	3.2	3.5	3.0
Oleic (9c-18:1)	24.6	26.3	21.8
Linoleic (9c, 12c-18:2)	46.8	47.2	42.4
Linolenic (9c, 12c, 15c-18:3)	0.4	0.6	0.2
Gadoleic (9c-20:1)	0.6	0.8	1.1

Compared to Soxhelet extraction, the unsaturated fatty acid levels decreased significantly during supercritical acetone extraction from 78.7% to 68.6%. Partial thermal degradation of the unsaturated fatty acids may occur in the supercritical acetone extraction due to high temperature (<513 K). The high temperature had a much greater effect on the polyunsaturated fatty acids than saturated and monounsaturated fatty acids. Under supercritical conditions partial thermal degradation occurs on the double bonds of unsaturated aliphatic carbons chains in fatty acids (Balat, 2009; Hashem, Hussein, Senousi, Saad, & Khoda, 2009). Oxidation of methyl esters might be causing the formation of hydroperoxides. Many of the vegetable oils contain polyunsaturated fatty acid chains and their double bonds are very reactive (Browne & Armstrong, 2000). Oxidation to CO_2 of the methyl ester results in the formation of hydroperoxides. The formation of the hydroperoxide follows a well known peroxidation chain mechanism. Oxidative lipid modifications occur through lipid peroxidation mechanisms in which free radicals and reactive oxygen species abstract a methylene hydrogen atom from polyunsaturated fatty acids, producing a carbon-centred lipid radical. Spontaneous rearrangement of the 1,4-pentadiene yields a conjugated diene, which reacts with molecular oxygen to form a lipid peroxyl radical (Porter, Wolfe, & Weenan, 1979). Abstraction of a proton from neighbouring polyunsaturated fatty acids produces a lipid hydroperoxide (LOOH) and regeneration of a carbon-centred lipid radical, thereby propagating the radical reaction (Browne & Armstrong, 2000). After a hydrogen is removed, oxygen attacks rapidly and a LOOH is ultimately formed where the polyunsaturation has been isomerised to include a conjugated diene. This reaction is a chain mechanism that can proceed rapidly once an initial induction period has occurred. The greater the level of unsaturation in a fatty oil or ester, the more susceptible it will be to oxidation. Once the LOOHs have formed, they decompose and inter-react to form numerous secondary oxidation products including higher molecular weight oligomers often called polymers.

The oxidative and thermal degradation occurs on the double bonds of unsaturated aliphatic carbons chains in fatty acids. Oxidation of the methyl esters result in the formation of hydroperoxides. The formation of the hydroperoxide follows a well known peroxidation chain mechanism. The olefinic unsaturated fatty acid oxidation is a multi-step reaction process where primary products (conjugated diene hydroperoxides) decompose and chemically interact with each other to form numerous secondary oxidation products. The oxidative and thermal instability are determined by the amount and configuration of the olefinic unsaturation on the fatty acid chains (Demirbas, 2008).

3.2. Physico-chemical properties

The physico-chemical properties of the tomato seed oils are given in Table 3. Acid value is a measure of the free fatty acid content in fats and oils. The acid value is the number of mg of potassium hydroxide necessary to neutralise the free fatty acids present in 1 g of oil or fat sample (Beare-Rogers, Dieffenbacher, & Holm, 2001). The saponification value (SV) is the milligrams of KOH necessary to saponify 1 g of oil sample. The iodine value (IV) is the amount of iodine (in grams) necessary to saturate 100 g of oil sample (Demirbas, 1998). The IV is a measure of the amount of unsaturation in fats and oils. The peroxide value (PV) is a measure of the extent of oxidation of a fat or oil. The value indicates the quantity of oxidised substances, normally hydroperoxides that liberate iodine from potassium iodide under specified conditions. The PV is expressed in milliequivalents of active oxygen per kg fat (Bala, 2005).

Table 3
Physico-chemical properties of the tomato seed oils.

Property	Soxhelet acetone extraction	Supercritical acetone extraction
Acid value (mg KOH/g oil)	0.241	0.006
Saponification value (mg KOH/g oil)	190.2	183.6
Iodine value (g I/l00 g oil)	126.8	109.7
Peroxide value (mmol peroxide/kg oil)	15.0	36.2
Moisture and volatility (%)	0.052	4.18
Specific gravity (g/mL)	0.9177	0.9185
Refractive index	1.4733	1.4714
Color	Yellow	Reddish yellow

3.3. Mineral matter analysis results

The average heavy metal levels (mg/kg, dry-weight basis) of the tomato samples are given in Table 4. Table 5 shows the average levels (mg/kg, dry-weight basis) of Na, K, Ca, and Mg in tomato samples.

From Table 4, the highest and the lowest Pb content was 0.48 ± 0.11 (0.48 is average value and 0.11 is s.d.) and 0.38 ± 0.07 mg/kg in the tomatoes, respectively. The highest 210 Cd content was determined as 0.71 ± 0.15 mg/kg. The highest Cu content was 18.7 ± 3.2 mg/kg. The highest Fe and Zn contents were 2.41 ± 0.34 and 78.4 ± 6.8 mg/kg, respectively. The heavy metal levels in the plants are hardly affected by pH and organic matter content of the soil (Gast, Jansen, Bierling, & Haanstra, 1988). From Table 5, the highest and the lowest Na content were 7.18 ± 0.69 mg/kg and 5.57 ± 0.53 mg/kg in the tomatoes, respectively. The highest and the lowest K contents are 20.81 ± 3.5 mg/kg and 16.59 ± 2.3 mg/kg in the tomatoes, respectively. The highest Ca and Mg contents were 3.54 ± 0.32 and 6.32 ± 0.55 mg/kg, respectively.

The mineral matter composition of vegetables characterises their nutrition conditions and indicates the yield potentials. Excessive amounts of K and Mg in tomato inhibits the Ca uptake and blossom-end rot, which is a result of Ca deficiency (Adams & Ho, 1993). In the case of Ca deficiency in growth substrate, the Ca and P levels in tomato plants have decreased (Morard, Pujos, Bernadac, & Bertony, 1996).

Heavy metals may have significant toxic and hazardous effects on human health, especially cadmium and lead, as non-essential elements (Bakirdere & Yaman, 2008). Chronic cadmium exposures result in kidney damage, bone deformities and cardiovascular

Table 4
Average levels (average ± s.d.) of heavy metals (Pb, Cd, Fe, Cu and Zn) in tomato samples (mg/kg, dry-weight basis).

Run	Pb	Cd	Fe	Cu	Zn
1	0.43 ± 0.08	0.65 ± 0.12	2.13 ± 0.30	14.1 ± 2.4	73.1 ± 6.2
2	0.38 ± 0.07	0.61 ± 0.11	1.98 ± 0.26	12.9 ± 1.8	64.8 ± 5.3
3	0.48 ± 0.11	0.71 ± 0.15	2.41 ± 0.34	18.7 ± 3.2	78.4 ± 6.8
4	0.42 ± 0.09	0.67 ± 0.13	2.32 ± 0.29	17.3 ± 3.0	67.5 ± 6.2
5	0.40 ± 0.10	0.69 ± 0.14	2.18 ± 0.27	16.9 ± 3.1	75.7 ± 6.6

Table 5
Average levels (average ± s.d.) of Na, K, Ca and Mg in tomato samples (mg/kg, dry-weight basis).

Run	Na	K	Ca	Mg
1	6.43 ± 0.62	18.26 ± 2.8	3.08 ± 0.28	5.26 ± 0.46
2	5.57 ± 0.53	16.59 ± 2.3	2.88 ± 0.23	4.22 ± 0.41
3	7.18 ± 0.69	20.81 ± 3.5	3.54 ± 0.32	6.32 ± 0.55
4	6.28 ± 0.61	17.86 ± 3.1	3.17 ± 0.30	6.02 ± 0.52
5	6.88 ± 0.65	19.09 ± 3.3	2.98 ± 0.24	5.89 ± 0.50

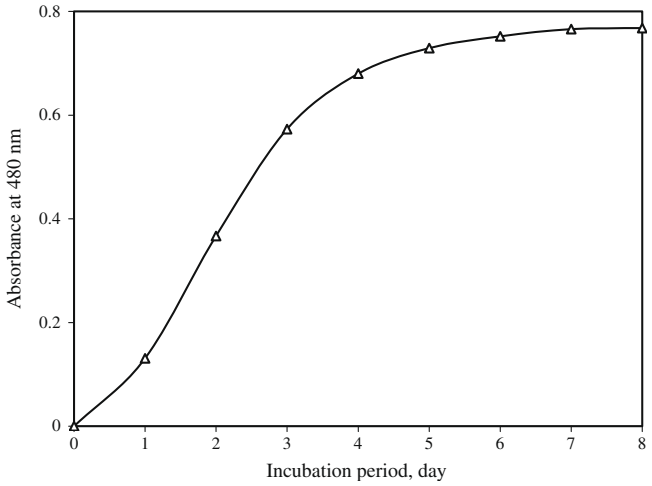

Fig. 1. Plot for antioxidative activity of phenolics determined by ferric thiocyanate method.

problems (Fritioff & Greger, 2007). It is known that copper is an essential element, but it may be toxic to both human and animals when its concentration exceeds the safe limits (Bakirdere & Yaman, 2008; Yaman, Akdeniz, Bakidere, & Atici, 2005).

3.4. Phenolic substances and antioxidative activity of phenolic substances

The highest and the lowest phenolic substance levels are 4.27 ± 0.36% and 2.48 ± 0.28% in the tomatoes, respectively. The average phenolic substance level was 3.50 ± 0.31%.

Fig. 1 shows the plot for the antioxidative activity of phenolics determined by ferric thiocyanate method. From Fig. 1, the antioxidative activity of phenolics increases sharply with time from 1 to 4 days when it reaches a plateau value.

4. Conclusion

The present work indicates that tomato seed wastes were a potential source of edible oil. The oil yield of tomato seeds was about 36% on a dry weight basis. Palmitic acid (18.1%) was the major saturated fatty acid, followed by stearic acid (4.0%) in tomato seed samples. Linoleic acid (46.8%) was the major unsaturated fatty acid followed by oleic acid (24.6%). This vegetable oil has low volatility, low sulphur, low ash content, and high viscosity.

There were considerable differences in the mineral matter composition among the tomato samples. The phenolic component yield of the tomato samples was about 3.5% on a dry weight basis. The antioxidative activities of phenolic compounds sharply increased with time from 1 to 4 days.

ABSTRACT

The degradation of flavanols had been studied both in the litchi pericarp during the storage and in the model system containing PPO and flavanols of litchi pericarp. The results showed that (−)-epicatechin was the optimal endogenous substrate of litchi pericarp PPO, and the procyanidins of litchi pericarp were oxidised very slowly when incubated alone with PPO. However, (−)-epicatechin could accelerate the oxidation of the other flavanols in litchi pericarp through a coupled oxidation pathway. The results obtained allowed us to draw a conclusion that the oxidation of (−)-epicatechin was a precursor of litchi pericarp browning. A pathway of enzymatic browning of litchi pericarp was proposed as follows: with the loss of cellular compartmentation, the litchi pericarp PPO and flavanols mixed and, then, (−)-epicatechin was oxidised by the PPO and *o*-quinones formed. The *o*-quinones reacted with other flavanols and anthocyanins, accelerating the oxidation of other polyphenols. Finally, the oxidation of (−)-epicatechin and other polyphenols led to the formation of the brown-coloured compounds, resulting in the enzymatic browning of litchi pericarp.

1. Introduction

Litchi (*Litchi chinensis Sonn.*) is a subtropical fruit of high commercial value for its white, translucent aril and attractive red colour. However, the fruit rapidly loses its bright red colour and turns brown once harvested. Postharvest browning of litchi was thought to be caused by the rapid degradation of the red pigment and oxidation of phenolic compounds by polyphenol oxidase (PPO), producing brown-coloured products (Akamine, 1960; Huang, Hart, Lee, & Wicker, 1990; Jiang, Zauberman, & Fuchs, 1997; Tan & Li, 1984).

Enzymatic browning is caused by the oxidation of phenolic substrates by PPO to produce reactive quinones. These quinones are highly reactive species involved in different reaction pathways. They are powerful electrophiles which may suffer nucleophilic attack by other polyphenols, amino acids, proteins to produce dark-brown or black pigment in senescent and postharvested fruits and vegetables (Cabanes, García-Cánovas, & García-Cármona, 1987; Fulcrand, Cheminat, Brouillard, & Cheynier, 1994; García-Carmona, Cabanes, & García-Cármona, 1987; Hurrel & Finot, 1984; Matheis & Whitaker, 1984).

In our previous studies, we found that (−)-epicatechin was the main endogenous substrate of PPO in litchi pericarp (Liu et al., 2007a, 2007b), and the enzymically generated (−)-epicatechin *o*-quinone could induce anthocyanins degradation (Liu, Cao, Xie, Sun, & Wu, 2007c). However, those results were obtained in the model systems, and whether those proposed reactions occurred in the litchi pericarp was ambiguous. Thus, the purpose of the present work was to investigate the relationship between the polyphenols oxidation by PPO and the litchi pericarp browning during the storage, so as to confirm our previous conclusions and give a further understanding for the mechanism of litchi pericarp browning.

2. Materials and methods

2.1. Plant material

The fruit of litchi (*Litchi chinensis Sonn. cv.* Feizixiao) at commercial maturation were obtained from Guangdong. The fruit arrived in the laboratory within 24 h after harvest. Fresh fruits were distributed randomly into groups of 10 fruits, packed in 0.03 mm thick PPE bags (20 × 30 cm) and airproofed with rubber bands, and stored at 3 °C.

2.2. Chemicals

(−)-Epicatechin, (+)-catechin, catechol, 4-methylcatechol and chlorogenic acid were purchased from Sigma (St. Louis, MO),

doi:10.1016/j.foodchem.2009.05.019

procyanidin B2 was purchased from Nakahara Science Co. (Ltd). Procyanidin A2 and epicatechin-(4β→8, 2β→O→7)–epicatechin-(4β→8)–epicatechin were obtained and characterised in our previous study (Liu et al., 2007a).

2.3. Colour measurements of litchi pericarp

The Hunter L^*, a^* and b^* values were measured using an UltraScan XE colourimeter (Hunterlab). Hunter L^* values show a gradual lightness of the pericarp. The Hunter a^* values indicate a measure of redness (or $-a^*$ of greenness) and b^* indicate a measure of yellowness (or $-b^*$ of blueness) on the hue-circle. Chroma C^* gives further information on the saturation or intensity of colour. Chroma C^* was calculated as follow equation:

$$C^* = (a^{*2} + b^{*2})^{1/2}$$

2.4. Membrane permeability measurement of litchi pericarp

Membrane permeability, expressed by relative leakage rate, was determined according to the method of Jiang and Chen (1995a) with some modifications. Discs were obtained by using a cork borer (10 mm in diameter) from 10 fruit pericarps. Twenty discs were rinsed twice and then incubated in 25 ml of distilled water at 25 °C, and shaken for 30 min. Electrolyte leakage was determined with a conductivity meter, and then the discs and incubated solution were boiled for 15 min and then cooled to 25 °C to assess total electrolytes. The relative leakage was expressed as a percentage of the total electrolytes.

2.5. Extraction of flavanols from litchi pericarp

Fresh litchi pericarp (5 g) from 5 fruits was extracted using acidified methanol (methanol:1.5 N HCl (85:15)) in a domestic ultrasonic bath (Kunshan), at room temperature for 0.5 h. The extract was filtered and the filter residue re-extracted using the same method until a colourless solution was obtained. Filtrates were combined and the final volume was adjusted to 100 ml in a volumetric flask. The sample was filtered through a 0.45 μm filter before RP-HPLC analysis.

2.6. Reversed-phase HPLC analysis

The analysis of flavanols of litchi pericarp by reversed-phase HPLC was performed on a Varian liquid chromatograph, and the detection was carried out using a photodiode array detector. The column was a VP-ODS column (150 mm × 4.6 mm ID, 5 μm particle size, SHIMADZU). The method utilised a binary gradient with a mobile phase of 2.5% v/v aqueous formic acid (mobile phase A) and acetonitrile/water/formic acid (57.5:40:2.5, v/v/v) (mobile phase B). A 10-μl sample solution was injected and the elution conditions were as follow: a linear gradient from 5% to 35% B in 40 min, from 35% to 50% B in 5 min, and from 50% to 80% B in 5 min, followed by washing and reconditioning of the column. Flow rate was 1 ml/min. Calibrations were performed for each compound by injection of known dilutions. Quantifications were based on peak areas at 280 nm for flavanols, at 510 nm for anthocyanins.

2.7. PPO activity analysis

Fresh litchi pericarp (5 g) from 5 fruits were triturated with liquid nitrogen, and then homogenised with 50 ml of 0.1 M phosphate buffer (pH 7.5) and 1 g of PVPP for 10 min. After centrifugation at 8000*g* for 5 min, the supernatant was collected and the final volume was adjusted to 100 ml in a volumetric flask. PPO activity was assayed spectrophotometrically at 25 °C using (−)-epicatechin as a substrate by monitoring at 440 nm (Liu et al., 2007b). The reaction medium (3 ml) contained 1 ml of 3 mM (−)-epicatechin, 1.98 ml of 50 mM of phosphate buffer (pH 7.5), and 0.02 ml of the enzyme solution. One unit of enzyme was defined as the amount of enzyme that caused an increase in absorbance of 0.001/min at 25 °C.

2.8. Statistical analysis

The Hunter L^*, a^* and b^* values were measured 10 times on each of the 10 fruits, and the average Hunter values were calculated. For enzyme activity measurement and quantification of flavanols, each sample was assayed in triplicate. Means were compared using Tukey Test with a significance level $P < 0.05$.

3. Results and discussion

3.1. Change in PPO activity of litchi pericarp during the storage

To evaluate the role of PPO activity played in the browning of litchi pericarp, we investigated the change in the PPO activity during the storage. However, there was no significant change ($P > 0.05$) in the PPO activity of litchi pericarp during the whole storage (Fig. 1). This suggested that the change in the PPO activity had no correlation with the browning of litchi pericarp, and the browning might be more dependent on whether the PPO mixed with its phenolic substrates.

3.2. Changes in polyphenols and membrane permeability of litchi pericarp during the storage

According to the previous structural identifications (Liu et al., 2007a, 2007c), we found that cyanidin 3-rutinoside was the major anthocyanins and (−)-epicatechin, procyanidin A2, procyanidin B2 and epicatechin-(4β→8, 2β→O→7)–epicatechin-(4β→8)–epicatechin were the four major flavanols in the litchi pericarp (Fig. 2). These results were in agreement with the previous descriptions (Le Roux, DoCo, Sarni-manchado, Lozano, & Cheynier, 1998; Sarni-manchado, Le Roux, Le Guerneve, Lozano, & Cheynier, 2000).

To investigate the relationship between the change of polyphenols and litchi pericarp browning, the contents of cyanidin 3-rutinoside and each major flavanol, the membrane permeability and browning of litchi pericarp were measured at intervals of 7 days during the storage. Browning of litchi pericarp during the storage

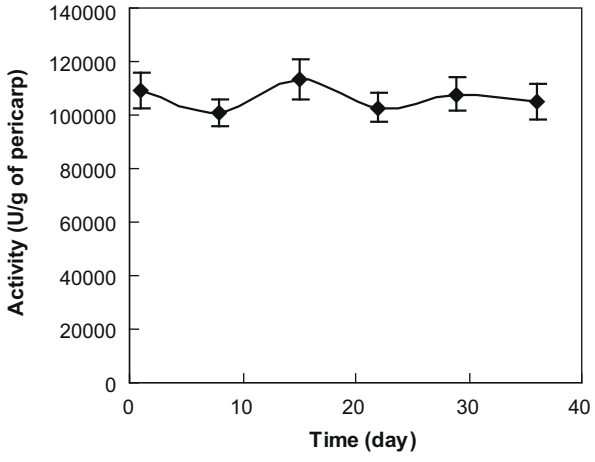

Fig. 1. Change in the PPO activity during storage at 3 °C. Vertical bars indicate SD.

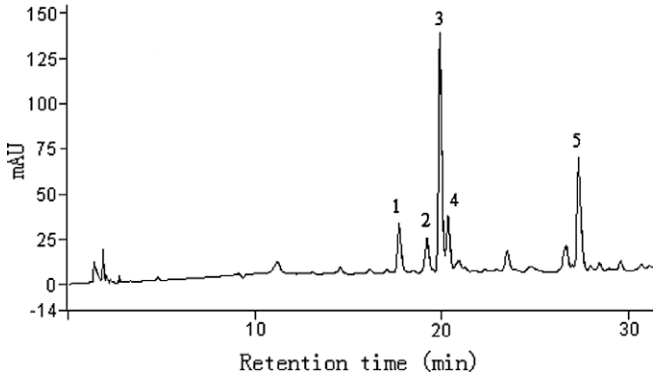

Fig. 2. RP-HPLC chromatographic profile of polyphenols of litchi pericarp, detected at 280 nm. 1: procyanidin B2; 2: cyanidin 3-rutinoside; 3: (−)-epicatechin; 4: epicatechin-(4β→8, 2β→O→7)–epicatechin-(4β→8)–epicatechin; 5: procyanidin A2.

was assessed by the changes of pericarp colour, expressed as the Hunter L^*, a^*, b^* and C^* values. The contents of each major flavanol had no significant change ($P > 0.05$) in the first 22 days with storage at 3 °C (Table 1). Simultaneously, the membrane permeability did not increase significantly ($P > 0.05$) and litchi pericarp browning did not occur (Table 2).

However, the membrane permeability began to increase and browning occurred after 22 days storage (Table 2). This result agreed with the previous description that the loss of cellular compartmentation, associated with the enhanced lipid peroxidation, reduced membrane fluidity and increased membrane permeability would occur during the storage of litchi (Jiang & Chen, 1995a, 1995b; Lin et al., 1988). Our results also showed that the contents of major flavanols and anthocyanins began to decline after the membrane permeability increased (Table 1). For example, the content of (−)-epicatechin declined to 71.12% over 29 days, and then only 21.39% of the content remained at day 36. This could easily be explained by the fact that the deterioration in membrane function allows PPO and polyphenols to mix, causing the oxidation of flavanols and the degradation of anthocyanins in the litchi pericarp.

3.3. Oxidation of endogenous polyphenols of litchi pericarp by PPO

In our previous study, we found that (−)-epicatechin was the main endogenous substrate of PPO in litchi pericarp (Liu et al., 2007b), while cyanidin 3-rutinoside was not a direct substrate for PPO (Liu et al., 2007c). However, the oxidation of the other endogenous polyphenols, especially flavanols in litchi pericarp by PPO is unknown. In an attempt to determine the optimal endogenous substrate of litchi pericarp PPO, the reaction of litchi pericarp PPO with endogenous flavanols of litchi pericarp had been investigated.

Table 2
Changes in colour and membrane permeability of litchi pericarp during storage at 3 °C.

Day	Hunter colour parameters				Membrane permeability (%)[a]
	L^*	a^*	b^*	C	
1	35.61a	15.61a	22.72a	27.57a	17.54 ± 2.87c

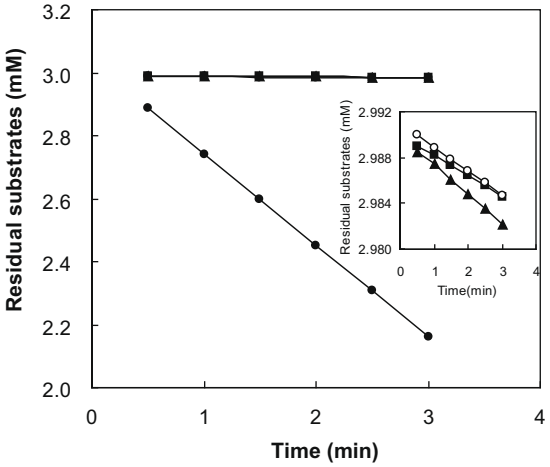

Fig. 3. Oxidation rate of (−)-epicatechin (●), procyanidin A2 (▲), procyanidin B2 (○) and epicatechin-(4β→8, 2β→O→7)–epicatechin-(4β→8)–epicatechin (■) by PPO of litchi pericarp. Inset: amplified plot for the oxidation rate of procyanidin A2 (▲), procyanidin B2 (○) and epicatechin-(4β→8, 2β→O→7)–epicatechin-(4β→8)–epicatechin (■) by PPO of litchi pericarp.

From Fig. 3, we found that the oxidation rate of (−)-epicatechin by litchi pericarp PPO was much faster than the other flavanols of litchi pericarp. The low oxidation rates of procyanidin A2, procyanidin B2 and epicatechin-(4β→8, 2β→O→7)–epicatechin-(4β→8)–epicatechin indicated that procyanidins in litchi pericarp were poor substrates for PPO (Fig. 3). This result was in agreement with the previous studies on apple and grape (Cheynier, Owe, & Rigaud, 1988; Cheynier & Silva, 1991; Le Bourvellec, Le Quere, Sanoner, Drilleau, & Guyot, 2004).

However, those three procyanidins of litchi pericarp disappeared much faster than expected in the litchi pericarp during the storage (Table 1). This was probably due to the fact that those

[b] Mean ± SD.

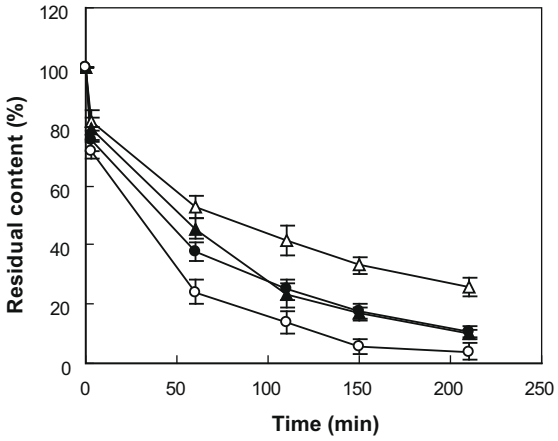

Fig. 4. Changes of (−)-epicatechin (●), procyanidin A2 (▲), procyanidin B2 (○) and epicatechin-(4β→8, 2β→O→7)–epicatechin-(4β→8)–epicatechin (Δ) during the reaction between PPO and flavanols extract of litchi pericarp. The reaction medium (3 ml) contained 1 ml of 0.5 mg/ml litchi pericarp flavanols, 1.98 ml of 50 mM of phosphate buffer (pH 7.5), and 0.02 ml of the enzyme solution. Vertical bars indicate SD.

procyanidins were oxidised by the enzymatically generated *o*-quinone of (−)-epicatechin. Interestingly, procyanidin B2 disappeared even faster than (−)-epicatechin in litchi pericarp during the storage (Table 1). This was probably attributed to the high antioxidant activity of procyanidin B2, which could more easily react with the *o*-quinone of (−)-epicatechin, resulting in the reduction of the *o*-quinone of (−)-epicatechin back to (−)-epicatechin and the oxidation of itself.

In order to confirm the above conclusion that the *o*-quinone of (−)-epicatechin could accelerate the oxidation of flavanols, this oxidation had been investigated in the model system which contained both flavanols and PPO of litchi pericarp. The rate of this reaction was very fast and the solution turned dark yellow-brown rapidly. The HPLC analysis showed that the degradation rates of procyanidin B2, procyanidin A2 and epicatechin-(4β→8, 2β→O→7)–epicatechin-(4β→8)–epicatechin were similar to the degradation rate of (−)-epicatechin in this model system (Fig. 4), confirming the above conclusion. A similar result had been obtained by Cheynier et al. (1988) who suggested that caftaric acid could induce coupled oxidation of other polyphenols in grape must-like model solutions containing grape PPO.

The degradation of flavanols could be observed both in the litchi pericarp during the browning of litchi pericarp and in the model system containing PPO and flavanols of litchi pericarp. This indicated that oxidation of flavanols by PPO played an important role in litchi pericarp browning. The results presented in this paper further indicated that the oxidation of flavanols in litchi pericarp was mainly caused by the couple oxidation of (−)-epicatechin *o*-quinone. Moreover, it has been described previously that (−)-epicatechin *o*-quinone could induce the degradation of anthocyanins in litchi pericarp through the couple oxidation pathway (Liu et al., 2007c). Thus, we proposed that the oxidation of (−)-epicatechin was a precursor of litchi pericarp browning.

In accordance with these results, the pathway of enzymatic browning of litchi pericarp was probably as follows: with the loss of cellular compartmentation, the litchi pericarp PPO and flavanols mixed. Then, (−)-epicatechin was oxidised by PPO and *o*-quinones formed. The *o*-quinones reacted with other flavanols and anthocyanins, accelerating the oxidation of the other polyphenols. Finally, the oxidation of (−)-epicatechin and other polyphenols led to the formation of the brown-coloured compounds, resulting in the enzymatic browning of litchi pericarp.

Fermented sausages
Pediococcus pentosaceus

ABSTRACT

The effect of fermentation with *Pediococcus pentosaceus* at different temperatures ranging from 15 to 37 °C on the quality characteristics of silver carp sausages was investigated. Higher temperature stimulated the rapid growth of lactic acid bacteria, resulting in a rapid decline in pH, and consequently suppressed the growth of *Pseudomonas*, *Micrococcaceae* and *Enterobacteriaceae*. However, increasing fermentation temperature gave a progressive increase in total volatile basic nitrogen and biogenic amines in fermented silver carp sausages. Histamine was the main biogenic amine, exceeding 100 mg/kg after 48 h of fermentation at temperatures above 30 °C. Higher content of non-protein nitrogen and α-amino nitrogen correlated with the electrophoretic studies, which showed that proteolysis of high molecular weight myofibrillar and sarcoplasmic proteins was more prominent at higher fermentation temperatures. Products fermented at 23–30 °C showed greatest consumer preference and most favourable textural properties.

1. Introduction

In China, freshwater fishes account for about 45% of total aquacultural production, reaching 18 million tons in 2004. Silver carp (*Hypophthalmichthys molitrix*) is one of the main freshwater fish species, due to its fast growth rate, easy cultivation, high feed efficiency ratio as well as high nutritional value (Luo, Shen, Pan, & Bu, 2008). However, freshwater fish including silver carp often have strong earthy/musty taste and odour, due to significant concentrations of geosmin or 2-methyl-isobomeol (MIB) in fish flesh (Howgate, 2004). Furthermore, silver carp contains many intramuscular small bones. Therefore, the consumption of silver carp has been limited and the price of the fish is low.

Lactic acid fermentation is an important method of preserving perishable fish and marine products in developing countries (Adams, Cooke, & Twiddy, 1987). Lactic acid bacteria (LAB) could cause rapid acidification of the raw material, through the production of organic acids, mainly lactic acid and acetic acid, and also produce a variety of antimicrobial substances, which can consequently prevent the growth of most hazardous food microorganisms (Hu, Xia, & Ge, 2008).

Fermented minced fish, which is an excellent source of protein, is widely consumed throughout Southeast Asia. It is typically composed of freshwater fish species, salt (2–7%), a carbohydrate source and spices (Paludan-Müller, Huss, & Gram, 1999). Nevertheless, most fish fermentation is still conducted as spontaneous processes at household or small-scale levels in developing countries. Initiation of a spontaneous fermentation process takes a relatively long time, and the quality of the products varies considerably, limiting their acceptability and commercial importance (Twiddy, Cross, & Cooke, 1987).

The use of starter cultures in food fermentation has been studied widely and introduced into commercial practice to increase processing rates and product consistency in recent years. Using starter cultures to develop novel fish products, which would be free of fishy odour and taste, is attracting increasing interest (Hu et al., 2008). A minced fish-salt-glucose system with *Lactobacillus plantarum* and *Pediococcus pentosaceus* was investigated for its ability to promote rapid fermentation at 30 °C (Twiddy et al., 1987). *P. pentosaceus*, *L. plantarum* and *Leuconostoc mesenteroides* were inoculated into the minced frozen fillet of yellowfin tuna and fermented at 8 °C to develop novel fish food products with desired meat properties (Glatman, Drabkin, & Gelman, 2000). *L. plantarum*, *Pediococcus acidilactici*, and *P. pentosaceus* BT520 have been used for the production of Som-fug, a Thai fermented fish at 30 °C (Riebroy, Benjakula, & Visessanguan, 2008). Yin, Pan, and Jiang (2002) used several LAB, including *L. plantarum* CCRC10069, *Lactococcus lactis* subsp. *lactis* CCRC 12315 and *Lactobacillus helveticus* CCRC 14092, as starter cultures to ferment mackerel mince at 37 °C, which could substantially inhibit the development of volatile basic nitrogen, suppress the growth of spoilage microflora and improve the organoleptic qualities and digestibility of the product. Mixed starter cultures were

doi:10.1016/j.foodchem.2009.05.008

also reported to substantially suppress the accumulation of biogenic amines, and improve the flavour and nutritional value of fish muscle at 30 °C (Hu, Xia, & Liu, 2007b; Hu et al., 2008). A fermented cold-smoked fish with lactic acid bacteria was prepared at 20–22 °C (Petäjä, Eerola, & Petäjä, 2000).

Although these widely varying temperatures are used on different types and batches of fermented fish, there are only a few publications concerning the effect of fermentation temperature on the characteristics of fermented fish products (Adams et al., 1987). Temperature is one of the key environmental parameters that affect the microbial growth and the rate of fermentation. Better understanding of the temperature effects on the fermentation process will facilitate improvement of product quality and safety.

The objectives of this study were to develop a value-added product, a sausage using silver carp meat, and to investigate the effect of temperature on the characteristics of the sausages inoculated with *P. pentosaceus*, in terms of microbial and physicochemical changes during fermentation.

2. Materials and methods

2.1. Preparation of starter culture

P. pentosaceus was obtained from the Technology Center of the Shuanghui Group (Luohe, Henan, China). *P. pentosaceus* was subcultured twice in de Man Rogosa Sharpe (MRS) broth at 30 °C for 24 h. Cells were harvested by centrifugation at 10,000*g* for 15 min at 4 °C, and washed twice with saline water (0.85% NaCl); then the cell pellets were resuspended in the same saline water. After adjusting the level of cells to 7–8 log CFU/ml by using a UV-2100 spectrophotometer (Unico, Shanghai, China), the resulting cell suspension was stored at 4 °C for the inoculation of fish mince on the same day.

2.2. Preparation of silver carp sausages

Frozen silver carp (2–3 kg/fish), purchased from a local market (Wuxi, Jiangsu, China), was thawed in running tap water and then beheaded, gutted, and scaled. Prepared fish was then manually filleted. The fillets were passed through a deboner (Model 694, Baader North America, New Bedford, MA) with a drum having 5 mm-diameter perforations, to remove many intramuscular small bones and to obtain the mince. The fish mince was then mixed uniformly with 2% NaCl, 1% glucose, 4% sucrose, 0.05% sodium ascorbate, and 0.5% seasoning mix. Finally, an appropriate amount of *P. pentosaceus* suspension was inoculated to a final level of 6–7 log CFU/g fish mince, and well mixed using a sterile glass rod. The resulting mince was then stuffed into collagen casings (38 mm diameter) and incubated at 15, 23, 30 and 37 °C, RH 90–93% for 2 days. Sausage samples were taken every 12 h for analysis.

2.3. Microbiological analysis

Ten grams of sausage sample were aseptically transferred into a sterile plastic bag and stomached for 2 min in a stomacher (Lab-Blender 400; Seward Medical, London, UK) with 90 ml sterile peptone saline diluent (containing 0.1% peptone and 0.85% NaCl). Appropriate decimal dilutions of the samples were prepared with the same diluent and 0.1 ml aliquots of appropriate dilution were spread on the different agar plates and incubated as follows: total aerobic bacteria on plate count agar (PCA, Oxoid, CM325), incubated at 37 °C for 48 h; lactic acid bacteria on de Man Rogosa Sharpe agar (MRS, Oxoid, CM0361), incubated anaerobically at 30 °C for 48 h; *Enterobacteriaceae* on violet red bile dextrose agar (VRBD, Oxoid, CM485) with double layer, incubated at 37 °C for 24 h; *Micrococcaceae* on mannitol salt agar (MSA, BD Difco), incubated at 30 °C for 48 h; *Pseudomonas* on *Pseudomonas aeromonas* selective agar base (GSP Agar, Merck, Nr 10230), incubated at 26 °C for 72 h. Bacteria counts were expressed as log CFU/g sample.

2.4. Determination of pH and water content

Each of five-gram sausage samples was homogenised (Ultra Turrax homogeniser, IKA Labortechnik, Selangor, Malaysia) with 45 ml of boiled distilled water at 11,000 rpm for 1 min, and the pH was measured (Mettler Toledo 320-s, Shanghai, China). Water content was determined by drying 3–5 g of sausage sample at 100–102 °C to a constant weight (AOAC, 1998).

2.5. Determination of non-protein nitrogen (NPN), α-amino nitrogen (AAN) and total volatile basic nitrogen (TVB-N)

NPN was extracted from 5–10 g of sausage sample with 5% (w/v) trichloroacetic acid (TCA) for Kjeldahl procedure. The α-amino nitrogen (AAN) was analysed according to the Sorensen method by titration with formaldehyde (AOAC, 1998). TVB-N content was determined by the Conway micro-diffusion technique (Cobb, Alaniz, & Thompson, 1973).

2.6. Sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS–PAGE)

Sarcoplasmic proteins and myofibrillar proteins were extracted according to the method of Joo, Kauffman, Kim, and Park (1999) with slight modification. Using a homogeniser (Ultra Turrax), 2 g of sausage sample were homogenised (12,000 rpm, 1 min) with 20 ml of chilled 0.025 M potassium phosphate buffer (pH 7.2) and centrifuged at 5000*g* for 20 min. The supernatant was used as sarcoplasmic proteins. The resulting precipitate was homogenised (Ultra Turrax homogeniser) with 20 ml of chilled 1.1 M potassium iodide in 0.1 M phosphate buffer (pH 7.2) at 12,000 rpm for 1 min. The supernatant was collected by centrifugation at 5000*g* for 20 min and used as myofibrillar proteins.

SDS–PAGE was carried out in a vertical gel electrophoresis unit (Mini-Protean-3 Cell, Bio-Rad, Richmond, CA) according to the method of Laemmli (1970), using 10% separating gel and 4% stacking gel. Aliquots of 10 μl were injected in each well including standard protein marker. Electrophoresis was done at 90–120 V. After electrophoresis was completed, gels were stained with 0.125% Coomassie Brilliant Blue R-250 in 25% methanol and 10% acetic acid. Destaining was performed using 40% methanol and 10% acetic acid.

2.7. Determination of biogenic amines

Finely ground sausage sample (5 g) was transferred to 50-ml centrifuge tubes and homogenised (Ultra Turrax homogeniser) with 20 ml of 5% TCA solution for about 2 min. The supernatant was collected by centrifugation (10,000*g*, 4 °C, 10 min) and the residue was extracted again with an equal volume of TCA solution. Both supernatants were combined and filtered through a filter paper (Whatman No. 4). The filtrate was made up to 50 ml with 5% TCA solution and stored at 0–4 °C for high-performance liquid chromatography (Agilent 1100 Series; Agilent, Santa Clara, CA) analysis within a week.

The derivatisation reagent was prepared by transferring 100 mg *o*-phthalaldehyde (OPA), 1 ml acetonitrile and 130 μl 2-mercaptoethanol to a 10-ml volumetric flask, and then diluting with 0.4 M borate buffer (pH 10.2) to 10 ml. The resulting solution was mixed well, and stored refrigerated and used within 24 h. Pre-column derivatisation with OPA was performed automatically.

A reverse-phase Hypersil ODS C_{18} (125 × 4.60 mm, particle size 5 μm) column was used for separation. The column temperature

and flow rate were set at 40 °C and 1.0 ml/min, respectively. The mobile phase consisted of solvent A (pH 7.2), 7.35 mM sodium acetate solution:triethylamine:tetrahydrofuran (500:0.12:2.5 v/v), and solvent B (pH 7.2), 7.35 mM sodium acetate solution:methanol:acetonitrile (1:2:2 v/v). Fluorescence was monitored at an emission wavelength of 450 nm using an excitation wavelength of 340 nm.

Biogenic amine standards, tyramine, tryptamine, putrescine dihydrochloride, cadaverine dihydrochloride were purchased from Sigma (St. Louis, MO) and histamine dihydrochloride from Fluka Biochemica (Buchs, Switzerland). Double-distilled and deionised water was used for dilution and chromatographic separation.

2.8. Texture profile analysis (TPA)

Texture profile analysis was carried out as described by Bourne (1978), using a Universal TA-XT2i texture analyser (Stable Micro Systems, Godalming, UK) equipped with a cylindrical P/25 probe. Three slices of sausage sample (1.5 cm thick and 2.0 cm diameter) were allowed to equilibrate to room temperature and then compressed twice to 50% of their original height. A time of 5 s was allowed to elapse between the two compression cycles. Force–time deformation curves were obtained with a 25 kg load cell applied at a cross-head speed of 1 mm/s. Hardness, springiness, cohesiveness, adhesiveness and chewiness were calculated using Texture Expert software version 1.22 (Stable Micro Systems).

2.9. Sensory evaluation

The sensory qualities of taste, flavour, texture, and overall acceptability of fermented silver carp sausages were evaluated by 15 untrained panellists, who were graduate students and teachers in the School of Food Science and Technology. The nine-point hedonic scale was used for evaluation, with 9 being extreme liking, 5 being neither like or dislike and 1 being extreme dislike.

2.10. Statistical analysis

For data analysis, analysis of variance (ANOVA) was used. Significant differences were defined at $p < 0.05$. Comparisons of group means were obtained using Duncan's multiple range test. All statistical analysis was performed using SPSS 11.0 for windows software (SPSS Inc., Chicago, IL).

3. Results and discussion

3.1. pH and water content

As shown in Fig. 1, with the progress of fermentation, the decrease in pH was directly proportional to the increase in fermentation temperature from 15 to 37 °C. The pH of fish mince decreased rapidly during fermentation, from initial values of around 6.7–4.5 within 48 h at the higher temperature, whilst fermentation at 15 °C caused the pH to remain above 6.0 after 48 h. The rapid decrease in pH was also related to the higher growth rate of LAB noted in Fig. 2. According to Adams et al. (1987), rapid growth of LAB causing pH to decrease to below 4.5 within 2 days is essential to prevent spoilage and to ensure safety of the product.

Water content decreased continuously during fermentation (Fig. 1). The rate of decrease increased as the fermentation temperature increased. The results indicated that higher fermentation temperature caused faster dehydration. This was probably related to rapid decline of pH to a value close to the isoelectric point of fish proteins, caused by the rapid growth of LAB at higher temperatures, resulting in lower water-holding capacity of the fish muscle proteins in the sausages (Huff-Lonergan & Lonergan, 2005).

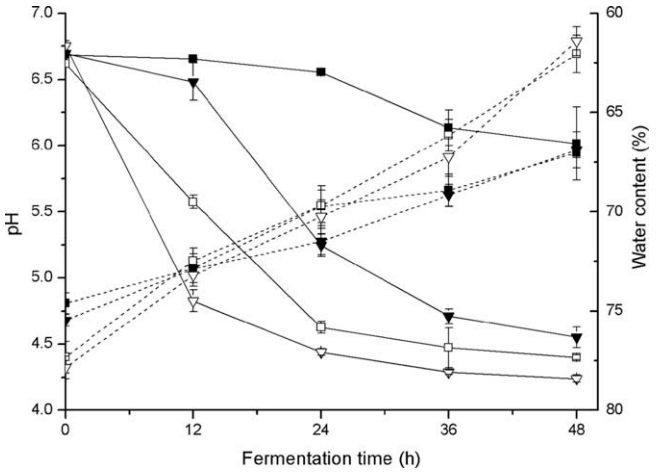

Fig. 1. Changes in pH and water content in silver carp sausages during fermentation at different temperatures (■) 15 °C; (▼) 23 °C; (□) 30 °C; (▽) 37 °C.

3.2. Microbiological analysis

Microbial changes during fermentation at different temperatures are shown in Fig. 2. The initial counts of LAB in inoculated fish mince ranged from 6.5 to 7.0 log CFU/g. During fermentation, LAB showed a faster growth at higher temperatures, reaching up to 8 log CFU/g within 24 h. In contrast, the growth of LAB at 15 °C was clearly slowed and it took longer for the population to reach 8 log CFU/g. It took 36 h at 15 °C, 24 h at 23 °C, and 12 h at both 30 °C and 37 °C to reach 8 log CFU/g for the total bacteria. LAB count showed a similar trend. This indicates that LAB was considered the dominant species during fermentation at the given temperatures.

Micrococcaceae numbers showed an increase at first to 5–6 log CFU/g and a subsequent decrease during fermentation at temperatures above 23 °C, whilst for fermentation at 15 °C, the counts increased continually up to 6.3 log CFU/g after 48 h of fermentation. Hugas and Monfort (1997) have reported that acidification and anaerobic conditions inhibited the growth of *Micrococcaceae* during ripening of fermented sausages. The growth of *Enterobacteriaceae* and *Pseudomonas* exhibited a similar pattern with *Micrococcaceae*. The results indicated that temperature had a pronounced influence on the growth of these microorganisms during lactic fermentation. At higher temperature, LAB grew more rapidly. This quickly lowered the pH, thereby inhibited the growth of undesirable microorganisms. Several authors have also reported that growth of the majority of spoilage bacteria and pathogens present in minced fish was inhibited more effectively by rapid attainment of low pH (Adams et al., 1987; Hu, Xia, & Ge, 2007a; Yin et al., 2002). The inhibition of spoilage and pathogenic bacteria was probably due to the accumulation of lactic acid produced by the starter culture, which could cause acidification of the cytoplasm (Lambert & Stratford, 1999). Although the rate of pH reduction was slower at lower temperature, little variation was encountered in the LAB counts after 48 h of fermentation at different temperatures, and this is in accordance with the findings by Adams et al. (1987). Temperature is a major factor in food deteriorative reactions, especially for microbial spoilage, since specific growth rate and lag phase are highly temperature-dependent (Cayre, Vignolo, & Garro, 2003).

3.3. TVB-N

The levels of TVB-N increased progressively with the increase in temperature and time during fermentation (Table 1). Increasing temperature clearly enhanced the development of TVB-N. After

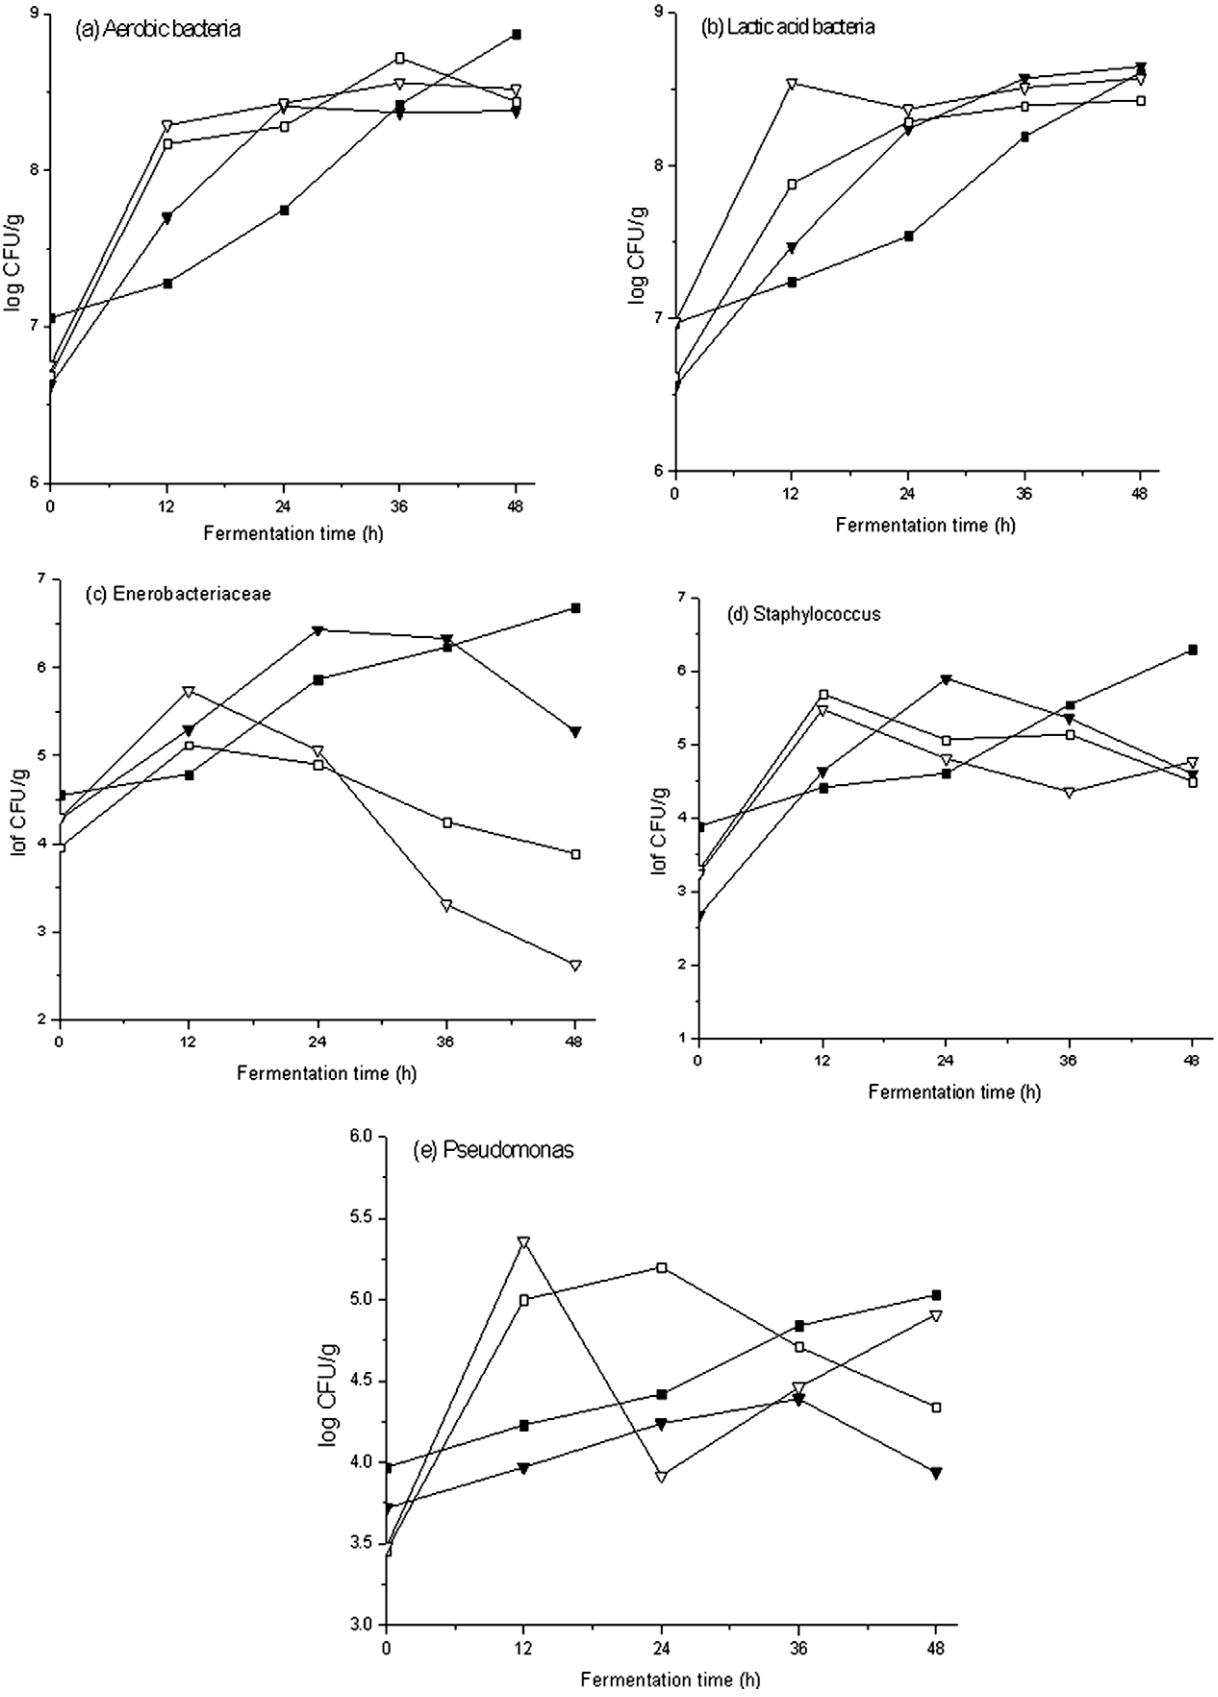

Fig. 2. Microbiological changes in silver carp sausages during fermentation at different temperatures (■) 15 °C; (▼) 23 °C; (□) 30 °C; (▽) 37 °C.

48 h of fermentation, the TVB-N content was less than 30 mg/100 g fish meat at all tested temperatures except for 37 °C. TVB-N content of 30 mg/100 g is generally regarded as the acceptable limit for fish (Riebroy, Benjakul, Visessanguan, & Tanaka, 2007). The results

Table 1
Changes in TVB-N in silver carp sausages during fermentation at different temperatures (mg/100 g)[1].

Fermentation temperatures (°C)	Fermentation time (h)				
	0	12	24	36	48
15	8.35 ± 0.86^{aA}	9.21 ± 0.91^{aA}	11.8 ± 0.72^{aB}	12.6 ± 0.95^{aB}	14.3 ± 1.11^{aC}
23	8.93 ± 0.79^{aA}	9.83 ± 0.61^{aA}	12.9 ± 1.18^{aB}	14.6 ± 0.89^{bC}	16.7 ± 1.24^{aD}
30	7.97 ± 0.58^{aA}	11.7 ± 0.63^{bB}	15.1 ± 0.83^{bC}	18.7 ± 0.94^{cD}	20.9 ± 1.31^{bE}
37	8.80 ± 0.78^{aA}	15.9 ± 0.88^{cB}	19.8 ± 1.24^{cC}	26.3 ± 1.15^{dD}	31.2 ± 2.33^{cE}

indicated that although the growth of undesirable bacteria (Fig. 2) could be effectively suppressed by LAB at higher temperature, the metabolic activity for the production of TVB-N still continued. Several authors have reported that fermentation with LAB in fish could substantially inhibit the accumulation of TVB-N (Glatman et al., 2000; Hu et al., 2008; Yin et al., 2002).

3.4. Proteolysis

Proteolysis-related parameters (AAN and NPN) showed a different behaviour during fermentation of fish sausages (Table 2). Values of NPN did not change significantly ($p < 0.05$) at lower temperature (15, 23 and 30 °C) after 12 h of fermentation, whilst AAN contents showed a continuous increase across the same temperature range and fermentation period. However, higher contents of AAN and NPN were obtained at 37 °C. This suggested that a relatively intense proteolysis occurred at higher temperature. This was probably attributed to the enhanced activity of both endogenous and microbial proteolytic enzymes at the higher temperature, especially at low pH, which could stimulate acidic proteinase activity. Similar results in dry sausage have been reported by Bover-Cid, Izquierdo-Pulido, and Vidal-Carou (2001). Several investigators have reported that acidic pH could improve activity of proteolytic enzymes, especially cathepsins (Molly et al., 1997; Riebroy et al., 2008).

SDS–PAGE electrophoretograms of the sarcoplasmic and myofibrillar proteins in fish sausages after 48 h of fermentation are shown in Fig. 3. Sarcoplasmic and myofibrillar proteins with molecular weights of 40–200 kDa and lower than 30 kDa disappeared or decreased in intensity to different degrees after 48 h of fermentation, depending on the temperature applied. Furthermore, the intensity of a polypeptide with a molecular weight of ~35 kDa progressively increased with increasing temperature. This is partially due to the intense degradation of sarcoplasmic and myofibrillar proteins at higher temperature (23, 30 and 37 °C). In contrast, there was no marked degradation of proteins after 48 h of fermentation at 15 °C. Martin, Cordoba, Antequera, Timon, and Ventanas (1998) also found that intense proteolysis took place in Iberian ham when higher temperature was applied. Both endogenous and microbial proteases contributing to the degradation of muscle proteins have been reported by other studies (Fadda et al., 1999). The initial hydrolysis of muscle proteins is attributed mainly to endogenous cathepsins, followed by the action of microbial peptidases, which further degrade the protein fragments to small peptides and free amino acids, and consequently have an important influence on meat flavour development (Fadda et al., 1999; Molly et al., 1997).

It should be noted that the bands with high molecular weight disappeared completely after 48 h of fermentation at temperatures above 23 °C, whilst no proportional increase in intensity of the bands with lower molecular weight was observed. It is possible that proteins denatured and formed large aggregates with higher molecular weights, through covalent bonds and non-disulphide covalent bonds as pH decreased during fermentation, which prevented proteins being extracted under the experimental conditions.

3.5. Biogenic amines

As shown in Table 3, the higher fermentation temperature resulted in higher amounts of biogenic amines, coinciding with higher free amino acid contents (AAN, Table 2). Histamine was quantitatively the most important biogenic amine formed during fermentation in fish sausages, reaching up to 100 mg/kg after 48 h of fermentation at 30–37 °C, which exceeded the limit of 50 mg/kg established by the FDA for Scombridae (FDA, 1996). It is remarkable that histamine content in sausage samples fermented at 23 °C was even lower than that before fermentation. This can be explained that histamine might have been consumed by the fermenting microflora as a nitrogen source (Bover-Cid et al., 2001). Histamine is potentially hazardous and the causative agent of amine intoxication associated with the consumption of seafood (Flick, Oria, & Douglas, 2001).

A minor production of less than 8 mg/kg of tyramine was observed at tested temperatures, which was much less than that in dry sausages (Bover-Cid et al., 2001). The allowable level of tyramine in foods is 100–800 mg/kg whilst 1080 mg/kg is toxic (Shalaby, 1996).

Table 2
Changes in AAN[2] and NPN[3] in silver carp sausages during fermentation at different temperatures[1].

Fermentation time (h)	AAN (mg/100 g dry matter)				NPN (mg/g dry matter)			
	15 °C	23 °C	30 °C	37 °C	15 °C	23 °C	30 °C	37 °C
0	237 ± 7.98^{aA}	236 ± 14.3^{aA}	249 ± 12.7^{aA}	249 ± 12.1^{aA}	9.54 ± 0.20^{bA}	9.66 ± 0.27^{cAB}	10.2 ± 0.11^{bB}	10.2 ± 0.29^{abB}

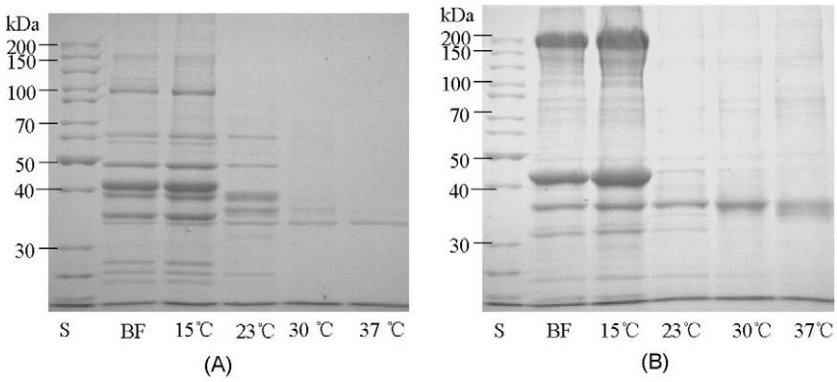

Fig. 3. SDS–PAGE profile of sarcoplasmic proteins (A) and myofibrillar proteins (B) in silver carp sausages after 48 h of fermentation at different temperatures. BF, before fermentation.

Lower levels of putrescine, cadaverine and tryptamine were also observed at tested temperatures in this study. Putrescine is produced by decarboxylation of either ornithine or agmatine, and cadaverine is produced by decarboxylation of lysine (Özogul, Ahmad, Hole, Özogul, & Deguara, 2006). Although putrescine and cadaverine have no direct adverse effect on human health, they play an important role in food poisoning, as they can potentiate the toxicity of histamine by inhibiting histamine-metabolising enzymes, such as diamine oxidase and histamine methyl transferase; they can also react with nitrites to form nitrosamines, which are carcinogenic compounds (Shakila, Vasundhara, & Kumudavally, 2001).

From the results it may be concluded that the increase in biogenic amines in fish sausages was due to the enhanced residual activity of microbial decarboxylase and the higher amounts of precursor amino acids resulting from proteolysis at elevated temperatures. Besides the use of good quality raw material, fermentation at low temperature is necessary to prevent the formation of increased amounts of biogenic amines during the manufacture of fermented fish sausages. It has been reported that biogenic amines production was attributed to both surviving microorganisms and residual activity of decarboxylase produced by microorganisms (Komprda, Neznalova, Standara, & Bover-Cid, 2001). In fermented foods, besides the active growth of microflora, the acidification and the proteolytic processes occurring during fermentation make the environment particularly favourable for biogenic amine production (Bover-Cid et al., 2001).

Table 3
Biogenic amines content in silver carp sausages after 48 h of fermentation at different temperatures.

Samples	Biogenic amines (mg/kg)				
	Histamine	Tyramine	Putrescine	Cadaverine	Tryptamine
BF[a]	21.4	2.61	0.95	0.22	0.19
15 °C	44.9	5.13	1.22	1.01	0.79
23 °C	18.6	4.09	1.10	1.91	1.37
30 °C	102	5.66	2.69	60.4	36.3
37 °C	129	6.72	4.68	31.5	19.5

3.6. Sensory evaluation and TPA analysis

Sensory evaluation and the texture profile for fish sausages fermented at different temperatures are shown in Table 4. No significant differences in appearance, taste, flavour, and acceptability were observed amongst batches fermented at 23–37 °C. Lower acceptance in all attributes was observed in sausages fermented at 15 °C, and this was due to less sourness, too fishy a smell, and a grey colour. The better taste of the sausages fermented at higher temperature could be linked to higher concentration of free amino acids (Hu et al., 2007a). In addition, the lactic acid produced not only gives the product a unique lactic acid flavour, masking or suppressing fishy smell, but also increases the firmness and mouthfeel resulting from the acid denaturation of muscle proteins (Yin & Jiang, 2001).

As shown in Table 4, fermentation temperature had a great influence on the textural properties of silver carp sausages. At the end of fermentation, sausage samples showed a marked increase in all TPA

Table 4
Sensory evaluation[1] and texture profile analysis[2] of silver carp sausage after 48 h of fermentation at different temperatures.

Parameter	Sample				
	BF[3]	15 °C	23 °C	30 °C	37 °C
Appearance	ND[4]	1.81 ± 0.46^{a}	7.06 ± 1.37^{b}	6.43 ± 1.27^{b}	6.38 ± 148^{b}
Flavour	ND	2.89 ± 0.78^{a}	5.90 ± 1.10^{b}	6.00 ± 1.06^{b}	5.25 ± 1.28^{b}

texture attributes, compared to the samples before fermentation. Products at higher temperature (23–37 °C) seemed to possess greater hardness, whilst no significant differences in other TPA parameters, like springiness, cohesiveness, adhesiveness and chewiness, were observed across the same temperature range. The development of firmness is related to pH reduction and moisture removal (Baumgartner, 1980). Riebroy et al. (2008) also reported that texture formation of fermented fish mince was closely associated to the rapid decline in pH, which induced conformational changes of muscle proteins and caused the formation of acid-induced gelation. Higher acidity in the sausages resulted in superior organoleptic properties.

4. Conclusions

Temperature is a technologically important parameter to control fish sausage fermentation. Higher fermentation temperature would be advisable for faster and shorter fermentation. However, the production of fermented silver carp sausages at higher temperature could cause some quality defects, such as higher content of biogenic amines and TVB-N. Further research should be conducted to improve the overall quality of the product.

Erysimum corinthium
Brassicaceae
Glucosinolates
Isothiocyanates
Volatile constituents
Antimicrobial and cytotoxicity

ABSTRACT

Fresh leaves, roots and ripe seeds of *Erysimum corinthium* Boiss. (Brassicaceae) were investigated to uncover their glucosinolate contents through natural autolysis and exogenous myrosinase hydrolysis. The hydrolysis products were submitted to GC–MS analysis. Six glucosinolates were identified for the first time in this plant; namely, sinigrin, progoitrin, glucoiberin, 3-(methylcarbonyl)propyl glucosinolate, glucocheirolin and glucoerysolin. Glucocheirolin was the major compound accumulated in the seeds and progoitrin was the major compound in the roots, while 3-(methylcarbonyl)propyl glucosinolate was the major compound in the leaves. Other volatile constituents, e.g., terpenes and fatty acids esters were also identified. Seeds and leaves showed higher antimicrobial activity than roots. Seeds showed a marked cytotoxicity *in vitro* against colorectal, hepatic and Hela cell lines.

1. Introduction

Glucosinolates are an important group of phytochemicals present exclusively in 15 botanical families of the order Capparales and very abundant in Brassicaceae (Barbieri, Pernice, Maggio, De Pascalr, & Fogliano, 2008). The crucifer family Brassicaceae is an economically important family for its many food and oilseed crops, as well as containing many important ornamental plants and noxious weeds (Vaughn & Borhow, 2005).

Chemically, glucosinolates are glucose and sulfur-containing organic compounds whose decomposition products are produced when plant cells are ruptured, and the glucosinolates present in vacuoles are hydrolysed by the enzyme myrosinase (β-thioglucosidase glucohydrolase (EC 3.2.3.1). These hydrolysis products include substituted isothiocyanates, nitriles, thiocyanates, epithionitriles and oxazolidinethiones (Fig. 1), which vary depending on the plant species studied, side-chain substitution, cell pH and cell iron concentration (Fenwick, Heaney, & Mullin, 1983; Gil & MacLeod, 1980).

Many glucosinolate degradation products are of interest because of their biological activities. Several of these hydrolysis products have biocidal activity against a wide variety of organisms, such as insects, plants, fungi and bacteria (Vaughn, 1999), while others have cancer chemoprotective attributes (Fahey, Zalcmann, & Talalay, 2001). Moreover, the consumption of cruciferous vegetables has been associated with a reduced risk of cancer of the lung, stomach, breast, prostate, pancreas, colon and rectum, which has been attributed to its isothiocyanate contents (Heber, 2004; Higdon, Delage, Williams, & Dashwood, 2007).

Taxonomically, *Erysimum* is one of the most complex genera of the Cruciferae (Al-Shehbaz & Al-Shammary, 1987). Erysimum plants are characterised by the presence of methylthioalkyl, methylsulfinylalkyl and methylsulfonylalkyl glucosinolates (Daxenbichler et al., 1991). To our knowledge, there is no pervious report or publication on the chemistry and biological activities of *Erysimum corinthium*. Thus, this encouraged us to investigate glucosinolate contents and the possible biological activity of this plant.

2. Materials and methods

2.1. Plant materials

E. corinthium (Boiss.) Wettst. (*Cheiranthus corinthius* Boiss.) seeds were collected from Al-Sharkya district, Egypt and cultivated in the botanical garden, Faculty of Pharmacy, Zagazig University. The plant material was collected in April to May 2005. It was identified by Dr. Sean Edwards, Botanical Herbarium, Manchester University. Voucher samples are kept in the Pharmacognosy Department Herbarium, Faculty of Pharmacy, Zagazig University. Other samples are kept in Manchester University Herbarium.

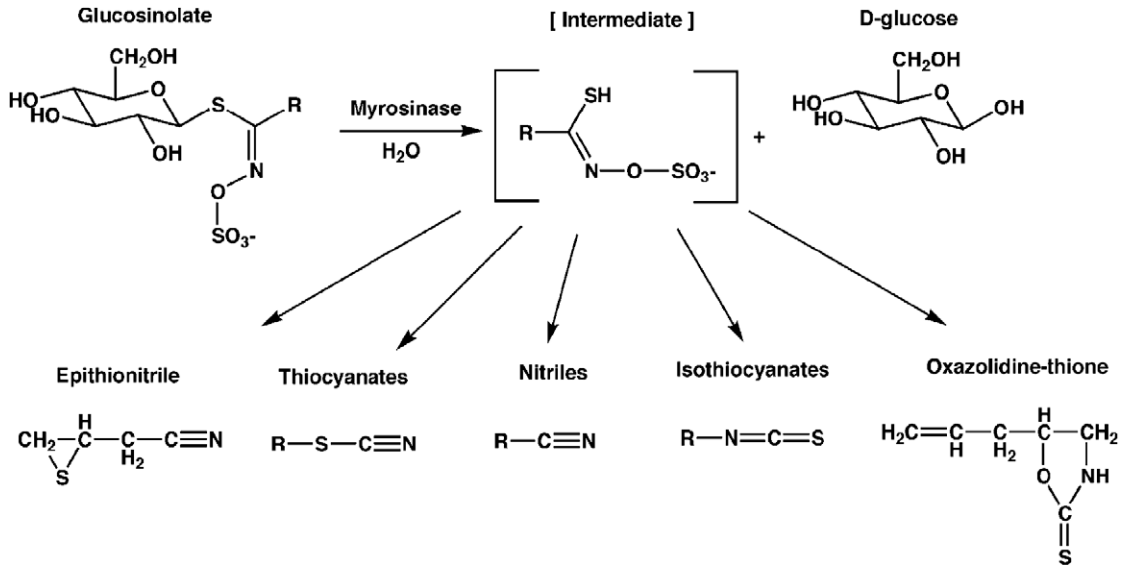

Fig. 1. The general structure of glucosinolates and their enzymatic degradation products (adapted from Rask et al. (2000)).

2.2. Preparation of hydrolysis products

2.2.1. Exogenous myrosinase hydrolysis (method ***A***)

Crushed undefatted seeds (500 mg), fresh leaves (10 g) and fresh roots (10 g) were homogenised separately with distilled water (200 ml), myrosinase enzyme (1–2 units, Sigma) and 2–5 mg L-ascorbic acid and allowed to hydrolyse for 2 h. Dichloromethane (50 ml) was added, the mixtures were shaken for 30 min and separated by centrifugation for 5 min at 3500 rpm. The separated organic layer was dried over anhydrous sodium sulfate, and concentrated under nitrogen to about 0.5 ml. The concentrated hydrolysate was kept (in a tightly closed vial) in a freezer until analysis (Al-Gendy & Lockwood, 2003).

2.2.2. Natural autolysis (method ***B***)

Each plant organ was homogenised separately with distilled water (200 ml) and left for natural autolysis overnight (17 h) at room temperature, followed by extraction as described above (Al-Gendy, 2008; Al-Gendy & Lockwood, 2003).

2.3. Identification and quantitative determination of breakdown products using gas chromatography–mass spectrometry (GC–MS)

One microlitre aliquots of the concentrated extract prepared by methods **A** and **B** were subjected to GC–MS analysis using a Trace GC 2000 gas chromatograph attached to a Finnigan MAT SSQ 7000 mass spectrometer operated at 70 eV. The column used was a DB-5MS fused silica capillary column (30 m × 0.25 mm × 0.25 μm; Agilent, Santa Clara, CA). The carrier gas was helium and the flow rate was 1 ml/min. The injector temperature was 250 °C and the temperature program was 50 °C initially for 2 min, followed by an increase of 5 °C/min to 280 °C.

2.4. Antimicrobial activity

Plant extracts prepared by natural autolysis and exogenous myrosinase hydrolysis were concentrated under a stream of nitrogen to dryness, weighed and dissolved in DMSO at concentration of 1 mg/ml.

For screening of antimicrobial activities, the Gram-positive bacteria used were *Bacillus subtilis, Staphylococcus aureus* and *Streptococcus faecalis,* while *Escherichia coli*, *Neisseria gonorrhea* and *Pseudomonas aeroginosa* were the used Gram-negative bacteria. *Candida albicans* and *Aspergillus flavus* were the used fungi. The standard antibiotic was tetracycline while the standard antifungal was amphotericin B.

A sterilised filter paper disc saturated with 1 mg of each sample was placed on a plate containing solid bacterial medium (nutrient agar broth) or fungal medium (Dox's medium), the latter of which had been heavily seeded with a spore suspension of the tested organism. After incubation, the diameter of the clear zone of inhibition surrounding the sample was taken as a measure of the inhibitory power of the sample against the particular test organism (Irobi, Moo-Young, & Anderson, 1996; Muanza, Kim, Euler, & Williams, 1994).

2.5. Cytotoxic activity

Crushed seeds (500 mg) were boiled with 200 ml water for 5 min to inactivate the natural enzyme. Light petroleum ether (50 ml) was added to extract fatty materials and the pH of the separated aqueous layer was adjusted to 6.5. Then, 1–2 units of myrosinase enzyme and 2–5 mg L-ascorbic acid were added and allowed to hydrolyse for 2 h, followed by extraction as described above.

Potential cytotoxicity of the seeds' crude extract (containing glucosinolate hydrolysis products) was tested using the method reported by Skehan et al. (1990). The tested cell lines were colorectal (HCT116), hepatic (HEPG2-1) and Hela. Cells were plated in 96-multiwell plate (10^4 cells/well) for 24 h before treatment with the extracts, to allow attachment of cell to the wall of the plate. Different concentrations of hydrolysate (1, 2.5, 5 and 10 μg/ml) were added to the cell monolayer and triplicate wells were prepared for each individual dose. Monolayer cells were incubated with the hydrolysates for 48 h at 37 °C and in an atmosphere of 5% CO_2. Cells were then fixed, washed and stained with Sulfo-Rhodamine-B stain. Excess stain was washed with acetic acid and attached stain was recovered with Tris–EDTA buffer. Colour intensity was measured in an ELISA reader and the relation between surviving fraction against the extract concentration was plotted to get the survival curve of each tumour cell line.

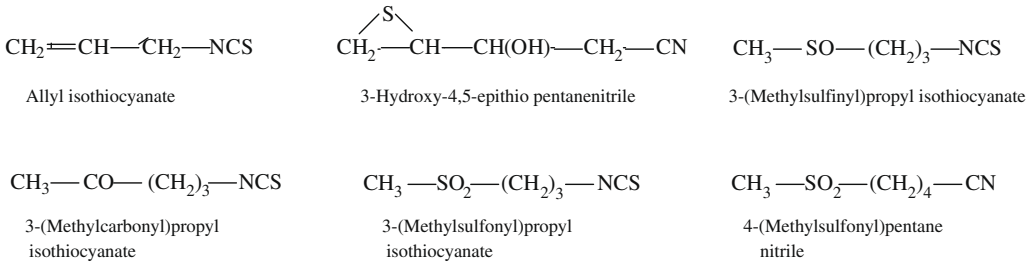

Fig. 2. Structure of glucosinolate hydrolysis products identified in *E. corinthium*.

3. Results and discussion

3.1. Identification of glucosinolate hydrolysis products and other volatile components

GC–MS analysis of extracts obtained by exogenous myrosinase hydrolysis and natural autolysis of seeds, leaves and roots of *E. corinthium* revealed the presence of glucosinolate hydrolysis products and other volatile components, e.g., terpenes and fatty acid methyl esters. Structure and mass spectra data of isothiocyanates, nitriles and epithioalkane nitriles formed by glucosinolate break down are given in Fig. 2 and Table 1 while other volatile components are given in Table 2.

Individual peaks were identified by comparing their retention time and mass spectrum with spectra in our home-made library, as well as with the literature data (Adams, 1995; Al-Gendy,

2008; Al-Gendy & Lockwood, 2003; Odham & Stenhagen, 1972, chap. 8; Spencer & Daxenbichler, 1980; Vaughn & Borhow, 2005) and computer matching against the Wiley database.

3.1.1. Seeds

Four glucosinolates were identified: sinigrin, progoitrin, glucoiberin and glucocheirolin (Fig. 3). The major hydrolysis product of the seeds was cheirolin, liberated from glucocheirolin, which represents a major glucosinolate for many *Erysimum* species (Bennett, Mellon, & Kroon, 2004; Daxenbichler et al., 1991). Allyl isothiocyanate liberated from sinigrin was detected only by natural autolysis, while iberin liberated from glucoiberin could be detected by the two applied methods.

Bennett et al. (2004) had investigated the seeds of eight *Erysimum* species; glucoiberin was identified in all of them, while glucocheirolin was detected in six of them. Also, glucoerysolin and sinigrin were detected in two species. According to their results, they recommend *Erysimum pumillum* as the best seed source for glucoiberverin. Our results recommend *E. corinthium* as a good source for isolation and commercial production of glucocheirolin. Moreover, Daxenbichler et al. (1991) had investigated 12 *Erysimum* species, where glucoiberin and glucocheirolin were the most common glucosinolates identified.

3-Hydroxy-4,5-epithio pentanenitrile liberated from progoitrin was detected by natural autolysis only. To our knowledge, there is no previous report for the identification of progoitrin hydrolysis products in *Erysimum* species. Glucosinolate concentration in the reproductive tissues (florets, flowers and seeds) are often as much as 10–40 times higher than in the vegetative tissues. Thus, seed material can be a very good source of glucosinolates (Bennett et al., 2004). Our results are in agreement with this concept, due to the high concentration of glucocheirolin in the seed materials, compared to leaves, and its absence in the root.

The seeds contained volatile compounds including terpenes, e.g., 1,8-cineole and γ-terpinene, fatty acid esters, such as methyl oleate, and other miscellaneous volatile compounds formed mainly by natural autolysis. On the other hand, only 1-methyl-4-(methylthio)benzene is detected by exogenous myrosinase hydrolysis.

3.1.2. Leaves

The glucosinolate contents of the leaf are much smaller than those of the seeds. Only four glucosinolates were identified: progoitrin, 3-(methylcarbonyl)propyl glucosinolate, glucocheirolin and glucoerysolin (Fig. 3). On the other hand, many volatile components were detected by natural autolysis, while only two compounds, dioctyl adipate and methyl palmitate, were detected after exogenous hydrolysis (Table 2).

3.1.3. Roots

Our results showed that the root has the highest concentration of progoitrin and glucoerysolin, compared to leaves and seeds (Table 1). On the other hand, no glucoiberin and glucocheirolin were detected. It is clear that the amount of glucosinolate hydrolysis products obtained by exogenous hydrolysis is higher than that of natural autolysis.

Regarding the other volatile compounds, the root seems to be a poor source for these compounds as only sicol (1.6%) was detected by exogenous hydrolysis.

3.2. Antimicrobial activity

The antimicrobial activities of the applied plant extracts obtained by methods **A** and **B** of seeds, leaves and roots are given in Table 3. All tested extracts showed inhibition of growth for the tested organisms, except *A. flavus*, which means that *E. corinthium* has the ability to inhibit the growth of Gram-positive and

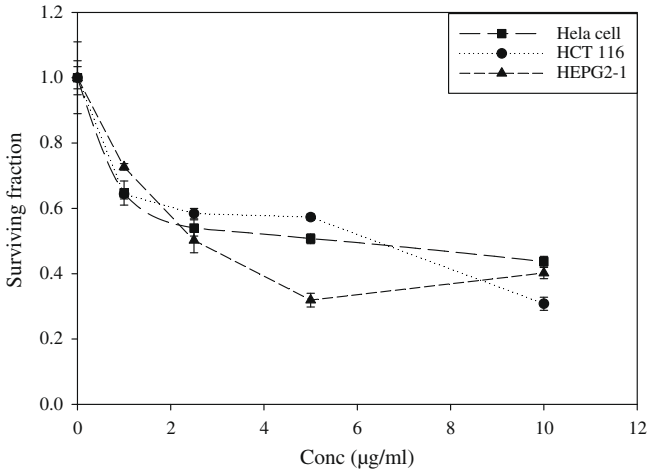

Fig. 4. Cytotoxic activity of *Erysimum corinthium* seeds.

Gram-negative bacteria, as well as fungi. The obtained results showed that the hydrolysis products of seeds have the highest activity while the hydrolysis products of roots have the lowest activity.

Although the concentration of cheirolin liberated by method **A** in seeds is nearly double that liberated by method **B**, the antimicrobial activity of seed extract prepared by method **B** is higher than that prepared by method **A**, especially against Gram-positive bacteria. This is mostly due to the presence of allyl isothiocyanate, which could not be detected by method **A** and also due to 3-hydroxy-4,5-epithio pentanenitrile liberated from progoitrin, and the higher concentration of iberin. Sinigrin, glucoiberin and progoitrin previously showed a marked similar activity that was attributed to their hydrolysis products (Brabban & Edwards, 1995; Manici, Lazzeri, & Palmieri, 1997; Tolonen et al., 2004).

In an earlier report, allyl isothiocyanate and crude plant extracts containing allyl isothiocyanate exhibited similar antimicrobial properties (Kanemaru & Miyamoto, 1990). Moreover, allyl isothiocyanate was reported to reduce *E. coli* in fresh ground beef during refrigerated or frozen storage (Nadarajah, Han, & Holley, 2005).

The toxic activity of glucosinolate hydrolysis products has been demonstrated towards a range of fungi *in vitro*, including both pathogens and non-pathogens (Fenwick et al., 1983; Osbourn, 1996). Also, allyl isothiocyanate was found to be one of the most fungitoxic glucosinolate hydrolysis products (Mithen, Lewis, Fenwick, & Heaney, 1986). Previously, allyl isothiocyanate showed nematocide effect for *Globodera rostochiensis,* which suggests the use of autolysis products of plant materials containing sinigrin to control the potato cyst nematode in soil (Buskov, Serra, Rosa, Sørensen, & Sørensen, 2002).

The antimicrobial activity of leaf extracts prepared by the two described methods is nearly equal. On the other hand, root extract prepared by method **A** showed higher activity than that prepared by method **B**.

3.3. Measurements of cytotoxic activity

The purified crude extract of seeds of *E. corinthium* could inhibit the growth of colorectal HCT 116, hepatic HEPG2-1 and Hela cells *in vitro*. The IC_{50} values were 6.7, 2.5 and 6.5 μg/ml, respectively, which means that hepatic HEPG2-1 cells are the most sensitive towards the tested plant extract (Fig. 4).

The hydrolysis products of sinigrin, progoitrin and glucocheirolin had previously showed a marked *in vitro* cytotoxicity against human erythroleukaemic K562 cells. Although it has been proposed that some isothiocyanates inhibit protein synthesis and affect carbohydrate metabolism, the activity of these compounds seems to be mainly ascribed to the chemical reactivity of the isothiocyanate group, which can bind easily to protein. Moreover, some hydrolysis products could be considered as antimitotic substances, given their strong antiproliferative activity (Nastruzzi et al., 1996).

A previous report showed that allyl isothiocyanate could inhibit cell cycle progression of Hela cells at G_2/M phase in a dose-dependent manner and the IC_{50} was about 15 μM (Hasegawa, Nishino, & Iwashima, 1993).

Rats fed a broccoli diet, which has a high concentration of sulforaphane, showed a significant increase in colon and hepatic quinone reductase (Keck, Qiao, & Jeffery, 2003). In adult male rats, oral administration of a mixture of glucosinolate derivatives, including iberin, caused a modification of both phase I and phase II detoxification enzymes, which was greater than the sum of the effects of individual components (Staack, Kingston, Wallig, & Jeffery, 1998).

4. Conclusion

There is a variation of glucosinolate levels in seeds, leaves and roots of *E. corinthium*. The highest percentage of glucosinolates is detected in seeds. A significant difference was observed between glucosinolate hydrolysis products identified by exogenous myrosinase hydrolysis and natural autolysis. The leaves showed the highest percentage of non-glucosinolate volatile components, while the roots showed the lowest. The seeds extract showed the highest antimicrobial activity, compared to the leaves and roots. Moreover, the seeds extract could participate in inhibiting the proliferation of colorectal HCT 116, hepatic HEPG2-1 and Hela cells *in vitro*.

Acknowledgement

The authors are very grateful to the staff of Micro-Analytical Center, Faculty of Science, Cairo University and Cancer Biology Unit, National Cancer Institute, Cairo University, for their great help in carrying out antimicrobial and cytotoxic activities, respectively.

Iranian tuna fish
Processing
Yellowfin
Skipjack
Electrothermal atomic absorption spectrometry

ABSTRACT

The contents of Pb and Cd in two species of Iranian tuna fish (*yellowfin* and *skipjack*), which were caught from the Persian Gulf and Oman Sea, and the effects of canning processing steps on their contents were assessed by electrothermal atomic absorption spectrometry. The results revealed that the levels of lead and cadmium throughout the processing steps in *yellowfin* were in range of 0.154 ± 0.019–0.441 ± 0.025 μg/g and 0.029 ± 0.002–0.084 ± 0.0005 μg/g, respectively. Pb and Cd concentrations from received fish to final product in *skipjack* were found to be in range of 0.072 ± 0.031–0.218 ± 0.031 μg/g and 0.016 ± 0.001–0.062 ± 0.002 μg/g, respectively. The limit of detection for lead and cadmium were 0.058 μg/g (11.6022 μg/l) and 0.0007 μg/g (0.1485 μg/l), respectively. Results from paired sample *t*-test analysis showed that defrosting, cooking, and sterilisation by autoclave would reduce the contents of lead and cadmium, considerably.

1. Introduction

A great number of major pollutants have entered aquatic systems such as rivers, lakes, and oceans (Rashed, 2001). Several pollutants such as heavy metals (e.g., lead and cadmium) are very toxic, stable and not easily biodegradable (Ikem & Egibor, 2005). The ingestion of food is known as an important way of exposure to heavy metals. Heavy metals such as lead and cadmium can be very harmful even at low concentrations when ingested over a long time (Celik & Oehlenschlager, 2004; Tuzen & Soylak, 2007; Voegborlo, El-Methnani, & Abedin, 1999). Amongst food, fish are constantly exposed to heavy metals present in polluted water. These heavy metals can accumulate in their tissues in different amounts depending on the size and age of fish (Burger et al., 2002; Demirezen & Uruc, 2006; Emami khansari, Ghazi – khansari, & Abdolahi, 2005; Kagi & Schaffer, 1998; Marijic & Raspor, 2007; Tuzen & Soylak, 2007). Thus, fish have been found to be good bioindicators or biosensor of heavy metal contamination in aquatic systems (Burger et al., 2002; Keskin et al., 2007; Kuroshima, 1987).

Consumption of fish is very popular amongst people all around the world because it has high protein content, low saturated fatty acids, and high omega fatty acids content (Ikem & Egibor, 2005; Tuzen & Soylak, 2007). In Iran, like many other countries the consumption of canned fish especially canned tuna fish is privilege because of its convenient and affordable use. The main source of providing fish for Iranian canned tuna fish factories are the Persian Gulf and Oman Sea where the possibility of heavy metal contamination is high because of heavy trafficking of oil.

Processing steps may change the concentration of heavy metals in fish before consumption. In this study the influence of processing steps on the concentration of lead and cadmium in two species of tuna fish (*yellowfin* and *skipjack*) has been investigated since such effects has not been previously investigated.

2. Materials and methods

2.1. Apparatus

A Varian Spectra AA-220 (Melbourne, Australia) atomic absorption spectrometer equipped with a GTA-100 graphite furnace atomiser, deuterium lamp as a background corrector, a Varian programmable sample dispenser, wavelengths 217 nm and 326.1 nm, spectral bandwidth 1 nm and 0.5 nm monochromator were used for determination of lead and cadmium, respectively.

All glassware used in analytical work were soaked in commercial detergent for 24 h, rinsed with water, soaked in sulfochromic solution, rinsed with deionised water then kept in an oven at 110 °C until needed.

2.2. Reagents and standards

All reagents used were of analytical reagent grade. Standard stock solutions of lead and cadmium were prepared by diluting concentrated solutions to obtain a solution of 1000 mg/l with deionised water, Nanopure water system with specific resistivity of 18.3 MΩ cm^{-1} (Millipore), was used for all working and standard solutions.

2.3. Sample preparation and digestion

Samples of two species of tuna fish were collected before and after four processing steps (defrosting, butchery, cooking, and sterilisation by autoclave) from canned tuna fish factories in Tehran-Iran, which provide their fish from the Persian Gulf and Oman Sea. First, the oil content of samples (before and after sterilisation) was drained off, and all samples were homogenised in a food blender with stainless steel cutters, followed by digestion.

For the determination of lead and cadmium 5 ± 0.01 g of each samples was weighed into a 150 ml beaker and 50 ml of freshly 1:1 (v/v) H_2O_2 (30%):HNO_3 (65%) was added slowly in portion. Each beaker was covered with a watch glass and stored at room temperature for 48 h. The samples were heated on hot plate until the solutions were clear. The solutions were then allowed to cool and sonicated for five minutes. The clear solutions were transferred into 25 ml flasks and diluted to the mark with deionised water and transferred into lidded tubes in a water-bath of 60 °C for 30 min. Finally, 170 μl of phosphoric acid as a modifier was added to each tube and shaken using a tube-shaker. The concentrations of cadmium and lead were determined using a Graphite Furnace Atomic Absorption Spectrophotometer (GFAAS) in different samples. The GFAAS determinations were carried out in triplicate.

3. Results and discussion

3.1. The influence of different species on concentrations of lead and cadmium

The concentrations of Pb and Cd in *yellowfin* and *skipjack* species which were caught from the Persian Gulf and Oman Sea are shown in Table 1. Literature values for lead were reported as 0.58–4.03 μg/g dry weight (Sharif, Mustafa, Hossain, Amin, & Safiullah, 1993), 0.5–9 μg/g (Aucoin et al., 1999), 4.9–5.30 μg/g (Chale, 2002), 0.22–0.85 μg/g dry weight (Tuzen, 2003), 0.7–2.4 μg/g (Mendil et al., 2005), 0.09–6.95 μg/g dry weight (Turkmen, Turkmen, Tepe, & Akyurt, 2005), 0.068–0.874 μg/g (Yilmaz, Ozdemir, Demirak, & Tuna, 2007) & 0.33–0.93 μg/g (Uluozlu, Tuzen, Meendil, & Soylak, 2007).

Cadmium concentrations in literature have been reported in the range of 0.04–0.13 μg/g dry weight (Sharif et al., 1993), 0.25–0.39 μg/g (Chale, 2002), 0.09–0.48 dry weight (Tuzen, 2003), 0.01–4.16 μg/g dry weight (Turkmen et al., 2005), 0.1–1.2 μg/g (Mendil et al., 2005), 0.010–0.084 μg/g (Yilmaz et al., 2007), and 0.45–0.90 μg/g (Uluozlu et al., 2007).

The concentration of lead in *yellowfin* was slightly higher than the permissible level for tuna fish according to European communities (EC) (0.4 Pb μg/g). Also, the concentrations of cadmium in both species were lower than the permissible levels for tuna fishes established by (EC) (0.1 Cd μg/g) (Commission of the European Communities (2001)).

The concentrations of lead and cadmium were significantly higher in *yellowfin* than those in *skipjack* (Table 1). Statistical analysis based on student paired sample *t*-test showed significant differences ($p < 0.05$) between the two species for the amount of lead and cadmium, which could be related to the bigger size of *yellowfin* and the differences between these species were attributed to their behaviours and habitats.

3.2. Processing effects on lead and cadmium contents

Statistical analysis using paired sample *t*-test showed that the concentrations of lead (Table 2) and cadmium (Table 3) in *skipjack* were significantly different ($p < 0.05$) before and after cooking and sterilisation by autoclave. Significant differences ($p < 0.05$) were also found in the lead (Table 2) and cadmium (Table 3) concentrations of *yellowfin* before and after defrosting, cooking, and sterilisation.

Thus defrosting might significantly reduce the concentration of lead and cadmium in canned tuna fish due to possible separation of serum. Furthermore, it could be concluded that cooking and sterilisation might decline the concentration of lead and cadmium in tuna fish during processing. The reduction in metal contents of fish during the heating process may be related to the decrease of protein content and release of these metals with the loss of water as free salts, possibly associated with soluble amino acids and uncoagulated proteins (Atta, El-sebaie, Noaman, & Kassab, 1997; Howarth & Sprague, 1978 Bryan & Hummerstone, 1971).

Table 4 shows the concentrations of Pb and Cd in final canned products of *yellowfin* and *skipjack* species. Lead concentrations in literature have been reported as 0.18–0.40 μg/g (Voegborlo et al., 1999), 0.0126–0.0726 μg/g (Emami khansari et al., 2005), 0.0–0.03 μg/g (Ikem & Egibor, 2005), and 0.09–0.40 μg/g (Tuzen & Soylak, 2007). Literature values for cadmium were reported in the range of 0.09–0.32 μg/g (Voegborlo et al., 1999), 0.0046–0.0720 μg/g (Emami khansari et al., 2005), 0.0–0.05 μg/g (Ikem & Egibor, 2005), and 0.06–0.25 μg/g (Tuzen & Soylak, 2007).

The concentrations of lead and cadmium in all canned tuna fish samples were found to be lower than the limits established by the Institute of Standards and Industrial Research of Iran (ISIRI), and European communities (Commission of the European Communities, 2001; Institute of Standards and Industrial Research of Iran, 2003).

3.3. Analytical Figures of merit

Sensitivity was studied by means of the limit of detection (LOD), defined as follows:

$$\mathrm{LOD} = \frac{3\delta_b}{m}$$

where δ_b is standard deviation of eight successive measurements of blank; m means the slope of the standard calibration curve.

Table 1
Assessment of heavy metal concentrations (μg/g wet weight) in tuna fish species of the Persian Gulf and Oman Sea (expressed as mean concentration ± SD, $N = 10$).

Fish species	Pb (X ± SD)	Permissible[a] level of Pb μg/g	Mean differences of Pb	Significance level of Pb	Cd (X ± SD)	Permissible[a] level of Cd μg/g	Mean differences of Cd	Significance level of Cd
Yellowfin	0.441 ± 0.025	0.4	0.223	0.018	0.084 ± 0.0005	0.1	0.022	0.026
Skipjack	0.218 ± 0.031	0.4			0.062 ± 0.002	0.1		

[a] European communities.

Table 2
The effect of four steps of processing on concentration of lead in *skipjack and yellowfin*.

Fish species	Steps	Significance level	Standard deviation	Differences
Skipjack	Before and after defrosting	0.064	0.012	0.084
	Before and after butchery	0.318	0.008	−0.011
	Before and after cooking	0.041	0.002	0.021
	Before and after sterilisation by autoclave	0.042	0.006	0.061
Yellowfin	Before and after defrosting	0.012	0.004	−0.029

Skipjack	0.072 ± 0.031	0.2	0.5	0.016 ± 0.001	0.05	0.1

[a] European communities.
[b] Institute of Standards and Industrial Research of Iran.

According to this equation, the LOD of lead and cadmium were 0.058 μg/g (11.6022 μg/l) and 0.0007 μg/g (0.1485 μg/l), respectively.

Precision, which is a measure of reproducibility, expressed as percent relative standard deviation (RSD) within the liner range, was obtained by using the following equation (Saber-Tehrani, Givianrad, & Hashemi-Moghadam, 2006a; Saber-Tehrani, Hashemi-Moghadam, Givianrad, & Aberoomand-Azar, 2006b):

$$\mathrm{RSD} = \frac{100\delta}{\bar{x}}$$

The repeatability of measurements, as the means of RSD was 1.7% for lead and 0.9% for cadmium for 8 successive individual measurements of the same sample. In addition, RSD of the whole procedure, expressed as the RSD of the concentration measured for three replicated analyses of the same sample, were 2.2% for lead and 0.2% for cadmium.

The accuracy of method has been investigated by means of spiking different amounts of lead and cadmium into samples (Saber-Tehrani et al., 2006a; Saber-Tehrani et al., 2006b). The recoveries were found within the range of 86%–90% for lead and 85%–92% for cadmium, which are tabulated in Table 5.

3.4. Pearson

Correlation analysis based on Pearson coefficient was performed. Significant positive correlation is the relationship between two sets of data in which the values of two variables increase or decrease together significantly (Saber-Tehrani, Givianrad, & Kahkashan, 2007; Saber-Tehrani et al., 2006a).

In this study, positive correlations in the non-thermal process were found between the lead concentration of *skipjack* and *yellowfin* and also, between the cadmium concentration of *yellowfin* and lead concentration of *skipjack* at a confidence level of 95% (Table 6). Moreover positive correlations in the thermal process were found amongst cadmium concentrations of *yellowfin* and *skipjack*, and also, between the cadmium concentration of *skipjack* and lead concentration of yellowfin at a confidence level of 95% (Table 6). Furthermore, in whole process cadmium concentration in *skipjack*

Table 5
Recoveries corresponding to lead and cadmium by means of spiking different contents of lead and cadmium to the samples.

Lead content (μg l^{-1})	Lead spiked (μg l^{-1})	Recovery (%)	Cadmium content (μg l^{-1})	Cadmium spiked (μg l^{-1})	Recovery (%)
	25	85.8		25	84.8
26.86	50	90.1	1.2	50	89.1
	100	87.3		100	92.1

Table 6
Pearson correlation matrix for lead and cadmium contents of tuna fish species in thermal, non-thermal, and whole process.

	Lead content of *yellowfin*	Lead content of *skipjack*	Cadmium content of *yellowfin*	Cadmium content of *skipjack*
Lead content of *yellowfin*	1	0.635	0.539	0.569
		0.598	0.572	0.592
		0.571	**0.558**	0.531
Lead content of *skipjack*		1	0.661	0.573
			0.673	0.521
			0.584	0.496
Cadmium content of *yellowfin*			1	0.541
				0.683
				0.563
Cadmium content of *skipjack*				1

Note: Bold numbers indicate a significant correlation (99% confidence) and underline numbers show a significant correlation (95% confidence). The numbers in the first row correspond to non-thermal process, those in the second row correspond to thermal process, and those in the third row correspond to whole process of canned tuna fish.

and lead concentration in *yellowfin* had positive correlations at a confidence level of 95%. In addition, positive correlations were recognised at a confidence level of 99%, amongst lead and cadmium concentrations in both species and amongst cadmium concentration in *yellowfin* and lead concentration in *skipjack* (Table 6). Thus, whole process (defrosting, butchery, cooking, and sterilisation by autoclave) can reduce lead and cadmium concentrations in both species.

4. Conclusion

A suitable and sensitive method was developed for determination of lead and cadmium in biological samples by ETAAS. Moreover, by considering the concentrations of lead and cadmium in unprocessed tuna fish species, it can be commented that nowadays the pollution of the Persian Gulf and Oman Sea is in the permissible range.

It was also found that the concentration of lead and cadmium in *yellowfin* was significantly higher than those of *skipjack*.

More importantly, defrosting, cooking, and sterilisation could result in a significant reduction of lead and cadmium in the final product. Therefore, the consumption of Iranian canned tuna fish of the Persian Gulf and Oman Sea can be safe for human health in spite of possible contamination with heavy metals.

Acknowledgments

The authors are grateful to the Canned Tuna Fish Factories of Tehran-Iran for providing the samples, Laboratory Complex of Islamic Azad University for valuable technical assistance and also, Prof. H. Lelieveld and Dr. K. Shamsi for their cooperative guidance.

5-Hydroxytryptophan
Roasting

ABSTRACT

The levels of free and total tryptophan and of 5-hydroxytryptophan (5-HTP) were investigated in green and roasted grains and beverages of *Coffea arabica* L. (Arabica) and *Coffea canephora* Pierre var. *robusta* (Robusta). Grains were light, medium and dark roasted. Free and protein tryptophan were extracted before and after hydrolysis. The levels of tryptophan and 5-HTP were quantified simultaneously by ion-pair HPLC and fluorimetric detection after derivatisation with *o*-phthalaldehyde. Robusta green coffee had higher total and protein tryptophan, whereas Arabica had higher free tryptophan levels. 5-HTP was not detected in the samples before and after roasting. Free tryptophan was completely degraded during roasting. Roasting significantly affected protein tryptophan. The rate of loss was smaller in Arabica compared to Robusta at every roasting degree. A beverage prepared the Brazilian way with a medium-roasted coffee provided 1.4–2.5 mg tryptophan/50 ml cup.

1. Introduction

Coffee plays a major social and economical role. It is one of the most widely consumed beverages throughout the world due to its pleasant taste and aroma and stimulant effect. It is the second major commodity commercialised worldwide, losing only to petroleum. It represents an important financial source for developing countries, involving a large number of workers in the production chain (Embrapa Café, 2007). Brazil is the largest green coffee producer and exporter, accounting for approximately 30% of the world market. Among the most economically relevant Brazilian coffee species are *Coffea arabica* and *Coffea canephora* (Perrone, Farah, Donangelo, de Paulis, & Martin, 2008).

Recent studies have attributed beneficial health effects to coffee. Coffee is frequently recommended as a stimulant and to prevent hypertension; furthermore, it is a bronchodilator and a good source of potassium in the diet. Studies have also described the association of the daily moderate consumption of coffee with lower prevalence of cirrhosis, lower risk of diabetes type 2, decreased prevalence of some types of cancer, inhibition of fat absorption and activation of lipid metabolism in the liver (Higdon & Frei, 2006).

Several epidemiological studies have associated coffee intake with beneficial effects in the central nervous system (CNS). Coffee consumption has been positively associated with alertness, humour, lower risk of suicides, lower incidence of Parkinson disease, prevention of depression, and decrease of alcohol consumption and cigarette smoking (Dórea & Da Costa, 2005; Higdon & Frei, 2006). The majority of the studies blame caffeine for these effects. However, coffee has many other compounds, and, therefore, the possible functional role of other substances present in coffee must be investigated.

Serotonin – 5-hydroxytryptamine or 5-HT (3-(2-aminoethyl)-1H-indol-5-ol) – is a neurotransmitter in the CNS. It is synthesised from the amino acid L-tryptophan by a short metabolic pathway consisting of two enzymes: tryptophan hydroxylase (EC 1.14.16.4) and amino acid decarboxylase (EC 4.1.1.28) with 5-hydroxytryptophan (5-HTP) as an intermediate (Fig. 1). Serotonin has broad activities in the brain, playing an important role in the modulation of anger, aggression, body temperature, mood, sleep, human sexuality, appetite, and metabolism, as well as stimulating vomiting (Ruddick et al., 2006; Shaw, Turner, & Del Mar, 2009; Turner, Loftis, & Blackwell, 2005). Cirilo et al. (2003) detected the presence of serotonin in green and roasted coffee. According to their study, an increase in the degree of roasting resulted in a significant increase in serotonin levels. The authors suggested that serotonin could have been formed by the thermal degradation of their precursors – tryptophan and 5-hydroxytryptophan (5-HTP) – during roasting. However information is scarce on the levels of serotonin and its precursors in coffee and also, how they are affected during production and processing.

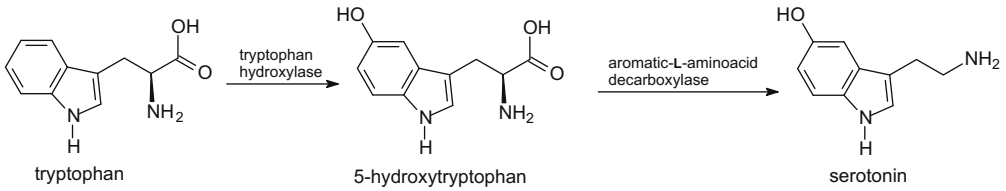

Fig. 1. Metabolic pathway from tryptophan to serotonin.

According to Lyons and Truswell (1988) and Goihl (2006), serotonin taken orally does not pass into the serotonergic pathways of the CNS because it does not cross the blood–brain (hematoencephalic) barrier. However, tryptophan and 5-hydroxytryptophan, from which serotonin is synthesised, cross the blood–brain barrier. Synthesis and turnover of brain serotonin depend directly on the uptake of its precursors – tryptophan and 5-hydroxytryptophan – across the blood–brain barrier.

Tryptophan (2-amino-3-(1H-indol-3-yl)-propionic acid) is an essential amino acid in the human diet. Besides acting as building blocks in protein biosynthesis, tryptophan functions as a biochemical precursor for serotonin, melatonin and niacin. Serotonin is synthesised *via* tryptophan hydroxylase. However, it can be converted to melatonin. Niacin is synthesised from tryptophan *via* kynurenine and quinolinic acids as key biosynthetic intermediates (Delgado-Andrade, Rufian-Henares, Jimenez-Perez, & Morales, 2006; Goihl, 2006; Ruddick et al., 2006).

5-Hydroxytryptophan or 5-HTP (2-amino-3-(5-hydroxy-1H-indol-3-yl) propanoic acid) is a naturally occurring amino acid. It is decarboxylated to serotonin by the aromatic-L-amino-acid decarboxylase in the presence of vitamin B6. This reaction occurs both in nervous tissue and in the liver (Birdsall, 1998; Shaw et al., 2009).

Both serotonin precursors – tryptophan and 5-HTP – in the diet can affect brain serotonin levels. High levels of non-protein (free) tryptophan, which is easily absorbed, could increase its availability in the brain. 5-HTP has advantages over tryptophan, as its intestinal absorption does not require the presence of a transporter and it is not affected by the presence of other amino acids and carbohydrates in the diet (Birdsall, 1998; Comai et al., 2007; Higdon & Frei, 2006; Turner et al., 2005).

Very little information is available regarding the levels of serotonin precursors in coffee. Therefore, the objective of this study was to determine the levels of free and total tryptophan and of 5-HTP in green coffee beans and to investigate the influence of roasting on their levels.

2. Material and methods

2.1. Standards and chemicals

Tryptophan and 5-hydroxytryptophan were purchased from Sigma Chemical Co. (St. Louis, MO, USA). All reagents were of analytical grade, except HPLC solvents which were chromatographic grade. LC water was used throughout the experiments (Milli-Q System, Millipore Corp., Bedford, MA, USA).

2.2. Coffee samples, roasting and beverage preparation

Samples of green economically relevant Brazilian coffee – *C. arabica* L. cv Catuaí Amarelo (Arabica) and *C. canephora* Pierre var. *robusta* (Robusta) – were kindly provided by Incofex Armazéns Gerais LTDA, Viçosa, MG, Brazil. These samples included two good cup quality green samples of Arabica (Catuaí amarelo, hard beverage, 2007/2008) from Viçosa, MG, and Robusta (soft beverage, 2006/2007) from Lajinha, MG. Samples from three different lots of each species were used.

The green coffee grains (100 g) were roasted in a commercial fluidised bed (hot air stream) roaster (i-Roast® Model No. 40009, Hearthware Home Products, USA) at three different conditions: 171 °C/8 min, 171 °C/15 min, and 210 °C/15 min to obtain light, medium and dark roasts, respectively. A 1 min cooling period was included in the roasting procedure. Roasting degrees of the coffee were determined by means of percent weight loss during roasting and colour characteristics (CIE $L^*a^*b^*$ colour system) of the roasted coffee (Almeida, Farah, Silva, Nunan, & Gloria, 2006; Perrone et al., 2008).

Before and after roasting, the coffee grains were ground and analysed for free and protein-bound tryptophan, 5-hydroxytryptophan, moisture content and total nitrogen levels.

The beverages were prepared the Brazilian way with medium-roasted samples of Arabica and Robusta coffee (Almeida et al., 2006). 20 g of ground coffee (20 mesh) were added to 150 ml of water at 90 °C. The mixture was kept under agitation for 3 min and was filtered through filter paper (No. 102, Melita, São Paulo, SP, Brazil). The beverages were also analysed for total solids, extraction yield and concentration.

The samples were analysed immediately. When necessary, samples were stored under nitrogen, refrigeration (−23 °C) and protected from light in order to minimise tryptophan loss due to oxidation.

2.3. Weight loss during roasting

The percent weight loss (%WL) of the coffee beans after roasting was calculated by using the following equation (Perrone et al., 2008)

$$\%\,\mathrm{WL} = 100(\mathrm{WBR} - \mathrm{WAR})/\mathrm{WBR}$$

where WBR is the weight before roasting and WAR is the weight after roasting.

2.4. CIE $L^*a^*b^*$ colour characteristics

The CIE $L^*a^*b^*$ colour characteristics were determined using a ColorTec colourimeter PCM (Accuracy Microsensor, Pittsford, NY, USA) with standard illumination D_{65} and colourimetric normal observer angle of 10°. The L^* (luminosity), a^* (intensity of red (+) and green (−)) and b^* (intensity of yellow (+) and blue (−)) values were taken straight from the equipment. The chroma $[c = (a^2 + b^2)^{1/2}]$ and the hue angle [h = arctg a/b] were calculated. The L^*, chroma and hue values were used to infer the degree of roasting of the coffee (Almeida et al., 2006).

2.5. Determination of moisture content

The moisture content of ground green and roasted coffee was determined by dehydration in an oven with forced air ventilation (Tecnal, Piracicaba, SP, Brazil) at 105 ± 2 °C until constant weight (Reh, Gerber, Prodolliet, & Vuataz, 2006). This information was used to express the amounts of the analytes on a dry weight basis.

2.6. Determination of total nitrogen levels

The total levels of nitrogen were determined by the Micro-Kjeldahl method, and the levels of protein were estimated using 6.25 (AOAC, 2000).

2.7. Simultaneous HPLC determination of tryptophan and 5-hydroxytryptophan

Free and protein-bound tryptophan were extracted from the samples with 50% methanol before and after hydrolysis with 4.2 N NaOH, respectively (AOAC, 2000). The levels of tryptophan and 5-HTP were quantified simultaneously by ion-pair HPLC, post-column derivatisation with *o*-phthalaldehyde and fluorimetric detection at 340 and 445 nm of excitation and emission, respectively (Martins, 2008).

2.8. Extraction rate and concentration of the beverage

The beverages were analysed for solid content (dehydration in air-oven at 105 ± 2 °C). Extraction rate and concentration were calculated as the percentage of total solids per amount of coffee used and beverage volume, respectively (López-Galilea, De Peña, & Cid, 2007).

2.9. Statistical analysis

The analyses were performed in duplicate. Data are presented as means ± standard deviations. The data were submitted to ANOVA (one way and two-way) followed by Tukey test at 5% probability using SIGMA STAT 2.0 (Systat Software Inc, Richmond, CA, USA). Pearson correlation was used to correlate the levels of serotonin precursors with the degree of roasting.

3. Results and discussion

3.1. Physico-chemical characteristics and serotonin precursors in green coffee

The levels of moisture, protein, 5-HTP and tryptophan in green Arabica and Robusta coffee are indicated on Table 1. Robusta coffee had significantly higher moisture content compared to Arabica. The moisture levels found and the difference between green Arabica and Robusta coffee is reported in the literature with values ranging from 8 to 12 g/100 g (Casal, Mendes, Oliveira, & Ferreira, 2005; Mazzafera, 1999; Montavon, Mauron, & Duruz, 2003).

In order to eliminate interference of the moisture content between samples, the levels of the other analytes were expressed on a dry weight basis (dw). Protein levels were of approximately 13 g/100 g dry weight basis (dw), with no significant difference between the two species. The levels found are similar to literature values ranging from 8.7 to 13.6 g/100 g (Casal et al., 2005; Mazzafera, 1999). However, these results are probably over-estimated as part of the levels of nitrogen detected by the Kjeldahl method in green coffee is not only available as amino acids or proteins, but other sources of nitrogen such as caffeine, and trigonelline (Bekedan, Schols, Van Boekel, & Smit, 2006; Mazzafera, 1999). According to these investigators, non-protein nitrogen corresponds to approximately 17–30% of the total levels.

Table 1
Levels of moisture, protein, 5-hydroxytryptophan (5-HTP) and free and protein-bound tryptophan in Arabica and Robusta green coffee.

Parameters	Green coffee[a]	
	Arabica	Robusta
Moisture (g/100 g)	8.65 ± 0.21^{B}	10.24 ± 0.16 ^{A}
Protein (g/100 g, dw[c])	13.92 ± 0.98	13.73 ± 0.74
5-HTP (mg/100 g, dw)	nd[b]	nd
Tryptophan		
Free (mg/100 g, dw)	22.08 ± 1.53^{A}	3.09 ± 0.10^{B}
Protein-bound (mg/100 g, dw)	120.8 ± 3.3^{B}	154.0 ± 4.5^{A}
Total (mg/100 g, dw)	142.9 ± 2.9^{B}	157.0 ± 4.5^{A}

[a] Mean values (±standard deviation) with different capital letters in the same line are significantly different (ANOVA, $p \leqslant 0.05$).
[b] Not detected (<0.3 mg/100 g).
[c] dw = dry weight.

The presence of serotonin precursors in green coffee was investigated for the first time. 5-HTP was not detected in any of the green coffee samples analysed; whereas tryptophan was present at high levels (Table 1). Free tryptophan was present at higher concentrations in Arabica (22.08 mg/100 g dw) compared to Robusta (3.09 mg/100 g dw). It corresponded to 15% and 2% of the total tryptophan levels in Arabica and Robusta coffees, respectively.

Significantly higher protein-bound tryptophan (154.0 mg/100 g dw) was found in Robusta green coffee compared to Arabica (120.8 mg/100 g dw). These values represent 1.12 and 0.87 g tryptophan/100 g of protein, respectively. Therefore, Robusta green coffee had significantly higher protein-bound tryptophan compared to Arabica.

The levels of tryptophan found are similar to reported values (Arnold & Ludwig, 1996; Casal, Alves, Mendes, Oliveira, & Ferreira, 2003; Casal et al., 2005). Differences in the profile and levels of amino acids in coffee can result from several factors, among them, species, varieties, degree of ripening, post-harvest conditions, and method of analysis (Arnold & Ludwig, 1996; Casal et al., 2003; Mazzafera, 1999).

According to Comai et al. (2007), tryptophan is a minor amino acid in the human diet. However, it is one of the most abundant free amino acids in green coffee, along with alanine, proline, asparagine, glutamic acid and phenylalanine (Casal et al., 2003; Mazzafera, 1999). Therefore, green coffee is a good source of free and protein-bound tryptophan.

3.2. Roasting effects on weight loss, CIE colour characteristics, moisture and protein levels

The weight loss during roasting, the CIE colour characteristics and the levels of moisture and protein in the roasted coffee samples are indicated on Table 2. There was a significant loss of weight of samples after roasting. The weight loss increased with an increase in the intensity of the roasting process for both coffee species. A significant difference was also observed between species, with higher weight loss in Robusta compared to Arabica in every degree of roasting. Similar results were reported by Perrone et al. (2008).

A significant difference was observed on the CIE $L^*a^*b^*$ colour characteristics among roasted samples. According to the literature, the degree of roasting can be inferred by coffee's colour: the stronger the roasting degree, the lower the L^* values will be (Almeida et al., 2006; Cirilo et al., 2003; Summa, De La Calle, Brohee, Stadler, & Anklam, 2007). Significant differences were also observed for the chroma, which refers to the perceived colourfulness. It decreased significantly throughout the roasting process. Such differences during roasting of distinct varieties under the same conditions have also been observed in previous studies. According to Murkovic and Derler (2006), the higher sucrose content of Arabica compared to Robusta coffee, can favour colour development during roasting. The significant difference in the weight loss during roasting and in colour characteristics (L^* and chroma values) confirmed that the samples were submitted to three different degrees of roasting – light, medium and dark (Perrone et al., 2008).

Table 2
Colour characteristics, levels of moisture and protein in Arabica and Robusta coffee submitted to different roasting conditions.

Parameter	Coffee roasting[a]		
	Light (171 °C/8 min)	Medium (171 °C/15 min)	Dark (210 °C/15 min)
Weight loss (%)			
Arabica	13.90 ± 0.20^{BZ}	17.91 ± 0.85^{BY}	29.55 ± 0.99^{BX}
Robusta	16.40 ± 0.10^{AZ}	21.22 ± 0.56^{AY}	33.07 ± 0.94^{AX}
CIE colour			
L^* (luminosity)			
Arabica	27.97 ± 2.00^{AX}	18.97 ± 0.78^{AY}	12.74 ± 0.83^{BZ}
Robusta	28.84 ± 1.61^{AX}	18.67 ± 1.32^{AY}	14.53 ± 2.06^{AZ}
Chroma			
Arabica	27.90 ± 3.43^{AX}	12.20 ± 1.46^{AY}	2.64 ± 1.24^{BZ}
Robusta	29.10 ± 2.90^{AX}	11.67 ± 1.12^{AY}	$5.65 + 1.57^{AZ}$
Hue			
Arabica	66.97 ± 5.28^{BY}	57.59 ± 8.32^{AY}	220 ± 52.2^{BX}
Robusta	70.88 ± 4.03^{AZ}	56.53 ± 10.22^{AY}	164 ± 25.3^{AX}
Moisture content (g/100 g)			
Arabica	1.31 ± 0.38	1.40 ± 0.38	1.53 ± 0.49
Robusta	1.63 ± 0.33	1.45 ± 0.30	1.57 ± 0.38
Protein (g/100 g)			
Arabica	13.37 ± 1.58	14.26 ± 1.64	14.67 ± 2.70
Robusta	14.10 ± 0.66	14.39 ± 1.27	14.78 ± 1.72

[a] Mean values (±standard deviation) with different letters (AB) for the same parameter in the same column and with different letters (XYZ) in the same line are significantly different (Tukey tests, $p \leqslant 0.05$).

There was a significant loss of moisture content after roasting – 85% loss – for both Arabica and Robusta coffee, reaching values which did not differ significantly between species and among the different roasting degrees. During coffee roasting there are two major phases: dehydration and pyrolysis. Most of the water is lost during dehydration, at the beginning of the roasting process, reaching very low levels. During pyrolysis, there is still water loss, along with CO_2 and CO, however at a very slow rate (Casal et al., 2005; Montavon et al., 2003). The gravimetric method used in the determination of moisture is not sensitive enough to detect such a small loss.

The levels of protein in the roasted coffee varied from 13.37 to 14.78 g/100 g. Similar results are described in the literature (Casal et al., 2005). However, these results are also over-estimated because of other sources of nitrogen in the roasted coffee such as caffeine, trigonelline and the Maillard reaction derived melanoidins (Bekedan et al., 2006; Mazzafera, 1999). There was no significant difference on total nitrogen levels between species or roasting degrees.

3.3. Influence of roasting on the levels of serotonin precursors in Arabica and Robusta coffee

5-HTP was not detected (<0.3 mg/100 g) in any of the roasted coffee samples, similar to what was found in green coffee. Free tryptophan, which was present in green coffee, was not detected (<0.3 g/ml) in roasted coffee either. Its total loss during roasting indicates the sensitivity of free tryptophan, irrespective of the degree of roasting.

Protein-bound tryptophan was detected in the roasted samples at levels which decreased as the intensity of the roasting process increased (Fig. 2). No significant difference was observed on tryptophan levels between species at each degree of roasting. During the initial minutes of roasting there was a significant decrease on the levels of tryptophan in Robusta coffee compared to Arabica. The loss of tryptophan correlated significantly (Pearson correlations, $R^2 \geqslant 0.979$) with the roasting degree, with higher rates for Robusta (−39.504) compared to Arabica (−29.925). This result suggests that there might be factors in Arabica coffee which decreased tryptophan loss. The higher lipid content of Arabica coffee could afford this protective effect (Casal et al., 2003).

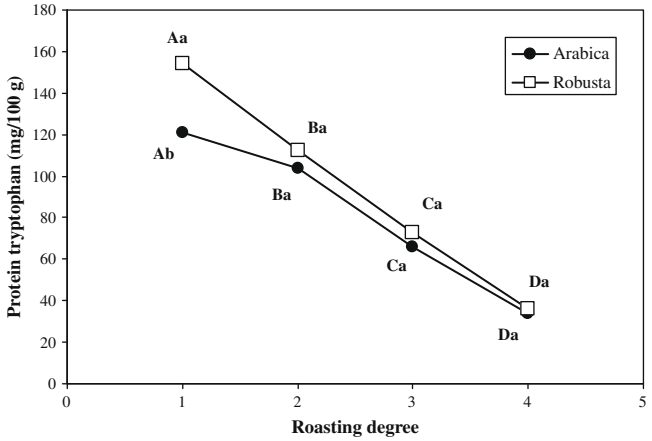

Fig. 2. Levels of protein-bound tryptophan in Arabica and Robusta green (1) and roasted coffee to different degrees: (2) light roast – 171 °C/8 min, (3) medium roast – 171 °C/15 min and (4) dark roast – 210 °C/15 min. Mean levels with different letters ab for species and ABCD for roasting degree are significantly different (Tukey test, $p \leqslant 0.05$).

According to Turner et al. (2005) and Ruddick et al. (2006), 5-HTP can be formed through oxidation of free or protein-bound tryptophan, however, it is much more susceptible to oxidation than tryptophan itself. Furthermore, 5-HTP can be decarboxylated during roasting forming serotonin (Cirilo et al., 2003). Therefore, it is possible that 5-HTP could have been produced and degraded during roasting.

3.4. Serotonin precursors in Arabica and Robusta coffee beverages

The coffee beverages prepared with the medium-roasted coffee (171 °C/15 min) had ~24% extraction rate (Table 3), which is typical of a homemade beverage with good body (López-Galilea et al., 2007). The levels of nitrogen detected by the Kjeldahl method overestimates protein levels as indicated previously.

5-HTP and free tryptophan were not detected. However, protein-bound tryptophan was found in the beverages from both species. Significantly higher tryptophan levels were detected in Robusta compared to Arabica beverage. The levels of tryptophan in the beverages varied from 28.1 to 49.5 μg/ml, which represents 1.4 to 2.5 mg of tryptophan/50 ml cup. Based on these results, three cups of coffee a day would provide the recommended daily intake (DRI, 2005).

Table 3
Total solids, extraction rate, protein, 5-hydroxytryptophan (5-HTP), free and protein-bound tryptophan in coffee beverage from medium-roasted Arabica and Robusta.

Parameters	Levels[a]	
	Arabica	Robusta
Total solids (mg/ml)	32.74 ± 0.39^{B}	$33.87 \pm 0.18^{*}$
Extraction rate (g/100 ml)	24.56 ± 0.29^{a}	24.40 ± 0.14^{A}
Protein (g/100 ml)	0.11 ± 0.01^{B}	0.12 ± 0.01^{A}
5-HTP (mg/100 ml)	Nd[b]	nd
Tryptophan	nd	nd
Free (mg/100 ml)	nd	nd
Protein-bound (μg/ml)	28.1 ± 4.1^{B}	49.5 ± 4.6^{A}

[a] Mean values ± standard deviation with the different capital letters in the same line are significantly different ($p \leqslant 0.05$).
[b] nd – not detected (<0.3 μg/ml).

The presence of tryptophan in coffee beverages suggests that it might contribute to the diet tryptophan pool. However its uptake as a precursor of the neurotransmitter serotonin must be further investigated, as it will also depend on protein digestibility, presence of anti-nutritional factors, ratio of tryptophan/neutral amino acids and presence of added carbohydrates to the beverage (Comai et al., 2007; Lyons & Truswell, 1988).

4. Conclusions

Based on these results, green coffee did not have 5-HTP, however it was observed to be a good source of free and protein-bound tryptophan. During roasting, there was a complete degradation of free tryptophan and the levels of protein bound-tryptophan decreased with the intensity of the roasting process. A beverage prepared with medium-roasted Arabica and Robusta coffee provides a good dietary source of protein-bound tryptophan.

Milk
Trolox
Ascorbic acid
Singlet oxygen

ABSTRACT

Antioxidant activities and the mechanism of water-soluble Trolox and ascorbic acid on the oxidation of riboflavin in milk were studied. Trolox or ascorbic acid at 0, 100, 250, 500, or 1000 ppm was added to milk with or without added 50 ppm riboflavin and stored under light at 27 °C. Headspace oxygen was analysed by GC and Trolox, ascorbic acid, and riboflavin were determined by HPLC. The headspace oxygen of milk with added 50 ppm riboflavin depleted faster than that of milk without added riboflavin ($p < 0.05$). Trolox and ascorbic acid decreased during storage under light and riboflavin was completely destroyed within 24 h. As the concentration of Trolox or ascorbic acid increased, the riboflavin loss decreased. Riboflavin, Trolox, and ascorbic acid competed to react with singlet oxygen which was formed in the presence of riboflavin under light. Trolox and ascorbic acid protected riboflavin in milk under light by reacting with singlet oxygen.

1. Introduction

Riboflavin (Vitamin B2) is required for the metabolism of fats, carbohydrates and proteins and for red blood cell formation and respiration. Riboflavin is also essential in healthy hair and nail growth and thyroid activity (Choe, Huang, & Min, 2005; Siassi & Ghadirian, 2005). Riboflavin must be obtained from foods because the body does not synthesise or store the vitamin.

Milk is the most important source of riboflavin. Children between the ages 3–5 get approximately one-fifth of their total riboflavin intake from milk (Wells, 2000). Children ages 8–11 who drank no school milk, as compared to children who drank milk everyday at school, were more likely to have riboflavin intakes below the recommended levels (Cook, Altman, Jacoby, & Holland, 1975). The Recommended Daily Allowances for men is 1.3 mg/day, 1.1 mg/day for women and up to 0.9 mg/day for children up to age 14 (Institute of Medicine, 1998). Milk is stored in refrigerated dairy cases and exposed to fluorescent light to enhance consumer attraction prior to purchase at the supermarket (Bradley, Kim, & Min, 2006; Cladman, Scheffer, Goodrich, & Griffiths, 1998; Shiota, Ikeda, Konishi, & Yoshioka, 2002; Van Aardt et al., 2005). The light exposure lowers the nutritional quality of milk by destroying riboflavin rapidly. The vitamin content claimed on the label may not be the actual vitamin content upon purchase (Whited, Hammond, Chapman, & Boor, 2002). Riboflavin loss is dependant on light intensity and wavelength, exposure time, and packaging materials (Min & Boff, 2002). Researchers are continually studying effective ways to protect riboflavin in foods.

Oxidation of milk during light storage causes a significant loss of vitamins and produces off-flavours. The type, concentration, and solubility of oxygen can increase the oxidation of milk. Triplet oxygen oxidation is temperature dependant requiring higher activation energies, whilst singlet oxygen oxidation occurs at very low temperatures (Huang, Choe, & Min, 2004a; Min & Boff, 2002). Milk fat can affect the formation of off-flavours, where pentanal, heptanal and hexanal levels increased as the fat content increased from 0.5% to 3.4% (Lee, 2002). High concentrations of riboflavin in milk produce high amounts of volatile compounds (Huang et al., 2004a; Jung, Yoon, Lee, & Min, 1998; Lee, 2002).

In addition to protecting milk from light through the use of modified packaging materials, food additives can be used to prevent oxidation of milk. Tocopherols are the most powerful hydrophobic natural antioxidants. Trolox is an α-tocopherol derivative. The hydrophobic phytyl group of tocopherol has been replaced with a hydrophilic carboxylic group to produce Trolox, which is soluble in water (Priyadarsini, Kapoor, & Naik, 2001). Trolox is a synthetic compound that has been used as a food additive and as an active ingredient in cosmetic products (Carlotti, Sapino, Vione, Pelizzetti, & Trotta, 2004; Delicado, Ferrer, & Carmona, 1997). Studies show that the phytyl group of tocopherol has little effect on its antioxidant activity (Niki et al., 1985). α-Tocopherol and Trolox donate hydrogen from the hydroxyl group of a chroman ring to food radicals. Since the active antioxidant site for α-tocopherol and

doi:10.1016/j.foodchem.2009.05.017

Trolox are the same, the hydrogen-donating ability of Trolox will be similar to that of α-tocopherol.

Trolox reduced lipid oxidation and oxymyoglobin oxidation in bovine muscle (O'Grady, Monahan & Brunton, 2001) and protein oxidation in chicken breast meat (Lin & Liang, 2002). Cardiac recovery was significantly enhanced with Trolox after ischaemia and reperfusion (Sagach et al., 2002). Trolox inhibited the formation of thiobartituric acid reactive substances, which are indirect makers of lipid oxidation (Sagach et al., 2002). Trolox reduced the oxidation of blood plasma (Barclay, Basque, Stephenson, & Vinqvist, 2003). Many studies have reported the antioxidant effects of Trolox in food and biological systems but none have reported the antioxidant effect of Trolox in milk during light storage. The objective of this research was to study the antioxidant activities and mechanisms of Trolox and ascorbic acid to protect riboflavin in milk during storage under light.

2. Materials and methods

2.1. Materials

Commercial whole milk was purchased from a local grocery store (Krogers, Columbus, OH, USA). Teflon-coated rubber septa, aluminium caps and glass serum vials were purchased from Supelco, Inc. (Bellefonte, PA, USA). Riboflavin, ascorbic acid, and Trolox™ ((±)-6-Hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). A Milli-Q purification system was obtained from Millipore Co. (Bedford, MA, USA).

2.2. Sample preparation and storage

Two gallons of milk were sterilised before experimentation to reduce microbial growth during storage. Milk was commercially sterilised by Abbott Nutrition Supply Chain (Columbus, OH, USA.) and aseptically packaged in a can (200 ml). Trolox or ascorbic acid at 0, 100, 250, 500, or 1000 ppm was added to sterilised milk with or without the addition of 50 ppm riboflavin. Ten millilitres of milk sample was transferred to a 20-ml serum vial (22.6 × 150 mm, Supelco Inc., Bellefonte, PA, USA). Sample vials were sealed airtight with a Teflon-coated rubber septa and aluminium caps and stored under light at 27 °C. The light source was four Sylvania fluorescent lamps (General Electrics, Cleveland, OH, USA) with 1500 Lux light intensity. Samples were prepared in duplicate at each sample analysis. Headspace oxygen of samples was measured daily for 3 days. Riboflavin, Trolox, and ascorbic acid in milk were analysed every 3 h for 12 h.

2.3. Determination of headspace oxygen by GC

Headspace oxygen in the milk bottle was measured by injecting 100 μl of headspace gas into a Hewlett–Packard 5890 gas chromatograph (GC) equipped with a thermal conductivity detector. A stainless steel column (1.8 m × 0.32 cm) packed with 80/100 molecular sieve 13× (Alltech Asso Inc., IL, USA) was used. High purity (99.995%) helium was used as the carrier gas at 20 ml/min. The temperature of injection port, oven, and detector were 120, 40, and 150 °C, respectively. The gas chromatographic peak was measured by electronic count using a HP 3396A integrator. The percent of headspace oxygen of the sample bottle was determined by comparing the gas chromatographic peak of that of air which was considered to have 20.9% oxygen (Huang, Choe, & Min, 2004b; King & Min, 1998).

2.4. Determination of Trolox, ascorbic acid, and riboflavin by HPLC

To analyse Trolox and ascorbic acid in milk, 5 ml of 3% metaphosphoric acid in 50% methanol solution was added to 5 ml milk. Milk samples were filtered with a 0.45 μm membrane filter (25 mm i.d., Whatman, NY, USA) and collected into a 2-ml vial. Trolox and ascorbic acid were also determined by HPLC (Agilent 1100, Agilent Technologies, Inc., Santa Clara, CA, USA) equipped with a multiple wavelength detector and a Discovery C18 column (5 μm 4.6 mm × 15 cm, Supelco Inc., Bellefonte, PA, USA). The injection volume was 100 μl. The flow rate of mobile phase was 1 ml/min. The mobile phase for Trolox analysis was 60% methanol in 50 mM potassium phosphate. The mobile phase for ascorbic acid analysis was 50 mM potassium phosphate. Trolox and ascorbic acid was detected at 290 nm and 254 nm, respectively.

To analyse riboflavin in milk, 20 ml of 3% metaphosphoric acid in water was added to 10 ml milk to precipitate proteins. Milk samples were diluted with 50 ml deionised water and 1 ml was filtered with a 0.45 μm membrane filter into a vial. The riboflavin of milk was measured by reverse phase liquid chromatography using a High Pressure Liquid Chromatography system (HPLC, Agilent 1100, Agilent Technologies, Inc., Santa Clara, CA, USA) equipped with an Ultrasphere IP column (C-18, 5 μm 4.6 mm × 15 cm, Fullerton, CA, USA). The injection volume was 50 μl. The flow rate of the mobile phase, 10% acetonitrile in 4.0 mM aqueous octane sulphonate with 0.74% triethylamine at pH 4.09 (adjusted with 1% formic acid), was 0.8 ml/min. Riboflavin was measured by a fluorescence detector at an emission wavelength of 518 nm with an excitation at 366 nm.

2.5. Statistical analysis

All experiments were done in duplicate. Two-way analysis of variance and Tukey's test were used to analyse the effects of Trolox and ascorbic acid on the headspace oxygen content and riboflavin content using XLSTAT at $\alpha = 0.05$ (Microsoft 2007).

3. Results and discussion

3.1. Milk sample preparation

A preliminary work showed that microorganisms in milk depleted headspace oxygen in the sample bottle during storage under light. In the current study, the oxidation of milk during storage under light was studied by headspace oxygen determination in the sample bottle. To eliminate the depletion of headspace oxygen by microorganisms in milk, milk was sterilised. Riboflavin contents of milk with and without sterilisation were analysed and essentially the same.

3.2. Reproducibility of GC and HPLC analyses

The coefficients of variation for measuring headspace oxygen by GC and Trolox, ascorbic acid, and riboflavin content by HPLC for 5 replicates were 2.1, 1.7, 1.4, and 1.4%, respectively (data not shown). The low coefficients of variations were considered good to determine headspace oxygen by GC and Trolox, ascorbic acid, and riboflavin content in milk by HPLC.

3.3. Effect of riboflavin concentration on headspace oxygen of milk

The riboflavin content of milk measured by HPLC was 1.3 ppm. Milk added with 50 ppm riboflavin contained a total amount of 51.3 ppm riboflavin. Milk with 0 ppm riboflavin was prepared by passing milk through a Florisil column according to Jung et al.

Table 1
Effect of riboflavin on the headspace oxygen of milk during 3 days of storage under light and in dark at 27 °C.

Storage	Riboflavin (ppm)	Headspace oxygen (%)[a]			
		0 day	1 day	2 day	3 day
Light	0	20.9 ± 0.02	20.7 ± 0.03	20.6 ± 0.02	20.7 ± 0.04
	1.3	20.9 ± 0.02	18.2 ± 0.25	17.3 ± 0.26	15.9 ± 0.22
	51.3	20.9 ± 0.02	15.1 ± 0.24	13.0 ± 0.32	11.2 ± 0.35
Dark	0	20.9 ± 0.02	20.8 ± 0.04	20.7 ± 0.07	20.6 ± 0.04
	1.3	20.9 ± 0.02	20.9 ± 0.03	20.8 ± 0.09	20.7 ± 0.06
	51.3	20.9 ± 0.02	20.8 ± 0.03	20.8 ± 0.06	20.7 ± 0.03

[a] Values are the average of three measurements ± standard deviation.

(1998). The effects of 0, 1.3, and 51.3 ppm riboflavin on the headspace oxygen of milk under light and in dark for 3 days at 27 °C are shown in Table 1. Riboflavin had a significant effect on the depletion of headspace oxygen in milk under light ($p < 0.05$). The headspace oxygen of milk with 0, 1.3, and 51.3 ppm riboflavin under light for 1 day decreased from 20.9% to 20.7, 18.2, and 15.1%, respectively. The depletion of headspace oxygen in the airtight bottle was assumed to be a result of the reaction between oxygen and milk components. The headspace oxygen of milk with 0, 1.3, and 51.3 ppm riboflavin stored in dark were essentially the same, remaining at approximately 20.9% throughout storage. Riboflavin accelerated the depletion of headspace oxygen in milk under light but not in dark. Riboflavin in milk or soymilk increased the formation of volatiles and the depletion of headspace oxygen under light (Bradley et al., 2006; Huang et al., 2004a, 2004b; King & Min, 1998; Lee, 2002). Riboflavin-free milk did not produce volatiles during 8 h of storage under light (Jung et al., 1998).

Riboflavin increased the depletion of headspace oxygen in milk under light but not in dark (Table 1). It suggested that the type of oxygen in milk under light may not be the same type of the oxygen in milk in the dark. The chemical reaction of riboflavin under light is shown in Fig. 1. Ground state riboflavin having conjugated double bonds easily absorbs light and becomes excited singlet riboflavin (^{1}Riboflavin$*$). The excited singlet state riboflavin becomes excited triplet riboflavin (^{3}Riboflavin$*$) through intersystem crossing mechanism. The diradical excited triplet riboflavin reacts with diradical triplet oxygen to produce singlet oxygen by triplet–triplet annihilation (Huang et al., 2004b; Min & Boff, 2002). Singlet oxygen

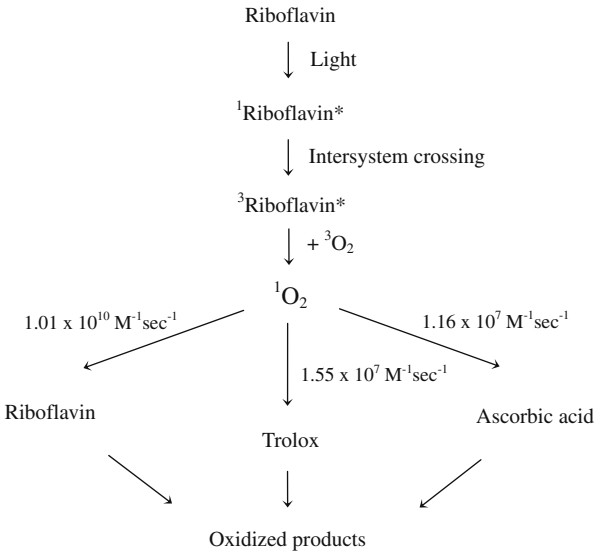

Fig. 1. Formation of singlet oxygen by riboflavin under light and the reaction rates of riboflavin, Trolox, and ascorbic acid with singlet oxygen in milk system.

is an electrophilic, very reactive, and high-energy molecule. Singlet oxygen quickly reacts with food components containing double bonds such as riboflavin, polyunsaturated lipids, aromatic amino acids, and vitamins. Singlet oxygen was detected in skim milk by electron spin resonance spectroscopy (Bradley et al., 2006), which showed singlet oxygen was formed in the presence of riboflavin and triplet oxygen under light. The headspace oxygen in milk did not deplete during storage in dark but rapidly depleted under light (Table 1). Singlet oxygen can not be formed in dark, even in the presence of riboflavin. Therefore, the headspace oxygen in milk under light decreased due to singlet oxygen which reacted with food components such as riboflavin, unsaturated lipids, aromatic or sulphur containing proteins, or vitamins in milk to form oxidised products (Jung et al., 1998; King & Min, 1998; Lee, 2002).

3.4. Effect of Trolox or ascorbic acid on headspace oxygen of milk without or with added 50 ppm riboflavin

The effects of 0, 100, 250, 500 and 1000 ppm Trolox on the headspace oxygen of milk without or with added 50 ppm riboflavin are shown in Fig. 2. As the concentration of Trolox increased from 0 to 100, 250, 500, and 1000 ppm, the depletion of headspace oxygen increased ($p < 0.05$). After 3 days of storage under light, the headspace oxygen of milk without added riboflavin with 0 ppm Trolox and 1000 ppm Trolox decreased from 20.9% to 15.9% and 11.1%, respectively (Fig. 2A). The addition of 1000 ppm Trolox nearly doubled headspace oxygen depletion in milk without added riboflavin. In the milk with added 50 ppm riboflavin, the addition of Trolox increased the rate of headspace oxygen depletion (Fig. 2B). The headspace oxygen of milk with added 50 ppm riboflavin containing 250, 500, and 1000 ppm Trolox were significantly lower than that of 0 ppm or 100 ppm Trolox ($p < 0.05$).

The effects of 0, 100, 250, 500 and 1000 ppm ascorbic acid on the headspace oxygen of milk without or with added 50 ppm riboflavin are shown in Fig. 3. As the concentration of ascorbic acid increased, the depletion of headspace oxygen increased. The headspace oxygen of milk without added 50 ppm riboflavin containing ascorbic acid were significantly lower than milk with 0 ppm ascorbic acid ($p < 0.05$). The headspace oxygen of milk with added 50 ppm riboflavin decreased more than those of milk without added riboflavin. The headspace oxygen content of milk with added 50 ppm riboflavin containing 500 and 1000 ppm ascorbic acid were significantly lower than those containing 100 and 250 ppm ascorbic acid ($p < 0.05$).

As the concentration of Trolox and ascorbic acid in milk increased, the headspace oxygen depletion increased. The higher depletion of headspace oxygen in milk containing Trolox and ascorbic acid might be due to the reaction between Trolox or ascorbic acid and oxygen in the sample vial during storage.

3.5. Effect of Trolox or ascorbic acid on riboflavin destruction of milk without or with added 50 ppm riboflavin

The effects of 0, 100, 250, 500 and 1000 ppm Trolox or ascorbic acid on the riboflavin content of milk without added 50 ppm riboflavin under light for 12 h are shown in Fig. 4. Milk initially contained 1.3 ppm riboflavin. Milk with 0 ppm Trolox lost 100% riboflavin for 9 h under light. Riboflavin in milk with 100, 250, 500 and 1000 ppm Trolox after 12 h of storage under light were 0, 0.07, 0.07, and 0.10 ppm, respectively (Fig. 4A). As the concentration of Trolox increased from 0 to 100, 250, 500, and 1000 ppm, the riboflavin destruction decreased ($p < 0.05$). Riboflavin in milk with 100, 250, 500 and 1000 ppm ascorbic acid after 12 h of storage under light were 0.06, 0.05, 0.09, and 0.27 ppm, respectively (Fig. 4B). Ascorbic acid protected more riboflavin than Trolox at the corresponding concentration.

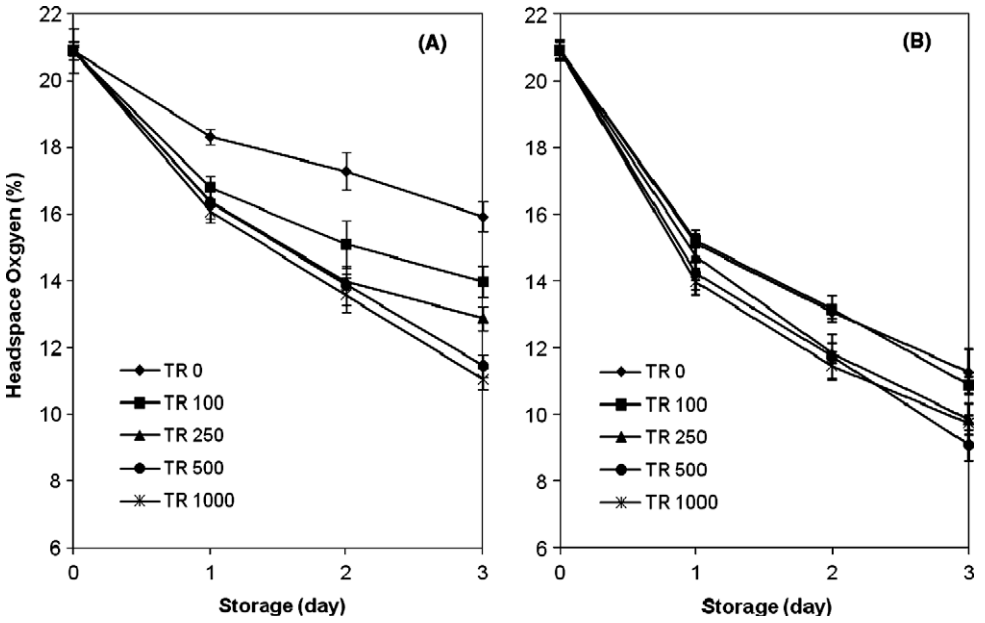

Fig. 2. Effects of 0, 100, 250, 500, and 1000 ppm Trolox on the headspace oxygen of milk without (A) and with (B) added 50 ppm riboflavin during the storage of 3 days under light at 27 °C (TR: Trolox).

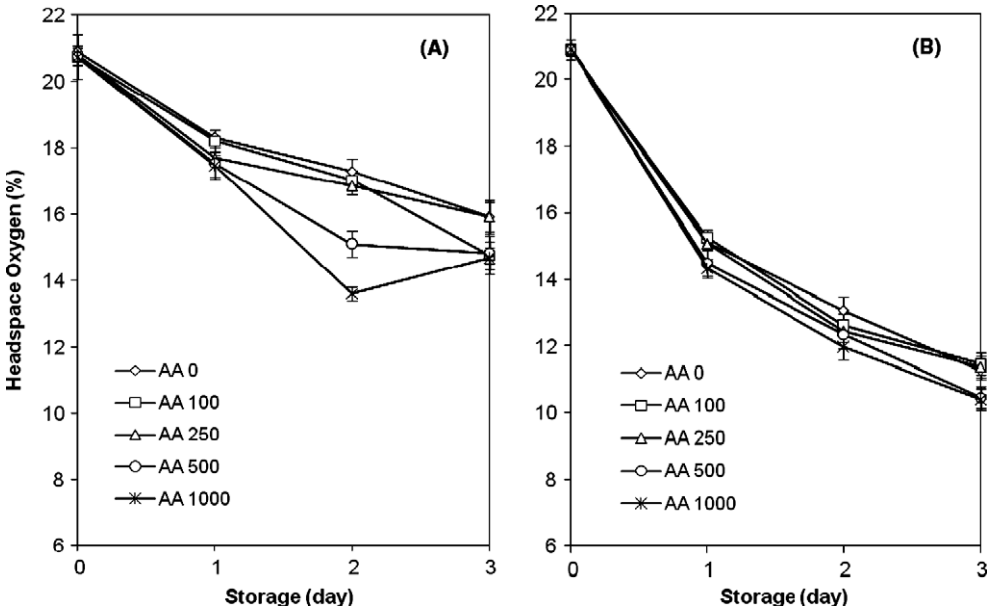

Fig. 3. Effects of 0, 100, 250, 500, and 1000 ppm ascorbic acid on the headspace oxygen of milk without (A) and with (B) added 50 ppm riboflavin during the storage of 3 days under light at 27 °C (AA: ascorbic acid).

The effects of 0, 100, 250, 500 and 1000 ppm Trolox or ascorbic acid on the riboflavin content of milk with added 50 ppm riboflavin under light for 12 h are shown in Fig. 5. Milk without Trolox or ascorbic acid lost 92% riboflavin after 12 h and 100% riboflavin after 24 h of storage under light. As the concentration of Trolox increased from 0 or 100 ppm to 250, 500, and 1000 ppm, the riboflavin destruction significantly decreased ($p < 0.05$) (Fig. 5A). After 24 h under light, milk with 1000 ppm Trolox contained 3.7 ppm riboflavin whilst riboflavin in milk without Trolox was completely lost. As the concentration of Trolox increased from 0 or 100 ppm to 250, 500, and 1000 ppm, the riboflavin destruction significantly decreased ($p < 0.05$) (Fig. 5B). Riboflavin in milk containing 1000 ppm ascorbic acid was 4.3 ppm after 24 h of storage under light. Ascorbic acid was effective at minimising riboflavin destruction in milk. The destruction of riboflavin in milk with 500 or 1000 ppm ascorbic acid was significantly slower than milk with 0, 100, or 250 ppm ascorbic acid ($p < 0.05$).

The concentrations of 1000 ppm Trolox or 1000 ppm ascorbic acid in milk with added 50 ppm riboflavin during storage under light are shown in Table 2. As the storage time increased from 0 to 24 h, Trolox and ascorbic acid in milk decreased from 1000 ppm to 333 and 285 ppm, respectively. Ascorbic acid decreased faster than Trolox during storage under light. The decrease of Trolox and ascorbic acid required both riboflavin and light during storage. The effects of singlet oxygen on the stability of ascorbic acid and tocopherol (Trolox is α-tocopherol derivative) have al-

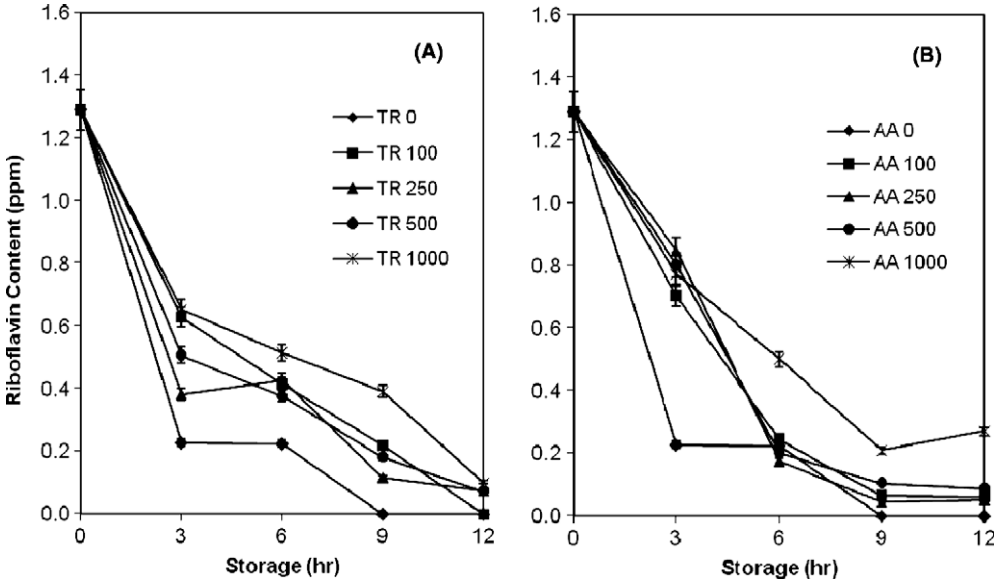

Fig. 4. Effects of 0, 100, 250, 500, and 1000 ppm Trolox (A) and ascorbic acid (B) on the riboflavin content of milk without added 50 ppm riboflavin during the storage of 12 h under light at 27 °C (TR: Trolox, AA: ascorbic acid).

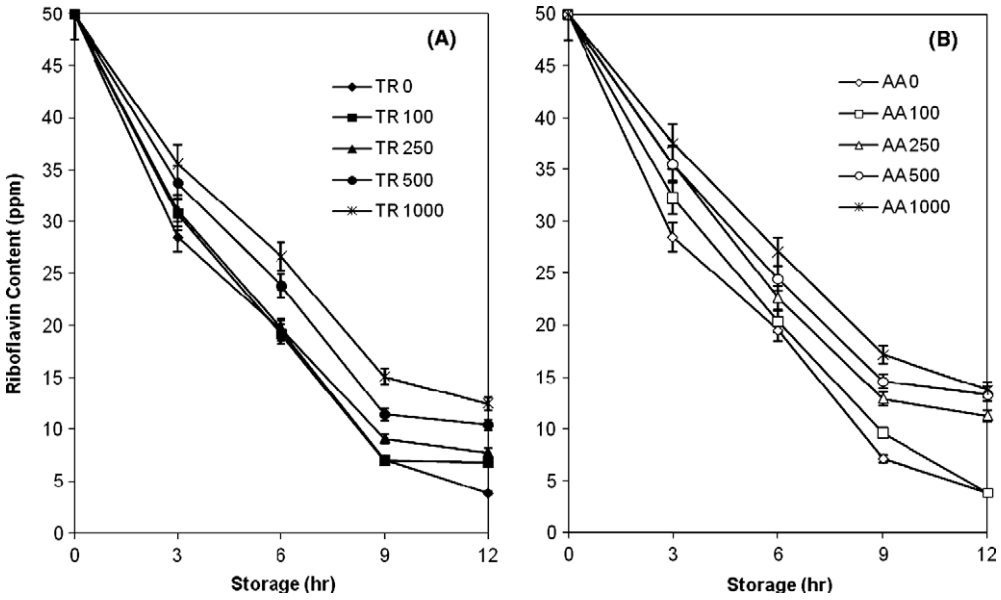

Fig. 5. Effects of 0, 100, 250, 500, and 1000 ppm Trolox (A) and ascorbic acid (B) on the riboflavin content of milk with added 50 ppm riboflavin during the storage of 12 h under light at 27 °C (TR: Trolox, AA: ascorbic acid).

ready been studied (Jung, Kim, & Kim, 1995; Jung et al., 1998; Kim, Lee, & Min, 2006). Ascorbic acid was completely destroyed after 12 min light exposure with 6 ppm riboflavin added, whereas only 2% was destroyed in the sample to which no riboflavin was added or stored in the dark (Jung et al., 1995). Kim et al. (2006) reported that the loss of tocopherols in the absence of a photosensitiser under light or in the presence of a photosensitiser in the dark was not detectable. Singlet oxygen formed in the presence of riboflavin under light reacted with Trolox and ascorbic acid in milk.

3.6. Reaction of riboflavin, Trolox, and ascorbic acid with singlet oxygen

Trolox is a polar antioxidant and locates itself in the water phase of milk (Huang, Hopia, Schwarz, Frankel, & German, 1996).

Table 2
Trolox and ascorbic acid concentration in milk with added 50 ppm riboflavin during storage under light.

Storage (h)	Trolox (ppm)	Ascorbic acid (ppm)
0	1000	1000
3	867 ± 13.56	792 ± 19.55

Trolox was reported to prevent protein oxidation effectively but lipid oxidation less effectively in chicken dispersions because it partitioned more into the water phase (Lin & Liang, 2002). The

effectiveness of an antioxidant is dependant on its location within a multiphase system, such as milk. The affinity of Trolox or ascorbic acid to the water phase and lipid phases of milk may determine its effectiveness as an antioxidant. Riboflavin is water-soluble and will locate itself in the water-phase of milk. The protection of riboflavin by Trolox may not be as efficient as the protection by ascorbic acid which could be more soluble in the water phase than Trolox. Partitioning studies on Trolox and ascorbic acid may explain why milk with Trolox lost more headspace oxygen and more riboflavin than milk with ascorbic acid.

Electrophilic singlet oxygen reacts with the double bond containing riboflavin, Trolox, and ascorbic acid (Fig. 1). Huang et al. (2004b) reported that the reaction rate between riboflavin and singlet oxygen in purified water was $1.01 \times 10^{10}\,M^{-1}\,s^{-1}$, which is a diffusion-controlled rate and explained the extremely fast degradation of riboflavin in foods under light. The reaction rates of Trolox and ascorbic acid with singlet oxygen in water were $1.55 \times 10^{7}\,M^{-1}\,s^{-1}$ and $1.16 \times 10^{7}\,M^{-1}\,s^{-1}$, respectively (Yettella & Min, 2008). Trolox and ascorbic acid could rapidly react with singlet oxygen. Riboflavin, Trolox, and ascorbic acid in milk will compete to react with singlet oxygen at different reaction rates.

Singlet oxygen in milk was formed in the presence of riboflavin and triplet oxygen under light. Trolox, ascorbic acid, and riboflavin in milk competed to react with singlet oxygen. As the concentration of Trolox and ascorbic acid in milk increased, the amount of singlet oxygen to react with riboflavin decreased. The more Trolox or ascorbic acid added to milk, the less singlet oxygen reacted with riboflavin. Trolox and ascorbic acid protected riboflavin in milk under light by reacting with singlet oxygen.

In conclusion, the concentration of riboflavin and the addition of Trolox or ascorbic acid affected the headspace oxygen depletion and riboflavin destruction of milk during storage under light. The depletion of headspace oxygen in milk could be attributed to the formation of singlet oxygen and the subsequent oxidation of food components in milk, including riboflavin, Trolox, and ascorbic acid. Trolox and ascorbic acid protected riboflavin in milk under light by reacting with singlet oxygen but did not completely protect it.

Bioactive compounds
Fatty acids
Antioxidant
Antiproliferative activities

ABSTRACT

The aim of this investigation was to compare the bioactive and nutrient compounds, fatty acids, and antioxidant and antiproliferative activities of Mon Thong durian at different stages of ripening. It was found that the total polyphenols, flavonoids, flavanols, ascorbic acid, tannins and the antioxidant activity determined by four assays (CUPRAC, DPPH, ABTS and FRAP) differed in immature, mature, ripe and overripe samples. The content of polyphenols and antioxidant activity were the highest in overripe durian, flavonoids were the highest in ripe durian, and flavanols and antiproliferative activity were the highest in mature durian ($p < 0.05$). FTIR spectra of polyphenols, HPLC profiles of fatty acids, the antioxidant and antiproliferative activities can be used as indicators to characterise different stages of durian ripening.

1. Introduction

Durian (*Durio zibethinus Murray*) is one of the most important seasonal fruits in tropical Asia. Durian cultivars are derived from *D. zibethinus Murray*, originating in the Malay Peninsula (Voon, Hamid, Rusul, Osman, & Quek, 2007). The importance of this fruit is mostly connected with its composition and antioxidant properties (Arancibia-Avila et al., 2008; Leontowicz et al., 2008; Toledo et al., 2008). It has been reported that durian has additional valuable health properties: polysaccharide gel, extracted from the fruit hulls, reacts on immune responses and is responsible for cholesterol reduction (Chansiripornchai, Chansiripornchai, & Pongsamart, 2008). The glycaemic index of durian was the lowest in comparison with papaya and pineapple (Daniel, Aziz, Than, & Thomas, 2008). The heath properties of durian are based not only on the antioxidant properties, but also on its fatty acid composition. Cholesterol hypothesis implied that reducing the intake of saturated fats and cholesterol while increasing that of polyunsaturated oils is effective in lowering serum cholesterol, and thereby in reducing coronary heart disease. The protective activity is linked with a high supply of $n-3$ fatty acids coming from fish and seafood, and high consumption of wholegrain products, as well as fruits and vegetables (Siondalski & Lysiak-Szydlowska, 2007). Durian is rich in $n-3$ fatty acids, compared to some other fruits (Phutdhawong, Kaewkong, & Buddhasukh, 2005).

Recently, it has been shown that individuals who eat daily five servings or more of fruits and vegetables have approximately half the risk of developing a wide variety of cancer types, particularly those of the gastrointestinal tract (Gescher, Pastorino, Plummer, & Manson, 1998). Therefore the antiproliferative activities of methanol extracts of Mon Thong durian at different stages of ripening on human cancer cell lines (Calu-6 for human pulmonary carcinoma and SNU-601 for human gastric carcinoma) were determined using MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay. As far as we know there are no published results of such investigations.

2. Materials and methods

2.1. Chemicals

6-Hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), 2,2-azino-bis(3-ethylbenzthiazoline-6-sulphonic acid) (ABTS), 1,1-diphenyl-2-picrylhydrazyl (DPPH), Folin–Ciocalteu reagent (FCR), lanthanum (III) chloride heptahydrate, $FeCl_3{\cdot}6H_2O$, $CuCl_2{\cdot}2H_2O$, 2,9-dimethyl-1,10-phenanthroline (neocuproine), ascorbic acid and butylated hydroxyanisole (BHA) were purchased from Sigma Chemical Co., St. Louis, MO. 2,4,6-Tripyridyl-*s*-triazine (TPTZ) was purchased from Fluka Chemie, Buchs, Switzerland. Individual fatty acids were purchased from Sigma–Aldrich (Steinheim, Germany). All solvents used as reaction media were of analytical grade and were obtained from POCh (Gliwice, Poland). Acetonitrile (ACN) and tetrahydrofuran (THF) used as mobile phases were of HPLC grade and were purchased from Merck (Darmstadt, Germany).

2.2. Samples and preparation

All durian samples were harvested in May, 2008, from a 25-year old Mon Thong commercial durian orchard, in Chantaburi province, eastern Thailand.

The maturity of the durian fruits was determined by combined techniques: day count, character of fruit spines, tapping the fruit, colour and shape of the fruit (Yaacob & Subhadrabandhu, 1995). The Mon Thong durian samples at various stages of ripening (1, immature; 2, mature; 3, ripe; 4, overripe) were chosen according to the following criteria:

1. Immature durian (80% maturity) was taken 5 days before the harvest.
2. Mature durian (100% maturity): harvested around 120–125 days after fruit set, using several methods and was prepared 1 day after harvest. Harvesting and determination of durian maturity was carried out by skilled workers. The mature samples were cut with peduncle intact and brought down carefully. The samples were left for 1 day and cut open to get mature durian flesh with firm texture and no smell.
3. Ripe durian: mature samples were left to soften (the stage that can be consumed), which normally takes 3–5 days till the flesh is losing contact with the thick shell.
4. Overripe durian: ripe durian after 3–5 days of ripening.

2.3. Fourier-transform infrared (FTIR) spectra of polyphenols

The presence of polyphenols (flavonoids and phenolic acids) in the investigated durian samples was studied by Fourier-transform infrared (FTIR) spectroscopy. A Bruker Optic GMBH Vector FTIR spectrometer (Bruker Optic GMBH, Attingen, Germany) was used to record IR spectra. A potassium bromide microdisk was prepared from finely ground lyophilised powder of 2 mg of durian sample with 100 mg of KBr (Edelmann & Lendl, 2002).

2.4. Determination of nutrients, polyphenols, flavonoids, flavanols, tannins and ascorbic acid

Elemental analysis, minerals and trace elements were determined as previously described (Poovarodom & Phanchindawan, 2006). The following solvents were used for extraction of bioactive compounds: sample/methanol, sample/water and sample/acetone as 25, 25 and 40 mg/ml, respectively, at room temperature for 2 h twice as previously described (Leontowicz et al., 2008, 2007). To determine the total amount of polyphenols in the studied extracts, Folin–Ciocalteu reagent (FCR) was used, and the measurement was performed at 765 nm with gallic acid as the standard. Results were expressed as mg of gallic acid equivalents (GAE). Flavonoids, extracted with 5% $NaNO_2$, 10% $AlCl_3{\cdot}6H_2O$ and 1 M NaOH, were measured at 510 nm. The total flavanols were estimated using the *p*-dimethylaminocinnamaldehyde (DMACA) method, and then the absorbance at 640 nm was read. The extracts of condensed tannins (procyanidins) with 4% methanol vanillin solution were measured at 500 nm. (+)-Catechin served as a standard for flavonoids, flavanols, and tannins, and the results were expressed as catechin equivalents (CE).

Total ascorbic acid was determined by CUPRAC assay (Ozyurek, Guclu, Bektasoglu, & Apak, 2007). The water extract was prepared from 100 mg of lyophilised sample and 5 ml of freshly prepared nitrogen-bubbled water, and stirred for 30 min at 4 °C and centrifuged. This extract (1 ml) was mixed with 2 ml of 3.0 mM lanthanum (III) chloride heptahydrate, also prepared with nitrogen-bubbled water. Ethyl acetate (EtAc) was used for extraction of flavonoids, in order to avoid interference. The remaining tannin in aqueous solution of fruit extracts after ethyl acetate treatment was checked.

Ascorbic acid was quantified in the aqueous phase. One millilitre of Cu (II)–neocuproine (Nc), in ammonium acetate-containing medium at pH 7, was added to 1 ml of the obtained extract. The absorbance of the formed bis-(Nc)–copper (I) chelate was measured at 450 nm (Ozyurek et al., 2007).

2.5. Determination of the antioxidant activity

The following four tests were applied:

1. Cupric reducing antioxidant capacity (CUPRAC) is based on utilising the copper (II)–neocuproine [Cu (II)–Nc] reagent as the chromogenic oxidising agent. To the mixture of 1 ml of Cu (II), Nc, and NH_4Ac buffer solution, extract of durian sample (or standard) solution (x ml) and H_2O [$(1.1 - x)$ ml] was added to make a final volume of 4.1 ml. The absorbance at 450 nm was recorded against a reagent blank (Apak, Guclu, Ozyurek, & Karademir, 2004).
2. 1,1-Diphenyl-2-picrylhydrazyl (DPPH) solution (3.9 ml, 25 mg/l) in methanol was mixed with the samples extracts (0.1 ml). The reaction progress was monitored at 515 nm until the absorbance was stable (Ozgen, Reese, Tulio, Scheerens, & Miller, 2006).
3. 2,2-Azino-bis(3-ethyl-benzothiazoline-6-sulphonic acid) diammonium salt ($ABTS^{\cdot+}$) was generated by the interaction of ABTS (7 mM) and $K_2S_2O_8$ (2.45 mM). This solution was diluted with methanol until the absorbance reached 0.7 at 734 nm (Ozgen et al., 2006).
4. Ferric-reducing/antioxidant power (FRAP) assay measures the ability of the antioxidants contained in the samples to reduce ferric-tripyridyltriazine (Fe^{3+}-TPTZ) to a ferrous form (Fe^{2+}), which absorbs light at 593 nm (Ozgen et al., 2006; Szeto, Tomlinson, & Benzie, 2002).

2.6. Fatty acids

2.6.1. Chromatographic procedure

2.6.1.1. Sample preparation. Lyophilised durian samples (~150 mg) were hydrolysed with 1 ml of 2 M KOH in MeOH:H_2O (1:1; v/v) at 80–85 °C for 1.5 h in PTFE linked screw-capped amber coloured tubes. After cooling, the hydrolysates were acidified with 4 M HCl (~0.5 ml) to pH ~2, and the free fatty acids were extracted twice with 1 ml of *n*-heptane. The upper organic layer was separated, dried with Na_2SO_4, and then heptane was removed under

a gentle stream of nitrogen at 40 °C. The residue was used for derivatisation (Czauderna & Kowalczyk, 2001).

2.6.1.2. Derivatisation procedure. Fatty acid standards (0.5–100 μg/ml) and fatty acids released by saponification from durian lipid extract were converted to fatty acid *p*-bromophenacyl ester, according to the modified method of Wood and Lee (1983) (Fig. 1). To the residue in a PTFE linked screw-capped amber coloured tube 200 μl of α-bromoacetophenone solution (10 mg/ml in acetone) and 200 μl of triethylamine solution (10 mg/ml in acetone) were added. The contents were ultrasonicated and heated for 30 min at 50 °C in an ultrasonic bath. The resulting solution was evaporated to dryness under a gentle stream of nitrogen at 40 °C. A 250 μl volume of acetonitrile:acetone (1:1; v/v) was added to the tube. The resulting solution was filtered and injected into the column. Analytes were dissolved in a mixture of acetonitrile:acetone (1:1; v/v) and 5 μl of the solution were injected onto the chromatographic column. A mixture of **A**, water and **B**, ACN + THF (99:1; v/v), was used as a mobile phase in gradient mode at flow rate of 2.0 ml min^{-1}. Gradient at 5 min was 80% **B**; at 8 min – 85% **B**; at 20 min – 98% **B**. The UV detector was operated at 258 nm (diode-array detector in single wavelength mode). All analyses were thermostatted at 40 °C. The concentrations of fatty acids in biological samples were calculated using fatty acid standards and an internal standard (hexadecanoic acid) as a measure of extraction yield. The limit of detection (LOD) was calculated as a signal-to-noise ratio of three, while the limit of quantification (LOQ) was defined as 10 times the noise level (Czauderna & Kowalczyk, 2001; Meyer, 1999; Wood & Lee, 1983).

2.6.1.3. Apparatus. Chromatographic analyses were performed using liquid chromatograph Series 1200 (Agilent Technology Inc., Santa Clara, CA) equipped with quaternary pump, autosampler, thermostatted column compartment and diode-array detector. Supelcosil LC-18 HPLC column (150 × 4.6 mm; particle size 3 μm) was obtained from Supelco (Bellefonte, PA).

2.7. Determination of the antiproliferative activity

The antiproliferative activities of 100% methanol extracts of four stages of durian ripening on human cancer cell lines (Calu-6 for human pulmonary carcinoma and SNU-601 for human gastric carcinoma) were measured using MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay. The cell lines were purchased from Korean Cell Line Bank (KCLB: Seoul, Korea). Cells were grown in RPMI-1640 medium at 37 °C under 5% CO_2 in a humidified incubator. Cells were harvested, counted (3×10^4 cells/ml), and transferred into a 96-well plate, and incubated for 24 h prior to the addition of methanol extracts of durian. Serial dilutions of the extracts were prepared by dissolving compounds in dimethyl sulfoxide (DMSO), followed by dilution with RPMI-1640 medium to give final concentrations at 125, 250, 500, 1000 and 2000 μg/ml. Stock solutions of samples were prepared for cell lines at 90 μl and samples at 10 μl, and incubated for 72 h. MTT solution at 5 mg/ml was dissolved in 1 ml of phosphate buffer solution (PBS), and 10 μl of it were added to each of the 96 wells. The wells were wrapped with aluminium foil and incubated at 37 °C for 4 h. The solution in each well containing media, unbound MTT and dead cells were removed by suction and 150 μl of DMSO were added to each well. The plates were then shaken and optical density was recorded using a microplate reader at 540 nm. Distilled water was used as positive control and DMSO as solvent control (Chon, Heo, Park, Kim, & Gorinstein, 2009). The effect of the durian extract on the proliferation of cancer and normal cells was expressed as relative cell survival rate:

$$\text{percent survival rate} = 100 \times (OD \text{ of durian extract treated sample}/OD \text{ of non-treated sample}),$$

where *OD* is optical density (Kim et al., 2006).

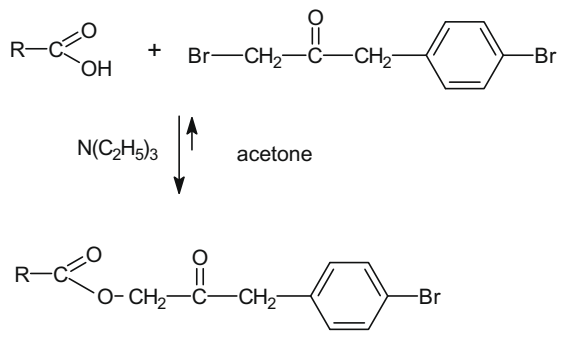

Fig. 1. Free fatty acids derivatisation reaction.

2.8. Statistical analyses

The results of this investigation *in vitro* are means ± SD of five measurements. Differences between groups were tested by two-way ANOVA. In the assessment of the antioxidant potential, Spearman correlation coefficient (*r*) was used. Linear regressions were also calculated; *p* values of <0.05 were considered significant.

3. Results

3.1. Bioactive compounds

The soil of the durian orchard was a sandy loam with pH 4.2, EC 224 μS/cm, organic matter 2.8%, available P (BrayII) 200 mg/kg, exchangeable (NH_4OAc) K, Ca and Mg, 156, 347 and 51 mg/kg, respectively; extractable (DTPA) Fe, Mn, and Zn, 17.7, 2.0 and 2.4 mg/kg, respectively. It was suggested that KCl could be used as an effective replacement for K_2SO_4 in this soil. These results were similar with our previous data (Poovarodom & Phanchindawan, 2006). According to the results summarised in Table 1, the contents of most nutrients were significantly higher ($p < 0.05$) in the immature samples (P, Ca, Mg, Fe, Cu, Zn and B). Durian samples at different stages of ripening are relatively rich in all nutrients.

The wavenumbers of FTIR spectra for catechin at 827, 1039, 1115, 1143, 1286, 1478, 1511 and 1610 cm^{-1} were assigned to

Table 1
Nutrient concentration in durian flesh at four different maturities (mg/kg DW).[A,B]

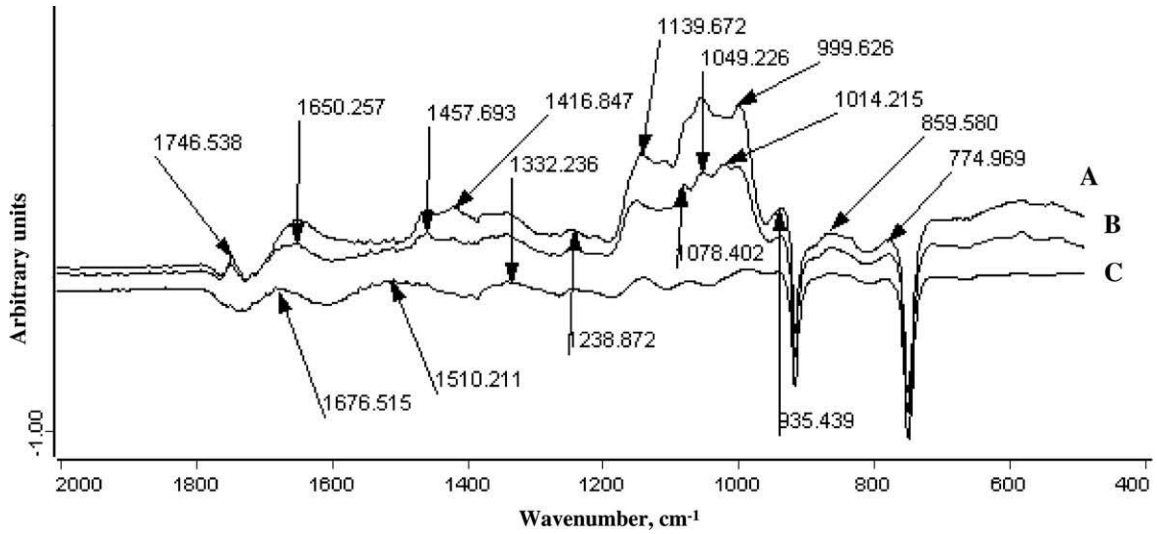

Fig. 2. FTIR spectra of ripe (C), mature (B) and overripe (A) durian samples.

C–H alkenes, –C–O alcohols, C–OH alcohols, –OH aromatic, C–O alcohols, C–H alkanes, C=C aromatic ring and C=C alkenes. Gallic acid showed the following wavenumbers (cm^{-1}) of 866, 1026, 1238, 1450, 1542 and 1618. Immature, mature, ripe and overripe durian samples in the region of polyphenols showed slightly different bands than the standards, but the wavenumbers of the bands were similar in this group (Fig. 2). The absorption bands at 1650, 1458, 1417 and 1014 cm^{-1} were absent in ripe durian, in comparison with the immature, mature and overripe samples. Oppositely, bands at 1677 and 1510 cm^{-1} were observed in ripe durian. Other bands in the durian samples were slightly shifted in comparison with the standards (Fig. 2).

3.2. Polyphenols, flavonoids, flavanols, tannins and ascorbic acid

Different solvents (water, acetone and methanol) showed variation in the amounts of the bioactive compounds. Methanol was the most effective solvent based on extraction yield. The amount of polyphenols (mg GAE/g) extracted from four durian samples with methanol, water and acetone was 12.3, 10.3 and 7.2, respectively (Tables 2 and 3). The contents (Table 2) of polyphenols in overripe durian, flavonoids in ripe durian, flavanols in mature durian, and tannins in mature and ripe durian were the highest in methanol extracts ($p < 0.05$). Polyphenols in acetone extracts were the highest in overripe samples (Table 2, $p < 0.05$). The contents of flavanols and ascorbic acid were the highest in overripe samples extracted with water (Table 3).

3.3. Antioxidant activity

The antioxidant activity of the methanol extract of overripe sample was the highest ($p < 0.05$), according to CUPRAC, DPPH, ABTS and FRAP tests. Acetone extract of immature sample by CUPRAC and ABTS (Table 4) showed the lowest value. The antioxidant activity of the water extracts (Table 5) was the highest in mature and ripe durian using ABTS test and in overripe durian using FRAP test samples ($p < 0.05$).

3.4. Fatty acids

The contents (Table 6) of capric acid was the highest in overripe durian, myristic and palmitic acids in overripe and ripe durian, oleic acid in ripe and linoleic acid in immature and mature samples ($p < 0.05$). The HPLC profiles (Fig. 3) revealed that the major unsaturated fatty acids were oleic and linoleic, while the main saturated was palmitic. Capric, myristic, stearic and arachidic acids were determined in the samples. Palmitic (16:0), oleic (18:1) and linoleic (18:2) acids were among the major fatty acids throughout the maturation and ripening of the fruits. The levels of these fatty acids were found to be significantly different ($p < 0.05$) between the four maturity stages. These results show that durian has moderate levels of fatty acids that significantly changed during maturation and ripening.

3.5. Antiproliferative activity

It was observed that the antiproliferative activities of the methanol extracts of immature, mature, ripe and overripe durian samples on two cell lines (Calu-6 for human pulmonary carcinoma and SNU-601 for human gastric carcinoma) were different (Fig. 4). The cell survival rate (%) for concentrations of 2000 μg/ml for mature durian on Calu-6 was 86.8 ± 1.5, and on SNU-601 was 88.5 ± 2.5%, showing the highest antiproliferative activity in comparison with other samples. Our investigation shows that antioxidant activity of the studied samples was not always correlated with their antiproliferative activity.

4. Discussion

Fruits and vegetables contain a variety of phytochemicals, including flavonoids, which have antioxidant and anticancer properties. The purpose of this study was to evaluate the bioactive and nutrient compounds, fatty acids, antioxidant activity and the antiproliferative effects of durian at different stages of ripening on human cell lines.

Our results in observation of FTIR polyphenol spectra were in accordance with others (Edelmann & Lendl, 2002; Sinelli, Spinardi, Di Egidio, Mignani, & Casiraghi, 2008). FTIR spectroscopy can be used as an additional tool to screen fruits for the content of phenolic compounds during their ripening.

Our results correspond with Harris and Brannan (2009), who reported that total phenolics were affected by ripeness, so the concentration of total phenolics in pawpaw pulp were in the order: underripe = ripe > overripe, while the concentration of flavonoids was in the order: ripe < underripe < overripe. Total phenolics were positive correlated with reducing and radical-scavenging potentials. These results indicate that pawpaw pulp of varying ripeness levels is a potential source of natural phenolic and flavonoid antioxidants that could lead to the development of value-added products from pawpaw. Durian, like pawpaw, can be used as a nutritional supplement to the everyday diet.

Our results were compared with Chaisuksant, Boonyuen, and Sunthornwat (2008), where immature green, mature green and orange ripe fruits of bullet wood (*Mimusops elengi*) were investigated. The methanol–acetone extracts were further separated into three different fractions designated as free phenolic acid (F1), soluble phenolic ester (F2) and insoluble phenolic acid ester (F3). The relative antioxidant capacities of extracts of immature and mature fruits, expressed as gallic acid equivalents, were F2 > F3 > F1 and of ripe fruit F2 = F3 > F1. The antioxidant capacity of crude methanol–acetone extract from immature fruit was higher than that of either the mature or the ripe fruit. Our results differ and showed that the antioxidant activity of overripe fruit was higher than the other samples.

The antioxidant activity of some fruits at different stages of ripening depends on the scavenging methods used for their determination (Lin, Wu, Tsai, Yang, & Chen, 2007). For example the oxygen-scavenging capacity of mature meifruit (*Prunus mume Seibu. et Zucc*) in water fraction was lower than that of Trolox. However, both oxygen- and hydroxyl-scavenging capacities of

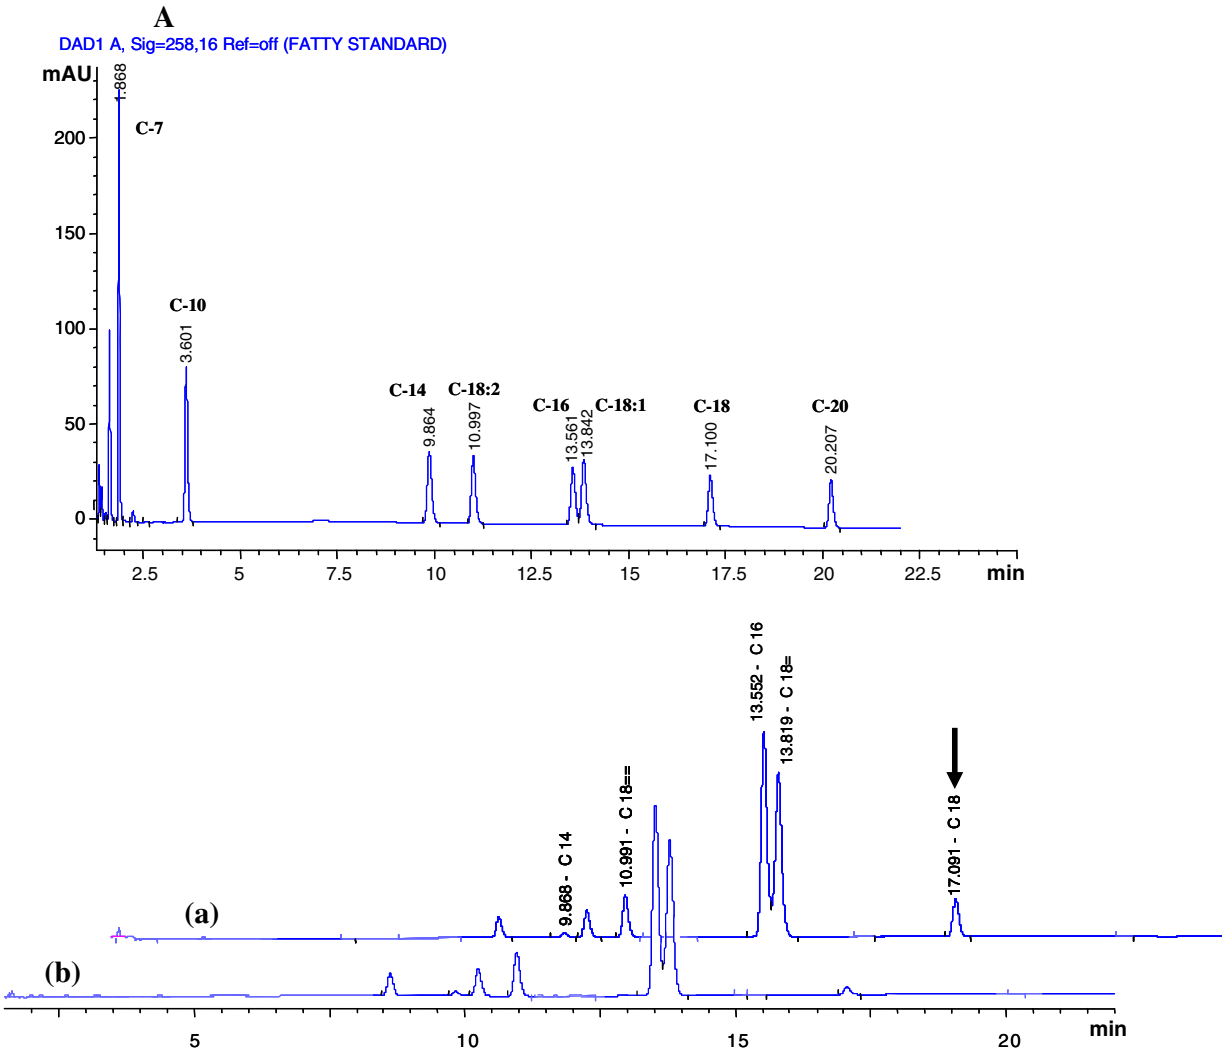

Fig. 3. (A) The typical chromatogram of fatty acids standard solution. Analytes: C-7, enanthic acid; C-10, capric acid; C-14, myristic acid; C-18:2, linoleic acid; C-16, palmitic acid; C-18:1, oleic acid; C-18, stearic acid; C-20, arachidic acid. (a) Chromatograms of derivatised mature durian hydrolysates spiked with C_{18} fatty acid; (b) not spiked.

immature fruit and hydroxyl-scavenging capacities of mature fruit showed no significant difference from Trolox. Similar results were obtained with the ABTS-scavenging method in durian samples of water extracts. The amount of polyphenols in this fruit was about 5 times higher than in overripe durian water extract (Table 3).

The change in the amount of polyphenols during ripening was reported also in three apricot cultivars (Dragovic-Uzelac, Levaj, Mrkic, Bursac, & Boras, 2007). The content of individual polyphenols during ripening was quite similar, whereas their amounts differed significantly. Immature fruits showed the highest level of polyphenols, which decreased at semi-mature fruits and did not change remarkably in mature fruits. The quantity of polyphenols during fruits ripening depends on cultivars, therefore this comparison would not give results similar to those for durian fruit.

The fatty acid composition in durian samples similar to other reports with some slight differences (Phutdhawong et al., 2005): the most prominent component was stearic acid Me ester (35.9%), then palmitic acid Me ester (32.9%), oleic acid Me ester (4.67%), myristic acid Me ester (2.5%) and linoleic acid Me ester (2.2%). Other authors found that during ripening the content of fatty acids increases significantly. Wissem, Baya, and Brahim (2008), reported that total fatty acid contents of *Myrtus communis* var. italica fruit varied from 0.8% to 3.1% during fruit maturation and the predominant fatty acids were linoleic (12.2–71.3%), palmitic (13.6–37.1%) and oleic (6.5–21.9%) acids. The linoleic acid proportions correlated inversely with palmitic and oleic acids during all the stages of ripening.

The content of fatty acids in durian was similar to the banana fruit. The most abundant fatty acids in the banana pulp (29–90% of the total amount of lipophilic extract), were linoleic, linolenic and oleic acids (Oliveira, Freire, Silvestre, & Cordeiro, 2008).

This information can be used by nutritionists and food technologists to improve the nutrition of local people and develop food products that would be beneficial to human health.

Epidemiological studies have consistently linked abundant consumption of fruits and vegetables to a reduction of the risk of developing several types of cancer. The methanolic fractions of different durian samples showed the highest antioxidant activity in comparison with the acetone and water extracts. The methanol fractions were selected for testing of their effect on cells. In most cases, however, the identification of specific fruits and vegetables that are responsible for these effects is still lacking, retarding the implementation of effective dietary-based chemopreventive approaches. Our previous investigations showed that the results of the antiproliferative effect of different plants of Korean salads were not consistent with the findings of DPPH radical-scavenging activ-

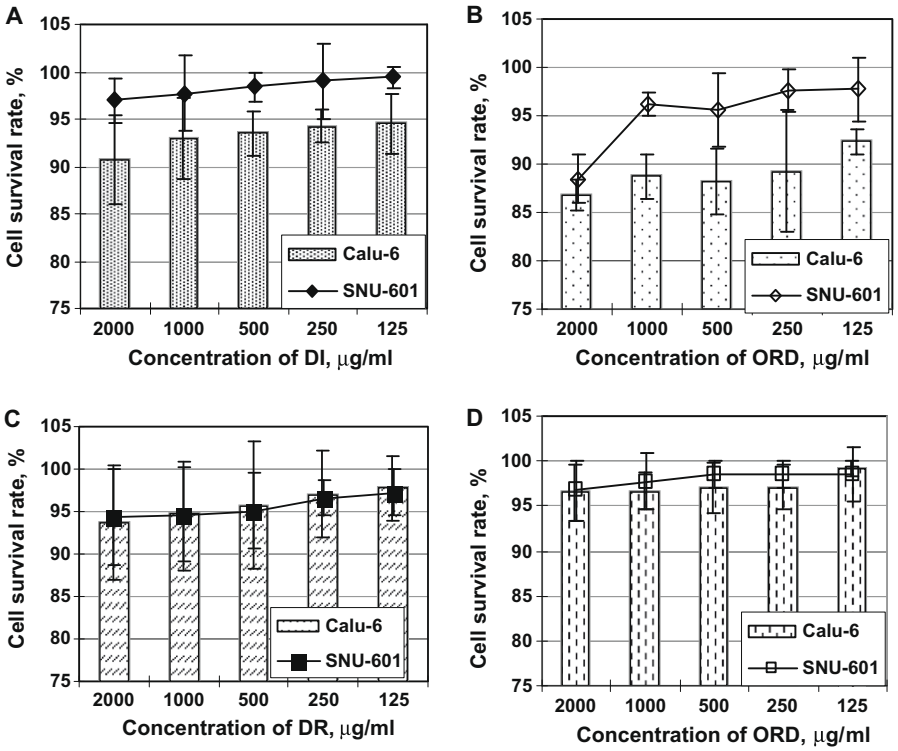

Fig. 4. Cytotoxic effect of methanol extracts from durian samples on human cancer cell lines Calu-6 (for human pulmonary carcinoma) and SNU-601 (for human gastric carcinoma): (A) DI, durian immature; (B) DM, durian mature; (C) DR, durian ripe; (D) ORD, overripe durian.

ity or total phenolic content (Chon et al., 2009). Mature durian sample showed the highest antiproliferative activity. This can be explained not only by relatively high antioxidant activity, but by the amount of flavonoids and other bioactive compounds. The results on cell proliferation can be explained as a synergistic effect of flavonoids, flavanols and ascorbic acid in mature durian. Our data correspond with others (Campbell, King, Harmston, Lila, & Erdman, 2006), that combinations of flavonoids, which are naturally present in whole fruits and vegetables, are more effective in cancer cell growth inhibition than the individual flavonoids. Durian can be used as a potential source of high-value phytochemicals with nutraceutical and functional food additive applications.

5. Conclusions

It was found that the contents of polyphenols, flavonoids, flavanols, ascorbic acid and tannins in Mon Thong durian cultivar in its different stages of ripening (immature, mature, ripe and overripe) and the antioxidant activity as determined by four complementary assays (CUPRAC, DPPH, ABTS and FRAP) was different. The content of flavonoids was the highest in ripe durian and flavanols in mature samples ($p < 0.05$). The antiproliferative activity of mature durian was the highest ($p < 0.05$).

Acknowledgements

Authors thank to Dr. Prof. Resat Apak (Analytical Chemistry Division, Faculty of Engineering, Istanbul University, Turkey) for sending us his data in spectrophotometric determination of ascorbic acid by the modified CUPRAC method with extractive separation of flavonoids–La (III) complexes as well as for making useful suggestions in this matter; to Dr. Elena Katrich (Hebrew University of Jerusalem, School of Pharmacy) for her technical assistance in determination of antioxidant activity. We also wish to thank the reviewer who made useful suggestions that hopefully improved the arguments and presentation of this paper.

Lipid peroxidation
LDL oxidation

ABSTRACT

Protective activities of components of *Mallotus japonicus* leaves, namely mallotinic acid, mallotusinic acid, corilagin, and geraniin, against oxidation of both intracellular and extracellular proteins including lipoproteins and lipids were evaluated. These four components dose-dependently protected bovine serum albumin (BSA) against protein degradation by ClO·, one of the reactive oxygen species (ROS) generated in the human body, in a manner similar to epigallocatechin gallate (EGCG), a strong antioxidant in green tea. Lipid peroxidation assay indicates they also inhibit lipid peroxidation suggesting they may protect elements of the human body against oxidation induced diseases. As a model element, low-density lipoprotein (LDL) was chosen and the anti-LDL oxidation activity of the four tannin components were evaluated. All four showed strong protective activity against LDL oxidation at levels greater than EGCG. These observations suggest that the leaves of the edible plant, *M. japonicus*, containing mallotinic acid, mallotusinic acid, corilagin, and geraniin, may be useful in controlling oxidative stress in the human body.

1. Introduction

ROS cause damage to intracellular and extracellular proteins, lipids, and nucleic acids (DNA and RNA), and play important roles in the development of tissue damage, various diseases, and the acceleration of the aging process (Ramarathnam, Osawa, Ochi, & Kawakishi, 1995). The potential of antioxidants for preventing oxidation in human tissue has therefore attracted much attention. It has been suggested that certain plant extracts or products such as green tea (Cabrera, Gimenez, & Lopez, 2003), and wine (Kanner, Frankel, Granit, German, & Kinsella, 1994), which contain phenolic components serve to control oxidation activity (Katsube et al., 2006; Kim & Lee, 2004) and reduce the risk of illness such as cardiovascular disease including atherogenesis (Katsube et al., 2004; Sanches-Moreno, Jimenez-Escrig, & Saura-Calixto, 2000). Notably, green tea exhibits strong antioxidative activity, and catechins such as EGCG, a principal component, have been isolated as the active components (Cabrera et al., 2003). Polyphenols such as catechins, are present in many edible plants and vegetables (Chen et al., 1998). Furthermore, EGCG was found to have strong antioxidative activity (Kim & Lee, 2004). As a result, EGCG is often used as a standard for assessing antioxidative activity.

We have previously reported the screening for antioxidants in edible plants, using low-density lipoprotein (LDL) oxidation, DPPH radical-scavenging, and Folin–Ciocalteu assays (Katsube et al., 2004). It was suggested that the combination of LDL oxidation assay and DPPH radical-scavenging assay is useful for assessing antioxidative potential in plants. A 70% ethanol extract of *Mallotus japonicus* leaf, a plant used in drugs and folk medicine, showed the strongest antioxidative activity among 52 edible plant extracts including extract of green tea. We have previously isolated and evaluated the radical-scavenging activity of antioxidants in *M. japonicus* leaves (Tabata et al., 2008). Certain phenolic components, including four tannins, namely mallotinic acid, mallotusinic acid, corilagin, and geraniin, were isolated and identified as the chemical components responsible for such activity in the *M. japonicus* leaves. We clarified that these four tannins have activity to scavenge radicals such as the DPPH, superoxide, and hydroxyl radicals. These radical-scavenging activities were much greater than those of gallic acid, rutin, quercetin, and chlorogenic acid, and were as strong as EGCG.

Since oxidative modification of protein and lipid peroxidation are important models, there are numerous reports describing the protective activity for proteins and lipids against oxidation stress (Nagasawa, Yonekura, Nishizawa, & Kitts, 2001; Srinivasan, Sabitha, & Shyamaladevi, 2007; Terashima, Nakatani, Harima, Nakamura, & Shiba, 2007). It has also been reported that tea extract and its components such as EGCG protect proteins and lipids (Aldini, Yeum, Carini, Krinsky, & Russell, 2003; Hodgson et al., 1999). We therefore

doi:10.1016/j.foodchem.2009.05.033

compared the protective activities of the four tannin components with those of EGCG. It is believed that oxidative modification of a component of human plasma, LDL, plays a key role in the pathogenesis of early artherosclerosis (Aviram, 1993; Steinberg, Parthasarathy, Carew, Khoo, & Witztum, 1989). Further studies suggest that antioxidants from plants protect LDL from oxidative modification *in vitro* (Hodgson et al., 1999) and decrease morbidity in heart disease (Enstrom, Kanim, & Klein, 1992; Rimm et al., 1993).

In the present study, we evaluated the protective activity of the *M. japonicus* leaf components, namely mallotinic acid, mallotusinic acid, corilagin, and geraniin, for proteins, lipids, and LDL against oxidative damage.

2. Materials and methods

2.1. Chemicals, reagents, and solvents

BSA was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). EGCG was obtained from SIGMA–ARDRICH CO. (St. Louis, USA). All other chemicals and solvents used were of analytical grade.

2.2. Extraction and isolation

The lyophilised samples of *M. japonicus* leaves in distilled water was boiled in a hot water bath. The supernatant was concentrated to dryness under reduced pressure, and the residue was used as the dried hot water extract (HWE). Mallotinic acid, mallotusinic acid, corilagin, and geraniin were isolated from *M. japonicus* leaves (Tabata et al., 2008). Each structural formula is shown in Fig. 1. The supernatant from the hot water extract was applied to an ODS-80Ts column (21.5 × 300 mm i.d.) (TOSOH Co.) using an AKTA purifier (Amersham Biosciences Co.), and eluted with a stepwise gradient of 0–50% acetonitrile containing 0.1% formic acid (0%: 218 ml, 15%: 218 ml, 30%: 648 ml, and 50%: 218 ml) at a flow rate of 5 ml/min and fractionated. Mallotinic acid, mallotusinic acid, corilagin, and geraniin were repeatedly applied to the same column, and eluted with 15% acetonitrile containing 0.1% formic acid until purified.

2.3. Analysis of protein protective activity

After the extracts were adequately diluted with distilled water, protein protective activity was determined. One hundred-fifty microliters of 3 mg/ml BSA in PBS, 5 μl of PBS, and 80 μl of each sample were pipetted into a microtube. Fifteen microliters of 83 mM sodium hypochlorite were added and incubated for 30 min at 37 °C. After denaturing with mercaptethanol, 8 μl of the solution were applied to 12.5% SDS–PAGE. Coomassie staining detection was carried out by Quick-CBB (Wako Pure Chemical Industries, Ltd., Osaka, Japan). The protein protective activities were calculated by densitometric analysis.

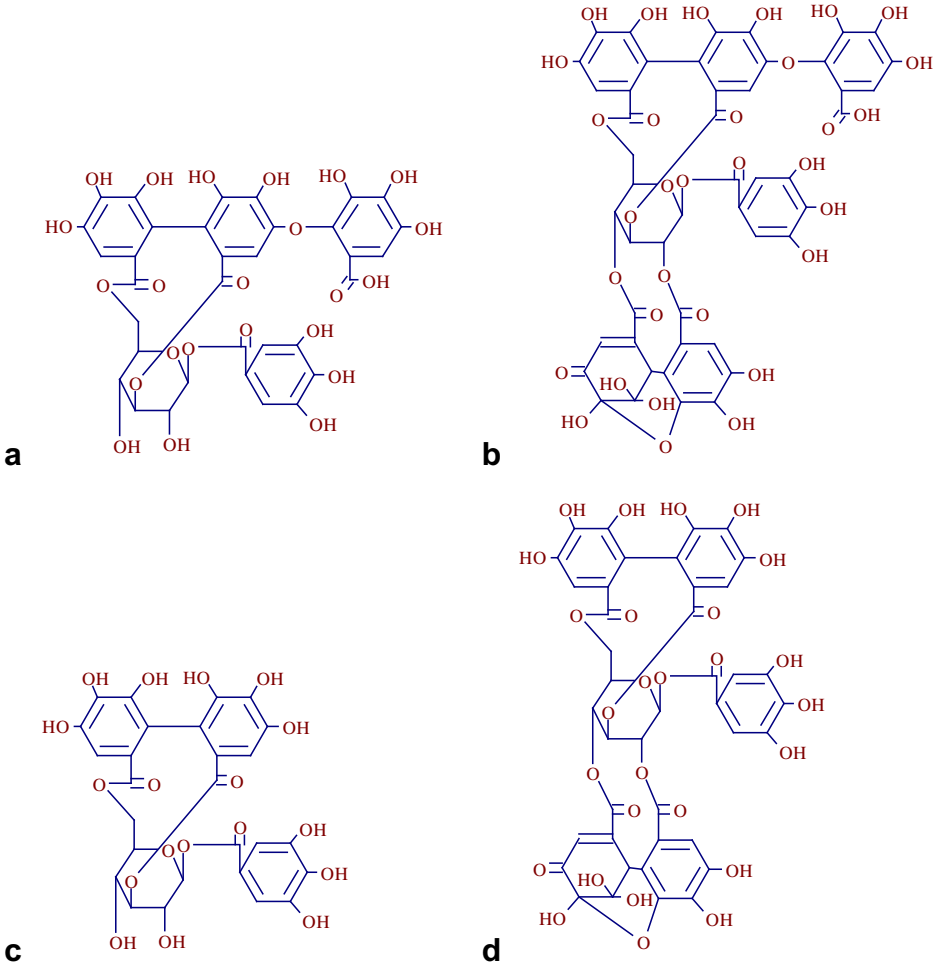

Fig. 1. Structural formulas of (a) mallotinic acid ($C_{34}H_{26}O_{23}$), (b) mallotusinic acid ($C_{48}H_{32}O_{32}$), (c) corilagin ($C_{27}H_{22}O_{18}$), and (d) geraniin ($C_{41}H_{28}O_{27}$).

2.4. Densitometric analysis

A densitometric assay was performed using a MultiImage Light Cabinet (Alpha Innotech Co., San Leandro, CA) controlled by Alpha-Imager software.

2.5. Lipid peroxidation assay

A modified thiobarbituric acid-reactive species (TBARS) assay (Banerjee, Dasgupta, & De, 2005) was used to measure the lipid peroxide formed, using egg yolk as lipid-rich media.

One hundred microliters of egg yolk homogenate (10% v/v) and sample were added to a test tube and filled up to 190 μl with distilled water. Ten microliters of $FeSO_4$ (0.01 M) were added to induce lipid peroxidation and incubated at 37 °C for 30 min. Then 300 μl of 20% acetic acid (pH adjusted to 3.5 with NaOH), 300 μl of 0.8% (w/v) TBA in 1.1% sodium dodecyl sulfate, and 10 μl of 20% TCA were added and the mixture was vortexed and heated in a boiling water bath for 60 min. After cooling, 1 ml of butan-1-ol was added to each tube and centrifuged at 3000 rpm for 10 min. As the blank, 10 μl of $FeSO_4$ were added after incubation. The absorbance of the upper layer was measured at 540 nm using a Multilabel Counter (PerkinElmer, Inc., Wellesley, MA). Inhibition of lipid peroxidation (%) by the sample was calculated according to $(1\text{-}(E - E_b)/(C - C_b)) \times 100$ where E is A_{540} of the sample, E_b is A_{540} of the sample blank, C is A_{540} of the fully oxidised control (distilled water), and C_b is A_{540} of the control blank.

2.6. Lipoprotein separation

Venous blood was obtained from fasting, healthy adult human volunteers into a tube containing ethylenediamine-N,N,N′,N′-tetra-acetic acid (EDTA). LDL was isolated from freshly separated plasma, to which butylhydroxytoluene had been previously added as an antioxidant, by preparative ultracentrifugation according to described technique (Rodriguez-Sureda, Julve, Llobera, & Peinado-Onsurbe, 2002). Isolated LDL was subdivided and stored at −80 °C and used within a 2-month period. LDL was concentrated and desalted using a Centricon-3 (Amicon, Inc., Beverly, MA). Protein concentration in LDL was determined using a Protein Assay Rapid kit (Wako Pure Chemical Industries, Ltd., Osaka, Japan).

2.7. LDL oxidation assay

LDL oxidation assay was carried out (Katsube et al., 2004). After preincubation with water-diluted sample solution for 5 min, reaction was initiated by adding 5 μM $CuSO_4$ to a 20 μg/ml LDL mixture in phosphate-buffered saline (pH 7.4) at 37 °C. Formation of conjugated dienes was monitored continuously at 234 nm for 7 h using a spectrophotometer (Shimadzu UV-1700, Tokyo, Japan) equipped with a 16-position automated sample changer.

Oxidation kinetics were analysed on the basis of oxidation lag time, defined as the interval between initiation of oxidation and the intercept of the tangent for the slope of the absorbance curve during the propagation phase. Antioxidant activity was calculated as EGCG equivalent.

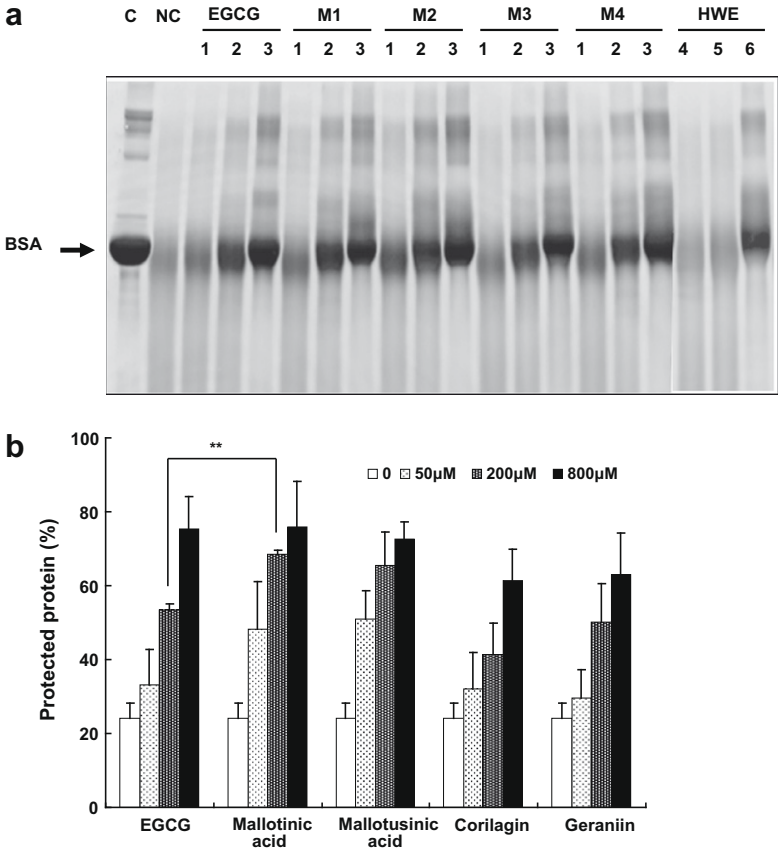

Fig. 2. Protective activity of HWE and four components of *M. japonicus* leaf against degradation of BSA by $ClO^{\cdot}$. (a) Coomassie staining after SDS–PAGE of: C; non-treated with $ClO^{\cdot}$ (control), NC; without antioxidant (negative control), M1; Mallotinic acid, M2; Mallotusinic acid, M3; Corilagin, M4; Geraniin, 1; 50 μM, 2; 200 μM, 3; 800 μM, 4; 40 μg/ml, 5; 160 μg/ml, 6; 640 μg/ml. (b) The result of densitometric analysis. $^{**}p < 0.01$ vs. EGCG.

2.8. Statistical analysis

Data was subjected to analysis of variance using *T*-test to evaluate the significance difference among samples and standards.

3. Results

3.1. Protective activity against degradation of BSA by ClO·

The protective activity against degradation of BSA by ClO·, of HWE and components, mallotinic acid, mallotusinic acid, corilagin, and geraniin is shown in Fig. 2. Coomassie staining after SDS–PAGE clearly shows the protective activity against protein degradation (Fig. 2a). The BSA band was detected in the non ClO·-treated sample (control). While the BSA band almost disappeared in the sample treated with ClO· in the absence of antioxidative material (negative control), the BSA band was retained in the antioxidative material-added samples (EGCG, HWE, and four components). As a result of the densitometric scanning of the SDS–PAGE gel (Fig. 2b), it was shown that all tannin components as well as EGCG dose-dependently protected BSA from degradation. The relative intensity of the negative control sample was 24% (vs. control), and the intensity increased as the concentration of the added antioxidant increased. At 200 μM, the order in terms of protein protective activity was as follows: mallotinic acid > mallotusinic acid > EGCG > geraniin > corilagin; however, statistic analysis suggests that there was no significant difference between each component and EGCG except for mallotinic acid. There were no significant differences at 50 and 800 μM.

3.2. Protective activity against lipid peroxidation

When the lipids in the egg yolk were peroxidated by Fe^{2+}, the absorbance of the reaction mixture containing TBARS at 595 nm increased. The protective activity against lipid peroxidation was evaluated by calculating the ratio of blank mixture and materials-treated mixture. HWE dose-dependently inhibited lipid peroxidation, and the inhibitory effect was evident even at a concentration of 0.03 mg/ml (Fig. 3a). All tannin components, and EGCG, also dose-dependently inhibited lipid peroxidation (Fig. 3b). The levels of inhibitory activity were almost the same at concentrations from 30 to 300 μM, and there were no significant differences between each component and EGCG. Only at the concentrations of 10 μM, corilagin and mallotusinic acid showed significantly weaker activity than that of EGCG. All materials inhibited lipid peroxidation more than 60% at 100 μM and more than 80% at 300 μM.

3.3. Protective activity against LDL oxidation

Protective activity of components, mallotinic acid, mallotusinic acid, corilagin, and geraniin were assessed using Cu^{2+}-induced LDL oxidation. When LDL oxidation was induced by Cu^{2+}, the absorbance at 234 nm increased. Changes in lag time of LDL oxidative modification were observed following the addition of various concentrations of EGCG, HWE, and the four components. As shown in Fig. 4, lag time without EGCG was about 38 min and increased dose-dependently with the addition of EGCG. Similar results were observed when each of HWE and the four components were added (data not shown). The lag time plots of EGCG and four components were straight lines from 0 to 0.4 μM and that of HWE were from 0 to 0.75 μg/ml, and each correlation coefficient was greater than 0.99 (Fig. 5). LDL protective activity was calculated using the ratio of the slope, and the results are summarised in Table 1. HWE showed LDL protective activity and the value was 0.32 mg EGCG equivalent/mg. All the four components showed higher anti-LDL oxidation activity than that of EGCG, and Mallotusinic acid showed the highest activity. As compared with EGCG, the relative protective activity ranged from 128% (corilagin) to 192% (mallotusinic acid).

4. Discussion

Our previous systematic screening for antioxidative activity in edible plants using LDL oxidation assays, DPPH radical-scavenging assays, and Folin–Ciocalteu assays revealed that the *M. japonicus* leaf extract exhibited the strongest activity among 52 edible plant extracts (Katsube et al., 2004). In a more recent study, we reported that the active compounds in *M. japonicus* leaf had been isolated

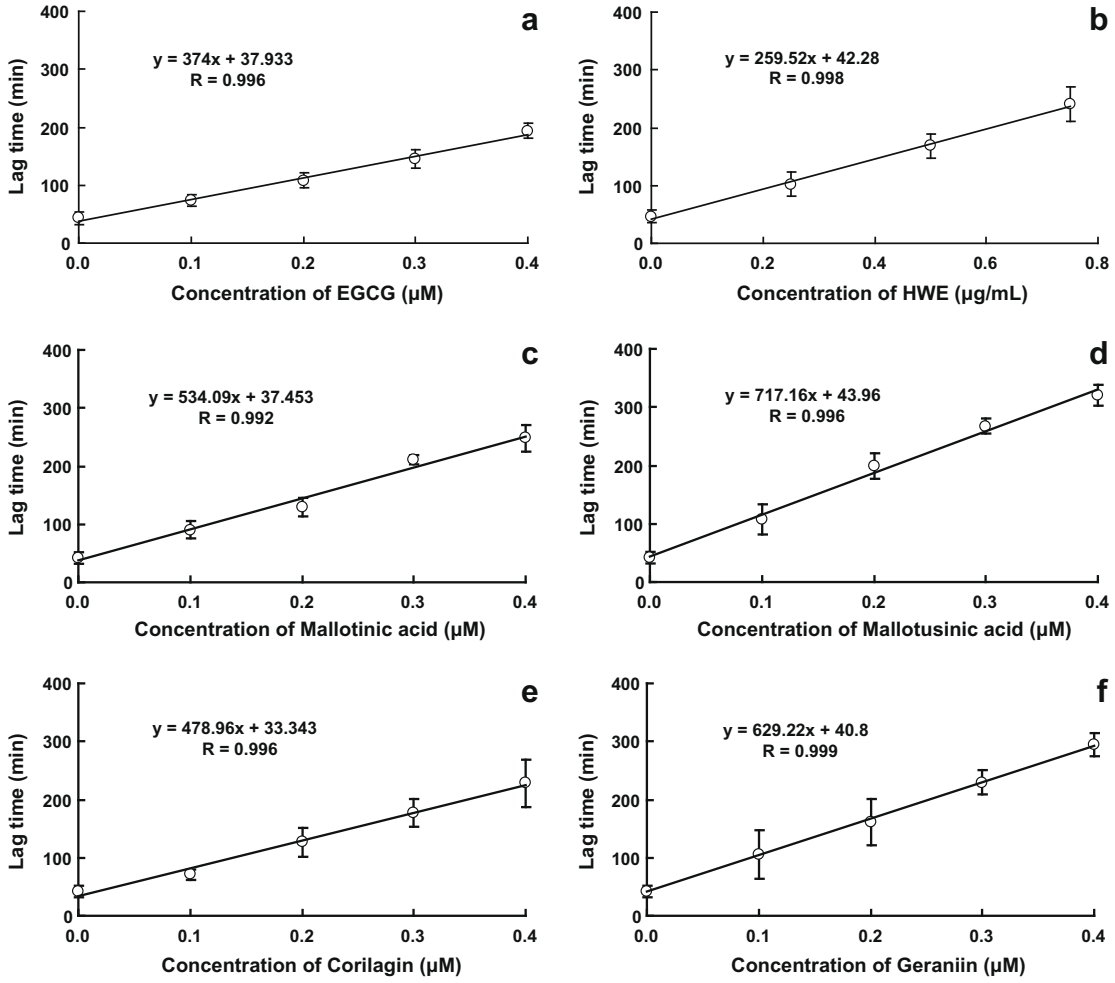

Fig. 5. Protective activity of four components of *M. japonicus* leaf against LDL oxidation. (a) EGCG, (b) HWE, (c) Mallotinic acid, (d) Mallotusinic acid, (e) Corilagin, and (f) Geraniin.

Table 1
Summary of protective activity against LDL oxidation.

	Slop	Relative activity (%)	Relative activity (mg EGCG eq./mg)
EGCG	374	100	
Mallotinic acid	534	143	
Mallotusinic acid	717	192	
Corilagin	479	128	
Geraniin	629	168	
HWE	260		0.32

and identified, and four of them, mallotinic acid, mallotusinic acid, corilagin and geraniin, exhibited strong radical-scavenging activity (Tabata et al., 2008). In the present study, we attempted to evaluate the protective activity of these four *M. japonicus* leaf components against oxidation of intracellular and extracellular protein and lipid, and plasma LDL.

We first evaluated the protective activity against degradation of protein, BSA by $ClO^{\cdot}$.

$ClO^{\cdot}$ is generated from H_2O_2 by myeloperoxidase (MPO) produced by activated neutrophils. The MPO system of activated phagocytes is central to the normal host defense mechanism, and dysregulated MPO contributes to the pathogenesis of inflammatory disease states ranging from atherosclerosis to cancer. It has been suggested that materials exhibiting protective activity for proteins against oxidative stress-induced modification may be useful in controlling diseases and aging generally (Hipkiss, Worthington, Himsworth, & Herwig, 1998). HWE and the four antioxidative components in *M. japonicus* leaf all protected BSA from oxidative modification. The components, as well as EGCG, exhibited significant protective activity at 200 μM, and 60–75% of BSA was protected at 800 μM (Fig. 2a). The fact that HWE, the four tannin components, and EGCG showed similar activity to protect against oxidative modification of proteins indicated that the four tannin components are active compounds in HWE for protecting protein against ROS.

Lipid peroxidation is a free-radical mediated process and damages cells (Upasani, Khera, & Balaraman, 2001). It has been shown that EGCG exhibits protective activity against lipid peroxidation (Chen & Ho, 1995). Therefore, we next evaluated the ability of HWE and four *M. japonicus* leaf components to protect against lipid peroxidation. Although the protective activity of EGCG against lipid peroxidation was stronger than that of mallotusinic acid and corilagin at 10 μM, the activity of all the four tannin components were comparable to EGCG (Fig. 2). We suggest that they have the potential to protect lipids in the body.

LDL oxidation is one aspect of the process of atherogenesis. Since the *M. japonicus* leaf antioxidative components showed potential for protective activity for proteins and lipids, we evaluated protective activity for LDL against oxidative modification by Cu^{2+}. All of EGCG, HWE, and the *M. japonicus* leaf antioxidative components showed dose-dependent activity (Fig. 5). The activity of four

components was greater than that of EGCG; particularly, that of mallotusinic acid was 1.92 fold stronger than EGCG (Table 1). As shown in Fig. 1, the number of the hydroxyl substitutions of the four components are larger than 10 and larger than that of EGCG. Since the hydroxyl substitutions play an important role in antioxidative activity, the level of antioxidative activity appeared related to the number of them, and we previously reported a similar trait on radical-scavenging activity (Tabata et al., 2008). It has also been noted that methylated derivatives of catechines have a lower protective activity against lipid oxidation than their corresponding precursors (Su et al., 2004). Since the physiological concentration of phenolic compounds is less than a few μM, our results suggest that the *M. japonicus* leaf antioxidative component of mallotinic acid, mallotusinic acid, corilagin, and geraniin can protect intracellular and extracellular components against oxidative stress under the physiological conditions.

In the present study, we suggest that four components of the *M. japonicus* leaf provide protective activity in the human body against oxidative stress and various related diseases. As the major phenolic components of the *M. japonicus* leaf are mallotusinic acid (2.3% of flesh leaf weight) and geraniin (1.2% of flesh leaf weight), their relative content (% of total) being 50.9% and 28.2%, respectively (Tabata et al., 2008), they show the greatest potential for such purposes. As the *M. japonicus* leaf is edible and contains potent antioxidative components, it may prove to be a natural functional food.

Total flavonoid contents

ABSTRACT

The antioxidant potentials of buntan pumelo (*Citrus grandis* Osbeck) and its fermented products were determined. The essential oil from peel had higher total phenolic (214 mM) and flavonoid (134 mg QE/g of dried material) contents than those of different solvent extracts from fruit pulp. In addition, DPPH free radical-scavenging activity and ferric-reducing antioxidant power values determined for the essential oil were 26.1 ± 1.2% and 2.3 ± 0.3 mM, respectively, which were significantly higher than those of various fruit pulp extracts. The ethanol-fermented products of pumelo juice had higher total phenolic and flavonoid contents than those of fresh juice. For maintenance of the substantial antioxidant properties of pumelo products, ethanol-fermented juice rather than fresh or acetate-fermented juice is recommended. Through correlation analysis, the phenolic compounds in the fermented pumelo products were found to be the major contributors to the free radical-scavenging activity and ferric-reducing power.

1. Introduction

Many researchers have reported that high consumption of fruits and vegetables is associated with a lowered incidence of degenerative diseases, including cancer, heart disease, inflammation, arthritis, immune system decline, brain dysfunction and cataracts (Di Matteo & Esposito, 2003; Gerber et al., 2002; Kris-Etherton et al., 2002). In the past decade, the essential oils and various extracts of fruits have been screened for their potential uses as alternative remedies for the treatment of many infectious diseases and the preservation of foods from the toxic effects of oxidants (Lis-Balchin & Deans, 1997).

The protective action of citrus fruits has been attributed to the presence of antioxidants, especially polyphenolic compounds, such as tannins and anthocyanins, and antioxidant vitamins, including ascorbic acid, tocopherol and β-carotene (Saskia et al., 1996; Soong & Barlow, 2004; Wang, Cao, & Prior, 1997). Citrus plants are also rich in naturally-occurring flavonoids, which are primarily found in peel. Flavonoids have a wide range of biological activities, such as cell-proliferation-inhibiting, apoptosis-inducing, enzyme-inhibiting, antibacterial, and antioxidant effects (Cao, Sofic, & Prior, 1997; Havsteen, 2002). Moreover, flavonoids possess various clinical properties, such as anti-atherosclerotic, anti-inflammatory, anti-tumour, anti-thrombogenic, anti-osteoporotic, and antiviral effects (Havsteen, 2002; Hertog, Feskens, Hollman, Katan, & Kromhout, 1993).

The Chinese fruit, *Citrus grandis* Osbeck is also known as buntan pumelo. Buntan pumelo is a fruit indigenous to tropical regions of Asia, which contains an array of biologically active phytochemicals. Buntan pumelo is also a traditionally popular fruit consumed at the Mid-Autumn Festival in Taiwan. Fruits of pumelo are rich in vitamin C and dietary fibre, which can reduce the risk of cardiovascular disease, similar to the effect of other citrus fruits. Although some researchers have investigated the antioxidant capacity of the buntan pumelo, few studies have focused on the stability of its antioxidant compounds. The results of Mokbel and Suganuma (2006) revealed that 100% and 80% methanol extracts of buntan fruits albedo contained groups of compounds including sitosterol, limonoids, fatty acids, coumarins, furanocoumarins, etc. Mokbel and Hashinaga (2006) evaluated the antioxidant activity of buntan using various solvents. Their work indicated that ethyl acetate extracts of flavedo and albedo from buntan fruits showed a high DPPH free radical-scavenging effect. However, they did not reveal the principal compounds related to these antioxidant activities.

Research has indicated that the antioxidant activities of fruits or vegetables could be affected by fermentation (Su & Chien, 2007; Yang, Paulino, Janke-Stedronsky, & Abawi, 2007). For maintenance of the substantial antioxidant properties of fermented products, determination of the principal antioxidant components is vital.

The antioxidant properties of various solvent extracts from buntan pumelo have been reported (Mokbel & Hashinaga, 2006). However, the principal components contributing to antioxidant

doi:10.1016/j.foodchem.2009.05.020

capacity need to be determined. In order to evaluate its potential use as an antioxidant in food, the antioxidant capacity of buntan pumelo cultivated in Taiwan was determined. The objectives of this study were: (1), to compare the antioxidant (phenolic and flavonoid) content and antioxidant activity of different extracts of the peel and pulp of buntan pumelo, (2), to compare the same for pumelo juice and its ethanol and acetate-fermented products, and (3), to correlate the antioxidant load with the antioxidant activity of the extracts.

2. Materials and methods

2.1. Sample preparation and chemicals

Buntan pumelo (*C. grandis* Osbeck) fruit was purchased in Yunlin County, Taiwan. The pumelo fruits were peeled and dried at 45 °C for 7 days. The fruit pulps were cut into small pieces (about 1 cm^3), freeze-dried at –20 °C, and then pulverised into fine powder. The peels of pumelo were cleaned, and also cut into small pieces. All of the samples, including dried fruit pulp powder and peels, were then stored in pill vials at room temperature until further use. Ethanol, methanol, acetone, and ethyl acetate were purchased from Fisher Scientific, Loughborough, UK.

2.2. Extraction of fruit material

The dried pumelo pulp powder was treated using distilled water, acetone, ethyl acetate, ethanol and methanol, respectively. Two grams of the dried fruit pulp powder were extracted 3 times using 20 ml of each solvent at 37 °C; 24 h for each extraction. The extracts were dried using a rotary evaporator at 40 °C for further analysis. The extracts were then diluted with each solvent. The peel part was squeezed with a juice squeezer to obtain the essential oil.

2.3. Preparation of fermented products from buntan fruit

Saccharomyces sp. SH 26 was inoculated in a sugar solution (13 °Brix). *Acetobacter* sp. was cultivated in a nutrient broth at 37 °C. One hundred grams of pumelo fruit pulp, obtained as described above, were homogenised with 400 ml distilled water in a juicer. The pumelo juice was obtained after filtration through gauze. The sugar content of the juice filtrate was adjusted with sucrose to 13 °Brix using a digital refractometer. The diluted citrus solution was inoculated with a 5% (v/v), 48-h-old yeast solution and fermented at 25 °C until the concentration of ethanol reached 10%. A portion of the ethanol solution was inoculated with a 5% (v/v), 48-h-old *Acetobacter* solution and statically incubated at 37 °C for 14 days until reaching 2.7% acidity. Total phenolic content and total flavonoid content of the ethanol-fermented products (EFP) and the acetate-fermented products (AFP) were determined as described in the following sections. Antioxidant activities of the ethanol or acetate-fermented products were then determined using DPPH radical-scavenging and ferric-reducing antioxidant power (FRAP) assays.

2.4. Determination total phenolics content

The Folin–Ciocalteu reagent assay was used to determine the total phenolics content (Su & Silva, 2006). The fruit pulp extracts or essential oil (0.5 ml) was mixed with 0.5 ml Folin–Ciocalteu reagent previously diluted with 7 ml deionised water. The solution was allowed to stand for 3 min at 25 °C before adding 0.2 ml of saturated sodium carbonate solution. The mixed solution was diluted to 10 ml with deionised water and allowed to stand for another 120 min before the absorbance at 725 nm was measured. Gallic acid was used as standard for the calibration curve. The total phenolic content was expressed as mmol gallic acid equivalents (GAE) per litre of sample (mM).

2.5. Determination total flavonoid content

The total flavonoid contents were determined according to the aluminium chloride colorimetric method described by Chang, Yang, Wen, and Chern (2002). Briefly, aliquots of 0.1 ml of fruit pulp extracts or essential oil were dissolved and mixed with 0.9 ml of 95% alcohol, 0.1 ml of 10% aluminium chloride hexahydrate, 0.1 ml of 1 M potassium acetate, 4.3 ml of 80% ethanol and 2.8 ml of deionised water. After incubation at room temperature for 40 min, the absorbance of the reaction mixture was measured at 415 nm against a deionised water blank using a spectrophotometer (Hitachi Model 100-20; Hitachi, Tokyo, Japan). Quercetin was chosen as a standard. Using a seven point standard curve (0–50 mg/l), the total flavonoid contents were determined in triplicate, respectively. The data were expressed as milligram quercetin equivalents (QE)/g lyophilised powder. The data were then converted into milligram quercetin equivalents (QE) per gram of fresh matter from fruit, based on the moisture contents of lyophilised powder and fresh fruit materials.

2.6. DPPH free radical-scavenging assay

The DPPH free radical-scavenging assay was carried out according to the modified method of Su and Chien (2007). Five millilitres of 0.03 g/l DPPH (2,2-diphenyl-1-picrylhydrazyl) methanol solution were reacted with 0.1 ml fruit pulp extracts or essential oil at room temperature. The extraction solvent was used as control. The absorbance was measured at 517 nm after 30 min of reaction in the dark. The DPPH radical-scavenging activity was calculated as follows:

DPPH radical-scavenging activity (%) = $100 \times (1 - A_s/A_c)$, where A_c is the absorbance reading of DPPH without sample (control) at 517 nm, A_s is the absorbance reading of DPPH added to sample at 517 nm.

2.7. Ferric-reducing antioxidant power (FRAP) assay

The FRAP assay was carried out, using a modified version of the method of Benzie and Szeto (1999). A 20-μl aliquot of the fruit pulp extract or essential oil was mixed with 1.8 ml of FRAP reagent and 1.8 ml deionised water. Deionised water was used as control. The absorbance reading at 593 nm was taken after standing at 37 °C for 30 min. Aqueous solutions of 0–5 mM ferrous sulphate heptahydrate were used for calibration and reducing power was expressed as mM.

2.8. Statistical analysis

The triplicate data were subjected to an analysis of variance for a completely random design, using Statistical Analysis System (SAS Institute Inc., Cary, NC) program. Comparison of means was analysed by Duncan's multiple range test and differences were considered significant when $p < 0.05$.

3. Results and discussion

3.1. Total phenolic contents and total flavonoid contents of buntan pumelo fruit pulp extracts and peel essential oil

The total phenolic content of fruit pulp and peel extracts of buntan pumelo is shown in Table 1. Total phenolic contents from different fruit pulp extracts ranged from 4.8 ± 0.3 to 1.5 ± 0.2 mM GAE. This study showed that total phenolic contents in the various

Table 1
Total phenolic contents, total flavonoid contents and antioxidant properties of buntan pumelo fruit pulp extracts and essential oil of peel.

Buntan pumelo sample	DPPH free radical-scavenging activity (%)	FRAP (mM)	Total phenolic contents (mM GAE)	Total flavonoid contents (mg QE/g)
Ethyl acetate extracts	10.3 ± 1.5B[a]	0.4 ± 0.1A	3.5 ± 0.3B	0.2 ± 0.0A
Methanol extracts	15.5 ± 0.5D	1.0 ± 0.2C	4.6 ± 0.4C	0.3 ± 0.0A
50% ethanol extracts	4.8 ± 0.3A	0.7 ± 0.1B	1.5 ± 0.2A	0.2 ± 0.0A
Acetone extracts	12.9 ± 0.5C	1.1 ± 0.1C	4.0 ± 0.2B,C	0.2 ± 0.0A
Water extracts	16.3 ± 0.6D	1.2 ± 0.2C	4.8 ± 0.3C	0.3 ± 0.0A
Essential oil	26.1 ± 1.2E	2.3 ± 0.3D	214 ± 10.3D	134 ± 0.2B

[a] Data are expressed as the average of three determinations ± SD. Data with different capital case letters in the individual plant extracts are significantly different at 5% level according to Duncan's multiple range test.

extracts of fruit pulp as: water (4.8 ± 0.3 mM GAE) > methanol (4.6 ± 0.4 mM GAE) > acetone (4.0 ± 0.2 mM GAE) > ethyl acetate (3.5 ± 0.3 mM GAE) > 50% ethanol (1.5 ± 0.2 mM GAE). The essential oil from peels had higher total phenolics content than the extracts of fruit pulp. Total phenolic concentrations of essential oil from peel were 214 ± 10.3 mM GAE. The total flavonoid contents in the fruit pulp and essential oil varied considerably. The essential oil from peels had higher total flavonoid contents than the extracts of fruit pulp. Total flavonoid contents of essential oil from peel were 134 ± 0.2 mg QE/g. However, total flavonoid contents in the extracts of fruit pulp ranged from 0.2 ± 0.0 to 0.3 ± 0.0 mg QE/g. The results showed that pumelo peel possesses high concentrations of phenolic compounds and flavonoids; results were similar to previous reports about citrus peel (Bocco, Cuvelier, Richard, & Berset, 1998; Zia-ur-Rehman, 2006).

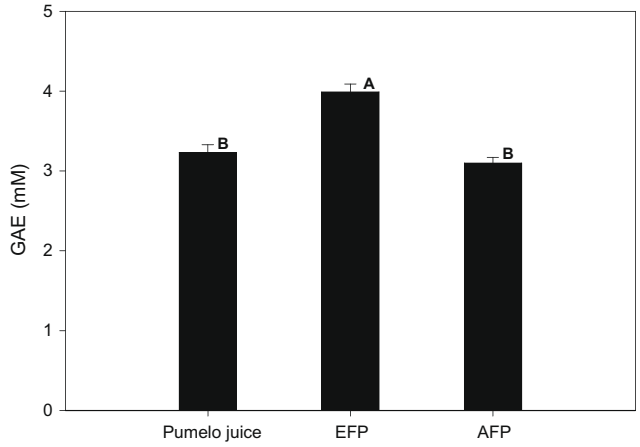

Fig. 1. Total phenolics content of buntan pumelo juice and its fermented products. Data are expressed as the average of three determinations ± SD. Data that do not share the same capital case letter on the top of vertical bar are significantly different at 5% level according to Duncan's multiple range test. EFP, ethanol-fermented products; AFP, acetate-fermented products.

3.2. Antioxidant properties of buntan pumelo fruit pulp extracts and peel essential oil

The DPPH free radical-scavenging activity of pumelo fruit pulp extracts and peel essential oil are also presented in Table 1. The results were shown as relative activities against the control. The relative activities of essential oil were 26%, which were higher than those of freshly-prepared fruit pulp extracts. The DPPH free radical-scavenging activity of various fruit pulp extracts were between 5% and 16%. In addition, relative activities of water or methanol extracts were significantly higher than acetone, ethyl acetate, or 50% ethanol extracts. Due to different antioxidant potentials of different compounds, the antioxidant activity of citrus extracts is strongly dependent on the extraction solvent.

The reducing power of fruit pulp extracts and essential oil using FRAP assay are also shown in Table 1. Among all citrus preparations investigated, essential oil from peel had higher FRAP value (2.3 mM) than those of fruit pulp extracts. The essential oil of pumelo peel also showed stronger antioxidant activities than the fruit pulp extracts. There was more than 3-fold difference between FRAP values in various fruit pulp extracts. The FRAP values of water, acetone or methanol extracts were over 1 mM, which were significantly higher than those of ethyl acetate or 50% ethanol extracts. Comparing all of the fruit pulp extracts, the water extracts had the highest FRAP value (1.2 mM) followed by the acetone extracts, methanol extracts, 50% ethanol extracts and ethyl acetate extracts.

EFP, ethanol-fermented products; AFP, acetate-fermented products.

3.3. Total phenolic contents and total flavonoid contents of fruit pulp extracts and fermented products

As shown in Fig. 1, total phenolics content of the EFP (4.0 mM GAE) of buntan pumelo juice was higher than that of pumelo juice. During the alcoholic fermentation, the polyphenols in the product increased. The reason is that less oxidation of polyphenols occurred during the fermentation process. Phenolic compounds can act as antioxidants and also can easily be oxidised. In order to retain or increase antioxidant activity of products, oxidation of the phenolic composition should be taken into account. Salmon (2006) proposed that the yeast *Saccharomyces cerevisiae* used in the alcoholic fermentation required oxygen for lipid synthesis, and can consume much oxygen with no detrimental effect on the fermentation process. As yeasts have much higher affinities for oxygen than polyphenols, viable yeast and yeast lees compete with phenolic compounds. However, total phenolics content in the AFP was not significantly different from that of pumelo juice. According to the studies of Su and Chien (2007), oxidation may still affect phenolic content during the acetification process. The results of their study are in agreement with Andlauer, Stumpf, and Furst (2000), who reported alterations in total phenolic content of vinegars due to the acetification process.

Total flavonoid contents of the buntan pumelo fermented products are shown in Fig. 2. In general, total flavonoid contents did not show a significant difference between the pumelo juice and the fermented products. Total flavonoid content did not vary between the EFP and the AFP; total flavonoid contents in the EFP and the AFP were 0.6 ± 0.1 and 0.5 ± 0.0 mg QE/g, respectively. The results showed that contents of flavonoid were low in the buntan pumelo and its fermented products.

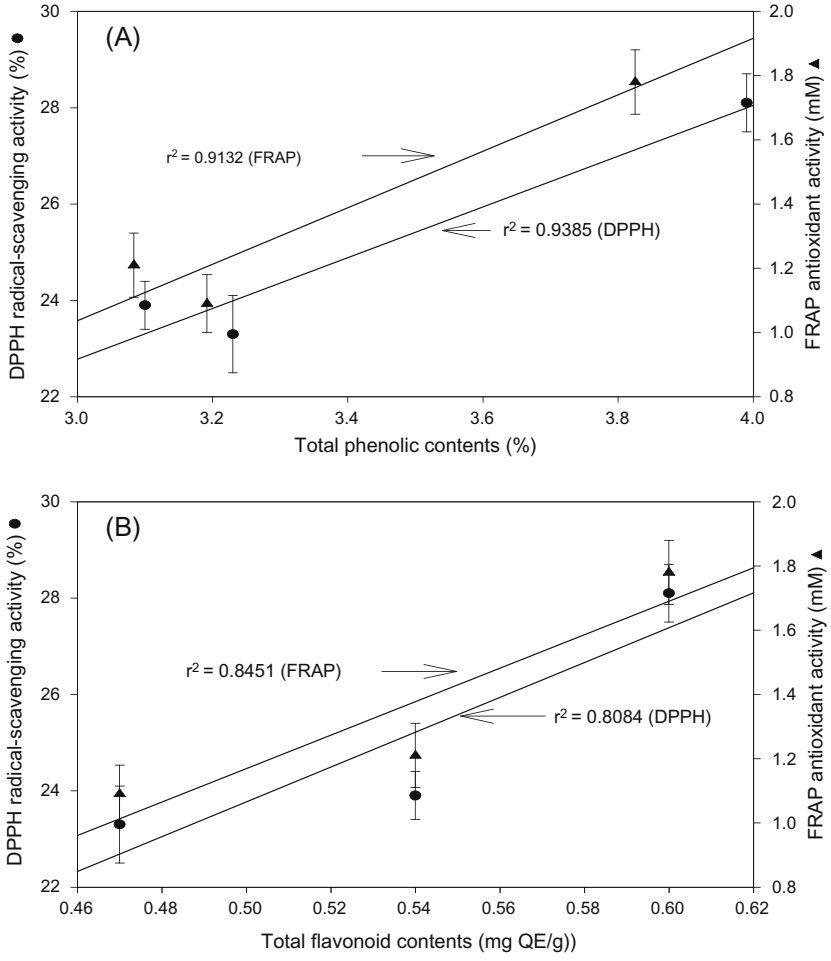

Fig. 5. Correlation of total phenolic contents (A) or total flavonoid contents (B) with antioxidant properties. Data are expressed as the average of three determinations ± SD.

3.4. The DPPH free radical-scavenging activity of fruit pulp extracts and its fermented products

As shown in Fig. 3, the DPPH free radical-scavenging activities of fermented products ranged from 24% to 28%, which were higher than those of fresh pumelo juice (23%). Furthermore, the EFP had higher DPPH free radical-scavenging activity than AFP. We postulated that the higher free radical-scavenging activity in AFP and EFP might be due to the higher total phenolic and total flavonoid contents in the fermented products. The DPPH free radical-scavenging activity of essential oil was similar to the results reported by Mokbel and Hashinaga (2006). Furthermore, The DPPH free radical-scavenging activity of pumelo fruit pulp extract was about 13% higher than the result described by Su, Shyu, and Chien (2008).

3.5. FRAP assay of fruit pulp extracts and its fermented products

The FRAP values of the various fermented products ranged from 1.2 to 1.8 mM; the EFP had higher reducing power using FRAP assay than that of AFP. The FRAP values of EFP were significantly higher than those of pumelo juice; however, those of AFP and pumelo juice were not significantly different (Fig. 4). The results suggested that the EFP had higher reducing power than the pumelo juice without fermentation. The higher total phenolic and total flavonoid contents might account for the higher reducing power in the EFP using FRAP assay.

3.6. Correlation of total phenolic contents or total flavonoid contents with antioxidant properties

Correlation analysis was used to elucidate if phenolic compounds or flavonoids conferred stronger antioxidant activity in the pumelo juice or its fermented products. Statistical analysis revealed that the total phenolic contents in the pumelo juice or its fermented products and the DPPH free radical-scavenging activity or reducing power using FRAP assay were positively correlated (Fig. 5A). Correlation between free radical-scavenging ability ($r^2 = 0.939$) or reducing power ($r^2 = 0.913$) and total phenolic contents in pumelo juice and its fermented products in this study was high and significant. According to some studies, free radical-scavenging activity depends on the structural conformation of phenolic compounds (Bors, Michel, & Stettmaier, 1997; Larrauri, Ruperez, & Calixto, 1996). Thus, free radical-scavenging activity is greatly influenced by the phenolic composition of the sample. However, the correlation between the total flavonoid contents in the pumelo juice or its fermented products and both free radical-scavenging activity ($r^2 = 0.808$) and reducing power ($r^2 = 0.845$) were lower, compared to the effect of total phenolic contents, and not significant (Fig. 5B). This indicates that the flavonoid components might not have good free radical-scavenging ability and reducing power. In addition, we might conclude that the total phenolic contents could be used as an index for free radical-scavenging and reducing power in the buntan pumelo fruit pulp juice or its fermented products.

4. Conclusions

The contents of phenolic and flavonoid compounds obtained from the essential oil of pumelo peel were approximately 45-fold higher than those of fruit pulp extracts. The free radical-scavenging and antioxidant activities of water or methanol extracts were highest among the various extracts of pumelo fruit pulp. The total phenolic contents and antioxidant capacity varied considerably from pumelo juice to its fermented products in this study. For maintenance of the antioxidant properties of pumelo products, ethanol-fermented juice is recommended. Furthermore, the correlation analysis revealed that the total phenolic contents could be used to evaluate the antioxidant capacity of the pumelo extracts.

ABSTRACT

In order to utilise sardinelle (*Sardinella aurita*) protein by-products, which is normally discarded as industrial waste in the process of fish manufacturing, heads and viscera proteins were hydrolysed by different proteases to obtain antioxidative peptides. All hydrolysates showed different degrees of hydrolysis and varying degrees of antioxidant activities. Hydrolysate generated with crude enzyme extract from sardine (*Sardina pilchardus*) displayed high antioxidant activity, and the higher DPPH radical-scavenging activity (87 ± 2.1% at 2 mg/ml) was obtained with a degree of hydrolysis of 6%. This hydrolysate was fractionated by size exclusion chromatography on a Sephadex G-25 into eight major fractions (P_1–P_8). Fraction P_4, which exhibited the highest DPPH scavenging activity, was then fractionated by reversed-phase high performance liquid chromatography (RP-HPLC). Seven antioxidant peptides were isolated. The molecular masses and amino acids sequences of the purified peptides were determined using ESI-MS and ESI-MS/MS, respectively. Their structures were identified as Leu-His-Tyr, Leu-Ala-Arg-Leu, Gly-Gly-Glu, Gly-Ala-His, Gly-Ala-Trp-Ala, Pro-His-Tyr-Leu and Gly-Ala-Leu-Ala-Ala-His. The first peptide displayed the highest DPPH radical-scavenging activity (63 ± 1.57%; at 150 μg/ml) among these peptides.

The results of this study suggest that sardinelle by-products protein hydrolysates are good source of natural antioxidants.

1. Introduction

Lipid oxidation is of great concern to the food industry and consumers because it leads to the development of undesirable off-flavours, odours and potentially toxic reaction products (Lin & Liang, 2002). Furthermore, cancer, coronary heart disease and Alzheimer's diseases are also reported to be caused in part by oxidation or free radical reactions in the body (Diaz, Frei, Vita, & Keaney, 1997). To prevent foods from undergoing such deterioration and to provide protection against serious diseases, it is very important to inhibit lipid peroxidation occurring in foodstuffs and the living body. Antioxidants are used to preserve food products by retarding discolouration and deterioration as a result of oxidation (Decker, Warner, Richards, & Shahidi, 2005).

Many synthetic antioxidants, such as butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT), are used as food additives to prevent deterioration. Although these synthetic antioxidants show stronger antioxidant activities than those of natural antioxidants, such as α-tocopherol and ascorbic acid, the use of these chemical compounds has begun to be restricted because of their induction of DNA damage and their toxicity (Ito et al., 1986). In recent years, there has been great interest in finding new antioxidants from natural sources for use in food and medicinal materials to replace synthetic antioxidants. Vitamin C, α-tocopherol and phenolic compounds, which are present naturally in vegetables, fruits and seeds, possess the ability to reduce oxidative damage associated with many diseases, including cancer, cardiovascular diseases, atherosclerosis, etc. Recently, the ability of phenolic substances, including flavonoids and phenolic acids to act as antioxidants has been extensively investigated (Katalinic, Milos, Kulisic, & Jukic, 2006; Madhujith & Shahidi, 2006; Miraliakbari & Shahidi, 2008; Rice-Evans, Miller, & Paganda, 1996; Shahidi, 2008; Shahidi, Alasalvar, & Liyana-Pathirana, 2007; Wong, Li, Cheng, & Chen, 2006; Zhong, Khan, & Shahidi, 2007).

In recent years, hydrolysed proteins from many animal and plant sources have been found to possess antioxidant activity, such as milk casein (Blanca, Ana, Lourdes, & Isidra, 2007), soybean (Gibbs, Zougman, Masse, & Mulligan, 2004), rice bran (Parrado et al., 2006), quinoa seed protein (Aluko & Monu, 2003), canola (Cumby, Zhong, Naczk, & Shahidi, 2008), egg-yolk protein (Sakanaka, Tachibana, Ishihara, & Juneja, 2004) and porcine myofibrillar

doi:10.1016/j.foodchem.2009.05.021

proteins (Saiga, Tanabe, & Nishimura, 2003). In addition, aquatic products and by-products have also proven to be good sources of antioxidant peptides, such as smooth hound (*Mustelus mustelus*) protein (Bougatef et al., 2009), capelin protein (Amarowicz & Shahidi, 1997), mackerel protein (Wu, Chen, & Shiau, 2003), jumbo squid skin (Mendis, Rajapakse, Byun, & Kim, 2005), hoki frame protein (Kim, Je, & Kim, 2007), yellowfin sole frame protein (Jun, Park, Jung, & Kim, 2004), yellow stripe trevally (*Selaroides leptolepis*) (Klompong, Benjakul, Kantachote, & Shahidi, 2007), yellowfin sole skin gelatine hydrolysate (Kim, Lee, Byun, & Jeon, 1996), Alaska pollack skin gelatine hydrolysate (Kim et al., 2001), and Alaska pollack frame protein hydrolysate (Je, Park, & Kim, 2005).

In Tunisia, sardinelle (*Sardinella aurita*) catches were about 13,300 tonnes in 2002 (F.A.O., 2004). During processing, solid wastes including heads and viscera are generated and constitute as much as 30% of the original material. These wastes, which represent an environmental problem to the fishing industry, constitute an important source of proteins. Traditionally, this material is transformed into powdered fish flour for animal feed (Ström & Eggum, 1981). Nevertheless, novel processing methods are required to convert sardinelle by-products into more profitable and marketable products. An interesting alternative would be to transform fish proteins by-products into biologically active peptides by protease treatments.

In this study, we investigated the antioxidative activity of sardinelle heads and viscera protein hydrolysates obtained by various enzymatic treatments. Furthermore, seven new antioxidative peptides were isolated from the hydrolysate obtained by treatment with crude enzyme extract from sardine viscera and their amino acids sequences were determined.

2. Materials and methods

2.1. Reagents

Chemicals required for the assays including 1,1-diphenyl-2-picrylhydrazyl (DPPH), BHA, α-tocopherol and linoleic acid were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Sephadex G-25 was from Pharmacia (Uppsala, Sweden). Other chemicals and reagents used were of analytical grade.

2.2. Materials

Sardinelle (*S. aurita*) was purchased from the fish market of Sfax city, Tunisia. It was washed twice with water; heads and viscera were separated, rinsed with cold distilled water, and then stored in sealed plastic bags at −20 °C until used.

2.3. Enzymes

The enzyme preparations used were: Alcalase® 2.4L serine-protease from *Bacillus licheniformis* supplied by Novozymes® (Bagsvered, Denmark), crude enzyme preparation from *Aspergillus clavatus* ES1 (Hajji, Kanoun, Nasri, & Gharsallah, 2007), alkaline proteases from *B. licheniformis* NH1 (El Hadj-Ali et al., 2007), and crude enzyme extract from viscera of sardine (*Sardina pilchardus*) (Bougatef, Souissi, Fakhfakh, Triki-Ellouz, & Nasri, 2007).

2.4. Preparation of endogenous enzyme extract from sardine viscera

Viscera from sardine (150 g) were homogenised for 60 s with 300 ml of extraction buffer (10 mM Tris–HCl, pH 8.0). The homogenate was centrifuged at 8500*g* for 30 min at 4 °C and the supernatant was collected. The supernatant referred to as the crude enzyme extract was stored at 4 °C prior to analysis. All enzymatic assays were conducted within a week after extraction. For a long conservation, supernatant was lyophilised.

Crude enzymes from *B. licheniformis* NH1 and *A. clavatus* ES1 were prepared in our laboratory as described by El Hadj-Ali et al. (2007) and Hajji et al. (2007).

The protease activity in the crude enzyme extract was determined by the method of Kembhavi, Kulkarni, and Pant (1993) using casein as a substrate. One unit of protease activity was defined as the amount of enzyme required to liberate 1 μg of tyrosine per minute under the experimental conditions used.

2.5. Preparation of sardinelle protein hydrolysates using various proteases

Heads and viscera (500 g), in 500 ml distilled water, were first minced, using a grinder (Moulinex Charlotte HV3, France) then cooked at 90 °C for 20 min to inactivate endogenous enzymes. The cooked heads and viscera sample was then homogenised in a Moulinex® blender for about 2 min. The samples were adjusted to optimal pH and temperature for each enzyme; crude enzyme from NH1 (pH 10.0; 50 °C), Alcalase and crude enzyme extract from sardine viscera (pH 8.0; 50 °C) and crude enzyme from ES1 (pH 8.0; 40 °C). Then, the substrate proteins were digested with enzymes at a 0.27:1 (U/mg) enzyme/protein ratio for 3 h. Enzymes were used at the same activity levels to compare hydrolytic efficiencies. During the reaction, the pH of the mixture was maintained at the desired value by continuous addition of 4 N NaOH solution. The enzymatic hydrolysis was stopped by heating the solutions at 80 °C during 20 min. The protein hydrolysates were then centrifuged at 5000*g* for 20 min to separate soluble and insoluble fractions. Finally, the soluble fraction was freeze-dried using freeze-dryer (Bioblock Scientific Christ ALPHA 1-2) and stored at −18 °C for further use. The powders were used as sardinelle protein hydrolysates.

2.6. Determination of the degree of hydrolysis

The degree of hydrolysis (DH), defined as the percent ratio of the number of peptide bonds broken (h) to the total number of peptide bonds per unit weight (h_{tot}), in each case, was calculated from the amount of base (NaOH) added to keep the pH constant during the hydrolysis (Adler-Nissen, 1986) as given below:

$$\mathrm{DH}\,(\%) = \frac{h}{h_{tot}} \times 100 = \frac{B \times Nb}{MP} \times \frac{1}{\alpha} \times \frac{1}{h_{tot}} \times 100$$

where B is the amount of NaOH consumed (ml) to keep the pH constant during the reaction, Nb is the normality of the base, MP is the mass (g) of protein (N × 6.25), and α is the average degree of dissociation of the α-NH_2 groups released during hydrolysis expressed as:

$$\alpha = \frac{10^{\mathrm{pH}-\mathrm{pK}}}{1 + 10^{\mathrm{pH}-\mathrm{pK}}}$$

where pH and pK are the values at which the proteolysis was conducted. The total number of peptide bonds (h_{tot}) in a fish protein concentrate was assumed to be 8.6 meq/g (Adler-Nissen, 1986).

2.7. Antioxidant activity

2.7.1. DPPH radical-scavenging assay

The DPPH radical-scavenging activity of the hydrolysates was determined as described by Bersuder, Hole, and Smith (1998). Samples dissolved in 500 μl of distilled water (2 mg/ml for hydrolysates H1–H4; 1 mg/ml for G-25 fractions and 150 μg/ml for RP-HPLC fractions) were mixed with 500 μl of 99.5% ethanol and

125 μl of a DPPH solution (0.02% in 99.5% ethanol). The mixtures were incubated for 60 min in the dark at room temperature, and the reduction of DPPH radicals was measured at 517 nm. In its radical form, DPPH has an absorption band at 517 nm which disappears upon reduction by an antiradical compound. Lower absorbance of the reaction mixture indicated higher free radical-scavenging activity. DPPH radical-scavenging activity was calculated as:

$$\text{DPPH radical} - \text{scavenging activity } (\%) = \frac{\text{Absorbance of control} - \text{Absorbance of sample}}{\text{Absorbance of control}} \times 100$$

The control was conducted in the same manner, except that distilled water was used instead of sample. BHA was used as positive standard. The test was carried out in triplicate.

2.7.2. Inhibition of linoleic acid autoxidation

The lipid peroxidation inhibition activity of hydrolysates was measured in a linoleic acid emulsion system according to the method of Osawa and Namiki (1985). A 20 mg of hydrolysates, dissolved in 10 ml of 50 mM phosphate buffer (pH 7.0), was added to a solution of 0.13 ml of linoleic acid and 10 ml of 99.5% ethanol. The total volume was then adjusted to 25 ml with distilled water. The mixture was incubated in a 50 ml assay tube with a screw cap at 40 ± 1 °C for 5 days in a dark room. The degree of oxidation of linoleic acid was measured using the ferric thiocyanate method of Mitsuda, Yasumoto, and Iwami (1996). To 0.1 ml of the reaction mixture were added 4.7 ml of 75% ethanol, 0.1 ml of 30% ammonium thiocyanate, and 0.1 ml of 20 mM ferrous chloride solution in 3.5% HCl. After 3 min incubation, the colour development, which represents the linoleic acid oxidation, was measured at 500 nm. α-Tocopherol, a natural antioxidative agent, was used as reference and 50 mM phosphate buffer (pH 7.0) as control. The antioxidative capacity of inhibiting the peroxide formation in linoleic acid system was expressed as follows:

$$\text{Inhibition } (\%) = \left[1 - \frac{\text{Absorbance of sample}}{\text{Absorbance of control}}\right] \times 100$$

2.7.3. Reducing power assay

The ability of the protein hydrolysates or purified peptides to reduce iron(III) was determined by the method of Yildirim, Mavi, and Kara (2001). An aliquot of 1 ml sample (2 mg of hydrolysate/ml) was mixed with 2.5 ml of 0.2 M phosphate buffer (pH 6.6) and 2.5 ml of 1% (w/v) potassium ferricyanide. The mixtures were incubated at 50 °C for 30 min. After incubation, 2.5 ml of 10% (w/v) trichloroacetic acid was added and the reaction mixtures were centrifuged for 10 min at 1650*g*. Finally, 2.5 ml of the supernatant solution were mixed with 2.5 ml of distilled water and 0.5 ml of 0.1% (w/v) ferric chloride solution. After a 10 min reaction time, the absorbances of the resultant solutions were measured at 700 nm. Higher absorbance of the reaction mixture indicated higher reducing power. The test was carried out in triplicate.

2.8. Purification and characterisation of antioxidant peptides

2.8.1. Fractionation of protein hydrolysates with Sephadex G-25 gel filtration

The freeze-dried hydrolysate (1 g), with a DH of 6% obtained by treatment with crude alkaline protease extract from sardine was suspended in 20 ml of distilled water, then loaded onto a Sephadex G-25 gel filtration column (2.5 cm × 54 cm), pre-equilibrated and eluted with distilled water. Fractions (5 ml each) were collected at a flow rate of 60 ml/h, and absorbance was measured at 226 nm to determine the elution profile of the sample. Fractions associated with each peak showing antioxidant activity were pooled and freeze-dried.

2.8.2. Reversed-phase high pressure liquid chromatography (RP-HPLC)

The peptide mixture in fraction P_4 from Sephadex G-25, which exhibited the highest DPPH scavenging activity, was dissolved in distilled water, filtered through 0.22 μm filters, and then separated by RP-HPLC on a Vydac C_{18} column (10 mm × 250 mm). Peptides were eluted with eluent A (water containing 0.1% trifluoric acetic acid (TFA) for 10 min), then with a linear gradient of acetonitrile (0–100% in 25 min) containing 0.1% TFA at a flow rate of 1 ml/min. On-line UV absorbance scans were performed between 200 and 300 nm at a rate of one spectrum per second with a resolution of 1.2 nm. Chromatographic analyses were completed with Millennium software. The antioxidative activities of the eluted peaks were determined.

The liquid chromatographic system consisted of a Waters 600E automated gradient controller pump module, a Waters Wisp 717 automatic sampling device and a Waters 996 photodiode array detector. Spectral and chromatographic data were stored on a NEC image 466 computer. Millennium software was used to plot, acquire and analyse chromatographic data.

2.8.3. Determination of the amino acid sequence of the purified peptides

The molecular mass and peptide sequencing were done on positive ion mode using Electrospray ionisation-mass spectrometry (ESI-MS) and the tandem mass spectrometry (MS/MS). ESI mass spectrometry was performed using a triple quadrupole instrument Applied Biosystems API 3000 (PE Sciex, Toronto, Canada) equipped with an electrospray ion source. The system is controlled by the Analyst Software 1.4, allowing the control of the spectrometer, the analysis and the processing data. Interpretations of spectra MS–MS were made with the Bioanalyst software. The freeze-dried samples from RP-HPLC were dissolved in acetonitrile/water (20/80; v/v) containing 0.1% formic acid for the positive mode. The solution was injected with a flow rate of 5 μl/min. The potential of ionisation was of 5000 V in positive mode. At the time of the recording of the spectrum, 30 scans on average were added (MCA mode) for each spectrum. The gases used (nitrogen and air) were pure (up to 99%) and produced by a compressor Jun-Air 4000-40M and a nitrogen generator Whatman model 75–72 (Whatman Inc, Haverhill, MA the USA). The polypropylene glycol was used for the calibration and the optimisation of the machine. The peptide sequence was determined from the CID spectrum of the protonated analyse $[M+H]^+$ by MS/MS experiments. Peptide sequences were done using the bioanalyst software (Applied Biosystems, USA).

2.9. Statistical analysis

Statistical analyses were performed with Statgraphics ver. 5.1, professional edition (Manugistics Corp., USA) using ANOVA analysis. Differences were considered significant at $p < 0.05$.

3. Results and discussion

3.1. Preparation of protein hydrolysates using various proteases

It has been demonstrated that the antioxidant activities of proteins can be increased through hydrolysis with certain enzymes, and some peptides or fractions possess stronger antioxidant potential than others (Chen, Muramoto, & Yamauchi, 1995). Further, the antioxidant activity of protein hydrolysates depends on the protein substrate, the specificity of the enzyme, the conditions used during proteolysis and the degree of hydrolysis. Since enzymes have

specific cleavage positions on polypeptides chain, protein hydrolysates were prepared from sardinelle by-products by treatment with different enzymes to obtain peptides with different amino acids sequences and peptides length. Alcalase®, crude enzyme preparations from *B. licheniformis* NH1 and *A. clavatus* ES1, and crude enzyme extract from sardine viscera were used in the present study. The hydrolysis curves of sardinelle by-products proteins after 3 h of incubation are shown in Fig. 1. Enzymes were used at the same activity levels to compare hydrolytic efficiencies.

The hydrolysis of the sardinelle by-products proteins was characterised by a high rate of hydrolysis for the first 1 h. The rate of enzymatic hydrolysis was subsequently decreased, and then the enzymatic reaction reached the steady-state phase when no apparent hydrolysis took place. Crude enzyme preparation from *B. licheniformis* NH1 was the most efficient while crude enzyme preparation from *A. clavatus* ES1 was the lowest efficient. After 3 h of hydrolysis, the DH reached about 11% with crude enzyme preparation from NH1 strain, 8% with Alcalase® and crude extract from sardine viscera, and 5% with crude enzyme preparation from *A. clavatus* ES1. The shape of the hydrolysis curves is similar to those previously reported for sardine (Quaglia & Orban, 1987), Atlantic salmon (Kristinsson & Rasco, 2000), yellowfin tuna (Guérard, Dufossé, De La Broise, & Binet, 2001), and sardinelle (Bougatef et al., 2008).

3.2. Antioxidant activity of sardinelle by-products hydrolysates

The resulting hydrolysates were freeze-dried and assayed for antioxidative activity using various antioxidant assays, including 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical-scavenging activity, reducing power and lipid peroxidation inhibition assay.

3.2.1. DPPH free radical-scavenging activity

DPPH is a stable free radical that shows maximum absorbance at 517 nm. When DPPH radicals encounter a proton-donating substrate such as an antioxidant, the radicals would be scavenged and the absorbance is reduced (Shimada, Fujikawa, Yahara, & Nakamura, 1992). The decrease in absorbance is taken as a measure for radical-scavenging activity.

Fig. 2 shows the DPPH radical-scavenging activity of sardinelle by-products hydrolysates at 2 mg/ml and BHA. The results clearly indicated that hydrolysate obtained by treatment with crude enzyme from sardine viscera exhibited the highest radical-scavenging activity (53.76 ± 1.2%), while the lowest DPPH radical-scavenging activity was obtained with crude enzyme from *A. clavatus* ES1 (10.55 ± 1.55%). However, all hydrolysates showed lower radical-scavenging activity than BHA (2 mM; 92.5 ± 1.7%). The results obtained suggested that some peptides within sardinelle protein hydrolysates were significantly strong radical scavengers.

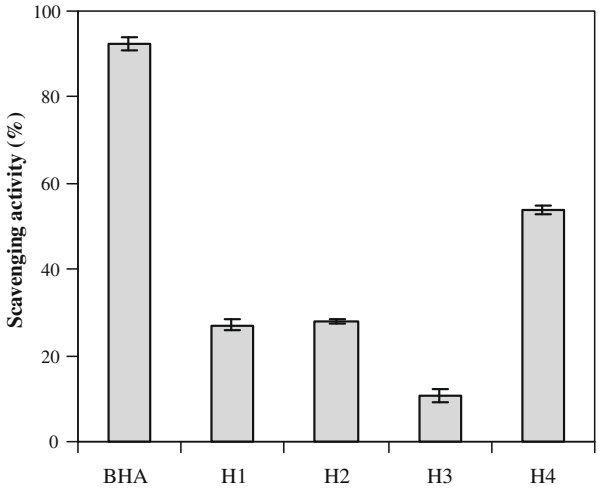

Fig. 2. DPPH scavenging activity of sardinelle by-products protein hydrolysates. H1, H2, H3 and H4 are hydrolysates obtained by treatment with Alcalase® (DH = 8%), crude enzymes from *B. licheniformis* NH1 (DH = 11%) and *A. clavatus* ES1 (DH = 5%), and crude enzyme extract from sardine viscera (DH = 8%), respectively. Values presented are the mean of triplicate analyses.

3.2.2. Reducing power

The reducing power assay is often used to evaluate the ability of an antioxidant to donate an electron or hydrogen (Yildirim et al., 2000). Many reports have revealed that there is a direct correlation between antioxidant activities and reducing power of certain bioactive compounds. In this assay, the ability of hydrolysates to reduce Fe^{3+} to Fe^{2+} was determined. The presence of antioxidants in the protein hydrolysate results in reduction of the Fe^{3+}/ferric cyanide complex to the ferrous form. Therefore, the Fe^{2+} complex can be monitored by measuring the formation of Perl's Prussian blue at 700 nm. Fig. 3 shows the reducing power activities (as indicated by the absorbance at 700 nm) of the different protein hydrol-

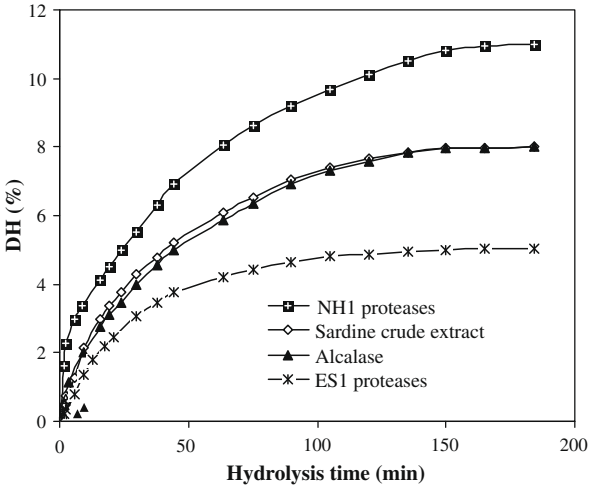

Fig. 1. Hydrolysis curves for sardinelle by-products treated with different enzymes.

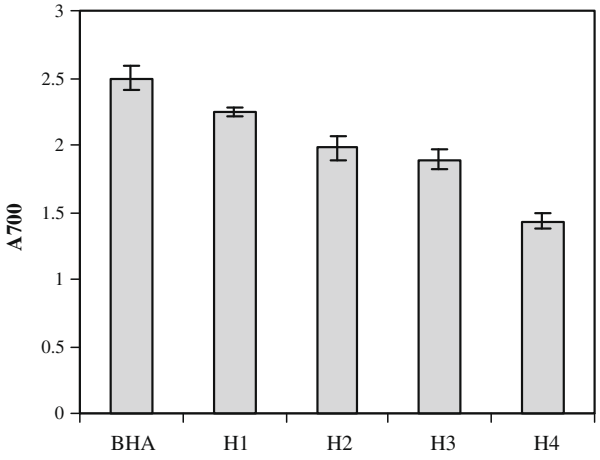

Fig. 3. Reducing power activity of the different hydrolysates. H1, H2, H3 and H4 are hydrolysates obtained by treatment with Alcalase® (DH = 8%), crude enzymes from *B. licheniformis* NH1 (DH = 11%) and *A. clavatus* ES1 (DH = 5%), and crude enzyme extract from sardine viscera (DH = 8%), respectively. Values presented are the mean of triplicate analyses.

ysates compared with BHA as standard. All hydrolysates showed some degree of electron donation capacity. The hydrolysate obtained by treatment with Alcalase® was the most potent reducing power (2.24 ± 0.48) followed by that obtained by treatment with crude enzyme preparation from *B. licheniformis* NH1 (1.98). The hydrolysate treated with sardine crude enzyme extract showed the weakest activity. However, all hydrolysates showed lower reducing power than BHA.

3.2.3. Lipid peroxidation inhibition assay

Peroxidation of lipids is a complex process that involves formation and propagation of lipid radicals and lipid hydroperoxides are formed as primary oxidation products in the presence of oxygen. The antioxidative activity of the four hydrolysates at 2 mg/ml, against the peroxidation of linoleic acid, was investigated and compared to α-tocopherol which has been widely used as a natural antioxidative agent. As shown in Table 1, the control (without antioxidant) had the highest absorbance value, indicating the highest degree of oxidation among samples, while the sample with α-tocopherol, used as a reference, had the lowest absorbance. All hydrolysates prevented linoleic acid peroxidation, which was smaller than α-tocopherol providing about 77% inhibition of linoleic acid peroxidation. Hydrolysate obtained by treatment with crude enzyme from sardine viscera, exhibited the highest inhibition of lipid peroxidation in the linoleic acid emulsion system (53.76 ± 0.42%), and followed by Alcalase and NH1 crude enzyme hydrolysates.

3.3. Antioxidant activity at different degrees of hydrolysis

The above results demonstrated that hydrolysate obtained by treatment with crude enzyme extract from sardine viscera exhibited high antioxidant activity. Therefore, this crude extract was chosen for the isolation and identification of antioxidant peptides.

The degree of hydrolysis is a measure of the extent of hydrolysis degradation of a protein, and it is the most widely used indicator for comparison among different protein hydrolysates. During hydrolysis, a wide variety of larger, medium and smaller peptides are generated, depending on enzyme specificity. In order to study the effect of the DH on the evolution of antioxidative properties, protein hydrolysates having DH values of 2%, 4%, 6% and 8% were generated from heads and viscera of sardinelle by treatment with sardine crude enzyme extract. As shown in Table 2, hydrolysate with 6% DH exhibited the highest DPPH radical-scavenging activity (87 ± 2.1%). In addition, according to the results reported in Table 2, the reducing power was correlated with the degree of hydrolysis, and higher activity (1.43 ± 0.77) was obtained with DH of 8%. From this result, it appears that protein hydrolysate from sardinelle by-products could function by donating electrons to the free radicals.

3.4. Isolation and purification of antioxidant peptides

To purify antioxidant peptides, hydrolysate with 6% DH, which exhibited the highest DPPH scavenging activity, was initially separated into eight fractions (P_1–P_8) by size exclusion chromatography on Sephadex G-25 column (Fig. 4). Each fraction was pooled, lyophilised and its antioxidant activity was assayed. As shown in Fig. 4, all fractions (at 1 mg/ml) displayed antioxidant activities. Fraction P_4 possessed the highest radical-scavenging activity (48%) among all fractions. This fraction was further separated by reversed-phase HPLC and fractionated into six major sub-fractions ($P_{4\text{-}1}$, $P_{4\text{-}2}$, $P_{4\text{-}3}$, $P_{4\text{-}4}$, $P_{4\text{-}5}$ and $P_{4\text{-}6}$). The elution profile of peptides is shown in Fig. 5. Fractions were collected separately through repeated chromatography using reversed-phase HPLC column and concentrated in vacuo prior to testing the radical-scavenging activities. As shown in Fig. 5, all fractions showed varying degrees of DPPH radical-scavenging activity, and sub-fraction $P_{4\text{-}3}$ possessed the strongest activity (63 ± 1.57%; at 150 μg/ml).

Table 2
DPPH radical-scavenging activity and reducing power of sardinelle by-product hydrolysates, with different DHs, produced by treatment with crude extract from sardine viscera.

DH (%)	DPPH (%)	Reducing power (A700)
2	47.5 ± 0.22	0.3 ± 0.06
4	47.77 ± 0.18	0.36 ± 0.04
6	87 ± 1.5	0.8 ± 0.23
8	53.76 ± 1.2	1.43 ± 0.77
BHA	92.5 ± 1.7	2.5 ± 0.12

The concentration of protein hydrolysates was 2.0 mg/ml. BHA (2.0 mM; 0.36 mg/ml) was used as standard.

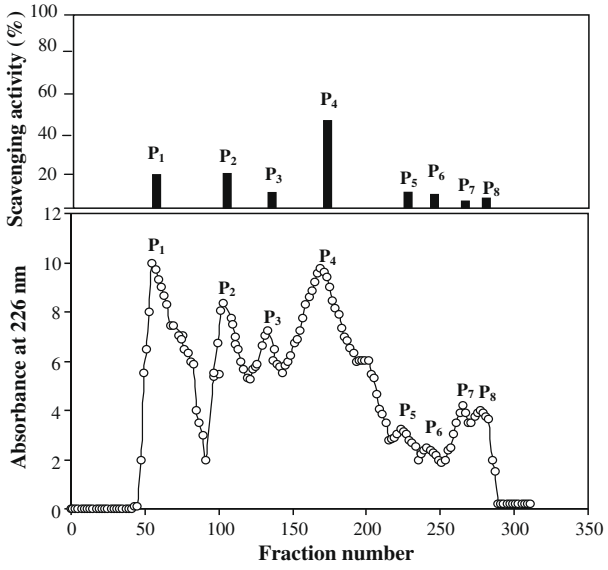

Fig. 4. Elution profile of sardinelle by-product protein hydrolysates separated by size exclusion chromatography on Sephadex G-25 (lower panel) and the DPPH radical-scavenging activities of the separated fractions (upper panel). The column (2.5 cm × 54 cm) was equilibrated and eluted with distilled water at a flow rate of 60 ml/h. Values presented are the mean of triplicate analyses.

Table 1
Antioxidant activity of sardinelle by-products hydrolysates in linoleic acid autoxidation system measured by the ferric thiocyanate method.

	Absorbance at 500 nm	Inhibition (%)	DH (%)
Control	2.65 ± 0.02	0	–
Alcalase®	1.75 ± 0.01	33.96 ± 0.6	8
Proteases from *B. licheniformis* NH1	1.85 ± 0.01	28.14 ± 0.52	11
Proteases from *A. clavatus* ES1	2.25 ± 0.015	15 ± 0.3	5
Crude extract from sardine viscera	1.28 ± 0.012	53.76 ± 0.42	8
α-Tocopherol	0.6 ± 0.01	77.35 ± 0.11	–

The concentration of protein hydrolysates was 2.0 mg/ml. α-Tocopherol (2.0 mM; 0.86 mg/ml) was used as standard.

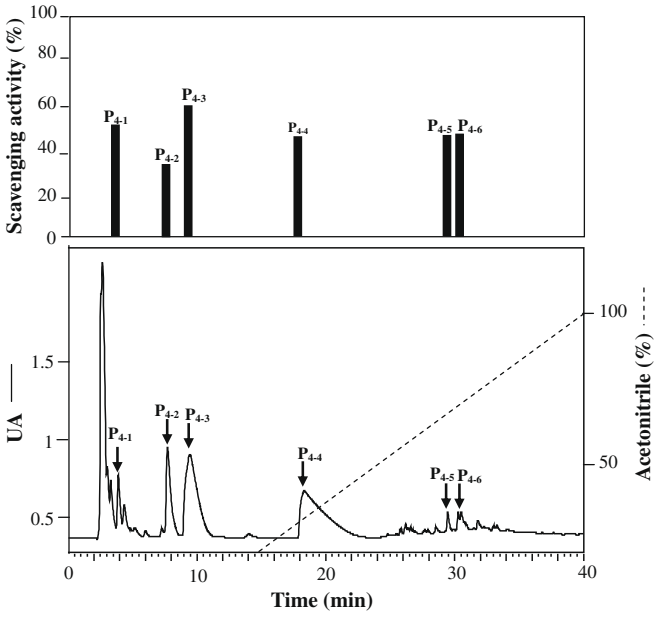

Fig. 5. Reversed-phase HPLC pattern on a Vydac C_{18} column of the P_4 fraction obtained from Sephadex G-25 gel filtration (lower panel). The antioxidant activity of the eluted peaks was measured by DPPH radical-scavenging effect (upper panel). Flow rate, 1 ml/min; monitoring absorbance, 215 nm. Values presented are the mean of triplicate analyses.

3.5. Identification of antioxidative peptides

Peptides in sub-fractions (P_{4-1}–P_{4-5}) were analysed by ESI-MS for molecular mass determination and ESI-MS/MS for the characterisation of peptides. Four purified peptides were identified in sub-fractions P_{4-1} (Leu-Ala-Arg-Leu), P_{4-2} (Gly-Gly-Glu), P_{4-3} (Leu-His-Tyr) and P_{4-5} (Gly-Ala-Leu-Ala-Ala-His) (Table 3). Leu-His-Tyr displayed the highest DPPH radical-scavenging activity (63 ± 1.57% at 150 μg/ml). In addition, sub-fraction P_{4-4} contains three peptides and the antioxidant activity if this sub-fraction may result from the three peptides, which contained His, Trp or Tyr residues. In fact, Da'valos, Miguel, Bartolome, and Lo'pez-Fandino (2004) reported that among the amino acids, Trp, Tyr and Met showed the highest antioxidant activity, followed by Cys, His and Phe. The antioxidant activity of histidine-containing peptides has been reported and attributed to the chelating and lipid radical-trapping ability of the imidazole ring (Murase, Nagao, & Terao, 1993; Park, Jung, Nam, Shahidi, & Kim, 2001; Uchida & Kawakishi, 1992).

In this study, four of the seven antioxidant peptides identified had His residue. Further, Leu-His-Tyr peptide, which displayed high activity, may be due to the presence in this sequence of both His and Tyr residues. All identified peptides are novel peptides with antioxidant activity that had never been reported.

Table 3
Peptides identified by MS/MS in fractions P_{4-1}, P_{4-2}, P_{4-3}, P_{4-4} and P_{4-5} separated by RP-HPLC.

Fractions	MW (Da)	Sequence	DPPH scavenging activity (%)
P_{4-1}	471.3	Leu-Ala-Arg-Leu	51 ± 1.31
P_{4-2}	263.08	Gly-Gly-Glu	38 ± 1.27
P_{4-3}	431.2	Leu-His-Tyr	63 ± 1.5
P_{4-4}	283.1	Gly-Ala-His	
	403.1	Gly-Ala-Trp-Ala	52 ± 1.44
	528.2	Pro-His-Tyr-Leu	
P_{4-5}	538.2	Gly-Ala-Leu-Ala-Ala-His	54 ± 1.38

4. Conclusions

In the present study, sardinelle by-products protein hydrolysates obtained by various proteases were found to possess antioxidant activity. Among four proteolytic preparations, the hydrolysis with crude extract from sardine viscera resulted in the production of the hydrolysate with the highest antioxidant activity.

By gel permeation chromatography on Sephadex G-25, and reversed-phase HPLC, seven antioxidant peptides were purified from the combined heads and viscera of sardinelle hydrolysates (DH 6%) and their sequences were identified by ESI/MS/MS and molecular weight analysis. The peptide Leu-His-Tyr displayed the highest radical-scavenging activity.

These results suggest that hydrolysate from sardinelle by-products could be used as natural antioxidant in enhancing antioxidants properties of functional foods and in preventing oxidation reactions in food processing.

Further research should be done in order to purify and identify antioxidative peptides in the other fractions collected by gel filtration.

Proteome

ABSTRACT

Beer proteins were analysed by two-dimensional gel electrophoresis (2DE). The protein species associated with major spots on 2DE gels were identified by mass spectrometry followed by a database search to construct a comprehensive beer proteome map. As a result, 85 out of 199 protein spots examined were positively identified and categorised into 12 protein species. A total of 11 beer samples were brewed from the malt of eight cultivars having different levels of protein modification. This experiment was designed to demonstrate the influences of barley cultivar and malt modification on beer protein composition and beer quality characters. The beers produced from these brewing trails were subsequently analysed by 2DE and their proteomes were compared. Cultivars and malt modification affected the concentration of several proteins in beer. Beer protein concentration was associated with differences in the desirable beer quality trait, foam stability. In addition, expression of yeast derived proteins were observed that may also influence beer quality. Overall, the application of a comprehensive beer proteome map provides a strong platform for detection and potential manipulation of beer quality related proteins.

1. Introduction

Beer foam quality is one of the important characteristics that a consumer uses to determine beer quality. Foam quality is defined by its stability, lacing, whiteness, intensity, strength, and creaminess (Bamforth, 1985). In clear beer, colloidal haze formation is also a serious quality problem. Consumers judge a beer as stale or not fit to drink if it displays colloidal haze. Foam stability (Bamforth, 1985; Evans & Sheehan, 2002) and haze formation (Asano, Shinagawa, & Hashimoto, 1982; Iimure et al., 2009; Siebert, 1999) have been assumed to be major quality traits controlled by proteins. In beer foam stability, several beer proteins have been identified as either foam-positive or negative. Previous reports suggested that protein Z (Evans, Sheehan, & Stewart, 1999; Evans et al., 2003; Kaersgaard & Hejgaard, 1979; Maeda, Yokoi, Kamada, & Kamimura, 1991) and lipid transfer protein 1 (LTP1) (Jégou, Douliez, Mollé, Boivin, & Marion, 2000; Sorensen, Bech, Muldbjerg, Beenfeldt, & Breddam, 1993) play important roles in beer foam stability. In addition, recent studies have suggested that barley dimeric α-amylase inhibitor-1 (BDAI-1) and yeast thioredoxin are foam-positive and foam-negative proteins, respectively (Iimure et al., 2008; Okada et al., 2008). In beer colloidal haze, CMe component tetrameric α-amylase inhibitor (CMe), BDAI-1 and hordein were suggested as haze active (Asano et al., 1982; Evans et al., 2003; Iimure et al., 2009; Robinson et al., 2007; Siebert, 1999). However, conclusive identification of protein factors causing beer foam stability and haze formation still requires validation. One of the reasons for the poor understanding of protein factors may come from the lack of knowledge of the spectrum of proteins in beer. Thus, comprehensive analysis of beer protein identity is necessary to reveal the relationship between beer proteins with respect to quality characters including foam stability and haze formation.

Barley cultivar and the level of protein modification during malting are also known as important malting related factors that can modify beer quality (Evans, Nischwitz, Stewart, Cole, & MacLeod, 1998; Iimure et al., 2008). Protein modification is judged by malt modification which is conventionally measured in the brewing industry as the Kolbach index (soluble nitrogen/total nitrogen × 100). Therefore, the understanding of beer protein also requires an understanding of the effect of different barley cultivar and malt modification combinations in important quality proteins (i.e., hordeins, protein Z).

Proteome analysis, which separates a sample of proteins by two-dimensional gel electrophoresis (2DE) which is followed by mass spectrometry analysis and database searches, is a powerful tool to comprehensively detect the spectrum of proteins present in a beer sample. In several reports, proteins from barley grain and malt were analysed by 2DE and major protein spots were

identified (Bak-Jensen, Laugesen, Roepstorff, & Svensson, 2004; Østergaard, Finnie, Laugesen, Roepstorff, & Svensson, 2004). Also major beer proteins were identified by mass spectrometry (Hao et al., 2006; Perrocheau, Rogniaux, Boivin, & Marion, 2005). Similarly, Iimure et al. (2008) and Iimure et al. (2009) identified foam proteins and haze active proteins using a proteome analysis.

To expand these pioneering analyses, this study develops a comprehensive proteome map of beer for Japanese style lager beer. Recent advancements in protein analysis enable the development of a proteome map with greater resolution by identifying relatively minor spots. The use of the proteome map is applied practically, to assess eleven beer samples that were prepared with different barley cultivars and levels of malt modification. The efficient application of protein spot intensities on 2DE images is discussed to control foam stability and haze formation.

2. Materials and methods

2.1. Barley sample, malting and malt quality analysis

The barley-malt materials used in this study are described in Table 1. Each 75 kg barley grain sample from a single cultivar (>2.5 mm screen) was processed according to Okada et al. (2008). For cultivars F, G and H, two different ex-steep moisture levels, i.e., low (36–37%) and high (43–44%), were used to influence malt modification, thus assess its influence on beer protein composition. Malt quality characters were analysed according to the standard methods of the European Brewery Convention (European Brewery Convention & Analytica, 1987).

2.2. Pilot-scale brewing

Wort was prepared and fermented at a 400 l pilot-scale plant according to Okada et al. (2008), except for mashing in temperature which was either 50 or 60 °C (Table 1). Beer quality characteristics were analysed according to the standard methods of European Brewery Convention (European Brewery Convention, Analytica, 1987). Beer foam stability (NIBEM value) was scored by foam stability tester type NIBEM-T (Haffmans B. V., Venlo, Holland) according to the manufacturer's instructions. Colloidal stability was scored by a forcing test (FT-3). For the FT-3 haze test, the bottled beer samples were stored at 60 °C for 3 days and then 0 °C for 1 day. Subsequently, the beer clarity, FT-3, was measured in terms of haze formation (Iimure et al., 2009).

2.3. Two-dimensional gel electrophoresis (2DE)

Completely degassed beer samples were desalted using a PD-10 column (GE Healthcare Biosciences, Japan). After the protein concentration was determined by the Bradford method using bovine serum albumin as a standard, desalted protein was lyophilised. The lyophilised protein was dissolved in 8 M urea (Wako, Japan) + 2% 3-[(3-cholamidopropyl) dimethylammonio] propanesulfonic acid (CHAPS) (Dojindo Laboratories, Japan) solution containing 0.28% dithiothreitol (Wako, Japan). Subsequently, the protein solution was applied to IPG dry strips pI 3–10 or 4–7 or 6–9 (GE Healthcare Bioscience, Japan). 2DE and silver staining were carried out according to Okada et al. (2008).

2.4. Mass spectrometry analysis

The protein spots were excised from the gels and decolorised by a solution containing 15 mM potassium ferricyanide and 50 mM sodium thiosulphate. Sample gels were treated for in gel reduction using dithiothreitol and S-alkylation using monoiodoacetic acid. After adding ammonium hydrogencarbonate buffer containing trypsin, sample gels were incubated for 4 h at 37 °C. The resultant sample solution was desalted using Zip-Tip (Nihon Millipore Ltd., Japan), and eluted with 80% acetonitrile. The sample was analysed using matrix-assisted laser desorption ionisation time-of-flight mass spectrometry (MALDI-TOF-MS) using Voyager-DE STR (Applied Biosystems, USA). Internal mass was calibrated using trypsin autolysis products. Protein species were identified by peptide mass fingerprinting (PMF) on the non-redundant amino acid database of the National Center for Biotechnology Information (NCBI-nr) using the MASCOT search engine (Perkins, Pappin, Creasy, & Cottrell, 1999). The following parameters were used for searches in MASCOT. Database: NCBInr; Taxonomy: all entries, enzyme: trypsin, number of missed cleavages: up to 1 missed cleavage, fixed modification: carbamidometyl cysteine, variable modification: oxidation of methionine, peptide tolerance: below 50 ppm, mass values: MH+. The protein was considered as a positive candidate when it satisfied all of the following three criteria, (1) significant MASCOT score ($P < 0.05$), (2) more than four peptides matched and (3) sequence coverage of more than 15%. When candidate was not identified in NCBI-nr, barley gene index (http://compbio.dfci.harvard.edu/tgi/), HarvEST #31 (http://harvest.ucr.edu/) and mass spectrometry protein sequence database (MSDB) (http://proteomics.leeds.ac.uk/bioinf/msdb.html) were searched under the same conditions to attempt protein identification. When a protein was not identified by PMF analysis using trypsin as proteinase, the sample was double digested by trypsin and lysil endopeptidase. The decolorised sample gel was treated with a Tris–HCl buffer (pH 8.0) containing lysil endopeptidase and incubated for 3 h at 35 °C. After adding trypsin, the sample was incubated for 20 h at 35 °C. Subsequently, the samples were analysed by liquid chromatography mass spectrometry/mass spectrometry (LC-MS/MS) by following conditions. The sample solution was ap-

plied to LC-MS/MS as follows. Equipment: MAGIC 2002 (Michrom BioResources Inc., USA), column: MAGIC C18 (0.1 × 150 mm, Michrom BioResources Inc.), mobile phase: 2% acetonitrile + 0.1% formic acid, and 90% acetonitrile + 0.1% formic acid, flow rate: 250–300 nL/min, mass spectrometer: Q-Tof2 (Micromass, UK), ionisation method: Nanoflow-LC ESI, ionisation mode: positive mode, electric potential of capillary: 1.8 kV, collision energy: 20–56 eV. In order to identify protein species, NCBI-nr was searched by resultant values of product ion from all precursor ions using MASCOT search engine.

3. Results

3.1. Identification of major beer proteins on the 2DE gels

Proteins in standard beer samples (i.e., Beer F(L)), were separated by 2DE (pI 4–7 and 6–9) (Fig. 1) and individual protein spots were analysed by MALDI-TOF-MS or LC-MS/MS followed by database searches to determine spot identity. The search engines identified 85 out of 199 protein spots which were categorised into 12 protein species (Table 2). According to the source of sequences

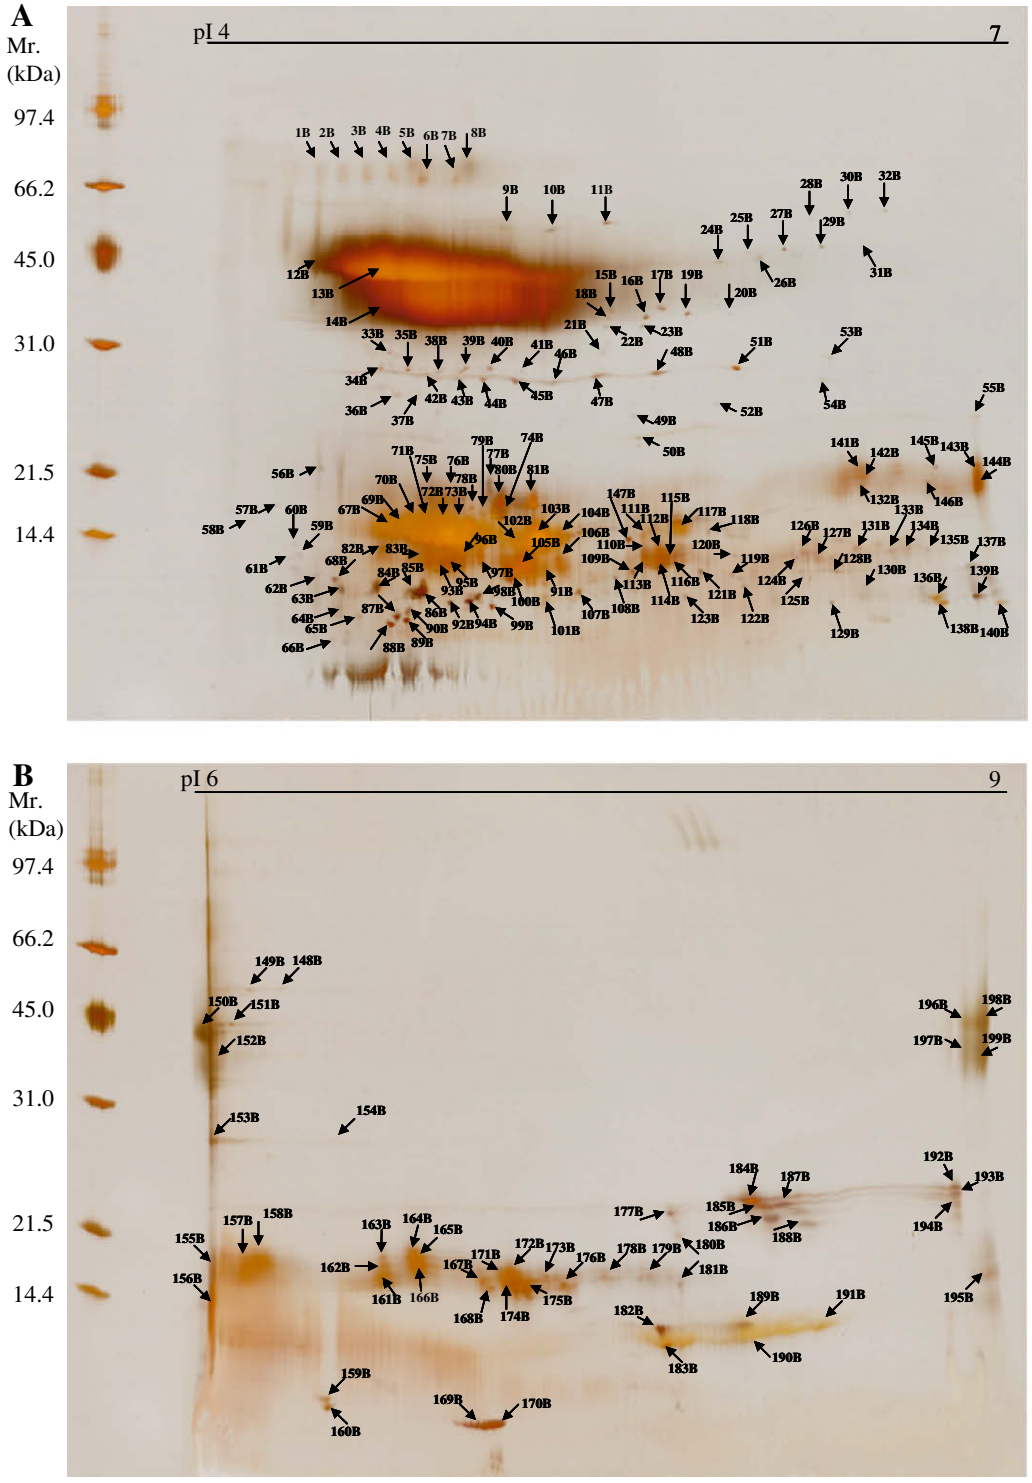

Fig. 1. Two-dimensional gel electrophoresis (2DE) images of proteins of Beer F(L). (A) 2DE image of pI 4–7, (B) 2DE image of pI 6–9. Arrows indicate spot numbers in Table 2.

In B and C, arrows indicate the protein spots of enolase, and in D and E arrows indicate the protein spots of TPI.

on the databases, 8 out of the 12 protein species were derived from *Hordeum vulgare* subsp. *vulgare* and the remaining four proteins were derived from *Saccharomyces cerevisiae*.

3.2. The contribution of barley cultivars on beer proteins

To estimate differences of the beer protein composition among barley cultivars, we processed five beer samples from cultivars A–E (Table 1). The beer proteins were separated by 2DE and their images were compared (Figs. 2 and 3). Major differences were observed in gel Regions 1–3 (Fig. 2A).

The spot intensities of these three Regions in the five beer samples are summarised in Table 3. As shown in Fig. 1 and Table 2, Regions 1 and 2 contained the *S. cerevisiae* protein spots of enolase and triose phosphate isomerase (TPI), respectively. Among five beer samples, the spots of yeast enolase (at Region 1) in Beer E were intense compared to the other four samples (Fig. 2B and Table 3). On the other hand, these spots were not observed in Beer B. Spots of TPI (at Region 2) in Beers B and E were less intense than the others (Fig. 2D and Table 3).

In Region 3, five protein species were identified (Fig. 3A). The protein spots were not detectable in Beer F(L) but were detectable in Beer H(L), to allow identification by mass spectrometry analysis (Fig. 3B). The spot of yeast thioredoxin (y-TRX2p) in Beer D was less intense than the others (Fig. 3C and Table 3). In Beer A, the spot intensities of alpha amylase/trypsin inhibitor CMb precursor (CMb) were more intense than the others. Comparatively, the spot of lipid transfer protein 1 (LTP1) in Beer A was relatively low. The spot of LTP1 on Beer E was the most intense among the five beer samples.

3.3. The influence of malt modification levels on beer proteins

Malt modification can be influenced by increasing the ex-steep moisture during malting. Beers were brewed from cultivars F, G and H with low (36–37%) or high (43–44%) levels of ex-steep moisture. Low ex-steep moisture resulted in relatively low KI/modification while high ex-steep moistures provided malt with relatively high KI/modification. The 2DE images of the beer proteins made from these malts were compared to detect interactions between cultivar and malt modification levels on beer protein composition. As expected the spot intensities of proteins derived from yeast were almost constant in all three cultivars despite the level of malt modification being changed, although some changes in the level of enolase in Beer G and y-TRX2p in Beer H was observed (Figs. 2 and 3). In Beers F(L) and F(H), spot intensities of barley proteins TAI, CMb and LTP1 were lower at the higher malt modification level. However, these spot intensities were unchanged in Beers H(L) and H(H) at both malt modification levels. In addition, in Beers H(L) and H(H), the spot intensities of barley dimeric α-amylase inhibitor-1 (BDAI-1) were almost constant at both malt modification levels. On the other hand, they were lower in beers made from the more modified malts for Beers G(L) and G(H) and faint in both Beers F(L) and F(H).

4. Discussion

A total of 85 protein spots on 2DE gels (Fig. 1 and Table 2) together with data set for the 2DE images were identified in the current proteome analysis. Perrocheau et al. (2005) also analysed beer proteins by 2DE and mass spectrometry but resulted in identification of only 31 protein spots. Hao et al. (2006) identified major proteins in beer foam by mass spectrometry following sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS–PAGE), which made protein composition comparison difficult between samples. Thus, we assume the data set in current protein analysis as one of the most comprehensive beer proteome maps yet to be made.

Multiple proteomic locations for beer proteins were observed for protein Z4, LTP1, BDAI-1, and triose phosphate isomerase from

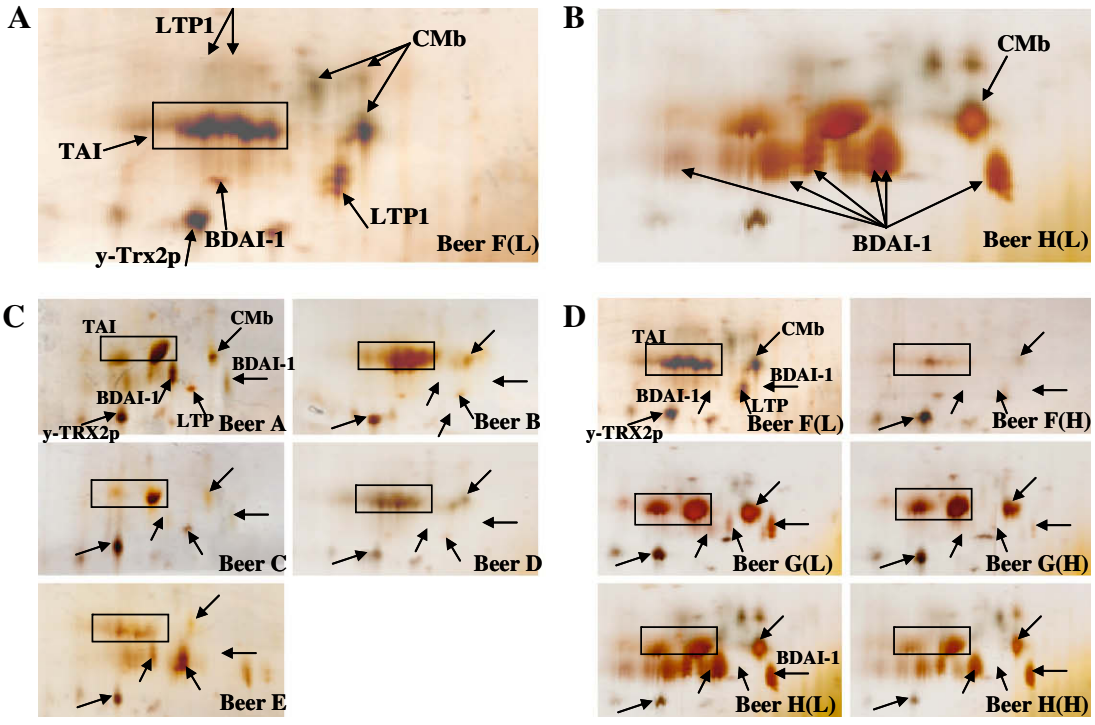

Fig. 3. The differences of two-dimensional gel electrophoresis (2DE) images on Region 3 (see Fig. 2A). (A) The 2DE image of proteins in Beer F(L). (B) The 2DE image of proteins in Beer H(L). (C) 2DE images of the beers brewed from each five cultivars. (D) 2DE images of the beers from each three cultivars with low(L) or high(H) malt modifications. The squares indicate the spot region of TAI.

yeast (Fig. 1 and Table 2). For the barley proteins it is known that for each protein there is only one or a small number of barley genes from which these proteins are transcribed. Therefore, electrophoretic mobility of these beer proteins is assumed to be the result of various relatively minor protein modifications such as reduction of disulphide bonds, partial proteolytic cleavage, glycosylation and phosphorylation. These protein modifications have important implications for the properties of these proteins with respect to the beer quality properties that they influence. LTP1, in particular has been well studied with respect to these modifications (Perrocheau, Bakan, Boivin, & Marion, 2006; van Nierop, Evans, Axcell, Cantrell, & Rautenbach, 2004). In future work, beer quality related proteins such as protein Z4 and BDAI-1 will be more intensively studied to better understand the implications for modifications that occur during the malting and brewing processes.

The present beer proteome map shows eight species of barley proteins, which includes protein Z-type serpin (protein Z4), serpin-Z7 (protein Z7), BDAI-1, CMb, LTP1, TAI, BTI-CMe and subtilisin-chymotrypsin inhibitor CI-1B. These beer proteins mostly have inhibitory properties such as protease or amylase inhibitors except LPT1 which may also have antimicrobial properties (Kader, 1996). These beer proteins survive the malting and brewing process relatively intact, retaining their apparent molecular weight as well as their immunochemical identity (Hejgaard, 1977; Kaersgaard & Hejgaard, 1979; Sorensen et al., 1993). As shown in Fig. 3 and Table 3, it has been suggested that the beer protein composition and level is substantially dependent on barley cultivar and level of malt modification.

Recent studies have shown that BDAI-1 may be a foam-promoting protein (Iimure et al., 2008; Okada et al., 2008). Among five beer samples from the five cultivars, the spot intensities of beer BDAI-1 were invisible in Beers B–D that had lower foam stability (NIBEM = 226–232 s), compared to Beers A and E which had higher levels of BDAI-1 and higher foam stability (NIBEM = 247–258 s) (Table 3). Significantly in cultivar H (higher foam stability at both lower and higher malt modification), the spot intensities of BDAI-1 were not changed by malt modification conditions. In comparison the spot intensities of BDAI-1 were invisible in Beer F(L) in spite of the highest foam stability. This is perhaps not surprising as beer foam stability cannot be explained by a single protein in isolation but combination of proteins and by several processing factors (Evans & Bamforth, 2008; Iimure et al., 2008). Although beer foam stability was not completely explained by only BDAI-1, these data support the hypothesis that BDAI-1 is a foam-promoting protein (Iimure et al., 2008).

The spot intensity of LTP1, long identified as foam-promoting protein (Sorensen et al., 1993), was more intense in Beer E that had higher foam stability (NIBEM = 247 s) (Table 3). However, the spot for LTP1 in Beer A (higher foam stability: NIBEM = 258 s) was relatively low. The contribution of LTP1 to foam stability depends on its modification and conformation (Perrocheau et al., 2006; van Nierop et al., 2004). During the kettle boil, LTP1 is irreversibly denatured, which substantially reduces its immuno-reactivity to the barley LTP1 antibodies (Bech, Vaag, Heinemann, & Breddam, 1995; Lusk, Goldstein, & Ryder, 1995), but improves its foam-promoting properties (Bech et al., 1995; Lusk et al., 1995; Sorensen et al., 1993). Conversely, van Nierop et al. (2004) observed that increased denaturation of LTP1 by boiling could in fact be detrimental to foam stability due to the reduced ability of denatured LTP1 to bind foam destabilizing lipids. Where the level of lipids in beer was low or the level of LTP1 was high there was little impact on beer foam stability; however, where the level in beer of LTP1 was low, and the level of lipids high, substantial reductions in foam stability were observed. The observations of this study imply that LTP1 with acidic pI has relatively low foam stabilizing properties. In addition, there were 30 LTP1 spots identified at both acidic and basic pI (Fig. 1 and Table 2). The protein spots of LTP1 on the basic side were not comparable between samples due to their relatively poor resolution. Because of difficulties to compare beer LTP1 concentrations by only one LTP1 spot in Region 3, our results could not confirm that LTP1 is foam-positive. Thus, a more reliable detection system, e.g., LTP1 specific antibody, is required to further investigate the relationship between LTP1 and foam stability.

Recently it was observed that CMb, CMe and BDAI-1 were not major haze active proteins but were factors promoting haze formation (Iimure et al., 2009). As shown in Table 1, FT-3 in Beer D was the highest (most hazy) among the beers produced in this study. However, in Beer D, CMb was relatively low and BDAI-1 was invisible (Fig. 3C and Table 3). Similarly, spot intensities of CMb and BDAI-1 were relatively low or invisible in beer samples with higher FT-3 (Beers B and C). These results confirmed that CMb and BDAI-1 are not predominant haze active proteins. However, in our previ-

ous paper, CMb, CMe and BDAI-1 were contained in all four haze samples examined; therefore CMb, CMe and BDAI-1 may be factors promoting haze formation, actually being concentrated in the haze particles being formed (Iimure et al., 2009). In this study, a protein spot directly corresponding to haze stability was not observed in the beer samples. Accordingly, no haze active or predominant protein was detected by the 2DE analysis. It is suggested that beer protein contents may depend not only on the barley cultivar of origin, but also proteolytic activity during malting and mashing (Kihara et al., 2002). Therefore, to improve the levels of foam-positive proteins, i.e., BDAI-1, and to decrease the proteins promoting haze formation, i.e., CMb and CMe, it is important that relationship between protein and malt protease activity is better understood.

Four species of yeast proteins, enolase, TPI, y-TRX2p and yeast phosphorelay protein Ypd1 were identified in Beer F(L) (Fig. 1 and Table 2). The contributions of yeast enolase, TPI and yeast phosphorelay protein Ypd1 to beer quality is not unknown at present. y-TRX2p is reported as an intracellular protein (Gan, 1991; Pedrajas et al., 1999). Generally, glycolytic enzymes including enolase and TPI are cytoplasmic, but it was reported that several glycolytic enzymes locate at cell surfaces (López-Villar et al., 2006). In this study, these three yeast proteins were identified in beer. Perrocheau et al. (2005) also identified enolase and TPI in beer. These results suggest that yeast cells were damaged during brewing, resulting in release of these yeast proteins to beer. On the other hand, there were no obvious accordance for spot intensity levels in enolase, TPI and y-TRX2p (Table 3). For example enolase was not detected but y-TRX2p was distinct in Beer B. On the other hand, enolase and TPI were distinct, although y-TRX2p was relatively low in Beer H(H). If these three yeast proteins in beer are dependent on only cell damage, the spot intensities of these proteins should be correlated with each other. Therefore, these protein concentrations in beer might depend not only on the yeast cell damage but also the expression level of the proteins. Since y-TRX2p is upregulated under oxidative stress (Kuge & Jones, 1994), levels of these proteins might relate to the stresses exposure in yeast cells during brewing processes. It has been suggested that the physiological condition of yeast cells influences several quality traits including foam stability (Dreyer, Biedermann, & Ottesen, 1983) and flavour stability (Guido, Rodrigues, Rodrigues, Gonçalves, & Barros, 2004). However, evaluation methods for physiological conditions of yeast cells are not well established even there are several methods such as the acidification power test (Fernandez, Gonzalez, & Sierra, 1991) and flow cytometry analysis (Hutter, 2002). If the relationships between each yeast protein such as enolase, TPI and y-TRX2p and the level of stress conditions on yeast cells are confirmed, these proteins may become excellent markers to monitor the brewing process.

Among four yeast proteins, y-TRX2p was suggested as a foam-negative protein (or indicator) (Iimure et al., 2008). In Beer H(H) (higher foam stability), the spot intensity of y-TRX2p was lower than the other beer samples (Fig. 3D and Table 3). However, y-TRX2p in Beer D (lower foam stability) was also low. As described by Iimure et al. (2008), foam stability may not be controlled by a single protein, but by a combination of a number of factors such as protein Z, BDAI-1 and y-TRX2p. In addition, it has been shown that the extent of LTP1 denaturation has important consequences for foam stability if the levels of foam destabilizing lipids are relatively high (van Nierop et al., 2004). Hop iso-α-acids isomerised from α-acids during wort boiling play important roles for beer bitter taste. Beer bitterness unit derived from hop iso-α-acids is also an important factor for beer foam stability (Evans, Surrel, Sheehy, Stewart, & Robinson, 2008; Kunimune & Shellhammer, 2008). Accordingly, the lower foam stability in Beer D could result from the lower beer BDAI-1 and beer bitterness unit (Tables 1 and 3) or higher levels of lipid in the beer which was beyond the scope of this study. Therefore, if the beer bitterness unit and/or BDAI-1 were higher, the beer foam stability could be improved by a synergetic effect with lower y-TRX2p.

Overall, the current comprehensive beer proteome map provides a strong detection platform for the behaviours of beer quality related proteins. For instance, foam stability is a useful beer quality target whose level could be manipulated using the procedures applied in this report. The nucleotide and amino acid sequences defined by the protein identification in the beer proteome map may have advantages for barley breeding and process control for beer brewing. The nucleotide sequences also give us access to DNA markers in barley breeding by detecting sequence polymorphisms. As such, DNA markers of such target proteins could be applied to selection of barley lines to optimise the level of these proteins in future barley malting cultivars with higher brewing quality. Additionally, the amino acid sequences from both barley and yeast can supply control methods during the brewing processes to potentially enable monitoring of protein expression levels. Further development of efficient and rapid (real time) techniques for protein detection in the commercial brewing industry are expected to maximise the use of the beer proteome map developed in this investigation.

Quantification

ABSTRACT

Indirect enzyme-linked immunosorbent assays (ELISA) technique was used to identify and quantify the use of dried egg white (DEW) and whey protein concentrate (WPC) in crabsticks. The use of SDS–PAGE for the quantification of protein additives has had limited success due to the high shear and high temperature processes of surimi crabstick. Monoclonal (anti-heat-denatured ovalbumin) and polyclonal (anti-β-lactoglobulin) antibodies were used. Antibodies showed no significant cross-reactivity with non-target crabstick proteins. An optimised extraction solution of 10% SDS and 2.5% 2-ME yielded high extractability with improved consistency. Quantification of DEW and WPC was achieved using the optimised extraction solution and indirect ELISA. Estimated DEW values were within 7% of actual values, WPC samples were within 17%. Inter-assay coefficients of variance for DEW ranged from 0.9% to 3.1% and those of the WPC were 1.0–8.0%.

1. Introduction

The crabstick industry does not have a standard of identity established for protein additives such as dried egg white (DEW) and whey protein concentrate (WPC). A lack of standard of identities can lead to increased use and/or abuse of protein additives in the crabstick formulation, which decreases surimi quantity and correlates to lower quality product if the usage is not properly optimised. Surimi refers to refined fish myofibrillar proteins used as an intermediate product in many seafood flavoured products. Surimi is produced through heading, gutting, mincing, washing, dewatering and concentrating the fish myofibrillar proteins (Lee, 1984; Park & Lin, 2005). The concentrated myofibrillar protein is mixed with cryoprotectants such as sugar, sorbitol, and polyphosphates which serve to stabilize the fish myofibrillar protein during frozen storage (Park & Lanier, 1987; Park, Lanier, & Green, 1988). Surimi is comminuted with other ingredients such as starch, DEW, WPC, and other flavours in the production of crab-flavoured seafood (crabsticks). DEW has been used extensively as a functional food ingredient because of its gelling and foaming properties (Mine, 1995). β-Lactoglobulin (β-LG) is largely responsible for the physicochemical properties as well as the functional behaviour of food products that contain whey protein (Foegeding, Davis, Doucet, & McGuffey, 2002). Burgarella, Lanier, Hamann, and Wu (1985) showed that DEW and WPC can be used in low concentrations to provide an additive effect of increased gel strength and deformability.

One method used to quantify protein additives in crabstick is SDS–PAGE coupled with gel densitometry (Reed & Park, 2008). We found that SDS–PAGE was useful for detection of DEW but was not appropriate for the quantification of DEW. Enzyme-linked immunosorbent assays (ELISA) take advantage of the interaction between proteins and antibodies and can be used to qualify and quantify protein additives in food. Commercial ELISA kits are available for the detection of egg, milk, wheat, buckwheat, and peanut proteins. It is mandatory for these five allergens to be labelled in Japan (Matsuda et al., 2006) and in most countries including United States. Due to the severity of some food allergies the use of ELISA has become widespread for detection of allergenic proteins (Faeste, Egaas, Lindvik, & Lovberg, 2007; Fuller, Goodwin, & Morris, 2006). ELISA has also been shown to be effective in quantifying egg white in processed pork products (Leduc et al., 1999). Dupont et al. (2006) have developed an ELISA for bovine lactoferrin to determine lactoferrin concentrations in milk, whey, and cheese. Ovalbumin (OA) is the most abundant of egg white proteins, comprising 54% of the total proteins (Stevens, 1991). Of the whey proteins in bovine milk, β-lactoglobulin (β-LG) is the most abundant (Farrell et al., 2004).

Extraction of protein from the cooked gel sample is one of the most critical steps in obtaining a clean and reproducible ELISA assay. Commonly, Tris-buffered saline (TBS) and phosphate buffered saline (PBS) have been used to extract protein from the sample matrix. Asensio et al. (2003) used 0.85% saline solution to extract proteins from grouper, wreck fish and Nile perch fillets. Hefle, Jeanniton, and Taylor (2001) used PBS to extract proteins from pasta for the detection of egg residues in food, while Holden, Fæste,

doi:10.1016/j.foodchem.2009.05.023

and Egaas (2005) used 0.1 M Tris, 0.5 M glycine at pH 8.7 for the extraction of lupine from several baked goods. Preliminary studies revealed that, when crabstick samples were extracted with PBS alone either overnight at room temperature or at 90 °C for an hour, results were not reproducible. Due to the strong gel matrix of high protein content, different extraction methods were investigated.

Watanabe et al. (2005) investigated the use of an extraction solution containing sodium dodecyl sulphate (SDS) and 2-mercaptoethanol (2-ME) for the detection of raw and processed egg. In their study they found the total protein extracted using TBS could be increased 10–100-fold with the addition of 1% SDS and 7% 2-ME to the TBS extraction solution. Ochiai and Watabe (2003) found that using an extraction solution of urea, SDS, and 2-ME, allowed for species identification of processed fish products.

The overall goal of this study was to develop an indirect ELISA assay for the qualification and quantification of dried egg white and whey protein concentrate when used as an additive to a cooked and pasteurised crabstick product. In addition, we attempted to develop an optimised extraction method for fish protein gels with strong texture.

2. Materials and methods

2.1. Food products and chemicals

Alaska pollock (*Theragra chalcogramma*) surimi (FA grade, 10 kg blocks), were obtained from Western Alaska Fisheries (Seattle, Wash., USA) and stored frozen at −18 °C. The 10 kg blocks were cut into approximately twenty 1 kg blocks, individually vacuum packed, and stored at −18 °C until used for surimi crabstick paste preparation. Ingredients used for surimi crabstick paste preparation were NaCl (Morton Iodised Salt, Morton International, Inc., Chicago, Ill., USA), corn starch (Corn Products International, Westchester, Ill., USA), wheat starch (Midsol 50, MGP Ingredients, Inc., Atchison, Kans., USA), modified waxy maize starch (Polartex 06727, Cargill, Inc., Cedar Rapids, Iowa, USA), sugar (used to represent all flavour components) (Pure Cane Sugar, C&H Sugar Company, Inc., Crockett, Calif., USA), and culinary tap water. The protein additives were dried egg white (DEW) (K-200, Henningsen Foods, Omaha, Nebr., USA) and whey protein concentrate (WPC 8600, Hilmar Ingredients, Hilmar, Calif., USA). All other chemicals were reagent grade.

2.2. Antibodies

Affinity purified rabbit polyclonal antibodies produced against bovine β-lactoglobulin (pAb anti-β-LG) and goat anti-mouse IgG coupled with horse radish peroxidase (HRP-anti-mIgG) were obtained from Bethyl Laboratories (Montgomery, Tex., USA). Mouse monoclonal antibodies against heat denatured hen ovalbumin (Ab anti-H-OA) were purchased from Abcam, Inc. (Cambridge, Mass., USA). Goat anti-rabbit IgG coupled with HRP (HRP-anti-rIgG) was purchased from Sigma–Aldrich, Inc. (St. Louis, Mo., USA). All antibodies were delivered at a concentration of 1 mg/mL. Antibodies were tested against a serial dilution of purified ovalbumin (OA) or β-lactoglobulin (β-LG) which produced a linear response. The antibodies were also tested against crabsticks. When tested against crabsticks, antibodies showed no reactivity with proteins other than the target protein.

2.3. Sample preparation

2.3.1. Basic surimi paste batches

Crabsticks were made with base ingredients including: surimi (40%), water (45%), salt (2%), starches (8%), and sugar (5%). Three formulations for crabstick were made containing base ingredients and protein additives such as DEW only, WPC only, and 50/50 mixture of DEW/WPC. For each of the three formulations a total of nine batches per formulation were made. Six standard batches containing various protein additives were made (0.00%, 0.25%, 0.50%, 1.00%, 1.50%, and 2.00% protein additives). Three additional verification batches were also made (0.375%, 0.750%, and 1.750% protein additives). For batches with protein additives, starch was replaced in a 1:1 ratio (w/w) by protein additive resulting in an equal moisture concentration of approximately 75%. Final batch sizes were approximately 1300 g. Frozen surimi was allowed to thaw at room temperature (≈23 °C) for approximately 1 h and then cut into small pieces. All chopping was performed using a Stephan vertical vacuum cutter (model UM 5 universal, Stephan Machinery Co., Columbus, Ohio, USA). Surimi pieces were added to the chopping bowl and chopped at 1800 rpm for 1 min. Salt (26 g) was then added to the chopped surimi and chopping continued at 1800 rpm for 1 min. Following the integration of the salt, 65 g of sugar was added in addition to starch (50:40:10 corn:wheat:modified waxy maize), protein additive when required, and water followed by chopping at 1800 rpm for 1 min. A vacuum of 40–60 kPa was applied to the surimi paste and chopping continued for 3 min at 3000 rpm. Surimi paste was then placed in a plastic bag and refrigerated until samples were cooked.

Approximately 20–25 g of labelled surimi paste was placed into a sheet mould (stainless steel 25 cm × 7.5 cm × 1.4 mm) formed on top of a piece of aluminium foil, which had been sprayed with no-stick cooking spray (Pam® Original, ConAgra Foods, Inc., Omaha, Nebr., USA). Excess raw surimi paste was vacuum packed and frozen at −80 °C. Food grade plastic film was laid over the top of the paste and a stainless steel tube roller (11.5 cm × 4 cm dia.) was used to evenly spread out the paste to form a crabstick sheet. After the film was removed the aluminium foil containing the crabstick sheet was cooked in a steam bath (93 °C) for 90 s. After initial cooking, crabstick sheets were cut in half, wrapped in plastic film and then placed back in the 93 °C steam bath for 30 min to simulate commercial pasteurisation. Pasteurised samples were submerged in ice water to cool for 15 min. If samples were not to be used within 48 h they were frozen at −80 °C until needed.

For the verification process, three batches per formulation were made (0.375%, 0.75%, and 1.75% protein additive) and the protein concentrations were estimated using the linear equation produced from the five standard batches (0.25%, 0.50%, 1.00%, 1.50%, and 2.00% protein additives). Using Microsoft Excel software the standard curves were obtained by plotting the absorbance at 450 nm vs the protein additive concentrations of 0.25%, 0.50%, 1.00%, 1.50%, and 2.00%. The standard curve was fitted to a linear equation ($y = mx + b$), where y = absorbance at 450 nm, m = slope of the line, x = protein additive %, and b = intercept of the line. Calculation of the verification samples were given by the following equation: $x = (y - b)/m$.

2.4. Optimised sample extraction

During our preliminary experiments, we realised the optimisation of the extraction solution was extremely important to obtain consistent data. In a preliminary optimisation step 25 extraction solutions were tested. Extraction solutions contained various levels of SDS (2.5%, 5%, and 7.5% w/v), Tween 20 (0.05%, 0.075%, and 0.1% v/v) and 2-ME (5%, 7.5%, and 10% v/v). All extraction solutions were incubated for 1, 2, or 3 h at 90 °C (results not shown). A final optimised extraction protocol was achieved using 10% SDS w/v and 2.5% 2-ME v/v. Tween 20 was determined to have no significant effect on the extraction of the protein from the crabstick samples. This may be due to the much more substantial amount of SDS used as both are detergents. Samples used for the standard curve pro-

duced a linear response which then allowed for the estimation of the DEW and WPC content of the verification batches.

Approximately 2 g of sample was accurately weighed into a 50 mL centrifuge tube and 20 mL of solution containing 10% SDS and 2.5% 2-ME was added. Samples were homogenised for 1 min at speed 4 (Powergen 700, Fisher Scientific, Pittsburgh, Pa., USA) followed by extraction for 1 h at 90 °C. Extracted samples were centrifuged at 7796*g* (Sorvall RC-5B, DuPont Co., Newton, Conn., USA) for 20 min. The supernatant was filtered (70 mm dia. # 541, Whatman International Ltd., Maidstone, UK) into a 25 mL volumetric flask and brought to volume using additional 10% SDS and 2.5% 2-ME solution.

2.5. Indirect ELISA

Ovalbumin (OA) from chicken egg white, grade VI (Sigma–Aldrich, Inc., St. Louis, Mo., USA) and β-lactoglobulin (β-LG) from bovine milk (Sigma–Aldrich, Inc., St. Louis, Mo., USA) were serially diluted using PBS, containing 137 mM NaCl, 2.7 mM KCl, 10 mM phosphate buffer (Omnipur 10× PBS Concentrate, EMD Chemicals, Inc., Gibbstown, NJ, USA) and assayed in both the OA and β-LG ELISA checking for linearity and cross-reactivity. OA and β-LG were solubilised in 5% SDS (w/v) and heated at 90 °C for 1 h. Total protein content was determined using the Lowry method (Lowry, Rosebrough, Farr, & Randall, 1951). Samples were serially diluted with PBS to 25 ng/mL and tested in triplicate. Indirect ELISA results were given as the average of the three serial dilutions.

Crabstick samples were serially diluted in PBS to a final dilution of 1:10,000. Polystyrene 96 well microtiter plates (Nalge Nunc International, Rochester, NY, USA) were coated with 100 μL of serially diluted samples (6 wells/sample) and were incubated overnight at 4 °C. The plates were washed three times with PBS containing 0.5% (v/v) Tween 20 (PBS-T) and blocked with 100 μL of Superblock® blocking buffer in PBS with 0.05% Tween 20 (Thermo Scientific, Rockford, Ill., USA) at 37 °C for 30 min. After the plates were washed three times with PBS-T, 100 μL of diluted (1:5000, 1 mg/mL) Ab anti-H-OA or pAb anti-β-LG antibodies were added to the wells and incubated at 37 °C for 1 h. After three PBS-T wash cycles, 100 μL of diluted (1:5000, 1 mg/mL) HRP-anti-mIgG when detecting Ab anti-H-OA and HRP-anti-rIgG when detecting pAb anti-β-LG were added to each well and incubated at 37 °C for 30 min. Plates were washed three times using PBS-T after which 100 μL of 3,3′,5,5′-tetramethylbenzidine, 1-Step Ultra TMB ELISA (Thermo Scientific, Rockford, Ill., USA) was added and allowed to develop for 8 or 12 min at room temperature, for the DEW and WPC samples, respectively. Colour development was stopped by the addition of 100 μL of 2 N sulphuric acid per well. The plate was read at 450 nm using a Biolog Microlog (Biolog, Hayward, Calif., USA).

2.6. Immunoblotting

SDS–PAGE was performed as outlined by Laemmli (1970) using a 12.5% (% T) separating gel and a 4% (% T) stacking gel. The crabstick samples used for SDS–PAGE and immunoblotting contained both DEW and WPC. A 0.5 mL aliquot of extracted sample, that was used for the indirect ELISA, was mixed with 0.5 mL of Laemmli sample buffer (0.6 mL 1 M Tris–HCl (pH 6.8), 5.0 mL glycerol, 2.0 mL 10% (w/v) SDS, 0.5 mL 2-ME, 1.0 mL 1% (w/v) bromophenol blue, 0.9 mL H_2O). Sample and buffer were vortexed and then heated for 3 min at 90 °C to disrupt any disulphide bonds. Samples were separated using a Mini-Protean III Cell (Bio-Rad, Hercules, Calif., USA) according to the operating manual.

After electrophoresis the gels were removed and equilibrated in Towbin solution (25 mM Tris, 192 mM glycine, 20% methanol (v/v) at pH 8.3) for 20 min and transferred to a nitrocellulose membrane (Bio-Rad, Hercules, Calif., USA) using a Mini Trans-Blot® Electrophoretic Transfer Cell (Bio-Rad, Hercules, Calif., USA) using a slight modification of an earlier published method (Towbin, Staehelin, & Gordon, 1979). The membrane was blocked using Superblock® blocking buffer in PBS with 0.05% Tween 20 (Thermo Scientific, Rockford, Ill., USA) for 30 min at 25 °C. The blocked membrane was washed three times for 5 min using PBS-T. The membrane was incubated with either Ab anti-H-OA or pAb anti-β-LG (1:15,000) for 60 min at 25 °C after which the membrane was washed three times. The membrane was incubated with HRP-anti-mIgG when detecting Ab anti-H-OA and was incubated with HRP-anti-rIgG when detecting pAb anti-β-LG antibodies (1:15,000) at 25 °C for 60 min followed by three additional wash cycles. Bands were visualised using 1-Step™ TMB-Blotting (Thermo Scientific, Rockford, Ill., USA). Development was stopped by the addition of dd water. Molecular weight was determined by comparison to the Kaleidoscope™ protein standard (Bio-Rad, Hercules, Calif., USA) also run in each SDS–PAGE.

2.7. Statistical methods

For determination of the inter-assay precision, the mean coefficients of variation (CV) were based on three extractions performed on separate days. Each day an extraction was performed and the extract was assayed in triplicate on the same day. All calculations were done using Microsoft Excel (Microsoft Corporation, Redmond, Wash., USA). Each assay contained six replicates of each sample. The lower limit of detection (LLD) for the indirect assay was given as three times the standard deviation plus the background of blank wells. The lower limit of quantification (LLQ) was taken to be the lowest point (0.25% protein additive) of the standard curve.

3. Results and discussion

3.1. Optimised sample extraction

Extracting the proteins with 10% SDS and 2.5% 2-ME for 1 h at 90 °C was found to be the optimum condition yielding reproducible and reliable data for the ELISA assay. Fig. 1 shows the increased accuracy and decreased variation obtained when the optimised extraction solution was used. The calculated protein was determined using the standard curve created from the standard crabstick batches. In Fig. 1A, it is shown that the calculated % protein for DEW (calculated protein divided by protein added) ranges from 91.5% to 120.1% for the pre-optimised extraction solution (1% SDS (w/v) and 5% 2-ME (w/v)). It is our opinion that the addition of SDS and 2-ME was successful in disrupting the bonds formed during gelation. The gel matrix formed during the cooking of the crabsticks is believed to have caused steric hindrance during adsorption onto the ELISA plate. Due to the steric hindrance, some of the antibody epitopes were not available for interaction with the antibody. For the optimised extraction solution the range narrows to 100.0–101.7%. The standard deviation for the pre-optimised solution ranged from 4.6% to 24.0% and that of the optimised solution was 4.0–6.3%. The WPC extraction optimisation showed a similar trend. The pre-optimised calculated % protein ranged from 85.9% to 134.4% with a standard deviation range of 5.7–40.0%. The calculated % protein for WPC using the optimised extraction solution ranged from 95.6% to 116.7% with a standard deviation ranging from 1.7% to 11.4%.

3.2. Reactivity testing and immunoblotting

Purified OA and β-LG proteins were examined for reactivity and cross-reactivity with the Ab anti-H-OA and pAb anti-β-LG. In

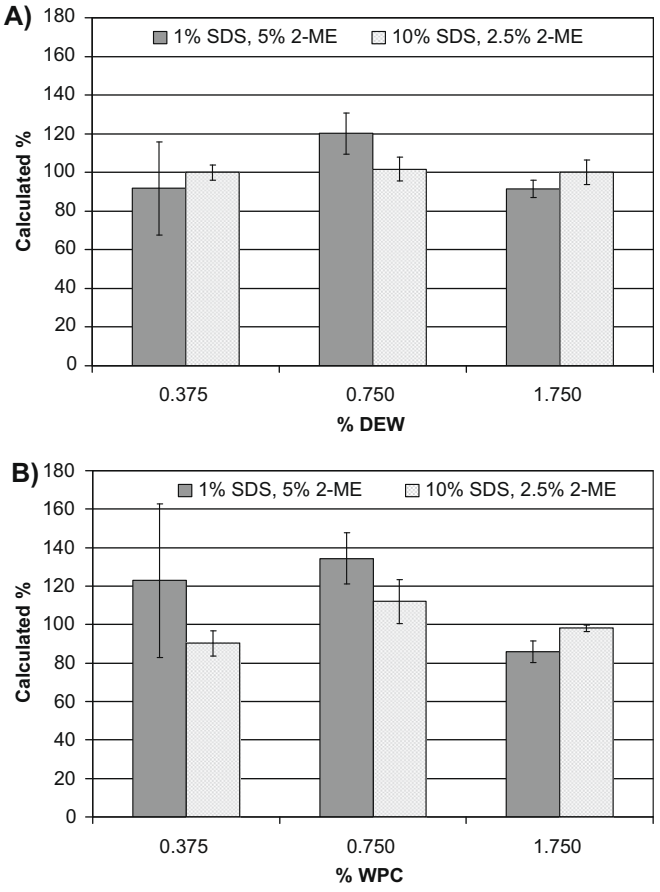

Fig. 1. Protein extraction using pre-optimised solution (1% SDS and 5% 2-ME) and optimised solution (10% SDS and 2.5% 2-ME) (A) crabstick containing DEW (B) crabstick containing WPC. The calculated protein was determined using the standard curve created from the standard crabstick batches.

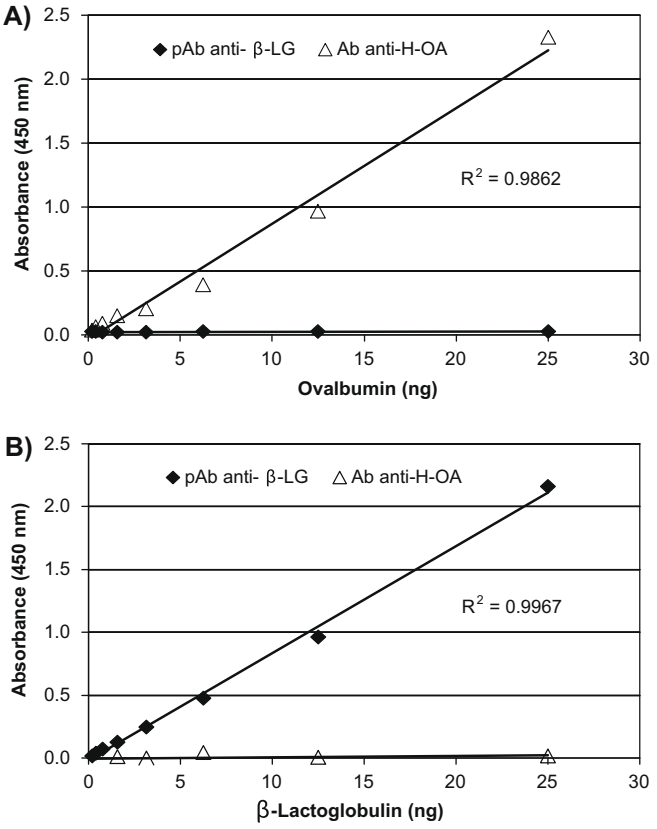

Fig. 2. Linear response of Ab anti-H-OA (A) and pAb anti-β-LG (B) tested against ovalbumin and β-lactoglobulin.

Fig. 2A, there is a linear response for OA passively absorbed to the microtiter plate and incubated with Ab anti-H-OA, while virtually no binding was observed with β-LG when incubated with the same Ab anti-H-OA. In Fig. 2B, a linear response was observed for β-LG when incubated with pAb anti-β-LG. Again virtually no response was made for the OA incubated with pAb anti-β-LG. Immunoblotting of crabstick samples for DEW detection using Ab anti-H-OA showed similar patterns to those produced from purified ovalbumin and DEW only samples (Fig. 3A). Fig. 3B shows similar results for samples tested for the presence of β-LG using pAb anti-β-LG.

3.3. Lower limit of detection vs lower limit of quantification (LLD vs LLQ)

Blank wells (36 total) were tested using Ab anti-H-OA with an average absorbance of 0.044 ± 0.006 and a LLD of 0.062 absorbance. The LLQ for the ELISA assay was calculated as the lowest point on the standard curve using 0.25% protein additives (16.5 and 12.4 ng/mL for DEW and WPC, respectively). The average absorbance value for the 0.25% DEW sample was 0.361 ± 0.034. The control sample (0% DEW) had an average absorbance of 0.101 ± 0.021 which was 3.6 times lower than that of the 0.25% DEW sample. The absorbance of the control sample was higher than the LLD but still below the LLQ. The average absorbance for the blanks were calculated using the standard curve the resulting values were negative showing that the blank values lie outside of the linear range of the standard curve. A similar trend was found using the blank values and standard curve for the WPC. The blank wells for WPC had an average absorbance of 0.057 ± 0.007 and a LLD of 0.078. The absorbance of the LLQ for WPC was 0.476 ± 0.037. The control sample (0% WPC) had an average absorbance of 0.085 ± 0.008. Again the control sample was slightly higher than the LLD but still much lower than the LLQ. The range for the standard curve was chosen so as to cover the most commonly added amounts of protein additive.

3.4. Indirect ELISA of DEW and WPC in crabstick

Using the most abundant proteins found in the respective protein additives helped in creating an accurate assay. Finding antibodies that will bind well with the heat-denatured form of OA and β-LG was a key for the success of the assay development. An indirect ELISA was used to qualify and quantify the use of DEW and WPC in prepared crabstick. Due to the highly processed nature of the crabstick, the proteins found in the sample have been completely denatured. Chemical (addition of salt) and physical (chopping and cooking) processing made it even more difficult to find the antibodies that could detect the denatured protein. The Ab anti-H-OA was produced to bind strongly with OA in denatured and modified forms such as heat-denatured and reduced. The antibody used to detect β-LG was created using native β-LG. Table 1 shows the results of the verification batches for DEW, WPC, and their mixture (DEW/WPC). The calculated % protein was determined by dividing the determined protein % from the standard curve by the actual protein % added. Samples containing DEW had a calculated % protein that ranged from 98.8% to 106.6% and a standard deviation range of 2.5–6.3%. All calculated % protein values for the samples that contained DEW were within 7% of the actual added protein value. The WPC had a calculated % protein that ranged from 90.3% to 116.7% and a standard deviation range of

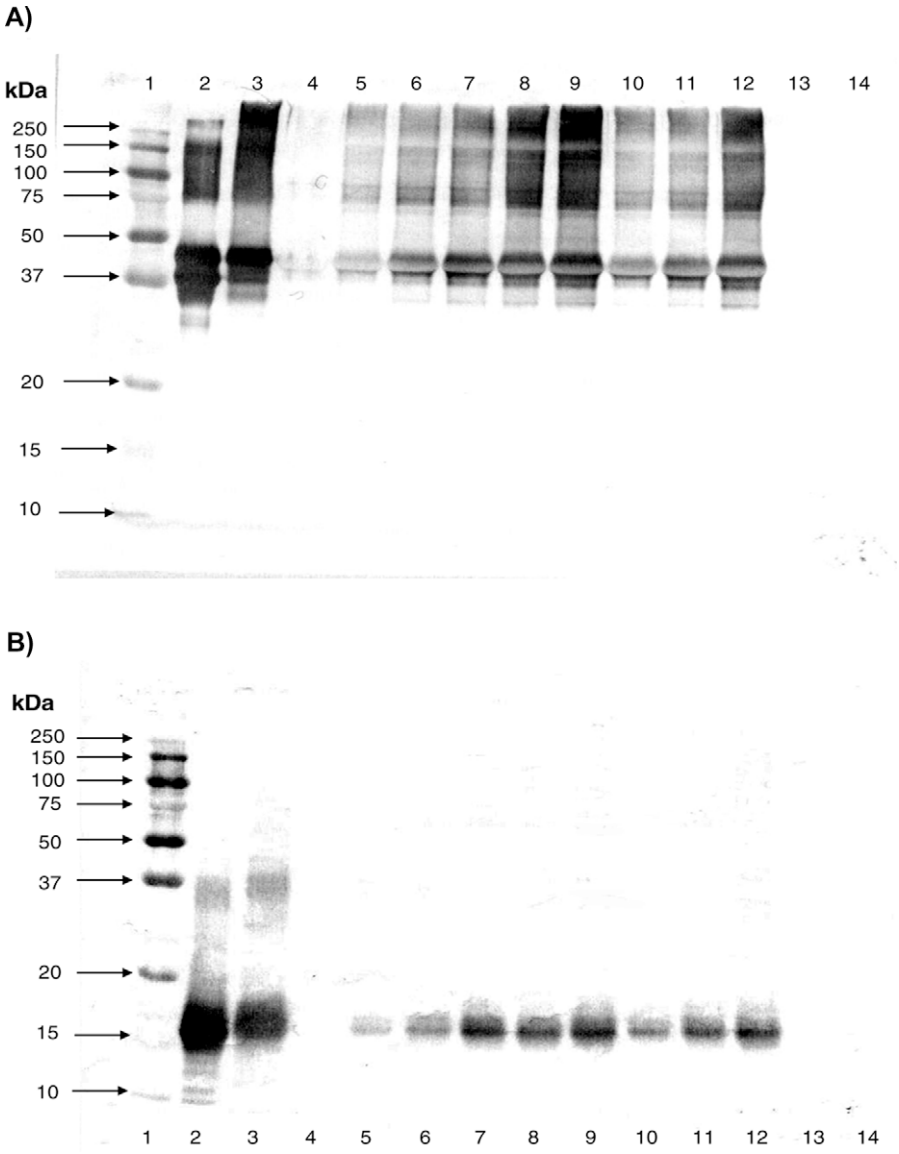

Fig. 3. Immunoblotting of DEW/WPC mixture tested using Ab anti-H-OA (A) and pAb anti-β-LG (B). (B) Lane (L) (1) Kaleidoscope marker, (2) β-LG, (3) WPC, lanes 4–12 crabstick batches (% DEW/WPC) (4) 0%, (5) 0.25%, (6) 0.5%, (7) 1.0%, (8) 1.5%, (9) 2.0%, (10) 0.375%, (11) 0.75%, (12) 1.75%, (13) ovalbumin, (14) DEW.

1.3–11.4%. All calculated % protein values for WPC samples were within 17%.

To understand the precision of the assay, the CV were analysed and reported in Table 2. Overall assay CV for DEW samples ranged from 0.9% to 3.1% while those for the WPC samples ranged from 1.0% to 8.0%. The difference in CV range for the two assays may be due, in part, to the nature of the antibodies used. The Ab anti-H-OA was developed against heat denatured OA. However the pAb anti-β-LG was created using the native form of β-LG. The difference in the CV may be because of increased avidity of the Ab anti-H-OA with denaturation. An antibody produced using heat denatured β-LG may possibly lead to an antibody with a stronger avidity for heat denatured β-LG.

Breton, Phan Thanh, and Paraf (1988) found that affinity purified antibodies raised against native ovalbumin had higher avidity against heat-denatured ovalbumin than against the native ovalbumin molecule. Rumbo, Chirdo, Fossati, and Anon (1996) found that avidity peaked and then began to decrease as heating time increased. This trend held true for samples tested between 70 and 100 °C. They attributed the decrease in avidity to an increase in OA unfolding. Luis, Perez, Sanchez, Lavilla, and Calvo (2007) showed that the use of native β-LG as an antigen, still allowed for the detection of highly denatured β-LG in food products including meat, bakery products, sauces, and snacks. Chicón, Belloque, Alonso, and López-Fandiño (2008) found that high pressure treatment of β-LG at 200 and 400 MPa actually increased the binding of β-LG-specific rabbit IgG antibodies when tested in an indirect ELISA format. According to Svenning, Brynhildsvold, Molland, Langsrud, and Vegarud (2000), β-LG antibody antigenicity was reduced due to the WPC processing. However, they stated that the reduction may be due to lower protein solubility. For WPC that was heated without any hydrolysis they showed 61% protein solubility and a 500-fold decrease in antigenicity. With pre-heated and hydrolysed WPC, they showed 100% protein solubility and a

10-fold decrease in antigenicity. Their study pointed out that β-LG antibody antigenicity was affected not only by processing conditions, but also by protein solubility.

4. Conclusions

Obtaining antibodies that would bind the target protein in the highly processed crabstick proved to be a key for the success of the assay development. Ab anti-H-OA and pAb anti-β-LG were shown to be highly specific for the target protein and showed no cross-reactivity with non-target proteins found in the prepared crabstick. An optimised solution for extraction was made with 10% SDS and 2.5% 2-ME. This optimised extraction solution demonstrated high reproducibility for the prepared crabsticks. An indirect ELISA assay was tested and proved as an effective method for the qualification and quantification DEW and WPC in a cooked and pasteurised crabstick. All three levels of DEW protein additive were estimated to less than 7% of the actual value and those of the WPC were estimated to less than 17%. Accuracy of the WPC assay may be improved by producing an antibody from the heat denatured form of β-LG.

Gel filtration
Tandem mass spectrometry

ABSTRACT

Buckwheat protein (BWP) isolate was subjected to a two-stage *in vitro* digestion (1 h pepsin followed by 2-h pancreatin at 37 °C). The antioxidant potential of the BWP digests was compared by assessing their capacity to scavenge 2,2′-azinobis (3-ethylbenzothiszoline-6-sulphonic acid) ($ABTS^{+\cdot}$) and hydroxyl (·OH) radicals. The 2-h pancreatin digest, which demonstrated the strongest activity against both radicals, was subjected to Sephadex G-25 gel filtration. Of the six fractions collected, fractions IV (456 Da) and VI (362 Da) showed the highest $ABTS^{+\cdot}$ scavenging activity and were 23–27% superior to mixed BWP digest ($P < 0.05$). Fraction VI was most effective in neutralising ·OH and was 86% and 24% more efficient ($P < 0.05$) than mixed BWP digest and fraction IV, respectively. LC–MS/MS identified Trp-Pro-Leu, Val-Pro-Trp, and Val-Phe-Pro-Trp (IV), Pro-Trp (V) and tryptophan (VI) to be the prominent peptides/amino acid in these fractions.

1. Introduction

The gastrointestinal (GI) tract is one of the most vulnerable tissues inside the human body to oxidative attack by reactive oxygen species (ROS). Oxidative stress is believed to be one important cause of GI inflammation, ulcer, and colitis (Blau, Rubinstein, Bass, Singaram, & Kohen, 1999). The upper GI mucosa, itself a natural defence layer, is constantly exposed to ROS derived from endogenous as well as exogenous sources, i.e., foods, which can contain high amounts of unsaturated lipids, prooxidant transition metal ions and even directly, free radicals. For example, a diet containing iron and ascorbic acid in the presence of unsaturated fatty acids predisposed the GI lining to hydroxyl radical (·OH) mediated injury, which can lead to colitis (Carrier, Aghdassi, Platt, Cullen, & Allard, 2001). Moreover, it has been demonstrated that ·OH can form in the gastric juice, and the radical generation is implicated in GI mucosa damage and ensuing ulcer (Nalini, Ramakrishna, Mohanty, & Balasubramanian, 1992). Hence, identifying potential antioxidants that may help neutralise radicals, particularly ·OH, thereby protecting the GI system, is of great importance.

There has been growing interest in recent years to produce bioactive peptides that can exert radical scavenging activity. Carnosine, a naturally occurring dipeptide rich in muscle foods, is a classical example of peptides that can act as a strong radical scavenger and inhibit ROS-initiated lipid oxidation (Boldyrev & Johnson, 2002). Most reported antioxidants are derived from common food protein sources using commercial enzymes. For example, canola protein hydrolysate prepared using flavourzyme was shown to be antioxidative and can enhance water-holding capacity in cooked pork meat (Cumby, Zhong, Naczk, & Shahidi, 2008). Hydrolysed animal proteins, e.g., gelatin hydrolysate from Alaska polluck skin (Kim et al., 2001), also show antioxidant activity in food model systems.

Proteins in raw and processed foods can possess antioxidant peptide sequences and structural domains; the active fragments are released during the GI digestion process. Reported high-efficiency radical scavenging peptides released through *in vitro* pepsin and pancreatin digestion include those from casein (Hernandez-Ledesma, Amigo, Ramos, & Recio, 2004), maize zein (Zhu, Chen, Tang, & Xiong, 2008), oyster protein (*Crassostrea gigas*) (Qian, Jung, Byun, & Kim, 2008), and mussel protein (*Mytilus coruscus*) (Jung et al., 2007).

Buckwheat, a traditional grain widely considered as a functional food source, has gained its fame due to published studies that linked its proteins to various health benefits, e.g., cholesterol reduction (Kayashita, Shimaoka, Nakajoh, Yamazaki, & Norihisa, 1997), tumour inhibition (Liu et al., 2001), and hypotension regulation (Ma, Bae, Lee, & Yang, 2006). Because many of the health promoting functions are inherently related to the radical scavenging activity of peptides from the protein digests, it is hypothesised that hydrolysis of buckwheat protein can release the peptide fragments capable of

doi:10.1016/j.foodchem.2009.05.024

stabilising ROS and inhibiting lipid oxidation. A preliminary study supported this hypothesis (Ma & Xiong, 2009). However, the specific peptides or peptide fractions responsible for the antioxidant functions have not been elucidated.

In the present study, the ability of mixed as well as individual fractions of *in vitro* pepsin–pancreatin sequential digests of buckwheat protein to stabilise ·OH and $ABTS^{+\cdot}$ radicals was investigated. The objective was to identify the most effective antioxidant peptide fraction(s) from buckwheat *in vitro* digests. Initially, the digest with the highest radical scavenging capacity was fractionated by means of gel filtration. The ability to stabilise hydroxyl radical by each post-column fraction was subsequently examined, and the prominent peptides in active fractions were sequenced by liquid chromatography–tandem mass spectrometry (LC–MS/MS).

2. Materials and methods

2.1. Extraction of buckwheat protein (BWP)

Low-fat buckwheat flour was purchased from Bulkfoods.com (Toledo, OH, USA). The product specification sheet from the supplier indicated 3.6% fat, 71.4% total carbohydrate and 25% protein. Before protein extraction, the flour was stirred with hexane (1:1 w/v, four changes) for 48 h to remove residual fat. After vacuum evaporation of residual hexane, the dried defatted flour powder was subjected to the process of protein extraction according to the method of Tomotake, Shimaoka, Kayashita, Nakajoh, and Kato (2002) with some modifications. Defatted buckwheat flour (1 kg) was manually dispersed into 10 L of deionized water, and the pH was adjusted to 8.0 using 1 M NaOH. After stirring with a propeller (~50 rpm) at 4 °C for 2 h, the suspension was centrifuged at 5000*g* for 20 min. The supernatant (protein extract) was decanted and adjusted to pH 4.5 using 1 M HCl to isoelectrically precipitate protein. The protein precipitate was washed with deionized water two times and then neutralised with 0.1 M NaOH before lyophilisation. Freeze dried BWP powder was stored at −20 °C before use.

2.2. Preparation of protein digests

BWP *in vitro* digests were prepared according to the method of Lo and Li-Chan (2005). The suspension of BWP (5%, w/v) in nanopure deionized water was adjusted pH 2.0 with 1 M HCl, followed by the addition of pepsin (4%, w/w, protein basis). The mixture was incubated 1 h in a shaking water bath set at 37 °C to allow pepsin digestion. Subsequently, the pH was adjusted to 5.3 using 0.9 M $NaHCO_3$. After the addition of pancreatin (4% w/w, protein basis), the pH was adjusted to 7.5 with 1 M NaOH. The digestion was restarted and continued in the 37 °C shaking water bath for another 2 h. Aliquots of hydrolysates were removed at 0, 30, 60, 90, 120, and 180 min during the pepsin → pancreatin sequential digestion, adjusted to neutrality (pH 7.0) with 1 M NaOH/HCl, and heated at 96 °C for 5 min to inactivate the enzymes. Each aliquot was freeze dried and kept at –20 °C before use.

2.3. Gel filtration

Preliminary results showed that the two-stage *in vitro* digestion yielded a high radical scavenging activity in the final BWP digest (i.e., 180 min total digestion time). Therefore, this digest, referred to as "$D_{180\ min}$", was subjected to peptide fractionation using a low-pressure size exclusion chromatography with a 2.6 cm (dia.) × 70 cm (length) Sephadex G-25 fine column (Pharmacia XK 26/70, Piscataway, NJ, USA).

A 2 mg/mL of $D_{180\ min}$ solution, prepared from lyophilised powder by dissolving in the elution buffer (0.02 M phosphate, pH 7.4), was clarified and sterilized through a 25-mm syringe filter with a 0.22 μM membrane (Fisher Scientific, Pittsburgh, PA). The purified solution (10 mL) was loaded to the Sephadex column and eluted in a 4 °C cold room with the elution buffer at a 0.9 mL/min flow rate. Peptide fractions were collected using an automated fraction collector, and the absorbance (215 nm) of the eluents was measured. In order to collect enough peptides for antioxidant assays, a total of 23 chromatographic runs were conducted. The corresponding peptide fractions from the 23 replicates were pooled and lyophilised. Freeze dried fractions were stored at –20 °C for further analysis.

Molecular weight (MW) distribution of the individual peptide fractions was estimated from a MW calibration curve generated from the elution volume of the following standards (Sigma Chemical Co., St. Louis, MO) that were chromatographed separately in the Sephadex G-25 column under the same condition as described above: cytochrome C (12327 Da), aprotinin (6512 Da), bacitracin (1423 Da), and tetrapeptide GGYR (452 Da). The evolution volume (mL) of blue dextran was used to establish the void volume of the column. Data were fitted in the exponential decay model (modified single with three parameters) of the SigmaPlot Ver. 9 software (Systat Software Inc., Chicago, IL, USA), which yielded the following equation:

$$LogMW = 2.3429e^{\left(\frac{34.8528}{Vol-79.1592}\right)}$$

2.4. Radical scavenging activity (RSA)

The RSA of BWP *in vitro* digests and the peptide fractions of the final digest ($D_{180\ min}$) was evaluated using ·OH and $ABTS^{+\cdot}$ systems. The ·OH assay involved the inhibition of radical formation rather than scavenging radicals that are already produced (i.e., pre-existed), while the $ABTS^{+\cdot}$ scavenging assay was carried out by using pre-generated cationic radicals. Furthermore, $ABTS^{+\cdot}$, a synthetic radical species, is much larger in size than ·OH, which is known to be most reactive of all the reactive oxygen species in food systems. Therefore, the analysis of RSA of BWP digests in the two different radical generation systems may lead to a better understanding of RSA of BWB peptides than would the individual assay systems.

2.4.1. ·OH scavenging

The ·OH scavenging activity measurement was carried out according to the method of Moore, Yin, and Yu (2006). Briefly, 30 μL samples were each mixed with 170 μL of 9.28×10^{-8} M fluorescein in a 96-well polystyrene plate (Fisher Scientific, Pittsburgh, PA, USA), followed by the addition of 40 μL of 0.1999 M H_2O_2 and 60 μL $FeCl_3$. The mixed solution was immediately transferred to a Cary Eclipse fluorescence spectrophotometer equipped with a microplate reader (Varian, Victoria, Australia). The measurement with 0.1 s reading time per well and 1 min per plate was conducted with a 485 nm excitation wavelength and a 535 nm emission wavelength for 3 h to obtain the fluorescein decay curve. The ·OH scavenging capacity was expressed as trolox equivalent (μM), which was determined from the regression equation built on a series of trolox standards (20, 40, 80, and 100 μM). The concentration of the standards was set as the *x*-axis and the net area under the decay curve was set as the *y*-axis. The calculation of the area under curve (AUC) is shown below, where *f* represents the fluorescence value at a particular time during the decay:

$$AUC = 0.5 + f_1/f_0 + f_2/f_0 + f_3/f_0 + \cdots + f_{i-1}/f_0 + 0.5(f_i/f_0)$$

2.4.2. $ABTS^{+\cdot}$ scavenging

The $ABTS^{+\cdot}$ scavenging ability was determined by the decolorization assay (Re et al., 1999). Briefly, $ABTS^{+\cdot}$ was generated by a mixed solution of 7 mM ABTS and 2.45 mM potassium persulphate. After

12–16 h reaction, a dense green–blue coloured solution with excessive accumulation of $ABTS^{+\cdot}$ radical was diluted with 0.2 M phosphate buffer (pH 7.4) to the absorbance level of 0.7 ± 0.02 at 734 nm. The RSA was then determined by mixing 10 μL samples (2 mg/mL protein) and 990 μL diluted $ABTS^{+\cdot}$ solution for digestion aliquots (0, 30, 60, 90, 120 and 180 min) assay, and 100 μL samples (0.189 mg/mL protein) into 900 μL of diluted $ABTS^{+\cdot}$ solution for post-column fractions and final digest mixture ($D_{180\ min}$) for comparison. The absorbance was recorded at 1, 2, 5 and 10 min during the reaction. The extent of decolorization represented the magnitude of scavenging ability and was calculated from a standard curve generated with 50, 100, 250, 500, and 1000 μM of trolox. Trolox equivalent antioxidant capacity (TEAC) was used to express RSA.

2.4.3. LC–MS/MS

Gel filtration fractions (5 μL each) that exhibited strong radical scavenging activity were subjected to LC–MS/MS analysis using a QSTAR XL quadruple time-of-flight mass spectrometer (Applied Biosystems, Foster City, CA, USA) coupled with a nano-flow HPLC system (Eksigent Technologies, Dublin, CA, USA) through a nano-electrospray ionisation source (Protana, Toronto, Canada) (Lu & Zhu, 2005). The samples were injected by an autosampler, desalted on a trap column (300 μm i.d. × 5 mm length, LC Packings, Sunnyvale, CA, USA), and subsequently separated by reverse phase C18 column (75 μm i.d. × 150 mm length, Vydac, Columbia, MD, USA) at a flow rate of 200 nL/min. The HPLC gradient was linear from 5% to 80% mobile phase B in 55 min using mobile phase A (H_2O, 0.1% formic acid) and mobile phase B (80% acetonitrile, 0.1% formic acid).

Peptides eluted out of the reverse phase column were analyzed online by mass spectrometry (MS) and selected peptides were subjected to tandem mass spectrometry (MS/MS) sequencing. The automated data acquisition using information-dependent mode was performed on QSTAR XL under control by Analyst QS software (Applied Biosystems, Foster City, CA, USA). Each cycle typically consisted of one 1-s MS survey scan from 150 to 1200 (m/z) and two 2-s MS/MS scans of singly, doubly and triply charged species with mass range of 100–1200 (m/z). The spectra were interpreted using the *de novo* peptide sequencing module of the Analyst QS software.

2.5. Statistical analysis

The study employed a randomized complete block design with replication as the block. There were a minimum of three replications. Each analysis was done in duplicate. Data were subjected to analysis of variance using the general linear model's procedure of the Statistix software 9.0 (Analytical Software, Tallahassee, FL). When a treatment effect was found significant, Tukey HSD all-pair-wise multiple comparisons were performed to identify significant differences between individual means.

3. Results and discussion

3.1. RSA of BWP in vitro digests

In the ·OH scavenging test, the potential of an antioxidant to inhibit ·OH formation or to stabilise the radical was indicated by the rate of fluorescence decay of fluorescein (Moore et al., 2006). All BWP *in vitro* digest samples showed a slower fluorescence decay than non-hydrolysed BWP (data not shown), indicating that hydrolysis improved ·OH scavenging activity of BWP. Despite some variations, there was an overall trend that the ·OH scavenging activity increased with digestion (Fig. 1). In the Fenton reaction ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {\cdot}OH + OH^-$), the impact of ·OH on susceptible compounds could be restrained by either Fe^{2+} chelation or ·OH stabilisation or both. Hence, the strong ·OH elimination activity of BWP digests, notably that of $D_{180\ min}$, can be attributed to the removal of free Fe^{2+} prooxidant and stabilisation of radicals through hydrogen or electron donation. The first mechanism was a postulation on the basis of the ·OH assay, which can be supported by the strong iron chelation ability of 2 h pancreatin digests (i.e., $D_{180\ min}$) (Ma & Xiong, 2009).

The $ABTS^{+\cdot}$ radical scavenging activity assay also demonstrated a positive and more consistent rise in the scavenging capacity with digestion time, culminating at 2 h of pancreatin treatment (i.e., end of the total 180 min *in vitro* digestion) (Fig. 2). In the $ABTS^{+\cdot}$ method, the antioxidant activity was measured exclusively by the ability of an antioxidant to act as a hydrogen or electron donor to neutralise preformed $ABTS^{+\cdot}$ radicals (Re et al., 1999). However, in the ·OH method, a test antioxidant is placed in a radical generation system where the antioxidant capacity was expressed both as inhibition of the radical initiation and elimination of formed radi-

cals (Moore et al., 2006). The remarkable similarity in the results of ·OH and $ABTS^{+\cdot}$ assays on different digests suggested that inhibition of radical initiation was probably not a critical factor determining the efficacy of BWP digests as antioxidants.

3.2. Peptide fractionation

Six peptide fractions were obtained by the Sephadex G-25 size exclusion gel filtration (Fig. 3). Based on the regression equation between elution volume and MW of each standard, the estimated mean MWs of these fractions were 3611 (I), 960 (II), 529 (III), 456 (IV), 365 (V), and 362 Da (IV). Assuming an average MW of 135 Da for amino acids, fraction I would be a peptide mixture consisting predominantly of those with 26 amino acid residues, and fractions II, III, IV and V or VI would have a preponderance of heptamerci, tetrameric, trimeric, or dimeric peptides, respectively. Fraction VI would also contain free amino acids. Based on the nitrogen analysis of the freeze dried eluent powders, these fractions accounted for 23.7% (I), 60.2% (II), 10.5% (III), 3.2% (IV), 1.4% (V), and 1.0% (VI) of the total eluent protein.

The incomplete separation of fractions I–IV suggested that they each contained peptides with various sizes, some of which were overlapping in neighbouring fractions. A relatively broad distribution of molecular weight masses in hydrolysed proteins is commonly associated with gel filtration (Adler-Nissen, 1986). The tailing parts of the eluents (fractions V and VI) would consist of mixed short peptides and free amino acids (Zhu et al., 2008). Thus, a more robust separation system (e.g., a high performance liquid chromatography) that enables a precise MW distribution measurement is desirable for better elucidating the relationship of peptide MW distribution with antioxidant activity.

3.3. RSA of peptide fractions

The ·OH and $ABTS^{+\cdot}$ scavenging activities of various gel filtration fractions of the final BWP *in vitro* digest ($D_{180\ min}$) are shown in Fig. 4 (·OH scavenging capacity vs. fractions) and Fig. 5 ($ABTS^{+\cdot}$ scavenging capacity vs. fractions). Fraction VI exhibited the strongest ·OH scavenging activity, which was 86% greater ($P < 0.05$) than the

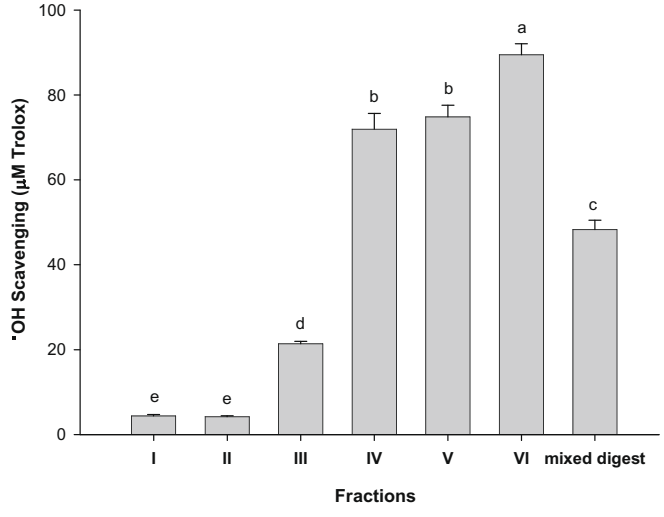

Fig. 4. Hydroxyl radical scavenging capacity of gel filtration fractions of final *in vitro* digest (180 min total digestion time) of buckwheat protein. Means ($n = 3$) without a common letter differ significantly ($P < 0.05$). Sample solutions: 0.10 mg/mL protein.

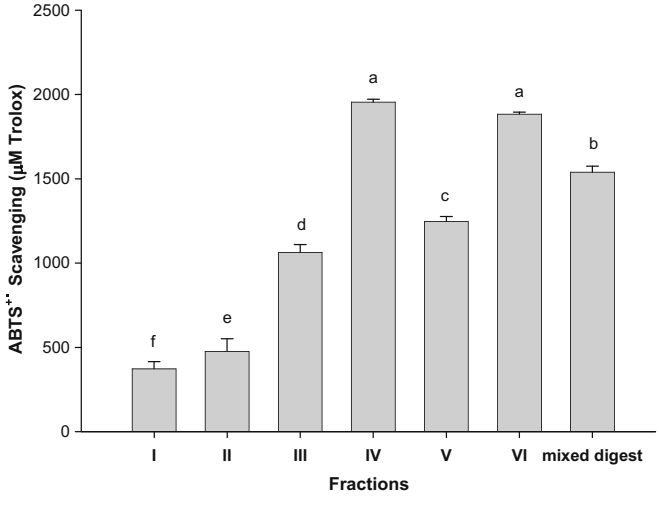

Fig. 5. $ABTS^{+\cdot}$ scavenging capacity of gel filtration fractions of the final *in vitro* digest (180 min total digestion time) of buckwheat protein. Means ($n = 3$) without a common letter differ significantly ($P < 0.05$). Sample solutions: 0.159 mg/mL protein.

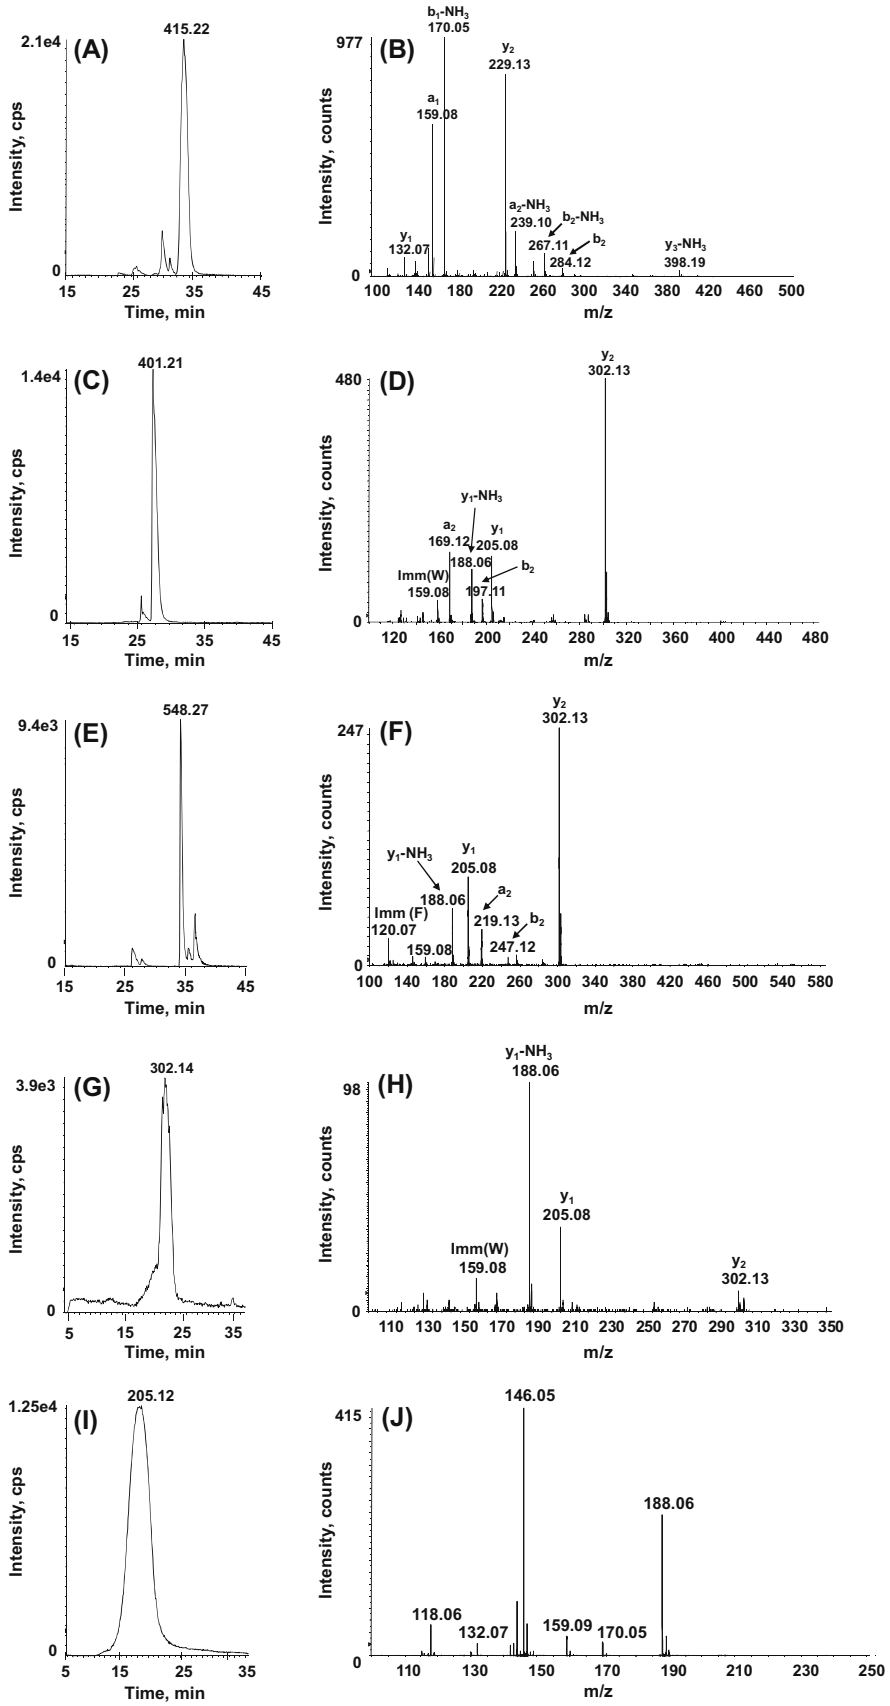

Fig. 6. Extracted ion chromatograms (A, C, E, G, I) and tandem MS/MS spectra (B, D, F, H, J) of the prominent peptides present in gel filtration fractions IV (A–F), V (G; H), and VI (I; J). The peptides/amino acid were identified as Trp-Pro-Leu (B), Val-Pro-Trp (D), Val-Phe-Pro-Trp (F), Pro-Trp (H) and Trp (J).

mixed BWP final digest ($D_{180\ min}$). Fractions IV and VI showed the highest potential in scavenging $ABTS^{+\cdot}$, and the activity was enhanced by an average of 24.5% ($P < 0.05$) compared to mixed final digest.

Although the $ABTS^{+\cdot}$ scavenging activity of fractions IV and VI indicated no significant differences, fraction VI showed a particularly strong ·OH elimination activity and was 24% more effective than fraction IV. These results suggested that fractions IV and VI were primary contributors to the radical scavenging capacity of the final BWP *in vitro* digest. The weaker antioxidant activity of the final mixed digest compared to the individual fractions IV and V can be explained by the dilution effect of relatively ineffective larger peptides. Fractions I (3611 Da), II (960 Da) and III (529 Da), which were present in the mixed final digest ($D_{180\ min}$), all displayed extremely low activity against $ABTS^{+\cdot}$ and ·OH. Yet, they made up the bulk of the total proteins/peptides in the mixed final digest.

3.4. Peptide sequence

Gel filtration fractions IV, V and VI, which exhibited relatively strong radical scavenging activity as indicated above, were subjected to individual peptide separation and sequence identification. The extracted ion chromatograms (XIC) and the tandem MS/MS spectra of the prominent peptides in these fractions are shown in Fig. 6. There were three prominent peptides in fraction IV, their XICs with the m/z values of 415.22, 401.21 and 548.27 are displayed in panels (A), (C) and (E), respectively. Their MS/MS spectra are shown in panels (B), (D) and (F). *De novo* sequencing determined the sequences of the peptides as Trp-Pro-Leu (B), Val-Pro-Trp (D) and Val-Phe-Pro-Trp (F), respectively. Fraction V produced relatively lower total signals in the LC–MS/MS analysis. A peptide with the m/z value of 302.14 was evident (panel G) and the MS/MS spectrum (panel H) supported the sequence of dipeptide Pro-Trp. Fraction VI showed a dominant XIC peak with elution time from 10 to 25 min (m/z at 205.12, panel I). The MS/MS spectrum displayed a characteristic pattern of fragments (m/z values of 118, 146 and 188) of the amino acid tryptophan as previously reported (Yamada, Miyazaki, Shibata, Hara, & Tsuchiya, 2008). Tryptophan was also detected in fractions V and IV with lower abundance (data not shown). The decreasing sizes of the prominent peptides in fractions IV, V and VI were consistent with the estimated molecular weights based on the gel filtration fractionation (Fig. 3).

These results were in concert with the general finding that short peptides with 2–10 amino acids exert greater antioxidant potential and other bioactive properties than their parent native proteins or large polypeptides (Kitts & Weiler, 2003). Through peptide bond cleavage, hydrolysis allows the release of active peptides capable of sequestering oxygen radicals, chelating prooxidant metal ions, and inhibiting lipid peroxidation in food systems (Elias, Kellerby, & Decker, 2008). For example, an oligopeptide with the sequence of His-Gly-Pro-Leu-Gly-Pro-Leu (797 Da), which was purified from fish skin hydrolysate, showed strong activity against ROS as well as linoleic acid peroxidation (Mendis, Rajapakse, & Kim, 2005). Two antioxidant short peptides, with the sequences of His-Val-Thr-Glu-Glu and Pro-Val-Pro-Ala-Glu-Gly-Val, were identified from chicken essence (Wu, Pan, Chang, & Shiau, 2005). Proline, as well as leucine, were found to play an important role in the antioxidant activity of peptides derived from soy protein, e.g., Leu-Leu-Pro-His-His (Chen, Muramoto, Yamauchi, & Nokihara, 1996). In our study, proline was present in all four prominent peptides identified in BWP digest fractions that showed strong antioxidant activity. In addition, valine was also present in two of four peptides. Zhu et al. (2008) reported that the peptide fractions rich in di-, tri-, and tetrapeptides from the zein *in vitro* digest (1–8 mg/mL protein) had comparable or stronger antioxidant activity than that of 0.1 mg/mL ascorbic acid or BHA. These peptides were superior to non-hydrolysed zein.

The dominant existence of tryptophan in fraction VI suggested that tryptophan was a potent antioxidant in BWP digests, consistent with previous findings (Christen, Peterhans, & Stocker, 1990; Elias, McClements, & Decker, 2005). It is noteworthy that tryptophan was also present in all four peptides with significant abundances in the three strong radical scavenging fractions (IV, V, VI), further supporting its antioxidant property. Furthermore, because short peptides are smaller molecules than intact proteins, at an equal weight concentration basis, the peptides' molar concentration would be significantly greater than that of intact proteins. This difference would also contribute to the higher antioxidant activity of BWP peptides.

In conclusion, free radical scavenging activity of BWP was accentuated by *in vitro* digestion, especially after 2 h pancreatin digestion following the 1 h pepsin treatment. On an equal weight concentration basis, fractions enriched with di-, tri- and tetrameric peptides containing tryptophan and proline exhibited the strongest radical scavenging activity. These short peptides are implicated in the protection of the upper digestive tract of humans from oxidative stresses and may partially explain why dietary BWP promotes the health of the GI system.

Oxidative stress
Antioxidant activity

ABSTRACT

The levels of the biologically important thiols in aqueous extracts of different spices were determined using a sensitive high performance liquid chromatography (HPLC) technique. The spices analysed: turmeric, ginger, cardamom, mustard, fenugreek, and coriander showed different levels of thiols. Biologically important thiols or biothiols measured in these spices included glutathione (GSH), cysteine (CYS), N-acetylcysteine (NAC), homocysteine (HCYS), and γ-glutamyl cysteine (GGC). Our results showed that thiol levels varied from 4 to 1089 nM/g weight (dry or wet). Furthermore, none of the biothiols analysed were found in cumin, nutmeg, clove or star anise. We also studied the antioxidant abilities of these aqueous extracts using various *in vitro* antioxidant methods to correlate between the levels of these thiols and their antioxidant effects. Our results suggested that antioxidant activities may be independent of thiol content and may be, in part the combination of all the phytochemicals present. These results may be useful in explaining the effect of spices on thiol levels in *in vitro* and *in vivo* studies.

1. Introduction

Free radical mediated cell damage has been implicated in the pathology of various human chronic diseases such as Alzheimer's, Parkinson's, Crohn's, and certain cancers (Sies, 1985; Halliwell & Gutterbridge, 1989). These radicals may be generated as byproducts of various metabolic pathways, due to the metabolism of xenobiotics or by originating from the environment. These highly reactive radicals can react with biological molecules such as cell membrane lipids and DNA, which ultimately results in cell death (Kappus, 1986). However, they are also formed endogenously to perform biological functions. Radical induced damage is prevented in the body by various enzymatic antioxidant defence systems including superoxide dismutase, catalase, glutathione S-transferase, and also by biologically important thiols (biothiols) such as glutathione (GSH), cysteine (CYS), homocysteine (HCYS), and γ-glutamylcysteine (GGC) (Ross, 1989; Stoecker & Frei, 1991).

Biothiols are important antioxidants which protect the cells from oxidative damage (Meister & Anderson, 1983; Sen & Packer, 2000; Wlodek, 2002). Excessive oxidative damage can result in reduced levels of these biothiols. Over the past few decades, research has been dedicated to find natural sources of antioxidants, including biothiols. We previously reported several biothiols (mentioned above) in fruits and vegetables, including rare thiols like N-acetylcysteine (NAC) (Demirkol, Adams, & Ercal, 2004). NAC has long been used as a mucolytic agent for treating chronic bronchitis, as well as an effective antidote for acetaminophen poisoning (Bowman, Backer, Larsson, Melander, & Whalander, 1983; Prescott & Critchley, 1983).

Dietary sources like vegetables, fruits, contain a wide variety of phytochemicals like phenols and flavanoids that possess bioactive properties which may protect cellular systems against oxidative damage. Along with the phytochemicals, a significant level of thiols, known to enhance the antioxidant properties of fruits and vegetables have been reported in these dietary sources (Jones et al., 1992).

Spices, like turmeric, fenugreek, mustard, ginger, etc. may offer many health benefits and have been proven to counteract oxidative stress in *in vitro* and *in vivo* systems (Ahmed, Seth, & Banerjee, 2000; Modak et al., 2007). Most of these spices have been intensely studied only for their active components like phenolic acids, flavanoids (Kikuzaki & Nakatani, 1993). To the best of our knowledge, no known data or study is available regarding the presence of biothiols in spices. Therefore, the objective of this paper was to investigate the content of various biologically important thiols in spices. Furthermore, we wanted to determine whether the spices possessing higher thiols had higher antioxidant properties than their counterparts.

2. Materials and methods

2.1. Reagents and chemicals

All chemicals were purchased from Sigma (St. Louis, MO) unless otherwise stated. Acetonitrile, acetic acid, water, and phosphoric acid [all high performance liquid chromatography (HPLC) grade] were purchased from Fisher (St. Louis, MO). N-(1-Pyrenyl) maleimide (NPM) was purchased from Aldrich (Milwaukee, WI). Spice powders and ginger were purchased from major chain markets in Rolla and St. Louis MO.

2.2. Preparation of aqueous spice extracts

All Spices (0.1 g each), were suspended in 1 mL of serine borate buffer (100 mM Tris–HCl, 10 mM borate, 5 mM serine, and 1 mM diethylenetriaminepentacetic acid, pH 7.0). For ginger, (0.1 g) slices were homogenised in 1 mL of serine borate buffer using a tissue tearor (Model 985-370, type 2, Biospec Products Inc.) on ice for 2 min, with 5-s intervals of homogenisation. The slurry was centrifuged at 5000*g* for 1 min at 4 °C and the supernatants were filtered through 0.2 μm acrodisc. About 100 μL of the supernatant was used for the *in vitro* antioxidant assays. All samples were placed on ice during the experiments.

2.3. Determination of NAC, GSH, CYS, HCYS, and GGC by the HPLC method

An HPLC method for determining thiols was developed in this laboratory by analysing γ-glutamyl cycle intermediates (Winters, Zukowski, Ercal, Matthews & Spitz; 1995). All spices (0.1 g each) were placed in a 1 mL of serine borate buffer and homogenised on ice for 2 min. Ginger samples were prepared as described above. The slurry was centrifuged at 5000*g* for 1 min at 4 °C and supernatant (250 μL) was derivatized with 750 μL of NPM (1 mM in acetonitrile). This compound reacts with the free sulfhydryl groups to form fluorescent derivatives. The resulting solution was mixed and incubated at room temperature for 5 min. Ten micro litres of 2 N HCl were added to stop the reaction. After filtration through a 0.2 μm acrodisc, the derivatized samples were injected onto a 5 μm C_{18} column in a reverse phase HPLC system. NAC, GGC, CYS, and HCYS were determined concurrently with GSH since they also form fluorescent derivatives with NPM.

2.4. HPLC system

The HPLC system (Thermo Electron Corporation) consisted of a Finnigan™ SpectraSYSTEM SCM1000 Vacuum Membrane Degasser, a Finnigan™ SpectraSYSTEM P2000 Gradient Pump, a Finnigan™ SpectraSYSTEM AS3000 autosampler, and a Finnigan™ SpectraSYSTEM FL3000 fluorescence detector (λ_{ex} = 330 nm and λ_{em} = 376 nm). The injection volume was 5 μL for all of the samples. The HPLC column was a Reliasil ODS-1 C_{18} column (5 μm packing material) with 250 × 4.6 mm i.d. (Column Engineering, Ontario, CA, USA). The mobile phase was 30 percent water and 70% acetonitrile, containing 1 mL/L acetic acid and 1 mL/L *o*-phosphoric acid. The NPM derivatives were eluted from the column isocratically at a flow rate of 1 mL/min. Quantitation of the peaks from the HPLC system was performed with a Chromatopac, model C-R601 (Shimadzu).

2.5. Calibration curves

Calibration curves were constructed by using integrated peak areas as the *y*-axis vs concentrations as the x-axis. Linearity was achieved for NAC, GSH, GGC, CYS, and HCYS over a concentration range of 25–2500 nM ($r^2 > 0.995$).

2.6. Radical scavenging power

Radical scavenging power (RSP) of aqueous extracts of spices and ascorbic acid were assessed by the method of Hsu et al. with slight modifications (Hsu, Coupar, & Ng, 2006). The reaction mixture was a total volume of 3 mL, which included 2.9 mL of 2,2-diphenyl-1-picrylhydrazyl (DPPH, 1×10^{-4} M) and 100 μL of aqueous extracts of the corresponding spice. The solutions were left in the dark at room temperature for 30 min, and the resulting colour was measured spectrophotometrically at 520 nm against blanks. A decreasing intensity of purple colour was related to a higher RSP percentage, which was calculated using the following equation;

$$\mathrm{RSP} = [1 - (A_{s\cdot30}/B_{S\cdot30})] \times 100$$

where $A_{s.30}$ is absorbance of sample and $B_{S.30}$ is absorbance of blank at 30 min reaction time.

2.7. ·OH–scavenging activity assay

Hydroxyl radical (·OH) scavenging ability was measured according to the literature procedure with a few modifications (Smirnoff & Cumbes, 1989). The reaction mixture (2.1 mL) contained 1 mL $FeSO_4$ (1.5 mM), 0.7 mL H_2O_2 (6 mM), 0.3 mL sodium salicylate (20 mM) and 100μL of aqueous extracts of spices. This mixture was incubated at 37 °C for 1 h, after which the absorbance of the hydroxylated salicylate complex was measured at 562 nm. The percentage scavenging effect was calculated as:

$$\text{Scavenging effect} = [1 - (A_1 - A_2)/A_0] \times 100\%$$

where A_0 was the absorbance of the control (without extract) and A_1 was the absorbance in the presence of the extract, A_2 was the absorbance without sodium salicylate.

2.8. Fe^{2+}-chelating activity assay

Fe^{2+}-chelating activity was measured according to a literature procedure with a few modifications (Cheng, Kuo, Chan, Ko, & Teng, 1998). The reaction mixture (2.00 ml) contained 100μL of spice extract, 100μL $FeCl_2$ (0.6 mM), and 1.7 mL deionised water. The mixture was shaken vigorously and left at room temperature for 5 min; 100 μL of ferrozine (5 mM in methanol) were then added, mixed, and left for another 5 min to complex the residual Fe^{2+}. The absorbance of the Fe^{2+} - ferrozine complex was measured at 562 nm against a blank. Disodium Ethylenediaminetetracetic acid (EDTA-Na_2) was used as the control. The chelating activity of the extract for Fe^{2+} was calculated as:

$$\text{Chelating effect} = [1 - (A_1 - A_2)/A_0] \times 100\%$$

where A_0 was the absorbance of the control (without extract) and A_1 was the absorbance in the presence of the extract, A_2 was the absorbance without ferrozine.

2.9. Determination of total polyphenolic compounds

Total phenolic content was determined by the Folin–Ciocalteau method (Ordonez, Gomez, Vattuone, & Isla, 2006). Spice extracts (100μL) was mixed with 2.5 ml of 0.2 M Folin–Ciocalteau reagent for 5 min and 2.0 ml of 75 g/L Na_2CO_3 were then added. The absorbance was measured at 760 nm after 2 h of incubation at room temperature. Results were expressed as μg/mL of gallic acid equivalents (GAE).

2.10. Statistical analysis

All results presented in this study are the average of at least three measurements. Means ± standard deviations are shown in figures. One way Analysis of Variance (ANOVA) was performed followed by Bonferroni's multiple comparison tests.

3. Results and discussion

Due to the increased interest and commercialisation of botanicals because of their health-related benefits, many spices have been evaluated to determine their potential benefits. Several spices have exhibited antioxidant properties and, as a result, additional studies are being conducted to determine their specific health benefits. Natural antioxidants are known to protect cells from damage induced by oxidative stress, which is generally considered to be a cause of ageing, degenerative disease, and cancer (Ringman, Frautschy, Cole, Masterman, & Cummings, 2005).

Turmeric and its components, which have been widely studied over the last 25 years, have been reported to induce GSH synthesis in *in vitro* models (Dickinson, Iles, Zhang, Blank, & Forman, 2003). Thiol levels in oxidative stress conditions were increased in studies with ginger extracts (Ajith, Nivitha, & Usha, 2007; Amin & Hamza, 2006). Fenugreek extracts have been shown to produce beneficial effects, such as neutralising of free radicals and enhancing of antioxidant status (Anuradha & Ravikumar, 1998). Initiation, as well as propagation phases, of $FeCl_3$ induced lipid peroxidation was inhibited by cardamom extracts (Yadav & Bhatnagar, 2007). Although most of the antioxidant activities in these studies are attributed to polyphenolic compounds present in these spice extracts, the idea that these extracts may be sources of biothiols like GSH is ignored in most of the studies. In addition antioxidant activity does not always correlate with the presence of large quantities of these polyphenolic compounds. Hence, the presence of other antioxidants (like biothiols) in the aqueous spice extracts was determined and the correlation between antioxidant activity and thiol levels were investigated using various antioxidant assays.

In situ derivatization of the spice extracts with NPM produced the NPM-NAC, NPM-GSH, NPM-GGC, NPM-CYS, and NPM-HCYS adducts, which were rapidly separated by the HPLC system employed for this study (Demirkol et al., 2004). Fig. 1a shows a chromatogram of the mix standards using the NPM method. The chromatogram prepared from fenugreek illustrates the well-defined separation of the NPM-GSH, NPM-GGC, NPM-CYS, and NPM-HCYS adduct peaks achieved by this method.

The NAC, GSH, GGC CYS, and HCYS concentrations in the aqueous extracts of the spices are reported in Table 1. Amongst the biological thiols the highest levels of GSH and CYS were found in ginger extracts (1076 nM/g and 387 nM/g wet weight, respectively). Coriander extracts showed very low levels of thiols amongst all the spices analysed with only 35 nM/g dry weight of GSH present. Fenugreek showed the highest levels of HCYS, (62 nM/g dry weight), followed by turmeric. GGC was detected only in mustard and fenugreek as seen in Figs. 1b and 1c, respectively. Mustard contained the highest level of GGC. NAC was not detected in any of spice samples studied. Coriander had the lowest level of biological thiols amongst the spices analysed, with only GSH present in its aqueous extracts.

Our study showed that the spices analysed contained different levels of biothiols. It was therefore, necessary to determine whether the spices containing higher levels of thiols were more potent antioxidants than their counterparts with lower thiol levels. Accordingly, the antioxidant abilities of the aqueous extracts of the spices were evaluated using different *in vitro* methods. As most of the thiols were susceptible to oxidation, all of the spice samples were extracted in SBB and placed on ice during the experimental process. Ascorbic acid and EDTA-Na_2were used as standards to compare the *in vitro* antioxidant properties.

2,2-Diphenyl-1-picrylhydrazyl (DPPH) is widely used to test the ability of compounds to act as free radical scavengers or hydrogen

Table 1
Thiols concentration in spices (nM/g dry or wet weight).[a]

Spices	Botanical name	NAC	GSH	CYS	HCYS	GGC
Mustard	Brassica hirta	ND	820 ± 24	53 ± 3	ND	46 ± 6
Fenugreek	*Trigonella foenum-graecum* L.	ND	519 ± 52	57 ± 4	62 ± 1	42 ± 10
Ginger[b]	*Zingiber officinalis*	ND	1076 ± 18	387 ± 6	ND	ND

donors, and to evaluate antioxidant activity of foods. It has also been used in recent years to quantify antioxidants in complex biological systems. Mustard extract showed the highest DPPH activity with cardamom being the lowest of all, as seen in Fig. 2a. Ascorbic acid showed a 50% DPPH scavenging activity at 125 μg. Although mustard did not have the highest levels of thiols, the radical scavenging power of mustard extract was highest, in comparison with the other spice extracts.

The highly reactive radical (·OH) reacts with biomolecules resulting in damage to cells. Hydroxyl radicals are produced through various biological reactions; one of the common reactions is the Iron (II) - based Fenton reaction. Hydroxyl radical scavenging activity of aqueous extracts of spices was evaluated to determine their hydroxyl radical scavenging activity. Hydroxylation of salicylate is widely used as an index of hydroxyl radical formation *in vitro*. The present study showed that coriander extract, of all the spices extracts, was the strongest scavenger of hydroxyl radical, as seen in Fig. 2b. It is also noteworthy that cardamom, ginger, and turmeric extracts also showed a scavenging ability similar to that of the coriander extract.

Iron can initiate lipid peroxidation by Fenton reaction and also accelerate peroxidation by decomposing lipid hydroperoxides into peroxyl and alkoxyl radicals that can abstract hydrogen and perpetuate the chain reaction (Gülçin, Büyükokuroglu, & Küfrevioglu, 2003; Halliwell, 1991). Chelating ferrous ions illustrates one of the significant antioxidant properties. EDTA-Na_2, a standard chelator was used to compare the chelating effects of the extracts. The chelating effects of the spice extracts are as follows: cardamom › fenugreek › mustard › coriander › turmeric › ginger. Even at a minimal concentration of 20 μg, the standard chelator EDTA-Na_2, showed a 50% chelating as seen in Fig. 2c.

In vitro antioxidant assays performed to establish a relation between thiol levels and the antioxidant abilities did not show a thiol dependent effect. As most of the antioxidant abilities are attributed to the phenolic content of the samples, an experiment was performed to see if the antioxidant abilities measured were directly related to the levels of the phenols present in the extracts. It was observed that the antioxidant properties were independent of the phenolic content. Recent studies have also shown that many flavanoids and polyphenols contribute significantly to the total antioxidant activity in fruits and vegetables (Luo, Basile, & Kennelly, 2002). Although mustard extract showed the highest phenolic content as seen in Fig. 2d, none of the antioxidant studies showed a

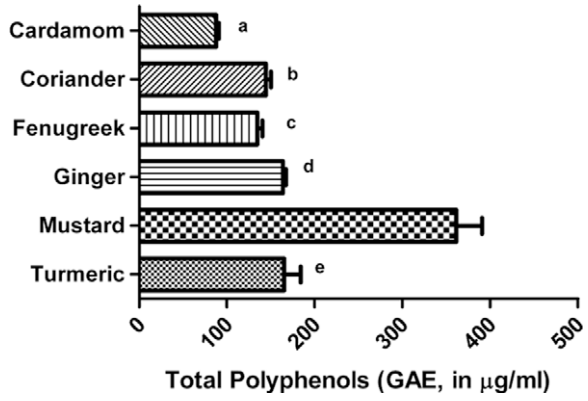

Fig. 2d. Polyphenol content of water extracts from spices. Total polyphenol content is expressed in gallic acid equivalents (GAE). Mean values ± S.D. followed by different letters are significantly different (p < 0.05).

predominant effect of mustard due to its phenolic content. It can be concluded from these studies that the antioxidant abilities of spices observed in this present study may not only be a result of the phenolic content of the spices, but may also be attributed to the presence of other potent antioxidants like thiols and flavanoids.

The findings of the present study suggest that spices can be a significant source of thiols and, along with the phenols present, can enhance the antioxidant status of the biological system. The high levels of thiols observed in some spices may reinforce the idea that incorporation of spices into everyday meals may be very beneficial, and could promote good health by protecting against oxidative stress related problems.

Vacuum drying

ABSTRACT

The present work was aimed at studying the effects of drying methods and conditions (i.e., ambient drying, hot air drying at 40 °C, vacuum drying and low-pressure superheated steam drying within the temperature range of 70–90 °C at an absolute pressure of 10 kPa), as well as the concentration of Indian gooseberry extract, (added to edible chitosan film-forming solution as a natural antioxidant, at concentrations of 1, 2 and 3/100 g), on the residual total phenolic content (TPC) of the films. The swelling and release behaviour of TPC from the films were also studied. Drying methods and conditions were found to have significant effects on the percentage of residual TPC. The release characteristics, swelling and functional group interaction of the antioxidant films, as assessed by Fourier-transform infrared (FTIR) spectroscopy, were found to be affected by the drying methods and conditions, as well as the concentration of the Indian gooseberry extract.

1. Introduction

Edible films have recently received increased attention due to their various advantages including biodegradability and edibility. Among many materials that can be used to form edible films, chitosan (β-(1,4)-2-amino-2-deoxy-D-glucose) is one of the most promising as it has a good film-forming ability, which makes it suitable for use as a food packaging. Many investigators have evaluated chitosan films for many food-related applications (Han, Zhao, Leonard, & Traber, 2004; Sebti, Martial-Gros, Carnet-Pantiez, Grelier, & Coma, 2005). To make edible films even more useful, functional edible films that contain active agents have been developed, to enhance food quality and product shelf-life (Suppakul, Miltz, Sonneveld, & Bigger, 2003).

Chitosan can be easily formed into films by a casting/solvent evaporation technique. Different drying methods and conditions have been used to prepare chitosan films. Numerous researchers prepared chitosan films by drying them at ambient temperature (Caner, Vergano, & Wiles, 1998; Hwang, Kim, Jung, Cho, & Park, 2003; Wiles, Vergano, Barron, Bunn, & Testin, 2000); other researchers prepared chitosan films by oven drying (Butler, Vergano, Testin, Bunn, & Wiles, 1996) or infrared drying (Srinivasa, Ramesh, Kumar, & Tharanathan, 2004). Recently, Mayachiew and Devahastin (2008a) investigated the influences of different drying methods and conditions on the drying kinetics and various properties of chitosan films. Drying at control conditions (ambient air drying and hot air drying at 40 °C) were compared with vacuum drying and low-pressure superheated steam drying (LPSSD) at an absolute pressure of 10 kPa and different drying temperatures (70, 80, and 90 °C). The properties of chitosan films, in terms of colour, tensile strength, percent elongation, water vapour permeability (WVP), glass transition temperature (T_g) and degree of crystallinity were determined. In terms of the drying kinetics, the drying methods were found to have a significant effect on the rates of moisture reduction of the samples. Vacuum drying and LPSSD required much shorter drying time than did ambient and hot air drying at 40 °C. In terms of properties it was found that LPSSD at 70 °C led to films with higher tensile strength and percent elongation than the films prepared by other drying methods and under other drying conditions. Ambient dried and LPSSD films had more crystallinity than the films dried by vacuum drying.

In terms of active agents that can be incorporated into films, plant extracts have recently received much attention and have a tendency of replacing synthetic agents. Generally, plant extracts which contain high concentrations of phenolic compounds possess strong antioxidant properties. Indian gooseberry (*Phyllanthus emblica* Linn.), or "Ma-khaam Pom" in Thai, is one of the most

doi:10.1016/j.foodchem.2009.05.027

often-used herbs and is widely available in most tropical and subtropical countries. Indian gooseberry has been shown to possess high antioxidant activity *in vitro* (Mayachiew & Devahastin, 2008b).

Recently, many antioxidant edible films have been developed to reduce oxidation in packed foods (Gómez-Estaca, Bravo, Gómez-Guillén, Alemán, & Montero, 2009; Han & Krochta, 2007; Oussalah, Caillet, Salmiéri, Saucier, & Lacroix, 2004). For example, Oussalah et al. (2004) studied the use of milk protein-based films containing essential oils for the preservation of whole beef muscle. Films incorporated with oregano stabilised lipid oxidation in beef muscle samples, while films incorporated with pimento possessed the highest antioxidant activity. Gómez-Estaca et al. (2009) investigated the antioxidant properties of gelatin-based edible films containing oregano or rosemary aqueous extracts. It was found that the films supplemented with antioxidant extracts exhibited higher reducing ability and free radical-scavenging capacity than the control films; the degree of antioxidant power was generally proportional to the amount of the added extract.

For functional edible films, controlled release of active agents from the films to food is important, since there is a need to maintain the concentration of active compounds in packed food (Buonocore, Del Nobile, Panizza, Corbo, & Nicolais, 2003). Although many studies have been made on the effects of many parameters on the release of active agents from many types of films (Jeon, Park, Kwak, Lee, & Park, 2007; Tovar, Salafranca, Sánchez, & Nerín, 2005), the effects of drying methods and conditions used to prepare functional edible films, in particular chitosan films, on the retention and release characteristics of added antioxidant compounds have not been well established. The objectives of this study were therefore to investigate the effects of drying methods (i.e., ambient-temperature drying, hot air drying, vacuum drying, low-pressure superheated steam drying) and conditions on the total phenolic content (TPC) of chitosan films incorporated with Indian gooseberry extract. A study of the release behaviour of the antioxidant compound from the films was also conducted. Fourier-transform infrared (FTIR) spectroscopy was performed to investigate functional group interaction between chitosan and added active agent. Swelling of the films was also measured, to help explain the release behaviour of the films.

2. Materials and methods

2.1. Materials

Chitosan (molecular weight of 900,000 Da and degree of deacetylation of 90.2%) was obtained from S.K. Profishery Co., Ltd. (Bangkok, Thailand). Glycerol was purchased from Carlo Erba (Val de Reuil, Italy) while acetic acid was obtained from Merck (Darmstadt, Germany). Folin–Ciocalteu reagent, sodium carbonate and absolute ethyl alcohol were purchased from Carlo Erba (Vigevano, Italy).

2.2. Preparation of chitosan solution

Chitosan solution (1.5% w/v) was prepared by dissolving chitosan in 1% (v/v) acetic acid under constant stirring at 300 rpm using a magnetic stirrer (Framo®-Gerätechnik, model M21/1, Eisenbach, Germany) at room temperature for 24 h. Glycerol 25% (w/w chitosan) was then added into the chitosan solution; stirring was continued at room temperature for 1 h. After mixing the solution was centrifuged for 15 min at 12,400 rpm using a refrigerated centrifuge (Hitachi, model Himac CR21, Ibaragi, Japan) to remove undissolved impurities and bubbles in the solution.

2.3. Preparation of Indian gooseberry extract

To prepare Indian gooseberry extract, Indian gooseberry powder (10 g dry basis), dried by a tray dryer at 40 °C with particle size between 125–425 μm, was extracted with 50 ml of 95% (v/v) ethanol (Ahmad, Mehmood, & Mohammad, 1998). The extract was filtered through a filter paper (Ø110 mm, Cat. no. 1001 110, Schleicher and Schuell GmbH, Dassel, Germany); the filtrate was collected and concentrated using a rotary evaporator (Resona Technics, Labo Rota 300, Gossau, Switzerland) at 40 °C for 10 min and kept at 4 °C in a dark bottle until use. For a detailed preparation method the reader is referred to Mayachiew and Devahastin (2008b).

2.4. Preparation of antioxidant chitosan films

Indian gooseberry extract was added to the chitosan solution at concentrations of 1, 2 and 3/100 g. The concentration of the extract was varied since it was hypothesised that different concentrations of the extract might lead to different polymer structure modification, which would in turn affect the release behaviour of the active compound. All mixtures were homogenised by a bench top homogeniser (Ika® Works (Asia), Model T 25 basic, Selangor, Malaysia) at 9500 rpm for 2 min. The film solution (21 g) was poured onto an acrylic plate with dimensions of 13 × 10 cm to cast an antioxidant film. Drying of the film was performed by four methods, which were ambient air drying, hot air drying at 40 °C, and vacuum drying and low-pressure superheated steam drying (LPSSD) at 10 kPa, both at 70, 80 and 90 °C following the procedures of Mayachiew and Devahastin (2008a). After drying the film was conditioned for at least 48 h in a desiccator containing saturated salt solution of magnesium nitrate (Ajax Finechem, Seven Hills, Australia), which produced a relative humidity (RH) of 53%.

2.5. Determination of total phenolic content of films

The total phenolic content (TPC) of the antioxidant film was evaluated by an elution technique described by Zhang and Kosaraju (2007) with some modification. A portion of the film (0.5 g; 2 × 2 cm) was placed in 50 ml of 0.1 M NaOH and shaken with an environmental incubator shaker (New Brunswick Scientific, Model G-24, Edison, NJ) at room temperature for 48 h. The sample was then taken to determine the TPC, using Folin–Ciocalteu reagent (Zhou & Yu, 2006). The reaction mixture contained 50 μl of the eluted sample, 250 μl of the Folin–Ciocalteu reagent, 0.75 ml of 20 g/100 ml sodium carbonate and 3 ml of pure water. After 2 h of reaction at ambient temperature the absorbance at 765 nm was measured using a Shimadzu UV-2101 spectrophotometer (Shimadzu Scientific Instruments, Kyoto, Japan); the absorbance was used to calculate the TPC, using gallic acid as a standard. The results were presented in terms of the percentage of residual TPC. The percentage of residual TPC was calculated according to the following equation:

$$\%\ \text{Residual TPC} = 100 \times \left(\frac{\text{Mass of dried sample} \times (\text{conc. of TPC in dried sample})}{\text{Mass of film solution} \times (\text{conc. of TPC in film solution})}\right) \quad (1)$$

where the mass of dried sample is the mass of the sample after a drying procedure has been applied.

2.6. Release of antioxidant agent from films

A release test was conducted in an environmental incubator shaker at room temperature. A film (2 × 2 cm) was placed in a bea-

ker containing 100 ml of distilled water. The solution sample was taken out at 15 min intervals until 1 h and every 1 h afterward, to determine the TPC of the solution in order to follow the release kinetics of the antioxidant from the film. The release result was reported in terms of the percentage of release of TPC:

$$\%\ \text{Released TPC}_t = 100 \times \frac{\text{TPC}_t}{\text{TPC}_0}. \quad (2)$$

where TPC_0 is the amount of TPC after drying, TPC_t is the amount of release of TPC at any time.

2.7. FTIR analysis

Attenuated total reflection/Fourier-transform infrared spectroscopic (ATR/FTIR) spectra were collected at 25 °C by coupling the ATR accessory to an FTIR spectrometer (Perkin–Elmer Inc., Model 1760X, Norfolk, CT) available at Chulalongkorn University, Bangkok. Time-resolved experiments were collected by averaging, depending on the experiment, 10 or 2 scans at 4 cm^{-1} spectral resolution at various time intervals.

2.8. Swelling of antioxidant films

A film was cut into sizes of 2 × 2 cm and dried in a vacuum oven (Sanyo, Model Gallenkamp/OM-09980, Loughborough, UK) at 70 °C at an absolute pressure of 100 mbar for 24 h. The film was weighed and left at ambient temperature in 30 ml of distilled water for 24 h. The film was then blotted with a tissue paper and the mass of the film was measured periodically with a microbalance (Sartorius, Model RC 250S, Göttingen, Germany) until equilibrium was reached. The degree of swelling was evaluated using Eq. (3):

$$\text{Degree of swelling} = 100 \times \left(\frac{\text{Mass of film (g)} - \text{Mass of dried film (g)}}{\text{Mass of dried film (g)}}\right) \quad (3)$$

2.9. Statistical analysis

All data were subjected to analysis of variance (ANOVA) using SPSS® software (Chicago, IL) and were presented as mean values with standard deviations. Differences between mean values were established using Duncan's multiple range tests at a confidence level of 95%. All experiments were performed in duplicate except where stated otherwise.

3. Results and discussion

3.1. Total phenolic content of antioxidant films

Phenolic compounds in plants have high antioxidant activities, mainly due to redox properties, which include free radical-scavenging, hydrogen-donating and singlet oxygen-quenching. Mayachiew and Devahastin (2008b) reported that Indian gooseberry extract had high antioxidant activity *in vitro* and that phenolics were the main compounds of the extract.

Table 1 shows the percentage of residual TPC of chitosan films incorporated with various concentrations of Indian gooseberry extract and prepared by different drying methods and conditions; the drying time to reach the desired final film moisture content of 14% (d.b.) is listed in Table 2. Indian gooseberry extract concentration did not seem to have any significant effect on the percentage of residual TPC. However, antioxidant films incorporated with higher concentrations of the extract showed higher intensity of absorption peaks at 1250, 1620 and 1720 cm^{-1} and lower intensity of absorption peak at 1566 cm^{-1} (Fig. 4), indicating more intermolecular interaction between chitosan film and Indian gooseberry extract when the concentration of the added extract increased.

Table 1
Percentage of residual total phenolic content of antioxidant films prepared by different drying methods and conditions.

Drying method	Indian gooseberry extract concentration		
	1%	2%	3%
Ambient drying	97.90 ± 1.88[a]	98.18 ± 1.32[a]	98.67 ± 0.49[a]
Hot air drying	96.54 ± 2.20[a]	96.50 ± 1.08[a]	96.68 ± 1.07[a]
Vacuum drying			
70 °C	84.78 ± 1.59[c]	85.65 ± 0.60[bc]	85.36 ± 0.49[c]
80 °C	81.65 ± 1.13[d]	81.83 ± 1.20[de]	82.69 ± 1.07[d]
90 °C	76.58 ± 1.24[e]	77.18 ± 1.08[f]	77.47 ± 0.66[f]
LPSSD			
70 °C	87.82 ± 1.81[b]	86.42 ± 0.72[b]	87.76 ± 0.33[b]
80 °C	83.81 ± 1.59[c]	84.72 ± 0.48[cd]	84.44 ± 1.40[c]
90 °C	79.65 ± 1.59[de]	80.15 ± 0.96[e]	80.39 ± 0.74[e]

Values in the same column with different superscripts mean that the values are significantly different ($p < 0.05$).

Table 2
Drying time to reach final moisture content of 14% (d.b.).

Drying method	Indian gooseberry extract concentration		
	1%	2%	3%
Ambient drying	52 h	50 h	47 h
Hot air drying	17 h	16 h	15 h
Vacuum drying			
70 °C	85 min	84 min	84 min
80 °C	65 min	64 min	64 min
90 °C	60 min	59 min	59 min
LPSSD			
70 °C	130 min	129 min	129 min
80 °C	95 min	94 min	94 min
90 °C	90 min	89 min	89 min

Regarding the effects of drying methods and conditions, it was noted that drying methods and conditions had significant effects on the percentage of residual TPC of the films. It was found that ambient dried films had the highest residual TPC. The higher losses of TPC were observed for films dried by vacuum drying and LPSSD; LPSSD films had slightly higher residual TPC than the vacuum-dried films, however. This may be due to the fact that the film temperature increased more rapidly and stayed at higher levels in the case of vacuum drying, thus inducing more thermal degradation of TPC compared with the LPSSD films (Mayachiew & Devahastin, 2008a). The temperature of the vacuum-dried films increased more rapidly than that of the LPSSD films, due to the fact that the electric heater was used more often during vacuum drying, since it was the only source of energy for drying. This might increase the amount of radiation absorbed by the film surfaces. The constant rate drying periods of vacuum-dried films were also shorter than those of LPSSD films. These are typical comparative characteristics of vacuum drying and LPSSD (Devahastin, Suvarnakuta, Soponronnarit, & Mujumdar, 2004).

Higher drying temperatures led to a lower percentage of residual TPC in both vacuum-dried films and LPSSD films. The antioxidant films prepared by LPSSD at 70 °C had the highest percentage of residual TPC, compared with films prepared at other conditions of LPSSD and vacuum drying. It is indeed well recognised that thermal treatment induces degradation of phenolic compounds (Chan et al., 2009; Guan, Cenkowski, & Hydamaka, 2005; Larrauri, Rupérez, & Saura-Calixto, 1997). The minimum percentage of residual TPC was found in the case of chitosan film incorporated with 1% Indian gooseberry extract and prepared by vacuum

drying at 90 °C. The presence of oxygen in the case of ambient and low-temperature hot air drying did not seem to have any significant effect on the percentage of residual TPC.

3.2. Release of antioxidant agent from films

Figs. 1–3 show the evolution of the percentage of release of TPC from antioxidant films prepared by different drying methods and conditions. At the same concentration of Indian gooseberry extract antioxidant chitosan films prepared by ambient drying, hot air drying and LPSSD at 70 °C showed the highest percentage of release of TPC; the release was lowest in the case of the films prepared by vacuum drying at 90 °C. This might be due to the different intermolecular interactions between the extract and chitosan films (as shown by the results of FTIR spectra in Section 3.3), the microstructure of the films, as well as different degrees of film swelling. The results on film swelling will be discussed in further detail in Section 3.4.

It can be seen in Fig. 1 that the percentage of TPC released from chitosan films incorporated with 1% (w/w) Indian gooseberry extract prepared by ambient drying, hot air drying and LPSSD at 70, 80 and 90 °C reached 92%, 90%, 87%, 84% and 79% within 24 h, respectively. The percentage of TPC released from vacuum-dried films at 70, 80 and 90 °C at 24 h was approximately 86%, 81% and 75%, respectively. TPC was released from LPSSD films faster than from vacuum-dried films prepared at the same temperature. The same trends were found in the cases of chitosan films incorporated with 2% and 3% (w/w) Indian gooseberry extract (see Figs. 2 and 3).

Regarding the effect of Indian gooseberry extract concentration, the percentage of antioxidant released decreased when the Indian gooseberry extract concentration increased. Chitosan films incorporated with 3% (w/w) Indian gooseberry extract had lower percentage of antioxidant release than the films incorporated with 1% and 2% extract. This might also be due to the effect of higher intermolecular interaction.

The release profiles of the antioxidant films could be separated into two parts. During an initial period (0–8 h), the release profiles were generally non-linear; the release of TPC was rapid at first and then slowed down with an increase in time. However, the release profiles of the films incorporated with 1% Indian gooseberry extract were linear within 2 h, which might be due to the fact that the films required a shorter time to become fully hydrated, as shown later by a higher degree of swelling; the rapid release of TPC from the films was thus attributed to the rapid swelling of the films in distilled water.

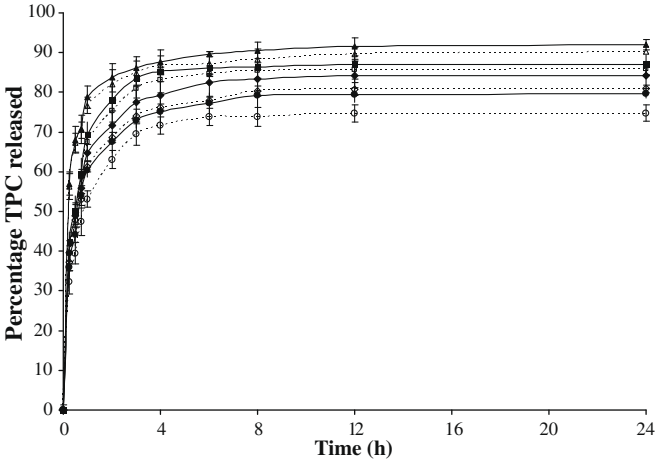

Fig. 1. Percentage of release of TPC from chitosan films enriched with 1% (w/w) Indian gooseberry extract and prepared by ambient drying (—▲—); hot air drying at 40 °C (---△---); LPSSD at 70 °C (—■—), 80 °C (—◆—), 90 °C (—●—); vacuum drying at 70 °C (---□---), 80 °C (---◇---), 90 °C (---○---).

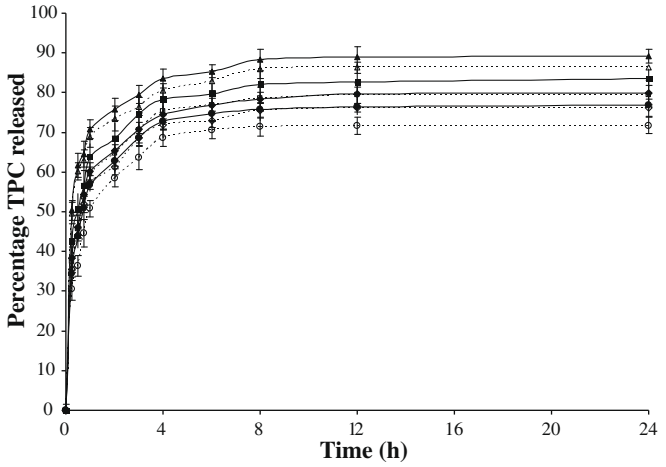

Fig. 2. Percentage of release of TPC from chitosan films enriched with 2% (w/w) Indian gooseberry extract and prepared by ambient drying (—▲—); hot air drying at 40 °C (---△---); LPSSD at 70 °C (—■—), 80 °C (—◆—), 90 °C (—●—); vacuum drying at 70 °C (---□---), 80 °C (---◇---), 90 °C (---○---).

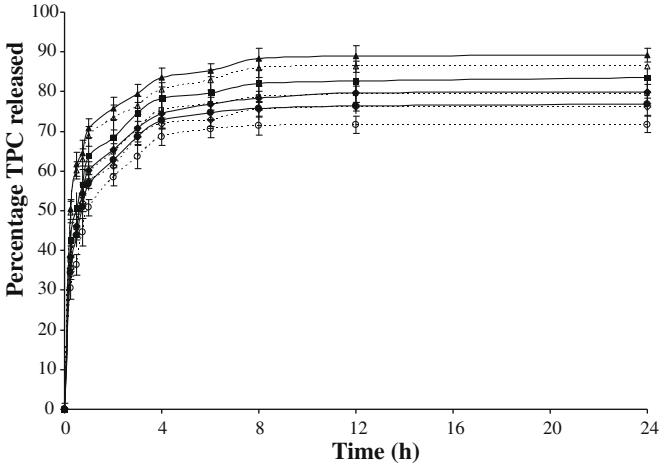

Fig. 3. Percentage of release of TPC from chitosan films enriched with 3% (w/w) Indian gooseberry extract and prepared by ambient drying (—▲—); hot air drying at 40 °C (---△---); LPSSD at 70 °C (—■—), 80 °C (—◆—), 90 °C (—●—); vacuum drying at 70 °C (---□---), 80 °C (---◇---), 90 °C (---○---).

In the second period (8–24 h) the release was rather constant. The constant rate of release might be due to the interaction of the extract with the chitosan matrix. Popa, Aelenei, Popa, and Andrei (2000) studied the interaction between chitosan and polyphenols extracted from spruce wood bark and found that chitosan and polyphenols formed a complex and that the release of polyphenols followed a two-step process as well.

Chitosan might interact with phenolic compounds of Indian gooseberry extract, mainly by weak interactions such as hydrogen bonding. Hydroxyl groups of phenolics could form H-bonds with NH_3^+ of chitosan (Kanatt, Chander, & Sharma, 2008). Moreover, the amine groups probably also contributed to ionic interactions with carboxylic groups of acid phenols (Spagna et al., 1996). These bound fractions could affect the release of phenolic compounds. On the other hand, phenolics retention might be achieved through strong covalent bonds (Popa et al. 2000).

3.3. FTIR analysis of antioxidant films

3.3.1. Effect of antioxidant agent

The interaction between chitosan and the extract was characterised by FTIR analysis. Fig. 4 shows the transmission infrared spectra of the chitosan films enriched with different concentrations of Indian gooseberry extract and prepared by ambient drying. Pure chitosan film had characteristic bands at 1631 cm^{-1} (amide I band) and 1566 cm^{-1} (amide II vibration). The present FTIR spectra are similar to the results described by many studies (Pranoto, Rakshit, & Salokhe, 2005; Ritthidej, Phaechamud, & Koizumi, 2002). Chitosan films showed a symmetric carboxylate anion stretching at 1413 cm^{-1}, indicating free chitosan films (Puttipipatkhachorn, Nunthanid, Yamamoto, & Peck, 2001).

When chitosan films were incorporated with Indian gooseberry extract, changes in FTIR spectra were noted. The spectra of antioxidant films exhibited small modifications of the positions of some bands within the range 1500–1700 cm^{-1}, which are related to amine and carbonyl groups. The new absorption peak at 1620 cm^{-1} (amide I band) was shifted from 1631 cm^{-1}. In addition, the peak was sharper with an increase in the extract concentration, indicating more interaction between chitosan and the extract. Pasanphan and Chirachanchai (2008) reported that chitosan could form a linkage with phenolic compounds, such as gallic acid, *via* an amide linkage, which is shown as the absorption peak at 1620 cm^{-1}.

Another important change was found as new peaks at 1720 cm^{-1}, indicating an ester linkage, which could be attributed to the more intensive interaction between chitosan and Indian gooseberry extract. However, the peak intensity at 1566 cm^{-1}, which is attributed to the amine group ($-NH_2$) of chitosan, decreased. The loss of this peak might be due to the interaction of the amine group with a functional group of the extract. In addition, the peak at 1250 cm^{-1}, which corresponds to C–O stretching of the phenol compounds, was stronger with an increase in the concentration of the extract.

Structurally, phenolics are compounds consisting of aromatic rings bonded to one or more hydroxyl substituents and range from simple phenolic molecules to highly polymerised compounds. Phenolic compounds are naturally present as conjugates with polysaccharides, linked to one or more of the phenolic groups and may also occur as functional derivatives such as esters (Balasundram, Sundram, & Samman, 2006). Therefore, chitosan could bind with phenolics when Indian gooseberry extract was incorporated into films.

3.3.2. Effects of drying methods and conditions

The effects of drying methods and conditions on functional group interaction were also investigated. The IR spectra of chitosan films enriched with 2% (w/w) Indian gooseberry extract and prepared by vacuum drying and LPSSD at 70 and 90 °C were compared with those of the film prepared at ambient conditions. It is seen in Fig. 5 that drying methods and conditions had some effects on the IR spectra. Antioxidant films prepared by LPSSD and vacuum drying showed stronger peak intensity of the amide linkage at 1620 cm^{-1} than did ambient dried film. However, LPSSD led to films of lower intermolecular interaction, which was shown by the lower peak intensity of the amide linkage at 1620 cm^{-1}, relative to that from vacuum drying. Drying led to intermolecular interaction in the films, which was shown by the alteration of the peak intensity at 1620 cm^{-1}.

The percentage of release of TPC decreased, due probably to an increase in the intermolecular interaction. The antioxidant film

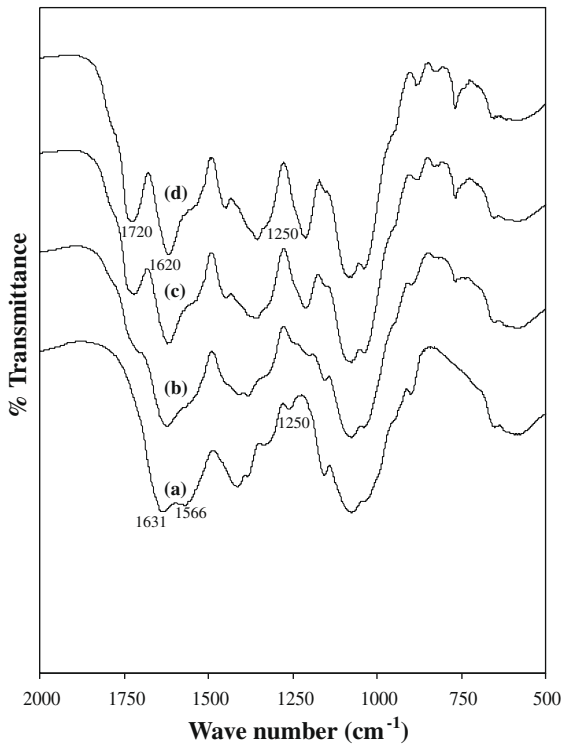

Fig. 4. FTIR spectra of ambient dried films with different concentrations of Indian gooseberry extract: (a) with no extract, (b) with 1% (w/w) Indian gooseberry extract, (c) with 2% (w/w) Indian gooseberry extract, (d) with 3% (w/w) Indian gooseberry extract.

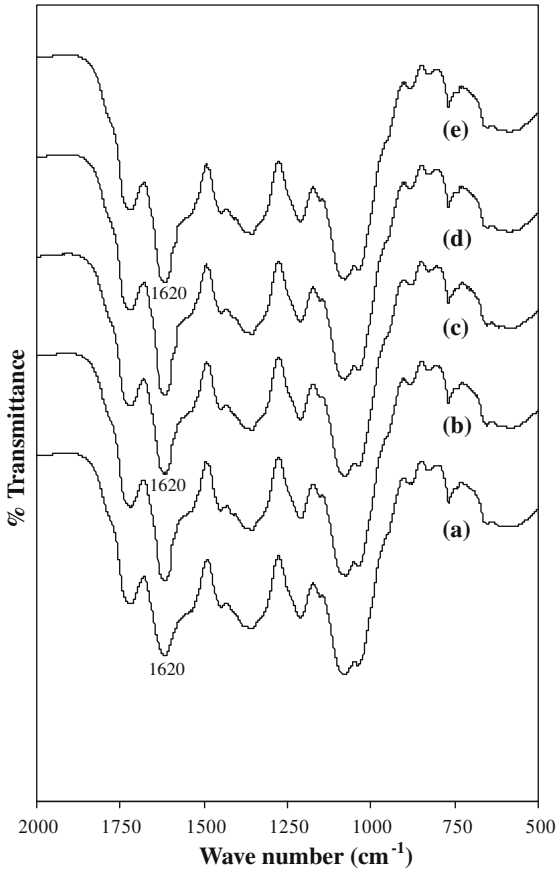

Fig. 5. FTIR spectra of chitosan films enriched with 2% (w/w) of Indian gooseberry extract prepared using different drying methods and conditions: (a) ambient drying, (b) vacuum drying at 70 °C, (c) LPSSD at 70 °C, (d) vacuum drying at 90 °C and (e) LPSSD at 90 °C.

dried by vacuum drying at 90 °C exhibited the lowest percentage of release of TPC and showed a different release profile compared with the film prepared by ambient drying. This may be due to the high intermolecular interaction between chitosan and phenolic compounds, such as gallic acid, in Indian gooseberry extract via amide linkage, which was shown by an absorption peak at 1620 cm^{-1} (Pasanphan & Chirachanchai, 2008). Muzzarelli and Muzzarelli (2005) reported that amidation, which was shown by the absorption peak at 1620 cm^{-1}, might lead to a decrease in swelling of the heat-treated films, resulting in the lower percentage of antioxidant release.

Regarding the effect of the drying temperature on intermolecular interaction, it was found that the peaks at 1620 cm^{-1} of the films dried at 90 °C were slightly sharper than those of the films dried at 70 °C. This might be due to the fact that the higher temperature induced more interchain crosslinkage, which involves NH_2 group with amide formation (Lim, Khor, & Ling, 1999). Ritthidej et al. (2002) reported that longer time of heat treatment led to a stronger peak intensity of amide I band. Higher intermolecular interaction due to the use of higher drying temperature might thus lead to the lower percentage of release of TPC mentioned earlier in Section 3.2. Lower percentage of release of TPC was observed for both LPSSD and vacuum-dried films.

Suppakul et al. (2003) indeed stated that different interactions between an active agent and chitosan had an effect on the release of the active agent from the film. Drying methods and conditions may thus be used to engineer chitosan films for controlled release applications.

3.3.3. FTIR of films after release study

FTIR spectroscopy was performed to determine the characteristics of the film matrix as well as the changes of the intermolecular interaction both before and after the release study. By considering the IR spectra of chitosan film enriched with 2% (w/w) Indian gooseberry extract prepared by ambient drying both before and after release study (Fig. 6) it was found that the polymer signal diminished when the film was in contact with water because of the sorption of moisture and subsequent film swelling (Lagaron, Fernandez-Saiz, & Ocio, 2007).

It was also found that the film after the release study exhibited a drop of the relative peak intensities at 1250, 1620 and 1720 cm^{-1}, indicating a decrease in the interaction of active agent with the film. The changes of the peak intensity could be due to the loss of active agent linkage with the chitosan matrix after being released into the liquid phase. It was indeed shown by the release profiles in Figs. 1–3 that the percentage of release of TPC from the films increased with time.

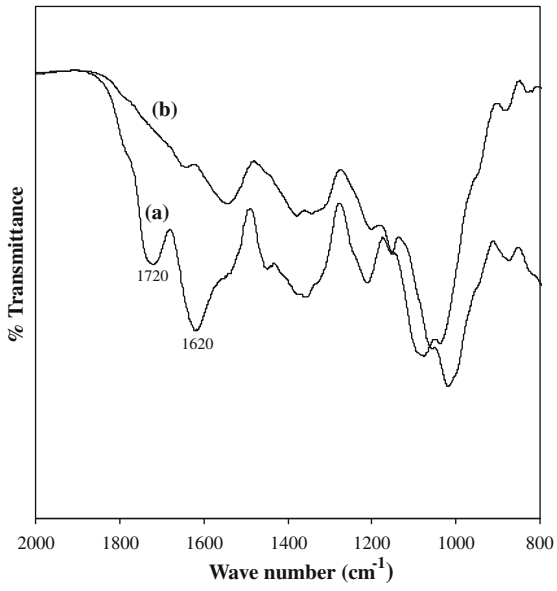

Fig. 6. FTIR spectra of chitosan films enriched with 2% (w/w) Indian gooseberry extract: (a) before release and (b) after release.

The peak remaining after release might be due to the interaction of the extract with the chitosan matrix, which was shown by the constant rate of release in the second period (8–24 h) of release study in Section 3.2. After the release study the film still retained some of the polymer signals, which indicated that part of the film still remained intact, as also observed visually.

3.4. Swelling of antioxidant films

The water resistance of films was measured in terms of swelling as shown in Table 3. It was observed that the swelling ability of antioxidant films was affected by the extract concentration. Swelling of pure chitosan film prepared at ambient conditions was around 173%, a value which is similar to that of Yao et al. (1996). The high value of swelling is due to the hydrophilic characteristic of chitosan. Nevertheless, from our observation, the films did not break apart even after the swelling study.

Swelling of the films was reduced when the films were incorporated with the extract. Although chitosan has hydrophilic groups, such as carboxylic groups, in its structure and these groups could easily interact with water, resulting in swelling of the films, upon being enriched with the extract intermolecular interaction between chitosan and the extract developed and this resulted in a decrease in the film swelling. In addition, a lower level of swelling could be attributed to the hydrophobic properties of the extract. Di Pierro et al. (2006) also reported that the degree of swelling of a polymeric material strongly depends on the amount and nature of intermolecular chain interactions.

It was noted that drying methods significantly affected the degree of swelling. It is seen in Table 3 that swelling of LPSSD and vacuum-dried films was less than that of films prepared at ambient conditions and at 40 °C. Swelling of the films could be reduced through an increase in the degree of cross-linkage. The lesser extents of swelling of LPSSD and vacuum-dried films were because of the higher extents of thermal cross-linkage, thus inducing less swelling of the films due to more rigid chains (Lim et al. 1999; Mayachiew & Devahastin, 2008a). In addition, thermal treatment of chitosan led to amide formation, which reduced the number of hydrophilic groups, thus decreasing swelling of the films (Muzzarelli & Muzzarelli, 2005; Ritthidej et al. 2002).

In addition, it was found that the degree of swelling slightly decreased with an increase in the drying temperature. This is again

Table 3
Percentage of swelling of antioxidant films.

Drying method	Indian gooseberry extract concentration		
	1%	2%	3%
Ambient drying	124.8 ± 2.8^{a}	84.0 ± 1.9^{a}	56.2 ± 0.9^{a}
Hot air drying	123.5 ± 2.6^{a}	83.0 ± 2.2^{a}	55.8 ± 1.6^{a}
Vacuum drying			
70 °C	103.9 ± 2.2^{bc}	68.3 ± 3.0^{bc}	44.0 ± 2.3^{bc}
80 °C	97.7 ± 1.9^{de}	64.3 ± 3.1^{cd}	39.9 ± 1.2^{cde}
90 °C	91.6 ± 2.8^{f}	60.7 ± 3.9^{d}	36.2 ± 2.9^{e}
LPSSD			
70 °C	109.4 ± 2.6^{bc}	73.4 ± 1.2^{b}	46.0 ± 2.6^{b}
80 °C	100.0 ± 2.7^{de}	66.6 ± 1.7^{cd}	42.6 ± 1.7^{bcd}
90 °C	95.6 ± 3.0^{ef}	62.4 ± 2.5^{cd}	38.4 ± 2.1^{de}

Values in the same column with different superscripts mean that the values are significantly different ($p < 0.05$).

because of thermal cross-linkage, which is accelerated by temperature (Lim & Wan, 1995). From release results in Figs. 1–3 it was found that higher drying temperatures of both LPSSD and vacuum drying led to lower percentage of release of TPC.

The results indicated that vacuum-dried films, which had lower degrees of swelling compared with the films prepared by LPSSD and drying at control conditions, showed the lowest percentage of release of TPC. The increased release that occurred with an increase in the degree of film swelling could be related to a change in the integrity of the film matrix (Sujja-areevath, Munday, Cox, & Khan, 1998). This is because the films might undergo relaxation during the release process, making the films become more flexible. This allowed the extract to diffuse out of the matrix more easily (Wu, Wang, Tan, Moochhala, & Yang, 2005). It was found from the release study that the films with lower degrees of swelling had lower percentage of release of TPC. Risbud, Hardikar, Bhat, and Bhonde (2000) also reported a direct correlation between the degree of swelling and release of antibiotics from chitosan films; the release of active agent from chitosan films normally increased with the degree of swelling.

In addition, release of the extract from the films might also be related to the film microstructure (Berger et al., 2004; Risbud et al., 2000). High-porosity film enhanced swelling, which was responsible for the release. It was found that at the same drying temperature LPSSD films had higher percentage of release of TPC than vacuum-dried films. This might be due to the higher porosity of the LPSSD films. It has been shown earlier that biomaterials undergoing LPSSD had higher porosity than products undergoing vacuum drying (Léonard, Blacher, Nimmol, & Devahastin, 2008).

4. Conclusion

The effects of drying methods and conditions on the percentage of residual TPC, release characteristics, intermolecular interaction and degree of swelling of chitosan films incorporated with different concentrations of Indian gooseberry extract were investigated. An increase in the extract concentration led to stronger functional group interaction, while the degree of swelling and percentage of release of TPC from antioxidant films decreased. The percentage of residual TPC, percentage of release of TPC, degree of swelling and functional group interaction were affected by drying methods and conditions. Ambient drying, low-temperature hot air drying and LPSSD at 70 °C led to antioxidant chitosan films with less intermolecular interaction, higher degree of swelling and percentage of release of TPC than did the other drying methods and conditions. Drying methods and conditions may be used to engineer chitosan films for controlled release in food packaging applications. Work is underway to develop a mathematical model that can be used to explain the release characteristics of TPC from chitosan films.

Breakages

ABSTRACT

Atlantic salmon (average body weight 2.9 ± 0.1 kg) were subjected to either minimal pre-slaughter crowding stress (NS group), 20 min (short-term stress, SS group) or about 24 h pre-slaughter crowding stress (long-term stress, LS group). Significant negative effects were mostly seen due to long-term stress (LS) at early stages *post-mortem*, but also short-term stress (SS) had significant negative impacts on muscle quality of *pre-* and *post-rigor* fillets. Pre-slaughter long-term stress (LS) significantly lowered muscle pH, softened the fillets and increased muscle *cathepsin L* gene expression, immediately *post-mortem.* A tendency of increased *cathepsin B* gene expression and cathepsin B total activity was also seen. Stress further accelerated the incidence of myofibre–myofibre detachments, increased the percentage of myofibre–myocommata detachments over the storage period and increased the percentage of myofibre breakages and contracted myofibres 96 h *post-mortem*. Significant correlations were observed between muscle pH and cathepsin B + L activity, muscle texture and muscle degradation parameters. Cathepsin B activity was correlated to muscle degradation and *cathepsin L* gene expression to muscle degradation and texture. Pre-slaughter stress, especially long-term stress (LS), thus seems to accelerate cathepsin activity, resulting in faster muscle degradation, directly or indirectly connected to the low initial muscle pH. No significant variation was observed between *pre-rigor* and *post-rigor* filleting, except that *pre-rigor* filleting significantly increased the percentage of myofibre breakages.

1. Introduction

Pre-slaughter handling stress is an important issue for salmon industry because of its effect on welfare and fillet quality. Several studies have shown that pre-slaughter stress accelerates fish fillet softening, increases gaping, affects skin and fillet colour and increases drip loss (Erikson & Misimi, 2008; Kiessling, Espe, Ruohonen, & Mørkøre, 2004; Morzel, Sohier, & Van de Vis, 2003; Mørkøre, Mazo, Tahirovic, & Einen, 2008; Roth, Slinde, & Arildsen, 2006; Skjervold, Fjæra, Østby, & Einen, 2001; Stien et al., 2005). Pre-slaughter stress accelerates the breakdown of ATP, resulting in earlier *rigor* onset and making it difficult to obtain and process *pre-rigor* fillets (Kiessling et al., 2004; Mørkøre et al., 2008; Sigholt et al., 1997; Skjervold, Fjæra, & Østby, 1999).

During stress and exhausting exercise, fish use anaerobic energy, leading to the production of lactic acid and resulting in low initial *post-mortem* pH in the muscle (Bagni et al., 2007; Erikson, Sigholt, & Seland, 1997; Lowe, Ryder, Carragher, & Wells, 1993; Poli, Parisi, Scappini, & Zampacavallo, 2005; Stien et al., 2005; Thomas, Pankhurst, & Bremner, 1999). Some authors suggested that this low initial pH could be responsible for the deteriorated final muscle quality (Lavety, Afolabi, & Love, 1988; Nakayama, Goto, & Ooi, 1996). Direct mechanical stress of the muscle fibrils or connective tissue, causing the release of proteases, could also contribute to the acceleration of muscle structure degradation (Roth et al., 2006).

Cathepsins are lysosomal proteases that are involved in mammalian and fish *post-mortem* muscle softening (Bahuaud et al., 2008; Chéret, Delbarre-Ladrat, de Lamballerie-Anton, & Verrez-Bagnis, 2007; Godiksen, Morzel, Hyldig, & Jessen, 2009; Taylor, Geesink, Thompson, Koohmaraie, & Goll, 1995; Yamashita & Konagaya, 1990, 1991). We have already underlined the importance, but complexity, of the mechanisms involving cathepsins in fish muscle degradation (Bahuaud et al., 2009). A potential role of these enzymes in the acceleration of *post-mortem* degradation of fish or mammalian muscle when subjected to pre-slaughter stress have

doi:10.1016/j.foodchem.2009.05.028

also been suggested (Bahuaud et al., 2009; Gil, Guerrero, & Sarraga, 1999; Vihko & Salminen, 1983). Calpains are calcium-dependent cytosolic proteases existing in two main ubiquitous forms according to the concentration of Ca^{2+} required for their activation: μ-calpain and m-calpain. It is well known that calpains are actively involved in *post-mortem* tenderisation of mammal muscle (Koohmaraie, 1992, 1996), but their participation in fish fillet softening, even if suggested, has drawn less attention (Chéret et al., 2007; Salem, Kenney, Killefer, & Nath, 2004). In fish, calpain activity seems to be difficult to characterise, probably due to the presence of its strong inhibitor, calpastatin (Chéret et al., 2007; Hultmann & Rustad, 2007; Salem, Nath, Rexroad, Killefer, & Yao, 2005), but the role of calpains in *post-mortem* softening is not to be excluded.

Today, most of the farmed salmon are filleted *post-rigor*, after 3–5 days of storage on ice; this period of storage being needed for an easier removal of pin bones and to avoid processing while the fish is still in *rigor*. Reducing pre-slaughter stress will increase the potential of *pre-rigor* filleting, thus providing higher freshness and quality products on the market, as *pre-rigor* fillets of Atlantic salmon have been shown to present less gaping, be thicker, firmer and offer a more intense colouration (Einen, Guerin, Fjæra, and Skjervold, 2002; Skjervold, 2002; Skjervold, Fjæra, Østby, Isaksson, Einen, et al., 2001; Skjervold et al., 2001).

Most of the studies on pre-slaughter stress in Atlantic salmon have so far focused on parameters like ATP, lactate and cortisol levels as primary stress responses, onset of *rigor mortis*, texture, colour and drip loss. The impact of pre-slaughter stress on muscle structure and the factors responsible for the quality degradation process have been less explored. The present study underlines the potential role of lysosomal cathepsins in muscle degradation, in relation to both short- and long-term pre-slaughter crowding stress.

2. Materials and methods

2.1. Fish and experimental setting

Atlantic salmon (*Salmo salar* L.) were raised in sea-water at Nofima Marin (previously Akvaforsk) Research Station, Averøy, on the west coast of Norway, where they were fed a standard commercial extruded dry feed (“Optiline S 800”, 9 mm, Skretting, Stavanger, Norway). Three weeks before slaughter, 600 salmon were randomly distributed into 4 net-pens (125 m^3) in the sea, each of them containing 150 fish. The salmon (average body weight of 2.9 ± 0.1 kg) were starved for 4 days before slaughter (sea temperature 12.7 °C, salinity 33‰) and were subjected to three different pre-slaughter handling procedures: Minimal crowding Stress (NS) (2 net-pens), Short-term crowding Stress (SS) (1 net-pen), or Long-term crowding Stress (LS) (1 net-pen). Salmon from the LS group were kept crowded in their net-pen by reducing the size of the net-pen in order to obtain a fish density of 300 kg/m^3, for about 24 h from the day before slaughter. At the day of slaughter, salmon from each group were transferred from their net-pen to a tank with refrigerated sea-water (RSW 2.0 °C ± 0.1 °C), where they were live-chilled and kept at either a low density of 65 kg/m^3 (NS group) or high density of 300 kg/m^3 (SS and LS groups) for 20 min. Salmon were then killed by percussive stunning, gill cut and bled in a tank with running RSW for 20 min. All the salmon used for analyses were collected in two harvests per group. To avoid any additional disturbance, 2 net-pens were attributed to the NS group only, so that each net-pen in this group had to be harvested only once.

Seventy-two salmon were taken from each net-pen without any specific criteria and killed for the present study; the rest of the salmon in the different net-pens being used for other studies not mentioned here. For the present study, the killed salmon (n = 72) were distributed in four batches (n = 18 in each batch, 6 salmon in each group NS, SS and LS). The first three batches were hand-filleted immediately *post-mortem* by experienced workers to obtain “*pre-rigor* fillets” that were placed on solid plastic trays in closed Styrofoam boxes with ice, and stored in a cold room (5 °C) for further analyses. Salmon from the last batch were packed as gutted fish on ice in Styrofoam boxes and stored in a cold room (5 °C) until they were filleted *post-rigor*, 96 h after slaughter, and analysed as “*post-rigor* fillets”. Only the left fillets were used for sampling and analyses in the present study. Each left fillet from each batch of salmon was used for sampling and analyses on maximum three locations at three different time-points *post-mortem*.

2.2. Instumental texture measurement (fillet firmness)

Fillet firmness was measured at 0 h, 12 h, 24 h, 48 h, 96 h and 192 h *post-mortem* on 6 *pre-rigor* fillets/time-point/group and at 96 h and 192 h *post-mortem* on 6 *post-rigor* fillets/time-point/group. Measurements were done on the front part of the fillets, in the dorsal section, above the mid-line.

A texture Analyser TA-XT2 (Stable Micro Systems Ltd., Godalming, UK) equipped with a 5 kg load cell was used for the measurements. A flat-ended cylindrical probe (12.5 mm diameter; type P/0.5) was used with a test speed of 1 mm s^{-1} and penetration depth 90% of the fillet height. The force required to puncture the fillet surface, i.e. the breaking force (F_{break}, N) was recorded from the time–force graphs. This response variable has been previously found to correlate well with sensory assessment of firmness (Mørkøre & Einen, 2003).

2.3. Measurement of muscle pH

Muscle pH was measured at 0 h, 12 h, 24 h, 48 h, 96 h and 192 h *post-mortem* on 6 *pre-rigor* fillets/time-point/group, and 96 h and 192 h *post-mortem* on 6 *post-rigor* fillets/time-point/group. The instrument used was a pH meter 330i SET (Wissenschaftlich-Technische-Werkstätten GmbH & Co. KG WTW, Weilheim, Germany) connected to a muscle electrode (Scott pH electrode, Blueline 21 pH 2.13/−5 °C/gel, WTW, Weilheim, Germany). The measurements were performed by inserting the electrode into the epaxial white muscle next to the point of instrumental texture measurement.

2.4. Microscopy of the muscle

Sampling for microscopic observations was performed at 0 h, 12 h, 24 h, 48 h and 96 h *post-mortem* on 6 *pre-rigor* fillets/time-point/group and 96 h and 192 h *post-mortem* on 6 *post-rigor* fillets/time-point/group. White muscle samples (2 x 2 × 3 mm) were taken directly after texture measurements, at the place of compression of the texture instrument’s probe, and fixed in 2.5% glutaraldehyde in cacodylate buffer, pH 7.3. Mechanical deformation of the muscle samples before sampling was made to ensure that all the samples had the same mechanical treatment and to enhance the detachments between muscle fibres and between muscle fibres and myocommata (Ando, Toyohara, Shimizu, & Sakaguchi, 1991; Nakayama et al., 1996). The fixed samples were kept at low temperature (4 °C) until they were embedded for histological analyses.

Briefly, after rinsing with cacodylate buffer (2 × 15 min) and dehydration in different gradients of ethanol (70 and 96% for 2 × 20 min and 100% for 20 min), the samples were embedded in a cold plastic resin based on hydroxyethylmethacrylate (Technovit 7100, Heraeus Kulzer). The direction of the myofibres in the embedded samples was oriented so as to obtain both cross – (for all time-points, *pre-* and *post-rigor* fillets) and longitudinal – (only for the 96 h samples, *pre-rigor* and *post-rigor* fillets) sections. Light microscopy observations at 10 and 20 time magnification were made on

thin sections (3 μm) stained in 0.05 g/100 ml toluidine blue dissolved in 0.1 M aqueous sodium acetate buffer using the method of Ofstad, Olsen, Taylor, and Hannesson (2006), with slight modifications.

In the cross-section samples, muscle degradation was evaluated according to the method of Taylor, Fjæra and Skjervold (2002) with slight modifications. Percentages of detachments between myofibres (myofibre–myofibre detachments) as well as detachments between myofibres and connective tissue (myofibre–myocommata detachments) were determined. Two plastic blocks embedding 1–2 muscle samples/fillet/time-point were analysed. For each sample, detachments were counted on minimum 250 junctions between myofibres, and 50 junctions between myofibres and connective tissue.

In the longitudinal-oriented samples, the percentage of myofibre breakages and contracted myofibres was evaluated. Two plastic blocks embedding 1–2 muscle samples/fillet were analysed. For each sample, the percentage of myofibre breakages or contracted myofibres was evaluated on a minimum of 100 myofibres/sample.

2.5. Cathepsin activity

White muscle samples were taken next to the place used for instrumental texture, pH and histology sampling and analyses, on the same 6 salmon fillets/group, 0 h *post-mortem*. The samples were immediately frozen in liquid nitrogen before being stored at −80 °C until further analyses. Cathepsin B + L, cathepsin B and cathepsin L total activities were determined by homogenising 300 mg of muscle in 1 ml extraction buffer (100 mM Na-acetate in 0.2% Triton X-100, pH 5.5) in Precellys tubes, with a Precellys 24 homogenizer (Bertin Technologies, France) (2 cycles of 20 s at 5500 rpm, separated by a 10 s break). The obtained homogenates were centrifuged at 16,000 *g* for 30 min and the supernatants were used to determine enzyme activities.

Cathepsin B + L and cathepsin B activities were measured fluorimetrically according to the method of Kirschke, Wood, Roisen, and Bird (1983). The release of the fluorogenic reagent 7-amido-4-methylcoumarin was determined by fluorescence measurement at excitation 360 nm and emission wavelengths 460 nm. N-CBZ-L-phenylalanyl-L-arginine-7-amido-4-methylcoumarin (Z-Phe-Arg-Nmec) for cathepsin B + L activity and N-CBZ-L-arginyl-L-arginine-7-amido-4-methylcoumarin (Z-Arg-Arg-Nmec) for cathepsin B activity were used as substrates. To get an idea of the level of cathepsin L activity, cathepsin B activity was subtracted from cathepsin B + L activity (Bahuaud et al., 2009; Chéret, Delbarre-Ladrat, de Lamballerie-Anton, and Verrez-Bagnis, 2007; De Ceuninck et al., 1995; Zhao et al., 2005). The assays were run twice in triplicates.

2.6. Cathepsin relative gene expression

Epaxial white muscle of Atlantic salmon was dissected immediately *post-mortem* (0 h samples) from 6 fillets/group, next to the place used for instrumental texture, pH, and histology sampling and analyses. The tissue samples were kept at −80 °C until analysis. Total RNA was isolated using TRIzol Reagent (Invitrogen, USA) according to the manufacturer instructions. Total RNA was DNase I treated with Turbo DNA-free kit (Ambion, USA). Purification of RNA was made by precipitation using 0.1 volume of 3 M Sodium Acetate and three volumes of 99% ethanol. After 30 min incubation at room temperature, centrifugation for 10 min at 4 °C and 10,000 *g*, the pellet was dried and then resuspended in 40 μl RNase free water.

Concentration and quality of RNA was measured with NanoDrop ND-1000 Spectrophotometer (NanoDrop Technologies, USA). cDNA was synthesised using oligod(T) primers from 0.5 μg RNA in a total volume of 50 μl using Taqman reverse transcriptase reagents (Applied Biosystems, USA) and according to the manufacturer protocol. BLAST search and Vector NTI Advance 10 (Invitrogen, USA) was used to identify and analyse salmon cathepsin B and cathepsin L sequences. Vector NTI Advance 10 was used to design real time PCR primers which were purchased from Invitrogen (Invitrogen, USA).

Real time PCR was performed in a LightCycler 480 Instrument (Roche Applied Science, Germany) with gene-specific primers for *cathepsin B* and *cathepsin L*. Both *RNA polymerase 2* (*rpol2*), *eukaryotic translation initiation factor 3* and *NADH-ubiquinone oxidoreductase* (*nour*) were evaluated as reference genes using Genorm (Vandesompele et al., 2002). *Rpol2* and *nour* were the most stably expressed reference genes, and the geometric mean of these was therefore used when calculating the relative gene expressions. Table 1 gives the real time PCR primer sequences for relative expression of *cathepsin B*, *cathepsin L*, *rpol2* and *nour*. PCR master mix consisted of 1 μl forward and reverse primer (final concentration of 0.5 μM), 4 μl 1:10 dilution of cDNA and 5 μl LightCycler 480 SYBR Green I Master (Roche Applied Science, Germany). All samples were analysed in triplicates with non-template control for each gene. The reaction condition was 95 °C for 5 min, 45 cycles of 95 °C/15 s and 60 °C for 1 min. A melting curve analysis (95 °C for 5 s and 65 °C for 1 min, 97 °C) was run to confirm the presence of a single PCR product. Primer efficiency was calculated for each primer pair.

The relative gene expression level was calculated according to the ΔΔCt method and adjusted for differences in primer efficiency (Plaffl, 2001).

2.7. Statistical analyses

Mean results per group (NS, SS and LS) were analysed by General Linear Model (GLM). We used SAS (Statistical Analysis System) release 8.02 (SAS Institute Inc., Cary, NC, USA) as statistical software, with "stress period length (NS, SS and LS)", "time *post-mortem*" and "time of filleting (*pre-/post-rigor)*" as explanatory variables. Significant differences among means were ranked by Least Squares Means at $p < 0.05$. Correlations between the different measured quality traits and muscle degradation parameters were obtained using the Pearson correlation coefficients, at the same level of significance.

Table 1
Real time PCR primer sequences for relative gene expression of *cathepsin B* and *cathepsin L* in the muscle.

Primer	Genbank no.		5′–3′
Cathepsin B	DR696159	Ssa cathepsin B F1	AGGGGGGAACTCCTTACTGGCT
		Ssa cathepsin B R1	CGATGCCACAGTGGTCCTTACCT
Cathepsin L	CB502996	Ssa cathepsin L F1	GTATAGTGAAATGTGTGACC
		Ssa cathepsin L R2	AACCAGAGCAATAATTCAAG
NADH-ubiquinone oxidoreductase (nour)	DW532752	Ssa nour L F1	CAACATAGGGATTGGAGAGCTGTACG
		Ssa nour L R2	TTCAGAGCCTCATCTTGCCTGCT
RNA polymerase 2 (rpol2)	CA049789	Ssa rpol2 F1	TAACGCCTGCCTCTTCACGTTGA
		Ssa rpol2 R1	ATGAGGGACCTTGTAGCCAGCAA

Multivariate analysis was performed on *pre-rigor* fillets only, using individual fish results from salmon batch number 1, at 0 h, 12 h and 48 h *post-mortem*, in order to map the overall correlations between muscle quality and stress. The data were analysed with Partial Least Squares Regression (PLSR) (Martens & Næs, 1989), using the measured muscle quality traits and muscle degradation parameters as explanatory variables and "stress period length (NS, SS and LS)" as binary response variable.

Table 2 gives a summary of the different analyses and sampling made at the different time-points on the *pre-rigor* and *post-rigor* fillets.

3. Results

3.1. Fillet firmness of pre-rigor and post-rigor fillets

Fillet firmness significantly changed with time of storage ($p < 0.0001$) in the *pre-rigor* fillets (Fig. 1). Over the whole storage period of the *pre-rigor* fillets, there was a tendency that pre-slaughter crowding stress had an effect on fillet texture (F_{break}) ($p = 0.087$) (Fig. 1) and long-term stress (LS) had a significantly different impact than short-term stress (SS) ($p = 0.029$). Immediately *post-mortem*, fillets from the LS group presented the softest fillets ($p_{(NS/LS)} = 0.0005$ and $p_{(SS/LS)} = 0.0002$). At 12 h *post-mortem*, fillets from the NS and LS groups did not present any significantly different fillet texture any longer, but the SS group showed the firmest fillets ($p_{(NS/SS)} = 0.041$ and $p_{(LS/SS)} = 0.001$). From 24 h *post-mortem*, no significant effect of crowding stress on fillet texture could be seen in the *pre-rigor* fillets.

In the *post-rigor* fillets, fillet firmness significantly decreased between 96 h and 192 h *post-mortem* ($p = 0.051$). There was a significant effect of pre-slaughter stress on fillet texture during this storage period in the *post-rigor* fillets ($p = 0.041$), with the SS group presenting the softest fillets significantly different from the NS group ($p = 0.046$). At 192 h *post-mortem*, the SS fillets were also softer than the LS fillets ($p = 0.028$) (Fig. 1).

At 96 h and 192 h *post-mortem*, time of filleting did not have any significant influence on fillet texture in general, but 96 h *post-mortem*, *pre-rigor* fillets from the NS group were significantly softer ($p = 0.054$) than *post-rigor* fillets from the same group. The same tendency could be observed in the SS group ($p = 0.080$), but these differences had disappeared by 192 h *post-mortem*.

3.2. pH of pre-rigor and post-rigor fillets

pH significantly decreased with time of storage ($p < 0.0001$) in the *pre-rigor* fillets (Fig. 2). Over the whole storage period of the *pre-rigor* fillets, a significant effect of pre-slaughter stress on muscle pH was seen in general ($p = 0.0003$), where the LS group presented the lowest pH values ($p_{(NS/LS)} = 0.002$; $p_{(SS/LS)} = 0.0001$). Fillets from the LS group also showed the lowest pH at 0 h ($p_{(NS/LS)} < 0.0001$; $p_{(SS/LS)} = 0.0001$) and 12 h *post-mortem* ($p_{(NS/LS)} = 0.004$; $p_{(SS/LS)} = 0.007$). From 24 h *post-mortem* to the end of the storage period, no significant differences in fillet pH were observed between the groups in the *pre-rigor* fillets.

Table 2
Summary: Different analyses and sampling made at the different time-points.

	Time *post-mortem* (h)	Batch	Texture	pH	Myofibre–myofibre detachments	Myofibre–myocommata detachments	Myofibre breakages	Contracted myofibres	Cathepsin B + L activity	Cathepsin B activity	Cathepsin L activity	*Cathepsin B* gene expression	*Cathepsin L* gene expression

	192	4	X	X	X	X							

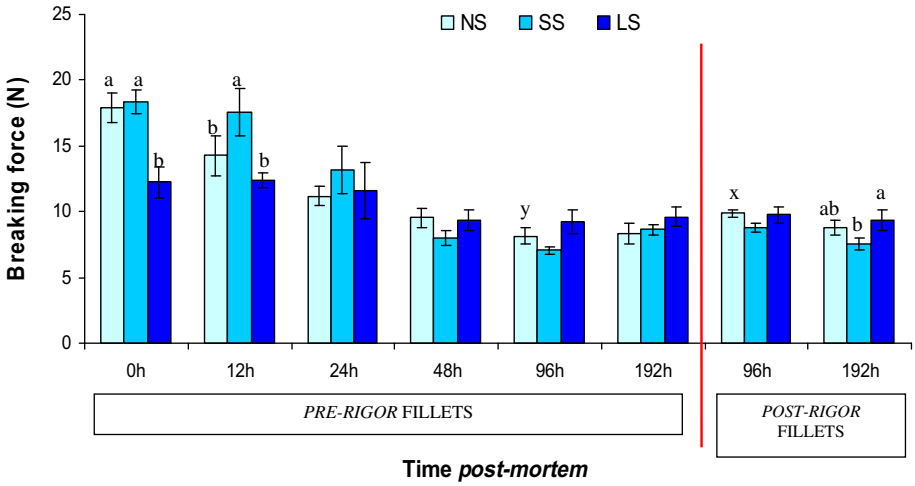

Fig. 1. Changes during the storage period (0–192 h *post-mortem*) of firmness (F_{break}) of *pre-rigor* and *post-rigor* fillets of Atlantic salmon subjected to minimal (NS), short-(SS) or long-term (LS) pre-slaughter crowding stress. Each histobar represents the mean value ± SE of one group at one time-point ($n = 6$). Different letters denote significant differences ($p < 0.05$) between the groups at the same time point (a, b) or between *pre-rigor* and *post-rigor* fillets at the same time-point within the same group (x, y).

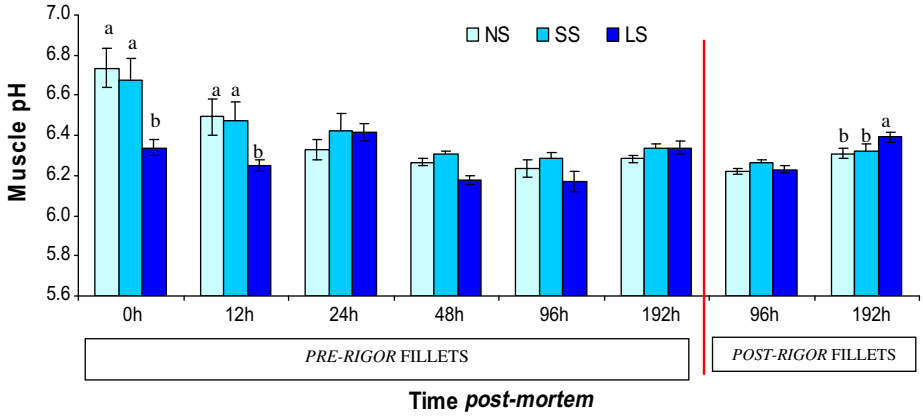

Fig. 2. Changes during the storage period (0 h to 192 h *post-mortem*) of pH of *pre-rigor* and *post-rigor* fillets of Atlantic salmon subjected to minimal (NS), short-(SS) or long-term (LS) pre-slaughter crowding stress. Each histobar represents the mean value ± SE of one group at one time-point ($n = 6$). Different letters denote significant differences ($p < 0.05$) with the other groups, at the same time-point.

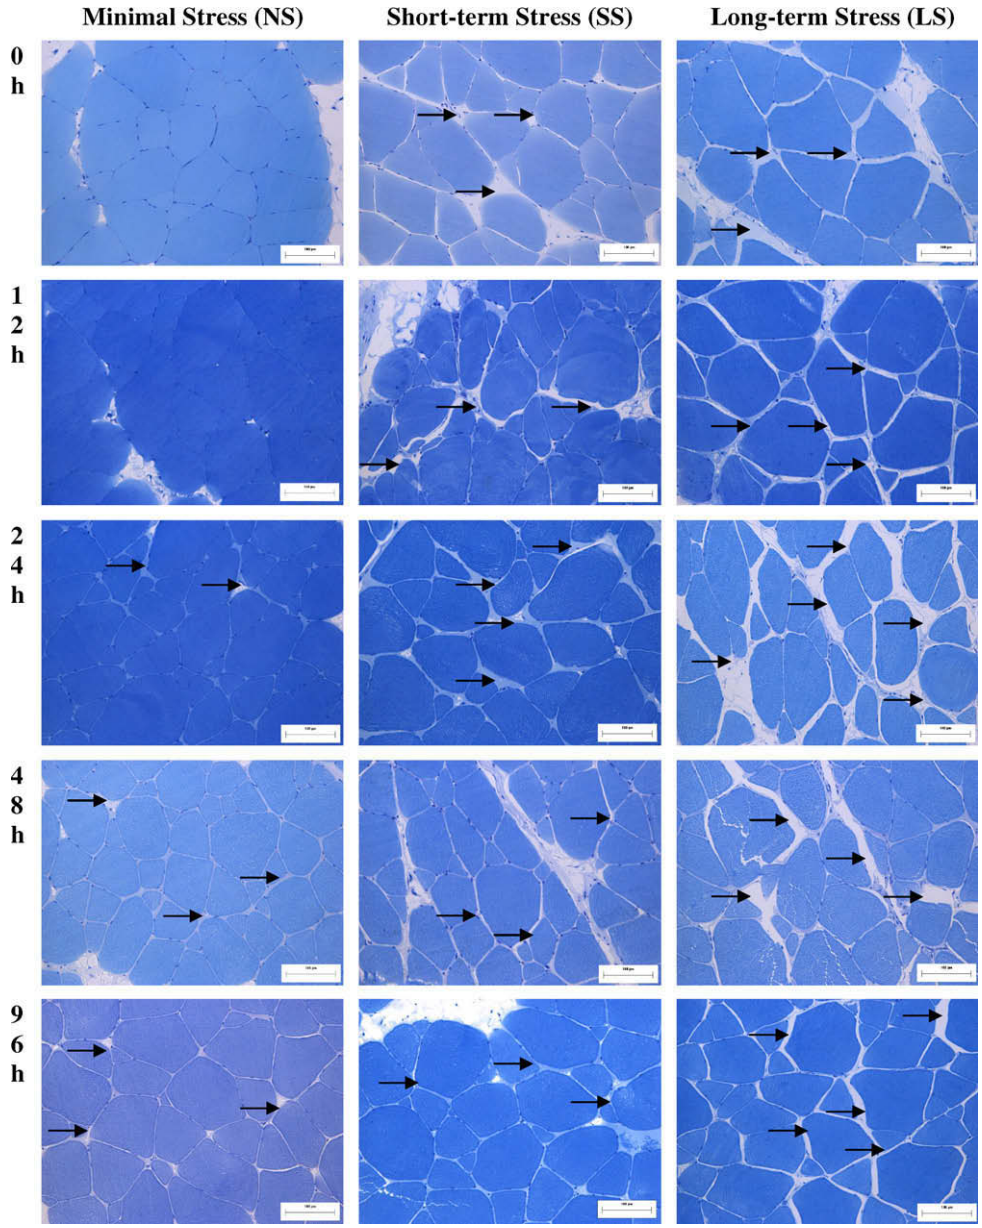

Fig. 3. Light microscopy observations (cross-sections) 0 h, 12 h, 24 h, 48 h and 96 h *post-mortem*, of *pre-rigor* fillets of Atlantic salmon subjected to minimal (NS), short-(SS) or long-term (LS) pre-slaughter crowding stress; magnification ×20. Arrows: myofibre–myofibre detachments.

In the *post-rigor* fillets, pH significantly changed between 96 h and 192 h *post-mortem* ($p < 0.0001$) but no significant effect of pre-slaughter stress was found in general during this period. At 192 h *post-mortem*, fillets from the LS group however presented the highest pH ($p_{(NS/LS)} = 0.019$ and $p_{(SS/LS)} = 0.043$) (Fig. 2).

Muscle pH values showed no significant difference between *pre-* and *post-rigor* fillets at 96 h and 192 h *post-mortem*.

3.3. Myofibre–myofibre detachments in pre-rigor and post-rigor fillets

In the *pre-rigor* fillets, the percentage of myofibre–myofibre detachments significantly increased with time of storage ($p < 0.0001$) and because of pre-slaughter crowding stress ($p < 0.0001$) (Fig. 3 and Fig. 4). Over the whole storage period, the LS group showed the highest percentage of myofibre–myofibre detachments ($p_{(NS/LS)} < 0.0001$ and $p_{(SS/LS)} < 0.0001$) in the *pre-rigor* fillets. Significant differences between groups at each time-point were mainly noticed before 24 h *post-mortem*. At 0 h *post-mortem*, salmon from the LS group showed significantly more myofibre–myofibre detachments than the NS group ($p = 0.003$), while the percentage of detachments was not significantly different between the SS and the NS groups; 12 h *post-mortem*, both the SS and LS groups presented more myofibre–myofibre detachments than the NS group ($p_{(NS/SS)} = 0.011$; $p_{(NS/LS)} < 0.0001$), the LS group showing an even more pronounced effect ($p_{(SS/LS)} < 0.0001$). At 24 h and 48 h *post-mortem*, there were no longer any significant differences in percentage of myofibre–myofibre detachments between the three groups, although the long-term stress (LS) numerically seemed to still result in more detachments. This trend was noticed until the end of the storage period, 96 h *post-mortem* in the *pre-rigor* fillets. At 96 h *post-mortem*, *pre-rigor* fillets from the SS group showed less detachments than the other groups, significantly when compared to the LS group ($p = 0.019$).

In general, no difference in percentage of myofibre–myofibre detachments was noticed between 96 h and 192 h *post-mortem* in the *post-rigor* fillets or between groups (Figs. 5 and 6). But 96 h *post-mortem*, as in the *pre-rigor* fillets, short-term stress (SS) resulted in less myofibre–myofibre detachments, significantly when compared to the NS group ($p = 0.040$). This difference had disappeared by 192 h *post-mortem*.

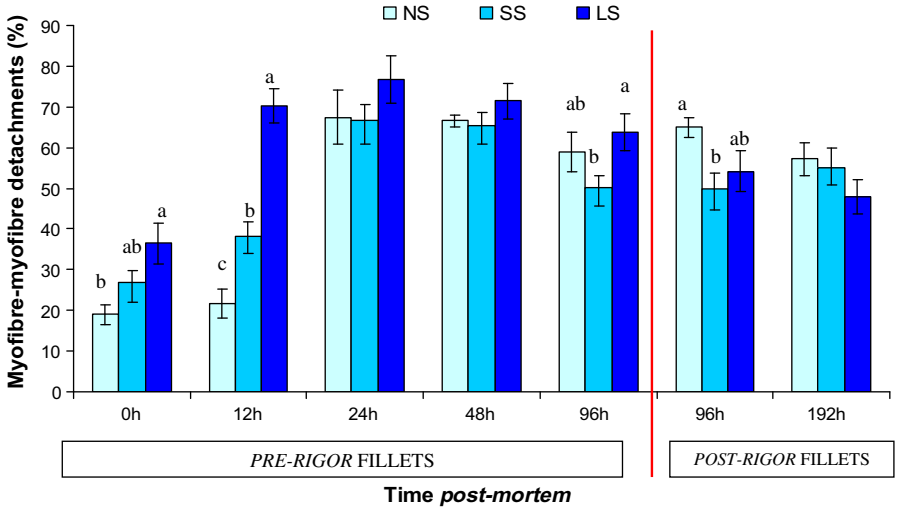

Fig. 4. Changes during the storage period (0 h to 192 h *post-mortem*) of myofibre–myofibre detachments (%) in *pre-rigor* and *post-rigor* fillets of Atlantic salmon subjected to minimal (NS), short-(SS) or long-term (LS) pre-slaughter crowding stress. Each histobar represents the mean value ± SE of one group at one time-point ($n = 6$). Different letters denote significant differences ($p < 0.05$) with the other groups, at the same time-point.

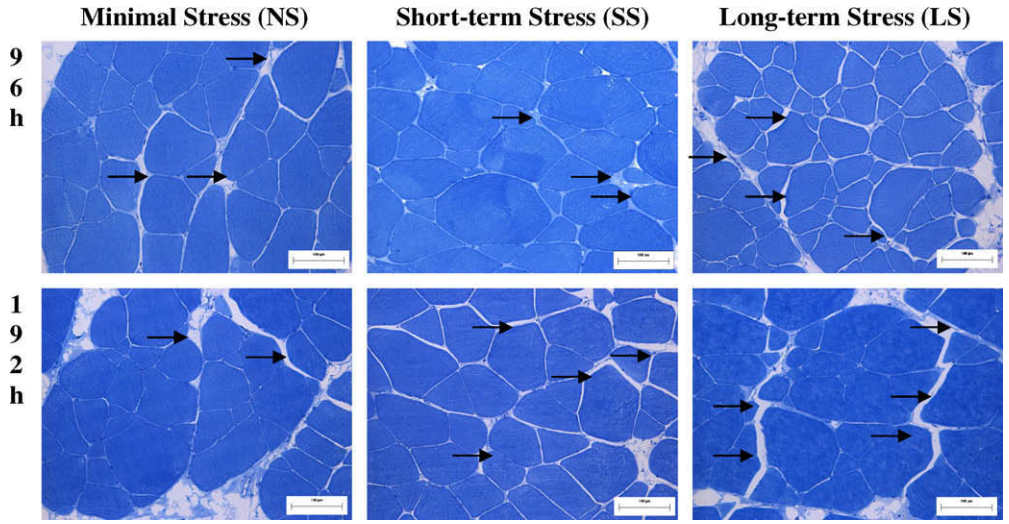

Fig. 5. Light microscopy observations (cross-sections) 96 h and 192 h *post-mortem*, of *post-rigor* fillets of Atlantic salmon subjected to minimal (NS), short-(SS) or long-term (LS) pre-slaughter crowding stress; magnification ×20. Arrows: myofibre–myofibre detachments.

At 96 h *post-mortem*, no significant differences in percentage of myofibre–myofibre detachments were found between the *pre-rigor* and the *post-rigor* fillets.

3.4. Myofibre–myocommata detachments in pre-rigor and post-rigor fillets

Due to the large variation in percentage of myofibre–myocommata detachments, no general effect of storage time was observed between 0 h and 96 h *post-mortem* in the *pre-rigor* fillets (Fig. 6). The percentage of myofibre–myocommata detachments was however significantly higher at 24 h ($p = 0.030$) and 96 h ($p = 0.033$) than at 0 h *post-mortem*. Pre-slaughter stress further increased significantly the level of myofibre–myocommata detachments in general ($p = 0.047$) over the whole storage period in the *pre-rigor* fillets, and significantly more myofibre–myocommata detachments were found in the SS ($p = 0.028$) and in the LS groups ($p = 0.037$) than in the NS group. When compared at individual time-points in the *pre-rigor* fillets, however, only the SS group 96 h *post-mortem* presented significantly more myofibre–myocommata detachments than the NS ($p = 0.042$) and LS groups ($p = 0.042$).

The level of myofibre–myocommata detachments significantly increased between 96 h and 192 h *post-mortem* ($p = 0.002$) in the *post-rigor* fillets (Fig. 6). Like in the *pre-rigor* fillets, the SS group showed significantly more myofibre–myocommata detachments than the NS group ($p = 0.035$) but this time only after 192 h of storage.

At 96 h *post-mortem*, *pre-rigor* filleting resulted in significantly more myofibre–myocommata detachments than *post-rigor* filleting, but only when salmon were subjected to short-term (SS) stress ($p = 0.034$).

3.5. Myofibre breakages and contracted myofibres in pre-rigor and post-rigor fillets

In the *pre-rigor* fillets, significantly more myofibre breakages were found in the LS than in the NS group ($p = 0.050$) (Figs. 7 and 8A). In the SS group, the percentage of myofibre breakages was numerically higher than the NS group, but the difference was not statistically significant. In the *post-rigor* fillets, no significant differences in percentage of myofibre breakages were noticed between the three groups (Fig. 8A). *Pre-rigor* filleting resulted in significantly more myofibre breakages than *post-rigor* filleting in general ($p = 0.003$), and especially when salmon were subjected to long-term stress (LS) ($p_{(LS\ pre\text{-}rigor/LS\ post\text{-}rigor)} = 0.009$).

In the *pre-rigor* fillets, pre-slaughter stress did not influence the percentage of contracted myofibres, whereas in the *post-rigor* fillets, short-term (SS) ($p = 0.058$) and long-term pre-slaughter stress (LS) ($p = 0.072$) tended to result in more contracted myofibres than minimal stress (Fig. 7 and Fig. 8A). There was also a tendency that *pre-rigor* filleting resulted in less contracted myofibres than *post-rigor* filleting ($p = 0.063$), and this difference was significant for salmon subjected to long-term stress (LS) ($p_{(LS\ pre\text{-}rigor/LS\ post\text{-}rigor)} = 0.040$).

3.6. Cathepsin activity in pre-rigor fillets

Pre-slaughter crowding stress (SS and LS) seemed to result in more cathepsin B + L activity in the muscle than minimal crowding stress (NS), even though these differences were not significant (Fig. 9A) ($p_{(NS/LS)} = 0.141$). Exactly the same pattern was observed when measuring cathepsin B activity alone (Fig. 9B) ($p_{(NS/LS)} = 0.084$), whereas cathepsin L activity did not seem to be affected by pre-slaughter crowding stress (average cathepsin L activity for NS: 1.281 ± 0.025 mU/g muscle; SS: 1.280 ± 0.029 mU/g muscle; LS: 1.281 ± 0.011 mU/g muscle).

3.7. Cathepsin relative gene expression in pre-rigor fillets

The relative gene expression of *cathepsin L* was significantly influenced by pre-slaughter stress ($p = 0.001$). When compared to the NS group, a significantly higher gene expression of *cathepsin L* was found in the LS group ($p = 0.011$), whereas no significant differences were seen with the SS group (Fig. 10). There was also a tendency that the gene expression of *cathepsin B* followed the same

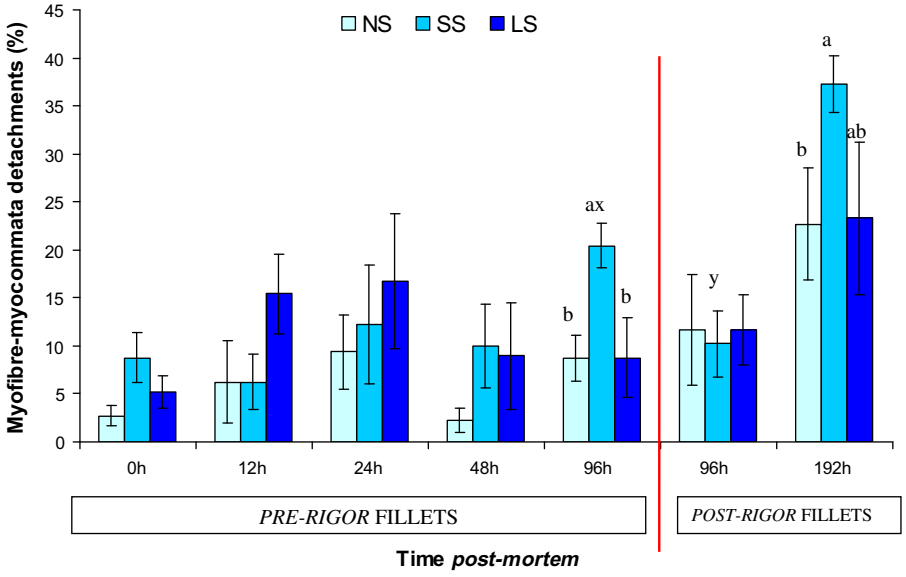

Fig. 6. Changes during the storage period (0 h to 192 h *post-mortem*) of myofibre–myocommata detachments (%) in *pre-rigor* and *post-rigor* fillets of Atlantic salmon subjected to minimal (NS), short-(SS) or long-term (LS) pre-slaughter crowding stress. Each histobar represents the mean value ± SE of one group at one time-point ($n = 6$). Different letters denote significant differences ($p < 0.05$) between the groups at the same time-point (a, b) or between *pre-rigor* and *post-rigor* fillets at the same time-point within the same group (*x*, *y*).

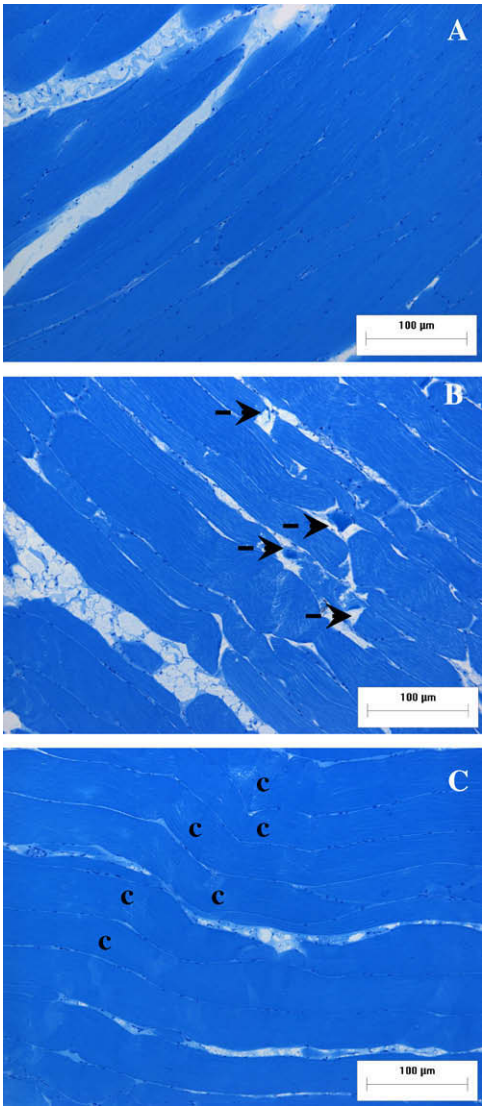

Fig. 7. Light microscopy observations (longitudinal-sections), 96 h *post-mortem*, of *pre-rigor* and *post-rigor* fillets of Atlantic salmon subjected to minimal (NS), short- (SS) or long-term (LS) pre-slaughter crowding stress; magnification ×20. A: intact myofibres; B: myofibre breakages (arrows); C: contracted myofibres (c).

pattern: a numerically higher expression was found in the LS group ($p_{(NS/LS)} = 0.186$), when compared to the NS and SS groups, even if these results were not significantly different.

3.8. Correlations between the quality traits and muscle degradation parameters in pre-rigor and post-rigor fillets

Table 3 summarises the significant effects of pre-slaughter stress and time of filleting (*pre-rigor*/*post-rigor*) on the quality traits and muscle degradation parameters measured in the present study and Table 4 gives the correlation coefficients between the results obtained.

The correlations between the different quality traits and muscle degradation parameters are also represented with a PLSR plot in Fig. 11. A correlation loading plot from PLSR summarises the data's overall covariance structure. It holds information about how the variables are related to each other, and how well each variable is explained by the model. In essence, variables located close to each other are positively correlated, while variables located on opposite side of an axis are negatively correlated. The distance from origo to each variable represents how well it is explained by the model; the inner ellipse represents 50% explained variance and the outer ellipse represents 100% explained variance. In the present study, the multivariate analysis of the data at 0 h, 12 h and 48 h *post-mortem* allowed explaining 73% of the total variation in stress-length period (NS, SS and LS). The first component (PC1) separates between long-term stress (LS) to the right and short-term (SS) or minimal crowding stress (NS) to the left. Quality traits and muscle degradation parameters that correlated with the first component were pH at 0 h, 12 h and 48 h and firmness at 0 h and 12 h to the left, and to the right we find myofibre–myofibre (MF–MF) detachments at 0 h and 12 h, myofibre–myocommata (MF–MC) detachments at 12 h, *cathepsin L* relative gene expression, cathepsin B + L activity and cathepsin B activity. This means that pH and firmness (F_{break}) were positively correlated in the present study, and salmon in the NS and SS groups had higher pH and firmness than salmon in the LS group. Myofibre–myofibre detachments were positively correlated to *cathepsin L* expression and cathepsin B activity, and negatively correlated to pH and firmness. Salmon from the LS group presented more myofibre–myofibre detachments, and higher cathepsin B activity and *cathepsin L* gene expression. The second component mainly separated between the SS and NS groups, but it only accounted for 10% of the muscle quality variation. The only variable showing some correlations with the second component is myofibre–myocommata detachments at 0 h, which had a tendency to be higher for short-term stressed (SS) salmon.

4. Discussion

Pre-slaughter stress accelerates anaerobic energy metabolism, and therefore produces a rapid increase in muscle lactic acid production (Poli et al., 2005). In the present study, salmon subjected to pre-slaughter long-term stress (LS) presented the lowest muscle pH immediately *post-mortem* and over the whole storage period. Our results agree with several other studies, which also showed a lower muscle pH immediately *post-mortem* or a higher lactate level in stressed fish than in unstressed ones (Bagni et al., 2007; Erikson, Beyer, & Sigholt, 1997; Erikson & Misimi, 2008; Lowe et al., 1993; Stien et al., 2005; Tejada & Huidobro, 2002; Thomas et al., 1999). The strong pH reduction in long-term stressed salmon immediately after slaughter may suggest an *in vivo* accumulation of lactic acid in the muscle, because long-term stress induced strong swimming activity and presumably a very slow release of lactic acid from the cells.

Ofstad et al. (2006) showed that both myofibre–myofibre and myofibre–myocommata detachments in cod and wolffish were mainly caused by fractures in the extracellular matrix, maybe due to degradation of proteoglycans and glycoproteins. In the present study, the percentage of myofibre–myofibre detachments increased with time until 24 h *post-mortem*, which has already been observed in previous studies (Bahuaud et al., 2008; Bahuaud et al., 2009) and translates the normal muscle degradation process during storage. Pre-slaughter stress significantly affected the integrity of the *pre-rigor* fillets by accelerating this degradation; the longer the pre-slaughter stress period, the faster the incidence of myofibre–myofibre detachments and this agrees with Ando et al. (2001) and Nakayama et al. (1996), who also showed that pre-slaughter stress increased the incidence of myofibre–myofibre detachments in chub mackerel and red sea-bream. Increase of plasma cortisol is a well-known primary stress response in fish, and in accordance with our results, Macdonald and Cidlowski (1982) showed that glucocorticoids in rat stimulate protein degradation. The acceleration of detachments between myofibres due to pre-slaughter stress and observed particularly in the LS group in the

present study, could also be directly or indirectly related to the significantly lower muscle pH immediately *post-mortem*, since a significant negative correlation was found between muscle pH and percentage of myofibre–myofibre detachments.

In the present study, pre-slaughter stress also increased significantly myofibre–myocommata detachments. Accordingly, Gomez-Guillen, Montero, Hurtado, and Borderias (2000) found that shear strength of the connective tissue fraction in stressed Atlantic salmon was lower, and this was associated with lower muscle pH. In earlier studies, such increase in myofibre–myocommata detachments was not noticed until 192 h *post-mortem* in Atlantic salmon and wolffish (Bahuaud et al., 2008; Bahuaud et al., 2009; Ofstad et al., 2006; Taylor, Fjæra, & Skjervold, 2002) and it was suggested that myofibre–myocommata detachments were associated with loss of *rigor* stiffness (Taylor et al., 2002). In the present study, the very low muscle pH found particularly in the LS group could be directly responsible for these detachments, as we also found a significant negative correlation between muscle pH and percentage of myofibre–myocommata detachments. Similarly, Lavety et al. (1988) showed a strong negative relationship between muscle pH and degree of gaping in salmon and rainbow trout, and also noticed that the lower the muscle pH, the easier it was to break the myocommata.

Our results on enzyme activities indicated that pre-slaughter stress increases cathepsin B total activity in the muscle, even if these results were not significant. Long-term pre-slaughter stress also enhanced significantly *cathepsin L* gene expression in the muscle, and a similar trend was seen for *cathepsin B*. These results agree with studies on rats and mice where, under stress conditions, cathepsin total activity (Pote & Altekar, 1980; Vihko & Salminen, 1983) or *cathepsin* gene expression in Atlantic salmon (Bahuaud et al., 2009) increased in the muscle. Measuring cathepsin total activity and *cathepsin* gene expression in fish muscle has been used to highlight the level of potential proteolysis (Bahuaud et al., 2009; Chéret, Hernandez-Andres, Delbarre-Ladrat, de Lamballerie, & Verrez-Bagnis, 2006; Chéret et al., 2007; Mommsen, 2004; Salem, Levesque, Moon, Rexroad, & Yao, 2006). An increase of cathepsin total activity and/or relative gene expression in fish muscle thus indicates a higher potential muscle degradation *pre-* and/or *post-mortem*. In the present study, cathepsin B activity was measured with its specific substrate. The substrate used to measure cathepsin B + L activity can be degraded by both cathepsin B and cathepsin L. To obtain cathepsin L activity, we subtracted our results of cathepsin B activity from our results of cathepsin B + L activity; this method may not truly represent the exact cathepsin L activity but was, however, previously used by several authors (Chéret,

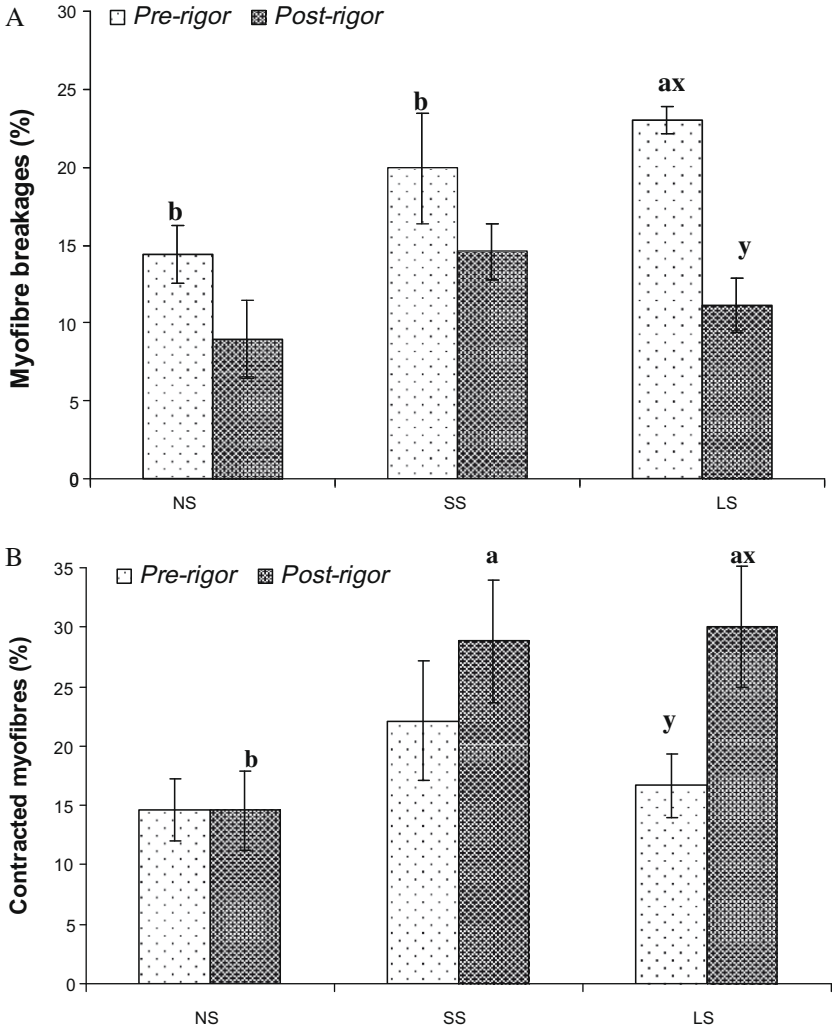

Fig. 8. A: Myofibre breakages (%); B: Contracted myofibres (%), 96 h *post-mortem,* in *pre-rigor* and *post-rigor* fillets of Atlantic salmon subjected to minimal (NS), short-(SS) or long-term (LS) pre-slaughter crowding stress. Each histobar represents the mean value ± SE of one group for a time of filleting (*pre/post-rigor* filleting) ($n = 6$). Different letters denote significant differences ($p < 0.05$) between the groups for the same time of filleting (*pre/post-rigor*) (a, b) or between *pre-* and *post-rigor* filleting within a group (*x*, *y*).

Delbarre-Ladrat, de Lamballerie-Anton, & Verrez-Bagnis, 2007; De Ceuninck et al., 1995; Zhao et al., 2005) and can at least give an idea of the level of cathepsin L activity.

In salmonids, cathepsin B and cathepsin L have been particularly associated with muscle softening, with an optimum pH for activity of 6.0–5.5 and 5.6 respectively (Aoki & Ueno, 1997; Aoki, Yamashita, & Ueno, 1995; Godiksen et al., 2009; Yamashita & Konagaya, 1990; Yamashita & Konagaya, 1991). In the present study, we found a significant negative correlation between muscle pH and level of cathepsin B + L activity. Pre-slaughter stress resulted in lower muscle pH immediately *post-mortem* than minimal-stress (NS), significantly for long-term stress (LS), and this

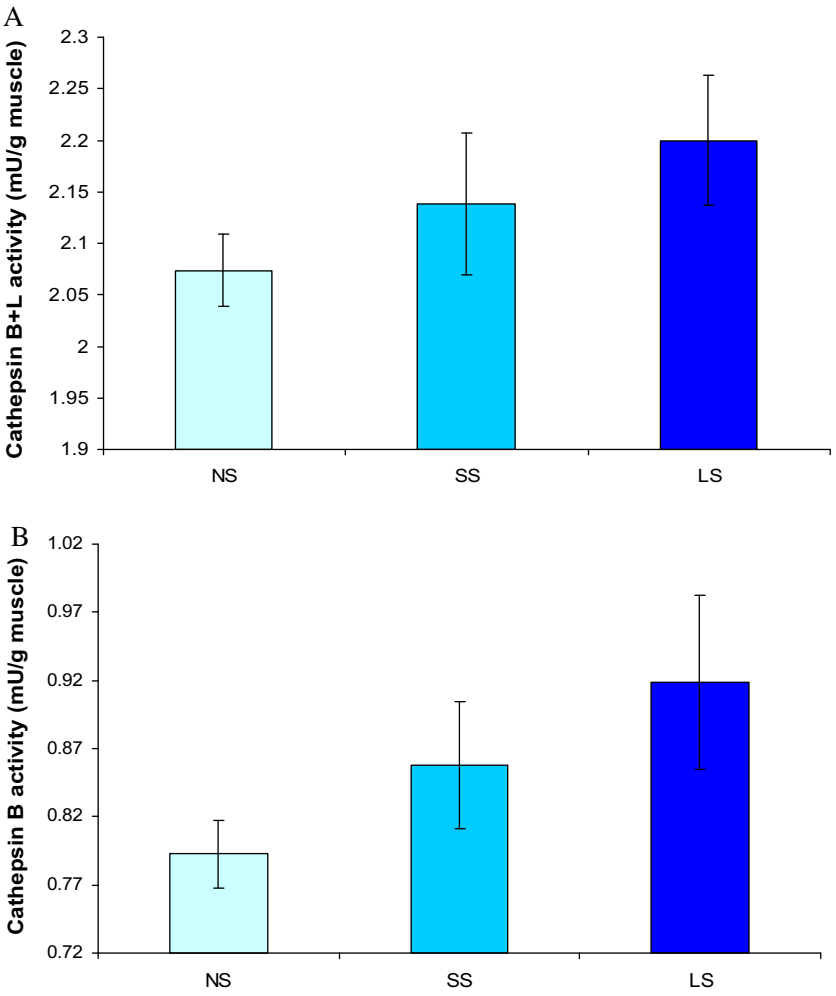

Fig. 9. A: Cathepsin B + L total activity; B: Cathepsin B total activity, 0 h *post-mortem*, in frozen *pre-rigor* fillet homogenates of Atlantic salmon subjected to minimal (NS), short- (SS) or long-term (LS) pre-slaughter crowding stress. low pH could be directly responsible for the earlier higher activity of cathepsin B in the muscle of the stressed salmon, especially the LS group. Gil et al. (1999) also measured a higher activity of cathepsin B and cathepsin B + L in PSE ham with low pH, when compared with normal quality ham. Accordingly, in mammals, Taylor et al. (1995) suggested that cathepsins participated in mammalian muscle proteolysis *post-mortem* as soon as muscle pH became low.

Significant positive correlations between percentage of myofibre–myofibre detachments and cathepsin B activity on one hand, and *cathepsin L* gene expression on the other hand, were observed, as well as between percentage of myofibre–myocommata detachments and cathepsin B activity. These results agree with Vihko and Salminen (1983), who found an increase in cathepsin D activity in exhausted rat muscle, and this activity increase was associated with muscle fibre injuries, necrosis and protein degradation. Gomez-Guillen et al. (2000) also noticed that pre-slaughter stress in Atlantic salmon resulted in myofibrillar protein denaturation and greater myosin proteolysis, knowing that cathepsins are able to degrade myosin easily (Aoki & Ueno, 1997; Ladrat, Verrez-Bagnis, Noel, & Fleurence, 2003; Taylor et al., 1995). In the present study, the significantly higher percentage of myofibre–myofibre detachments until 24 h *post-mortem* and significantly higher percentage of myofibre–myocommata detachments over the whole storage period found in the stressed groups could thus be a direct consequence of the action of cathepsin B activity in the muscle, the lower initial muscle pH *post-mortem* in these groups, especially in the LS group, allowing the action of this enzyme at earlier stages than in the NS group.

On the other hand, the higher percentage of myofibre–myofibre and myofibre–myocommata detachments observed in the present study could also be due to a mechanical stress directly applied to the muscle by pre-slaughter crowding stress. Muscle structure degradation of Atlantic salmon due to mechanical stress has already been suggested in our previous study (Bahuaud et al., 2009) and Roth et al. (2006) indicated that pre-slaughter stress in Atlantic salmon could affect myofibrils or connective tissue physically, thus releasing proteases and accelerating muscle degradation. Gomez-Guillen et al. (2000), Sigholt et al. (1997) and Yamashita and Konagaya (1991) also suggested that protein denaturation resulting from exposure of *post-mortem* muscle to low pHs, may facilitate the access of substrates by proteolytic enzymes and thus enhancing muscle proteolysis. The low muscle pH observed especially in the long stressed (LS) salmon could also have caused a direct damage of the muscle structure by shrinking myofibres, thus increasing the tensions on the endomysium or at the connective tissue level, resulting in a higher number of myofibre–myofibre and myofibre–myocommata detachments.

Pre-slaughter stress tended to increase the percentage of contracted myofibres in *post-rigor* fillets 96 h *post-mortem,* and the longer the pre-slaughter stress period, the higher the percentage of contracted myofibres. This is in accordance with several authors (Erikson & Misimi, 2008; Erikson, Sigholt, Rustad, Einarsdottir, & Jørgensen, 1999; Nakayama, Toyoda, & Ooi, 1994; Skjervold et al., 1999; Skjervold, Fjæra, Østby, Einen, 2001; Stien et al., 2005; Thomas et al., 1999; Veiseth, Fjæra, Bjerkeng, & Skjervold, 2006) who pointed out that pre-slaughter stress enhances *rigor* contraction in fish.

We also observed an increase in percentage of myofibre breakages in *pre-rigor* fillets with pre-slaughter stress, and the longer the pre-slaughter stress period, the higher the percentage of myofibre breakages. In the present study, salmon subjected to long-term stress (LS) presented the highest fillet contraction (Martinsen, 2006). The higher percentage of myofibre breakages observed in

the stressed salmon could thus result from the higher tension exerted on the fillet during *rigor* contraction (Erikson & Misimi, 2008; Erikson et al., 1999; Nakayama et al., 1994; Skjervold et al., 1999; Skjervold, Fjæra, Østby, Einen, 2001; Stien et al., 2005; Thomas et al., 1999; Veiseth et al., 2006). Taylor and Koohmaraie (1998) found more breakages in the I-band region of myofibrils in normal sheep muscle than in callipyge, where callipyge muscle was associated with less proteolytic activity. In the present study, the higher cathepsin B activity in the stressed salmon 0 h *post-mortem*, even not significant, could thus also be responsible for the higher percentage of myofibre breakages observed in these fish (significantly in the LS group), when compared to the NS group.

The effect of pre-slaughter stress on fillet firmness evaluated as breaking force could be seen until at least 12 h *post-mortem*, but after this point, no significant differences in fillet texture between the groups could be noticed, except at 192 h *post-mortem* in the *post-rigor* fillets where the SS group presented the softest texture. This agrees with Erikson, Beyer, et al., 1997, Skjervold, Fjæra, Østby, Einen (2001) and Stien et al. (2005), who noticed that pre-slaughter stress had the strongest impact at early stages *post-mortem* in Atlantic salmon and cod, but gradually became less pronounced. The soft texture observed only in the SS *post-rigor* fillets 192 h *post-mortem* was not easily understood, but agrees with Kiessling et al. (2004) who found that short-term stressed Atlantic salmon presented a softer muscle texture after around 1 week of storage. Immediately *post-mortem*, fillets from the LS group were significantly the softest of all, but short-stress (SS) did not have any impact on fillet texture at that time. Ando et al. (2001) also found that the breaking strength of stressed chub mackerel was lower than in non-stressed ones at early stages *post-mortem*. Like in the present study, this softer texture was associated with a higher incidence of myofibre–myofibre detachments and Taylor et al. (2002) also suggested that myofibre–myofibre detachments highly influenced Atlantic salmon fillet texture. Godiksen et al. (2009) also showed that cathepsin B, D and L were correlated to fillet texture in rainbow trout, and these results would agree with the ones obtained here on cathepsin B activity and *cathepsin L* gene expression.

In the present study, a strong significant correlation between muscle pH and fillet softness (F_{break}) was also observed, similar to the one suggested by Stien et al. (2005) on cod. This could indicate that the lower initial muscle pH as revealed in the LS group was responsible for muscle structure degradation, influencing fillet texture, as suggested by Morzel et al. (2003) in turbot. There were also significant correlations between muscle texture and percentage of myofibre–myofibre detachments, myofibre–myocommata detachments, and *cathepsin L* gene expression. Fillet texture thus resulted from a combination of different factors as already suggested by Skjervold, Fjæra, Østby, Isaksson, et al. (2001) and Taylor et al. (2002); pre-slaughter stress causing a lower initial muscle pH, activating cathepsins earlier, and these cathepsins acting directly on muscle integrity and influencing fillet texture. In the present study, the attention has been given to the lysosomal proteases cathepsins, as these enzymes have previously been involved in *post-mortem* degradation of fish, and we established a possible link between low pH due to pre-slaughter stress and cathepsin activity. In addition, the eventual participation of other proteases like calpains cannot be excluded and investigations on these cytosolic enzymes are currently being processed in our laboratory.

The influence of time of filleting (*pre-rigor* or *post-rigor*) was compared at 96 h and 192 h *post-mortem* and little impact on the observed quality traits and muscle degradation parameters was found. Our results are in accordance with Skjervold, Fjæra, Østby, Isaksson, et al. (2001), who noticed that quality differences between *pre-rigor* and *post-rigor* fillets are reduced with time. We found, however, that *pre-rigor* filleting increased the percentage of myofibre breakages 96 h *post-mortem*. *Pre-rigor* fillets are known to contract more than *post-rigor* fillets, as in *pre-rigor* fillets, *rigor*

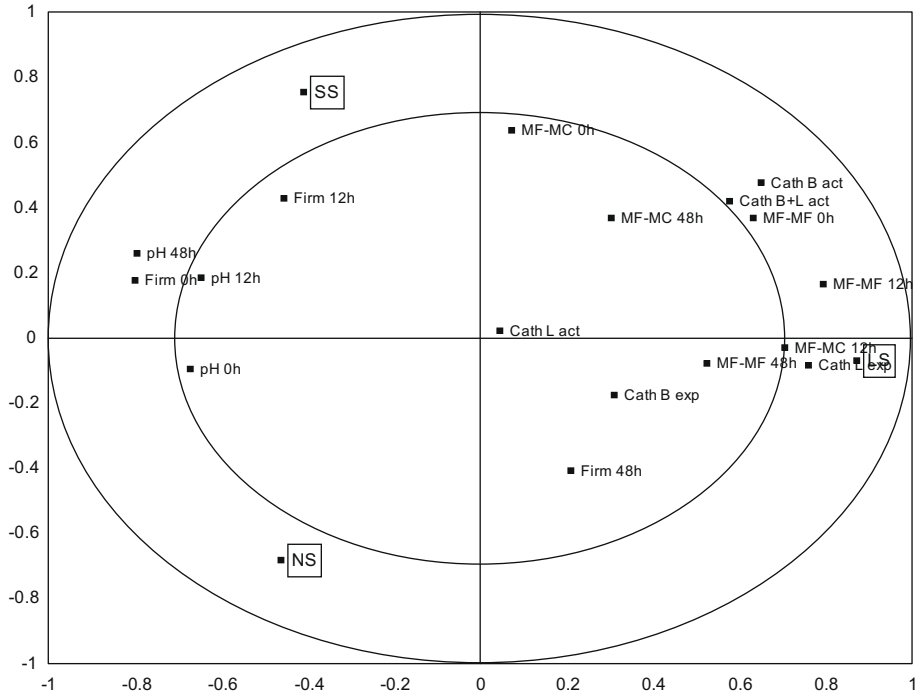

Fig. 11. Correlation loading plot from PLS regression. The first component (horizontal) (PC1) uses 34% of muscle quality variation to explain 38% of the variation in stress–length period, while the second component (vertical) (PC2) uses 10% of muscle quality variations to explain an additional 35% of variations in stress–length period. The inner and outer ellipse represent 50% and 100% explained variance respectively. MF–MF: Myofibre–myofibre detachments; MF–MC: Myofibre–myocommata detachments; Cath act: Cathepsin activity; Cath exp: *Cathepsin* relative gene expression; Firm: Fillet firmness.

contraction can progress without resistance from the fish backbone (Mørkøre et al., 2008; Skjervold, Fjæra, Østby, Isaksson, et al. 2001; Skjervold et al., 2001). This higher *rigor* contraction would then increase tensions in the myofibres, resulting in a higher number of breakages. Misimi, Erikson, Digre, Skavhaug, and Mathiassen (2008) and Mørkøre et al. (2008) also suggested that the effects of *ante-mortem* treatments (here pre-slaughter stress) are more pronounced in *pre-rigor* than *post-rigor* fillets, as significant effects of pre-slaughter stress usually occur before a noticeable onset of *rigor mortis*. *Post-rigor* filleting tending to increase the percentage of contracted myofibres 96 h *post-mortem* was, however, difficult to explain and therefore further investigations are necessary to understand this phenomenon.

5. Conclusion

Our results all converged to the fact that pre-slaughter crowding stress affects Atlantic salmon muscle quality, most significantly long-term stress (LS), especially at early stages *post-mortem*, and the longer the pre-slaughter stress period, the stronger the effects. It seemed that the low muscle pH immediately *post-mortem* resulting from the formation of lactic acid during stress, particularly in long-term stress (LS), accelerated cathepsin activity which consequently acted earlier on muscle proteolysis, leading to the acceleration of muscle degradation, when compared to minimal pre-slaughter crowding stress (NS). It can also be suggested that this low muscle pH or direct physical stress provoked shrinkage of the myofibrils; this mechanical stress increasing the tensions at the connective tissue level, and resulting in an acceleration of the muscle structure degradation. It is not excluded that other proteases like calpains could also be activated by pre-slaughter stress and may also participate in the degradation process, but this statement needs further investigations.

To conclude, pre-slaughter crowding stress in Atlantic salmon can decrease both *pre-rigor* and *post-rigor* fillet quality and has to be avoided in order to obtain high quality products. The degree of degradation seems to be related to the length of the pre-slaughter stress period; a long-term stress may produce more lactic acid and result in a lower muscle pH. *Pre-rigor* filleting still remains an interesting technique to provide fresher products on the market.

Acknowledgments

The authors would like to thank the Norwegian Research Council (NFR) for the financial support of this study, part of the Strategic University Project (SUP) 155015/110, "Atlantic salmon, our most important raw material for food production". Grethe Enersen and Målfrid T. Bjerke are warmly thanked for their help with sampling of the experimental material, as well as Ingrid Måge with the multivariate analysis of the data.

ABSTRACT

The Yesso scallop (*Patinopecten yessoensis*) is one of the most important aquacultural scallops in the north of China. We identified a rare colour variant that occurs in about 0.2% of the natural population. Orange variants have not been reported before in shellfish, including scallops. Identification of the molecular basis of this colour variation will provide guidance when developing a breeding plan for these scallops. The main pigment was isolated from the muscle tissues of the variant Yesso scallop by silica gel column chromatography, and was characterised by mass spectrometry and ^{1}H and ^{13}C nuclear magnetic resonance methods. Its structure was identified as that of pectenolone (3,3′-dihydroxy-β,β-caroten-4–one). This is the first report of pectenolone, a type of carotenoid, in the muscle of the Yesso scallop.

1. Introduction

The Yesso scallop (*Patinopecten yessoensis*) is one of the most important commercial aquacultural shellfish in the north of China and has been cultured mainly in Liaoning and Shandong provinces since it was introduced from Japan in 1982 (Wang, 1984). Annual production is about 200,000 tons and the Yesso scallop industry generated about 3 billion yuan in 2007–2008.

During the course of a research project aimed at optimising a breeding strategy for this scallop, we identified a rare colour variant that occurred in about 0.2% of the natural population. The muscle tissue of this variant was orange, as opposed to the usual white.

Colours appearing in the tissues of many aquatic animals are known to be due to the presence of carotenoids (Fox, 1979; Goodwin, 1984; Haard, 1992; Latscha 1990; Simpson, 1982; Ytrestøyl, Coral-Hinostroza, Hatlen, Robb & Bjerkeng, 2004). The principal carotenoids in shellfish are β-carotene, lutein A, zeaxanthin, diatoxanthin, and pectenolone. Most of these compounds were isolated and identified during the 1980s (Goodwin, 1984; Matsuno & Hirao, 1989; Matsuno, 1989). Interestingly, these compounds cannot be synthesised *de novo* by the animals; instead, they are the result of the accumulation of carotenoids from the diet or from specific chemical modifications by metabolic reactions (Buchecker, 1982).

The ovaries of almost all Yesso scallops will turn reddish-orange during their reproductive season and then return to white after ovulation. In 1981, Matsuno, Hiraoka and Maoka isolated and identified five carotenoids from the gonad of the Yesso scallop. However, the orange-coloured muscle tissue that we encountered has not been reported before. Therefore, we aimed to determine the type of pigment responsible for the orange colour and whether the pigment was molecularly identical to the pigments previously isolated from gonads.

To identify the pigment, we used thin-layer chromatography (TLC), column chromatography, and high-performance liquid chromatography (HPLC). In addition, mass spectrometry (MS) using electrospray ionisation (ESI) and ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectrometry were applied to determine the structure of the main pigment.

2. Materials and methods

2.1. Chemicals and samples

Ultrapure water was used during all analyses. Most of the solvents and chemicals used were of analytical grade. Methanol (MeOH) for HPLC was purchased from Tianjin Shield Company, Tianjin, China. Silica gel GF254 for TLC was obtained from Qingdao Haiyang Chemical Company, Quingdao, China.

2.2. Animals

The Yesso scallops with orange muscles (Fig. 1) were obtained from the Dalian Zhangzidao Fishery in February and March of 2007. The orange muscles were removed and stored at −80 °C until analysis.

2.3. Sample extraction

Approximately 2 kg of Yesso scallop muscle were homogenised in acetone and extracted at room temperature until the colour was no longer visible. A little was retained for carotenoid content analysis. To avoid degradation and isomerisation of carotenoids, amber glassware was used and the extractions were performed in an aphotic environment. The crude acetone extract was filtered under reduced pressure to remove particles, followed by evaporation under vacuum (temperature <30 °C) to a concentrated liquid and then flushed with nitrogen. The extraction was then frozen at −80 °C until isolation.

2.4. Isolation of the main pigment

The concentrated acetone extract was applied to a silica gel column under reduced pressure and eluted using increasing percentages of acetone in petroleum ether. Twenty-one fractions were collected according to colour. Silica gel column chromatography was repeated for fractions 16–18, which were red in colour; this time the eluant was chloroform ($CHCl_3$) and MeOH. Thirty-four subfractions were obtained, of which fractions 7–12 were deep red in colour. These fractions were believed to contain the main carotenoid and were analysed further.

2.5. Purity check of the main carotenoid

The purity of the main carotenoid isolated by column chromatography was evaluated by TLC and reverse-phase HPLC. TLC analysis used a mixture of $CHCl_3$:MeOH (20:1 v/v) as the developing agent. The conditions of reverse-phase HPLC analysis were an analytical-scale (250 × 4.6 mm inner diameter) C18 ODS column; 10-μl injection volume; 30 °C column temperature; water:methanol mobile phase (90:10, v/v); 1.0 ml per minute flow rate; 200–500-nm UV–vis detection. After confirming the purity of the compound, the main pigment was further evaluated by MS and NMR.

2.6. Electrospray ionisation-mass spectrometry

To obtain the mass spectrum of the carotenoid, a small amount of the compound was dissolved in 100% methanol and applied to the probe. ESI-MS was performed on a Q-TOF Ultima Global GAA076 LC–MS (Applied Biosystems, Foster City, CA) in the positive ion mode.

Fig. 1. Muscle tissue of *Patinopecten yessoensis*. The orange colour variant is shown on the right.

2.7. ^1H and ^{13}C nuclear magnetic resonance

The main carotenoid pigment was dissolved in 500 μl d_6-acetone. ^1H and ^{13}C NMR spectra were recorded on a JEOL ECP-600 spectrometer (600 MHz), using the acetone solvent peak as a reference; chemical shifts were recorded as δ values.

2.8. Quantitative evaluation of total carotenoids from the orange muscle of Yesso scallop

The total carotenoids content from Yesso scallop was determined by spectrophotometry (λ = 450 nm) and calculated by following formula:

$$\text{Total carotenoid content from Yesso scallop (mg)} = \text{optical density value} \times \text{volume (ml)} \times \text{dilution times} \times 10 \div 2500 \ (\text{mean value } A^{1\%}_{1cm}\ 2500 \text{ of coloured carotenoids}).$$

3. Results and discussion

3.1. Purity of the main carotenoid from the muscle of the Yesso scallop

The carotenoids present in the orange muscles of Yesso scallops were isolated and purified by acetone extraction and silica gel chromatography. In order to determine whether a single carotenoid was responsible for producing the deep red colour that we identified as the main pigment, we performed TLC and HPLC. TLC of the main carotenoid produced a single red dot with an R_f value of 0.455. HPLC analysis of the main carotenoid showed a single peak and the absorption maximum was at about 454.6 nm (MeOH). Photodiode array measurements of the spectral properties of the peak were determined at the upslope, apex, and downslope. The degree of agreement between the three spectra indicated the degree of purity; the results indicated that a single pure substance was responsible for producing the red colour of the main pigment.

3.2. Electrospray ionisation–mass spectrometry of the main carotenoid

The positive ESI-MS exhibited a quasimolecular peak at *m/z* 581.6 $[M + H]^+$ in full scan mode. Therefore, we assumed that the relative molecular weight of the carotenoid was about 580. The ion at *m/z* 665.6 was assumed to be the corresponding quasimolecular ion of the carotenoid.

3.3. Nuclear magnetic resonance spectra of the main carotenoid

The ^1H and ^{13}C NMR spectra data of the main carotenoid from the orange Yesso scallop are shown in Table 1.

The compound showed a quasimolecular ion peak in positive ESI-MS at *m/z* 581.6 $[M + H]^+$. The molecular formula of this compound was assigned to $C_{40}H_{52}O_3$ by ESI-MS, ^1H and ^{13}C NMR data. The ^1H NMR spectrum included multiple overlapped conjugated olefinic protons (δ 6.35–6.81) and two broad signals (δ 3.96 d, J = 2.3 Hz, 1H; δ 3.75 d, J = 4.6 Hz, 1H) attributed to substitution by two secondary hydroxyl groups. Ten singlet methyl signals were also observed on ^1H NMR (δ 1.12, 3H; δ 1.17, 3H; δ 1.89, 3H; δ 2.50, 6H; δ 1.35, 3H; δ 1.22, 3H; δ 1.89, 3H; δ 2.02, 6H).

The presence of 40 distinct signals in the ^{13}C NMR spectrum concurred with a unique signal for each carbon in the formula $C_{40}H_{52}O_3$ and an unsaturation index of 14. The ^{13}C NMR spectrum showed unique signals at δ 200.8 (s), corresponding to a keto group, and δ 99.1 (s), and δ 90.2 (s), corresponding to an acetylenic group, respectively. Eighteen olefinic carbons (δ 125.8d, δ 140.3s, δ 137.5s, δ 135.8d, δ 124.6d, δ 135.9d, δ 137.4s, δ 134.7d, δ 131.7d, δ 120.0s, δ 142.8d, δ 125.3d, δ 139.0d, δ 135.8s, δ 134.5d and δ 131.5d) indicated a conjugated chain system. Another four olefinic carbons (δ 127.6s, δ 162.0s, δ 138.9s and δ 124.8s) were assigned to the double bonds in the two six-membered ring systems. The data obtained for the main carotenoid agree with previous reports for pectenolone (Matsuno & Maoka, 1981; Hiraoka et al., 1982). No effort was made to determine the stereochemistry of the compound.

The structure of the purified carotenoid is presented in Fig. 2 and it corresponds to that of pectenolone (Campbell et al., 1967). Carotenoids have been reported to possess highly nutritional and therapeutic properties, such as increasing the cytotoxic activity of killer T cells, decreasing the rate of tumour growth (Nishino, 1998; Nishino et al., 2002), and promoting wound healing. The free form of this compound was previously isolated from the gonad of the Yesso scallop and it accounted for 73% of the carotenoids present (Matsuno, Hiraoka, & Maoka, 1981).

3.4. The total content of carotenoids from the orange muscle

The total content of carotenoids from the orange muscle of Yesso scallop was about 18.6 μg/g measured by spectroscopy.

4. Conclusions

In this study, the carotenoid pectenolone was proved to be the main molecular component responsible for the orange colour of the Yesso scallop muscle. Pectenolone was isolated by column chromatography and characterised by ESI-MS, ^1H NMR, and ^{13}C NMR, and is identical to the compound previously isolated from the gonad of the Yesso scallop. The muscle is the edible part of the scallop, making it the most important feature considered during breeding and farming. Increasing the frequency of the colour variant could have a positive impact on the economic value of Yesso scallops. Our breeding experiments determined that this colour variation is heritable; therefore, future research efforts will focus on developing breeding strategies to maximise production of this orange colour variant.

Acknowledgements

We wish to acknowledge the Zhangzidao Group for collecting the scallops. ABSTRACT

Banana powder (BP) was added to hard-red spring wheat (HRSW) flour intended for yeast-leavened bread formulation. Five different formulations containing 10%, 15%, 20%, 25%, and 30% BP were prepared with varying amounts of base flour, while vital gluten was maintained at 25% in all blends. Based on the added BP amounts only, the prepared bread could deliver 42.87–128.6 mg potassium/30 g of bread (one regular slice) and 0.33–1.00 g of fibre. Although the dough water absorption was increased, due to BP addition, the dough mixing tolerance (MTI) decreased. The bread loaf volume was significantly higher than the control except for the 30% blend, where the loaf volume was similar to the control. Bread staling increased with BP levels due to the high sugar content but, this effect was limited to the first two days of storage. Blends exhibited darker colour due to the high sugar and protein, while the 25% and 30% blends had the lowest percent of freezable water. The amounts of acetic acid extractable proteins from the dry blends and the dough decreased with increase in BP. The linear rheological properties of the control, 10%, and 30% blends exhibited similar viscoelastic solid behaviour, where both G' and G'' had plateaus ($G' > G''$) and they were parallel to each other over three decades of the frequency. Blends showed higher moduli values than the control.

Published by Elsevier Ltd.

1. Introduction

The addition of pre-hydrated plant fibre has been reported to improve dough water absorption and also to increase the loaf volume of high-fibre bread as well (Sosulski & Wu, 1988). Pomeranz, Shogren, Finney, and Bechtel (1977) reported that, the addition of various dry fibres to bread formulations increased dough water absorption, the mixing time, and decreased bread loaf volume. Addition of brewer's spent grain, a solid material remaining after malt brewing, to standard bread formulation resulted in low loaf volume (Prentice & D'Appolonia, 1977). The effect of oats-bran meal on dough stability and water absorption was shown to be minor as compared with bran from oat-groat (D'Appolonia and Youngs, 1978). In general, the presence of components with high water-binding capacity negatively affect flour water absorption, dough mixing, rheological properties and bread quality, such as loaf volume, crumb texture and colour (Holas & Tipples, 1978; Jelaca & Hylnka, 1971; Kim & D'Appolonia, 1977; McCleary, 1986; Michmiewicz, Biliadires, & Bushuk, 1990; Shelton & D'Appolonia, 1985). Baked products with high soluble fibre were formulated to target consumers interested in lowering their blood cholesterol (Mohamed, Rayas-Duarte, & Xu, 2008; Mohamed, Rayas-Duarte, Xu, Palmquist, & Inglett, 2004).

Barley flour and its fractions contain substantial amounts of soluble fibre, namely β-glucan in the form of (1–3)(1–4)-β-glucans (Berglund, Fastnaught, & Holm, 1992; Marlett, 1991).

The change in formulation was demonstrated to influence bread thermal properties. This was clearly established by differential scanning calorimetry (DSC), where the addition of soluble fibre was found to increase the melting temperature of ice in frozen bread (Mohamed et al., 2008; Vodovotz, Hallberg, & Chinachoti, 1996). A significant increase in loaf volume and specific loaf volume was observed upon the addition of water soluble non-starch polysaccharides (Rao, Manohar, & Muralikrishna, 2007). The dynamic mechanical analysis (DMA) testing of bread at very low temperatures (−70 °C) revealed various changes in viscoelastic properties (Hallberg & Chinachoti, 1992; Vittadini & Vodovotz, 2003).

Freeze-dried banana pulp showed a marked cholesterol-lowering effect when incorporated into a diet at the level of 300 or 500 g/kg. The soluble and insoluble components of dietary fibre participate in the hypocholesterolaemic effect of banana pulp (Horigome, Sakaguchi, & Kishimoto 1992). Potassium is the third most abundant mineral in the body and is critical in regulating blood pressure, water retention, and muscle activity. Banana is among the

☆ Names are necessary to report factually on available data; however, the USDA neither guarantees nor warrants the standard of the product, and the use of the name by the USDA implies no approval of the product to the exclusion of others that may also be suitable.

doi:10.1016/j.foodchem.2009.05.044

potassium-rich fruits along with raisins, orange juice, and potato skin (Young, Lin, & McCabe 1995). In 2004, the Food and Nutrition Board of the Institute of Medicine established an adequate intake level for potassium based on intake levels that have been found to lower blood pressure, reduce salt sensitivity, and minimize the risk of kidney stones. These levels were 3800 (mg/day) for children, 4700 for adults and pregnant women, and 5100 for breast-feeding (Food & Institute of Medicine. Potassium., 2004).

The objectives of this research were to develop yeast-fermented bread formulations with high banana powder content without compromising bread quality characteristics such as loaf volume, taste, and length of storage time. The possible interactions between the components of the formulation will be addressed. This product will assist consumers in meeting their daily recommended potassium intake by consuming bread.

2. Materials and methods

2.1. Materials

Freeze-dried banana (in ¼″ diced pieces) obtained from Van Drunen Farms (Momence, IL) was ground in a food processor for 5 min and sieved through 80 mesh before use. Hard-red spring wheat (HRSW) flour (Miller's Choice) was obtained from North Dakota State Mill (Grand Forks, ND). Vital wheat gluten was obtained from Midwest Grain (Pekin, IL). Ascorbic acid was obtained from Spectrum Chemical Mfg. Corp. (Gardena, CA), α-amylase (Doh-tone) was obtained from American Ingredients (St. Louis, MO), and instant dry yeast was obtained from Fleischmann's Yeast (Chesterfield, MO). Other bread ingredients (non-fat dry milk and Crisco shortening) were obtained from a local supermarket. The banana powder proximate analysis as described in the certificate of analysis provided by the supplier were; 4% moisture; 4.09% protein; 87.19 carbohydrates (68.9% sugars, 7.5 other carbohydrates, and 10.9% dietary fibre); 1.33 g potassium; 0.089 g magnesium. Five blends with the same amount of vital gluten were used in this research: Control (100% HRS wheat flour); 10% (10% banana, 65% flour, 25% gluten); 15% (15% banana, 60% flour, 25% gluten); 20% (20% banana, 55% flour, 25% gluten); 25% (25% banana, 50% flour, 25% gluten); and 30% (30% banana, 45% flour, 25% gluten).

2.2. Methods

2.2.1. Farinograph testing

The HRSW flour and the five blends (0%, 10%, 15%, 20%, 25%, and 30% banana powder) were tested using the Farinograph according to AACCI (2000) method No. 54–21, while moisture was determined as stated by AACCI (2000) method No. 39–06. The 10 g mixing bowl was used under standard conditions (60% absorption, 14% moisture, 500 FU consistency, and 20 min run time). The dough water absorption, mixing tolerance index (MTI), and stability profiles were calculated.

2.2.2. Baking procedure

The baking procedure was based on the modified AACCI (2000) method (10-09). The ingredients for the 35 g loaf used here were a mix of solutions and dry blends. Two solutions were prepared; 350 mg ascorbic acid in 100 ml water and α-amylase solution (105 mg α-amylase (Doh-tone) in 100 ml water). The dry ingredients were prepared by combining the following; 35 g flour (or flour/banana blend); 0.875 g (2.5%) instant dry yeast; 2.1 g (6%) shortening; 1.4 g (4%) non-fat dry milk. To the dry ingredients; 5 ml ascorbic acid solution (500 ppm) and 1 ml α-amylase solution were added. The blend was mixed in a Micro mixer (National Manufacturing, Lincoln, NE).

The water absorption, as determined by mixing and feeling the dough, was as follows: Control (100% HRSW flour) = 17.5 ml; 30% = 20 ml; 25% = 21 ml; 20% = 21 ml; 15% = 22 ml; 10% = 22 ml. These amounts were added plus the 5 ml ascorbic acid and 1 ml amylase solutions added to all samples equally. Mixing times were 6 min for the control and the 10% banana, 7 min for the 15%, 20%, and the 25% banana, while the 30% banana required 8 min mixing. During initial testing, it was found that addition of the sugar/salt solution (as specified in the AACC method) to the blends containing banana caused little or no dough development (gluten-network development) due to the elevated amount of sugar in the powdered banana (68% w/w) used in the blend. Therefore, sugar and salt were eliminated in the final formulations. The method was further modified to maximize loaf volume as follows: After dough-mixing, the different formulations were proofed for 1.5 h in baking pan without punching, rather than proofing in bowls first and punched and finally in baking pans. Formulations were baked in pre-heated oven at 425 °F for 18 min. Baking performance was done in triplicate and loaf volume was recorded according to AACCI (2000) method number 10-05.

2.2.3. Bread firmness

Bread samples were tested using TA-XT2i Texture Analyzer (Texture Technologies Corp., Scarsdale, NY). Although the Texture Analyzer was used, this method was based on the AACCI (2000) method number 74-09 with a 35 mm aluminum plunger and 20 mm bread-slices. Firmness testing was performed on bread loaves that were stored at 25, 4, and −20 °C for 2, 5, and 7 days using 5 kg load cell and a 6 mm cylinder probe as described by the texture analyzer manufacturer. The bread macro available in the applications software of the texture analyzer was used without modifications. The testing was performed in triplicate, and the force recorded in grams.

2.2.4. Colour analysis

After baking, bread samples were cooled and stored at room temperature in Double Zipper, Ziploc® Brand (SC Johnson, Racine, WI), for colour measurement at the same day. The L* (Lightness), a* (Redness), and b* (Yellowness) values of the crust and the crumb were measured utilizing a HunterLab LabScan XE Spectrophotometer with a D65 light source (Hunter Associates Laboratory, Inc., Reston, VA) in triplicate.

2.2.5. Differential scanning calorimetry (DSC) and freezable water

Bread samples were analyzed using a Q2000 DSC (TA Instruments, New Castle, DE). Samples (12–16 mg) were placed in hermetically-sealed aluminum pans and cooled to −80 °C using the refrigeration system connected to the DSC. The samples were then heated from −80 to 110 °C at a rate of 5 °C/min. The onset and peak temperatures were determined by the tangent method utilized by the instrument software, which minimizes error committed by the operator in determining the onset temperature. The amount of freezable water was determined from the DSC data according to the method of Vittadini and Vodovotz (2003).

2.2.6. Acetic acid protein extraction and HPLC

Doughs were ground using a coffee grinder (Coffee Grinder GX4100-11, Oceanside, NY). The grinding was done gradually with occasional stops so that to prevent temperature rise due to friction. Dry control and blends, and their ground dough samples (4 g) were dispersed in 40 ml 0.1 M acetic acid. In order to extract the acetic acid-soluble proteins from dry blends, samples were shaken for 1 h, while dough samples were shaken overnight (~14 h) using a 32-WBS-40 shaker (John-Sam, Boocheon, NJ). After extraction (shaking), samples were centrifuged at 6000×g for 30 min at 10 °C. The supernatant and the precipitate were freeze-dried sepa-

rately. The protein content of the dried precipitate and the liquid supernatant was determined using FP-528 Nitrogen Protein Analyzer (LECO, St. Joseph, MI) (Mohamed et al., 2008). The protein content was determined by multiplying the total nitrogen by a factor of 6.25.

Supernatant of acetic-acid extracted samples were filtered through a 0.45 μm syringe filter and analyzed using size exclusion HPLC (SE-HPLC HP) 1100 system (Hewlett Packard, Ramsey, MN) with automatic injection. Samples were injected (20 μl) on a Bio-Sep-SEC-S4000 column and detected at 214 nm. The eluting solvent was acetonitrile and water (1:1, v/v) containing 0.1% trifluoroacetic acid (TFA) at a flow rate of 0.5 ml/min for 60 min (Batey, Gupta, & MacRitchie, 1991).

2.2.7. Rheological measurements

Although all formulations were baked, only three out of the six blends were used for rheological testing, the control (100% HRS wheat flour); 10% (10% banana, 65% flour, 25% gluten); and 30% (30% banana, 45% flour, 25% gluten), where testing was done on 20% (wt.%) suspensions. Samples were dispersed in a 0.05 M sodium phosphate buffer, pH 7.0 (25 °C) (Xu, Bietz, Felker, Carriere, & Wirtz, 2001) using Polytron PT10-35 homogenizer with a "low-foam" mixing head PTA 20TS (Kinematica AG, Switzerland). A duplicate of each sample were well dispersed and stored at 4 °C and used within 2 days. Rheological properties of the suspensions were measured using Rheometrics ARES strain-controlled fluids rheometer (TA Instruments Inc., New Castle, DE) equipped with 50 mm diameter cone-plate geometry (Xu et al., 2001). The angle of the cone was 0.04 radians. The sample chamber was placed in a humidity-controlled chamber to prevent moisture loss during runs, while the temperature was set at 25 ± 0.1 °C and controlled via a water circulation system. Prior to dynamic rheological parameter measurements, a strain-sweep experiment was conducted to confirm the linear viscoelastic range throughout the experiment. Linear viscoelasticity indicates that the measured parameters are independent of shear strains. Below 0.3% of strain, all measured materials in this study were in the linear range. Small-amplitude oscillatory shear experiments (shear strain = 0.1%) were conducted over a frequency (ω) range of 0.1–500 rad/sec, yielding the shear storage G' and the loss G'' moduli. The storage modulus represents the non-dissipative component of mechanical properties. The viscoelastic solid or "rubber-like" behavior is suggested if the G' spectrum is independent of frequency and greater than the loss modulus over a certain range of frequency. The loss modulus represents the dissipative component of the mechanical properties and is characteristic of viscous flow. The phase shift (δ) is defined by $\delta = \tan^{-1}(G''/G')$, and indicates whether a material is solid ($\delta = 0$), or liquid ($\delta = 90°$), or somewhere in between. Non-linear rheological measurements were conducted as steady shear in the range of shear rate of 0.01–400s^{-1}. Each measurement was repeated at least two times with different samples, where the relative errors were all within the range of ±12%.

2.2.8. Dynamic mechanical analysis (DMA)

Samples were weighed in 25.4 × 50.8 × 3 mm stainless steel windows and put in carver press at room temperature for 10 min and 2000 lbs force (8896.5 N). The samples were removed and cut into strips and placed in torsion rectangular fixture for the TA ARES LS2 controlled strain rheometer. Each sample had different dimensions, which were recorded before testing. The samples were clamped in the fixtures using a torque wrench set at 20 cN.m. The bread samples were cooled to −60 °C and measured to as high as possible temperature before samples slipped out of grips due to change in dimensions. The temperature ramps were 2 °C/min, 0.1% strain and 1 rad/s. Storage, loss modulus, and tan δ were characterized, and the storage modulus was fitted into the Fermi Equation.

2.2.9. Statistics

The statistical analysis of the bread samples data was carried out using PROC GLM in SAS Version 8.2 for PC Windows. A completely random design (CRD) was used to compare the texture data of the control and the blends stored for 2, 5 and 7 days at 25, 4, and −20 °C. From the ANOVA, F-test value was obtained and a multiple comparison test was performed on the means, using Duncan's Multiple Range Test at 0.05 levels.

3. Results and discussion

3.1. Farinograph testing

The presence of banana fibre dictated the addition of supplemental vital gluten intended for maintaining dough viscoelasticity. In general, fibre dilutes wheat gluten functionality for two reasons; due to its high water holding capacity as well as lack of viscoelasticity. Mixing flour and water for dough development is the most critical step of dough formation that requires exact mixing time and enough available water. The importance of dough mixing is evident in the disulphide bond formation between gluten (wheat proteins) fractions, where gluten film is formed, which is required for holding dough components together, thus forming a viscoelastic mass. Farinograph was used to determine the effect of powdered banana on the water absorption of the control flour and the mechanical properties of the formed dough. The water required for dough maximum consistency in the Farinograph was different from that needed for the dough used for baking. That is due to the presence of other ingredients beside the water and the different type of mixing used relative to the Farinograph mixing. Despite the difference in the amount of water required for dough formation, the Farinograph is an appropriate tool to test the effect of dried banana on the mechanical rheology of wheat flour. The presence of banana powder increased the Farinograph water absorption of the control by 5.2, 7.5, 10.3, 12.5, and 15.2% for the 10, 15, 20, 25, and 30% banana added, respectively. The dough mixing tolerance index (MTI) is the difference in Brabender Units (BU) between the top of the Farinograph-profile peak and 5 min later, where larger differences indicate increasing banana powder influence on the control. MTI of wheat flour had decreased in the presence of the banana powder, where MIT of the 15% banana was 37% lower than the control (46 versus 29 BU). Further increase in banana content resulted in additional decrease in MIT of the control but, there was little difference between 10 and 15% blends, in addition to insignificant differences between the 20 and 25% blends. Dough stability was reduced by 22.3% (control 21.1 min and blends 16.4 min) in the presence of banana powder. Dough stability is the difference in min between the time when the top of the curve reaches 500 BU and the time where it leaves the 500 BU. The increase in the banana content in the blends didn't have further influence on the dough stability. The effect of the banana on the Farinograph profile of the control could be attributed to the presence of fibre and the sugars as well as the electrolytes such as potassium. The influence of these components on MIT and dough stability is due to their ability to compete with gluten for water as well as weakening the gluten network needed for dough formation. The purpose of adding vital gluten to the blends was to manage the negative influence of the banana on the dough rheology. This way, the quality of the final product, such as loaf volume and crumb quality, will be maintained. The arrival time is also one of the dough quality parameters obtained from the Farinograph testing. It is the time needed for the curve to reach the

500 BU mark, where longer arrival time indicates slower gluten development during mixing. Consequently, this will increase dough mixing time and delay bread production. The arrival time for the control flour was 1 min while the 15% blend needed 6 min to arrive.

One of the good measures of wheat flour quality as well as the effect of added ingredients on the final bread quality characteristics is the bread loaf volume. Although, the addition of vital gluten to banana blends will increase cost, it was necessary to maintain bread quality. Among other components, banana powder contained around 11% fibre, 69% sugars, 4% proteins, and 1.5% fat. Due to their structure, sugars and the fibre absorb a large amount of water, consequently interfering with gluten development during dough mixing. Lack of fully developed gluten has a direct effect on dough formation, mixing time, and bread quality. The 10%, 15%, 20%, and 25% blends exhibited significantly ($p \leqslant 0.05$) higher loaf volume compared to the control, whereas the 30% blend loaf volume was similar to the control (Fig. 1a). Keep in mind that all blends had the same amount of vital gluten added to the control (25%). Therefore, blends with less banana powder showed higher loaf volume indicating positive effect of vital gluten. The 30% blend appeared to be the most comparable to the control. It is worth mentioning here, because of the high sugar content of the banana powder, sugar was eliminated from the baking formulation of the blend while it was added to the control. The presence of higher sugar content, instigated competition with vital gluten for available water, which delayed gluten development. Another reason for eliminating sugars was their effect on the colour (high sugar darker colour), texture, and taste of the final product.

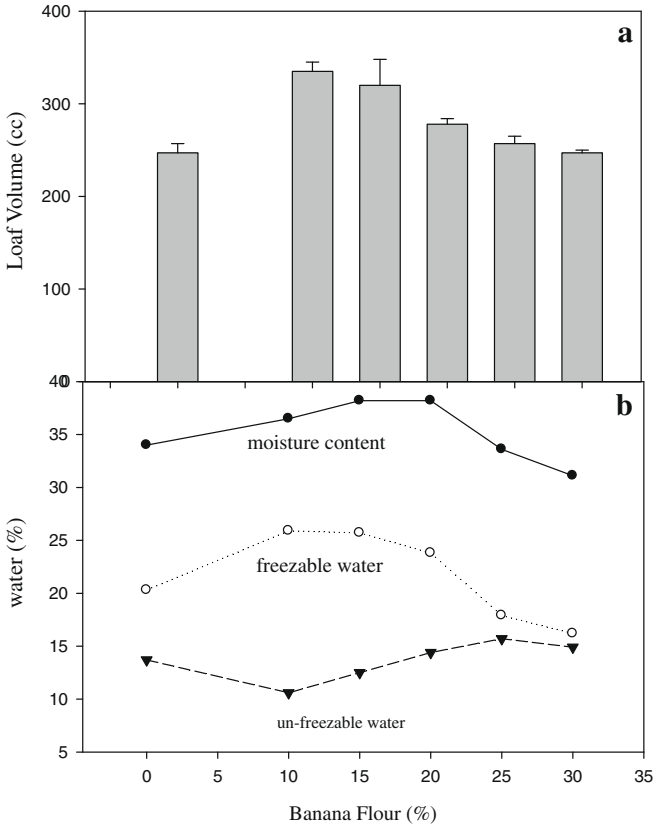

Fig. 1. (a) Loaf volume of the control and the blends. Samples with the same letter are not significantly different at 95% confidence interval. (b) Moisture content, freezable water, and un-freezable water of the control and the blends.

3.2. Bread staling

Bread staling is one of the important characteristic of stored bread, where bread aroma becomes less desired by consumers. Staling can be quantified by determining bread texture. Amylose and amylopectin retrogradation are believed to be the main cause of staling. Monoacylglycerols complexation with amylose was found to be effective in reducing staling (Willhoft, 1971). In order to determine the effect of storage time and temperature on bread, firmness testing was done at 25, 4.0, and −20 °C for 2, 5, and 7 days. The time and temperature were selected to imitate supermarket's storage conditions. The control (0% banana) exhibited higher firmness compared to the blends at all temperatures and storage time (Table 1). In addition to the increase in firmness with time, the lower temperature reduced the firmness at all storage time. The data in Table 1 also showed that higher banana powder content increased bread firmness due to the high sugar content. Elevated amounts of sugar had direct effect on water migration from other bread components, such as protein and gelatinized starch, thus causing bread stiffness. This moisture distribution and trapping by the sugars are the cause of higher firmness. Bread enriched with soluble fiber is one of the popular products in the baking industry. High soluble fibre and protein content, were found to have reduced bread firmness (Mohamed et al., 2008). The amount of banana powder added had a significant effect on bread firmness after storage, where most blends were significantly different from each other, within each temperature, except 25% and 30% blends (Table 1). Samples stored for two days at room temperature showed significantly lower firmness compared to the control, where samples with lower banana powder content exhibited lower firmness. After 5 and 7 days storage at room temperature, no significant difference in firmness was observed between blends, except the 10%, regardless of the amount of banana powder added (Table 1). At 4 °C storage, banana powder content seemed to have significant effect specially, after 5 and 7 days storage. Storage at −20 °C showed a pattern, where the 10% and 15% blends had similar firmness values, while the 20%, 25%, and 30% blends exhibited similar firmness (Table 1). The 10% blend stored at −20 °C showed the least firmness, while the greatest firmness recorded was the control stored at room temperature for 5 or 7 days.

Predicted mean values followed by the same letter within temperature and column are not significantly different based on overlap of the 95% confidence intervals.

3.3. Colour analysis

Considering the high protein content of the blends, due to the additional vital gluten, it was expected they will be darker than the control (lower L^* value). Similarly, samples with more banana powder will be darker, due to the excess sugar in the banana powder. The bread crust data in Table 2 showed just that, where the L^* value decreased significantly and in accordance to the banana powder content, where the 30% blend was the darkest and the 10% was the least. The crumb showed similar pattern with less significant differences between blends. The darkness of both, the crust and crumb, is a product of the Maillard Reaction between reducing sugars and proteins. The redness (a^*) and yellowness (b^*) of the crust was also significantly different between all samples. The redness values of the crumb significantly increased relative to the banana content, while the yellowness was not significantly different, where the 10% and 15% blends were significantly lower than the remaining blends including the control (Table 2). Unlike in the crust, this indicated the difficulty in locating regions on the crumb with major colour contrast compared to the control.

3.4. Freezable water

The percent freezable water (FW) was calculated according to Vittadini and Vodovotz (2003). The method is based on DSC analysis of bread by dividing the peak enthalpy of the water in the bread sample by the latent heat of fusion of ice. The initial moisture content of the tested bread samples was directly associated with the FW (Fig. 1b). As expected, the amount of banana powder in blends influenced the moisture content and consequently altered the %FW. The %FW value of the control was in the middle of those of the blends, despite the lower amounts of water added to the control initially during dough mixing. The 25% and the 30% blends showed the lowest %FW, while the 10% and 15%, and 20% blends were the highest (Fig. 1b). It is interesting to see the differences between samples with the same amounts of water during dough mixing display different %FW values as in blends 10% and 15% as well as 25% and 30%. The effect of the banana powder on the %FW was obvious in Fig. 1b. Although, the initial excess amounts of water added to the blends compared to the control managed to increase %FW as in the 10, 15, and 20, the increase in the amounts of banana powder brought it down as shown in the 25% and 30% blends (Fig. 1b). The high sugar content of the added banana powder have interacted with the water and lowered the quantity of free water hence reducing the overall %FW of the bread. The peak temperature data of ice melting gathered from DSC profile reflected similarities between the samples, where the 10% blend as well as the control melted at −2 °C and the 30% blend at −7 °C. This trend was not apparent, neither on the moisture content and the %FW nor in the bread firmness.

3.5. Acetic acid protein extraction and HPLC

Protein extractability can be used as a measure of interaction, where low extractability indicates protein interaction with other ingredients used in the formulation. A representative sample of wheat proteins can be extracted using 0.1 M acetic acid (Mohamed et al., 2008) because wheat gluten is partially soluble in acetic acid. Additionally, it is important to determine the effect of mixing on protein extractability by extracting proteins from both, dry mixes as well as dough. The amounts of proteins extracted from both, dry mixes or dough, decreased as the banana powder increased in the formulation, even though the ratio of protein:non-protein in the dry mix was kept the same by adding extra gluten. The amount of protein in the supernatant was determined and plotted against the amount of banana powder in the blends. A linear regression of the plotted data was used to show the linearity of the amount of proteins extracted from the dry mix and the dough as a function of banana powder content. The decrease in the extractable protein from the dry mixes followed a strait line with a good fit $Y = 36.9\ X - 0.68$ ($R^2 = 0.97$), whereas the dough had a poor fit with $R^2 = 0.40$ and $Y = 39.7\ X - 0.83$. This difference could be attributed to the formation of water-insoluble aggregates as part of the gluten-network formed during mixing while gluten transformed into a viscoelastic material. Considering the extra protein added to the blends one might expect the amount of extractable protein from control to be lower than the blends, but the data presented here showed otherwise. Except for the 10 and the 15% blends, the extractable protein from the remaining blends was lower than the control.

In an attempt to show changes in protein-fractions size, the extracted proteins were analyzed using a SE-HPLC. The dough profile showed a typical wheat protein profile with different peak intensity according to the amount of protein in each sample. The first peak around 11.5 min represents the high MW glutenins followed by the low MW glutenins and finally the gliadins (Fig. 2). The SE-HPLC profile of the blends showed similar trends regarding the type of protein extracted. Although, there is similarity in the type of the extracted protein, some fractions showed more glutenins

Table 2
Bread colour analysis of the control and the blends.

Banana (%)	L^* [A]	a^* [B]	b^* [C]
Crust			
0	56.51 ± 3.7[D] a	14.83 ± 1.2 c	36.36 ± 1.2 a

15	57.91 ± 2.9 bc	2.14 ± 0.3 c	17.72 ± 0.3 b
20	54.40 ± 4.1 c	3.10 ± 0.6 b	19.48 ± 1.2 a
25	53.52 ± 3.7 c	3.71 ± 0.2 ab	19.78 ± 0.7 a
30	56.83 ± 1.6 bc	3.94 ± 0.3 a	20.55 ± 0.8 a

[A] L^* = lightness, higher values indicate lighter colour.
[B] a^* = redness.
[C] b^* = yellowness; higher colour intensity is indicated by higher values.
[D] Predicted mean values followed by the same letter within a column are not significantly different based on overlap of the 95% confidence intervals.

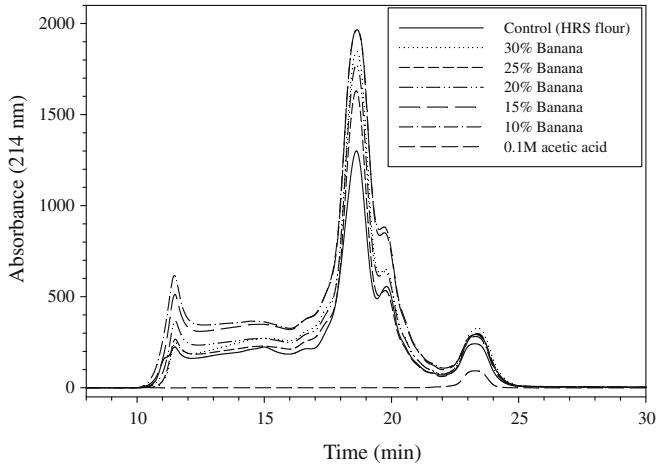

Fig. 2. SE-HPLC of acetic acid extractable proteins from doughs of control and blends.

than low MW glutenins (Fig. 2). The dry mixes extraction profile did not show sharp glutenins peak, instead, a broad peak appeared (data in not shown) between 12 and 16 min and another peak with higher intensity, compared to the dough profile. The presence of the broad peak could be due to the fact that, glutenins interacted with the banana powder while in the dough, glutenins formed aggregates, which allowed easy extraction, and thus the sharp peak was present.

3.6. Rheological measurements

The profile of the strain-sweep measurements at 1 rad/s frequency for the control (0% banana), 10%, and the 30% banana, where the linear range of control was less than 1% and the linear range of the 10% and 30% suspensions was less than 0.3% as well as the remaining blends. The elastic or storage modulus (G') for the 30% blend was the highest among the three blends. Although all samples had the amount of added vital gluten (25%), the high banana content of the 30% blend and the higher amount of gluten in the 10% blends are possibly the cause of the high G' relative to the control. The 30% blend contains higher fibre content, while the 10% blend was higher in gluten content due to the higher wheat flour in the blend. Therefore, the high fibre content facilitated the formation of a more solid like suspension, while gluten is known to have high elasticity than the other components in the flour causing higher G' of the two blends than the control. The linear rheological properties of the control, 10%, and 30% blends exhibited similar viscoelastic solid behavior (Ferry, 1980), where both G' and G'' had plateaus ($G' > G''$) and there were parallel to each other over three decades of the experimental frequency. Blends showed higher moduli values than the control. The storage or elastic moduli (G') and the phase shifts (δ) for the control were in a range of 20 to 90 Pa and 15 to 32°, respectively. The elastic moduli (G') and the phase shifts (δ) for the 10% blend were in a range of 99 to 437 Pa and 15 to 31°, respectively, while the 30% blend exhibited a 212–851 Pa elastic moduli (G') and the (δ) between 11 and 23° (Fig. 3b). The G' and the δ values of the remaining blends (10%, 15%, and 25%) were in between the 20% and 30% blend (data not shown). These results indicated that blends exhibited stronger viscoelastic solid properties than the control, suggesting that blends should have better baking quality than the control. However, the stronger viscoelastic solid-behaviour of the blends, partially caused by the fibre in the banana, may not have the same effect on the dough system and the baking process. Therefore, blends and the control flour might have similar baking quality despite their differences in the dynamic rheology testing. This is due to the difference between the suspension system tested here and the dough system used for baking, where the solid content of the dough system is much higher than the suspension used for dynamic rheology analysis.

The non-linear shear behavior of the control and the 10% as well as 30% blends showed shear-thinning behavior (Fig. 3a). The viscosity of the blends was higher than the control, whereas the viscosity of the 30% blend was highest (Fig. 3a). The remaining blends exhibited the same shear-thinning with values between the 10% and the 30% blends (data not shown), indicating that all blends has similar viscosities but, slightly higher than the control. Because the actual industrial processing shear rates are in the range of 1 to 100 s^{-1} (Bloksma, 1988), we could predict that, processing the control flour will require less mixing-energy than the blends due to the lower viscosities and should be easily processed. Although there were differences between the control and the blends in their rheological properties, it is reasonable to consider these differences being not substantial enough to cause changes in the final bread quality. Especially, if we consider the nutritional benefits due to the high potassium and fibre of the blends.

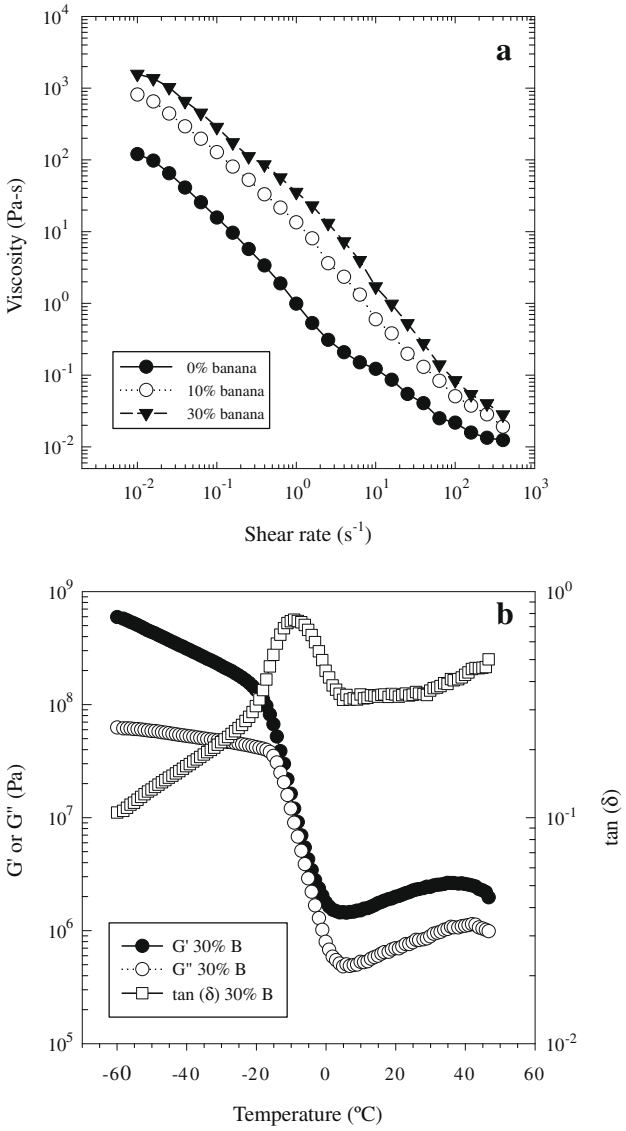

Fig. 3. (a) Non-linear steady shear viscosities for 20% suspensions of: control flour (●), 10% banana (○), and 30% banana (▼). (b) Dynamic mechanical analysis (DMA) profile of bread made from 30% banana blend G' (●), G'' (○), tan(δ) (□).

3.7. Dynamic mechanical analysis (DMA)

The storage moduli (G') obtained from DMA measurements of the bread made from the control flour and its various blends were fitted in the glass transitions model proposed by Peleg (1993, 1994). The model equation can be written as:

$$R(T) = 1/\{1 + \exp[(T - Tc)/a]\}$$

where $R(T)$ is stiffness ratio, T is temperature, Tc is temperature level which characterizes the transition region and is the inflection point of the stiffness, and a is indicator of the steepness of the curve of $R(T)$ vs. T (Fig. 3b). In our cases, $R(T)$ can be expressed as $R(T) = G'/G'$ (−30 °C). The fitting results are shown in Table 3, where all r^2 of the fitting results were above 0.71. The lower Tc value of the control bread relative to the blends signify slight shift of transition region to lower temperatures. The gradual drop in G' of the control might imply grater heterogeneity of the control compared to the blends. Overall, the variations in stiffness between the control and the blends were minimal according to the model fit, which indicated that the properties for these breads were similar around the glass transitions region.

Table 3
Storage moduli (G') obtained from DMA testing of control bread and blends.

Banana in bread (%)	*Tc* (°C)[A]	a (°C)[B]	r[B]
0	−13.1 ± 0.1	5.0 ± 0.1	0.85
30	−15.0 ± 0.2	4.4 ± 0.2	0.80
25	−15.9 ± 0.3	4.1 ± 0.3	0.71
20	−16.3 ± 0.3	4.0 ± 0.2	0.72
15	−17.3 ± 0.2	3.8 ± 0.1	0.80
10	−18.4 ± 0.1	3.3 ± 0.1	0.81

[A] *Tc* is the temperature level which characterizes the transition region and is the inflection point of the stiffness.
[B] a is indicator of the steepness of the curve of $R(T)$ vs. T; $R(T)$ is stiffness ratio; T is temperature.

4. Conclusions

Although it is considered specialty bread, by replacing up to 30% of the wheat flour, the final bread loaf volume was as good as or better than the control. The presence of BP increased the un-freezable water, which was reflected on the 50% reduction on bread staling as indicated by bread hardness. The rheological properties of the blends represented by Farinograph and the dynamic rheology showed that mechanical properties (Farinograph) are better predictor of the blends baking performance than dynamic rheology. This bread is a readily obtainable source for the daily recommended potassium intake per bread serving. This bread is also low in carbohydrates and higher in fibre relative to conventional bread.

Dry milling
Wet fractionation
Sonication

ABSTRACT

Field peas from two cultivars were dehulled and groats were processed by two protocols: (1) groats directly ground with water into a slurry and fractionated into fibre, protein and starch concentrates (groat wet fractionation, GWF), and (2) groats dry milled into flour and then wet fractionated using steps identical to that of protocol-1 (flour wet fractionation, FWF). The yield (%, w/w) and composition (%, w/w) of starch, protein and fibre concentrates from both protocols were determined. The data indicated that the FWF had significantly higher starch yield when compared to GWF. Scanning electron micrographs clearly suggested that better tissue fragmentation caused by dry milling may be responsible for better starch yield in FWF. The purity of starch isolate from FWF was lower than that of GWF. Brabender visco-amylographs showed differences in pasting properties of starches between protocols. Furthermore, the effect of sonication on starch yield and purity was studied between two wet fractionations. A combination of FWF with the sonication at 75% amplitude for 10 min showed better starch yield.

1. Introduction

Components of wet fractionated field pea grain offer advantages in food and non-food applications and livestock feed industries (De Graaf, Harmsen, Vereijken, & Monikes, 2001; Guillon & Champ, 2002; Hoover & Ratnayake, 2002; Otto, Baik, & Czuchajowska, 1997a; Ratnayake, Hoover, Shahidi, Perera, & Jane, 2001). Novel functional properties of purified starch, high nutritional value of protein and brighter color of dietary fibre from field pea are some of the positive attributes. Dry methods of fractionation tend to result in high starch damage and low purity starch concentrates (Czuchajowska & Pomeranz, 1994; Otto, Baik, & Czuchajowska, 1997b; Otto et al., 1997a). On the other hand, wet methods of starch fractionation are lengthy, laborious and costly. In addition, the wet fractionation process for legume starches has been problematic due to the presence of a highly hydrated fine fibre fraction and large amounts of insoluble flocculent protein (Reichert & Youngs, 1978; Schoch & Maywald, 1968).

During wet fractionation, fibre and protein components in the slurry decrease the starch sedimentation and co-settle with starch to produce undesirable brownish sediment. Low starch yield and purity may be due to inadequate breakage of cell wall and protein matrix structures, which prevents the separation of starch granules from fibre and protein. In the current commercial process for field pea fractionation, the grains are dehulled and then taken for wet milling prior to further fractionation. It is hypothesized that a front-end processing step that dry mills the groat into flour prior to wet milling would improve starch yield and purity.

Most wet fractionation studies on field peas have been carried out based on the original process developed by Schoch and Maywald (1968) for legumes. The initial slurry is typically prepared in alkaline solution. The use of alkaline chemicals (e.g. NaOH) is not well accepted by the food industry, since the necessary subsequent steps of alkali neutralization and salt removal are costly and time-consuming (Otto et al., 1997b; Sosulski, 1989). Whether the slurry is prepared from wet-milled groats or from flour affects the starch yield, recovery, purity and properties. A comparison of field pea groat wet fractionation (GWF) and flour/meal wet fractionation (FWF) in this regard has not been reported.

A simple quick fractionation technology was sought to maximize the yield and purity of starch isolated from field pea by optimising the type of wet fractionation method and sonication conditions. The objectives of this study were (1) to compare yield and chemical composition of the fractions obtained by GWF and FWF from selected field pea cultivars, (2) to compare the morphological and pasting characteristics of purified starch fractions isolated through GWF and FWF, and (3) to compare the effect of sonication on the starch yield and purity of field peas between GWF and FWF protocols.

2. Materials and methods

2.1. Materials

Field pea cultivars, CDC Mozart and Eclipse, were obtained from Crop Development Centre, University of Saskatchewan (Saskatoon, Canada). The fungal protease enzyme (Flavourzyme® 1000 L) was obtained from Novozymes North America, Inc. (Franklinton, NC, USA). Commercial field pea starch was provided by the Parrheim foods (Portage La Prairie, MB, Canada). Blending of groats was performed using a Waring blender −60 Hz (Dynamics Corp. of America, New Hartford, CT, USA), and stirring of flour was performed using a magnetic stir plate. The stainless steel sieve (75 μm openings) was from W.S. Tyler, St. Catharines, ON, Canada. The centrifugations were done using Beckman J2-21 high speed centrifuge (Beckman Instruments Inc., Palo Alto, CA, USA). Drying of samples were taken place in conventional oven (Fisher Isotemp® Oven, Model: 204, Pittsburgh, PA, USA) and freeze-drier (VirTis freeze dryer, Model: 50 SRC, Gardiner, NY, USA). Megazyme assay kits for the determination of total starch and starch damage were purchased from Megazyme International Ireland Ltd. (Wicklow, Ireland). All other chemicals and solvents were of ACS certified grade.

2.2. Sample preparation

Field pea seeds in 5 kg batches were dehulled in a "tangential abrasive dehuller" (manufactured by Engineering Services Branch, Alberta Agriculture and Food, Canada), that was equipped with

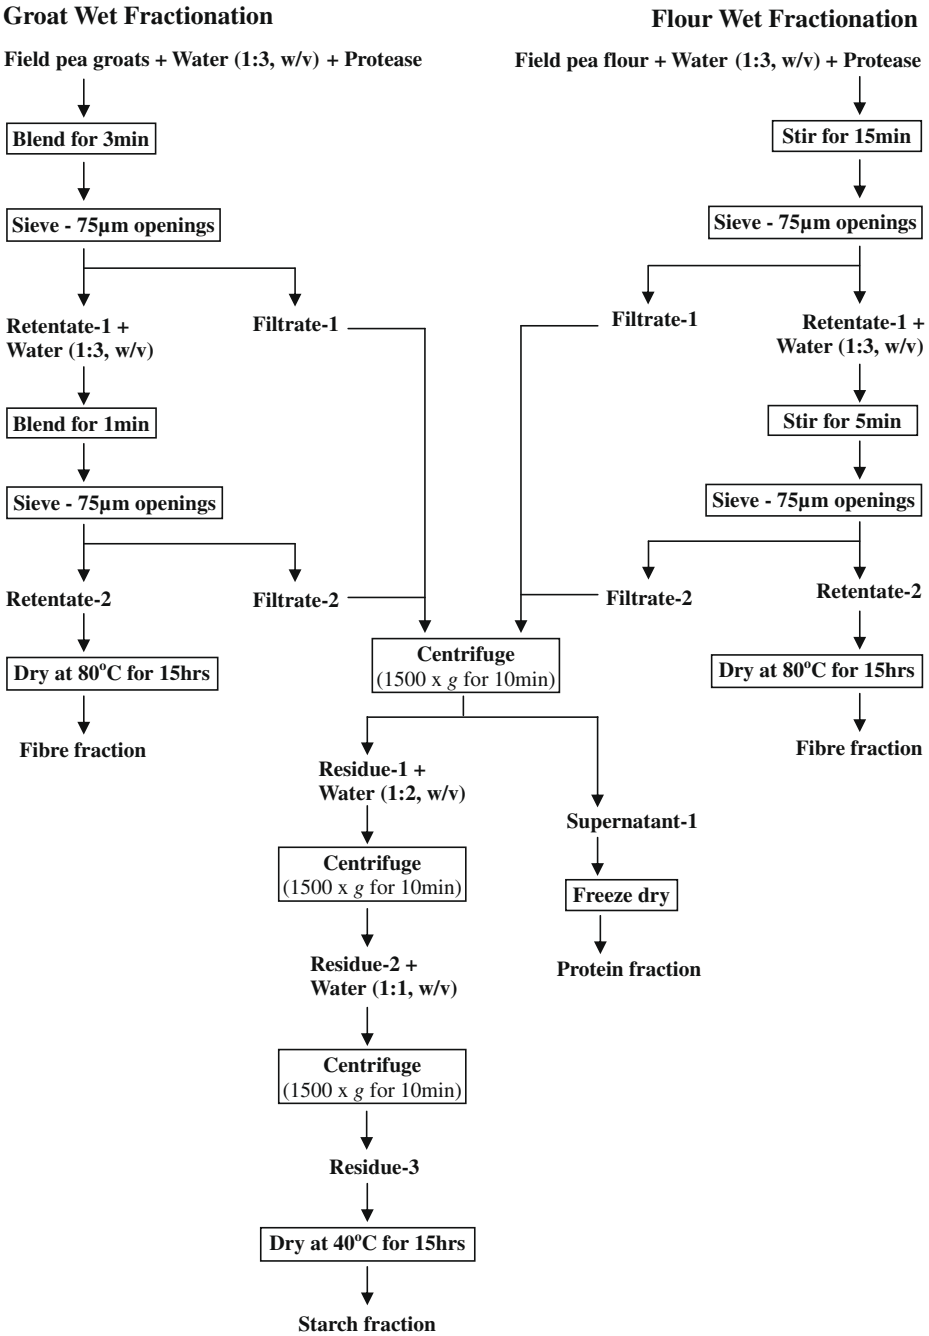

Fig. 1. Flow chart for the wet fractionations of field pea.

eight vertically oriented abrasive discs of 25 cm diameter operating at a speed of 60 Hz for 3 min. Then the dehulled grains were sifted through the Carter Day Aspirator Tester (Serial No: CD011721, Style No: COS3, Carter Day International, Inc., Minneapolis, MN, USA) at the airflow speed of 30% in order to separate the hulls from the cotyledons and the groats were collected separately for each cultivar. Field pea groats were dry milled using a lab scale cyclone sample mill (Udy Corp., Fort Collins, CO, USA) fitted with a sieve with 0.25 mm round openings. Both groats and flour from two cultivars of field pea were used in this study.

2.3. Addition of protease enzyme in wet fractionation

It is hypothesized that the addition of protease enzyme can effectively reduce the frothing during the wet fractionation process caused by its hydrolysing effect on protein. A simple experiment was conducted as wet grinding of field pea groats (100 g groats + 300 mL water) for 3 min with (1 mL) or without protease enzyme (Flavourzyme® 1000 L). Flavourzyme® 1000 L is a protease complex of both endo- and exo-protease, and it contains a concentration of aminopeptidase 15–20%. Its activity is 1.0 leucine aminopeptidase units (LAPU)/g. One LAPU is the amount of enzyme that hydrolyzes one micromole of leucine-p-nitroanilide per minute. After wet grinding of groats, with or without (control) protease enzyme, the slurry was quantitatively emptied into measuring cylinder and the volume of froth was measured in mL.

2.4. Wet fractionations

The procedure for wet fractionation of field pea groats (groat wet fractionation – GWF) and field pea flour (flour wet fractionation – FWF) is described in Fig. 1. Three replicate fractionations were done for each type of wet fractionation.

2.5. Application of sonication

Sonication treatment using a Sonic 300-Dismembrator (ARTEK Systems Corp., Farmingdale, NY, USA) was applied to the slurry of retentate-1 in both GWF and FWF (Fig. 1). The sonication amplitude was set at 60%, 75% or 90%, and the sonication duration was maintained for 10, 20 or 30 min. The temperature of the slurry during the sonication treatment was recorded. A standard wet fractionation process without sonication treatment as described in Section 2.4 (Fig. 1) was applied as a control for this experiment. Two replicated fractionations were done for each sonication treatment.

2.6. Granule morphology

Granule morphology of flour and starches was studied by scanning electron microscopy (SEM) following the procedure of Li, Vasanthan, Rossnagel, and Hoover (2001a).

2.7. Chemical composition

Moisture content was determined by the standard AACC (2004) procedure (method 44-15A). Protein content was measured by Leco® Carbon/Nitrogen determinator (TruSpec® CN, Leco Corporation St. Joseph, MI, USA). Ash content was quantified according to the AOAC (2000) procedure (method 923.03). Lipid was measured by the Goldfisch extraction method where petroleum ether was used to extract the lipid (AACC method 30.25, 2004). Total starch and damaged starch contents were estimated by the Megazyme assay procedures of AA/AMG 9/97 and SDA 11/01, respectively (Megazyme International Ireland Ltd., Wicklow, Ireland). Amylose content was determined according to the Standard Analytical Methods of the Member Companies of the Corn Refiners Association Inc., Washington, DC, USA.

2.8. Pasting properties of starch

Pasting characteristics (8% w/v, pH 5.5) of field pea starches were measured by Brabender viscometer (C.W. Brabender Instruments Inc., South Hackensack, NJ, USA) following the method of Li, Vasanthan, Rossnagel, and Hoover (2001b).

2.9. Statistical analysis

All experiments were carried out in a simple complete randomized design (CRD) at least with two replicates. One way Analysis of Variance (ANOVA) of the results was performed using General Linear Model (GLM) procedure of SAS® Statistical software, Version 9.1.2 (SAS® institute Inc., Cary, NC, 2004). The multiple comparison of the means was accomplished by Tukey (HSD) test at $\alpha = 0.05$ level. The means and standard deviations are reported.

3. Results and discussion

3.1. Composition of field pea

The chemical composition of flour from groats of two field pea cultivars, CDC Mozart and Eclipse, is summarized in Table 1. The

moisture, starch, protein, and ash contents of the pea flours were similar to values reported in the literature (Colonna, Gallant, & Mercier, 1980; Davydova, Leontev, Genin, Sasov, & Bogracheva, 1995; Otto et al., 1997b; Sosulski, Garratt, & Slinkard, 1976; Vose, Basterrechea, Gorin, Finlayson, & Youngs, 1976). Previous studies have shown a wide variation in field pea lipid and fibre contents; 0.7–4.7%, w/w (Gujska, Reinhard, & Khan, 1994; Otto et al., 1997b) and 1.1–27.6%, w/w (Otto et al., 1997b; Tian, Kyle, & Small, 1999), respectively. In the present study, the lipid content of field pea (0.80–0.99%, w/w) was on the lower side of the literature values.

3.2. Wet fractionation of field pea

Yield and composition of field pea flour and fractions are presented in Table 1. The fractionation method significantly affected the yields of starch, fibre and protein. FWF resulted in higher starch yield but lower fibre and protein yields than GWF. The yields of starch for GWF and FWF were in the range reported in the literature (30.0–44.0% (Hoover & Ratnayake, 2002; Schoch & Maywald, 1968) and 33.6–63.1% (Colonna et al., 1980; Otto et al., 1997b), respectively). The high starch yield from FWF might be attributed to the contamination of fine fibre (Chavan, Shahidi, Hoover, & Perera, 1999; Hoover & Ratnayake, 2002; Schoch & Maywald, 1968), however, the ash content was very low, which indicated minimal contamination by the high-ash containing fine fibre. Despite lower yield, the GWF process resulted in a starch fraction of slightly higher purity than the FWF protocol. Protein was the main contaminant in all starch fractions and constituted almost 1/3 of the original protein quantity present in the initial material. The lipid content of field pea starch isolate was within the range reported by other authors (Davydova et al., 1995; Hoover & Sosulski, 1991).

The composition of fibre and protein concentrates of FWF and GWF were significantly different. Compared to GWF, the fibre fraction of FWF had a lower starch and a higher protein content. Conversely, the protein concentrates of FWF had a higher starch and a lower protein content compared to GWF. Since both by-products of starch isolation are nutritionally good sources of fibre and protein, and have useful functional properties (Dalgetty & Baik, 2003; Guillon & Champ, 2002; Nunes, Raymundo, & Sousa, 2006; Sosulski & Sosulski, 1986; Vose, 1980; Wang, Bhirud, & Tyler, 1999), they could be formulated in human food and livestock feed preparation.

The total dry matter recovery (TDMR), starch separation efficiency (SSE) and protein separation efficiency (PSE) of field peas are presented in Table 2. TDMR is the total weight of the dry fractions (fibre, starch and protein) obtained through fractionation divided by the initial dry weight of the sample. The cultivar, but not the fractionation method, had a significant effect on TDMR. All TDMR values for wet fractionations were less than 100%, likely due to loss of dry matter in between processing steps. The starch

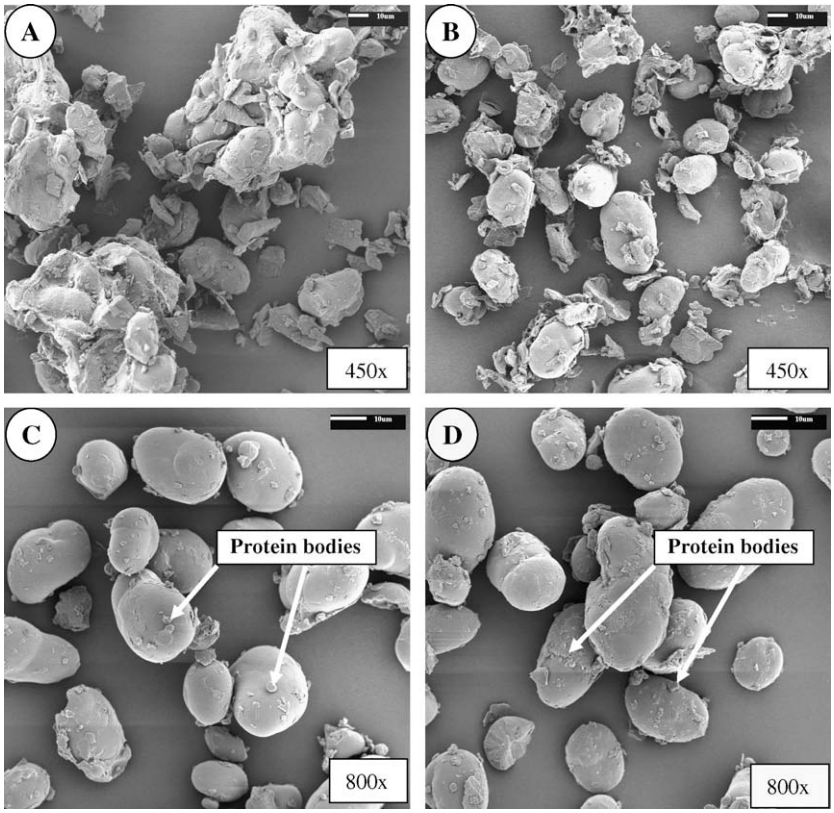

Fig. 2. Scanning electron micrographs (SEM) of flours and starches of field pea: (A) wet-milled flour, (B) dry milled flour, (C) starch isolated per groat wet fractionation (GWF), and (D) starch isolated per flour wet fractionation (FWF).

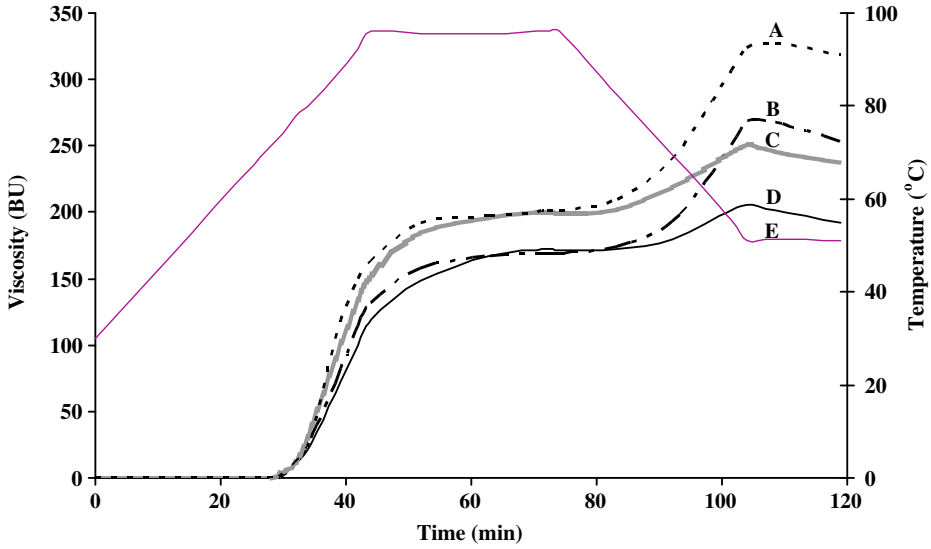

Fig. 3. Brabender viscoamylographs of field pea starches isolated by two different wet fractionation protocols: (A) Eclipse-FWF, (B) CDC Mozart-FWF, (C) Eclipse-GWF, (D) CDC Mozart-GWF, and (E) temperature (°C).

separation efficiency was higher for the FWF protocol, whereas the protein separation efficiency was higher for the GWF protocol. Sosulski (1989) previously reported separation efficiencies of starch and protein of 79.2% and 72.7%, respectively for filed pea.

To ensure efficient separation and purification, particle size distribution is crucial in a fractionation method. It was expected that dry milling prior to wet fractionation may cause the cell walls of cotyledon to disintegrate better and thereby free the embedded starch granules from the protein matrix more efficiently. Scanning electron micrographs (SEM) of flours clearly demonstrated the higher proportion of fragmented cotyledon cells with dry milling (Fig. 2B) as compared to that observed with wet milling (Fig. 2A). These observations present a reasonable explanation for higher starch yields obtained with FWF compared to GWF.

The major difficulties in purifying starch from legumes are the presence of a highly hydratable fine fibre fraction (cotyledon cell wall material) and a strong adherence of insoluble proteins to the starch granules (Schoch & Maywald, 1968). In addition, the protein causes significant frothing during grinding and screening operations that further complicates the wet fractionation process. It was observed in the present study that hydrolysing the protein with a fungal protease enzyme reduced frothing by 50–60%.

The main starch impurity was protein, which was present at levels higher than commercial field pea starch (0.55%) and literature values (0.25–0.44%, w/w) for both GWF and FWF (Otto et al., 1997b; Ratnayake et al., 2001). The scanning electron micrographs of starch isolate from GWF (Fig. 2C) and FWF (Fig. 2D), plainly show the adhered residual protein bodies on surfaces of starch granules. High residual protein content in starch fractions of the present study could be due to the following: (1) the absence of alkali use in the starch isolation, (2) brownish deposit from top of the starch layer after centrifugation was not removed, and (3) the conventional greater number of water washings was not used. However, the simple and gentle fractionation protocol used in the present study led to greatly reduced starch damage compared to other literature protocols (48%, w/w; Vose, 1977).

Due to high starch yield, dry milling of field pea groats followed by wet fractionation (FWF) used in this study was found to be more effective and efficient compared to wet grinding of groats only (GWF). In addition, the number of washings required to obtain a significant starch yield was reduced as compared to a flour wet fractionation method reported for field pea (Otto et al., 1997b).

3.3. Pasting characteristics of starches

The pasting characteristics of field pea starches are shown in Fig. 3. The four starches demonstrated a C-type amylograph pattern (low swelling and high hot paste stability) typical of most legume starches (Schoch & Maywald, 1968). The viscoamylographs showed restricted swelling and absence of peak viscosity, which is in agreement with previous studies on field pea starch (Gujska et al., 1994; Ratnayake et al., 2001; Schoch & Maywald, 1968). FWF starches had higher pasting temperatures and viscosities (notably high setback, and constant cold paste viscosity during agitation at 50 °C) compared to GWF. This effect may be due to shear effects of dry milling in the FWF procedure (Vose, 1977). In addition, the starch from cultivar Eclipse had higher viscosity than the starch from CDC Mozart in terms of corresponding wet processes. A number of intrinsic factors such as granule swelling, friction between swollen granules, amylose leaching, starch crystallinity, and amylopectin chain length may also play a role in increased viscosities observed in the present study (Ratnayake, Hoover, & Warkentin, 2002). A direct comparison between the present data and previous data is difficult, since different concentrations of starch were used in viscosity measurements.

3.4. Effect of sonication on starch yield and properties

Table 3 compares the yield, starch and protein contents of pea starch fractions for GWF and FWF methods under different sonication treatments. Sonication in GWF significantly increased starch yield by 5–8% (w/w) compared to the control, however, in FWF the starch yield was only improved by 2–3% (w/w). Higher starch yield in sonication-assisted GWF may be due to the disintegration of unfragmented cotyledon cells by ultrasound shear causing the release of more starch granules. In FWF, the cotyledon cells were already opened up by dry milling, thus no significant improvement on starch yield was expected or observed. The effect of sonication on starch yield is further supported by the SEM pictures of flour used for GWF and FWF methods (Fig. 2). It is evident in the SEM that the groat wet fractionation without sonication (control-GWF; Fig. 2A) showed presence of unfragmented cotyledon whereas control-FWF (Fig. 2B) showed highly disintegrated cotyledon structure with free starch granules.

[p] Data (mean of two replicates) followed by the same letters in the same column are not significantly different ($p < 0.05$) by Tukey test. All data reported on dry basis.
[q] Amplitude.
[r] GWF = groat wet fractionation.
[s] FWF = flour wet fractionation.

The sonication treatment in GWF significantly improved the purity of starch (Table 3). Sonication treatment of GWF caused a decrease in the protein content by 3.5–5.5% (w/w of original protein weight) and an increase in the starch content by 4–5% (w/w of original starch weight) compared to control-GWF (Table 3).

High-intensity ultrasound shear in the flour slurry creates uniform distribution of the flour particles (Wang & Wang, 2004) and disrupts the cell membranes causing the cotyledon cell wall to disintegrate and release more starch granules (Zhang, Niu, Eckhoff, & Feng, 2005). During sonication, the temperature of the slurry increased as the amplitude and time of sonication increased. At amplitude of 90% for 30 min during sonication, the temperature of the slurry was 54 °C. At this temperature, significantly higher starch yield was obtained in GWF, however higher temperatures negatively affect the physicochemical properties of starch. In order to avoid the pre-gelatinization of field pea starches, a temperature below 40 °C is considered safe. To optimize the effectiveness of the sonication but control temperature rise, the condition of 75% amplitude for 10 min was found to be best. At these conditions, and in combination with the FWF protocol, a maximum starch yield of 56.0–58.2% was obtained.

4. Conclusions

This study represents a new opportunity for future researchers to investigate and refine conditions that improve field pea starch purity. A simple wet fractionation method incorporating sonication and protease treatment was used to maximize yield and purity of field pea starch. Dry milling of field peas prior to wet fractionation, in combination with 10 min sonication treatment at 75% amplitude, was found to produce the highest starch yield of the studied conditions. However, initial direct wet milling of the groats resulted in starch of higher purity.

Acknowledgements

Financial support from the Natural Sciences and Engineering Research Council (NSERC) of Canada through a research grant to Dr. T. Vasanthan is gratefully acknowledged. The authors also thank Dr. T. Warkentin of the Crop Development Center, University of Saskatchewan, Saskatoon, Canada for providing field pea grains.

Physicochemical properties
Resistant starch

ABSTRACT

Starch from palmyrah (*Borassus flabellifer* L.) seed-shoot flour was isolated and its composition, morphology, structure and physicochemical properties were determined. The yield of starch was 38.4% on a whole flour basis. The shape of the granule ranged from round to elliptical. Bound lipid, total lipid, apparent amylose, total amylose and resistant starch contents were 0.03%, 0.04%, 30.9%, 32.7% and 32.2%, respectively. The X-ray pattern was of the A-type and relative crystallinity was 34.1%. Palmyrah starch exhibited a high proportion (31.8%) of short amylopectin chains (DP 6–12) and a low proportion (1.2%) of long amylopectin chains (DP > 36). Gelatinization temperatures were 73.1–82.0 °C and enthalpy of gelatinization was 13.6 J/g. Pasting temperature, viscosity breakdown and set-back were 76.5 °C, 147 and 74 BU, respectively. Palmyrah starch exhibited high granular swelling, and restricted amylose leaching. Susceptibility towards *in vitro* α-amylolysis and retrogradation was low. The results showed that physicochemical properties of palmyrah starch were largely influenced by strong interactions between amylose–amylose and/or amylose–amylopectin chains within the granule interior.

1. Introduction

Palmyrah (*Borassus flabellifer* L.) is a palm tree belonging to the family *Palmae* and the sub-family *Boracidae* (Jeyaratnam, 1986). The three most economically important species of *Borassus* are *Borassus aethiopum* Mart, *B. flabellifer* Linn, and *Borassus sundaicus* Becc. (Mohanadas, 2002). The species *B. flabellifer* L. is abundant in the arid tropics of South America, West Africa, India, Sri Lanka and Southeast Asia (Mohanadas, 2002; Morton, 1988). There are about 140 million palmyrah palms distributed worldwide with over 11 million in Sri Lanka (Mohanadas, 2002). Palmyrah provides a variety of edible and non-edible products. Foremost edibles of the palmyrah include the inflorescence sap, the sweet fruit pulp, the peeled seed-shoots (seedlings), and the kernel from both the very young and mature nuts (Barminas et al., 2008; Morton, 1988).

During germination of palmyrah seeds, the excess carbohydrate is stored in the form of starch in the scale leaf of the seedling (Fig. 1). The scale leaf becomes the edible part of the seedling (shoot) and is colloquially known as "palmyrah tuber" (Jeyaratnam, 1986). The palmyrah seed-shoot is high in starch and it is widely utilised in the preparation of starch based products such as porridge and soups (Sumudunie, Janz, Jayasekara, & Wickramasinghe, 2004).

Commercial production of palmyrah seed-shoot products in South America, West Africa, Southeast Asia, India and Sri Lanka is substantial and primarily for food purposes. The objective of this study was to fractionate the starch from palmyrah seed-shoot flour (*B. flabellifer*) and to compare its molecular structure, morphology, composition, and physicochemical properties with those of other palm (giginya [*B. aethiopum*], sago [*Metroxylon* spp.], oil palm [*Elaeis guineensis* Jacq.]) and wheat starches reported in the literature. An understanding of the structure–property relationships of palmyrah starch is important to form the basis for further investigations into physical and chemical modification to improve the use of palmyrah starch for food and industrial applications.

2. Materials and methods

2.1. Preparation of raw materials

Raw palmyrah seed-shoot flour was obtained from the local market of Northern Sri Lanka where the species *B. flabellifer* L. is grown abundantly. Representative samples were ground in a cyclone sample mill (Udy Corp., Fort Collins, CO, USA) fitted with a sieve with 0.25 mm round openings. Native wheat starch (MIDSOL 50) was obtained from Midwest Grain Products Inc., 1300 Main, Atchison, KS, USA.

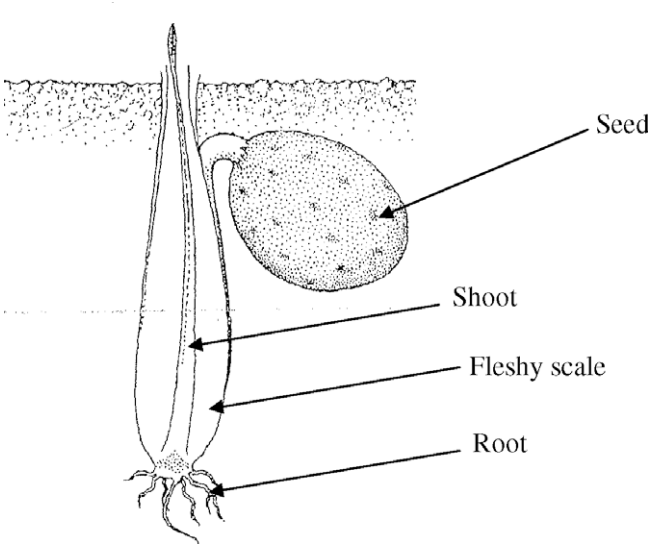

Fig. 1. Germinating palmyrah seed (adapted and modified from Arseculeratne, Panabokke, Tennekoon, & Bandunatha, 1971; Mason & Hendry, 1994).

2.2. Starch fractionation

Starch was fractionated from palmyrah seed-shoot flour according to the procedure outlined in Fig. 2. The palmyrah flour was stirred with water by means of a magnetic stirrer at medium speed. The resultant slurry was then screened using a stainless steel sieve (W.S. Tyler, St. Catharines, ON, Canada) and the filtrate-1 and retentate-1 were collected separately. The retentate-1 was mixed again with water and stirred. The filtrate (filtrate-2) was collected and retentate (retentate-2) was discarded after screening. The filtrate-1 and filterate-2 were combined together and centrifuged (Model J2-21 centrifuge, Beckman Instruments Inc., Palo Alto, CA, USA) with the conditions shown in Fig. 2. The supernatant-1 was discarded and the residual cake (residue-1) was mixed with water followed by stirred for 10 min at medium speed in a magnetic stirrer. The stirred slurry was then centrifuged with same centrifugal conditions. The supernatant-2 was decanted and residue-2 was mixed well with water and centrifuged as per previous conditions. Finally, the supernatant-3 was decanted and the residue-3 (starch cake) was quantitatively recovered and dried in a conventional oven (Fisher Isotemp® Oven, Model: 204, Pittsburgh, PA, USA) to obtain the starch fraction. Three replicated fractionations were done.

2.3. Chemical composition

Moisture content was determined by the standard AACC (2004) procedure (method 44-15A). Nitrogen was measured by Leco® Carbon/Nitrogen determinator (TruSpec® CN, Leco Corporation, St. Joseph, MI, USA). Ash content was measured according to the AOAC (2000) procedure (method 923.03). Starch lipids (free and bound) were determined by the procedures outlined in an earlier publication (Vasanthan & Hoover, 1992). Total starch, resistant starch and starch damage contents were estimated by the Megazyme assay procedures of AA/AMG 9/97, K-RSTAR 05/2008 and SDA 11/01, respectively (Megazyme International Ireland Ltd., Wicklow, Ireland). Apparent and total amylose concentrations were determined according to the Standard Analytical Methods of the Member Companies of the Corn Refiners Association Inc., Washington, DC, USA. Phosphorus content was determined by the method of Smith and Caruso (1964).

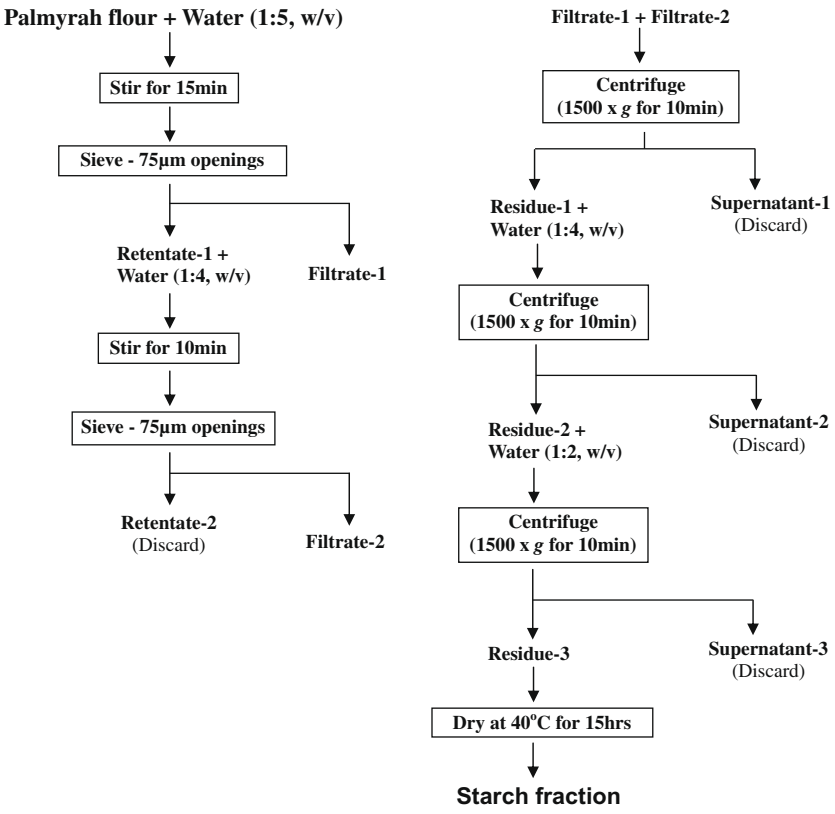

Fig. 2. Flow chart for wet fractionation of palmyrah flour.

2.4. Granule morphology and size estimation

Granule morphology of palmyrah starch was studied by scanning electron microscopy following the procedure of Li, Vasanthan, Rossnagel, and Hoover (2001a). The procedure outlined by Jayakody, Hoover, Liu, and Weber (2005) was used to measure the size and shape of starch granules using a Micromaster™ -Model CK (Japan) light microscope.

2.5. Molecular characterisation of amylopectin

The branch chain length distribution of isoamylase debranched amylopectin from debranched palmyrah starch was determined by high pressure anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD) following the procedure of Jayakody et al. (2005).

2.6. X-ray diffraction

Powder X-ray diffraction was carried out by the method outlined by Jayakody et al. (2007).

2.7. Swelling factor (SF) and amylose leaching (AML)

Swelling factor of palmyrah starch when heated in the temperature range from 40 to 90 °C in excess water was measured according to the method of Tester and Morrison (1990). The percent amylose leaching of native palmyrah starch when heated in the temperature range from 40 to 90 °C was determined following the procedure of Jayakody et al. (2005). The amylose content for AML was determined as the method referred in Section 2.3.

2.8. Differential scanning calorimetry (DSC)

Gelatinization parameters of palmyrah starch were examined by a Perkin–Elmer DSC-2 differential scanning calorimeter (Perkin–Elmer Ltd., Beaconsfield, UK) following the procedure outlined by Li, Vasanthan, Rossnagel, and Hoover (2001b). The thermograms were recorded with an empty aluminium pan as a reference.

2.9. Pasting properties of starch

Pasting characteristics (8% w/v, pH 5.5) of palmyrah starch was measured by Brabender viscometer (C.W. Brabender Instruments Inc., South Hackensack, NJ, USA) following the method of Li et al. (2001b).

2.10. Enzyme digestibility

Enzymatic digestibility studies on palmyrah and wheat starches were conducted following the procedure outlined by Jayakody et al. (2007) with some modifications. The following modifications were done in the later part of the procedure. Aliquots (5 mL) of reaction mixture were collected at 24-h intervals and immediately boiled in a water bath (95–98 °C) for 5 min to terminate the enzymatic reaction, and then immediately stored frozen at −18 °C until further analysis. The degree of hydrolysis or percent reducing value of all samples was determined using the method of Bruner (1964).

2.11. Retrogradation

The retrogradation characteristics of palmyrah starch were determined by turbidity measurements. Turbidity development during storage of palmyrah starch was measured according to the method of Craig, Maningat, Seib, and Hoseney (1989). Starch (50 mg) was suspended in water (5 mL) in screwcap tubes and placed in a boiling water bath for 30 min. The tubes were thoroughly shaken every 5 min. After cooling to room temperature (5 min), the percent transmittance (T%) at 650 nm was determined against a water blank in a Jenway 6300 spectrophotometer (Jenway Ltd., Essex, UK). The tubes containing the starch pastes were kept at 4 °C for a day and then at 40 °C for 12 days. T (%) was determined at 24-h intervals.

3. Results and discussion

3.1. Chemical composition of starch

Starch yield, composition, and granule morphology are presented in Table 1. The yield and purity of starch from palmyrah flour were 38.4% and 95.8%, respectively. Thus, the recovery of starch based on the flour (73.9% starch) is 49.8%. Starch yield from other palms and wheat have been shown to be in the range of 7.1–24.7% (Noor, Mohd, Islam, & Mehat, 1999; Barminas et al., 2008; Sun & Tomkinson, 2003) and 29.0% (Vansteelandt & Delcour, 1999), respectively. The protein content of palmyrah starch (2.5%) was higher than that reported for giginya (0.18%; Barminas et al., 2008), sago (0.1%; Swinkels, 1985), oil palm (0.9%; Noor et al., 1999) and wheat (0.25%; Vansteelandt & Delcour, 1999) starches. The higher protein content of palmyrah starch may be due to differences in starch isolation protocol or genetic differences. The phosphorus content (198 ppm) of palmyrah starch was higher than those reported for giginya (86 ppm; Barminas et al., 2008) and sago (110 ppm; Srichuwong, Sunarti, Mishima, Isono, & Hismatsu, 2005) starches. The total lipid content (0.04%) was slightly lower than those reported for giginya (0.09%; Barminas et al., 2008), sago (0.13%; Ahmad, Williams, Doublier, Durand, & Buleon, 1999), oil palm (0.30%; Noor et al., 1999) and wheat (0.70%; Hoover, Vasanthan, Senanayake, & Martin, 1994) starches. The total amylose content (32.7%) was higher than those reported for giginya (26.2%; Barminas et al., 2008), oil palm (19.5%; Noor

[h] [(Total amylose − apparent amylose)/total amylose] * 100.

et al., 1999), sago (24–31%; Ahmad et al., 1999) and wheat (27.3%; Hoover et al., 1994) starches.

The resistant starch (RS) content of palmyrah starch (32.2%) was much higher than the RS content (0.5–11.4%) of cereal and legume starches of nearly similar amylose content (Ranhotra, Gelroth, & Eisenbraun, 1991; Themeier, Hollmann, Neese, & Lindhauer, 2005). This suggests that the high RS content of palmyrah may be the result of strong interactions between amylose–amylose (AM–AM) and/or amylose–amylopectin (AM–AMP) chains within native starch granules. Crystallites resulting from the above interactions (especially those from AM–AM) could hinder the accessibility of glycosidic oxygens to hydrolytic enzymes. Thus, the RS of palmyrah starch could be categorised as RS2 according to the classification proposed by Englyst and Cummings (1987). There are no reports on the RS2 content of other palm starches. The RS2 content of palmyrah starch was higher than that of Hylon VII maize starch (23.0%), but lower than that in commercially available RS2 starches such as Hi-Maize 240 and Hi-Maize 260 in which the RS2 content is reported to be 42% and 60%, respectively (Champ, 2004). Starch damage during isolation of palmyrah starch was minimal (2.6%).

3.2. Morphological characteristics of starch granules

Microscopic examination showed that the starch granules of palmyrah had irregular shapes, which varied from round (5–16 μm; Fig. 3A) to oval and elliptical (shorter diameter, 8 μm; longer diameter, 32 μm; Fig. 3B). The granules were slightly smaller than oval granules of sago starch (20–40 μm; Ahmad et al., 1999), but slightly larger than granules of oil palm starch (3–25 μm; Noor et al., 1999). The granule surface of palmyrah starch appeared to be rough with indentations (Fig. 3B).

3.3. Amylopectin unit chain length distribution

The amylopectin glucan chains were classified into A (DP 6–12), B1 (DP 13–24), B2 (DP 25–36) and B3 (DP 37–50) on the basis of the number of glucose units per chain. The data are presented in Table 2A. The above distribution was similar to that reported for wheat starch (Sasaki & Matsuki, 1998) with respect to DP 13–24 and DP 25–36. However, the proportion of DP 6–12 (31.8%) and DP 37–50 (1.2%) of palmyrah starch amylopectin was different from that of wheat starch [DP 6–12 (24–25%), DP > 36 (15.9–18.1%); Sasaki & Matsuki, 1998]. There are no reports on the amylopectin chain length distribution of other palm starches.

3.4. X-ray diffraction and relative crystallinity

The X-ray diffraction pattern of palmyrah starch at 14% moisture is presented in Fig. 4A. The relative crystallinity (RC) was 34.1%. Sago palm starch, which has amylose content in the range

of 24–31%, exhibits a C-type X-ray pattern that is characteristic of starches with relatively high amylose content (Ahmad et al., 1999; Takeda, Takeda, Suzuki, & Hizukuri, 1989). Palmyrah starch, in spite of its higher amylose content (32.7%), exhibited the A-type X-ray pattern characteristic of cereal starches (Hizukuri, Kaneko, & Takeda, 1983; Zobel, 1988) and oil palm trunk starch (Noor et al., 1999). The difference in the X-ray spectra of palmyrah and sago is likely due to differences in their average amylopectin chain length ($\overline{CL}$ in DP), which was 16.5 for palmyrah, and 22.1 for sago (Takeda et al., 1989). Shorter chain lengths (DP < 19.7) are associated with A-type starches, whereas starches with chain lengths in the range 20.3–21.3 have been shown to exhibit A, B or C-type polymorphism (Hizukuri et al., 1983).

A low intensity peak characteristic of an amylose–lipid complex was evident in the X-ray spectrum (peak at $2\theta = 20^{\circ}$) of palmyrah starch (Hoover & Hadziyev, 1981). This was rather surprising, since the amount of lipid-complexed amylose chains in palmyrah starch was fairly low (5.6%). This finding suggests that the amylose–lipid complex in palmyrah starch is highly organised into a three dimensional crystalline structure.

3.5. Swelling factor (SF) and amylose leaching (AML)

The SF and AML of palmyrah starch heated in the temperature range 40–90 °C are presented in Fig. 4B. SF measures the amount of intragranular water, and has been shown to be influenced by: (1) amylopectin structure (Shi & Seib, 1992; Sasaki & Matsuki, 1998; Han & Hamaker, 2001; Patindol, Flowers, Kuo, Wang, & Gealy, 2006; Vandeputte, Vermeylen, Geeroms, & Delcour, 2003), (2) V-amylose–lipid complexes (Tester & Morrison, 1990), (3) amylose content (Morrison, Tester, Snape, Law, & Gidley, 1993), and (4) extent of interaction between amylose–amylose (AM–AM) and/or AM and amylopectin (AM–AMP) chains within the native granule (Hoover & Manuel, 1996). The SF increased gradually from 40 to 70 °C, increased sharply between 70 and 80 °C, and then tapered off again. At all temperatures, the SF of palmyrah starch was higher than that reported for wheat starch, although the trends were similar (Hoover & Vasanthan, 1994). A higher ratio of shorter (DP 6–12) to longer (DP > 36) amylopectin chains mean that the crystalline region would be more easily hydrated in palmyrah starch than in wheat starch. This finding together with the relatively low proportion of lipid-complexed amylose chains (5.6%, compared to 22.7% for wheat [Hoover & Vasanthan, 1994]) could explain the higher SF of palmyrah starch.

AML has been shown to be influenced by: (1) total amylose concentration, (2) extent of interaction between AM–AM and/or AM–AMP chains within the native granule, and (3) amount of lipid-complexed amylose chains (Hoover & Vasanthan, 1994). As shown in Fig. 4B, amylose leaching was detectable in palmyrah starch only at temperatures exceeding 60 °C. A rapid increase in AML occurred in the temperature range 70–85 °C, and then tapered off. A similar trend has been reported for giginya (Barminas et al., 2008) and wheat (Hoover & Vasanthan, 1994) starches. However, in giginya and wheat, AML begins at a lower temperature (~50 °C), and is more extensive than in palmyrah starch at the same temperature (Barminas et al., 2008; Hoover & Vasanthan, 1994). The small extent of leached amylose in palmyrah starch supports our earlier hypothesis that interactions between AM–AM and/or AM–AMP within the amorphous domains are much stronger than in wheat and other palm starches, and may contribute to the presence of resistant starch.

3.6. Gelatinization characteristics

Gelatinization characteristics of palmyrah starch are presented in Table 2B. At the same starch/water ratio and scanning speed,

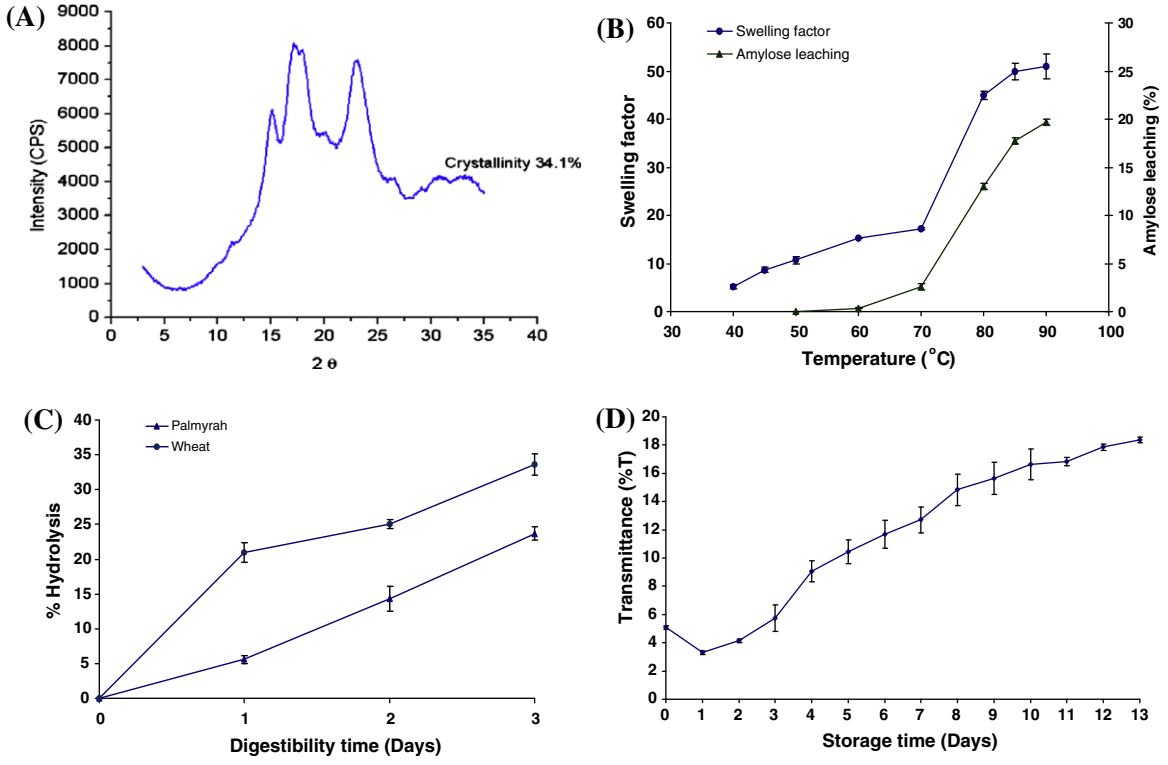

Fig. 4. Some physicochemical properties of palmyrah starch. (A) X-ray diffraction pattern of native palmyrah starch at 14% moisture; (B) swelling factor and amylose leaching of palmyrah starch at various temperatures; (C) time course of hydrolysis (%) of native palmyrah and wheat starches by porcine pancreatic α-amylase, (D) Retrogradation of palmyrah starch pastes monitored by determination of % transmission immediately after gelatinization (day 0), after storage at 4 °C (day 1) and during storage at 40 °C (days 2–13). Error bars represent standard deviations.

the gelatinization onset, peak, conclusion, range, and enthalpy of giginya starch are 61.1, 66.2, 74.2, 13.1 °C and 8.1 J/g, respectively (Barminas et al., 2008). The corresponding values for wheat starch are 57.0, 62.0, 67.0, 10 °C and 9.5 J/g, respectively (Hoover et al., 1994). The higher gelatinization temperatures and enthalpy, and the narrower gelatinization range of palmyrah starch reflect the melting of a crystalline structure of a higher stability and a lower degree of heterogeneity. The molecular architecture of the crystalline regions, which corresponds to the distribution of amylopectin short chains has been shown to have the greatest influence on gelatinization characteristics (Noda et al., 1998; Shi & Seib, 1992). The difference in the ratio of short chains (DP 6–12) to long chains (DP > 36) between palmyrah (27, Table 2A) and wheat (1.4, Sasaki & Matsuki, 1998) suggests that palmyrah starch should have exhibited lower gelatinization temperatures and enthalpy than wheat starch. The fact that palmyrah starch exhibits higher gelatinization temperatures and enthalpy (Table 2B) suggests strong interactions between AM–AM and/or AM–AMP chains (within the native granule) rather than amylopectin structure is the major factor influencing gelatinization transition parameters in palmyrah starch.

3.7. Pasting properties

Pasting properties of palmyrah starch are presented in Table 2C. Strong interactions between AM–AM and/or AM–AMP chains within the granule interior of palmyrah starch also influenced the pasting properties, as evidenced by the high pasting temperature (76.5 °C), low peak viscosity (275 BU), and low extent of viscosity breakdown (147 BU) during the holding cycle at 95 °C. The low set-back (74 BU) can be attributed to reduced amylose leaching, presence of granule fragments (due to a low breakdown viscosity) and a low proportion of long amylopectin chains (DP > 36).

3.8. α-Amylase hydrolysis

The susceptibility of palmyrah and wheat starches towards hydrolysis by α-amylase is presented in Fig. 4C. The hydrolysis data (wheat > palmyrah) suggests that stronger interactions between AM–AM and/or AM–AMP chains in palmyrah starch suggests negates the influence of bound lipid content (wheat > palmyrah), amylose content (palmyrah > wheat) and proportion of long (DP > 36) amylopectin chains (wheat > palmyrah) to α-amylase hydrolysis.

3.9. Retrogradation

Retrogradation occurs when the starch components in gelatinized starch reassociate in an ordered structure. In this study, retrogradation of palmyrah starch paste was determined by monitoring changes in light transmission during storage at 4 °C (day 1) and at 40 °C (days 2–13), as shown in Fig. 4D. The initial decrease in % T by 1.8% reflects an association between leached amylose chains. The extent of this decrease is more pronounced in wheat starch (2.7%), since AML during gelatinization is more extensive in wheat (Hoover & Vasanthan, 1994) than in palmyrah starch. Interactions involving leached starch chains have no significant impact on retrogradation in palmyrah starch because of the low degree of AML and weak interaction between amylopectin chains (due to a low proportion of long chains). The increase in % T after 24-h in palmyrah starch is likely a reflection of the disintegration of granule remnants.

4. Conclusions

This study revealed that the physicochemical properties of palmyrah starch are influenced to a large extent by strong interactions between starch chains within the amorphous domains of the granule. The high gelatinization temperature and thermal stability of palmyrah starch would make it potentially useful in products that are subjected to high temperature processing (canned foods, baby foods, sauces), whereas the low extent of retrogradation makes it suitable for use as a thickener in frozen foods. The high RS2 content may have important techno-functional benefits and physiological and/or health benefits.

Lignin
Cell wall polysaccharides

ABSTRACT

Loquat fruit were pretreated with 10 μM methyl jasmonate (MeJA) for 24 h at 20 °C, and then stored at 1 °C for 35 days to investigate the effect of MeJA treatment on cell wall modification in relation to chilling injury. Loquat fruit developed chilling injury, manifested as increased fruit firmness and internal browning, decreased extractable juice during storage. These chilling injury symptoms were significantly reduced by MeJA treatment. MeJA also markedly delayed the increases in lignin, alcohol insoluble residues, hemicellulose and cellulose. Meanwhile, the MeJA-treated fruit exhibited significantly lower activities of phenylalanine ammonia lyase, peroxidase, polyphenol oxidase and higher polygalacturonase activity than the control during storage. The levels of water- and CDTA-soluble pectins in MeJA-treated fruit were also significantly higher than that in the control. These results suggest that the reduction in chilling injury by MeJA may be due to inhibited lignin accumulation and enhanced cell wall polysaccharides solubilisation.

1. Introduction

Loquat (*Eriobotrya japonica* Lindl.) fruit is very perishable due to microbial decay and mechanical damage after harvest. Low temperature storage is an effective method to control pathogenic decay and preserve quality. However, chilling injury limits the storage period and shelf-life of red-fleshed loquat cultivars (Zheng, Li, & Xi, 2000). The major symptoms of chilling injury in loquat fruit are stuck peel, firm and juiceless texture (flesh leatheriness) and internal browning. These physiological disorders are the main problems when loquats are stored at low temperature. Thus, postharvest treatments that can alleviate chilling injury and extend shelf-life of loquat fruit are urgently needed.

Previous work has shown that the development of chilling injury in cold-stored loquat fruit is attributed to the abnormal changes in cell wall metabolism (Zheng et al., 2000). Cell walls are essentially composed of three complex interpenetrated macromolecular networks: cellulose–hemicellulose, pectin and lignin (Boudet, Kajita, Grima-Pettenati, & Goffner, 2003; Carpita & Gibeaut, 1993). Pectin-rich cell wall interfaces (middle lamella and cellular junctions) are thought to play a key role in cell–cell adhesion and tissue cohesion whilst the cellulose–hemicellulose network is thought to largely contribute to rigidity (Jarvis, Briggs, & Knox, 2003; Whitney, Gothard, Mitchell, & Gidley, 1999). From a functional point of view, lignin supports and strengthens the cell wall, prevents degradation of cell wall polysaccharides and facilitates water transport (Lewis & Yamamoto, 1990). Though a lot of work has been done on process and regulation of cell wall metabolism during fruit softening (Vicente, Saladie, Rose, & Labavitch, 2007), the mechanism of cell wall changes induced by chilling in loquat fruit has not been clarified, except for the association with lignin synthesis (Shan et al., 2008).

Evidence suggests that methyl jasmonate (MeJA), as a natural plant regulator, plays an important role in plant growth and development, fruit ripening and responses to environmental stresses (Creelman & Mullet, 1997). When exogenously applied, MeJA has been shown to result in an improved chilling tolerance and reduced incidence of chilling injury in several horticultural crops (González-Aguilar, Tizuado-Hernándoz, & Wang, 2006). Since MeJA treatment is easy to set up and inexpensive, it could be a useful technique to maintain quality in postharvest storage. In our previous studies, we found that MeJA treatment at 10 μM was effective in alleviating chilling injury of cold-stored loquat fruit (Cao et al., 2007) and the reduction in chilling injury by MeJA might be due to enhanced antioxidant enzyme activity and a higher unsaturated/saturated fatty acid ratio (Cao, Zheng, Wang, Jin, & Rui, 2009). However, little information is known about the effect of MeJA treatment as a factor that affects cell wall modification in loquat fruit during cold storage. The objective of the study was to investigate whether the MeJA-induced modification in cell wall metabolism is linked to the reduced chilling injury in cold-stored loquat fruit.

2. Materials and methods

2.1. Plant material and treatments

The plant material and treatments were the same as described in our previous study (Cao et al., 2009). Fruit samples were taken after MeJA treatment (time 0) and at 7-day intervals during storage for measurements of fruit firmness, extractable juice, internal browning, lignin content, cell wall polysaccharide composition and the activities of phenylalanine ammonia lyase (PAL, EC 4.3.1.5), peroxidase (POD, EC 1.11.1.7), polyphenol oxidase (PPO, EC 1.14.18.1), polygalacturonase (PG, EC 3.2.1.15) and pectin methyl esterase (PME, EC 3.1.1.11).

2.2. Determinations of fruit firmness, extractable juice and internal browning index

Fruit firmness was measured on two paired sides of 10 fruit from each replicate (skin removed) with a TA-XT2i texture analyser (Stable Micro System Ltd., UK) with a 5 mm diameter probe at a speed of 1 mm s^{-1}.

Extractable juice was estimated from the weight loss from placental tissue plugs in response to low-speed centrifugation. Four plugs (7 mm wide and 10 mm thick) were placed over sterile cotton in a 50 ml centrifuge tube and centrifuged for 10 min at 1700*g* at room temperature. The results are expressed as% fresh weight loss of the tissue plugs after centrifugation.

The internal browning (IB) index, manifested as browning discoloration near the core was evaluated visually using 10 fruit from each replicate after cutting the fruit longitudinally in half. For each fruit, IB was scored according to a 5-grade scale, where 0 = none; 1 = slight; 2 = moderate; 3 = moderately severe; 4 = severe. Results were expressed as an IB index calculated using the following formula: IB index (between 0 and 4) = [$\sum$(IB level) $\times$ (number of fruit at the IB level)]/(Total number of fruit in the treatment).

2.3. Enzyme assays

To measure the enzymes activity, ten fruit from each treatment replicate were peeled, cut into small pieces and the bulked fruit samples (from the ten fruit) were frozen in liquid nitrogen and stored at −20 °C until analysis. All extract procedures were conducted at 4 °C. PAL was extracted with 0.2 M sodium borate buffer at pH 8.7 containing 20 mM of β-mercaptoethanol. For PPO, 1 g of flesh tissue was ground with 5 ml of 0.2 M sodium phosphate buffer (pH 6.5) containing 1% polyvinylpyrrolidone (PVP), or with 50 mM sodium borate buffer at pH 8.7 for POD. For PME and PG, 1 g of flesh tissue was ground with 5 ml of 0.15 M NaCl, containing 1% PVP. The extracts were then homogenised and centrifuged at 10,000*g* for 20 min at 4 °C. The supernatants were used for the enzyme assays.

PAL was assayed by the method described by Zucker (1968). One unit of PAL activity was defined as the amount of enzyme that causes the increase in absorbance of 0.01 at 290 nm in one hour under the specified conditions.

PPO activity was assayed following the method of Murr and Morris (1974). One unit of PPO activity was defined as the amount of enzyme that causes the increase in absorbance of 0.01 at 410 nm in one minute under the specified conditions.

POD activity was assayed using guaiacol as a donor and H_2O_2 as a substrate according to the method of Kochba, Lavee, and Spiege (1977). One unit of POD activity was defined as an increase of 0.01 in absorbance per minute at 460 nm under the assay conditions.

PG activity was determined according to Zhou, Dong, Ben-Arie, and Lurie (2000a) and one unit of activity was defined as 1 μmol galacturonic acid released per mg of protein per hour.

PME activity was determined according to Zhou et al., 2000b and one unit of activity was calculated as 1 mM NaOH consumed per mg of protein per hour.

Protein content in the enzyme extracts was estimated using the Bradford method, using bovine serum albumin as a standard (1976). Specific activity of the enzymes was expressed as units per mg of protein.

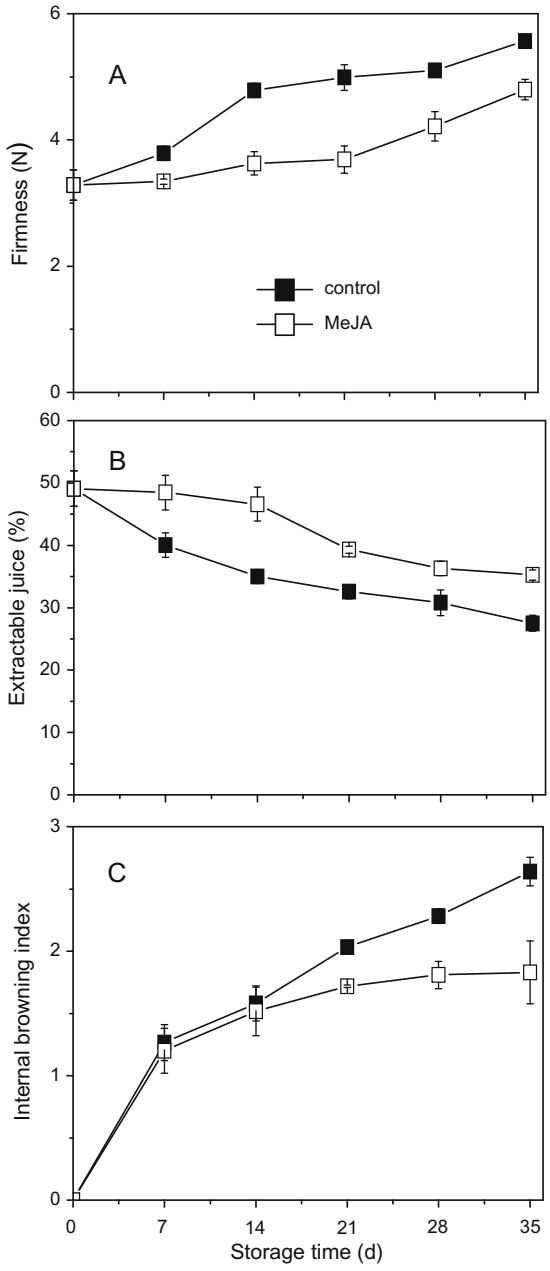

Fig. 1. Effects of MeJA on fruit firmness (A), extractable juice (B) and internal browning index (C) of loquat fruit during storage at 1 °C. Values for firmness and internal browning are the means ± SE of triplicate samples of ten fruit each. Values for extractable juice are the means ± SE of triplicate assays. Vertical bars represent the standard errors of the means.

2.4. Measurements of lignin content

The same frozen samples as used for the enzyme assays were used for lignin analysis. Lignin was gravimetrically determined according the method described previously (Cao et al., 2008). The result was expressed as a percentage.

2.5. Extraction and analysis for cell wall polysaccharides

The same frozen samples as used for the enzyme analysis were used for the extraction of alcohol insoluble residues (AIR). The AIR was prepared by homogenising 20 g of frozen tissues in 80 ml of cold 95% alcohol over ice for 3 min, which was then boiled for 25 min. The AIR was filtered under vacuum through glass fibre filters (GF/C, Whatman) and washed with 100 ml of 95% ethanol. The AIR was transferred to 100 ml of chloroform–methanol (1:1, v/v) and stirred for 30 min at room temperature. The AIR was filtered under vacuum through glass fibre filters (GF/C, Whatman) and washed with 100 ml of 100% acetone. The AIR samples were dried in an oven at 40 °C for 5 h and weighed. Results were expressed as 100 mg g^{-1} fresh weight (FW).

Then, the AIR (50 mg) was fractionated using the methods described previously (Deng, Wu, & Li, 2005). The uronic acid content in the water, CDTA and Na_2CO_3 fractions were determined by the m-hydroxydiphenyl method (Blumenkrantz & Asboe-Hansen, 1973). Galacturonic acid (Fluka) was used as the standard. Results were expressed as mg of galacturonic acid per 100 mg of AIR. The cellulose and hemicelluloses contents were quantified using a phenol–sulphuric acid method (Dubois, Gilles, Hamilton, Rebers, & Smith, 1956). Glucose was used as the standard for these assays. Results were expressed as mg of glucose per 100 mg of AIR.

2.6. Data analysis

Experiments were performed using a completely randomised design. All statistical analyses were performed with SPSS (SPSS Inc., Chicago, IL, USA). The data were analysed by one-way analysis of variance (ANOVA). Mean separations were performed by Duncan's multiple range tests. Differences at $p < 0.05$ were considered as significant.

3. Results

3.1. Effect of MeJA treatment on chilling injury

The major symptoms of chilling injury in loquat fruit are stuck peel, firm and juiceless texture and internal browning. Therefore, fruit firmness, internal browning and extractable juice were used to evaluate the development of chilling injury of loquat fruit in this work. Fruit firmness increased with increased storage time (Fig. 1A). The increase in firmness was significantly inhibited by MeJA treatment. Firmness of MeJA treated fruit was 14.1% lower than that of the control after 35 days of storage. There was also a positive effect of MeJA on extractable juice where the loss of juice was significantly ($p < 0.05$) inhibited by MeJA treatment (Fig. 1B). The internal browning index of loquat fruit increased gradually

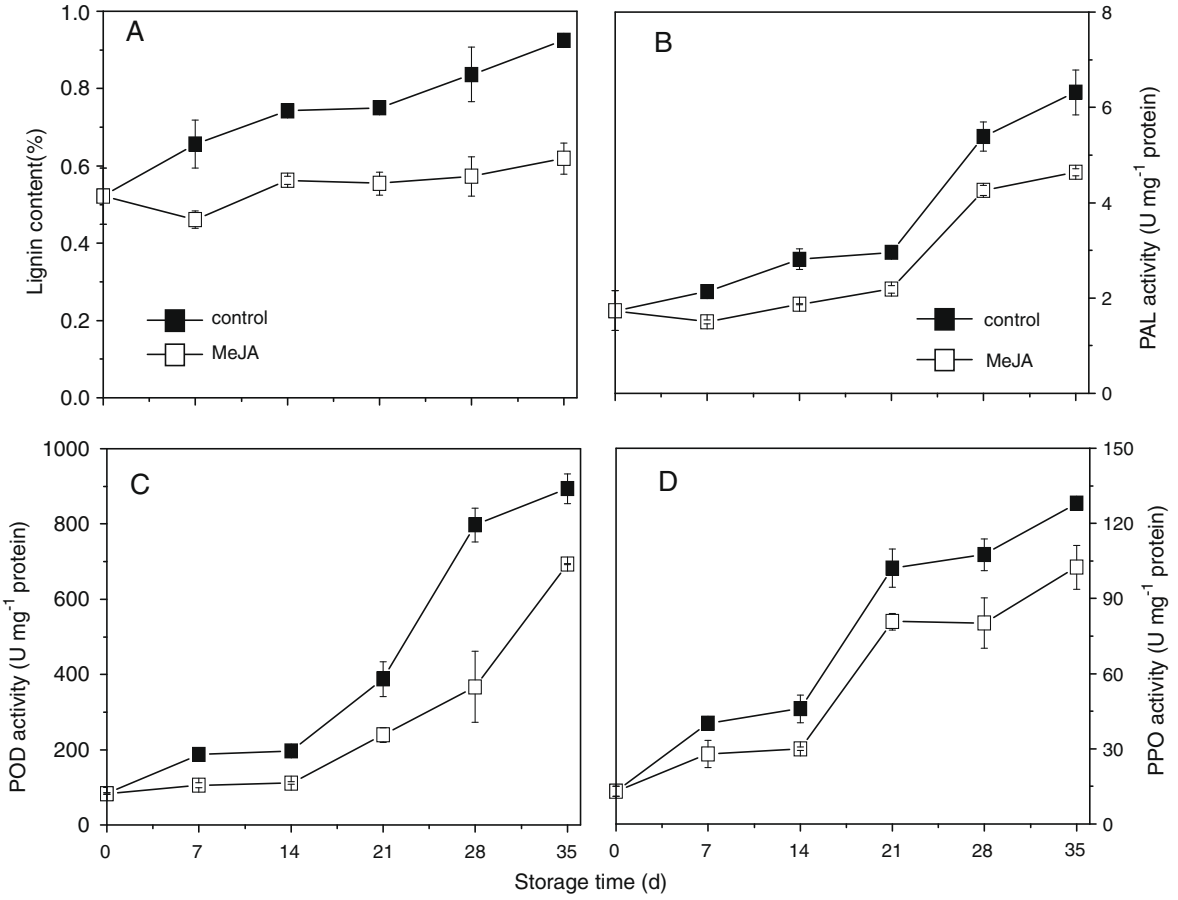

Fig. 2. Effect of MeJA on lignin content (A) and activities of PAL (B), POD (C) and PPO (D) in loquat fruit during storage at 1 °C. Values are the means ± SE of triplicate assays. Vertical bars represent the standard errors of the means.

with storage time but treatment with MeJA significantly ($p < 0.05$) inhibited the increase after 14 days of cold storage (Fig. 1C). The internal browning index increased to 264% and 183% of the initial values, respectively, in the control and the MeJA-treated fruit after 35 days of storage. The control fruit showed severe flesh leatheriness and a higher internal browning index after 21 days of storage at 1 °C. Treatment with MeJA delayed the increase in fruit firmness, internal browning index, and maintained higher levels of extractable juice, thereby delaying the development of flesh leatheriness and maintaining fruit quality.

3.2. Effect of MeJA treatment on lignin content and PAL, POD and PPO activities

The level of lignin increased steadily during the whole storage time. The lignin content in the control fruit was 76.9% higher than

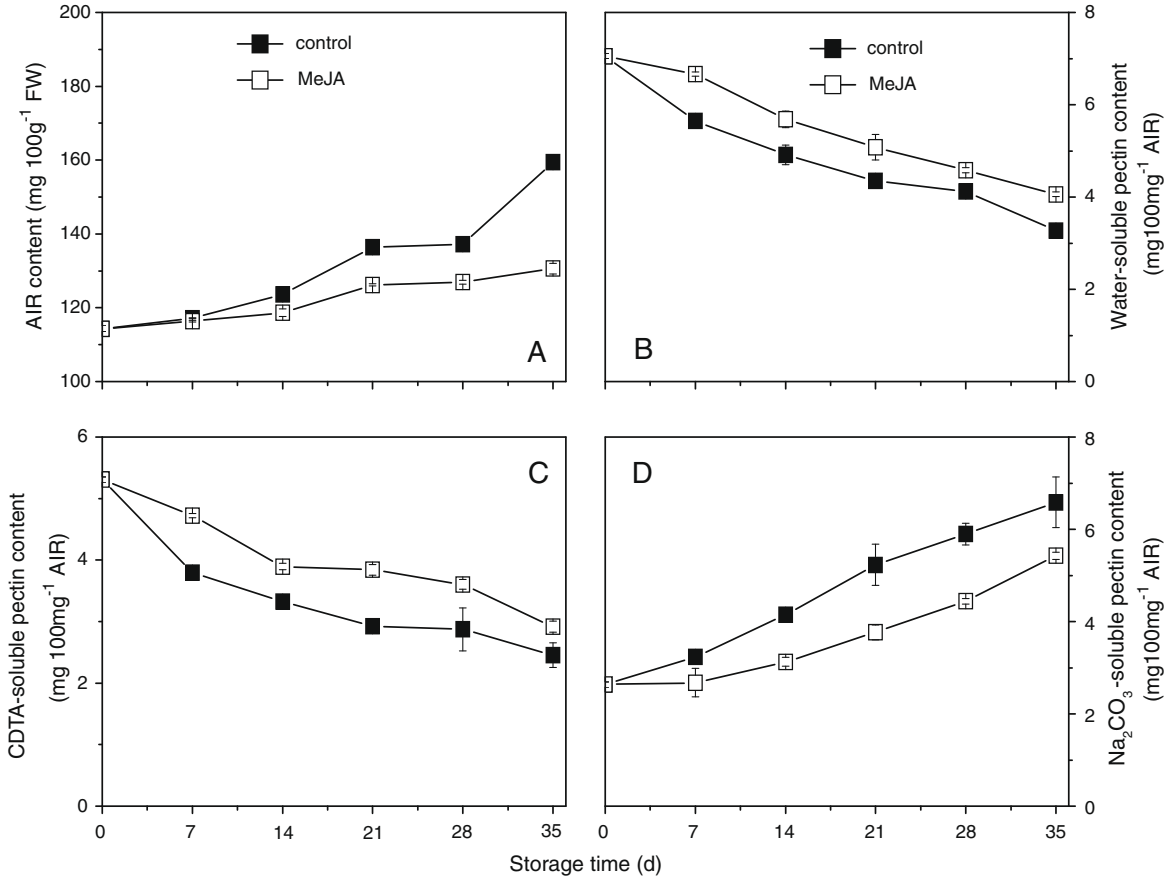

Fig. 3. Effect of MeJA on the contents of AIR (A), Water-(B), CDTA-(C) and Na_2CO_3-soluble pectins (D) in loquat fruit during cold storage at 1 °C. Values are the means ± SE of triplicate assays. Vertical bars represent the standard errors of the means.

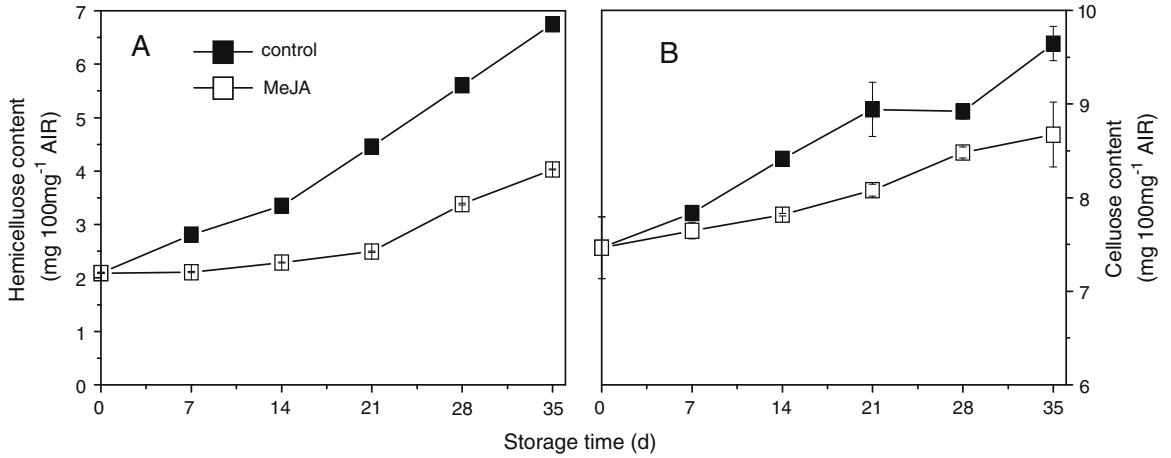

Fig. 4. Effect of MeJA on the contents of hemicelluose (A) and cellulose (B) in loquat fruit during cold storage at 1 °C. Values are the means ± SE of triplicate assays. Vertical bars represent the standard errors of the means.

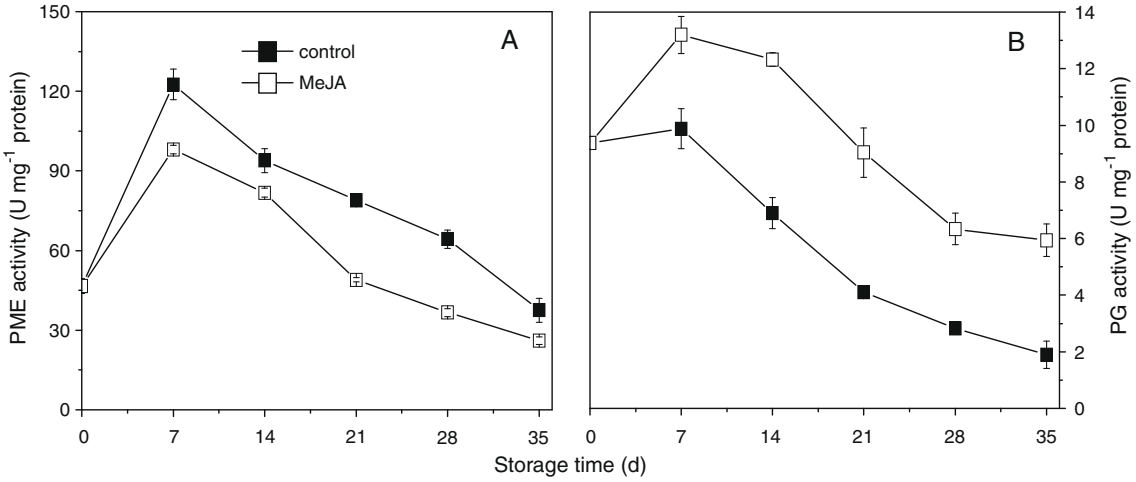

Fig. 5. Effect of MeJA on PME (A) and PG (B) activity in loquat fruit during storage at 1 °C. Values are the means ± SE of triplicate assays. Vertical bars represent the standard errors of the means.

the level at harvest. MeJA significantly ($p < 0.05$) inhibited the accumulation of lignin and after 35 days of storage the content was only 17.3% higher than the level at harvest (Fig. 2A). Activities of PAL, POD and PPO in loquat fruit increased with storage time (Fig. 2B–D). MeJA treatment significantly ($p < 0.05$) inhibited the increase in activities of these three enzymes. At the end of storage, the activities of PAL, POD and PPO in MeJA treated fruit were 26.7%, 22.3% and 20.3%, respectively, lower than that in control after storage for 35 days.

3.3. Effect of MeJA treatment on the AIR, and the water-, CDTA-, and Na_2CO_3-soluble pectins in loquat fruit

There was an increase in the AIR level over 35 days of storage (Fig. 3A). MeJA treatment significantly ($p < 0.05$) inhibited the increase of the AIR content. The AIR content in the control fruit was 39.5% higher than the level at harvest, whilst in the treated fruit it was only 14.0% higher than the amount of AIR at harvest. The levels of H_2O- and CDTA-soluble pectins decreased, whilst the Na_2CO_3 -soluble pectin level increased during storage (Fig. 3B–D) but, treatment with MeJA resulted in a significantly ($p < 0.05$) higher retention of H_2O- and CDTA-soluble pectins and a lower level of Na_2CO_3 -soluble pectin.

3.4. Effect of MeJA on contents of hemicelluose and cellulose in loquat fruit

The cell wall constituent hemicellulose and cellulose, in both the treated and the control fruit, increased progressively with storage time, however, their levels were significantly ($p < 0.05$) lower in MeJA-treated fruit. As shown in Fig. 4, the contents of hemicellulose and cellulose were, respectively, 40.2% and 10.4% lower than that in the control fruit on the 35th day.

3.5. Effect of MeJA treatment on PME and PG activities

The activity of PME increased sharply whilst that of PG increased slightly during the initial 7 days of storage, thereafter the activities of both enzymes decreased during storage. PG activity was significantly ($p < 0.05$) higher in MeJA-treated fruit than in the control fruit, whilst treatment with MeJA enhanced the decline of PME activity (Fig. 5), thus resulting in a significantly ($p < 0.05$) higher PG/PME ratio.

4. Discussion

It has been reported that lignin contributes to the development of chilling injury in cold-stored loquat fruit and its accumulation confers high rigidity and compression resistance to the cell wall (Zheng et al., 2000). Lignin synthesis is the result of coordinated action of many related enzymes including PAL, POD and PPO. PAL is a key enzyme that catalyses the conversion of phenylalanine to *trans*-cinnamic acid in the phenylpropanoid pathway, which is the first step in the biosynthesis of lignin in plants. POD catalyses the polymerisation of monolignol to form lignin. In addition, PPO can use as substrates those phenolic compounds which are precursors of lignin synthesis (Boudet et al., 2003). Therefore, the involvement of lignin synthesis in chilling injury and its related enzymes were analysed in this study. We observed an accumulation of lignin in response to low temperature after relatively long storage periods. It was also observed that MeJA treatment modified the time course of this response and reduced the magnitude of this particular response. Additionally, in all cases of lignin accumulation, increased activities of PAL, POD and PPO were detected. The activation of these three enzymes in loquat fruit has been reported in response to chilling stress (Shan et al., 2008). Treatments such as acetylsalicylic acid and 1-methylcyclopropene that reduced chilling injury have been shown to decrease the activities of PAL, POD and PPO (Cai, Li, & Chen, 2005; Cai et al., 2006). In the present study, treatment with MeJA significantly ($p < 0.05$) reduced chilling injury (Fig. 1) and decreased the activities of PAL, POD and PPO under low temperature stress (Fig. 2). These results suggest that the effect of MeJA in reducing the development of chilling injury was correlated to inhibited activities of enzymes involved in lignin synthesis. Moreover, PPO has been shown to be responsible for browning reactions during postharvest handling, storage and processing of fruits and vegetables. POD may participate in the oxidation and accumulation of phenolic materials and result in browning. The PAL activity can reflect the amount of the phenolic substrate. Hence, all of the three enzymes can also be involved in tissue browning (Peiser, Lopez-Galvez, Cantwell, & Saltveit, 1998), one of the symptoms of chilling injury in many fruits. In this study, loquat fruit had increasing PAL, POD and PPO activities, corresponding with an increase in the internal browning index during cold storage. MeJA treatment significantly inhibited the activities of the three enzymes, thus resulting in inhibition of the browning reaction and a lower internal browning index in loquat fruit.

Softening-associated changes in cell wall polysaccharides have been extensively documented in apple, carambola, mango and many tropical fruits (Vicente et al., 2007). Less attention has been paid to the changes in pectin, hemicellulose and cellulose content of loquat fruit during the development of chilling injury. In this study, we examined the possible role that cell wall polysaccharides might play in response to MeJA treatment under chilling stress. The AIR content accumulated during cold storage (Fig. 3A), and this increase was possibly related to higher firmness in cold-stored fruit as compared with freshly harvested fruit (Fig. 1A). As compared to untreated fruit, the significantly ($p < 0.05$) lower content of AIR in MeJA-treated fruit was an indicator of a higher degree of pectic polymers solubilisation. However, a previous study has shown that concomitant with the cell wall degradation in peach fruit, synthesis of cell walls also happened simultaneously during chilling injury development (Mao & Zhang, 2001). Therefore, cell wall synthesis might also be used to explain the accumulation of AIR in loquat fruit during cold storage and the chilling injury alleviation by MeJA might be partly attributed to inhibition of the synthesis.

In order to reveal the relationship between the cell wall polysaccharides and chilling injury in loquat fruit clearly, the AIRs obtained were further fractionated by sequential extraction with three pectic fractions, hemicellulose and cellulose. Typically, during fruit sofening, depolymerisation of cell wall polysaccharides was accompanied by increases in the levels of water- and chelator-soluble pectins, whilst the levels of Na_2CO_3-soluble pectin, hemicellulose and cellulose decreased (Chin, Ali, & Lazan, 1999; Redgwell, Melton, & Brasch, 1992). However, in loquat, we observed that the development of irreversible chilling injury symptoms, e.g., flesh leatheriness, was accompanied by decreased levels of water- and CDTA-soluble pectins and increased contents of Na_2CO_3-soluble pectin, hemicellulose and cellulose in the control fruit, whilst MeJA treatment maintained significantly ($p < 0.05$) higher contents of the first two pectins and lower contents of the latter three substances (Fig. 3B–D, Fig. 4). Our data presented here indicate that the chilling injury of loquat fruit might result from an increase in the cell wall stability by reducing the ability of enzymes to break down the bonds that hold the cell wall structure together, or by interacting with pectic polymers, hemicellulose and cellulose components. Loquat fruit treated with MeJA remained less firm, coinciding with higher retention of water- and CDTA-pectins and lower levels of hemicelluloses and cellulose.

The occurrence of chilling injury in loquat fruit during cold storage has been found to be associated with the imbalance of PG and PME activities (Zheng et al., 2000), which could lead to an excess of the de-esterified pectin matrix without subsequent depolymerisation (Zhou et al., 2000a). Our results indicated that the low PG activity, and the low PG/PME ratio in the control loquat fruit could induce the loss of juiciness and development of chilling injury. However, PG activity and the PG/PME ratio in MeJA-treated fruit was significantly ($p < 0.05$) higher than those in control, which was correlated with the higher levels of water- and CDTA-soluble pectins and lower incidence of chilling injury. Our results were consistent with the previous study in peach fruit (Feng et al., 2003), in which flesh leatheriness, one of the major symptoms of chilling injury in peach, was found to be a result of inhibited PME and PG activities during low temperature storage, whilst treatment with MeJA maintained significantly higher PME and PG activities, thereby preventing the development of chilling injury.

In conclusion, our data suggest that the role of MeJA treatment in reducing the incidence of chilling injury of loquat fruit appears to be mainly related to its ability to inhibit lignin accumulation and enhance the solubilisation of cell wall polysaccharides.

ABSTRACT

The aggregation state of (*E*)-resveratrol was studied in the presence and absence of hydroxypropyl-β-cyclodextrin (HP-β-CD) using absorption and steady-state fluorescence at different pH values. The results revealed that this potent antioxidant shows a monomer/aggregate equilibrium which is dependent on the protonation state of (*E*)-resveratrol. This equilibrium can be modified by the presence of HP-β-CD, which reduces the aggregation of the (*E*)-resveratrol molecules, producing individual molecules of the solute and preventing side effects due to aggregation phenomena. At pH values higher than the pK_{a1} of (*E*)-resveratrol, the coexistence of different protonated/deprotonated forms of this antioxidant does not permit the fluorimetric determination of the complexation constant (K_F) of (*E*)-resveratrol with HP-β-CD. However, when the Hildebrand–Benesi equation was used to calculate this constant at physiological pH, this problem was resolved, with a K_F value of 14490 ± 723 M^{-1} and the stoichiometry of the complexation process 1:1 for all the cases tested. The results obtained in this paper resolve the contradictory data published about the complexation process of (*E*)-resveratrol by cyclodextrins.

1. Introduction

Interest in the potential health benefits associated with the dietary consumption of (*E*)-resveratrol (3,5,4′-trihydrostilbene) has increased significantly in the past decade. Resveratrol is a member of the stilbene family, a group of compounds consisting of two aromatic rings joined by a methylene bridge, and can be found in several foods (Counet, Callemien, & Collin, 2006; Ragab, Van Fleet, Jankowski, Park, & Bobzin, 2006; Wang, Catana, Yang, Roderick, & van Breemen, 2002). The increased consumption of monomeric (*E*)-resveratrol and/or (*E*)-resveratrol-containing foods may be associated with improved health. These health benefits are related to a diverse range of biological activities such as anticancer, cardioprotection, antioxidant, antiviral, cytogenetic, oestrogenic and anti-inflamatory activities and the inhibition of platelet aggregation (Fang et al., 2002; Latruffe et al., 2002; Matsuoka et al., 2002; Stivala et al., 2001; Xu, Wang, Liu, Jiang Wang, & Fang Wang, 2007).

However, the problems concerning the physicochemical properties of (*E*)-resveratrol have meant that no novel food has been fortified with this antioxidant (López-Nicolás, & García-Carmona, 2008a). Despite the fact that (*E*)-resveratrol is one of the most potent antioxidants discovered in the recent years, few studies have focused on the structural determinants of this stilbene which influence its health-associated properties, such as the aggregation state, the protonation state or its solubility in aqueous solutions (López-Nicolás & García-Carmona, 2008b; Ovesná & Horváthová-Kozics, 2005), and it is these which are objectives of this work.

The aggregation state of many compounds may modify their biological activities (López-Nicolás, Bru, & García-Carmona, 1997). In solution, some molecules exhibit an aggregation behaviour that, depending on the pH, may lead to the formation of true micelles or merely to a dispersed oil phase (Bru, López-Nicolás, & García-Carmona, 1995). Thus, the knowledge of the possible equilibrium between the monomeric forms and the aggregates of this antioxidant may be essential for understanding the influence of (*E*)-resveratrol concentration on the properties attributed to it. For this reason, a study of the aggregation state of (*E*)-resveratrol in both the absence and presence of a type of compound which reduces the formation of aggregates at physiological pH is desirable.

Moreover, the aggregation of some molecules is strongly dependent on the protonation state of the molecule (López-Nicolás et al., 1997). Indeed, in the case of (*E*)-resveratrol the healthy properties of this stilbene can only be demonstrated when the three hydroxyl groups are present, i.e., when (*E*)-resveratrol is in its protonated form (Matsuoka et al., 2002). For this reason, the possible aggregation of (*E*)-resveratrol in different protonation states in the presence of modifiers of the aggregation state of this antioxidant is also worth studying.

Finally, the use of (*E*)-resveratrol as fortifier and nutraceutical is limited by its poor solubility in water and bioavailability (Trela & Waterhouse, 1996; Walle, Hsieh, Delegge, Oatis, & Walle, 2004; Wenzel & Somoza, 2005). For these reasons, the complexation of

doi:10.1016/j.foodchem.2009.05.039

(*E*)-resveratrol with the type of molecules which increase its bioavailability and solubility in aqueous solutions is strongly desirable.

To study these objectives we have used cyclodextrins (CDs), which are torus-shaped oligosaccharides made up of 6–8 glucopyranose units that originate from the enzymatic degradation of starch through the action of CD-glucano-transferase (Saenger, 1980; Szejtli, 1988; Szente & Szejtli, 2004). Poorly water-soluble compounds and hydrophobic moieties of amphiphilic molecules interact non-covalently with the CD cavity to form the so-called inclusion complexes, which are also highly water-soluble (López-Nicolás, Bru, Sánchez-Ferrer, & García-Carmona, 1995). Hydroxypropyl-β-cyclodextrin (HP-β-CD), a hydroxyalkyl derivative, is an alternative to α-, β- and γ-CD, with improved water solubility and may be slightly more toxicologically benign). As the first approved CD derivatives by FDA, HP-β-CDs have widely applications in food, agriculture and the pharmaceutical field (Yuan, Jin, & Li, 2008).

As opposed to other solubility-enhancing detergents, water-miscible solvents, etc., CDs produce individual molecules of the solute, thus preventing side effects, due to aggregation phenomena (Bru et al., 1995; Bru et al., 1996; López-Nicolás et al., 1997).

The effect of CDs on (*E*)-resveratrol has been reported in very few publications. Moreover, most works published have limited their investigation to the determination of complexation constants (K_F) using techniques such as solubility (Bertacche, Lorenzi, Nava, Pini, & Sinico, 2006), enzymology (Lucas-Abellán, Fortea, López-Nicolás, & Núñez-Delicado, 2007) or liquid chromatography, (López-Nicolás & García-Carmona, 2008a; López-Nicolás, Núñez-Delicado, Pérez-López, Carbonell, & Cuadra-Crespo, 2006). However, results concerning the K_F values of (*E*)-resveratrol complexed by CDs under different reaction conditions are contradictory. While some papers have claimed that natural CDs are the most suitable for the inclusion process (Bertacche et al., 2006), others have reported that modified CDs are the most appropriate to complex (*E*)-resveratrol (Lucas-Abellán et al., 2007). Moreover, papers have reported very different complexation constant values for the same type of complexes. Our study may help to resolve this problem because other publications have not take into account several important aspects of the complexation mechanism, such as the aggregation state of (*E*)-resveratrol, the pH values of the reaction medium, the pK_a values of the guest molecule and the UV–vis or fluorospectrometric properties of (*E*)-resveratrol in the presence of CDs.

Bearing in mind the above, this work has three principal objectives: (i) to study the aggregation state of (*E*)-resveratrol in the presence and absence of anti-aggregant agents such as CDs; (ii) to analyse the complexation of (*E*)-resveratrol with CDs in an aqueous medium under various experimental conditions and (iii) to obtain as wide a range of information as possible to clarify the contradictory data published in the literature about CD/(*E*)-resveratrol complexes.

To perform the study, several different methodologies are applied, which make use of changes in absorbance and fluorescence spectroscopic properties of (*E*)-resveratrol in the presence of CDs.

2. Material and methods

2.1. Reagents

The biochemicals were purchased from Fluka (Madrid, Spain). HP-β-CD was purchased from Sigma–Aldrich (Madrid, Spain) and used as received. (*E*)-resveratrol was from Sigma–Aldrich (Steinheim, Germany) and was used without further purification.

2.2. Stock standard solution of (*E*)-resveratrol

An accurately weighed 0.1 g standard sample of (*E*)-resveratrol was dissolved in ethanol, transferred into a 100-ml standard flask and diluted to the mark with ethanol and mixed well. The solution was stored at 4 °C. (*E*)-Resveratrol is sensitive to light and irradiation of solutions of the analyte induces the formation of (*Z*)-resveratrol and, if very intense, leads to the formation of a highly fluorescent compound. Because of this, the samples were stored in darkness. The stock standard solution was diluted to 30 μg/ml with sodium phosphate (0.1 M) before being used.

2.3. Fluorescence and absorbance spectroscopy

A PiStar-180 Spectrometer (Applied Photophysics Ltd., Leatherhead, United Kingdom) equipped with a xenon lamp source and quartz cell was used to perform all absorbance and fluorescence measurements. Excitation and emission bandwidths were both set at 2 nm. For both absorbance and fluorescence spectroscopy, excitation and emission spectra were recorded at 25 °C. To avoid inner filter effects, 2-mm quartz cells were used.

2.4. Influence of HP-β-CD concentration

The effect of HP-β-CD concentration on the absorbance and fluorescence intensity of (*E*)-resveratrol was studied. The (*E*)-resveratrol concentration was held constant at the values shown in Figs. 3–5, while the HP-β-CD concentration was varied. The HP-β-CD/(*E*)-resveratrol complexes were prepared according to the following procedure: a 1.0-ml aliquot of (*E*)-resveratrol solution at the concentrations shown in the figure legends (prepared by dilution of stock solution with water just before use) was transferred into a 5-ml volumetric flask and then an appropriate amount of HP-β-CD solution was added and the flask was filled to the mark with water. The resulting solutions were shaken and allowed to equilibrate and their fluorescence intensities were read within 1 h. All measurements were made at least in triplicate.

3. Results and discussion

3.1. Selection of the investigation conditions

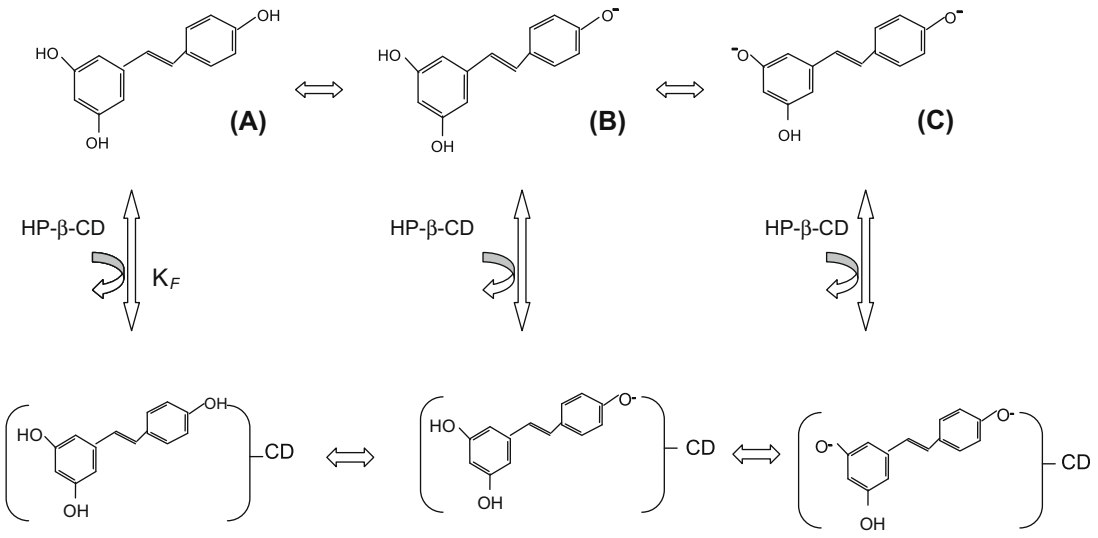
Since (*E*)-resveratrol is a trihydroxyl molecule, it is important to evaluate its behaviour with changes in pH. Bearing in mind the published data for the acidic dissociation constants (López-Nicolás & García-Carmona, 2008b), and to study the aggregation state of (*E*)-resveratrol and its complexation processes by HP-β-CD under various experimental conditions of pH and concentrations, the present investigation was planned by defining the following possible situations. In all these situations, changes in the spectra of UV–vis absorption of fluorescence excitation and emission were used to study the complexation process.

3.1.1. Physiological region ($pH < pK_{a1}$)

This region can be considered as the physiological zone where (*E*)-resveratrol maintains its biological activities. The guest is the totally protonated structure of (*E*)-resveratrol (Structure A, Scheme 1) and the host is a neutral molecule (HP-β-CD). A pH value of 6.5 was selected to study the complexation of (*E*)-resveratrol by HP-β-CD in the physiological region.

3.1.2. Enzymatic oxidation region: mild basic medium ($pK_{a1} < pH < pK_{a2}$)

The oxidation of (*E*)-resveratrol by several enzymes has been described in this region. The major guest is that corresponding to



Scheme 1. Complexation of protonated and deprotonated forms of (*E*)-resveratrol with HP-β-CD.

only one deprotonated hydroxyl group in the structure of (*E*)-resveratrol (Structure B, Scheme 1) but, as the pK_a values of (*E*)-resveratrol do not greatly differ, the coexistence of minority species, such as the totally protonated (Structure A, Scheme 1) and two deprotonated (Structure C, Scheme 1) hydroxyl groups in the structure of (*E*)-resveratrol is perfectly possible. On the other hand, in the pH value selected in this zone (pH 9.2) the host is a neutral molecule (HP-β-CD), and so this pH value was selected to study the complexation of (*E*)-resveratrol by HP-β-CD.

3.1.3. Strong basic medium (pK_{a2} < pH)

In this region, the majority species is the (*E*)-resveratrol containing two deprotonated hydroxyl groups in its structure (Structure C, Scheme 1). In this paper, the complexation of this stilbene by CDs is not studied for three reasons: (i) the basic hydrolysis of this antioxidant takes place very close to this zone; (ii) no physiological activities of (*E*)-resveratrol have been described in this pH region and (iii) the enzymatic oxidation of (*E*)-resveratrol is inhibited at these pH values.

3.2. UV–vis study of the aggregation of (E)-resveratrol in the presence of cyclodextrins

3.2.1. Physiological region

As indicated in introduction section, when the pH value of the reaction medium is situated below the first acidic dissociation constant (pK_{a1}), (*E*)-resveratrol shows its biological activities (Fang et al., 2002; Matsuoka et al., 2002; Stivala et al., 2001; Xu et al., 2007). For this reason, it is very important to study the aggregation of this molecule below the pK_{a1} value. Although several papers have reported substantial differences for the pK_a values of (*E*)-resveratrol (Cao, Chen, Du, Hou, & Tian, 2006; Galeano Díaz, Durán Merás, & Airado Rodríguez, 2007; López-Nicolás & García-Carmona, 2008a, 2008b; Takagai et al., 2005), at the selected pH value of 6.5, (*E*)-resveratrol is in its protonated form.

Fig. 1A shows the spectra of the pure (*E*)-resveratrol solutions in increasing concentrations at pH 6.5. The stilbene shows two absorption bands at around 215 and 300 nm in this pH region. Moreover, the results obtained show that the band around 300 nm presents a bandwidth of 20 nm and two small maxima centred at 305 and 316 nm. As can be seen in Fig. 2A (filled circles), although the absorbance at both 215 and 305 nm increases with the (*E*)-resveratrol concentration, the absorbance ratio of the stilbene at 215 and 305 nm was not constant as was to be expected according to the Lambert–Beer law, but increased. As suggested for other compounds (Guomei, Shaomin, Chuan, & Jinghao, 2003; Zhang, Jiang, Guo, & Li, 2008), variations in the absorbance ratio between different wavelengths would have been caused by the aggregation of (*E*)-resveratrol due to the monomer (M)/aggregate (A) equilibrium of (*E*)-resveratrol:

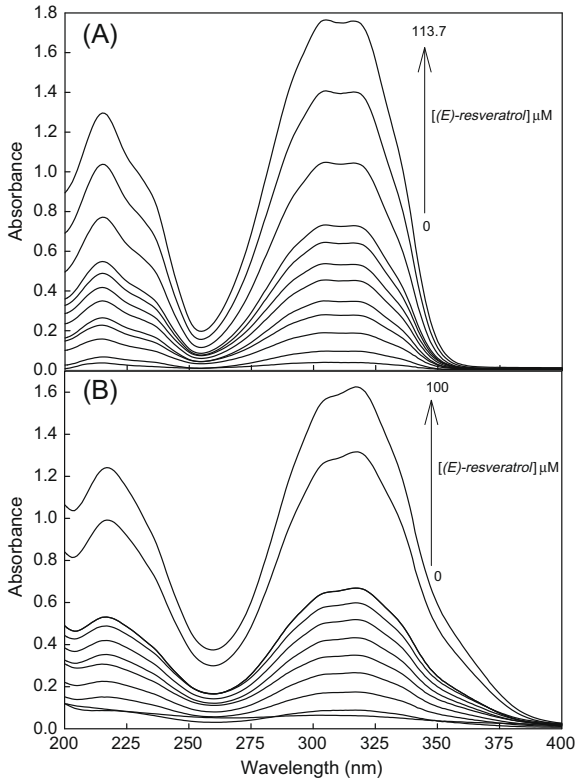


Fig. 1. The absorption spectra of (*E*)-resveratrol solutions (A) 1.26, 3.79, 7.59, 15.18, 18.93, 22.75, 26.57, 30.32, 45.56, 60.60, 76.90 and 113.7 μM at pH 6.5; and (B) 2.5, 5, 10, 15, 20, 25, 30, 35, 40, 80 and 100 μM at pH 9.2.

$$nM \rightleftharpoons A$$

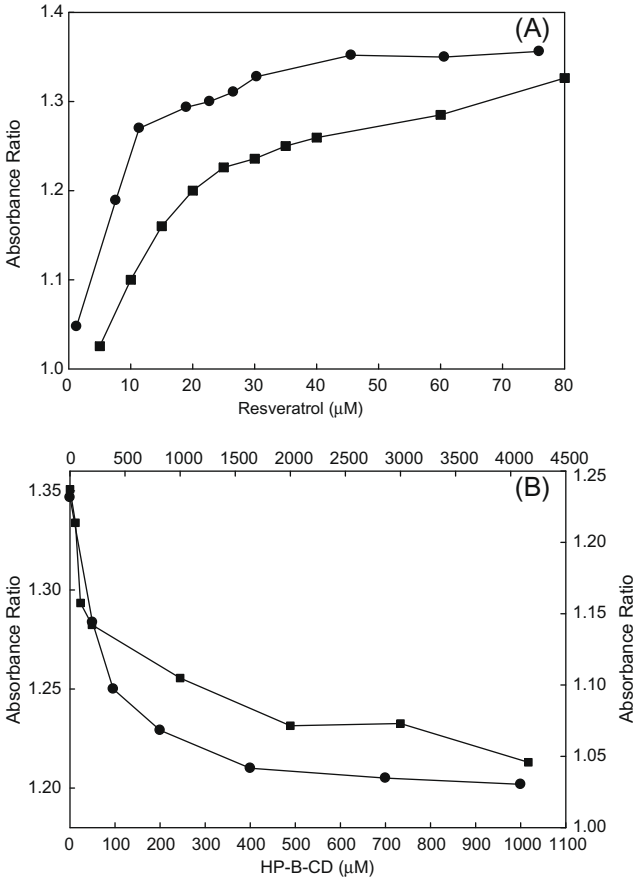

Fig. 2. (A) A plot of absorbance ratio of (*E*)-resveratrol at 305 and 215 nm versus the concentration of (*E*)-resveratrol at pH 6.5 (filled circles) and at 317 and 215 nm at pH 9.2 (filled squares); (B) the absorbance ratio of (*E*)-resveratrol in the presence of different concentrations of HP-β-CD at pH 6.5 (filled circles) and pH 9.2 (filled squares). (*E*)-Resveratrol concentration was maintained at 60.6 μM (pH 6.5) and 80 μM (pH 9.2).

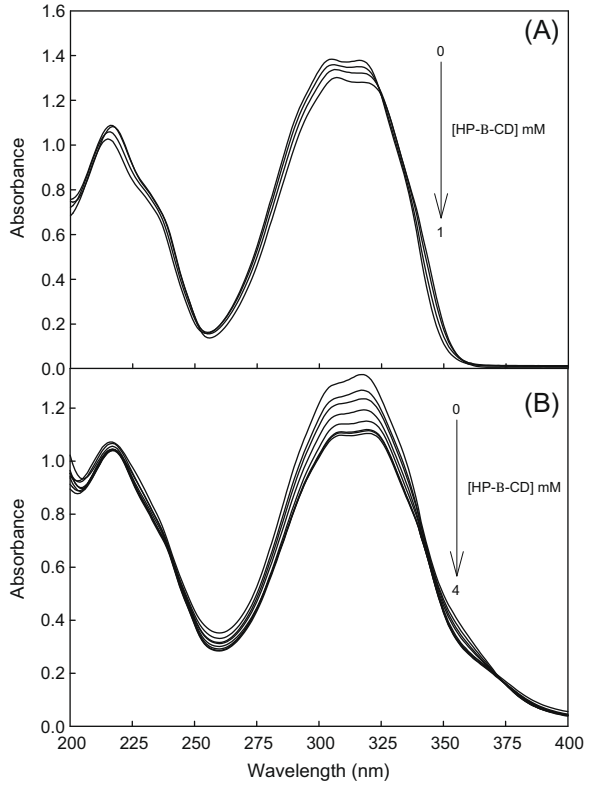

Fig. 3. (A) The absorption spectra of 60.6 μM (*E*)-resveratrol in the presence of increasing concentrations of HP-β-CD (0, 0.25, 0.5, 1 mM) at pH 6.5; and (B) absorption spectra of 80.0 μM (*E*)-resveratrol in the presence of increasing concentrations of HP-β-CD (0, 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4 mM) at pH 9.2.

As indicated in the introduction section, the aggregation state of a molecule is strongly related with its biological activity. For this reason, the use of antiaggregate compounds such as CDs, which maintains the monomer form of (*E*)-resveratrol, is advisable. Therefore, the next step was to study the effect of adding HP-β-CD on the aggregation state of (*E*)-resveratrol.

As can be seen from Fig. 2B (filled circles), the absorbance ratio of (*E*)-resveratrol at 215 and 305 nm decreased with increasing HP-β-CD concentration at pH 6.5, leading to an opposite effect to that observed in Fig. 2A (filled circles) in the absence of HP-β-CD. This may be explained by the capacity of HP-β-CD to modify the aggregation equilibrium existing in different molecules, producing individual molecules of the solute and preventing side effects due to aggregation phenomena, as has been seen to occur in polyunsaturated fatty acids (Bru et al., 1995; López-Nicolás et al., 1995). In this case, the presence of HP-β-CD modifies the equilibrium between free and aggregate (*E*)-resveratrol, leading to increase in the concentration of monomer (*E*)-resveratrol with respect to the aggregate forms as has been demonstrated by our group for other molecules (López-Nicolás et al., 1995).

To corroborate the formation of an inclusion complex between (*E*)-resveratrol and HP-β-CD, the UV–vis spectra of 60.6 μM (*E*)-resveratrol at pH 6.5 in the absence and presence of increasing concentrations of HP-β-CD are shown in Fig. 3A. With the addition of HP-β-CD the absorbance decreased gradually at around 300 nm, which suggests the formation of HP-β-CD/(*E*)-resveratrol complexes. Moreover, several works have reported that the presence (or not) of an isobestic point may determine the formation of a CD/guest complex (Guomei et al., 2003; Zhang et al., 2008). As shown in Fig. 3A, the isobestic points appears at 253 and 326 nm, which again suggests the formation of HP-β-CD/(*E*)-resveratrol complexes.

3.2.2. Enzymatic oxidation region

Although (*E*)-resveratrol shows its biological activities below the pK_{a1} value, it is still necessary to study the possible aggregation of this stilbene when (*E*)-resveratrol is deprotonated, to understand the oxidative process of this antioxidant by several enzymes, as in the case of lipoxygenase. Indeed, several authors have studied the oxidation of (*E*)-resveratrol by lipoxygenase at basic pH values (Fan & Mattheis, 2001; Lucas-Abellán et al., 2007; Pinto, García-Barrado, & Macías, 2003). However, these researchers did not take into account the aggregation and protonation state of (*E*)-resveratrol and, for this reason, this enzymatic oxidative pH region was the next region studied.

As shown in Fig. 1B, the band around 300 nm was reduced at higher pH values than those in the physiological zone, and the 340 nm band increased. However, as in the physiological region, the absorbance ratio of (*E*)-resveratrol at 215 and 317 nm increased with the (*E*)-resveratrol concentration (Fig. 2A filled squares), indicating the presence of aggregation phenomena at pH 9.2. As was also seen in the physiological zone, the absorbance ratio of (*E*)-resveratrol at 215 and 340 nm decreased with increasing HP-β-CD concentration at pH 9.2, modifying the aggregation equilibrium existing between monomeric and aggregate forms of (*E*)-resveratrol (Fig. 2B filled squares).

Demonstrating the formation of HP-β-CD/(*E*)-resveratrol inclusion complex at pH 9.2, Fig. 3B shows that the absorbance at

340 nm was significantly reduced when increasing concentrations of HP-β-CD were added to the reaction medium and that two new isobestic points appeared at 242 and 345 nm at this pH value.

The phenomenon of aggregation for (*E*)-resveratrol at different pHs described above may explain the different values reported by different researchers (Bertacche et al., 2006; Lucas-Abellán, Fortea, Gabaldón, & Núñez-Delicado, 2008), using linear regression of the phase solubility diagram to determine the K_F values at neutral pH for the (*E*)-resveratrol/CD complexes. Indeed, a technique based on the solubility of the guest molecule is not precise when aggregation phenomena of a guest molecule, such as (*E*)-resveratrol, occur in the region studied.

3.3. Effect of HP-β-CD on fluorescence of (E)-resveratrol at basic pH values

To obtain as wide a range of information as possible about the molecular interactions that drive the complexation process of (*E*)-resveratrol by HP-β-CD, a detailed fluorospectrometric study of the interaction between these compounds was carried out at different pH values.

Up to the date, in the literature there is only one paper that reports the fluorescence behaviour of (*E*)-resveratrol in the presence of CDs. Recently, Lucas-Abellán, Fortea, Gabaldón, and Núñez-Delicado (2008) studied the complexation of (*E*)-resveratrol with several types of CDs at different pHs using three different methods: enzymatic, solubility and fluorimetric. The comparison of the results obtained by the three methods by these researchers revealed that the fluorimetric method undervalued the K_F between (*E*)-resveratrol and all the CDs, while the enzymatic and solubility methods were more precise for calculating the K_F. For this reason, those researchers affirm that the fluorimetrically determined K_F is not correct.

However, the reasons for this behaviour were not explained and this fact must be clarified, taking into account different factors, such as the pK_a of the guest molecule, the medium pH, the fluorospectrometric properties of (*E*)-resveratrol and the aggregation state of this potent antioxidant.

In the paper published by Lucas-Abellán et al. (2008) only fluorescence intensity values at a single wavelength (380 nm) were presented but no excitation or emission spectra were shown. This fact led to several anomalous results, which are clarified in this paper, where an exhaustive study of the fluorospectrometric properties of (*E*)-resveratrol in the presence of CDs is carried out.

(*E*)-Resveratrol presents three relative emission bands (385 nm, 445 nm and 475 nm) depending on the pH of the reaction medium. When the pH value is lower than the pK_{a1}, (*E*)-resveratrol shows a characteristic emission spectrum with a principal emission band at λ = 385 nm, corresponding to the non-charged form of (*E*)-resveratrol (Structure A, Scheme 1). Moreover, when the pH of the medium is increased, a new emission band is showed at 445 nm which belongs to (*E*)-resveratrol with one hydroxyl group deprotonated (Structure B, Scheme 1) and, finally, when the pH value is increased to the region near to the third pK_a, the emission spectrum of (*E*)-resveratrol contains a new additional band at 475 nm (Structure C, Scheme 1), due to the deprotonation of two hydroxyl groups.

As shown in Fig. 4A, at the pH value studied in this section (9.2), (*E*)-resveratrol showed an equilibrium between its protonated/deprotonated structures (Scheme 1). Indeed, the principal emission band, in the absence of CDs, was 475 nm ((*E*)-resveratrol with two hydroxyl group deprotonated: Structure C, Scheme 1), followed by 445 nm ((*E*)-resveratrol with one hydroxyl group deprotonated: Structure B, Scheme 1) and finally 385 nm ((*E*)-resveratrol protonated: Structure A, Scheme 1).

As shown in Fig. 4A, the addition of increasing concentrations of HP-β-CD enhances the triple fluorescence emission of (*E*)-resveratrol when the protonated form is in equilibrium with deprotonated forms (Scheme 1). However, these three emission bands were surprisingly not enhanced with the same intensity. As is shown in Fig. 4A, the fluorescence intensity of the band near 385 nm increased more strongly in the presence of HP-β-CD, followed by the 445 nm band, and, finally, the 475 nm band. These results are due to the different capacity of HP-β-CD to complex the three protonated/deprotonated forms of (*E*)-resveratrol present at this pH value. However, this triple increase of the emission of (*E*)-resveratrol at different wavelengths in the presence of HP-β-CD could interfere in the determination of the complexation constants and thus explain the anomalous results showed by Lucas-Abellán et al. (2008). For this reason, the next step in our investigations was to determine the K_F values for the complexation of (*E*)-resveratrol with HP-β-CD at pH 9.2.

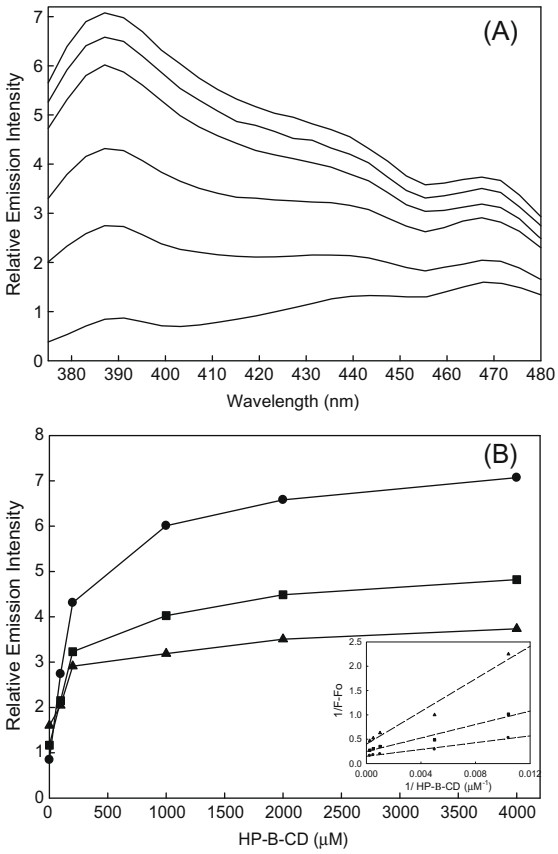

Fig. 4. (A) Emission fluorescence spectra of (*E*)-resveratrol (26.6 μM) at increasing concentrations of HP-β-CD (0, 96, 200, 1000, 2000, 4000 μM) at pH 9.2. Excitation wavelength: 344 nm. (B): Dependence of fluorescence intensities of (*E*)-resveratrol (26.6 μM) on HP-β-CD concentrations (0, 96, 200, 1000, 2000, 4000 μM) at three wavelengths: 385 nm (filled circles); 445 nm (filled squares) and 475 nm (filled triangles). *Inset:* Double reciprocal plot of (*E*)-resveratrol complexed to HP-β-CD for determination of the stoichiometry of HP-β-CD/(*E*)-resveratrol complexes: $1/(F - F_0)$ versus 1/[HP-β-CD] (assumption of 1:1 complex) at three wavelengths: 385 nm (filled circles); 445 nm (filled squares) and 475 nm (filled triangles).

3.4. Stoichiometry and complexation constant of the HP-β-CD/(E)-resveratrol complexes at basic pH values

The determination of the complexation constants for CD/(*E*)-resveratrol complexes is the subject of great controversy. Using linear regression of the phase solubility diagram, several papers have reported very different K_F values at neutral pH for the complexes between (*E*)-resveratrol and β-CD or HP-β-CD (Bertacche et al., 2006; Lucas-Abellán et al., 2008). Bertacche et al.

(2006) showed a higher K_F value using β-CD than HP-β-CD, while Lucas-Abellán et al. (2008) obtained opposite results. Moreover, the K_F values determined by Lucas-Abellán et al. (2008) were 4.5 times higher than those reported by Bertacche et al. (2006) for the same type of complex. Finally, as shown previously, Lucas-Abellán et al. (2008) reported different K_F values for the HP-β-CD /(*E*)-resveratrol, according to the method used to determine these constants.

In order to resolve these conflicting results, we have calculated the stoichiometry and K_F values for the HP-β-CD/(*E*)-resveratrol complexes at pH 9.2 using another analysis technique – steady-state fluorescence – which takes into account the changes in the physicochemical state of this antioxidant with concentration and following the Benesi–Hildebrand method.

Assuming that the composition of the complex was 1:1, the following expression can be written:

$$(E)\text{-resveratrol} + \text{HP-β-CD} \rightleftarrows \text{HP-β-CD-}(E)\text{-resveratrol} \quad (1)$$

The complexation constant, K_F is given by:

$$K_F = \frac{[\text{HP-β-CD}/(E)\text{-resveratrol}]}{[(E)\text{-resveratrol}][\text{HP-β-CD}]} \quad (2)$$

where [HP-β-CD], [(*E*)-resveratrol] and [HP-β-CD/(*E*)-resveratrol] are equilibrium concentrations.

From the experimental data of Fig. 4A, when three wavelengths corresponding to the three forms of (*E*)-resveratrol are considered, the difference in the intensity of the (*E*)-resveratrol emission fluorescence in the absence and presence of different amounts of HP-β-CD was plotted versus the HP-β-CD concentration (Fig. 4B). Representative plots of the variation in fluorescence intensity at the three wavelength bands analysed (385, 445 and 475 nm) as a function of HP-β-CD concentration were analysed by the Benesi–Hildebrand method.

The K_F value for the inclusion complex can be determined by the typical double reciprocal (or Benesi–Hildebrand) plots:

$$\frac{1}{F - F_o} = \frac{1}{(F_\infty - F_o)K_F[\text{HP-β-CD}]} + \frac{1}{F_\infty - F_o} \quad (3)$$

where [HP-β-CD] denotes the HP-β-CD concentration; F_0 the fluorescence intensity of (*E*)-resveratrol in the absence of HP-β-CD; F_∞ the fluorescence intensity when all of the (*E*)-resveratrol molecules are essentially complexed with HP-β-CD; and *F* the observed fluorescence intensity at each HP-β-CD concentration tested.

In our study, when a plot of $1/(F - F_0)$ versus 1/[HP-β-CD] is constructed (Fig. 4B inset) a straight line is obtained, which is indicative of a 1:1 stoichiometry for HP-β-CD/(*E*)-resveratrol at pH 9.2. On the other hand, assuming the stoichiometry of the inclusion complex to be 1:2, the following expression is obtained:

$$\frac{1}{F - F_o} = \frac{1}{(F_\infty - F_o)K'([\text{HP-β-CD}])} + \frac{1}{F_\infty - F_o} \quad (4)$$

When making a plot of $1/(F - F_0)$ against $1/[\text{HP-β-CD}]^2$, a non-linear relationship is obtained (data not shown), which indicates that the stoichiometry of the inclusion complex is not 1:2.

However, anomalous results were found when the complexation constants values were determined at the three wavelengths selected (385, 445 and 475 nm). Table 1 reports that the complexation constants obtained using fluorescence measurements for the three wavelengths selected were very different. The highest complexation constant value was determined at the wavelength where the totally protonated form of (*E*)-resveratrol (Structure A, Scheme 1) presents the emission maximum (385 nm) and the lowest complexation constant value was calculated at 475 nm, which is the wavelength where the structure of (*E*)-resveratrol with two deprotonated hydroxyl groups (Structure C, Scheme 1) presents its emission maximum. The fact that the complexation constant value was dependent on the wavelength selected to observe the increase of fluorescence in the presence of HP-β-CD proves that these constants are apparent complexation constants (K_{app}) and not true complexation constants (K_F).

Table 1
Apparent complexation constants (K_{app}) at pH 9.2 for the complexes between HP-β-CD and the three forms of (*E*)-resveratrol: protonated (385 nm) (Structure A, Scheme 1); one hydroxyl deprotonated (445 nm) (Structure B, Scheme 1) and two deprotonated (475 nm) (Structure C, Scheme 1). Complexation constant (K_F) at pH 6.5 for the complexes between HP-β-CD and (*E*)-resveratrol.

λ (nm)	pH 9.2		
	K_{app} (M^{-1})	K_{app} (M^{-1})	K_{app} (M^{-1})
385	4285 ± 105	–	–
445	–	3579 ± 89	–
475	–	–	2263 ± 78
	pH 6.5		
	K_F (M^{-1})		
385	14490 ± 723		

These results help explain the anomalous results obtained by Lucas-Abellán et al. (2008) mentioned above. A comparison of the results obtained by the three methods (enzymatic, solubility, and fluorimetric) by these researchers revealed that the fluorimetric method undervalued the K_F between (*E*)-resveratrol and several types of CDs. However, in the paper reported by Lucas-Abellán et al. (2008), fluorescence emission was only measured at 380 nm, i.e., the emission band of the protonated form of (*E*)-resveratrol, but the authors did not take into account the fact that, in the presence of HP-β-CD, the apparent complexation constants are dependent on the wavelength selected to analyse the interaction between the protonated form of (*E*)-resveratrol and HP-β-CD.

Moreover, although the results obtained in this work partially confirm the statement by Lucas-Abellán et al. (2008) that the steady-state fluorescence is not a suitable technique to determine the K_F between (*E*)-resveratrol and HP-β-CD because the K_F is undervalued, with respect to the values obtained using another techniques, it is very possible that this affirmation could be only correct at basic pH values, where different protonated/deprotonated forms of this antioxidant coexist complexed and not complexed by HP-β-CD (Scheme 1). However, the conclusion of Lucas-Abellán et al. (2008) may be not correct when only one structure of (*E*)-resveratrol is present in the medium. For this reason, the next step of our investigation was to study the complexation between (*E*)-resveratrol and HP-β-CD at pH values below the pK_{a1} of the stilbene. At the pH value selected (6.5) (*E*)-resveratrol shows a high biological activity and only its protonated form is present.

3.5. Effect of HP-β-CD on fluorescence of (E)-resveratrol at physiological pH values

As shown in Fig. 5A, the emission spectra of (*E*)-resveratrol at pH 6.5 in the absence and presence of HP-β-CD are very different from that observed at basic pH because, at physiological pH, only one emission band (385 nm) is presented, unlike the three emission bands observed at pH 9.2 (Fig. 4A). This result is due to the presence of only one form of (*E*)-resveratrol at pH 6.5 (protonated form, Structure A of Scheme 1).

Fig. 5A shows the fluorescence emission spectra of (*E*)-resveratrol in an aqueous solution at pH 6.5 containing different concentrations of HP-β-CD. As is shown, (*E*)-resveratrol emits relatively weak fluorescence in the absence of CDs. However, with the addition of HP-β-CD, the maximum emission wavelength slightly shifted to a shorter wavelength (from 392 to 384 nm); (Fig. 5A

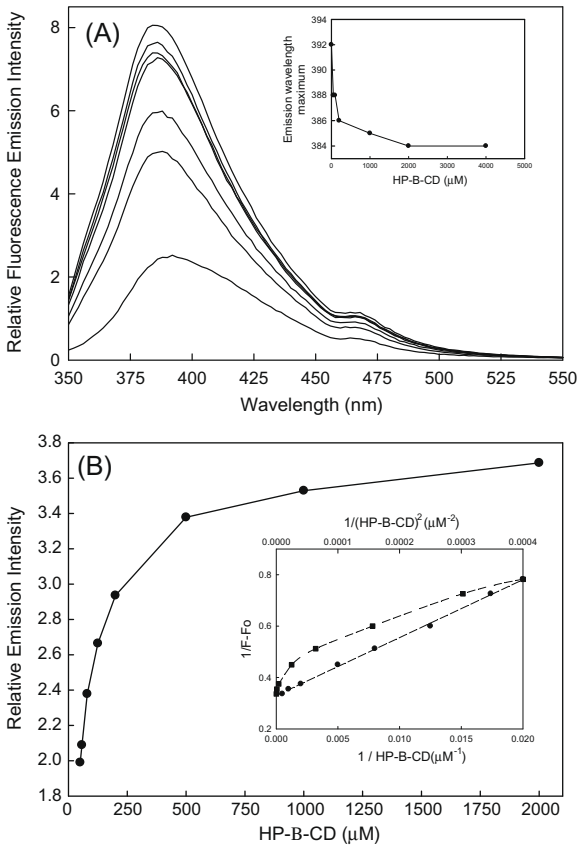

Fig. 5. (A) Emission fluorescence spectra of (*E*)-resveratrol (10 μM) at various concentrations (0, 50, 96, 200, 1000, 2000, 4000 μM) of HP-β-CD at pH 6.5. Inset: Dependence of emission wavelength maximum of (*E*)-resveratrol on HP-β-CD concentrations (0, 50, 96, 200, 1000, 2000, 4000 μM). Excitation wavelength: 334 nm. (B) Dependence of emission fluorescence intensities of (*E*)-resveratrol (10 μM) on HP-β-CD concentrations (50, 57, 125, 200, 500, 1000, 2000 μM). Excitation wavelength: 334 nm. Inset: Double reciprocal plot of (*E*)-resveratrol complexed to HP-β-CD for determination the stoichiometry of HP-β-CD/(*E*)-resveratrol complexes: $1/(F - F_0)$ versus 1/[HP-β-CD] (assumption of 1:1 complex) (filled circles); (b) $1/(F - F_0)$ versus $1/[\text{HP-β-CD}]^2$ (hypothesis of 1:2 complex) (filled squares).

inset) and the emission fluorescence intensity was markedly enhanced at pH 6.5. These changes were due to the interaction between HP-β-CDs and (*E*)-resveratrol, which again implied the formation of HP-β-CD/(*E*)-resveratrol complexes as has been reported for other guest/host interactions (Guomei et al., 2003; Zhang et al., 2008). When (*E*)-resveratrol is entrapped in the HP-β-CD cavity, this microenvironment with a smaller polarity and stronger rigidity would restrict the freedom of the guest molecules and increase the fluorescence quantum yield. Furthermore, the steric hindrance of the HP-β-CD torus would protect the excited states from non-radiative and quenching processes that normally occur in bulk aqueous solutions and enhance the fluorescence efficiencies of the guest molecule.

3.6. Stoichiometry and complexation constant of the HP-β-CD/(E)-resveratrol complexes at physiological pH values

In order to quantify the interaction between (*E*)-resveratrol and HP-β-CD in this region of pH, K_F was determined by a fluorimetric method at pH 6.5.

Following the same methodology that the applied to determine the K_F values for the complexation of (*E*)-resveratrol by HP-β-CD at basic pH, the relative emission intensity of this antioxidant was calculated at increasing HP-β-CD concentrations (Fig. 5A). The linear correlations obtained for all the fits were higher than 0.99, indicating that the presumed stoichiometry of the complexes formed was also 1:1 (Fig. 5B inset, filled circles). The plot of $1/(F - F_0)$ as a function of $1/[\text{HP-β-CD}]^2$ was also analysed because it was thought it would provide information about the presence of higher order complexes, especially at high HP-β-CD concentrations (Fig. 5B inset, filled squares). However, none of the experimental data provided a good linear fit in these plots, ruling out this possibility. Applying the data obtained to Eq. (3), the K_F value for this physiological pH was calculated ($K_F = 14490 \pm 723\ M^{-1}$).

The results obtained in this work may help to understand the interaction between (*E*)-resveratrol and HP-β-CD. If we compare the K_F obtained for the totally protonated structure of this stilbene with the K_{app} determined at basic pH (Table 1), we can observe that the K_F value determined at pH value below that of the pK_{a1} of (*E*)-resveratrol was always higher than the K_{app} calculated when (*E*)-resveratrol is partially deprotonated. This fact was expected since, in basic solutions, the complexation constant value is low, due to the presence of negative charges in its molecule, which induces better (*E*)-resveratrol solubilisation in the bulk solution rather than in the hydrophobic part of the CD. Moreover, these results are in accordance with other work published by our group (López-Nicolás et al., 2008a, 2008b), where CDs complex the protonated form of (*E*)-resveratrol (Structure A, Scheme 1) with higher efficiency than the deprotonated forms.

These results confirm that the use of fluorescence measurements to calculate the K_F value for the HP-β-CD/(*E*)-resveratrol complexes is not adequate when the pH of the medium is higher than the pK_{a1} of (*E*)-resveratrol because of the presence of different protonated/deprotonated forms (complexed or not complexed by HP-β-CD) of this stilbene. However, when (*E*)-resveratrol is presented in its totally protonated form (i.e., at pH values lower than its pK_{a1}) steady-state fluorescence is an adequate technique to study the interaction between (*E*)-resveratrol and HP-β-CD.

4. Conclusions

Although the biological activities of (*E*)-resveratrol have been studied in many papers, little information exists about the physicochemical structure of this potent antioxidant under different conditions. For this reason, its use as functional ingredient in novel foods (as a fortifier and nutraceutical compound) has been restricted to date. In this paper, we clarify diverse contradictory data existing in the literature about different properties of (*E*)-resveratrol, such as the aggregation and protonation state, which may have importance for its putative health-giving properties. Moreover, the lipophilic nature of this stilbene means that it needs a carrier which permits its "solubilisation" in aqueous media. The complete study of the complexation of (*E*)-resveratrol by cyclodextrins using absorbance and fluorescence techniques resolves the conflicting data existing in the literature about this type of complexation. Moreover, knowledge of the effect of HP-β-CD on the aggregation state of (*E*)-resveratrol and determination of the complexation constants of the different protonated and deprotonated forms of this potent antioxidant open up new possibilities for the use of (*E*)-resveratrol in the food and pharmaceutical industry.

Antioxidant activity
Oxidative stability
Sunflower oil

ABSTRACT

In vitro antioxidant activities and protective effects in stabilising sunflower oil of three rosemary extracts high in carnosic acid (CA) were tested. The CA contents (w/w) of the extracts were 24.9% (CA25), 60.5% (CA60) and 98.3% (CA98). Total phenolic contents of CA25 and CA60 were (3.58 ± 0.026 g/100 g) and (8.20 ± 0.027 g/100 g), (3.91 ± 0.029 g/100 g) and (8.10 ± 0.056 g/100 g) expressed in gallic acid and catechin equivalents, respectively. Reducing power of CA and other antioxidants at 0.5 mg/ml followed the order of L-ascorbic acid > CA98 > TBHQ > BHA > CA60 > BHT > CA25. The IC_{50} values in the DPPH assay obtained for CA25, CA60, CA98, BHA, BHT and TBHQ were 0.30 ± 0.002, 0.20 ± 0.003, 0.12 ± 0.002, 0.19 ± 0.002, 0.42 ± 0.010, and 0.09 ± 0.001 mg/ml, respectively.

Protective effects of CA in stabilising sunflower oil were tested, compared to synthetic antioxidants, by measuring their peroxide values, thiobarbituric acid-reactive substances, free fatty acid contents and *p*-anisidine value during accelerated storage. Results indicated that CA exhibited stronger antioxidant activity in sunflower oil than BHT and BHA. However, its antioxidant activity was less than that of TBHQ.

1. Introduction

Edible oils with higher contents of unsaturated fatty acids, especially polyunsaturated fatty acids, are more susceptible to oxidation. Lipid oxidation of oils can not only produce rancid odours, unpleasant flavours and discoloration, but can also decrease the nutritional quality and safety due to degradation products, resulting in harmful effects on human health (Esterbauer, Schaur, & Zollner, 1991; Lercker & Rodriguez-Estrada, 2002). To retard or prevent oxidative deterioration, synthetic antioxidants, such as butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT) and *tert*-butyl hydroquinone (TBHQ) have widespread use as food additives in many countries. Recent reports reveal that these compounds may be implicated in many health risks, including cancer and carcinogenesis (Hou, 2003; Prior, 2004). Hence, there is a tendency towards the use of natural antioxidants of plant origin to replace these synthetic antioxidants. The application of plant extracts to prevent edible oil rancidity had been studied (Mallet, Cerrati, Ucciani, Gamisons, & Gruber, 1994; Xiong, Yang, Zhang, & Xiao, 2001). Among them, rosemary (*Rosmarinus officinalis* L.) extracts with their powerful antioxidant activities are often the first choice for processed foods and widely used in the food industry (Nissen, Mansson, Bertelsen, Huynh-Ba, & Skibsted, 2000). The antioxidant activities of rosemary extracts are related to the presence of phenolic diterpene compounds, such as carnosic acid, carnosol and rosmanol, rosmariquinone and rosmaridiphenol, which break free radical chain reactions by hydrogen atom donation (Basaga, Tekkaya, & Acikel, 1997; Frankel, Huang, Aeschbach, & Prior, 1996; Thorsen & Hildebrandt, 2003).

Carnosic acid is the primary phenolic diterpene compound found in the leaves of rosemary (Richheimer, Bemart, King, Kent, & Bailey, 1996). Carnosic acid (Fig. 1) is a lipophilic antioxidant that scavenges singlet oxygen, hydroxyl radicals, and lipid peroxyl radicals, thus preventing lipid peroxidation and disruption of biological membranes (Aruoma, Halliwell, Aeschbach, & Loliger, 1992; Haraguchi, Saito, Okamura, & Yagi, 1995). Its radical-scavenging activity is caused by the presence of two *O*-phenolic hydroxyl groups found at C11 and C12 of the molecule (Richheimer et al., 1999).

Antioxidant potential of carnosic acid *in vitro* has been proved by Erkan, Ayranci, and Ayranci (2008). In addition to its antioxidant activity, it has been reported to possess anti-inflammatory, antiproliferative, antitumorigenic and neuroprotective effects (Aruoma et al., 1992; Chang et al., 2008; Danilenko et al., 2003; Erkan et al., 2008; Rau et al., 2006; Satoh et al., 2008).

In this paper, we describe the isolation of extracts with three different contents of carnosic acid from dried rosemary leaves. Furthermore, we studied *in vitro* their antioxidant effects and stabilisation of sunflower oil under accelerated conditions, compared with synthetic antioxidants, including BHA, BHT and TBHQ.

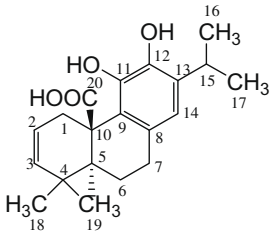

Fig. 1. Molecular structure of carnosic acid.

2. Materials and methods

2.1. Materials

Refined, bleached, and deodorised (RBD) sunflower oil was obtained from Standard Food Industries Ltd., Guangdong, China. It contained very low α-tocopherol (<4.3 mg/kg) and no synthetic antioxidants. Fresh leaves of *Rosmarinus officinalis* L. were harvested from the FuYang base of Zhe Jiang Hi Sun Pharmaceutical Co., China in September, 2007. All reagents and solvents were either of HPLC or analytical grade. Carnosic acid standard (⩾91%), L-ascorbic acid, BHA, BHT, TBHQ, Folin–Ciocalteu reagent, gallic acid standard, catechin standard, and DPPH (2,2-diphenyl-1-picrylhydrazyl) free radicals were purchased from Sigma–Aldrich Co. (St. Louis, MO).

2.2. Preparation and analysis of CA

Dried rosemary (*Rosmarinus officinalis* L.) leaves (1 kg); (carnosic acid content 2.09 g/100 g DW) were chopped into small parts with a blender and placed in a round-bottomed flask with 1 l of deionised water. The solution was steam-distilled for 60 min in a Clevenger-type apparatus for oil isolation. The residue was extracted using aqueous 80% ethanol solution by an ultrasound-assisted extraction (KQ-250DB, Kunshan Ultrasound Co. Ltd., Kunshan, China) at 40 °C for 30 min. This procedure was repeated twice, and the combined filtrate was evaporated in a rotary evaporator (Shanghai Qingpu Huxi Instrument Factory, Shanghai, China) at 50 °C, to give CA25 (70.3 g).

CA25 was dissolved in ethyl acetate (1:40, w/v), insoluble substances were removed by filtration, then 100 ml 0.8% sodium carbonate solution was added to the filtrate. The two phases were separated and the ethyl acetate layer was collected and combined with 200 ml 5% sodium chloride solution; the solution was concentrated under vacuum to a volume of about 50 ml, then filtered and the filtrate pH was adjusted to 4.5–5.0 with 10% HCl, and extracted by normal hexane. The hexane fractions were concentrated in a rotary evaporator at 50 °C (Shanghai Qingpu Huxi Instrument Factory, Shangai, China), to give crystals of CA60 (22.6 g).

CA60 was dissolved in ethyl acetate, insoluble materials were removed by filtration, then the filtrate was concentrated and purified through silica column chromatography eluted with ethyl acetate, and to give 9.0 g high purity carnosic acid (CA98).

The carnosic acid content of CA25, CA60 and CA98 were analysed by high-performance liquid chromatography (HPLC) on a Jasco HPLC system equipped with a UV detector (Jasco International Co. Ltd., Tokyo, Japan). Analyses were performed on a Curosil-PFP (4.6 mm × 250 mm, 5 μm) reversed-phase column (Phenomenex Inc., Torrance, CA). The UV detector was set at a wavelength of 230 nm. The mobile phase was acetonitrile:0.5% phosphorous acid (60:40, v/v) at a flow rate of 1 ml/min and the injection volume was 10 μl.

The carnosic acid recoveries were calculated relative to the amount of carnosic acid in dried rosemary leaves.

2.3. Determination of total phenolic content

The total phenolic contents of CA25 and CA60 were determined using the Folin–Denis method (Swain & Hills, 1959) with a little modification. This method is based on the reducing power of the phenolic hydroxyl groups (Hahn, Rooney, & Earp, 1984); 0.1 ml of CA25 or CA60 (10 mg/ml in ethanol) and 1.0 ml Folin–Ciocalteu reagent (1:1 with water) were mixed. After 5 min, 1 ml of 10% Na_2CO_3 was added and the volume was accurately adjusted to 25 ml. Then the mixture was left at room temperature for 60 min. The absorbance was measured with a spectrophotometer (Shimadzu UV-2550; Shimadzu, Kyoto, Japan) at 765 nm against a blank. The determination was performed three times. Total phenolic contents were calculated from standard curves of gallic acid ($y = 0.27x - 0.022$, $r = 0.993$) and catechin ($y = 0.29x - 0.023$, $r = 0.995$), respectively, and then expressed as g/100 g sample.

2.4. Measurement of reducing power

The reducing power of CA25, CA60, CA98 and positive standards L-ascorbic acid, BHA, BHT, TBHQ was determined according to the method of Ardestani and Yazdanparast (2007). The reducing power was measured using chemical reduction of Fe(III) to Fe(II). Various concentrations of sample (62.5–1000 μg/ml in ethanol) were mixed with sodium phosphate buffer (2.5 ml, 0.2 M, pH 6.6) and 2.5 ml of 1% potassium ferricyanide ($K_3Fe(CN)_6$). The mixture was incubated at 50 °C for 20 min, 2.5 ml of 10% trichloroacetic acid (TCA) was added to the mixture, which was then centrifuged for 10 min at 3000*g*. The upper layer of solution (2.5 ml) was mixed with distilled water (2.5 ml) and $FeCl_3$ (0.5 ml, 0.1%), and the absorbance was measured with multiplate spectrophotometer at 700 nm (UV-2550, Shimadzu, Kyoto, Japan). A higher absorbance indicates a higher reducing power.

2.5. DPPH radical-scavenging assay

DPPH (2,2-diphenyl-1-picrylhydrazyl) radical-scavenging activity of CA25, CA60 and CA98 compared with commonly-employed synthetic antioxidants BHA, BHT and TBHQ was measured according to the method of Blois (1958) and modified slightly. Briefly, 0.1 ml of sample at variable concentrations (62.5–1000 μg/ml in ethanol) was added to 3.9 ml of a DPPH solution (25 mg/l in ethanol) as the free radical source and kept for 30 min at room temperature. The decrease in the solution absorbance, due to proton-donating activity, was measured at 517 nm (UV-2550, Shimadzu, Kyoto, Japan). The DPPH radical-scavenging activity was calculated using the following formula:

$$\text{DPPH radical} - \text{scavenging activity } (\%) = [(1 - A_1/A_0) \times 100],$$

where A_0 is the absorbance of the control, and A_1 is the absorbance of CA25, CA60 and CA98 or the commercial synthetic antioxidants.

2.6. Oxidative stability determination

2.6.1. Sample preparation

CA25, CA60 and CA98 were added to sunflower oil at a concentration of 200 mg/kg. Synthetic antioxidants (BHA, BHT and TBHQ) were employed at their legal limit of 200 mg/kg (Duh & Yen, 1997) as reference. All the samples (250 ml) were placed in dark brown coloured reagent bottles with narrow necks and mixed for 30 min in an ultrasonic water bath of 60 °C (KQ-250DB, Kunshan Ultrasound Co. Ltd.). Then all the samples (250 ml) were stored in an incubator at a fixed temperature of 60 °C. Control samples without antioxidants were also maintained under the same storage conditions. Analyses were conducted at 4-day intervals for thiobarbituric

acid-reactive substances assay (TBARS) and 3-day intervals for all other assays.

2.6.2. Analysis of peroxide value

The peroxide value (*PV*) of all samples was measured according to GB/T 5009.37-2003 with a slight modification. Sunflower oil samples (2 g) were dissolved in 30 ml of chloroform:glacial acetic acid (3:2, v/v). Then 1 ml saturated solution of KI was added. The mixture was shaken by hand for 1 min and was then kept in the dark for 5 min. After the addition of 75 ml distilled water, the mixture was titrated against sodium thiosulfate (0.002 M) until the yellow colour almost disappeared. Then about 0.5 ml of starch indicator (1%) solution was added. Titration was continued until the blue colour just disappeared. The blank was also analysed under similar conditions. Peroxide value (meq/kg) was calculated according to the equation:

$$PV = C \times (V - V_k) \times 12.69 \times 78.8/m$$

where C is the concentration of sodium thiosulfate (M); V and V_k are the volume of sodium thiosulfate exhausted by sample and blank, respectively (ml); m is the mass of sunflower oil (g).

2.6.3. Thiobarbituric acid-reactive substances assay (TBARS)

Lipid oxidation of all samples was assessed by the 2-thiobarbituric acid (TBA) method according to GB/T 5009.181-2003 with a slight modification. In brief, 10 g of samples were homogenised in 10 ml of TCA (7.5%)–EDTA (0.1%) solution. This sample was shaken continuously for 0.5 h with a mechanical shaker, then filtered. Exactly 5 ml of filtrate was added to 5 ml of TBA (2.88 g/l) solution in a 25 ml colorimetrical tube, and heated in a water bath (90 °C) for 40 min for pink colour development. The tube was first cooled for 1 h, and was then centrifuged for 5 min at 3000*g*. The supernatant fluid was added to 5 ml of chloroform in another tube, and then shaken. This mixed solution was allowed to stand for at least 1 h. The absorbance was measured at 532 nm using a spectrophotometer (UV-2550, Shimadzu, Kyoto, Japan). TBARS were calculated from a standard curve of malondialdehyde (MDA), freshly prepared by acidification of TEP (1,1,3,3-tetraethoxypropane) in the range from 0.02 to 0.3 μg/ml ($y = 0.8885x + 0.0372$, $r = 0.9997$) and expressed as mg of malondialdehyde per kg sample.

2.6.4. Measurement of free fatty acids (FFA)

Free fatty acids, as oleic acid percentages in oil samples, were determined using an alkali titration method according to GB/T 5009.37-2003 with a slight modification. Samples (2 g) were dissolved in a 50 ml mixture of neutral ether:ethanol (2:1, v/v). Then the mixture was shaken by hand. After cooling to room temperature, the mixture was titrated against potassium hydroxide (0.05 M) using phenolphthalein solution (10 g/l) as an indicator. FFA value (mg/g) was calculated according to the equation:

$$[\mathrm{FFA}] = (V \times C \times 56.11)/m$$

where V is the volume of potassium hydroxide exhausted by samples (ml); C is the concentration of potassium hydroxide (M); m is the mass of sunflower oil (g).

2.6.5. Measurement of p-anisidine value

The *p*-anisidine value (*AnV*) was determined according to IUPAC method 2.504 (IUPAC, 1987). Sunflower oil samples (2 g) were dissolved in 25 ml isooctane and absorbance of this fat solution was measured at 350 nm using a spectrophotometer (UV-2550, Shimadzu, Kyoto, Japan). Five millilitres of the above mixture was mixed with 1 ml 0.25% *p*-anisidine in acetic acid (w/v) and after 10 min standing, absorbance was read at 350 nm using a spectrophotometer (UV-2550, Shimadzu, Kyoto, Japan). *AnV* was calculated according to the equation:

$$AnV = 25 \times (1.2A_s - A_b)/m$$

where A_s is the absorbance of the fat solution after reaction with the *p*-anisidine reagent; A_b is the absorbance of the fat solution; m is the mass of sunflower oil (g) sample.

2.7. Statistical analysis

Experiments were replicated twice on different occasions. All analyses were carried out in triplicate ($n = 3$) for each replicate which were reported as mean ± SD; an ANOVA test (using SPSS 11.5 statistical software; SPSS Inc., Chicago, IL) was used to compare the mean values of each treatment. Significant differences between the means of parameters were determined by using the Duncan test ($p < 0.05$).

3. Results and discussion

3.1. Analysis of carnosic acid

A calibration curve was prepared by plotting the peak areas of the carnosic acid standard samples. The standard curve gave a linear response for the carnosic acid concentrations and the peak areas in the range from 0.08 to 0.4 mg/ml ($y = 2 \times 10^7 x + 148{,}456$, $r = 0.9999$). The carnosic acid contents were calculated from a standard curve, and the contents were 24.9%, 60.5% and 98.3%, respectively. Recoveries of CA25, CA60 and CA98 were 83.9%, 65.5% and 42.4%, respectively. The structure of CA98 was identified by comparison of its spectral properties (^{1}H NMR) (Model: FD-PNMR-2; China Motion Network Technology Co. Ltd., Zhengzhou City, China) with those reported in the literature (Schwarz & Ternes, 1992). CA25, CA60 and CA98 were then kept in the dark at −20 °C until tested.

3.2. Total phenolic contents

Phenols are very important plant constituents because of their scavenging ability on free radicals due to their hydroxyl groups (Hatano et al., 1989). Therefore, phenolic contents of plants may contribute directly to their antioxidant action. The main phenolic compounds identified in rosemary are rosmarinic acid, carnosic acid, carnosol, methyl carnosate, rosmanol, epirosmanol and rosmadial (Ivanova, Gerova, Chervenkov, & Yankova, 2005). Total phenolic contents in CA25 and CA60 are presented in Table 1. The higher CA contents may account for the higher total phenolic content. Generally, total phenolic content of CA60 was 2–3 times higher than that of CA25. The results expressed as gallic acid equivalents or catechin equivalents were similar.

3.3. Reducing power assay

The reducing capacity of a compound may serve as a significant indicator of its potential antioxidant activity (Hsu, Coupar, & Ng, 2006). In the present study, the reducing power was assessed based on measurement of Fe^{3+} to Fe^{2+} transformation. Fig. 2 shows the reductive capability (absorbance at 700 nm) of CA25, CA60 and CA98, relative to L-ascorbic acid, BHA, BHT, and TBHQ. In this assay,

Table 1
Total phenolic contents of CA25 and CA60.

Sample	g Gallic acid equivalents/100 g sample	g Catechin equivalents/100 g sample
CA25	3.58 ± 0.026[a]	3.91 ± 0.029[a]
CA60	8.20 ± 0.027[a]	8.10 ± 0.056[a]

[a] Data are given as means ± SD, $n = 3$.

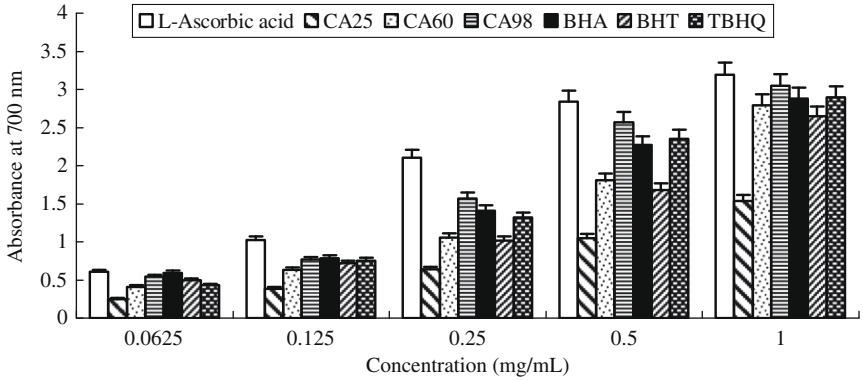

Fig. 2. Reducing capability of CA25, CA60, CA98 compared with commercial natural or synthetic antioxidants.

increased absorbance indicated increased reducing power. The reducing power of all these test compounds increased in a concentration-dependent manner. The reducing power of all these test compounds at 0.5 mg/ml was markedly lower than that of L-ascorbic acid. At the same concentration, reducing power of CA98 showed better activities than synthetic antioxidants. The reducing power of antioxidants at 0.5 mg/ml followed the order of L-ascorbic acid > CA98 > TBHQ > BHA > CA60 > BHT > CA25. These results suggest that carnosic acid has a remarkable potency to donate electrons to reactive free radicals, converting them into more stable non-reactive species and terminating the free radical chain reaction.

3.4. Scavenging effect on DPPH radicals

The DPPH assay, which measures the ability of compounds to transfer labile H-atoms to radicals, is the commonest method of antioxidant activity evaluation (Brand-Williams, Cuvelier, & Berset, 1995). The abstraction of hydrogen by this stable free radical is known to lead to bleaching with a maximum absorption band around 515–528 nm and can easily be monitored spectrophotometrically.

DPPH radical-scavenging abilities of CA25, CA60 and CA98 along with the reference standards BHA, BHT and TBHQ are shown in Table 2. A lower value of IC_{50} (defined as the concentration of compound that was able to inhibit 50% of the total DPPH radicals) indicates a higher antioxidant activity. All tested compounds demonstrated a concentration-dependent scavenging activity by quenching DPPH radicals; DPPH radical-scavenging activities of carnosic acids increased with increased content. Scavenging activities of CA25, CA60 and CA98 were significantly higher ($p < 0.05$) than that of BHT but less than that of TBHQ. As shown in Table 2, the scavenging activity of DPPH radicals decreased in the following order: TBHQ > CA98 > BHA > CA60 > CA25 > BHT, all values significantly different at $p < 0.01$.

These results indicated that CA has a noticeable effect on scavenging free radicals. This could be attributed to its molecular structure. It has been documented that antiradical scavenging activity is related to substitution of hydroxyl groups in the aromatic rings of phenolics, thus contributing to their hydrogen-donating ability (Brand-Williams et al., 1995; Yen, Chang, & Duh, 2005).

Table 2
Scavenging activity of antioxidants for DPPH radical; data are shown as IC_{50} (mg/ml) and % inhibition at 0.5 mg/ml of antioxidants.

Sample	IC_{50}[a,b]	Inhibition (%)[c]
CA25	0.30 ± 0.002	64.18 ± 0.12
CA60	0.20 ± 0.003	75.94 ± 0.10
CA98	0.12 ± 0.002	82.23 ± 0.08
BHA	0.19 ± 0.002	71.28 ± 0.11
BHT	0.42 ± 0.010	53.29 ± 0.13
TBHQ	0.09 ± 0.001	88.74 ± 0.07

[a] Defined as the concentration of the compounds that was able to inhibit 50% of the total DPPH radicals.
[b] Data are given as means ± SD, $n = 3$.
[c] % inhibition at 0.5 mg/ml.

3.5. Effect on peroxide value

Peroxide value (*PV*) is a measure of the concentration of peroxides and hydroperoxides formed in the initial stages of lipid oxidation. Peroxide value is one of the most widely-used tests for the measurement of oxidative rancidity in oils and fats. In this paper, oxidation degree on sunflower oil samples was determined by measuring *PV* in the absence and presence of antioxidants at 60 °C for 21 days. The influence of antioxidants during storage on *PV* in the sunflower oil samples is shown in Fig. 3. Results showed that peroxide value increased linearly with storage time and increased in acceleration after the ninth day. Sunflower oil samples without the antioxidant (control) reached a maximum *PV* of 272 ± 0.65 meq/kg after 21 days of storage. A significant difference ($p < 0.01$) in *PV* was observed between the control and sunflower oil samples containing CA and synthetic antioxidants, all of which slowed the rate of peroxide formation. The *PV* of sunflower oil samples with CA25, CA60, CA98, BHA, BHT and TBHQ were 75.7 ± 0.47, 61.5 ± 0.54, 39.4 ± 0.48, 205 ± 0.68, 160 ± 0.55 and 20.0 ± 0.49 meq/kg, respectively. The corresponding inhibition rates were 72.2%, 77.4%, 85.5%, 24.8%, 41.2% and 92.6%, respectively, after 21 days under accelerated storage conditions compared with the control. Furthermore, the antioxidant effects of CA25, CA60 and CA98 were better than BHT and BHA, and with the increase of content of CA, the antioxidant effect was better. However, among these treatments, TBHQ remained the most effective and gave the lowest *PV*.

3.6. Effect on thiobarbituric acid-reactive substances (TBARS)

TBA is defined as the quantity of malondialdehyde (in mg) present in 1 kg of sample. The TBA value is an index of lipid oxidation measuring malondialdehyde (MDA) content. Hydroperoxides, the initial reaction product of PUFA, reacted with oxygen to form MDA, which may contribute to off-flavour of oxidised oils. The method is based on the spectrophotometric quantification of the pink complex formed at an absorbance of 532 nm after reaction of one molecule of MDA with two molecules of 2-thiobarbituric acid (TBA). The effects of CA25, CA60, CA98 and synthetic antioxidants on TBARS values of sunflower oil at 60 °C for 24 days are shown in Fig. 4. TBARS values gradually increased in experimental

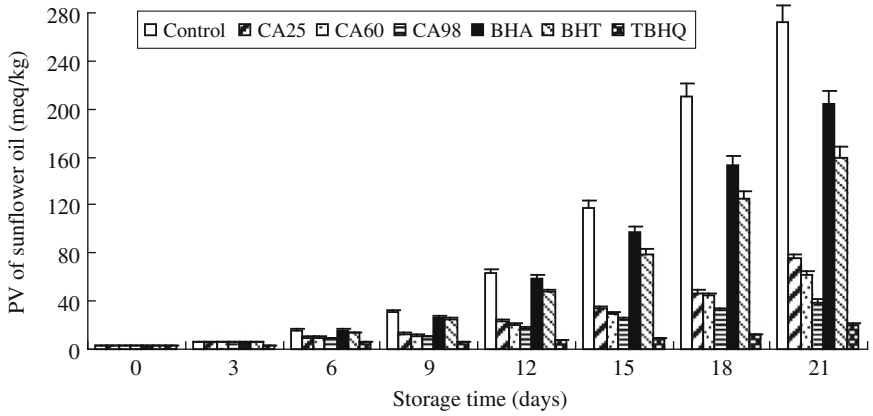

Fig. 3. Effect of adding antioxidants on *PV* of sunflower oil under accelerated storage at 60 °C for 21 days.

sunflower oil during the storage period, with increased acceleration after the fourth day. After 24 days of storage, TBARS value of the control sample reached a maximum of 0.3 ± 0.004 mg/kg, which was 1.86-fold higher than that of the sample treated with CA25, 1.99-fold higher than that of the sample treated with CA60, 2.86-fold higher than that of the sample treated with CA98. Additionally, TBARS value of the control was 1.75-fold, 1.63-fold and 4.35-fold higher than that of the sample treated with BHT, BHA and TBHQ, respectively. A significant difference ($p < 0.05$) was observed. We can see from Fig. 4 that CA inhibited the formation of TBARS at all concentrations: inhibitory effects on TBARS were stronger than BHA and BHT, but lower than TBHQ.

3.7. Effect on free fatty acids content (FFA)

Formation of free fatty acids might be an important measure of rancidity of foods. FFA are formed due to hydrolysis of triglycerides and may get promoted by reaction of oil with moisture (Frega, Mozzon, & Lercker, 1999).

Addition of antioxidants caused significant reductions in FFA of sunflower oil during 21 days' storage at 60 °C, as shown in Fig. 5. It is evident from these results that, as the content of CA increased, inhibitory effects on FFA also increased considerably, which increased acceleration after the ninth day. After 21 days' storage at 60 °C, FFA value of the control sample reached a maximum of 0.71 ± 0.05 mg/g. FFA values of sunflower oil treated with CA25, CA60 and CA98 were 0.45 ± 0.04, 0.42 ± 0.02, and 0.38 ± 0.02 mg/g, whereas values for oil treated with synthetic antioxidants BHA, BHT and TBHQ were 0.46 ± 0.03, 0.34 ± 0.03 and 0.20 ± 0.01 mg/g, respectively (Fig. 5). Significant differences ($p < 0.05$) in free fatty acids were observed between the control and the sunflower oil treated with CA25, CA60, CA98 and synthetic antioxidants. However, inhibitory effects of CA25, CA60 and CA98 on FFA were better than those of BHT, but lower than BHA and TBHQ.

3.8. Effect on p-anisidine value

p-Anisidine value (*AnV*) plays an important role in the oxidation process of edible oil and edible fats. Calculating *AnV* is one of the oldest methods for evaluating secondary lipid oxidation. It is based on the reactiveness of the aldehyde carbonyl bond on the *p*-anisidine amine group, leading to the formation of a Schiff base that absorbs at 350 nm (Laguerre, Lecomte, & Villeneuve, 2007):

$$\mathrm{R{=}CH{=}O + H_2N{-}\Phi{-}OMe \rightarrow R{-}CH{=}N{-}\Phi{-}OMe\ (Schiff\ base) + H_2O} \quad (1)$$

Results of *AnV* measurements are very similar to the results of TBARS values measurements, as shown in Fig. 6. We can see *AnV* increased significantly throughout the storage time, which increased in acceleration after the sixth day. Addition of CA25, CA60 and CA98 caused significant reduction in *AnV* of sunflower oil during 21 days' storage at 60 °C. It is evident from these results that, the same order of CA efficiency was observed as the content of CA increased, inhibitory effects on *AnV* also increased considerably, better than BHA and BHT but lower than TBHQ.

This difference in antioxidant activity may be accounted for on the basis of chemical structures. The stability of phenoxy radicals reduces the rate of propagation and further reactions and thus increases the oxidative stability of lipids (Gordon, 1990), with

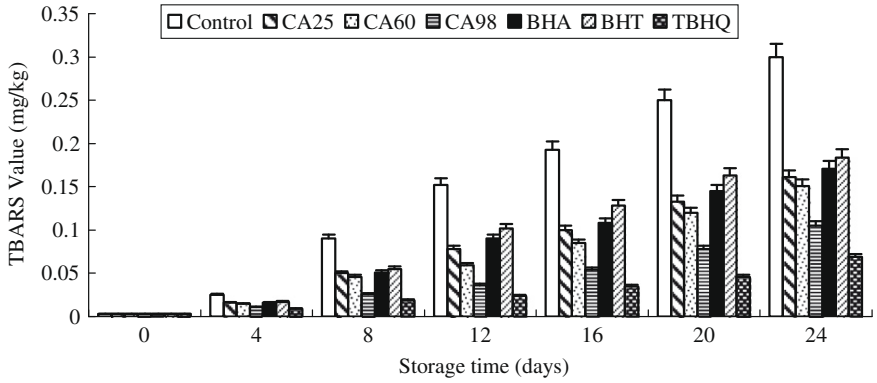

Fig. 4. Effect of adding antioxidants on TBARS of sunflower oil under accelerated storage at 60 °C for 24 days.

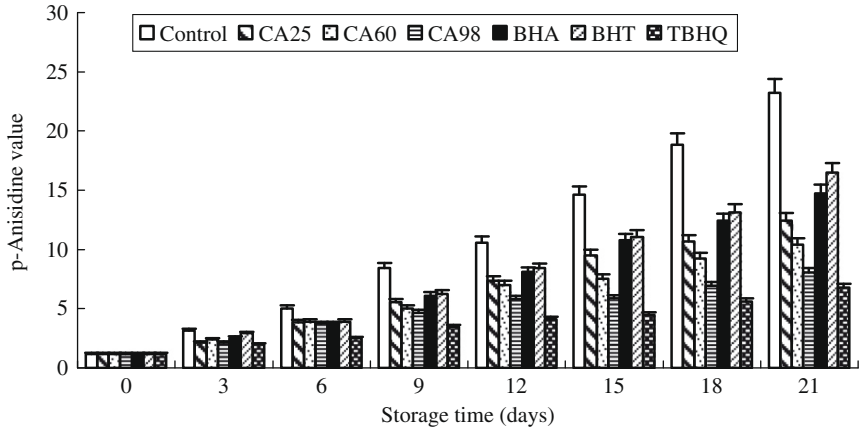

Fig. 6. Effect of adding antioxidants on *p*-anisidine value (*AnV*) of sunflower oil under accelerated storage at 60 °C for 21 days.

two phenolic hydroxyl groups (Fig. 1) being responsible for the higher antioxidant activity of CA. In addition, in most cases, of all the test compounds, the synthetic antioxidant TBHQ which has two *para*-hydroxyl groups can make the phenols more easily donate hydrogen atoms to active free radicals to interrupt the chain reaction of antioxidation (Jiang & Wang, 2006) and this is responsible for superior antioxidant activity in various edible oils (Madhavi, Singhal, & Kulkarni, 1995). In this study, in comparison with synthetic antioxidants, in addition to existing structural differences, effects of CA content may also play an important role in the observed trends.

4. Conclusions

Generally, results of the present study apparently indicated that CA25, CA60 and CA98, separated from rosemary dried leaves, executed very good antioxidant activity.

Though sunflower oil is difficult to stabilise because of high linoleic acid content, CA25, CA60 and CA98 were proved to show strong protective effects against lipid oxidation of sunflower oil during accelerated storage. They showed content-dependent inhibitory effects on retarding lipid oxidation of sunflower oil. This is in accordance with results of Braida, Mattea, and Cardarelli (2008) and Trojakova, Reblova, Nguyen, and Pokorny (2001), who have reported that there was high correlation between the carnosic acid content and the protection factor in high linoleic acid content oil. Also, CA98 was to a greater extent more effective than commonly-employed synthetic antioxidants BHT and BHA, but less effective than the synthetic antioxidant TBHQ. This is in accordance with results of Aruoma et al. (1992) who reported that in soybean oil carnosic acid was more active than BHT and BHA, but less active than TBHQ. Results observed in our experiments showed that CA25, CA60 and CA98 could be considered as satisfactory for large scale applications.

Pasting

ABSTRACT

The effect of betacyanin pigments from *Amaranthus tricolor* on the functional properties and colour of wheat flour in relation to the quality of Asian salted noodles was studied. Addition of *Amaranthus* pigments significantly decreased the viscosity of wheat flour pastes as well as hardness and adhesiveness of the gels. Low levels of *Amaranthus* pigments (0.1% and 0.5%) imparted a more pink shade to flour gels, dried raw noodles, and cooked noodles, whereas higher levels (1.0% and 2.0%) gave a more red shade with decreased brightness. Pigment addition at low levels had no significant effect on the cooking and textural properties of noodles, whereas high level (2.0%) did have a significant influence. Several RVA and textural parameters of wheat flour pastes and gels were highly correlated to quality of cooked noodles and may be used in predicting actual noodle quality in the presence of *Amaranthus* pigments.

1. Introduction

The perception of flavour is intrinsically linked to multisensory interactions including colour when tasting food (Auvray & Spence, 2008). Colour interferes with our judgments on flavour perception. For example, colour has been shown to be able to quantitatively replace sugar and still maintain sweetness perception in flavoured foods. Colour has also been indicated to considerably affect the acceptability of foods and is strongly related to different social segments (Clydesdale, 1993). It plays a critical role in the attractive appearance of beverages and foods. Favourable colour tone stimulates our appetite and contributes significantly to our enjoyment of foods (Auvray & Spence, 2008). For example, colour of tomato concentrates, whose colorant is mainly beta-carotene, has been shown to play an essential part in consumers' preference (Hayes, Smith, & Morris, 1998).

Many colorants are more than just for appearance. Natural pigments, such as carotenoids, anthocyanins, and betalains, can not only enhance the sensory properties of food products, but also functionally improve their nutritional quality due to their potential role in human health as natural antioxidants (Cai, Sun, & Corke, 2003; Stintzing & Carle, 2004). It has been shown that anthocyanins from various plants can be beneficial due to their potential bioactivities such as anti-carcinogenicity, anti-mutagenicity, anti-inflammation, protection against age-related declines of neuronal signal transduction, and cholesterol reduction (Galvano et al., 2004). It has also been clinically proved that consumption of cactus pear fruit, which is rich in betalain pigments with good antioxidant capacity, can positively influence the redox balance in human body, decrease oxidation to lipids, and improve antioxidant status in healthy humans (Tesoriere, Butera, Pintaudi, Allegra, & Livrea, 2004). Betanin, a major class of betalain, can inhibit the myeloperoxidase/nitrite-induced oxidation of human low-density lipoproteins by scavenging the initiator radical nitrogen dioxide and lipoperoxyl radical (Allegra, Tesoriere, & Livrea, 2007). Extracts from *Amaranthus spinosus* could inhibit spontaneous and dexamethasone-induced apoptosis in murine primary splenocytes (Lin, Li, & Lin, 2008).

Betalains, as a promising novel colorant with great potential for human health, has been recently gained increased research focus (Stintzing & Carle, 2004). Many new betalains, including the yellow betaxanthins and red or violet betacyanins, have been identified and characterised from various plant or fungal sources (Kumar & Sinha, 2004). Among them, *Amaranthus* betacyanin pigments from various species in the family Amaranthaceae have also been systematically researched (Cai, Sun, & Corke, 2005). It has been shown that betacyanins from plants in the Amaranthaceae could be good natural antioxidants against free radicals (DPPH·) *in vitro* (Cai et al., 2003). However, *Amaranthus* betacyanin pigments are not as developed or commonly used globally as betalains colorants from red beet, though some *Amaranthus* species have higher biomass yield potential than red beet. Cai and Corke (1999) applied betacyanin pigments from *Amaranthus cruentus* in model food systems, i.e. jelly, ice cream, and beverage for colouring and concluded that betacyanins may be a feasible natural colorant for jelly, higher

doi:10.1016/j.foodchem.2009.05.041

pH beverages, and ice cream under selected conditions. Another preliminary study showed that *Amaranthus* betacyanin pigments might be used as an efficient colorant in wheat-based system (Zhu, Cai, Sun, & Corke, 2008). However, no scientific report has been found on the application of *Amaranthus* betacyanins in staple foods.

Asian noodles are one of the most popular cereal foods. Noodles in various formulations and shapes have been staple foods for many Oriental countries since ancient times. Major types of Asian noodles are white salted noodles and yellow alkaline noodles. These two noodle types differ greatly in various aspects such as formulation, production procedures, and sensory attributes (Corke & Bhattacharya, 1999). Noodle quality has various aspects: appearance, eating quality, taste, cooking properties, etc., and is influenced by various factors such as the composition of protein subunits and starch properties (Corke & Bhattacharya, 1999). Though coloured pasta and bread products can be seen in the marketplace, no scientific report has been found on the development of novel coloured noodles incorporated with *Amaranthus* betacyanins.

Amaranthus tricolor was selected for this study because of its good colouring efficacy for foods and high biomass for betacyanin production, compared with other *Amaranthus* species (Cai et al., 2005; Zhu et al., 2008). Furthermore, pigment extract from *A. tricolor* (code: GB08.130) has been legally approved as a natural colorant according to Hygienic Standards for Food Additives in China (GB 2760-1996).

The objective of this study was to evaluate the effect of *Amaranthus* betacyanin pigments from mature leaves of *A. tricolor* in Asian salted noodles. This study may stimulate further utilisation of betalains as natural food colorants in novel food product development.

2. Materials and methods

2.1. Wheat flour

'Red Bicycle' brand, commercial wheat flour made from U.S. hard red winter wheat, was purchased from Hong Kong Flour Mills (Kowloon, Hong Kong). Proximate analysis (crude protein, ash, crude fat) of wheat flour (wet basis) was performed according to AACC methods in triplicate and the results were expressed as average. Moisture content was obtained using LJ16 Moisture Analyser (Mettler-Toledo, Switzerland). The contents of crude protein, ash, crude fat, and moisture were 11.6%, 0.43%, 1.35%, and 13.2% (w/w), respectively.

2.2. Amaranthus betacyanin pigments

The mature leaves of *A. tricolor* (Tr35) grown in Wuhan, Hubei Province, China were collected. Pigment extraction followed previous methods (Cai, Sun, & Corke, 2001) with minor modification. Briefly, the fresh leaves were washed, cut into small pieces, and extracted, followed by centrifugation, concentration, and freeze drying. The dried pigment extracts were tightly sealed in plastic bags and stored at 4 °C in the dark until use. The betacyanins in these two pigment extracts were identified as amaranthin and its isomer (Cai et al., 2001). On the basis of spectrophotometeric analysis, total betacyanin concentration of *A. tricolor* pigment extract was 86.5% (w/w, dry basis) (Zhu et al., 2008).

2.3. Pasting analysis

Pasting properties of various wheat flour systems were determined using a Rapid Visco Analyser (RVA, Model 3D, Newport Scientific, Warriewood, Australia) with Thermocline for Windows software (Version 2.0). Suspensions of pure double deionized water (24.6 g) with pure wheat flour (3 g, dry basis) as control, or flours (3 g, dry basis) with addition of pigment powder (28 mg, 140 mg, 280 mg, and 560 mg, respectively), were prepared to give a series of concentration of 0.0%, 0.1%, 0.5%, 1.0%, and 2.0% (w/w) *Amaranthus* betacyanins in the canisters, respectively. The suspension was then manually homogenised using the plastic paddle to avoid lump formation. Then, the pH of the wheat flour–water–pigments slurry was recorded by a pH meter (Orion model 720A, Boston, MA, USA) right before the RVA test. A programmed heating and cooling cycle (22 min) was used (Zhu et al., 2008). The samples were held at 50 °C for 1 min, heated to 95 °C in 7.5 min, held at 95 °C for 5 min before cooling to 50 °C in 7.5 min and holding at 50 °C for 2 min. The peak time (PT), peak viscosity (PV), hot paste viscosity (HPV), cool paste viscosity (CPV) and their derivative parameters: breakdown, BD = PV–HPV, setback, SB = CPV–PV were recorded. The viscosities were expressed in Rapid Visco Units (RVU). All tests were performed in triplicate.

2.4. Salted noodle preparation

Noodle making followed the previous methods (Sui, Lucas, & Corke, 2006; Wu & Corke, 2005) with some modifications. Wheat flour (30.0 g, moisture basis) was mixed with 10.0 g of 6% (w/w) NaCl solution to make salted noodles as control. For pigmented noodle production, *Amaranthus* betacyanins pigment powder (40 mg, 200 mg, 400 mg, and 800 mg) was completely dissolved in 10.0 g of 6% (w/w) NaCl solution before 30.0 g of wheat flour was added for mixture. The mixture was manually kneaded for 5 min in a plastic bowl to obtain a crumbly dough ball. After resting for 5 min in the bowl, the crumbly dough was then sheeted through the first roll gap 15 times and folded in half each time on a domestic-type electric pasta machine (Atlas Electric model 150, Marcato Co., Campodarsego, Italy). Then the dough sheet was further passed through the next six successively reduced gaps 8 times each without intermediate resting. Finally, the resultant thin dough sheet was cut through a slitter to produce noodles of around 2 mm width. The raw noodles were placed on tissue to dry at 25 °C for around 8 h in an oven with the ventilation setting for fresh air at six (maximum) (Model 600, Memmert Co., Schwabach, Germany). The dried raw noodles were stored in transparent plastic bags at room temperature (23–26 °C) until use within a week. For each group, final *Amaranthus* betacyanins pigment content of the noodles were 0%, 0.1%, 0.5%, 1.0%, and 2.0% (w/w), respectively.

2.5. Cooking properties

Noodle cooking followed the previous methods (Sui et al., 2006; Wu & Corke, 2005) with some modifications. After storage for one day and seven days, dried raw noodles (5 g) were cooked in boiling water (300 mL) in a beaker with lid for 5 min until the white core disappeared. They were cooled in cool water (~20 °C) for 10 s before dried on a paper towel for 15 min until further texture and colour testing.

For cooking yield and loss analysis, cooked noodle strands on the paper towel were softly blotted for about 1 min to remove the excess surface moisture on the noodles surface. Cooking yield (CY) was calculated as:

$$CY = Mco/Md$$

where Mco = weight of cooked noodles (g); Md = weight of dried raw noodles (g).

After cooking, the remaining water (~300 mL) in the beaker was further boiled for evaporation until around 20 mL was left. Then the beaker with left water was further dried in an oven at

95 °C until constant weight (Mc, g). Cooking loss % (CL) was calculated as:

$$CL\,\% = (Mc - Mb) \times 100/(Md - Mm)$$

where Mb = weight of beaker (g); Mm = weight of moisture in dried raw noodles. All analysis was conducted at least in triplicate.

2.6. Colour analysis

The Hunter colour parameters *L*, *a*, and *b* (CIE 1976) were measured by a colorimeter (Chroma Meter CR-301, Minolta Co., Osaka, Japan) through round plastic optical cells (21 mm in diameter and 5 mm in depth), standardised with calibration plate sets CR-A47 and a white plate. Colour results were expressed as tristimulus parameters (*L*, *a*, *b*, *C*, and *H*). *H* (hue angle = arctan *b*/*a*) indicates sample colour (0° or 360° = red; 90° = yellow; 180° = green; 270° = blue), and *C* [Chroma = $(a^2 + b^2)^{1/2}$] indicates colour purity or saturation (higher values are more vivid). All measurements were performed at least in triplicate.

Colour characteristics of flour gels during storage for one week were determined on the wheat flour gels from the RVA analysis. Gels were transferred into screw-capped and transparent cylinder plastic cups (5.5 cm in diameter and 5.5 cm in height for the cups, and around 1.1 cm in thickness for the gels in cup) right after RVA testing. The cups were sterilized beforehand by wiping with ethanol and subjecting to violet ray to prevent microbial growth. Colour characteristics of dried raw noodles were determined on their surface. Colour characteristics of cooked noodles were measured on their surface at around 20 min after cooking.

2.7. Textural analysis of flour gels and cooked noodles

All texture properties were analysed with an SMS Model TA-XT2*i* texture analyser (Stable Micro Systems Ltd., Godalming, Surry, England) equipped with Texture Expert software (version 1.2). The methods followed the previous studies (Collado & Corke, 1997; Wu & Corke, 2005; Zhu et al., 2008) with some modifications.

For the texture of flour gels, after RVA testing, the paddle was removed immediately and the paste in the canister was sealed tightly by parafilm and stored at room temperature for 24 h before testing. The testing mode was Texture Profile Analysis (TPA). The probe was a flat-ended stainless steel cylinder probe with a diameter of 5 mm (P/5). The pre-test, test, and post-test speeds were 1 mm/s. The distance in strain was 30%. The trigger type was auto with a trigger force of 2.0 g. The data acquisition rate was 25 pps.

For the tensile and compression tests of cooked noodles, noodles were cooked in separated batches and got tested separately between 15 and 20 min after cooking to avoid rapid textural changes of cooked noodles right after cooking (Corke & Bhattacharya, 1999). For tensile strength analysis, the instrument was equipped with spaghetti/noodle tensile grips (A/SPR). The noodle strand was winded two, three or four times around parallel friction roller of the grip to anchor the samples and avoid slippage. The distance between the parallel rollers was 4 cm. The mode was measure force in tension. Pre-test and test speeds were 3.0 mm/s, post-test speed was 3.0 mm/s. Distance was 100 mm. The trigger type was auto with a trigger force of 5.0 g. The data acquisition rate was 200 pps. The maximum force required to break down the strand was termed tensile force (g). At least 10 individual strands were tested for each group. The five minimum values were discarded. For compression analysis, the probe was a cylinder probe with a diameter of 36 mm (P/36). The mode was measure force in compression with single cycle. The pre-test, test, and post-test speeds were 2 mm/s. The strain was 30%. The trigger type was auto with a trigger force of 5.0 g. The data acquisition rate was 200 pps. Two noodle strands were put parallel on the platform and tested close together at a time. The maximum force (g) was noted firmness. For at least 6 times was tested each group.

2.8. Scanning electron microscopy (SEM)

Dried noodles stored at room temperature for a week were manually broken to expose the cross-sectional surface. The surfaces of both noodles and its cross-section were mounted on a silver specimen holder and coated with gold–palladium alloy under vacuum for 60 s. Morphology was randomly investigated by a Scanning Electron Microscope Hitachi S-4800 FEG (Tokyo, Japan). The images were obtained at an accelerating voltage of 5.0 kV at various magnifications.

2.9. Statistical analysis

Data analysis and statistical computations for analysis of variance (ANOVA), Pearson correlation analysis and Duncan's test were performed with the Statistical Analysis System (SAS Institute Inc., Cary, N.C., USA) and Microsoft Office Excel (Microsoft Corporation, Redmond).

3. Results and discussion

3.1. Effect of Amaranthus betacyanin pigments on the pasting properties of wheat flour

Addition of *Amaranthus* betacyanin pigments at various levels (0.1–2.0%) generally decreased the pasting viscosities of wheat flour (Table 1). *Amaranthus* betacyanin pigments at a concentration of 2.0% achieved the greatest reduction in both paste viscosity and peak time (PT), whereas that of 0.1% least changed them. Peak viscosity (PV) with addition of *Amaranthus* betacyanin pigments at 0.1% (229 RVU) was not significantly different to control (234 RVU). Addition of betacyanin pigments at higher levels significantly reduced PV (PV at 1.0% and 2.0% of 210 and 209 RVU, respectively). For hot paste viscosity (HPV), addition of *Amaranthus* betacyanin pigments at all levels decreased HPV considerably in a dose-dependent manner (the lowest value 52 RVU at 2.0%),

Table 1
Influence of *Amaranthus* betacyanin pigments on the pasting and gelling properties of wheat flours[a].

Pigment concentrations (%) (w/w)	pH	PV (RVU)	HPV (RVU)	BD (RVU)	CPV (RVU)	SB (RVU)	PT (min)	HD (g)	ADH (g s)	COH
0.0	5.92a	234a	126a	108a	251a	125a	9.00ab	11.9a	13.9a	0.436a
0.1	5.93a	229a	113b	116b	218b	106b	9.04a	10.1b	12.2a	0.518ab
0.5	5.87b	218b	81c	137c	162c	81c	8.97ab	7.5c	9.4b	0.524ab
1.0	5.79c	210c	67d	143d	137d	69d	9.02ab	5.6d	6.9c	0.580b
2.0	5.65d	209c	52e	157e	102e	50e	8.93b	3.7e	4.2d	0.776c

[a] Values in the same column with the same letters do not differ significantly ($p < 0.05$); PV = peak viscosity; HPV = hot paste viscosity; BD = breakdown; CPV = cold paste viscosity; SB = setback; PT = peak time; HD = hardness; ADH = adhesiveness; COH = cohesiveness.

compared with control (126 RVU). Breakdown (BD) is the derivative of PV and HPV and showed similar but negative trend with HPV. Pigment addition did not alter peak time (PT) except for a small effect at 2.0%. Cold paste viscosity (CPV) was considerably reduced in a dose-dependent manner (lowest value at 102 RVU at 2.0%), compared with control (251 RVU) by addition of the pigment. Setback (SB) is a derivative of CPV and PV and showed similar trend with CPV.

Pasting properties of flour are primarily related to the swelling and rupture of starch granules in a system (Rojas, Rosell, & de Barber, 1999). Different food additives in the system can alter the pasting behaviour to various extents. Several previous studies showed that sugars and sugar alcohols could increase the viscosity of various starch–water systems, depending on the type used (Gunaratne, Ranaweera, & Corke, 2007). For example, addition of various polyhydroxy compounds, i.e. sucrose, glucose, glycerol, and hydroxypropyl beta-cyclodextrin, increase all the pasting parameters of potato and wheat starches (Gunaratne et al., 2007). However, no such trend was observed here. On the other hand, acid treatments of various starches could decrease all the pasting parameters and increase the gelatinization parameters and cause early development of peak viscosity and delay the onset of gelatinization (Gunaratne & Corke, 2007). For example, hydrochloric acid treatments reduced peak viscosity (PV) in wheat, potato, and maize starches, both modified and unmodified (Gunaratne & Corke, 2007). This trend was also observed in this study. pH of the system has also been reported to be critical for the pasting and gelatinization behaviour of various starch and flour (Bao & Corke, 2002; Rodriguezsosa, Parsiros, & Gonzalez, 1981). For example, lower pH could result in viscosity reduction of pasting for rice flours (Bao & Corke, 2002). In this study, addition of betacyanin pigment reduced the pH of the suspension in the first place with the level at 2.0% achieved the greatest reduction by 0.27 with the exception of 0.1% which showed little effect (Table 1). The major constituents of *Amaranthus* betacyanin pigment are amaranthin and its isomer (Cai et al., 2001; Herbach, Stintzing, & Carle, 2006; Zhu et al., 2008). When subjected to heating, amaranthin and its isomer would degrade into a series of related chemicals with acid moieties (Herbach et al., 2006). Structurally, these compounds possess the sugar (glucose) and acid moieties (glucuronic acid and betalamic acid), and effect of the latter might surpassed the former as the data shown (Table 1). They may subject the wheat flour to acid presence during pasting and also altered the pH of the system as shown in Table 1.

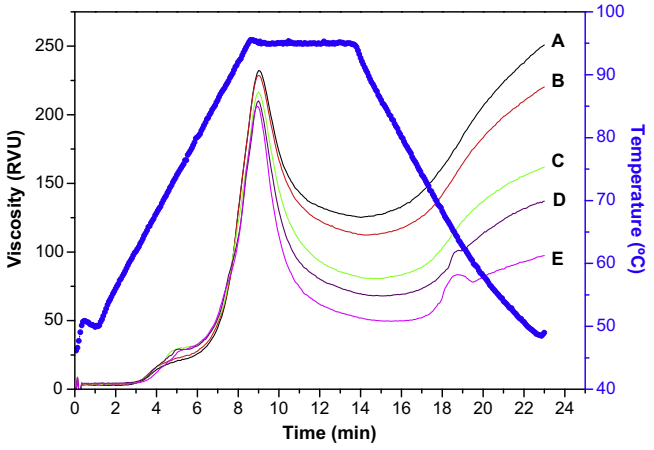

Fig. 1. Pasting characteristics of Red Bicycle flour as affected by *Amaranthus* betacyanin pigments at various concentration. (A) control; (B): 0.1%; (C): 0.5%; (D): 1.0%; (E): 2.0%.

Bump area appeared in the pasting profile during the cooling stage for pigment addition at concentrations of both 1.0% and 2.0% (Fig. 1). No observable bump area was noted for lower pigment concentrations (0.1% and 0.5%) or control. The bump area has been positively related with the extent of the formation and content of amylose–lipid complex during the cooling phase (Rojas et al., 1999). The amylose–lipid complex can retard the retrogradation of various gelatinized starch systems (Eliasson, 1994). Higher pigment concentration (2.0%) increased the size of the bump area compared with that at 1.0%, indicating that addition of betacyanin pigments could facilitate the formation of complex between amylose and free lipids present in wheat flour (1.35%).

3.2. Effect of Amaranthus betacyanin pigments on the textural properties of flour gels

Addition of *Amaranthus* betacyanin pigments at various levels generally decreased gel hardness (HD) and adhesiveness (ADH) and increased cohesiveness (COH) generally in a dose-dependent manner (Table 1). For example, addition of betacyanin pigments at 2.0% caused the greatest reduction in both HD and ADH by 8.2 g and 9.7 g s, respectively, and increased COH by 0.340. Statistically, pigments concentration at 0.1% showed no effect on both ADH and COH, whereas 0.5% had no effect on COH. Flour gel formed after gelatinization is a result of starch retrogradation, in 24 h mainly being attributed to amylose re-association and aggregation (Wang & Wang, 2001). As discussed in Section 3.1, amaranthin and its isomer isoamaranthin in the *Amaranthus* pigments may adversely affect molecular environment for amylose re-association, interacting with starch amylose chains, hinder amylose aggregation via hydrogen bonding in the paste, thus resulting softer gels (Gunaratne & Corke, 2007).

Pearson correlation analysis showed that several gel textural parameters correlated well with pasting parameters. For example, CPV was highly positively correlated with HD ($r = 0.997$), and BD with ADH ($r = 0.997$); whereas COH was highly negatively correlated with SB ($r = -0.898$). This is in accordance with previous studies (Wu & Corke, 1999).

3.3. Effect of Amaranthus betacyanin pigments on the colour of flour gels, dried, and cooked noodles

Addition of *Amaranthus* betacyanin pigments at various levels significantly ($p < 0.05$) changed the colour characteristics of wheat flour gels, and both dried and cooked noodles, imparting to all products shades of pink-redness to various extents (Table 2). The shades of gels, dried noodles, and cooked noodles for the control were generally in light grey with the low colour purity (C) compared with pigment-treated samples.

Addition of pigments significantly decreased lightness (L) of all products after cooking at day 1 and day 7 in a dose-dependent manner with the greatest reduction at 2.0% pigment addition. For example, at day 1, 2.0% level reduced lightness (L) by 32.8, 40.9, and 32.0 for gels, dried, and cooked noodles, respectively. High negative correlation existed between *Amaranthus* pigment concentration and lightness (L) of flour gels, dried, and cooked noodles ($p < 0.05$). For example, correlation coefficients (r) between pigment concentration and L of cooked noodles at day 1 and day 7 were −0.914 and −0.919, respectively. Addition of pigments considerably increased Chroma (C) of gels, dried, and cooked noodles, but not in a dose-dependent manner. For example, at day 1, 0.5% level most increased C of flour gels by 18.3, whereas 2.0% level most increased C of cooked noodles by 21.2, compared with control (1.8). Addition of pigments considerably imparted pink-redness to gels, dried, and cooked noodles as reflected in hue angle (H). For example, at day 1, addition of pigment at 2.0% decreased H of

Table 2
Influence of *Amaranthus* betacyanin pigments on the colour of flour gels, dried noodles and cooked noodles at day 1 and day 7[a].

Samples	Pigment concentrations (%) (w/w)	Day 1			Day 7

	2.0	38.7e	33.6e	357.4d	35.7e	32.2c	357.4d
Cooked noodles	0.0	73.9a	6.3a	99.1a	72.8a	6.2a	99.4a
	0.1	65.2b	10.3b	22.2b	65.7b	11.8b	23.7b
	0.5	54.0c	20.8c	8.5c	53.5c	20.2c	11.6c
	1.0	49.4d	23.5d	11.5d	50.2d	27.5d	11.6c
	2.0	41.9e	27.5e	9.5e	42.1e	30.0e	11.3c

[a] Values in the same column with the same letters do not differ significantly ($p < 0.05$); *L* = lightness; *C* = Chroma; *H* = hue angle.

cooked noodles from 99.1 (control) to 9.5 which is very "red". Generally, pigment addition levels at 0.5%, 1.0%, and 2.0% achieved more or less similar *H*. This indicated that efficient adjustment in pigment addition level could be done without compromising the colour shade or colour purity.

Cooking either increased or decreased lightness (*L*), depending on the pigment concentrations. Storage treatment didn't alter this trend. Take lightness changes at day 1 for example, cooking decreased *L* of control by 5.7. As for the noodles treated at lower pigment concentration (0.1% and 0.5%), cooking decreased their lightness, however, noodles with higher pigment concentration (1.0% and 2.0%) had the opposite trend. Cooking treatment generally decreased *C* and altered *H* with the greatest reduction at 0.1% pigment addition (16.9 for *C*, and 27.3 for *H*), whereas *C* and *H* were altered the least at 2.0% pigment addition (6.1 for *C*, and 12.1 for *H*). This indicated that increasing pigment concentration to certain degree may be used as an effective way to protect colour loss during noodle cooking.

Colour stability during storage could be reflected from the changes in colour parameters between day 1 and day 7. Dried noodles treated with *Amaranthus* betacyanin pigments at lower concentration showed much better colour stability compared with the flour gels which had much higher moisture content. The former had average moisture of 8.31% and the latter 90%. For example, with 0.5% betacyanin pigments, the change in *H* for flour gel from day 1 to day 7 was 10.8 whereas that for dried noodles was only 0.5. Higher pigment concentration increased colour stability for the flour gels. For example, the change in *H* for flour gel at 0.1% pigment concentration was 38.8, whereas that of 2.0% was only 2.3. This is generally consistent with previous studies (Zhu et al., 2008). *Amaranthus* betacyanin pigment used in wheat flour gels at 4 °C showed great stability (Zhu et al., 2008). In this study, the storage temperature was much higher (23–26 °C) and the colour stability was lower compared that at 4 °C reported in that study (Zhu et al., 2008), indicating that lower temperature could favour the colour retention in wheat gel system during storage.

3.4. Effect of Amaranthus betacyanin pigments on the microstructure of dried noodles

The surface and cross-section of dried raw noodles were examined using Scanning Electron Microscopy at magnifications of 1000 and 1500 (Fig. 2). Cross-sectional surfaces of dried noodles were heavily covered by non-uniform amorphous gluten protein. The starch granules (both the large size type A and small size type B) were imbedded deeply in the gluten network (Fig. 2A). Morphology of dried noodle surface (Fig. 2B) differed greatly from their cross-section. The starch granules were more clearly visible compared with their cross-sectional counterpart. The cracks between starch granule (type A) and gluten network were obvious, which might be attributed to the drying processing. No apparent distinction

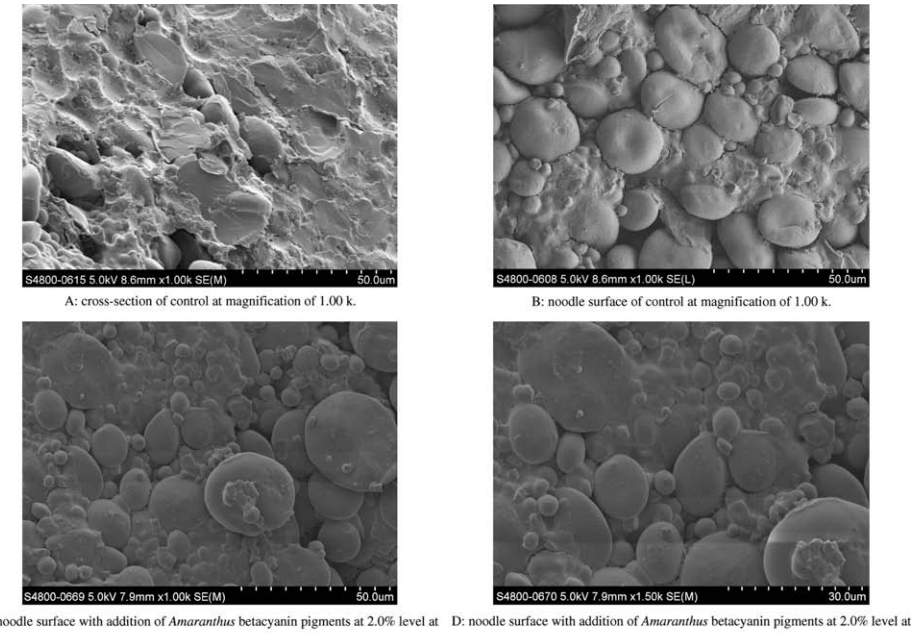

Fig. 2. Scanning electron micrographs of surface and cross-section of dried raw noodles at day 7. (A) cross-section of control (×1.0 k); (B) noodle surface of control (×1.0 k); (C) noodle surface with addition of *Amaranthus* betacyanin pigments at 2.0% level (×1.0 k); (D) noodle surface with addition of *Amaranthus* betacyanin pigments at 2.0% level (×1.5 k).

Table 3
Influence of *Amaranthus* betacyanin pigments on the textural and cooking properties of cooked noodles at day 1 and day 7[a].

Pigment concentrations (%) (w/w)	Day 1				Day 7			
	Tensile (g)	Firmness (g)	Cooking yield	Cooking loss (%)	Tensile (g)	Firmness (g)	Cooking yield	Cooking loss (%)
0.0	11.4ab	3061.5a	2.98a	0.39a	12.3a	2848.0a	2.95ab	0.38ab
0.1	12.3a	2984.3ab	2.91a	0.42a	11.0ab	2835.8a	2.92bc	0.31a

2.0	10.3b	2740.2c	2.71b	0.63b	10.1b	2547.1b	2.79c	0.54c

[a] Values in the same column with the same letters do not differ significantly ($p < 0.05$).

was observed on the micro-morphology of cross-section between control and samples treated with pigments. However, the surface of noodle with betacyanin pigment addition at 2.0% (Fig. 2C and D) was more coherent and smoother between gluten network and starch granules than the control (Fig. 2B), indicating that betacyanin pigment presence could improve the surface connectivity between starch granules and gluten for dried raw noodles, which may further influence the surface properties of cooked noodles (Ross, 2006).

3.5. Effect of Amaranthus betacyanin pigments on the textural and cooking properties of cooked noodles

Addition of *Amaranthus* betacyanin pigments influenced the textural and cooking properties of cooked noodles to various extents (Table 3). Addition of betacyanin pigments at low concentration had no significant effect on the tensile force ($p < 0.05$). For example, at day 7, addition levels at 0.1%, 0.5%, and 1.0% did not significantly change the tensile force compared with control. However, addition of 2.0% considerably decreased the tensile force by 2.2 g, compared with control (12.3 g). Similar trend was also found on day 1 test.

Compression tests were employed to assess the deformation properties of cooked noodles. The data in Table 3 indicated that only at higher concentrations did the addition of betacyanin pigments decrease the firmness of the cooked noodles. Similar trends were observed both at day 1 and day 7. For day 1, addition at 1.0% and 2.0% significantly reduced the firmness by 226.1 and 321.3 g, respectively, compared with control (3061.5 g), whereas lower addition levels had no effect ($p < 0.05$). For day 7, only addition level at 2.0% significantly reduced the firmness (by 300.9 g), in comparison with control (2848.0 g), whereas lower addition levels had little effect. It was reported that pH reduction in wheat flour dough could result in dough with less shear thinning and subsequently tensile strength and cutting force of extruded noodles, as well as increased gelatinization degree and cooking loss, whereas pH increase could increase both the tensile strength and cutting force (Shiau & Yeh, 2001). In this study, the decreases in both firmness and tensile strength in the presence of *Amaranthus* pigments may be attributed to the pH reduction effect caused by *Amaranthus* betacyanin pigments as discussed in pasting session. The trends in the changes of both firmness and tensile strength as affected by the betacyanin pigments were similar. This was generally in agreement with previous studies that some instrumental descriptors for noodle texture as well as wheat flour properties could be positively correlated (Shiau & Yeh, 2001; Lee et al., 2008).

After storage at room temperature for a week, the tensile force of noodles with or without pigment addition did not significantly vary, whereas the firmness of the noodles of both control and those with pigments was reduced to various extents. For example, during a week of storage the firmness of the control decreased by 213.5 g, whereas that of cooked noodles at 2.0% pigments addition level decreased by 203.1 g. This may be due to the endogenous amylase enzyme in the wheat flour which could soften the texture of noodles during storage (Cato, Halmos, & Small, 2006).

Noodles with high quality should require a minimum loss of solids into the water to maintain their integrity during cooking. And water absorption capacity of noodles could be reflected in their cooking yield. At day 1, addition of *Amaranthus* betacyanin pigments at lower levels (0.1% and 0.5%) did not affect both cooking yield and cooking loss significantly ($p < 0.05$). However, pigment addition at 2.0% increased cooking loss and decreased cooking yield significantly ($p < 0.05$), compared with control (0.39%). This indicated that addition level of pigment could be adjusted without compromising cooking properties of the noodles (e.g. cooking loss). At day 7, similar trends were observed on both the cooking loss and yield that pigment addition at 2.0% significantly increased the former and decreased the latter, indicating that noodle cooking quality was stable during one week storage at room temperature.

Pasting and textural properties of wheat flour correlated well with some parameters of noodle textural and cooking properties. The concentration of *Amaranthus* betacyanin pigments significantly and negatively correlated with noodle's firmness at both day 1 ($r = -0.970$) and day 7 ($r = -0.954$), whereas it highly and positively correlated with cooking loss at both day 1 ($r = 0.869$) and day 7 ($r = 0.871$). CPV and SB of wheat flour positively correlated with firmness of cooked noodle at day 1 ($r = 0.963$ and 0.968), and also at day 7 to some extent ($r > 0.8$). This was partially in agreement with previous studies on sweetpotato starch noodles (Collado & Corke, 1997). The flour gel textural properties also showed some high correlation with noodle quality. For example, hardness (HD) of the gels positively and highly correlated with cooked noodles' firmness at day 1 and day 7 ($r = 0.980$ and 0.819), whereas cohesiveness (COH) negatively and significantly correlated with cooked noodles firmness at day 1 and day 7 ($r = -0.951$ and -0.968). This was partially consistent with previous studies on rice noodles which suggested that some physicochemical properties of rice flour could be high correlated with quality of cooked rice noodles (Bhattacharya, Zee, & Corke, 1999). In this study, correlation analysis indicated that gels from RVA test or parameters from pasting analysis, which could be easily and accurately obtained, could be employed as alternative methods to predict the quality of wheat noodles in the presence of *Amaranthus* betacyanin pigments.

4. Conclusions

Addition of *Amaranthus* betacyanin pigments significantly decreased the pasting viscosities of wheat flour in a dose-dependent manner. Addition of pigment at 2.0% decreased the peak time. Addition of *Amaranthus* pigments decreased the hardness and adhesiveness of the gels from the RVA test and increased their cohesiveness. *Amaranthus* pigments imparted to Asian salted noodles and flour gels a colour shade of pink or red, with great colour stability during one week storage at room temperature. Addition of

Amaranthus pigments had no observable influence on the microstructure of cross-section of dried raw noodles, whereas the high addition level (2.0%) made the noodle surface smoother. Addition of *Amaranthus* pigments at low levels (0.1% and 0.5%) generally had little effect on the cooking and textural properties of cooked noodles. But high addition level (2.0%) significantly decreased the tensile strength and firmness, as well as the cooking yield, and increased the cooking loss of cooked noodles.

Amaranth grains have been under intensive development in China during the last two decades. This is the first report about *Amaranthus* betacyanin pigments applied in Asian noodles. This laboratory study may provide a basis for food technologists to develop novel coloured foods incorporating with functional natural colorants with good antioxidant capacity.

Table olives
Maslinic acid
Oleanolic acid
Triterpenic acid, variety

ABSTRACT

An experimental investigation was carried out for the first time on the triterpenic acids in table olives. Maslinic acid was found in a higher concentration than oleanolic acid in the flesh of 17, unprocessed olive varieties, with the Picual and the Manzanilla varieties showing the highest and almost the lowest contents, respectively. The level of triterpenic acids in several types of commercial black and green olives ranged from 460 to 1470 mg/kg fruit, which represents a much higher value than reported for virgin olive oils. In fact, the NaOH treatment employed to debitter black and green olives reduced the concentrations of these substances in the flesh because of their solubilisation into alkaline solutions. Thus, natural black olives, which are not treated with NaOH, showed a higher concentration than 2000 mg/kg in the olive flesh. These results will contribute to the reevaluation of table olives from a nutritional and functional point of view because of the promising bioactivity properties attributed to olive triterpenic acids.

Published by Elsevier Ltd.

1. Introduction

Triterpenic acids are widespread in plants in the form of free acids or aglycones for triterpenoid saponins. Their extracts have been used for centuries in folk medicine as anti-inflammatory, anti-diabetes and hepatoprotective agents (Liu, 1995) and they have recently attracted interest in the scientific community because of their anti-carcinogenic activity (He & Liu, 2007; Struch, Jaeger, Schempp, Scheffler, & Martin, 2008) which makes them very attractive for use in cosmetics and healthcare products as functional compounds.

Among the free triterpenic acids, oleanolic, betulinic, ursolic and maslinic are some of the most abundant in the plant kingdom. Olive fruits and leaves are especially rich in oleanolic and maslinic acids (Vázquez & Janer, 1969), and small amounts of ursolic and betulinic have also been occasionally described in olive products (Bianchi & Vlahov, 1994). Both oleanolic and maslinic acids are concentrated on the surface of olive leaves to form a physical barrier that prevents microbes from penetrating into the leaf (Kubo, Matsumoto, & Takase, 1985). They are also present in high concentrations in the epicarp of the fruit forming part of the waxes that cover them; and oleanolic acid has even been found in the endocarp, wood shell and seeds of olives (Bianchi & Vlahov, 1994).

The presence of triterpenic acids in olive oil is gaining interest because of their anti-tumour activities (Rodríguez-Rodríguez, Herrera, Álvarez de Sotomayor, & Ruíz-Gutiérrez, 2007). However, the concentration of these compounds in oils depends on the oil quality (Pérez-Camino & Cert, 1999): extra virgin olive oils with low acidity did not reach 200 mg/kg, virgin olive oils with acidity higher than 1% exceeded 300 mg/kg, and crude pomace olive oils had up to 10,000 mg/kg, although the latter oils have to be refined before consumption. In fact, an enrichment in triterpenic acids occurs in the crude pomace oil during the storage of the pomace paste (alpeorujo, García, Brenes, Dobarganes, Romero, & Ruíz-Méndez, 2008) but a significant loss in these substances is produced during the refining process of the oil, particularly when a neutralisation step is used (chemical refining, Pérez-Camino & Cert, 1999).

In the case of table olives, very few data on these substances are available. Earlier, Gaviña and Viguera (1964) detected oleanolic and maslinic acids in the sodium hydroxide solutions (lye) generated during the processing of Spanish-style green olives and this was confirmed later by other researchers (Bianchi, 2003; Vázquez & Janer, 1969), but, to our knowledge, no more data have been published until now. Because of the recent interest surrounding the triterpenic acids of olives, a deeper understanding of their contents in commercial table olives, their changes during olive processing and their contents in table olive varieties is required. At the same time, the olive triterpenic acids, oleanolic and maslinic, have been attributed with anti-oxidant (Tsai & Yin, 2008), anti-hyperglycemic (Liu, Hongbin, Weigang, Dongyan, & Luyong, 2007; Sato et al., 2007), anti-microbial (Horiuchi et al., 2007) and anti-cancer activity (Juan, Planas, Ruíz-Gutiérrez, Daniel, & Wenzel, 2008; Reyes-Zurita, Rufino-Palomares, Lupiáñez, & Cascante, 2009) They have also been proposed to feed rainbow trout (Fernández-Navarro, de la Higuera, Lupiáñez, Peragón, & Amores, 2008) and to enrich

vegetable oils as new functional compounds (Guinda, Albi, Pérez-Camino, & Lanzón, 2004).

Therefore, the aim of this research was to study the triterpenic acid contents of table olives as well as the wastewaters generated during their processing as a potential source of these high-value substances.

2. Materials and methods

2.1. Samples

Olive fruits of Ascolana, Domat, Aloreña, Arbequina, Morona, Conservolea, Gordal, Picual, Hojiblanca, Leccino, Koroneiki, Verdial, Picholine, Cacereña, Kalamata, Galega and Manzanilla varieties were hand-harvested with a green–yellow colour on the surface from two different orchards located in the provinces of Seville and Cordoba (Spain) during September–October.

Commercial table olives were purchased in Spanish and Greek markets. Three samples of three different commercial brands were obtained for each table olive preparation.

2.2. Processing Spanish-style green olives

Olive fruits of Manzanilla, Hojiblanca and Gordal varieties with a green–yellow colour on the surface were put into PVC vessels. Five kilograms of fruits were covered with 4 l of 2% NaOH and maintained in the alkaline solution until the alkali penetrated 2/3 the way to the pit of the olives. Subsequently, olives were washed with tap water for 16 h and covered with brine (11% NaCl). All experiments were run in duplicate.

2.3. Processing natural black olives

Olive fruits of the Manzanilla variety with a black colour on the surface were put into PVC vessels. Five kilograms of fruits were covered with an acidified brine (8% NaCl, 0.8% acetic acid) and maintained under anaerobic conditions by covering the surface of the brine with a floating cap. Experiments were run in duplicate.

2.4. Processing black olives

Olive fruits of Manzanilla and Hojiblanca varieties with a green–yellow colour on the surface were preserved as commented above for natural black olives for 6 months. Subsequently, fruits were treated in cylindrical containers over two consecutive days with NaOH solutions (lye) of 1.5% and 1.2%, which were permitted to penetrate 1–2 mm into the flesh and to the pit, respectively. After each lye treatment, tap water was added every day to complete a 24 h cycle. On the third day a new washing cycle of 24 h was used. Subsequently, fruits were suspended in a ferrous gluconate solution (0.1%) for another 24 h. Air was continuously bubbled through the mixture of fruits and liquid. Experiments were run in duplicate.

2.5. Extraction of triterpenic acids from liquids

An amount of 0.8 ml of sample (lyes, washing solutions and brines) was mixed with 2 ml of ethyl acetate in a 10 ml centrifuge tube. The mixture was vortexed for 1 min, centrifuged at 9500 rpm for 5 min at 20 °C, and the organic solvent was separated from the water phase. This step was repeated six times. Subsequently, the pooled organic ethyl acetate extract was vacuum evaporated and the residue dissolved in 0.8 ml of methanol, which was filtered through 0.2 μm pore size and an aliquot (20 μl) was injected into the liquid chromatograph. In order to check the exhaustiveness of the method, the pH of lyes and washing solutions was dropped below 3. Subsequently, triterpenic acids were extracted from the supernatant with ethyl acetate and they were not detected in these solutions. By contrast, the precipitate formed during pH correction was dissolved in methanol and it was analysed by HPLC. The amount of triterpenic acids in the precipitate was the same as found when lyes and washing solutions without any pH modification were analysed by using ethyl acetate as extracting solvent.

2.6. Extraction of triterpenic acids from olive flesh

Twenty grams of destoned and cut olive fruits were triturated, and desiccated at 105 °C until weight stabilisation. Subsequently, 1 g of dry olives were mixed in a 10 ml centrifuge tube with 4 ml of methanol/ethanol (1:1, v/v) and vortexed for 1 min, centrifuged at 9500 rpm for 5 min at 20 °C, and the solvent was separated from the solid phase. This step was repeated six times, and the pooled solvent extract was vacuum evaporated. The residue was dissolved in 2 ml of methanol, which was filtered through 0.2 μm pore size and an aliquot (20 μl) was injected into the liquid chromatograph.

2.7. HPLC analysis of triterpenic acids: UV and MS detection

The chromatography system consisted of a Waters 717 plus auto sampler, a Waters 600E pump, and a Waters 996 diode array detector (Waters Inc., Mildford, MA, USA). A Spherisorb ODS-2 (5 μm, 25 × 46 mm i.d.; Waters Inc.) column was used. The temperature of the column was kept constant at 35 °C by using a Waters column heater. The mobile phase (methanol/acidified water with phosphoric acid at pH 3.0, 92:8, v/v) was delivered to the column at a flow rate of 0.8 ml/min and the eluate was monitored at 210 nm. Triterpenic acids (oleanolic and maslinic acids) were quantified using oleanolic acid (Sigma, St. Louis, MO, USA) as external standard. A similar response factor was assumed for both triterpenic acids on the basis of their similar UV spectra. The calibration equation, concentration (mg/l) = 0.0001 × peak area, was calculated in a range of 0–3000 mg/l, and the determination coefficient was 0.996.

An Alliance Waters chromatography system connected to UV and MS detectors was used to identify the compounds. The chromatography method was similar to that explained above and the mass spectra were acquired using a quadrupole mass analyser (ZMD4; Waters Inc.), equipped with a electrospray ionisation (ESI) probe and working in the negative mode. Cone voltage fragmentation was at 10 V, capillary voltage was 3 kV, desolvation temperature was 200 °C, source temperature was 120 °C, and extractor voltage was 12 V. Standards linolenic, linoleic and oleanolic acids were used to identify peaks 2–4, respectively.

2.8. Statistical analysis

Statistica software version 6.0 was used for data processing (Statistica for Windows, Tulsa, OK, USA). Comparison between mean variables was made by the Duncan's multiple range tests and the differences considered significant when $p < 0.05$.

3. Results and discussion

Despite the recent relevance of olive triterpenic acids, there is no information on the amount of these substances in whole olive fruits. Some reports have indicated that they are concentrated in the epicarp of the fruits and contribute to more than 60% of the total waxes (Bianchi, 2003), with oleanolic and maslinic found in similar concentrations. In contrast, the amount of these substances in the mesocarp of olives is low and maslinic acid is the main com-

ponent. Nevertheless, the triterpenic acid contents in whole olive fruits have never been quantified, particularly in those intended for table olives.

In this study, oleanolic and maslinic acids were extracted from the olive fruits, which were previously dried to avoid water interference during the analysis, with a mixture of methanol/ethanol (1:1), a similar method to that employed for "alpeorujo" olive oil (García et al., 2008). The chromatographic system used was also the same developed to analyse triterpenic acids in "alpeorujo olive oil" and a similar chromatographic profile was obtained. A good separation of maslinic and oleanolic acid was achieved (Fig. 1), and the presence of peaks corresponding to linoleic and linolenic acids along with the absence of other triterpenic acids were confirmed by HPLC-MS. Compounds corresponding to these four peaks had molecular masses of 472, 278, 280 and 456 uma. Peak 1 had a molecular mass similar to that of maslinic acid and its fragmentation pattern was the same as that of oleanolic acid (peak 4). Besides, UV spectra of peaks 1 and 4 were similar. Based on all these results and literature data, peak 1 was assigned to maslinic acid.

The raw fruits of the varieties studied showed important differences in their triterpenic acid contents (Fig. 2). The sum of maslinic and oleanolic acids ranged from 1500 to 3000 mg/kg olive flesh, with the concentration of maslinic being higher than that of oleanolic acid for all the studied varieties. Surprisingly, olives of the Manzanilla variety, which is the main variety processed for table olives, practically had the lowest content in triterpenic acids, lower than other important table olive varieties such as Hojiblanca, Kalamata, Gordal or Conservolea. Indeed, the Manzanilla olive variety is rich in phenolic compounds (Romero et al., 2004) and triterpenic alcohols (López-López, Montaño, Ruíz-Méndez, & Garrido-Fernández, 2008) but this is not the case for maslinic and oleanolic acids. In contrast, the Picual variety, which is seldom used for table olives but it is the most important variety for olive oil worldwide, showed the highest content in maslinic and oleanolic acids.

Concerning the evolution of triterpenic acids during olive processing, Figs. 3 and 4 reflect the concentration of these substances in the different solutions generated during the two main table olive preparation methods: Spanish-style green olives and black olives. Triterpenic acids were extracted from the olive solutions (lyes, washing waters and brines) with ethyl acetate without any pH correction because it is well-known that the solubility of triterpenic acids is very low in aqueous media at pH below neutrality, and it increases at alkaline pH (Jäger, Winkler, Pfüller, & Scheffler, 2007), which is in accordance with results obtained in this study.

Results revealed that the alkaline treatment gave rise to the solubilisation of maslinic and oleanolic acids into the lyes and the washing solutions. It must be said that the pH of the lyes and washing water was in most cases higher than 8. Thus, maslinic acid was found in a range of 800–1000 mg/l in the lyes of the

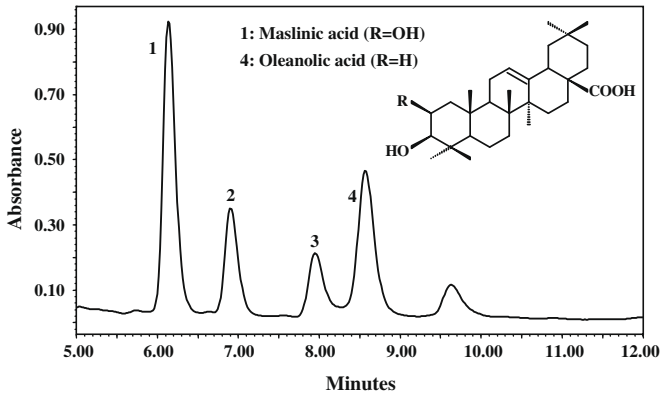

Fig. 1. HPLC chromatogram at 210 nm of the triterpenic acid extract of a Spanish-style green olives sample. Peaks: (1) maslinic acid; (2) linolenic acid; (3) linoleic acid; and (4) oleanolic acid.

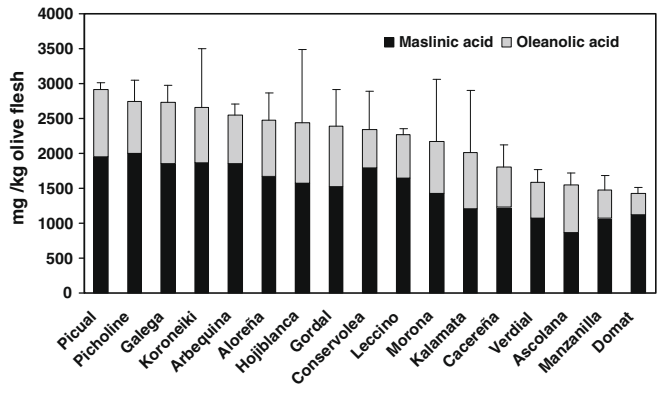

Fig. 2. Concentration in triterpenic acids of several raw olive varieties intended for table olives. Bars indicate the standard deviation of two samples obtained from different orchards.

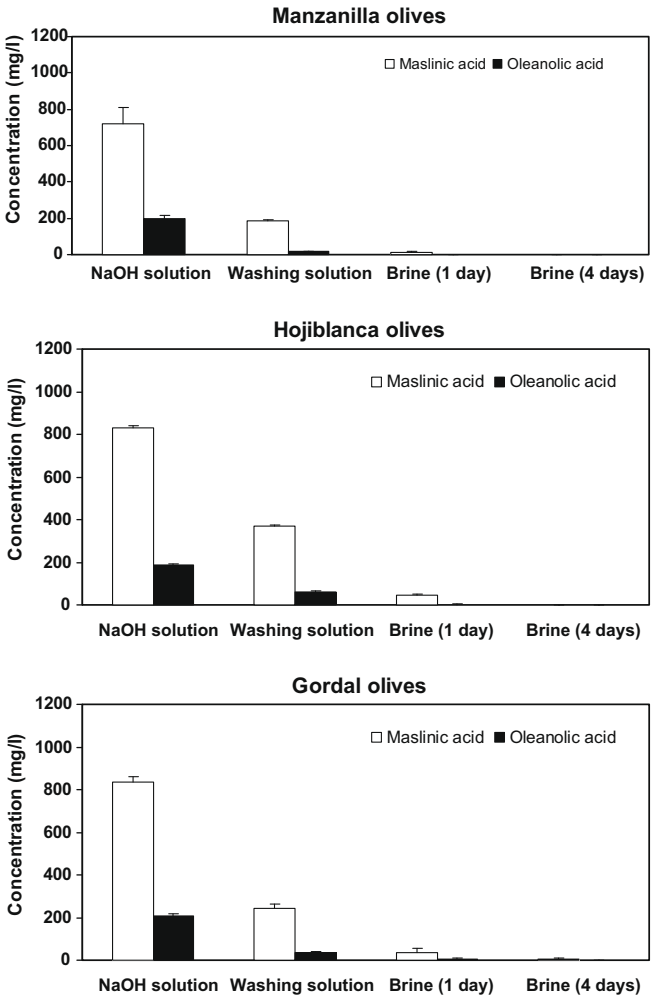

Fig. 3. Concentration in triterpenic acids of the different solutions generated during the processing of Spanish-style green olives of the Manzanilla, Hojiblanca and Gordal varieties. Bars mean the standard deviation.

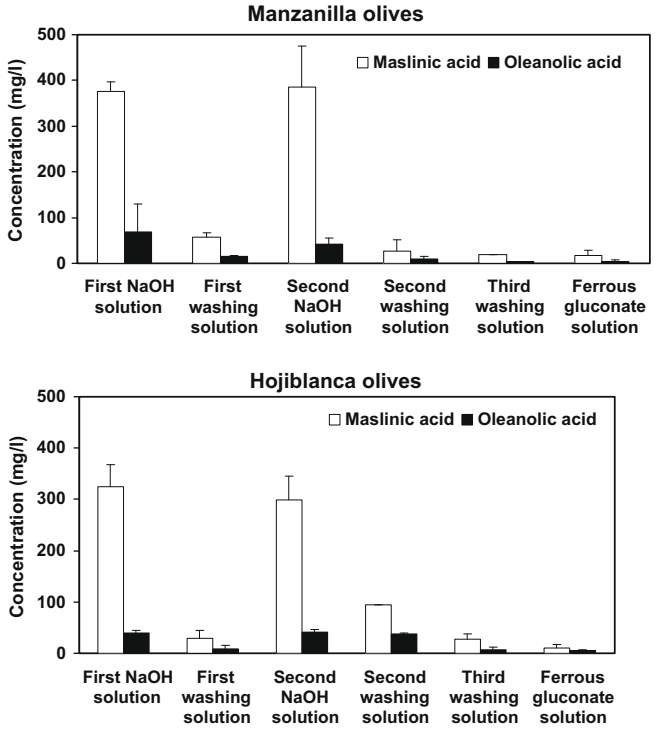

Fig. 4. Concentration in triterpenic acids of the different solutions generated during the processing of black olives of the Manzanilla and Hojiblanca varieties. Bars mean the standard deviation.

Manzanilla, Gordal and Hojiblanca varieties processed according to the Spanish-style green method. The values are comparable to those reported by Bianchi (2003) for the lyes of Italian varieties, and maslinic was always detected in a higher concentration than oleanolic. Although the concentration of triterpenic acids was lower in the washing solutions than in the lyes, the ratio maslinic/oleanolic was similar for both types of olive solutions. A low concentration of triterpenic acids was found in brines during the first days of fermentation when the pH varied from 9 to 7 and they were not detected thereafter as fermentation progressed and pH dropped below neutrality. Hence, it seems that these substances precipitated at low pH. In fact, an inhibitory activity against the lactic acid bacteria growth by a precipitate formed during the acidification of brines and washing waters has been reported (De Castro, Romero, & Brenes, 2005). Because triterpenic acids possess anti-microbial activity (Horiuchi et al., 2007) and are insoluble in aqueous media at acid pH, it can be supposed that these substances are components of this precipitate and could contribute to the anti-lactic acid bacteria activity of it. Moreover, it must be taken into account that Jäger et al. (2007) have reported that the solubility of triterpenic acids in plant extracts was higher than expected due to their interaction with large molecules or aggregates.

On the other hand, the most concentrated solutions in triterpenic acids of all the wastewaters generated during the processing of black olives were again the lyes, followed by the washing waters and the ferrous gluconate solutions, all of them having alkaline pH (Fig. 4). These streams, as well as those generated during the processing of green olives, represent a big environmental problem for the olive factories, and our results disclosed them as a good source of these new potential functional compounds, especially the lyes and the washing waters.

Likewise, maslinic and oleanolic acids were never found in the brines of natural black olives (data not shown) since they were not treated with NaOH, and were initially acidified with acetic acid up to pH 4. Therefore, this acidic medium did not allow the solubilisation of the triterpenic acids into the brines.

Olives and olive oil are recognised as healthy foods from a nutritional point of view because of their content in monounsaturated fatty acids, anti-oxidant phenolic compounds and others. Triterpenic acids could contribute to the good perception that consumer have of these products, although it is necessary to know their amounts in these foods. There are few data on the concentration of triterpenic acids in edible fruits (He & Liu, 2007; Cui et al., 2006; Frighetto, Welendorf, Nigro, Frighetto, & Siani, 2008), some on olive oil (Pérez-Camino & Cert, 1999) and none on table olives.

The data presented in Table 1 reflect the amount of maslinic and oleanolic acids in the main trade olive preparations. As could be expected from the data in Fig. 2–4, maslinic acid was always found in a higher concentration than oleanolic acid and olives non-treated with alkali (turning colour olives, natural black olives) were richer in these substances than those elaborated as green and black olives. Additionally, the pitting and stuffing steps did not significantly affect the concentration of triterpenic acids in olives as opposite to the decrease in hydrophilic phenolic compounds (Romero et al., 2004).

Regarding olive varieties, differences were also found, with the Hojiblanca variety having a higher amount of triterpenic acids than the Manzanilla. However, the concentration of triterpenic acids in commercial table olives was more affected by the alkaline treatment and further washing cycles than other variables. Thus, turning colour olives and natural black olives had an amount of triterpenic acids as high as 1000–2000 mg/kg olive flesh, much higher than reported for virgin olive oils (Pérez-Camino & Cert, 1999). Indeed, green and black olives also had a higher concentration in these substances than olive oils.

Table 1
Content in triterpenic acids (mg/kg olive flesh) of commercial table olives.

Cultivar	Presentation	Maslinic acid	Oleanolic acid
Manzanilla	Plain green olives	384.1 ± 50.0 a	202.6 ± 57.3 a
Manzanilla	Pitted green olives	497.3 ± 87.8 ac	330.0 ± 185.7 a
Manzanilla	Green olives stuffed with pimento	355.5 ± 88.4 a	191.2 ± 89.7 a
Hojiblanca	Plain green olives	904.7 ± 259.6 b	565.2 ± 107.1 bc
Gordal	Plain green olives	414.2 ± 89.3 a	294.3 ± 4.5 a
Manzanilla	Plain black olives	287.1 ± 66.6 a	178.8 ± 43.7 a
Manzanilla	Pitted black olives	290.7 ± 129.1 a	169.7 ± 121.0 a
Hojiblanca	Plain black olives	506.8 ± 232.5 ab	364.5 ± 242.3 ac
Cacereña	Plain black olives	295.1 ± 203.9 a	185.1 ± 121.1 a
Manzanilla	Plain turning colour olives	824.9 ± 179.5 bc	274.2 ± 61.4 a
Kalamata	Plain natural black olives	1318.4 ± 401.0 d	841.4 ± 162.9 b

Each value is the mean ± standard deviation of three samples. Letters within columns designate statistically significant differences ($p < 0.05$) according to the Duncańs New Multiple Range Test. Triterpenic acids were extracted from olives as described in Section 2.6.

4. Conclusions

On the basis of our results, it can be stated that table olives are a food product rich in triterpenic acids, in particular maslinic acid. However, the NaOH treatment used to debitter the fruits leads to the solubilisation of these substances into the alkaline solutions and, therefore, to significant losses in the final product. Likewise, the alkaline wastewaters have been revealed as a good source of these valuable triterpenic acids.

These results may contribute to the revaluation of table olives in view of the promising bioactivity properties attributed to olive triterpenic acids (Juan et al., 2008; Reyes-Zurita et al., 2009).

Scavenging ability

ABSTRACT

Water-soluble crude polysaccharide named as RVP was obtained from the fresh fruiting bodies of *Russula virescens* by boiling-water extraction. DEAE-Sepharose CL-6B column chromatography was used for the fractionation of polysaccharide RVP. Two fractions were obtained, namely RVP-1 and RVP-2. RVP-1 and RVP-2 were composed mainly of glucose, with the estimated equivalent dextran molecular weights of 3.1×10^5 and 4.2×10^5 Da, respectively. Analysis by Periodate oxidation–Smith degradation indicated that RVP-1 was composed of 68.3% (1 →)- or ((1 → 6)-glycosidic linkages and 31.7% (1 → 3)-glycosidic linkages, and RVP-2 7.9% (1 →)- or (1 → 6)-glycosidic linkages, 9.6% (1 → 2)-glycosidic linkages, 35.7% (1 → 4)-glycosidic linkages, and 46.8% (1 → 3)-glycosidic linkages. RVP-1 exhibited equivalent inhibiting power for self-oxidation of 1,2,3-phentriol to vitamin C (Vc), a little higher scavenging activity of superoxide radical and hydroxyl radical than Vc. The reducing power of RVP-1 at 20.0 mg/ml was 0.77, and RVP-1 was a good chelating agent for ferrous ions. Overall, RVP-1 possessed good antioxidant properties and should be developed as a novel potential antioxidant.

1. Introduction

Oxidation is essential to many organisms for the production of energy fuel biological processes. However, the uncontrolled production of oxygen-derived free radicals is involved in the onset of many diseases such as cancer, rheumatoid arthritis, and atherosclerosis, as well as in degenerative processes associated with aging (Mau, Lin, & Song, 2002). Almost all organisms have natural antioxidant properties and can repair oxidative damage in their systems, but these systems are unable to prevent the damage completely. Antioxidants are substances that can delay or prevent oxidative cellular oxidisable substrates. They work in two ways: by scavenging reactive oxygen species (ROS) and by inhibiting the generation of ROS. At present, synthetic antioxidants are used for industrial processing to preserve food quality. However, the most commonly used ones have been suspected of being responsible for liver damage and carcinogenesis (Grice, 1988; Qi et al., 2005). Thus, there has been increasing interest in finding natural, effective, and safe antioxidants, since they can protect the human body from free radicals and retard the progress of many chronic diseases (Kinsella, Frankel, German, & Kanner, 1993; Nandita & Rajini, 2004). Published data indicate that some plant polysaccharides have strong antioxidant activities and can be explored as novel potential antioxidants (Hu, Xu, & Hu, 2003; Jiang, Jiang, Wang, & Hu, 2005; Ramarahnam, Osawa, Ochi, & Kawaishi, 1995). In addition, polysaccharides extracted from mushrooms, such as *Grifola frondosa* and *Auricularia auricular*, have also shown antioxidant properties as shown by their free radical scavenging abilities (Fan, Zhang, Yu, & Ma, 2007; Lee et al., 2003; Liu, Ooi, & Chang, 1997).

Russula virescens is a wild mushroom that grows on the roots of pine trees, and has long been used as a folk remedy in traditional Chinese medicine. To date, no investigation has been carried out on polysaccharides that may account for the antioxidant activities of *R. virescens*. In this study, we reported on the extraction and purification of two novel water-soluble polysaccharides of *R. virescens* using DEAE-Sepharose CL-6B column chromatography. In addition, we attempted to investigate the molecular weights, chemical compositions, structure, and antioxidant activities, of the polysaccharides isolated from the fresh fruiting bodies of *R. virescens*.

2. Materials and methods

2.1. Materials

Fresh fruiting bodies of *R. virescens* were purchased from Chengdu, Sichuan Province, China. T-series dextrans of different molecular weights were purchased from Sigma Chemical Co. (St.

Louis, MO, USA). Nitro blue tetrazolium (NBT), phenazine methosulphate (PMS), dihydronicotineamidadenine dinucleotide (NADH), thiobarbituric acid (TBA), butylated hydroxyanisol (BHA), hydrogen peroxide (H_2O_2), ferrozine, 1,2,3-phentriol, α-tocopherol, deoxyribose, L-rhamnose, D-glucose, D-arabinose, D-xylose, D-fructose, D-galactose, and D-mannose were purchased from Sigma Chemical Co. (St. Louis, MO, USA), whilst DEAE-Sepharose CL-6B was from the Pharmacia Co. (Sweden). All other reagents used were of analytical grade.

2.2. Isolation and purification of the polysaccharide

A standard procedure was followed for the isolation of the polysaccharide. The fresh fruiting bodies of *R. virescens* were dried and powdered. The powder (100 g) was defatted with 95% ethanol at room temperature for 48 h under stirring, then autoclaved in 2 l of double-distilled water at 120 °C for 3 h and later filtered. The residue was further extracted with 750 ml of water for 1 h. The combined aqueous extracts were concentrated in a rotary evaporator under reduced pressure at 50 °C and filtered. The filtrate was then precipitated by adding ethanol (four times the volume of aqueous extract) at 4 °C, followed by centrifugation at 4800 rpm for 20 min. The precipitate was dissolved in 300 ml of water and deproteinised 20 times as described by Sevag (Staub, 1965). The resulting aqueous fraction was extensively dialysed against double-distilled water for three days and precipitated again by adding fourfold volume of ethanol. After centrifugation, the precipitate was washed with anhydrous EtOH and then dissolved in water and lyophilised to yield the crude polysaccharide (RVP). Further fractionation was performed in anion-exchange chromatography. RVP (1000 mg) was dissolved in 10 ml distilled water, centrifuged, and the supernatant was then injected to a column (4.6 × 30 cm) of DEAE-Sepharose CL-6B equilibrated with distilled water. After being loaded with the sample, the column was eluted with distilled water for 1000 ml at 4 ml/6 min, followed stepwise by NaCl aqueous solution (0 and 1 M) for 400 ml, respectively, at 40 ml/h. The elution was detected by the phenol–sulphuric acid method, using glucose as standard (Dubois, Gilles, Hamilton, Rebers, & Smith, 1956). The major polysaccharide fractions were collected with a fraction collector, dialysed against tap water and distilled water for 48 h, concentrated in a rotary evaporator, and finally lyophilised in a freeze dryer (Tokyo Rikakikai Co., Ltd., Japan).

2.3. Components analysis and properties

The protein content was measured according to Bradford's method (Bradford, 1976). The chemical composition of these polysaccharides was analysed following the procedure in Zhang's investigation (Zhang et al., 2007). The acetate derivatives were analysed by gas chromatography (GC) with a HP-5 capillary column (HP6820, Hewlett–Packard). The temperature programme was increased from 120 to 300 °C at an increment of 5 °C/min using N_2 as carrier gas. The standard monosaccharides were then measured following the same procedure.

The infrared spectra of the polysaccharides were recorded with a Nicolet NEXUS-470 FT-IR (Spectrum One, Perkin Elmer Co., USA) spectrometer in the range of 4000–500 cm^{-1} using the KBr disk method.

2.4. Determination of molecular weights

The molecular weights of RVP-1 and RVP-2 were evaluated and determined by high performance liquid chromatography (HPLC) on two Water Ultrahydrogel TM Linear 7.8 × 300 mm columns and were eluted with 0.1 M of sodium nitrate solution at a flow rate of 0.9 ml/min at 45 °C. Elution was monitored by a refractive index detector. The column was calibrated with glucose (molecular weight: 180 Da) and T-series Dextran standards (molecular weight: 4600, 10,000, 21,400, 41,100, 1,33,800, 4,82,000, and 20,00,000 Da). Individual molecular weight standard solutions were freshly prepared daily by dissolving 25 mg each of the eight standards from 180 to 20,00,000 Da in 50 ml DMSO. RVP-1 and RVP-2 solutions were prepared in a similar fashion. The standard solutions were then injected in duplicate in the order of decreasing molecular weight, with the GPC software (Thermo Labsystems, Shrewsbury, MA, USA) used to perform a narrow band linear regression standard calibration curve of log molecular weight versus HPLC retention time. The sample preparations were later injected in duplicate.

2.5. Periodate oxidation–Smith degradation

Sample (50 mg) was dissolved in 25 ml of distilled water and 25 ml of 30 mM $NaIO_4$ were added. The solution was kept in the dark at 4 °C, 0.1 ml aliquots were withdrawn at 6 h intervals, diluted to 25 ml with distilled water and read in a spectrophotometer at 223 nm. The reaction was complete when absorbency did not descend, and the excess of $NaIO_4$ was decomposed with glycol (2 ml). The solution of periodate product (2 ml) was sampled to calculate the yield of formic acid by 0.005 M sodium hydroxide, and the rest was extensively dialysed against tap water and distilled water for 24 h, respectively. The content inside was concentrated and reduced with sodium borohydride (160 mg), and the mixture was left for 24 h at 25 °C, neutralised to pH 6.0 with 50% acetic acid, dialysed as described above, and concentrated to a volume (10 ml). One-third of solution described above was freeze-dried and analysed with GC. Others were added to the same volume of 1 M sulphuric acid, kept for 40 h at 25 °C, neutralised to pH 6.0 with barium carbonate, and filtered. The filtrate was dialysed as foresaid, and the content out of sack was desiccated for GC analysis; the content inside was diluted with ethanol, and after centrifugation, the supernatant and precipitate were also dried out for the GC analysis.

2.6. Assay for antioxidant activity

2.6.1. Hydroxyl radical assay

The hydroxyl radical assay was measured by the method of Ghiselli, Nardini, Baldi, and Scaccini (1998) with a minor modification. Samples were dissolved in distilled water at 0 (control), 0.1, 0.2, 0.4, 0.8, 1.6, 3.2, 6.3, 12.5, 25, or 50 mg/ml. The sample solution (0.1 ml) was mixed with 0.6 ml of reaction buffer [0.2 M phosphate buffer (pH 7.4), 2.67 mM deoxyribose, and 0.13 mM ethylenediaminetetraacetic acid (EDTA)], 0.2 ml of 0.4 mM ferrous ammonium sulphate, 0.05 ml of 2.0 mM ascorbic acid, and 0.05 ml of 20 mM H_2O_2 was then added to the reaction solution. The reaction solution was incubated for 15 min at 37 °C, and then 1 ml of 1% thiobarbituric acid and 1 ml of 2.0% trichloroacetic acid were added to the mixture. The mixture was boiled for 15 min and cooled on ice. The absorbance of the mixture was measured at 532 nm. The inhibition percentage of hydroxyl radical was calculated as: (1 − absorbance of sample/absorbance of control) × 100%.

2.6.2. Superoxide radical assay

The superoxide radical assay was measured by the method of Robak and Gryglewski (1988) with a minor modification. Samples were dissolved in distilled water at 0 (control), 0.78, 1.56, 3.125, 6.25, 10, 20, 40, 50, 80, or 100 mg/ml. A 0.1-ml aliquot of each sample solution was mixed with 1 ml of 16 mM Tris–HCl (pH 8.0) containing 557 μm NADH, 1 ml of 16 mM Tris–HCl (pH 8.0) containing 45 μm PMS, and 1 ml of 16 mM Tris–HCl (pH 8.0) containing 108 μm NBT. After 5 min of incubation at 25 °C, the absorbance was measured at 560 nm. The superoxide radical effect was calcu-

lated as: scavenging activity (%) = (1 − absorbance of sample/absorbance of control) × 100%.

2.6.3. Self-oxidation of 1,2,3-phentriol assay

The scavenging ability for self-oxidation of 1,2,3-phentriol of all different contents were investigated according to the method of Marklund and Marklund (1974) with a minor modification. Briefly, samples were dissolved in distilled water at 0 (control), 5, 10, 40, or 80 mg/ml. The sample solution (0.1 ml) was mixed with 2.8 ml of 0.05 M Tris–HCl buffer (pH 8.0) containing 1 mM EDTA and 1,2,3-phentriol (0.2 ml, 6 mM), and was shaken rapidly at room temperature. The absorbance of the mixture was measured at 325 nm per 30 s for 4 min against a blank, and a slope was calculated as the absorbance per min. The ability of different scavenging abilities for self-oxidation of 1,2,3-phentriol of all fractions was calculated as: (1 − slope of sample/slope of control) × 100%.

2.6.4. Reducing power assay

The reducing power was determined according to the method of Oyaizu (1986). The different concentrations of samples (0.1–20 mg/ml, 2.5 ml) were mixed with phosphate buffer (2.5 ml, 0.2 M, pH 6.6) and 2.5 ml of potassium ferricyanide [$K_3Fe(CN)_6$] (1%, w/v). The mixture was incubated at 50 °C for 20 min. After 2.5 ml of trichloroacetic acid (10%, w/v) were added to terminate the reaction, the mixture was centrifuged at 2000 *g* for 10 min. The upper layer of solution (5 ml) was mixed with water (5 ml) and $FeCl_3$ (1 ml, 0.1%), and the absorbance was measured at 700 nm against a blank. Ascorbic acid, BHA, and α-tocopherol were used for comparison.

2.6.5. Metal chelating assay

Chelating ability was determined according to the method of Dinis, Madeira, and Almeida (1994). The different concentrations of samples (0.1–20 mg/ml, 1 ml) were mixed with 3.7 ml of methanol and 0.1 ml of 2 mM ferrous chloride. The reaction was initiated by the addition of ferrozine (0.2 ml, 5 mM). After 10 min at room temperature, the absorbance of the mixture was determined at 562 nm against a blank. Citric acid and EDTA were used for comparison. The ferrous ion-chelating activity was given by the following equation:

$$\text{Chelating ability}\ (\%) = (1 - \text{absorbance of sample/absorbance of control}) \times 100\%.$$

3. Results and discussion

3.1. Isolation, purification and composition of fractions

The crude polysaccharide was isolated from the hot water extract of *R. virescens* by a yield of 1.94%. After being fractioned on DEAE-Sepharose CL-6B column, RVP-1 (0.46%) and RVP-2 (0.17%) were obtained from the distilled water eluent and NaCl eluent, respectively. The protein content in RVP-1 and RVP-2 were 1.77% and 1.25%, respectively.

According to GC analysis, both RVP-2 and RVP-1 were composed of xylose, mannose, glucose, galactose and fructose, with molar ratios of 6.8:13.2:136.7:7.8:1.0 and 1.2:3.2:195.6:11.6:1.0, respectively. These data revealed great differences in the polysaccharides' distribution of xylose, mannose, glucose, galactose, and fructose, strongly indicating that the polysaccharides were heterogeneous. It is worth mentioning that the polysaccharides consisted mainly of glucose.

The infrared spectroscopy (IR) spectra of samples RVP-1 and RVP-2 displayed the characteristic IR absorption of polysaccharides at 1650 and 1250 cm^{-1}. The broadly stretched intense peak at 3400 cm^{-1} was due to the hydroxyl stretching vibration. A weak C–H group stretching band at 2930 cm^{-1} could also be observed. On the other hand, the absorptions at 1424 and 1371 cm^{-1} were possibly due to non-symmetrical and symmetrical CH_3 bending, respectively. A band at 1250 cm^{-1} caused by non-symmetrical C–O–C stretching vibration could likewise be observed.

3.2. Molecular weight

HPLC was applied to elucidate the molecular weights of RVP-1 and RVP-2. The equivalent dextran molecular weights of RVP-1 and RVP-2 were around 3.1×10^5 and 4.2×10^5 Da, respectively.

3.3. Structure characterisation of RVP-1 and RVP-2

Both RVP-1 and RVP-2 showed abundance HIO_4 uptake, whilst they were oxidised. The consumption of HIO_4 (1.369 mmol) in RVP-1 was about two times than the amount of formic acid (0.683 mmol) that was produced per mol sugar residue after 72 h of periodate treatment, indicating the existence of large amounts of monosaccharide which were 1 → linked or 1 → 6 linked or more branched. In addition, it was concluded that sugar residues oxidised or linkages of (1 →)-glycosidic linkages accounted for 68.3%. The periodate-oxidised products were hydrolysed and examined by gas chromatography. The presence of glucose revealed that there were (1 → 3)-glycosidic linkages, namely linkages that cannot be oxidised. Erythritol was absent, indicating there was no (1 → 4)-glycosidic linkage in RVP-1. According to the results above, the main chain linkages could be alternately arrayed by (1 → 3)-glycosidic linkages and (1 → 6)-glycosidic linkages, or the main chain linkages could be (1 → 6)-glycosidic linkages with branch (1 → 3)-glycosidic linkages.

Results from 96 h of Periodate oxidation of RVP-2 showed that the ratio of the consumption of HIO_4 (0.611 mol/mol sugar residue)

Table 1

to the production of formic acid (0.079 mol/mol sugar residue) was more than 2, indicating the existence of little amounts of monosaccharide which were 1 → linked or 1 → 6 linked and little branching. In addition, it was inferred that sugar residues oxidised and linkages of (1 →)-glycosidic linkages accounted for 53.2% and 7.9%, respectively. The periodate-oxidised products were hydrolysed and examined by gas chromatography (Table 1). The presence of glucose indicated (1 → 3)-glycosidic linkages, namely linkages that cannot be oxidised by HIO_4. The presence of mannose revealed some residues of mannose were (1 → 3)-linked, (1 → 2,3)-linked, (1 → 2,4)-linked, (1 → 3,4)-linked, (1 → 3,6)-linked, or (1 → 2,3,4)-linked, which cannot be oxidised by HIO_4. Results of Smith degradation analysis of fractions were summarised in Table 1. The glycerol and erythritol were found with a molar ratio of 1.00:1.32 by GC after conversion to the corresponding alditol acetates. It was thus deduced that (1 → 2)-glycosidic linkages accounted for 9.6%, and (1 → 4)-glycosidic linkages 35.7%. At the same time, the branching of RVP-2 was little, so the linkages of the main chain could be alternately arrayed by (1 → 3)-glycosidic linkages and (1 → 2)-glycosidic linkages or (1 → 4)-glycosidic linkages, according to the presence of glycerin and erythritol, or the linkages of main chain could be the (1 → 2)-glycosidic linkages or (1 → 4)-glycosidic linkages and the linkages of branches (1 → 3)-glycosidic linkages.

3.4. Scavenging activity of hydroxyl radical

Hydroxyl radicals can easily cross cell membranes, can readily react with most biomolecules including carbohydrates, proteins, lipids, and DNA in cells, and cause tissue damage or cell death. Thus, removing hydroxyl radicals is important for the protection of living systems.

Hydroxyl radicals, generated by the reaction of iron–EDTA complex with H_2O_2 in the presence of ascorbic acid, attack deoxyribose to form products which, upon heating with 2-thiobarbituric acid under acid conditions, yield a pink tint. Added hydroxyl radical scavengers compete with deoxyribose for the resulting hydroxyl radicals and diminish tint formation (Cheng, Ren, Li, Chang, & Chen, 2002). The above-mentioned model was used to measure inhibitory activities of all fractions on hydroxyl radicals.

Both RVP-1 and RVP-2 had higher scavenging effect than Vitamin (Vc) (Fig. 1). Their scavenging effects increased with increasing concentration. The scavenging effects of RVP-1 and RVP-2 were 0–67.3% and 3.3–98.1%, respectively, at the amount of 0.01–5.0 mg, and that of Vc was about 0–60.7%. This result proved that polysaccharides from the fresh fruiting bodies of *R. virescens* had a significant effect on scavenging hydroxyl radicals, and RVP-1 and RVP-2 were more pronounced than Vc.

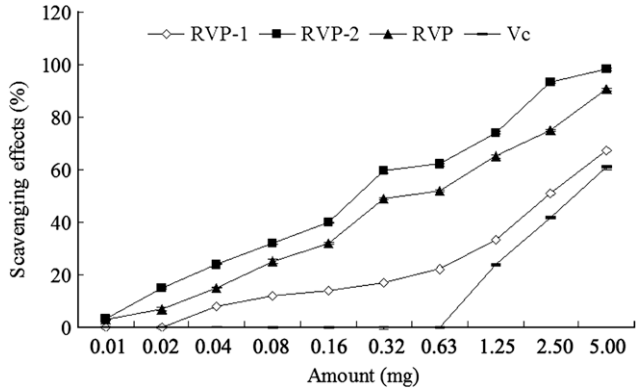

Fig. 1. Scavenging activities of hydroxyl radical by RVP-1, RVP-2, RVP and Vc. Each value is expressed as mean ± standard deviation ($n = 3$).

3.5. Scavenging activity of superoxide radical

Although superoxide was a weak oxidant, in most organisms, it could degrade continuously and form other active ROS, triggering peroxidation of lipids, and then induce pathological incidents such as arthritis and Alzheimer's disease. Thus, it is important to remove superoxide radicals.

Superoxide radicals were generated in a PMS/NADH system for assay in the reduction of nitro blue tetrazolium (NBT). The scavenging activities of RVP-1 on superoxide radicals were shown to be significant in a concentration-dependent fashion (Fig. 2). As shown in Fig. 2, RVP-1 was found to have more scavenging activities of superoxide radicals than RVP and Vc. The purification fraction RVP-2 showed no scavenging activities. At the amount of between 0.156 mg and 5.0 mg, the effects on scavenging superoxide of RVP-1 were 2.4–88.1%. However, the scavenging activity of Vc for superoxide radical was 0–83.1%. On the basis of these results, RVP-1 had stronger scavenging activity for superoxide radicals compared to vitamin C.

3.6. Scavenging activity of self-oxidation of 1,2,3-phentriol

Fig. 3 illustrates the scavenging power for self-oxidation of 1,2,3-phentriol of RVP-1 and RVP-2. Their scavenging powers correlated well with increasing concentrations. Moreover, the scavenging power of RVP-1 was stronger than those of RVP and RVP-2, and corresponded to that of Vc. These results indicate that RVP-1 has strong scavenging power for self-oxidation of 1,2,3-phentriol and should be explored as novel potential antioxidants.

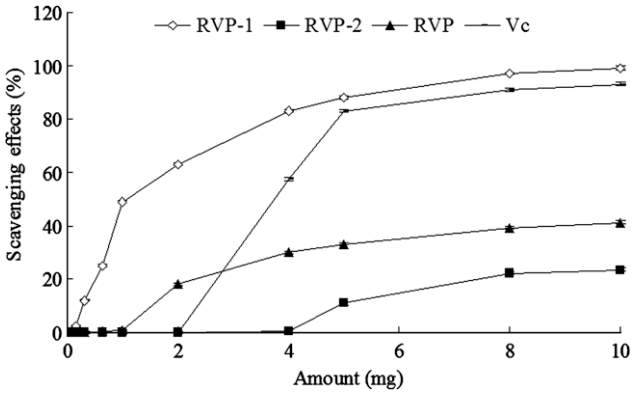

Fig. 2. Scavenging effects of RVP-1, RVP-2, RVP and Vc on super oxide radicals. Each value is expressed as mean ± standard deviation ($n = 3$).

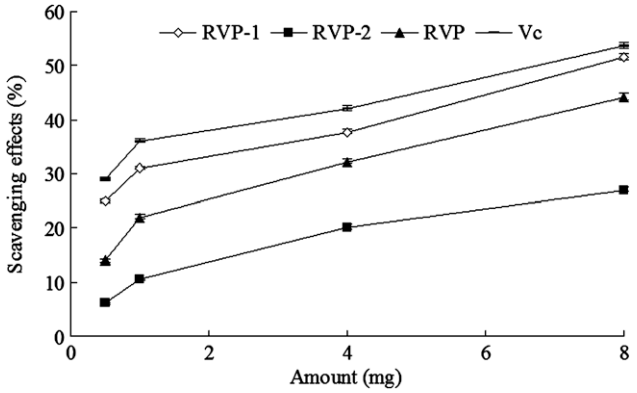

Fig. 3. Inhibitory effects of RVP-1, RVP-2, RVP and Vc on self-oxidation of 1,2,3-phentriol. Each value is expressed as mean ± standard deviation ($n = 3$).

3.7. Reducing power

Fig. 4 depicts the reducing power of tested samples. Higher absorbance value means stronger reducing power of samples. In this assay, the reducing power of the tested polysaccharides steadily increased with increasing sample concentration. The reducing abilities of RVP-1, RVP-2, and RVP at 20.0 mg/ml were 0.77, 0.96, and 0.46, respectively, which were weaker than those of butylated hydroxyanisol (BHA) and ascorbic acid. BHA showed a reducing power of 0.93 at 0.1 mg/ml and the reducing powers of ascorbic acid and α-tocopherol were 0.87 and 0.96 at 1 mg/ml, respectively. The reducing properties were generally associated with the presence of reductones, which have been shown to exert antioxidant action by breaking the free-radical chain which is done by donating a hydrogen atom. Zhu, Hackman, Ensunsa, Holt, and Keen (2002) reported that in most cases, irrespective of the stage in the oxidative chain in which the antioxidant action is assessed, most nonenzymatic antioxidative activities, such as scavenging of free radicals or inhibition of peroxidation, are mediated by redox reaction. Our data showed that the reducing power of these fractions probably play a role in the antioxidation of *R. virescens*.

3.8. Chelating effect on ferrous ions

At 5 mg/ml, RVP-1 chelated ferrous ions by 75.6% whereas the chelating abilities of RVP-2 and RVP were 30.1% and 50.8%, respectively (Fig. 5). At 10 mg/ml, the chelating abilities of RVP-1, RVP-2, and RVP were 93.3%, 51.2%, and 80.1%, respectively. However, EDTA showed an excellent chelating ability of 90.6% at 0.1 mg/ml. Citric acid was not a good chelating agent for ferrous ions in this assay and its chelating ability was 16.7% at 20 mg/ml.

Obviously, RVP-1 and RVP were good chelating agents for ferrous ions. Since ferrous ions are the most effective pro-oxidants in the food system (Yamaguchi, Tatsumi, Karo, & Yoshimitsu, 1988), the high ferrous-ion chelating abilities of polysaccharides from *R. virescens* would be somewhat beneficial.

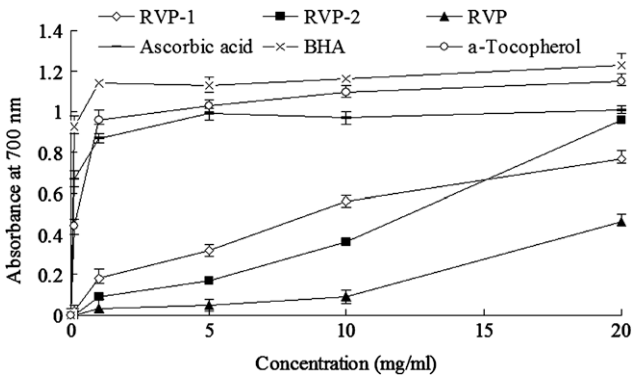

Fig. 4. Reducing power of RVP-1, RVP-2 and RVP. Each value is expressed as mean ± standard deviation ($n = 3$).

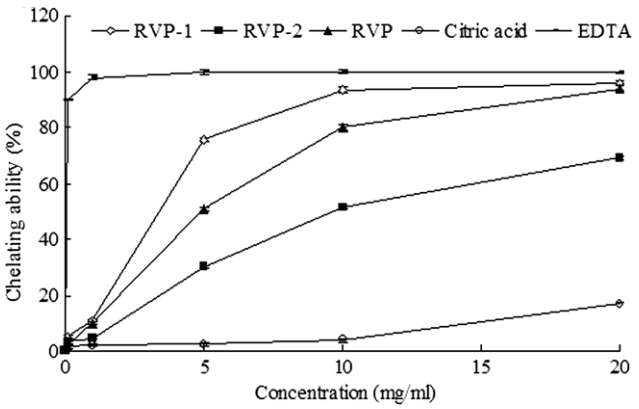

Fig. 5. Chelating effects of RVP-1, RVP-2 and RVP on ferrous ions. Each value is expressed as mean ± standard deviation ($n = 3$).

4. Conclusions

On the basis of the previously mentioned results, it was concluded that the water extracting crude polysaccharide of *R. virescens* contained predominantly two fractions (RVP-1 and RVP-2) purified by DEAE-Sepharose CL-6B column chromatography. RVP-1 and RVP-2 were heteropolysaccharides in which glucose was the major component. The estimated equivalent dextran molecular weights of RVP-1 and RVP-2 were around 3.1×10^5 and 4.2×10^5 Da, respectively. Analysis by Periodate oxidation–Smith degradation indicated that RVP-1 was composed of 68.3% (1 →)- or ((1 → 6)-glycosidic linkages and 31.7% (1 → 3)-glycosidic linkages, and RVP-2 7.9% (1 →)- or (1 → 6)-glycosidic linkages, 9.6% (1 → 2)-glycosidic linkages, 35.7% (1 → 4)-glycosidic linkages, and 46.8% (1 → 3)-glycosidic linkages.

RVP-1 and RVP-2 had a little higher scavenging activity of hydroxyl radical than that of Vc, and RVP-1 had a higher activity at scavenging superoxide radical compared to Vc and equivalent inhibiting ability to Vc on self-oxidation of 1,2,3-phentriol.

Overall, RVP-1 possessed good antioxidant properties and can be developed as a novel potential antioxidant for the treatment and prevention of some diseases relating to ROS. We can rationally assume that *R. virescens* has curative effect in traditional medicine partly because of antioxidation of polysaccharides in it. Thus, RVP-1 should be explored and investigated further in view of its potential as a therapeutic agent.

mechanisms for the high oxidative stability of SO during thermal oxidation have not been fully understood. Initial concentration of antioxidants including sesamol or tocopherol in SO may play a crucial role or other new antioxidant compounds may be formed during heating treatment.

Recently, our research group has developed a new method, which can predict the oxidative stability of edible oils by measuring absorbance of a mixture of DPPH and oil sample. Using this method, profile changes of antioxidants or radicals in thermally oxidised oils including olive oil, soybean oil, lard, and corn oil could be explained (Lee, Chung, Chang, & Lee, 2007). DPPH method may explain the exceptionally high oxidative stability of SO from roasted sesame seeds through monitoring the changes of hydrogen donating compounds and/or radicals with the combinations of sesamol and sesamolin analysis and other conventional methods such as conjugated dienoic acid (CDA) and headspace oxygen contents.

The objectives of this study were to determine the oxidative stability of SO pressed from sesame seeds roasted different time and temperature and to monitor major contributing factors for the extended oxidative stability of SO through a combination of DPPH, CDA, headspace oxygen analysis, and profile changes of sesamol and sesamolin.

2. Materials and methods

2.1. Materials

White sesame seeds in package were purchased from a local grocery market (Seoul, Korea). DPPH and sesamol were purchased from Sigma–Aldrich (St. Louis, MO, USA). Isooctane was bought from Junsei Chemical Co. (Tokyo, Japan). Other chemicals including sodium chloride, *n*-hexane, acetonitrile, and methanol were purchased from Daejung Chemical Co. (Seoul, Korea).

2.2. Sample preparation

2.2.1. Sesame oil preparation

Sesame seeds were put in a drum of a coffee roaster (Model CBR-101, Genesis Co., Ltd. Gyeonggi, Korea) and roasted at the temperature of 213, 230, or 247 °C with the duration of 14, 21, or 28 min. Therefore nine roasting condition (3 roasting temperature × 3 roasting time) was used in this study. Oil from roasted sesame seeds was extracted using an oil maker with a pressing unit (Model DO-9990, Dong-A Oscar Co., Ltd. Seoul, Korea). Crude SO was centrifuged (Model Mega 17R, Hanil Science Ltd. Gyeonggi, Korea) at 2208*g* for 20 min and supernatant was separated. Control was SO prepared from sesame seeds without roasting treatment. SO from sesame seed roasted at 247 °C for 28 min was designated as SO247/28. All samples were prepared triplicates.

2.2.2. Thermal treatment for oxidative stability of SO

One gram of SO was put in a 10-mL vial without caps. Samples were placed in a convection oven (Model LDO-250F, Win Science, Seoul, Korea) at 180 °C for 90 min and then analysed by CDA and DPPH methods at every 15 min.

Samples for the headspace oxygen analysis were prepared in 10-mL vials sealing air-tightly with Teflon-coated rubber septa and aluminum caps. Samples were thermally oxidised at 93 °C for 32 h and headspace oxygen contents was analysed at 0, 2.5, 4.5, 12, 16, and 32 h.

For the analysis of sesamol and sesamolin, SO from 213, 230, and 247 °C for 21 min were selected and thermally oxidised at 180 °C for 90 min in the convection oven (Win Science, Seoul, Korea). All samples were prepared triplicate.

2.3. CDA analysis

CDA of samples was measured according to AOCS (1980) method Ti la-64. The absorbance of oil sample in isooctane was determined at 233 nm using a UV–vis spectrophotometer (Model UV-1650PC, Shimadzu, Kyoto, Japan). CDA (%) was calculated using equation of $(0.84 \times A)/(bc - K_0)$, where A is the absorbance of samples at 233 nm, b is the cell length (cm), c is the gram per litre, and K_0 is the absorptivity by acid group, 0.03.

2.4. Analysis for headspace oxygen

Headspace oxygen in samples was analysed according to previous reports (Min, Li, & Lee, 1998; Yang, Lee, & Min, 2002; Lee & Min, 2009). The oxygen contents of headspace gas in sample bottles was determined by a gas chromatograph (GC) equipped with a thermal conductivity detector (TCD) (Agilent Technology, Palo Alto, CA, USA) and a stainless steel column (3.0 m × 0.2 cm) packed with 60/80 Molecular Sieve 5A (Restek, Bellefonte, PA, USA). Injection volume was 25 μL using an air-tight syringe and the flow rate of helium gas was 20 mL/min. Temperatures of oven, injector, and detector were 60, 180, and 180 °C, respectively.

2.5. DPPH measurement

DPPH method was adapted from a previous report of our research groups with minor modification (Lee et al., 2007). Briefly, 5 mL of 0.10 mM DPPH in isooctane was mixed with 56 μL oil samples and the absorbance of the sample mixture was measured at 509 nm after 30 min in the dark using the UV/VIS-spectrometer (Shimadzu, Kyoto, Japan).

2.6. Sesamol and sesamolin analysis

Sesamol and sesamolin in SO were separated and isolated using a high performance liquid chromatograph (HPLC) equipped with an ultraviolet detector (Model L-2400, Hitachi, Tokyo, Japan). A 4 μm Waters Novapak C_{18} reversed-phase HPLC column (150 mm × 3.9 mm I.D.) was used as stationary phase. Mobile phase was a mixture of deionized water and acetonitrile (70:30, v/v) at flow rate 1.0 mL/min. Sesame oil was diluted in *n*-hexane (0.1 g/mL) and 10 μL was injected. Sesamol and sesamolin in eluent were detected at 290 nm and identified based on the retention times of standard compound of sesamol and results of previous reports (Lee & Choe, 2006). Standard curves of sesamol were prepared to quantify the peak of sesamol in HPLC.

2.7. Statistical analysis

The data of CDA results, headspace oxygen of thermally oxidised SO at 32 h, and sesamol contents in SO before thermal oxidation were analysed statistically by ANOVA and Duncan's multiple range test using commercially available software package SPSS software program (SPSS Inc., Chicago, IL, USA). Also, contents of sesamol and sesamolin in thermally oxidised SO213/21, SO230/21, and SO247/21 were statistically analysed. A p value <0.05 was considered significant.

3. Results and discussion

3.1. CDA analysis

CDA values of SO during thermal oxidation at 180 °C for 90 min are shown in Table 1. CDA determines the formation of conjugated dienes or primary oxidation products of polyunsaturated fatty

acids. CDA values have been used to determine the oxidative stability of edible oils under thermal oxidation and to evaluate the antioxidant ability (Lee & Choe, 2006; Lee et al., 2007). CDA values of SO from roasted sesame seeds at 213 °C and SO 230/14 were not significant at 0 min ($p > 0.05$) while those of SO230/21, SO230/28, and SO from 247 °C roasted sesame seeds were significant compared to those of control ($p < 0.05$), which implies that SO were more oxidised when sesame seeds roasted at higher temperature and longer time (Table 1). Yoshida and Takagi (1997) analysed characteristics of sesame oils from different roasting conditions (160–250 °C) and observed minor increases in the lipid oxidation products including peroxide value, carbonyl value, anisidine value, and thiobarbituric acid reactive substances in more roasted samples.

Generally, SO from 230 to 247 °C roasted sesame seeds had significantly lower CDA values than SO from 213 °C roasted sesame seeds and control samples during thermal oxidation for 90 min ($p < 0.05$) (Table 1). For example, CDA values of control, SO213/14, SO230/14, and SO247/14 for 90 min oxidation at 180 °C were 1.362, 1.155, 0.685, and 0.723, respectively (Table 1), which shows that SO from sesame seeds received higher roasting temperature and longer duration possessed higher oxidative stability at 180 °C oxidation.

3.2. Analysis for headspace oxygen

Headspace oxygen of SO during thermal oxidation are shown in Fig. 1. Headspace oxygen contents in control samples decreased from 20.94% to 11.82% for 32 h at 93 °C while those from SO213/21, SO230/21, and SO247/21 changed by 5.69%, 3.00%, and 2.55%, respectively. Headspace oxygen of SO from 213 °C roasted sesame seeds was significantly higher than those from 230 to 247 °C ($p < 0.05$). As the degree of oxidation in oil increases, headspace oxygen in air-tight sample bottles decreases due to the reaction of oxygen with unsaturated fatty acids. Therefore, control samples had the lowest oxidative stability and SO247/28 had the highest oxidative stability. Measuring headspace oxygen is one of reliable methods to determine the oxidative stability of lipid samples (Min et al., 1998; Vittadini, Lee, Frega, Min, & Vodovotz, 2003; Yang et al., 2002). Generally, it is accepted that SO from roasting condition have relatively high oxidative stability (Miles & Doucette, 2001). In this study, SO from higher temperature and longer roasting time had higher oxidative stability than SO from lower temperature and shorter roasting time based on the results of CDA and headspace oxygen analysis, which agrees with previous reports (Miles & Doucette, 2001). However, major contributing factors for the high oxidative stability of SO during thermal oxidation are not understood yet.

3.3. DPPH analysis

Absorbance changes of DPPH in SO roasted at 213 (a), 230 (b), and 247 °C (c) are shown in Fig. 2. Absorbance of a mixture of DPPH

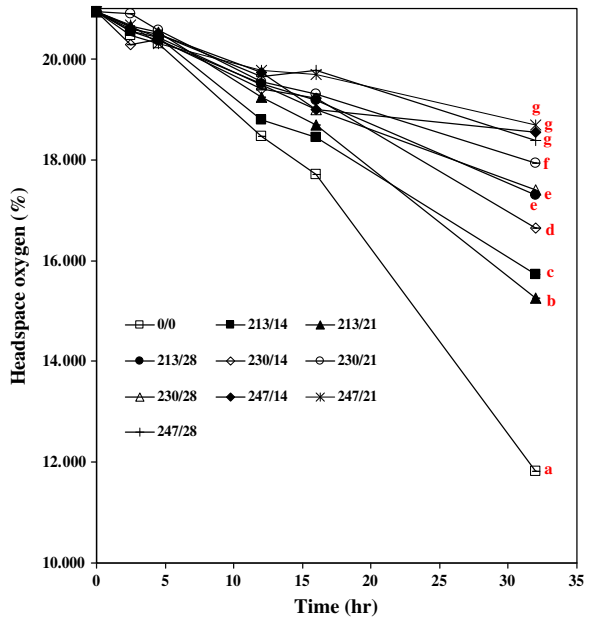

Fig. 1. Headspace oxygen of SO from roasted sesame seeds during thermal oxidation at 93 °C for 32 h. Statistical analysis was conducted on the headspace oxygen in SO oxidised at 32 h and different letters are significant at 0.05.

and control, SO213/21, SO230/21, or SO247/21 at 0 min were 0.589, 0.583, 0.451, and 0.220, respectively. SO from higher roasting temperature and longer roasting time had lower absorbance of DPPH at 0 min than control (Fig. 2). The low absorbance of DPPH implies that DPPH abstracted more hydrogen atom or electrons from SO and escaped from radical state. SO247/21 may have relatively higher concentration of free radical scavenging compounds or oxidised lipid radicals than control. Absorbance of control (symbol of 0/0 in Fig. 2) increased up to 45 min oxidation and started to decrease. This pattern of DPPH absorbance of control samples agrees with the previous reports on the oxidation of edible oils such as olive oil, soybean oil, lard, and corn oil (Lee et al., 2007).

As oxidation time increased, the absorbance of DPPH in SO from sesame seeds roasted at 213 °C with 14, 21, and 28 min increased gradually (Fig. 2a). The increase of absorbance implies that hydrogen donating free radical scavengers in SO was continuously depleted to retard the formation of lipid radicals. SO from sesame seeds roasted at 230 °C showed different pattern of DPPH absorbance depending on the roasting time (Fig. 2b). Absorbance of DPPH from SO230/14 increased up to 45 min and stared to decrease like control samples. However, the decreasing patterns of absorbance between control and SO230/14 were different. The thermal oxidation time for pattern changes of DPPH absorbance

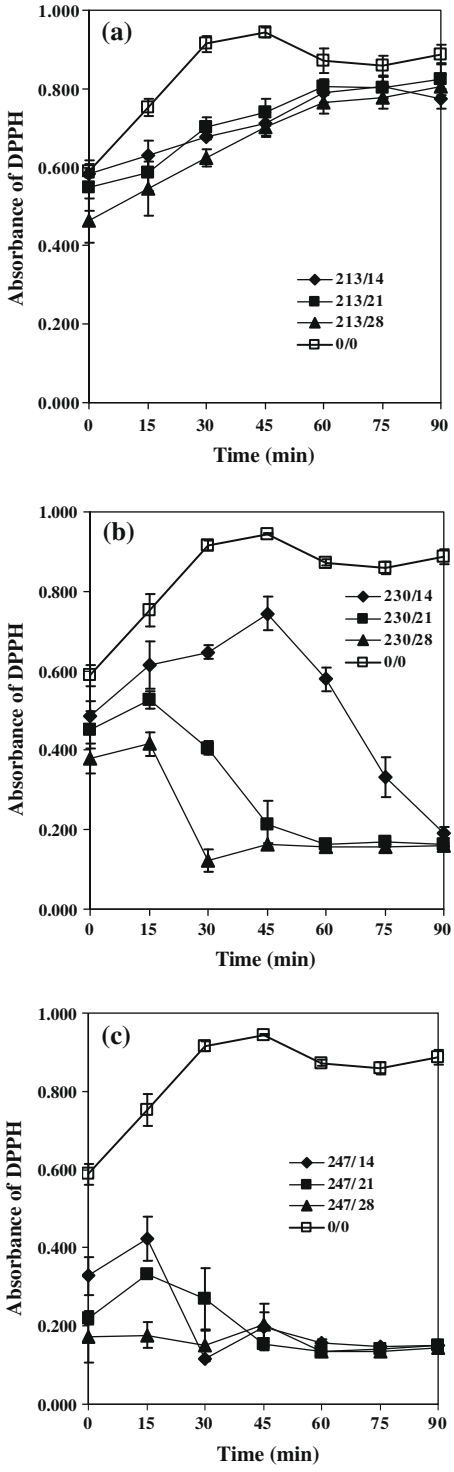

Fig. 2. Changes of absorbance of DPPH in SO from roasted sesame seeds at 213 °C (a), 230 °C (b), and 247 °C (c) during thermal oxidation at 180 °C.

in both SO230/21 and SO230/28 was 15 min rather than 45 min of SO230/14 (Fig. 2b). It is interesting that SO from sesame seeds roasted at longer roasting time showed shorter time for pattern changes. This trend can be observed in SO from sesame seeds roasted at 247 °C. SO247/28 did not show great changes of absorbance while SO247/14 and SO247/21 showed increases of DPPH absorbance up to 15 min and started to decrease like SO230/21 and SO230/28 (Fig. 2c). This observation of DPPH results implies that new free radical scavenging compounds may be generated continuously in SO from 230 to 247 °C roasted sesame seeds during thermal oxidation. Therefore, SO from sesame seeds roasted at higher temperature may have enough free radical scavenging compounds and absorbance of DPPH did not change during heat treatment. This observation was confirmed by the results of sesamol and sesamolin analysis.

3.4. Sesamol and sesamolin analysis

Effects of roasting condition on the sesamol contents in SO before heat treatment are shown in Fig. 3. As roasting time and temperature increased, contents of sesamol in SO significantly increased ($p < 0.05$). Sesamol contents in SO247/28 were significantly higher than those in SO213/14 by 6.42 times while control samples did not contain sesamol. Wu (2007) analysed lignan contents of 14 brands of sesame oils, and found their mean of total lignans as 11.5 mg/g; 82% and 15% of the lignans were sesamin and sesamolin, respectively. The author reported that sesamol contents were relatively higher in darker coloured SO. Previous studies showed that extended oxidative stability of SO from roasting conditions was closely related with the sesamol contents and γ-tocopherol (Frank, 2005).

Changes of sesamol and sesamolin contents in SO prepared from sesame seeds roasted at 213, 230, and 247 °C for 21 min at 180 °C oxidation are shown in Fig. 4. As heat treatment increased from 0 to 90 min, concentration of sesamol in SO230/21 and SO247/21 increased significantly and peak areas of sesamolin decreased significantly ($p < 0.05$). DPPH absorbance did not change in SO247/21 during thermal oxidation (Fig. 2c), which may be due to the sufficient amount of sesamol generated from sesamolin (Fig. 4). In case of SO230/21, relative peak areas of sesamolin changed from 100% to 6.61% for 90 min, while concentration of sesamol in SO230/21 increased from 0.16 to 0.42 mM. DPPH absorbance in SO230/21 started to decrease from 15 min oxidation, which was the time for the increases of sesamol contents. Therefore, increase of sesamol in SO230/21 seemed to be closely related with the decrease of DPPH absorbance like SO247/21. Suja et al. (2004) showed that second order rate constants of sesamol and DPPH were 11.1 and 30.7 times higher than those of sesamin and sesamolin, respectively. Therefore, formation of sesamol from sesamolin played important roles on the decreases of DPPH absorbance and exceptional thermal stability of SO during heat treatment. The results of this study agree with the previous reports of Fukuda et al. (1986) and Shahidi & Naczk (2004).

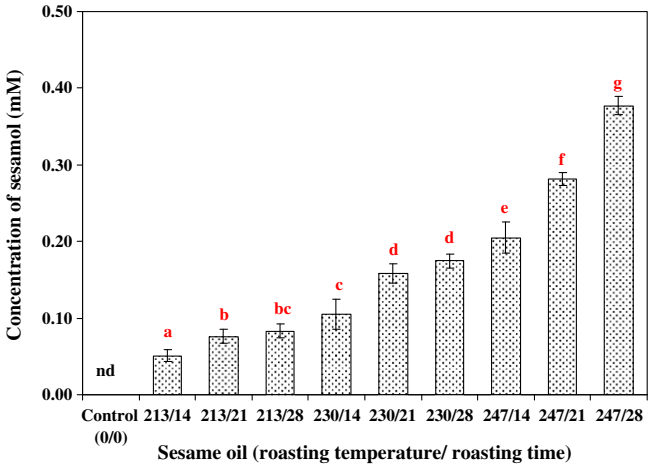

Fig. 3. Effects of roasting condition on the sesamol contents in SO before thermal oxidation at 180 °C. nd: not detected. Different letters are significant at 0.05.

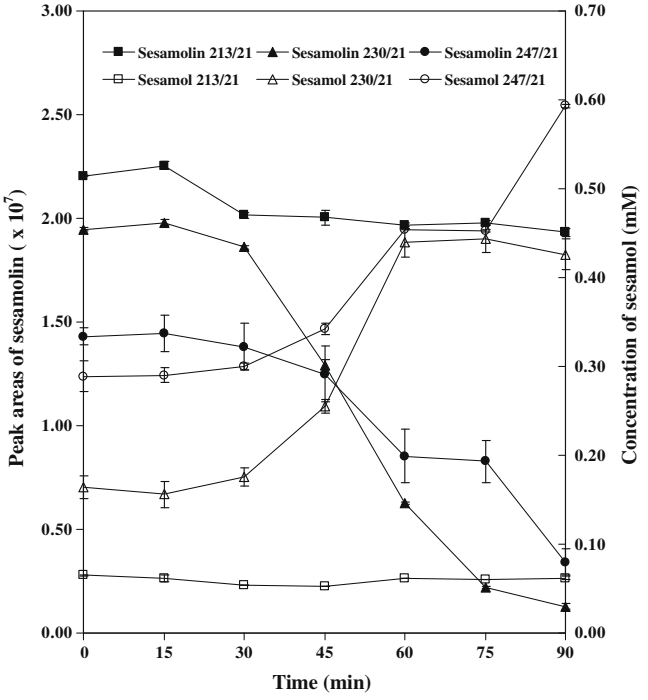

Fig. 4. Changes of sesamol and sesamolin in SO from roasted sesame seeds at 213, 230, or 247 °C for 21 min at 180 °C thermal oxidation. Right and left *Y*-axes are for the peak areas of sesamolin and concentration of sesamol, respectively.

Interestingly, changes of sesamol and sesamolin in SO from 213 °C were relatively smaller than those in SO from 230 to 247 °C during thermal oxidation, which matched the patterns of DPPH absorbance in Fig. 2. The pattern changes of SO from 230 to 247 °C strongly indicates that new free radical scavenging compounds were continuously formed and this antioxidant compound was tentatively confirmed as sesamol from the decomposition of sesamolin (Figs. 2 and 4).

The decreases in the absorbance of DPPH showed that SO from roasted sesame seeds already contained substantial amounts of hydrogen donating antioxidants and oxidised lipid radicals before thermal treatment. CDA values and sesamol contents in SO confirmed the presence of oxidised lipids and hydrogen donating free radical scavengers, respectively. If conventional methods like CDA and headspace oxygen analysis methods were used only, sesamol and antioxidants such as γ-tocopherol in SO would be concluded as a crucial ingredient for the extraordinary high oxidative stability of SO during heat treatment. DPPH method has revealed that hydrogen donating compounds were continuously generated in SO from 230 to 247 °C roasted sesame seeds. This speculation was confirmed by sesamol and sesamolin analysis showing the formation of sesamol from sesamolin during 180 °C treatment.

It is well-known that the concentration of γ-tocopherol decreases as thermal oxidation prolonged. Therefore, γ-tocopherol could be one factor for the decreases of absorbance of DPPH in SO before thermal oxidation. However, γ-tocopherol may not be a major compound for the decreases of DPPH during thermal oxidation at 180 °C. Rather than this, formation of sesamol is more important factor for the low absorbance of DPPH in SO. Interestingly, SO213/21 produced low concentration of sesamol compared to samples at SO230/21 and SO247/21 during thermal oxidation (Fig. 4). The formation rate of sesamol from sesamolin should be similar in SO at 180 °C oxidation irrespective of roasting temperature for sesame seeds. Therefore, other factors in SO from 230 to 247 °C roasted sesame seeds may influence the stability of sesamolin and the formation of sesamol, which needs further researches.

teins; and oxidants have been considered in eye disorders such as cataract and retrolental fibroplasia. Aldose reductase, the key enzyme of the polyol pathway, has been demonstrated to play an important role in the etiology of the complications of diabetes (Enomoto et al., 2004).

2. Material and methods

2.1. Plant material

The aerial parts of *S. brevibracteata* P.H. Davis were collected from C3 Antalya: Alanya, Alanya-Türbelinaz road, around Bektaş, calcareous rocks, in macchie, 200 m, N 36° 33.560′, E 32° 00 484′, by *Hayri Duman* 875, 27.05.2001. Voucher specimens (coll. *Hayri Duman* 875) are deposited in the Botany Department Herbarium at Gazi University (GAZI) Turkey.

2.2. General experimental procedures

CC: silica gel 60 (70–230 mesh, Merck, Darmstadt, Germany); thin layer chromatography (TLC): silica gel 60 F_{254} precoated aluminium plates (0.2 mm, Merck, Germany). Detection: UV fluorescence and spraying 1% vanillin/H_2SO_4, followed by heating at 105 °C for 1–2 min. IR spectra were recorded on Jasco FT/IR 420 spectrometer (Japan) as KBr pellets. UV spectra: Shimadzu UV-1601 (Japan), UV–visible spectrophotometer. ^{1}H- and ^{13}C-NMR spectra were measured with Varian Mercury 400 FT-NMR spectrometer (Varian Inc., Palo Alto, CA, USA). The spectra were measured in CD_3OD and referenced against residual non-deuterated solvent. Electrospray ionization mass spectrometer (ESI-MS) (Manchester, UK) was recorded using Waters Micromass Spectrometer ZQ.

2.3. Extraction and isolation

The air-dried and powdered aerial parts of *S. brevibracteata* (350 g) were extracted with 3500 ml MeOH in a Soxhlet apparatus for 12 h. The MeOH extract was then evaporated in vacuum (40 °C). The residue (82.80 g) was dissolved in 500 ml H_2O–MeOH mixture (9:1, v/v), then partitioned three times with chloroform (3 × 250 ml), AcOEt (3 × 250 ml) and *n*-BuOH saturated with water (3 × 250 ml). These three phases were evaporated under reduced pressure and total extracts of chloroform (10.50 g), AcOEt (9.38 g) and *n*-BuOH (25.11 g) were obtained. An aliquot of *n*-BuOH extract (2.72 g) was subjected to medium-pressure liquid chromatography (MPLC), using water (200 ml) and H_2O–MeOH mixtures (5 → 45% MeOH in steps of 5% of MeOH (each 200 ml)). Flavonoids were eluted in the following order: **1** (88 mg) (fractions 61–62), **2** (142 mg) (fractions 65–69), **3** (87 mg as crude) (fractions 71–74), **4** (292 mg) (fractions 79–81), **5** (118 mg) (fractions 82–83) and **6** (44 mg) (fractions 86–87). Fractions 71–74 (87 mg) containing crude compound **3** were subjected to a silica gel using $CHCl_3$–MeOH–H_2O mixtures (90:10:1 → 61:27:7, v/v/v) as solvent system yielding pure **3** (13 mg). Rechromatography of fractions 59–60 (64 mg) on a silica gel column using $CHCl_3$–MeOH–H_2O solvent mixtures (80:20:1 → 80:20:2, v/v/v) afforded compound **7** (27.2 mg). Compounds **1**–**7** were also obtained from the AcOEt extract.

2.4. Medium-pressure chromatography

MPLC separations were carried out using a Buchi glass column (C-690: 04437; 460 × 26 mm i.d.) packed with Lichroprep C_{18} (Merck, Germany) using Buchi 681 chromatography pump combined with a Buchi 684 fraction collector.

2.4.1. Hypolaetin 7-O-[6‴-O-acetyl-β-D-allopyranosyl-(1 → 2)]-β-D-glucopyranoside (*1*)

Amorphous yellow powder. UV λ_{max} nm (MeOH): 276, 302, 342; IR ν_{max} cm^{-1} (KBr): 3408 (OH), 2924 (C–H), 1717 (ester C=O), 1655 (γ-pyrone C=O), 1614, 1585, 1505 (aromatic ring); ESI-MS: m/z 691.14 $[M + Na]^+$, calculated for $C_{29}H_{32}O_{18}$; ^{1}H NMR (CD_3OD, 400 MHz); ^{13}C-NMR (CD_3OD, 100 MHz). All data were similar to those previously reported (Lenherr & Mabry, 1987; Rodriguez-Lyon et al., 2000) and assignments confirmed by COSY, HMQC and HMBC.

2.4.2. Isoscutellarein 7-O-[6‴-O-acetyl-β-D-allopyranosyl-(1 → 2)]-β-D-glucopyranoside (*2*)

Amorphous yellow powder. UV λ_{max} nm (MeOH): 276, 307, 325(sh); IR ν_{max} cm^{-1} (KBr): 3400 (OH), 2923 (C–H), 1725 (ester C=O), 1658 (γ-pyrone C=O), 1608, 1585, 1503 (aromatic ring); ESI-MS: m/z 675.15 $[M + Na]^+$, calculated for $C_{29}H_{32}O_{17}$; ^{1}H NMR (CD_3OD, 400 MHz); ^{13}C-NMR (CD_3OD, 100 MHz). All data were in good accordance with those previously reported (Albach et al., 2003; Lenherr & Mabry, 1987; Rios et al., 1992).

2.4.3. 3′-hydroxy-4′-O-methylisoscutellarein 7-O-[6‴-O-acetyl-β-D-allopyranosyl-(1 → 2)]-β-D-glucopyranoside (*3*)

Amorphous yellow powder. UV λ_{max} nm (MeOH): 279, 299(sh), 339; IR ν_{max} cm^{-1} (KBr): 3410 (OH), 2921 (C–H), 1732 (ester C=O), 1659 (γ-pyrone C=O), 1614, 1585, 1506 (aromatic ring); ESI-MS: m/z 705.19 $[M + Na]^+$, calculated for $C_{30}H_{34}O_{18}$; ^{1}H NMR (CD_3OD, 400 MHz); ^{13}C-NMR (CD_3OD, 100 MHz). All data were in accordance with reported data (Lenherr & Mabry, 1987; Rios et al., 1992).

2.4.4. Hypolaetin 7-O-[6‴-O-acetyl-β-D-allopyranosyl-(1 → 2)]-6″-O-acetyl-β-D-glucopyranoside (*4*)

Amorphous yellow powder. UV λ_{max} nm (MeOH): 276, 301, 343; IR ν_{max} cm^{-1} (KBr): 3410 (OH), 2920 (C–H), 1723 (ester C=O), 1659 (γ-pyrone C=O), 1610, 1585, 1503 (aromatic ring); ESI-MS: m/z 733.19 $[M + Na]^+$, calculated for $C_{31}H_{34}O_{19}$; ^{1}H NMR (CD_3OD, 400 MHz); ^{13}C-NMR (CD_3OD, 100 MHz) and assignments confirmed by COSY, HMQC and HMBC. All data were similar to those previously reported (Lenherr & Mabry, 1987; Rodriguez-Lyon et al., 2000).

*2.4.5. Isoscutellarein 7-O-[6‴-O-acetyl-β-D-allopyranosyl-(1 → 2)]-6″-O-acetyl-β-D-glucopyranoside (**5**)*

Amorphous yellow powder. UV λ_{max} nm (MeOH): 277, 307, 325(sh); IR ν_{max} cm^{-1} (KBr): 3410 (OH), 2920 (C–H), 1725 (ester C=O), 1659 (γ-pyrone C=O), 1608, 1585, 1504 (aromatic ring); ESI-MS: m/z 717.20 $[M + Na]^+$, calculated for $C_{31}H_{34}O_{18}$; ^1H NMR (CD_3OD, 400 MHz); ^{13}C-NMR (CD_3OD, 100 MHz). All data were in accordance with reported data (Lenherr & Mabry, 1987; Skaltsa et al., 2000).

*2.4.6. 3′-hydroxy-4′-O-methylisoscutellarein 7-O-[6‴-O-acetyl-β-D-allopyranosyl-(1 → 2)]-6″-O-acetyl-β-D-glucopyranoside (**6**)*

Amorphous yellow powder. UV λ_{max} nm (MeOH): 279, 298(sh), 338; IR ν_{max} cm^{-1} (KBr): 3420 (OH), 2922 (C–H), 1726 (ester C=O), 1659 (γ-pyrone C=O), 1613, 1585, 1503 (aromatic ring); ESI-MS: m/z 747.20 $[M + Na]^+$, calculated for $C_{32}H_{36}O_{19}$; ^1H NMR (CD_3OD, 400 MHz); ^{13}C-NMR (CD_3OD, 100 MHz). All data were similar to those previously reported (Lenherr & Mabry, 1987).

*2.4.7. Verbascoside (**7**)*

Amorphous colourless powder; UV λ_{max} nm (MeOH) = 220, 234 (sh), 290, 329; IR ν_{max} (KBr) cm^{-1} = 3390 (OH), 1700 (conjugated ester C=O), 1630 (conjugated C=O), 1604, 1523 (aromatic ring), $C_{29}H_{36}O_{15}$; ^1H- and ^{13}C-NMR (CD_3OD). All data were in accordance with reported data (Sticher & Lahloub, 1982).

2.5. Pharmacological procedures

2.5.1. Animals

Male Swiss Albino mice (20–25 g) were purchased from the animal breeding laboratories of Refik Saydam Central Institute of Health (Ankara, Turkey). The animals, left for two days for acclimatization to animal room conditions, were maintained on standard pellet diet and water *ad libitum*. The food was withdrawn on the day before the experiment, but animals were allowed free access to water. A minimum of six animals was used in each group. Throughout the experiments, animals were processed according to the suggested ethical guidelines for the care of laboratory animals.

2.5.2. Preparation of test samples for bioassay

All extracts were administered in 100 mg/kg dose after suspending in 0.5% sodium carboxymethyl cellulose (CMC) suspension in distilled water. The control group animals received the same experimental handling as those of the test groups except that the drug treatment was replaced with appropriate volumes of the dosing vehicle. Either indomethacin (10 mg/kg and 0.5 mg/ear) or acetyl salicylic acid (ASA) (100 mg/kg) in 0.5% CMC was used as reference drug.

2.5.3. Antinociceptive activity

p-Benzoquinone (PBQ)-induced abdominal constriction test (Okun, Liddon, & Lasagnal, 1963) was performed on mice for determination of antinociceptive activity. According to the method, 60 min after the oral administration of test samples, the mice were intraperitoneally injected with 0.1 ml/10 g body weight of 2.5% (w/v) PBQ (Merck) solution in distilled H_2O. Control animals received an appropriate volume of dosing vehicle. The mice were then kept individually for observation and the total number of abdominal contractions (writhing movements) was counted for the next 15 min, starting at the 5th min after the PBQ injection. The data represent the average of the total number of writhes observed. The antinociceptive activity was expressed as percentage change from writhing controls. Aspirin (ASA) at 100 mg/kg dose was used as the reference drug in this test.

2.5.4. Anti-inflammatory activity

2.5.4.1. Carrageenan-induced hind paw edema model. Carrageenan-induced hind paw edema model was used for determination of anti-inflammatory activity (Yeşilada & Küpeli, 2002). The difference in footpad thickness between the right and left foot was measured with a pair of dial thickness gauge calipers (Ozaki Co., Tokyo, Japan). Mean values of treated groups were compared with mean values of a control group and analyzed using statistical methods. One hour after the oral administration of the test sample or dosing vehicle, each mouse was injected with freshly prepared (0.5 mg/25 μl) suspension of carrageenan (Sigma, St. Louis, Missouri, USA) in physiological saline (154 nM NaCl) into the subplantar tissue of the right hind paw. As the control, 25 μl saline solutions were injected into that of the left hind paw. Paw edema was measured every 90 min for 6 h from induction of inflammation. The difference in footpad thickness was measured by gauge calipers (Ozaki Co., Tokyo, Japan). Mean values of the treated groups were compared with mean values of a control group and analyzed using statistical methods. Indomethacin (10 mg/kg) was used as the reference drug.

2.5.4.2. TPA-induced mouse ear edema. Each mouse received 2.5 μg of TPA (12-*O*-tetradecanoylphorbol 13-acetate) dissolved in 20 μl of EtOH 70% (De Young, Kheifets, Ballaron, & Young, 1989). This was applied by an automatic pipette in 20 μl volumes to both anterior and posterior surfaces of the right ear. The left ear (control) received the same volume of solvent (EtOH 70%) simultaneously with TPA. Indomethacin (0.5 mg/ear) was used as a standard drug. For evaluation of the activity, two methods were used as presented below.

1. The thickness of each ear was measured 4 h after induction of inflammation using gauge calipers (Ozaki Co., Tokyo, Japan). The edema was expressed as the difference between right and left ears due to TPA application and consequently, inhibition percentage was expressed as a reduction in thickness with respect to the control group.
2. After 4 h, the animals were sacrificed under deep ether anesthesia. Disks 6 mm in diameter were removed from each ear and weighed on a balance. The swelling was estimated as the difference in weight between the punches from right and left ears, and expressed as an increase in ear thickness.

2.5.4.3. Prostaglandin (PGE_2)-induced hind paw edema model. PGE_2-induced hind paw edema model was used for determination of anti-inflammatory activity (Kasahara, Hikino, Tsurufiji, Watanabe, & Ohuchi, 1985). The difference in footpad thickness between the right and left foot was measured with a pair of dial thickness gauge calipers (Ozaki Co., Tokyo, Japan). Mean values of treated groups were compared with mean values of a control group and analyzed using statistical methods. One hour after the oral administration of the test sample or dosing vehicle, each mouse was injected with freshly prepared (5 μg/5 μl) suspension of PGE_2 (Fluka Chemie AG, Art. 82475) in Tyrode's solution into the subplantar tissue of the right hind paw. As the control, 5 μl Tyrode's solution was injected into that of the left hind paw. Paw edema was measured every 15 min for 75 min from induction of inflammation. The difference in footpad thickness was measured by gauge calipers (Ozaki Co., Tokyo, Japan). Mean values of the treated group were compared with mean values of a control group and analyzed using statistical methods. Indomethacin (10 mg/kg) was used as the reference drug.

2.5.4.4. Acute toxicity. Animals employed in the carrageenan-induced paw edema experiment were observed over 48 h and mor-

bidity or mortality was recorded, if present, for each group at the end of the observation period.

2.5.4.5. Gastric-ulcerogenic effect. After the antinociceptive activity experiment, mice were sacrificed under deep ether anesthesia and stomachs were removed. The abdomen of each mouse was then opened through the greater curvature and examined under dissecting microscope for lesions or bleedings.

2.5.4.6. Statistical analysis of data. Data obtained from animal experiments were expressed as mean standard error (±SEM). Statistical differences between the treatment and control groups were evaluated by ANOVA and Students–Newman–Keuls post hoc tests. $p < 0.05$ was considered to be significant ($^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$).

2.5.5. Antioxidant activity

2.5.5.1. Reduction of DPPH radical. Methanolic solutions (0.1%) of compounds **1**–**7** were chromatographed on a silica gel plate using $CHCl_3$–MeOH–H_2O (70:30:3, v/v/v). After drying, TLC plates were sprayed with 0.2% 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical (Fluka, Switzerland) solution in MeOH. Compounds showing a yellow-on-purple spot were regarded as antioxidant (Takao, Kitatani, Watanebe, Yagi, & Sakata, 1994).

2.5.5.2. The lipid peroxidation of liposomes assay. The principal components of the assay, apart from the standardized liposomes source (Brain extract, Sigma, Germany), are ascorbic acid (Aldrich, Germany) and an iron source ($FeCl_3$, Sigma, Germany). Brain extract suspension was made in PBS (phosphate buffered saline, Sigma, Germany) and sonicated in an ice-water bath until all lipids had been suspended. For the test reaction of the pure compounds, a mixture of liposomes, $FeCl_3$, ascorbic acid and PBS was used. All of the tubes were incubated at 37 °C for 20 min. The TBA test was performed thereafter by adding butylated hydroxytoluene (Sigma, Germany) in ethanol followed by thiobarbituric acid (TBA, Sigma, Germany) in NaOH (Merck, Germany) and HCl (Merck, Germany). The tubes were heated to 90 °C for 30 min and then allowed to cool completely. The chromogens were extracted by *n*-butanol (Merck, Germany). The mixture was vortexed to ensure complete extraction of the chromogen and then centrifuged at 3500 rpm for 15 min at room temperature in order to separate the two layers. The absorbance of the upper layers, which contain the chromogen, was determined by a Shimadzu UV-1601(Japan) UV–vis spectrophotometer at 532 nm. The incorporation of any antioxidant compound in the mixture will lead to a reduction in the extent of peroxidation (Güvenç et al., 2005). The calculation of percentage inhibitions of lipid peroxidation was assessed by comparing the absorbance of the full reaction mixture with that of the extract test reaction mixtures where the substance to be assessed was included. The half-maximal inhibitory concentrations (IC_{50}) of compounds **1**–**7** were calculated by linear regression analysis.

Compounds were prepared in MeOH and seven different concentrations (1; 0.20; 0.04; 0.008; 0.0016; 0.00032; 0.000064 mg/ml). Propyl gallate was used as a reference compound in the same concentrations.

2.5.6. Effect on aldose reductase (AR)

2.5.6.1. Preparation of sample solution. All compounds were dissolved in dimethyl sulphoxide (DMSO). Usually a 3 μg/mL solution was prepared and diluted to the desired concentrations with DMSO.

2.5.6.2. Assay of AR activity. Assays were performed at 25 °C in 0.2 M sodium phosphate buffer (pH 6.2) containing 10 mM DL-glyceraldehyde, 0.5 mM NADPH and enzyme (3×10^{-3} unit) in a total volume of 1.0 mL. The effect of enzyme inhibition was determined by adding 3 μL of an inhibitor solution to the reaction mixture; the appropriate blank was prepared. The reaction was initiated by adding substrate, and the rate of NADPH oxidation was indicated by the decrease of absorbance at 340 nm on a Shimadzu UV 160A spectrophotometer (Enomoto et al., 2004). Quercetin was used as positive control.

2.5.6.3. Determination of IC_{50}. The concentration of inhibitors (μg/0.1 mL reaction mixture) giving 50% inhibition of enzyme activity was estimated from the least-squares regression line of the logarithmic concentrations plot against the remaining activities.

3. Results and discussion

For the scientific evaluation of the aerial parts of *S. brevibracteata*, used as an herbal tea in Turkish folk medicine, various extracts and pure compounds (**1**–**7**) were investigated. These extracts and pure compounds were then investigated for their *in vivo* anti-inflammatory activity using carrageenan-induced hind paw edema model (Table 1), PGE_2-induced hind paw edema model (Table 2) and TPA-induced mouse ear edema model (Table 3) and for their

antinociceptive activity using PBQ-induced writhing model in mice (Table 4); pure phenolic compounds of this plant were also studied *in vitro* for antioxidant and AR inhibitory activities (Table 5).

Compounds **1**–**7** were isolated with MPLC using reversed phase material (RP C-18) and increasing amount of MeOH in water as eluent from *n*-butanol extract of the MeOH extract of aerial parts of *S. brevibracteata*. Compounds **1**–**6** were obtained as yellow solids. Their IR spectra showed absorption bands for hydroxyl, ester carbonyl, conjugated carbonyl and aromatic ring. The UV spectra and NMR data resulted in grouping the compounds in three pairs (**1**/**4**, **2**/**5** and **3**/**6**). The UV, IR, ^{1}H- and ^{13}C-NMR data of compounds **1**/**4**, **2**/**5** and **3**/**6** were identical with those of hypolaetin 7-*O*-[6‴-*O*-acetyl-β-D-allopyranosyl-(1 → 2)]-β-D-glucopyranoside (**1**) (Lenherr & Mabry, 1987; Rodriguez-Lyon et al., 2000), isoscutellarein 7-*O*-[6‴-*O*-acetyl-β-D-allopyranosyl-(1 → 2)]-β-D-glucopyranoside (**2**) (Albach et al., 2003; Lenherr & Mabry, 1987; Rios et al., 1992), 3′-hydroxy-4′-*O*-methylisoscutellarein 7-*O*-[6‴-*O*-acetyl-β-D-allopyranosyl-(1 → 2)]-β-D-glucopyranoside (**3**) (Lenherr & Mabry, 1987; Rios et al., 1992), hypolaetin 7-*O*-[6‴-*O*-acetyl-β-D-allopyranosyl-(1 → 2)]-6″-*O*-acetyl-β-D-glucopyranoside (**4**) (Lenherr & Mabry, 1987; Rodriguez-Lyon et al., 2000), isoscutellarein 7-*O*-[6‴-*O*-acetyl-β-D-allopyranosyl-(1 → 2)]-6″-*O*-acetyl-β-D-glucopyranoside (**5**) (Lenherr & Mabry, 1987; Skaltsa et al., 2000), and 3′-hydroxy-4′-*O*-methylisoscutellarein 7-*O*-[6‴-*O*-acetyl-β-D-allopyranosyl-(1 → 2)]-6″-*O*-acetyl-β-D-glucopyranoside (**6**) (Lenherr & Mabry, 1987), respectively (Fig. 1). Compound **7** was identified as verbascoside (=acteoside). The UV, IR, ESI-MS and NMR data were in good accordance with those previously reported (Sticher & Lahloub, 1982).

Anti-inflammatory activity has been reported in different kinds of extracts of several *Sideritis* species (Alcaraz et al., 1989; Barberán, Manez, & Villar, 1987; Hernandez-Perez, Sanches-Mateo, Montalbetti-Moreno, & Rabanal, 2004). However, studies performed on the pure compounds are rare (Küpeli, Şahin, Çalış, Yeşilada, & Ezer, 2007; Villar, Gasco, & Alcaraz, 1984). In the present study, the results in Tables 1–4 indicated that the *n*-butanol extract of *S. brevibracteata* exhibited the highest anti-inflammatory and antinociceptive activity. These results are in good accordance with the uses of this genus. The dried flowering spikes of *Sideritis* species are used as herbal tea in the western and southern coastal regions of Turkey due to their pleasant smell and aroma. Tea is the hot water extract of a plant and it contains all water soluble extractives such as sugars, glycosides, phenolics, etc. (Başer, 1995). It was considered that the active compounds for both anti-inflammatory and antinociceptive activities could be flavonoids, which are the major components of the *n*-butanol fraction.

Propyl gallate	0.21 ± 0.01	
Quercetin		1.16

All the above arguments are in agreement with experiments undertaken by other research groups reporting similar chemical compounds from other *Sideritis* species (Alcaraz et al., 1989; Küpeli et al., 2007; Villar et al., 1984). As shown in Table 1, *n*-butanol extract was significantly active against carrageenan-induced edema. Hence, the phenolic compounds isolated from the *n*-butanol extract were also assayed in the same *in vivo* system. All extracts and the pure compounds were given in standard dose of 100 mg/kg, in order to make a direct comparison of their activities. Hypolaetin derivatives (**1**,**4**) and 3′-hydroxy-4′-*O*-methylisoscutellarein7-*O*-[6‴-*O*-acetyl-β-D-allopyranosyl-(1 → 2)-6″-*O*-acetyl-β-D-glucopyranoside] (**6**) showed activity in carrageenan-induced paw edema, ear edema and PBQ-induced writhings in mice. Compounds **1** and **6** were found to be active against PGE_2-induced paw edema in mice. Compound **7** showed activity in all the test systems. On the other hand, the anti-inflammatory properties of verbascosides (**7**) as a major constituent of *Stachytarpheta cayennesis* (L.C. Rich) Vahl were shown in a previous study (Penido et al., 2006).

Our results are supported by the previous studies showing the anti-inflammatory and antinociceptive activities of certain *Sideritis* species due to their flavonoid and phenylethanoid contents (Hernandez-Perez et al., 2004; Küpeli et al., 2007; Penido et al., 2006). Compounds **1** (hypolaetin 7-*O*-[6‴-*O*-acetyl-β-D-allopyranosyl-(1 → 2)-β-D-glucopyranoside]) and **7** (verbascoside) were found to be the most active compounds. Isoscutellarein derivatives (**2**, **5**) were found to have lower anti-inflammatory and antinociceptive activities.

The water soluble part of the MeOH extract was partitioned between chloroform and *n*-BuOH. According to the TLC autographic assay with DPPH**.**, seven compounds (**1**–**7**) were found to be responsible for the scavenging properties of *S. brevibracteata* (Takao et al., 1994). These compounds were rich in *n*-BuOH extract of the aerial parts of this species. The antioxidant activity of the compounds was investigated using TBA method, in which the highest activity was observed for compounds **1**, **4** and **7**. Among the flavone glycosides, hypolaetin derivatives (**1**, **4**) were found to have stronger activity than isoscutellarein. It was shown that compounds **3** and **6** have higher antioxidant activity than compounds **2** and **5**. Compounds **3** and **6,** which carry hydroxyl group at C-3′ position and methoxyl group at C-4′ position on ring B, are more active than compounds **2** and **5,** having one hydroxyl group at C-4′ position on ring B. These results are in good accordance with those reported by Rios et al. (Rios et al., 1992). *O*-glycosylation at C-7 has been reported as weakly negative on activity by Mora et al. (Mora, Paya, Rios, & Alcaraz, 1990). However, Rios et al. observed that compounds having the 6‴-acetylallopyranosyl-(1 → 2)-glucopyranoside group were also active (Rios et al., 1992). In the present study, it was observed that the acetyl group on the allose unit was ineffective on antioxidant activity. Furthermore, the antioxidant activity of compound **7** has been reported in previous studies (Aldini et al., 2006; Siciliano et al., 2005). Thus, the presence of *ortho*-hydroxyl groups on phenolic moieties is responsible for the remarkable antioxidant activity, as previously reported for flavonoids (Rios et al., 1992) and for phenylethanoid glycosides (Heilmann et al., 2000). Moreover, we examined six flavonoid compounds along with verbascoside for their inhibitory activities on human AR. A structure activity relationship among the seven compounds was not found in the AR inhibitory assay. However, among the flavone glycosides, hypolaetin derivatives (**1**, **4**) gave similar activity. Isoscutellarein derivatives (**2**, **5**) also showed the same activity.

The distribution of the flavone glycosides in the genus *Sideritis* is of interest from a taxonomic viewpoint. In particular, 8-OH-flavone glycosides are characteristic for some sections of *Sideritis*. The 7-allosylglycosides of hypolaetin, isoscutellarein and 3′-hydroxy-4′-*O*-methylisoscutellarein were also reported from different *Sideritis* species, as *S. hypsophila* (Rodriguez-Lyon et al., 2000), *S. javalambrensis* (Rios et al., 1992), and *S. mugronensis* (Alcaraz et al., 1989; Villar et al., 1984). In 1993, in contrast to the sections of *Empedocleopsis* and *Creticae*, the section *Marrubiastrum* was reported as one of the richest *Sideritis* species containing 8-OH-flavone glycosides (Gil, Ferreres, Marrero, Tomás-Lorente, & Tomás-Barberán, 1993). Among the Ibero-North African *Sideritis* species, species of the section *Sideritis* (*Eusideritis* Bentham) were also characterized by the accumulation of the 7-glycosides of 8-OH-flavones

(isoscutellarein, hypolaetin and their methyl ethers), as in this study (Barberán, Rejdali, Harborne, & Heywood, 1988). Moreover, the presence of 6-OH-flavone and 8-OH-flavone 7-glycosides is also a characteristic feature for the Lamiaceae, Scrophulariaceae and chemically related families (Barberán, Grayer-Barkmeijer, Gil, & Harborne, 1988).

Consequently, it was observed that *S. brevibracteata* became a good anti-inflammatory, antinociceptive, antioxidant and AR inhibitory herbal tea, since among the 17 species (18 taxa) of *Sideritis* investigated (Güvenç et al., 2005), this species was found to be richest in 8-OH-flavone glycoside content.

Acknowledgement

The authors thank Prof. Dr. Hakan Göker (Ankara University, Faculty of Pharmacy) for the measurements of the NMR spectra and Prof. Dr. Erhan Palaska (Hacettepe University, Faculty of Pharmacy) for the ESI-MS spectra of the compounds reported in this study.

2005). Similarly, chlorogenic acids were reported to accumulate with an increase in altitude in one study (Avelino et al., 2005) but to remain stable in another (Guyot et al., 1996). These discrepancies may be due to the fact that previous surveys were not performed using experimental sites that were strictly designed to study the effect of altitude: i.e. the soil–climatic conditions may also have varied at the sites (soil type and solar exposure, for example) as well as agricultural management. In addition, the studies covered a low altitude range ($\leqslant$400 m). However, a recent study investigated the effect of altitude on coffee bean composition using eight experimental plots located at regular intervals within an altitude range of 550 m on the same slope of the Poas volcano in Costa Rica (Bertrand et al., 2006). Positive statistical relationships were found between altitude and caffeine, CGA (on the basis of the main CGA component, 5-CQA), and total lipids of green beans, estimated by NIRS. Unfortunately, mesoclimate parameters were not recorded locally and it was therefore not possible to conclude whether the effects of altitude were mainly related to a temperature gradient or to other soil–climatic variables. Consequently, a rigorous study is still required to comprehensively analyse the relationships between main climatic variables (temperature, rainfall, irradiance and evapotranspiration potential) and the composition of the coffee seed.

Concerning post-harvest treatments, green coffee is traditionally produced by either wet or dry processing. Both methods aim to remove the pericarp of the coffee cherry and to dry the raw coffee seed to a moisture content of 10–12% fresh weight. In the dry process, whole coffee fruits are dried in the sun and then hulled mechanically. In the wet process, ripe coffee cherries are mechanically depulped and the mucilaginous residues are degraded during a 'fermentation' step and then washed off. The resulting beans are still covered by the endocarp, termed parchment. The parchment coffee is then dried and subsequently hulled. The chemical composition of wet- and dry-processed seeds may differ significantly, as observed for free amino acids, organic acids, and non-structural carbohydrates (Bytof, Knopp, Schieberle, Teutsch, & Selmar, 2005; Knopp, Bytof, & Selmar, 2006). Dry-processed coffees are generally characterised by more body, whereas in most *terroirs,* wet-processed coffees have a better aroma, generally resulting in higher acceptance (Selmar, Bytof, & Knopp, 2002). In both treatments, the freshly processed coffee beans remain viable and exhibit active metabolic processes (Bytof et al., 2007). This observation established a novel and stimulating bridge between two distant disciplines in the coffee community: seed physiology and the chemistry of green bean technology.

It is now widely accepted that the metabolic reactions that occur during wet-processing help generate pleasant cup quality attributes (Selmar et al., 2002). Based on the observation of the early induction of the isocitrate lyase gene involved in the glyoxylate cycle, it was recently suggested that the germination process was initiated during the course of wet processing (Selmar et al., 2006). The concomitant increase in the abundance of β-tubulin, a marker for cell division or elongation, corroborates this hypothesis (Bytof et al., 2007). While chemical differences between wet and dry-processed seeds are well documented, data on the changes induced by the treatment itself (metabolic shift between fresh and processed seeds) are very scarce. Moreover, in contrast to the knowledge acquired on the metabolic processes that occur in the course of coffee seed development (Joët et al., 2009), no data is available on how environmental factors and post-harvest processes interplay.

Considering the importance of *terroirs* and post-harvest treatments in the generation of flavour, a better understanding of the chemical transformations occurring during wet processing, and their relationships with the metabolic status of the seed at harvest, seems highly warranted. The present study was carried out using samples from 16 Arabica coffee plots located throughout Reunion Island. Its rich homogeneous volcanic soil and various microclimates within short distances, combined with a dense network of meteorological stations, make Reunion Island a valuable experimental site to document the effects of environmental factors on the final composition of the bean. In order to estimate these effects precisely, all plots were planted the same year with exactly the same cultivar and underwent identical agricultural management. We quantified changes in lipid, chlorogenic acid, sugar and caffeine contents caused by wet processing and analysed how these changes were affected by the chemical variations induced by the environment.

2. Materials and methods

2.1. Biological material

Experiments were performed in Reunion Island on seeds of *C. arabica* cv. 'Laurina' (a natural dwarf mutant of cv. 'Bourbon') presenting two specific traits identified so far: rather low caffeine content and a typical oblong shape. The experimental plots were planted in 2003 without shade and were in their second (2006) production year (about 2 m high). Plant spacing was 2 m between rows and 1 m within rows. Fertilisers were applied and pests and diseases were controlled according to locally recommended practices. Among 107 experimental plots available throughout the island, sixteen plots that maximise variations in altitude (150–1032 m asl.) and climatic conditions (Table 1) were selected. The survey unit was a compact plot of about 240 coffee trees.

2.2. Meteorological observations and date of harvests

Reunion Island hosts a dense meteorological network of more than 50 automated stations dedicated to sugarcane agronomy (this service is under the supervision of Meteo France and Cirad). Climatic conditions (temperatures, rainfall, total irradiance, and potential evapotranspiration) were estimated for each plot from records at the nearest meteorological stations (data from Meteo France and Cirad) and corrected taking into account the difference in altitude. Temperatures were also recorded locally (under the coffee canopy) using portable temperature recorders. Dates of harvest differed depending on the location (Table 1).

2.3. Berry harvest and processing

Coffee berries were collected at the harvest peak for each plot (from April to December 2006), when the coffee was of best quality. Only just-ripe cherries (when pericarp turns purple) were harvested. For each experimental plot studied, fruits were collected on 20 trees randomly selected in the experimental plot. After cross-section, fresh seeds were separated from the pericarp and locules and immediately frozen in liquid nitrogen in the field and then stored at −80 °C. Seeds that were subjected to wet processing were harvested in the morning (2 kg of coffee cherries), transported to the CIRAD processing factory (Ligne Paradis, Saint Pierre), and directly processed in the afternoon by the wet method (de-pulping, fermentation and drying) to obtain approximately 500 g of green coffee beans (11% moisture). The temperature was recorded during the fermentation process which was divided into three successive steps: 'dry' fermentation with only mucilage (24 h), maceration by adding water to cover the seeds (15 h) and, finally, washing by changing the water three times during this step (11 h) (Table 1). The green coffee samples were screened through a size 15 sieve and the defective beans were discarded. For chemical analysis, seed tissues were freeze-dried and ground to a fine powder using an analytical grinder (IKA A10, Staufen, Germany). Powdered seed

tissue from fresh and wet-processed seeds was stored over silica-gel in a hermetic plastic box at −20 °C until analysis.

2.4. Lipid, sugar, caffeine and chlorogenic acid determination

Lipids, sugars, caffeine and chlorogenic acids were determined as described in Joët et al. (2009). Roughly, fatty acid methyl esters (FAMEs) were prepared according to the ISO-5509 standard and measured by GC. Sugars were determined by High-Performance Anion Exchange Chromatography coupled with Pulsed Amperometric Detection (Dionex Chromatography Co., Sunnyvale, USA). The seed CWP content was estimated by measuring the defated alcohol insoluble residue (DAIR). Chlorogenic acids and caffeine were analysed by HPLC at 325 and 276 nm, respectively. All metabolites were analysed in triplicate (from 3 different extractions) using a completely random experimental design.

2.5. Statistical analysis

Statistical significance of variations in metabolite content due to wet processing was verified by analysis of variance (one-way ANOVA with fixed effect). Correlations between climatic variables and metabolites levels as well as correlations among metabolites levels were analysed by linear regression using Pearson's correlation coefficient. For both, ANNOVA and linear regression, a significance threshold of $P = 0.01$ was retained.

3. Results

3.1. Air temperature during seed development influences routing within sugar, chlorogenic acid and fatty acid metabolic pathways

CGA, caffeine, CWP, lipid and free sugar contents, as well as fatty acid composition, were measured in fresh mature seeds sampled in 16 experimental coffee plots. These plots showed very high climatic variations, especially a very broad temperature gradient, which was highly correlated ($R = 0.93$, $P = 0.0000$ for T_{min} and T_{aver}, $R = 0.92$, $P = 0.0000$ for T_{max}) with altitude, which ranged from 150 to 1032 m (Table 1).

Relationships between metabolite contents and environmental factors were analysed by linear regression (Table 2). With the exception of caffeine, the overall lipid, sugar, and CGA composition of fresh seeds (Table 3) did not differ from that previously observed in other varieties. No environmental factor significantly influenced the accumulation of the four main classes of storage compounds studied. Indeed, total CWP, total lipids, total free sugars and total CGA, did not show any significant correlation with any climatic variable. Caffeine was not influenced by any of the environmental factors we measured. However, within a given chemical family (CGA, lipids or free sugars), some components were significantly influenced by the environment. Out of the 28 metabolites analysed, half showed significant correlations with the mean average air temperature during the last five months of seed development – i.e. the period when storage compounds accumulate in the seed (Joët et al., 2009). Significant correlations were also found with altitude and with mean minimum and maximum daily temperatures (data not shown), but the highest correlation coefficients were with the daily average temperature. In contrast, no significant correlation was found between rainfall or potential evapotranspiration and any of the compounds studied and only weak correlations were found with solar irradiance.

Within a given chemical family, when significant ($P < 0.01$), the slope of regression equations could differ among the compounds of the family concerned. For instance, 3-caffeoyl quinate (3-CQA) and 4-CQA content were positively correlated with temperature while the reverse trend was observed for 5-CQA (Fig. 1A). Interestingly, the same phenomenon was found for di-CQA: i.e. di3.4-CQA and di-4.5-CQA were positively influenced by temperature while a negative correlation was observed for di3.5-CQA. These results suggest that temperature may act directly on routing towards the different isomers within the CGA metabolic pathway without affecting the final CGA content. A similar routing regulation was observed within the FA biosynthetic pathway. Indeed, the relative contents of the two major FA, namely linoleic and palmitic acids (35–45% each), were negatively correlated with environmental temperature, while stearic acid (about 7%) accumulated more in warmer conditions (Fig. 1B). Similarly, oleic acid (about 7% of FA) was positively correlated with temperature, but the correlation coefficient was weaker ($R = 0.57$; $P = 2.10^{-2}$, data not shown).

3.2. Wet processing affects storage compounds differently

Nine of the 28 metabolite variables analysed showed significant differences in fresh and wet-processed seeds, as tested by one-way ANOVA ($P < 0.01$; Table 3). At the level of the biochemical class, post-harvest treatment did not influence total free sugar, total CGA or caffeine contents. In contrast, wet processing caused a significant increase in total CWP and lipid contents, suggesting

Table 2
Correlation matrix between metabolite contents in fresh and wet-processed seeds and mean environmental factors calculated during the last 5 months of fruit development. Numbers in brackets are correlations with wet-processed seeds. R = Pearson's linear-correlation coefficients. R values in bold indicate P values < 0.01. T_{aver}, average daily temperatures; RAIN, rainfall; IR, irradiance; ETP, evapotranspiration potential; T_{ferm}, mean temperature during wet processing. CGA, chlorogenic acid; CQA, caffeoyl quinic acid; FQA, feruloyl quinic acid.

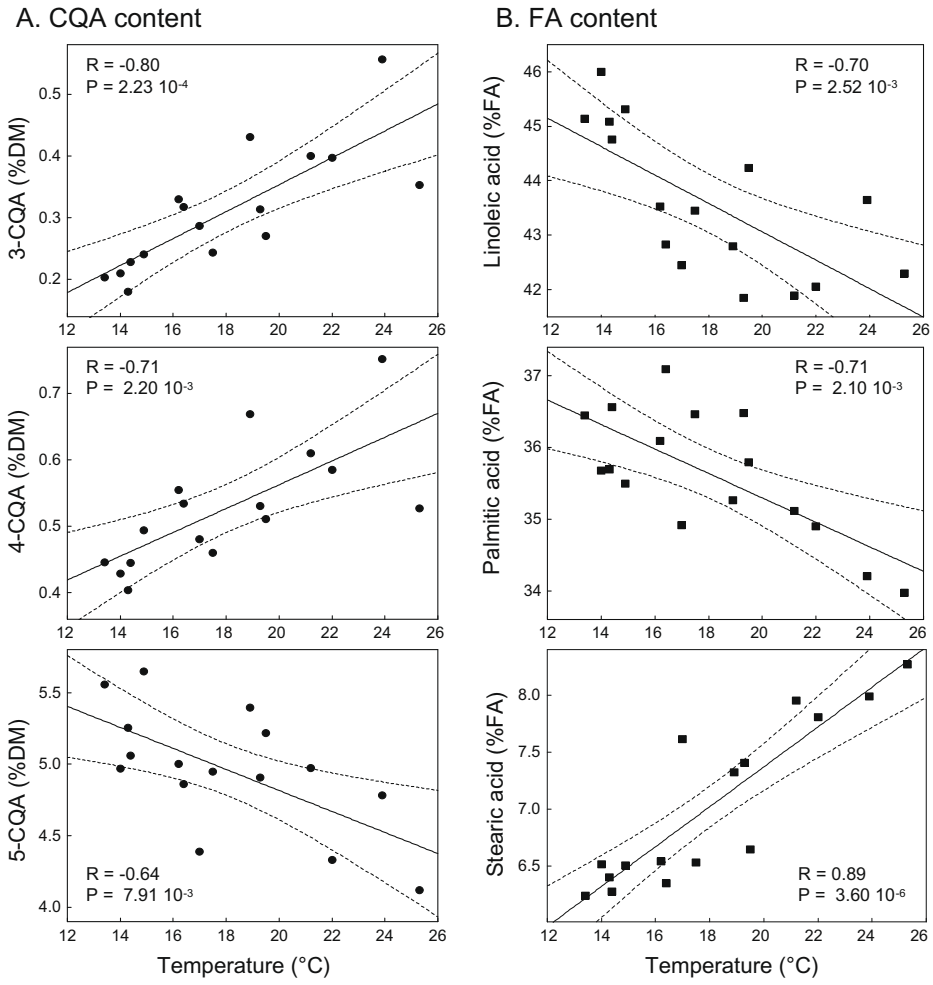

Fig. 1. Effect of the mean average temperature during the last 5 months of fruit development on the CGA composition (A) and FA composition (B) of fresh seeds. *R* and *P* = Pearson's linear correlation coefficient and probability of significance. Dotted lines represent the 95% confidence interval.

intense metabolic reconversion during this treatment. At the compound level within each class, free sugars (including sugar alcohols and oligosaccharides) were the most affected by wet processing since five out of the seven soluble sugars studied showed significant variations (Table 3). Moreover, while glucose, fructose and myo-inositol contents decreased during the post-harvest treatment, stachyose and sorbitol contents increased. In contrast, although lipid content increased, FA composition of total lipids was stable. Finally, CGA were relatively unaffected, as only two minor isomers underwent significant changes (a slight drop in di-3,5CQA and an increase in di-4,5CQA). However, the ratio between CQA and di-CQA increased significantly during wet processing.

3.3. Correlations between compound balances are possible indicators of metabolic inter-conversion

To better understand the reactions that occur during wet processing, the net gain or loss of each compound (difference between contents in wet-processed and fresh seeds) was calculated and correlations between the variations in the compounds were analysed by linear regression. Among the 45 relationships studied, only four were highly significant ($P < 0.01$). The increase in CWP induced by wet processing was highly correlated with loss of sucrose (Fig. 2) suggesting a link between sucrose mobilisation during wet processing and CWP metabolism. Similarly, the extent of sorbitol accumulation during wet processing was highly correlated with glucose and myo-inositol losses, suggesting that their variations were tightly inter-connected in the reactions that took place during wet processing. Indeed, the only one positive correlation was found between glucose and myo-inositol losses, most probably linked to the process of sorbitol accumulation (Fig. 2).

Relationships between metabolite contents and mean temperature during the fermentation process were also analysed by linear regression (Table 2). Myo-inositol was the only compound whose content showed a significant correlation with T_{ferm}. Similarly, when considering variations in compounds (data not shown), only net gains of stachyose ($R = -0.55$, $P = 0.027$), 3-CQA ($R = 0.55$, $P = 0.028$) and di3.4-CQA ($R = 0.57$, $P = 0.021$) showed significant correlations with T_{ferm}, underlining the modest role played by fermentation temperature on the metabolic interconversions that occur during post-harvest processing.

3.4. The metabolic status of the seed at harvest plays a primordial role in variations in soluble sugars during wet processing

Since CGA and fatty acids were almost unaffected by wet processing (Table 3), compounds of these two families which were significantly influenced by temperature in fresh seeds were, as expected, also significantly correlated with temperature in wet-processed seeds (Table 2). In contrast, among the soluble sugars, three compounds – glucose, stachyose and sorbitol – showed a

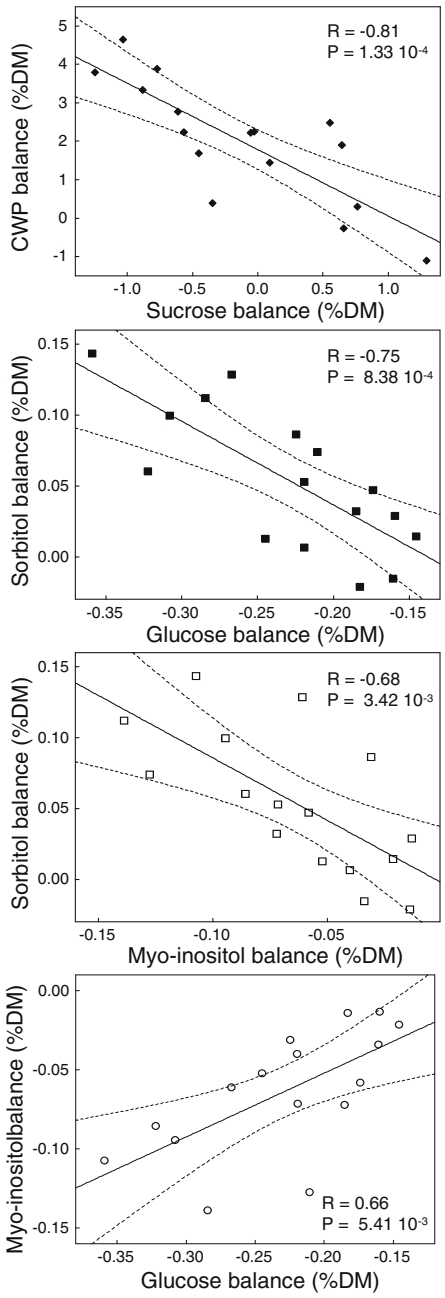

Fig. 2. Correlations between increases and decrease in free sugars caused by wet-processing. *R* and *P* = Pearson's linear correlation coefficient and probability of significance. Dotted lines represent the 95% confidence interval.

significant correlation with temperature in fresh seeds but not in processed seeds (or the reverse). For instance, the glucose content of fresh seeds was highly influenced by field temperature during development (Fig. 3A), but since glucose was almost completely degraded during post-harvest treatment (Table 3), the correlation between the two variables was lost in processed seeds (Fig. 3B). Interestingly, the reverse situation occurred for sorbitol (Fig. 3A and B). Since the glucose and sorbitol contents of the bean did not depend on the fermentation temperature (Table 2), one could logically hypothesise that during post-harvest treatment, sorbitol synthesis was directly influenced by glucose content (its precursor) in unprocessed seeds. This is a valuable example of the influence of the seed metabolic status at harvest on the interconversions that occur during wet processing.

4. Discussion

Through comprehensive metabolite profiling of samples from 16 experimental coffee plots, we showed for the first time that neither altitude, temperature, rainfall, irradiance nor evapotranspiration had a significant direct influence on final total CWP, CGA, lipid and caffeine contents of fresh (Laurina) coffee seeds. The only study which provides comparable data is that performed in Central America by Bertrand et al. (2006). These authors found that total lipid content of the seed was highly significantly correlated with altitude in the traditional variety Caturra but not in recent F1 hybrids. These authors hypothesised that trees of the variety Caturra suffered from a decreased leaf lifespan at low altitudes resulting in an impaired leaf-to-fruit ratio and therefore in a lower carbon supply to developing seeds (Vaast, Angrand, Franck, Dauzat, & Genard, 2005). By contrast, F1 hybrids exhibited high vigour in the whole range of altitudes tested, and thus no excessive fruit charge. We did not observe any noticeable differences in the leaf-to-fruit ratio with varying altitude in our Laurina field trials during the experiment. The relationships between altitude/temperature and final total CWP, CGA, lipid and caffeine contents thus appear to be highly dependent on the variety, even if a common trend towards 5-CQA accumulation with altitude was observed in both studies. However, it is not possible to ascertain whether the positive effect of altitude on seed lipid content observed by Bertrand et al. (2006) in Caturra was directly linked to temperature or to another climatic parameter. Clearly, the effects of climate on allocations to the main pools of storage compounds in the developing coffee seed require further investigations using a broad panel of *C. arabica* varieties.

However, our results evidenced for the first time in coffee that during seed development, environmental temperature had a direct impact on routing within several major metabolic pathways. Without affecting total CGA, lipid and soluble sugar contents, temperature directly influenced the composition of each of these three pools. For instance, the percentage of linoleic acid increased with decreasing temperatures, while the percentage of its precursor, oleic acid, decreased. Temperature has previously been shown to have a dramatic effect on the FA composition of the seed in many cold-tolerant crops such as soybean or rapeseed (Byfield, & Upchurch, 2007; Deng, & Scarth, 1998), and in the model plant *Arabidopsis thaliana* (Blodner, Goebel, Feussner, Gatz, & Polle, 2007). By contrast, to our knowledge, the influence of climatic conditions on seed FA has only very rarely been studied in cold-sensitive species such as coffee. Moreover, the response of each individual FA to temperature variations in coffee did not differ from that observed in the cold-tolerant species cited above. For instance, an increase in polyunsaturated FA (PUFA) and a decrease in oleic acid with decreasing temperature are mechanisms shared by all these species. It is therefore plausible that the effects of temperature on the FA composition of the bean are governed by mechanisms shared by this wide diversity of species. Temperature-mediated modulation of PUFA membrane content is believed to enable cell survival across a broad range of growth temperatures through the control of membrane fluidity (Kodama, Hamada, Horiguchi, Nishimura, & Iba, 1994). The modulation of FA composition in storage lipids may be controlled at both transcriptional and post-transcriptional levels (Byfield, & Upchurch, 2007; Tang, Novitzky, Griffin, Huber, & Dewey, 2005), but also through the O_2 concentration of the seed and the stability of the FA biosynthetic enzyme, which both depend directly on environmental temperature (Rolletschek et al., 2007). Interestingly, a recent study demonstrated that in cotton, another cold-sensitive subtropical crop, the leaf linoleic acid content also increased at low temperatures, together with a higher transcription of the gene encoding the enzyme that converts

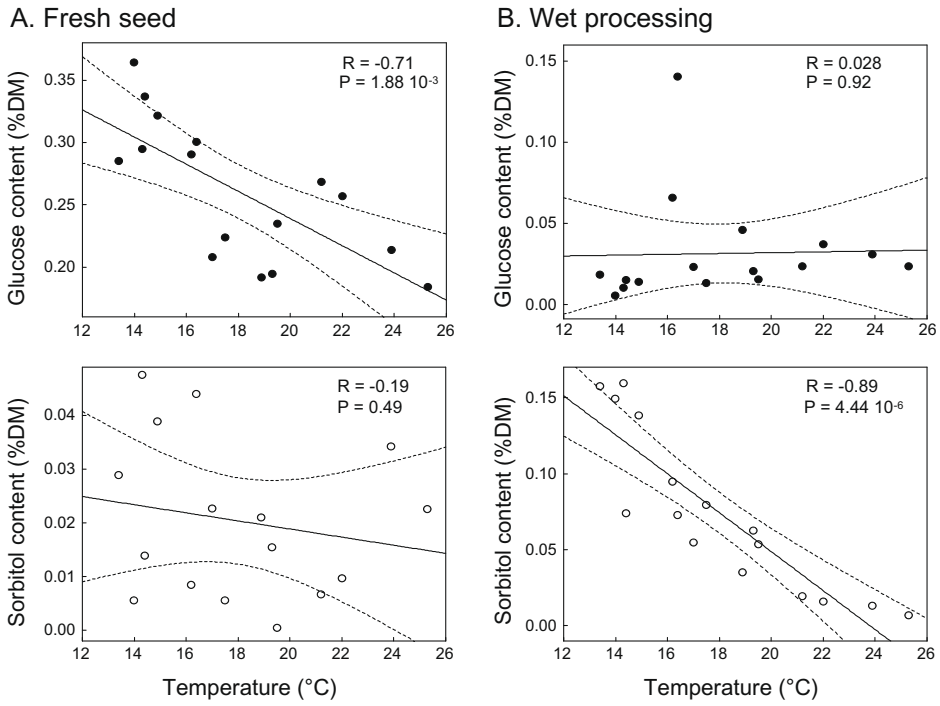

Fig. 3. Relationships between the mean average environmental temperature during the last 5 months of fruit development and seed glucose and sorbitol contents before (A) and after (B) wet-processing. *R* and *P* = Pearson's linear correlation coefficient and probability of significance. Dotted lines represent the 95% confidence interval.

oleic acid into linoleic acid, Δ12 desaturase (Kargiotidou, Deli, Galanopoulou, Tsaftaris, & Farmaki, 2008). Similarly, changes in phenolic compounds in the seed with variations in temperature could be a cold acclimation mechanism. For example, accumulation of anthocyanins and flavonoids was observed in *A. thaliana* under cold conditions (Leyva, Jarillo, Salinas, & Martinezzapater, 1995). Since changes in CGA isomer composition as a function of temperature is reported here for the first time, additional work is necessary to better understand its physiological role.

The chemical analysis of fresh and wet-processed seeds clearly confirmed the significant influence of post-harvest treatments on the final composition of green beans. The measurement of net gains and losses during wet processing illustrated the occurrence of an important catabolism, such as that of glucose and fructose, but also revealed the neo-synthesis of other non-structural carbohydrates, such as sorbitol, raffinose and stachyose. More importantly, we showed for the first time, that non-negligible amounts of CWP and lipids accumulated during this short period of time. Our results therefore reinforce the assumption that significant metabolism occurs within coffee seeds during wet processing. This was previously shown for free amino-acids and γ-aminobutyric acid on the one hand, and for reducing sugars on the other hand, whose contents respectively significantly increased (Bytof et al., 2005) and massively decreased (Knopp et al., 2006) during post-harvest treatment. In the latter study, variations in glucose and fructose contents were in the same range as those described in the present study. Moreover, as previously reported (Menezes, 1994), we showed that the CQA/diCQA ratio, reported as a marker of bean maturity and quality, was positively affected by wet processing. Our data are therefore in agreement with most previous reports and suggest that these metabolic processes are independent of the variety. Metabolic reactions that occur during wet processing are targeted towards particular metabolites, mainly non-structural carbohydrates and CWP, while most of the other compounds we studied, i.e. caffeine, most CGA isomers, and FA were unaffected by post-harvest treatment.

The major decrease in glucose and fructose contents that occurred during wet processing has previously been interpreted as a consequence of the glucose turnover due to anaerobic fermentation, which enables ATP biosynthesis in the coffee seed under the hypoxia conditions conferred by flooding (Knopp et al., 2006). However, the overexpression of the glyoxylate cycle-specific isocitrate lyase (ICL) gene during wet processing was also recently interpreted as an early mobilisation of reserves: in other words, the early induction of germination processes (Selmar et al., 2006). This assumption was reinforced by the observation using flow cytometry of a peak in cell division (4-C nuclei), concomitant with an increase in the abundance of β-tubulin, a marker for cell division or elongation (Bytof et al., 2007). One of the main features of germination metabolism is the mobilisation of reserves. Since free amino acids are typical products of storage protein hydrolysis, their increase during wet processing was interpreted as reflecting the mobilization of reserves (Bytof et al., 2005). Similarly, during seed germination, soluble carbohydrates are among the first components which are affected by the resumption of active metabolism. However, taken together, our results do not support the hypothesis of the mobilisation of reserves during wet processing. Conversely, we detected a significant accumulation of the two major storage compounds in coffee, namely CWP and lipids. Moreover, we observed the concomitant biosynthesis of oligosaccharides such as raffinose and stachyose. Finally, the decrease in glucose content was highly correlated to sorbitol biosynthesis, suggesting the conversion of glucose to sorbitol in addition to its catabolism through the ethanol fermentative pathway. Instead, our results argue for the induction of a stress metabolism linked to the hypoxia and the osmotic shock caused by flooding during wet processing. In this respect, the recent report of early induction of ICL gene expression under hypoxic conditions in submerged rice seedlings is worth mentioning (Lu, Wu, & Han, 2005). In flooded rice seedlings, the glyoxylate cycle appeared to be unrelated to the mobilisation of storage lipids but rather served to replenish carbons for the Krebs cycle (Fan, Lane, & Higashi, 2003). Similarly,

accumulation of the β-tubulin transcript has been linked to osmotic priming in tomato seeds (De Castro, Zheng, Bergervoet, De Vos, & Bino, 1995) and could be triggered in coffee seeds by the hypo-osmotic conditions that occur during wet processing.

The biosynthesis of sorbitol during wet processing, which was directly correlated with the decrease in the glucose and myo-inositol pools, is reported here for the first time. Sorbitol could be synthesised either from glucose-6P by sorbitol-6-phosphate dehydrogenase (S6PDH), as it is the case in fruit trees of the Rosaceae family, or directly from glucose *via* aldose reductase activity, as already evidenced in germinating soybean seeds (Kuo, Doehlert, & Crawford, 1990). Interestingly, an increase in the sorbitol pool was associated with myo-inositol depletion in transgenic tobacco overexpressing S6PDH (Sheveleva et al., 1998), suggesting that myo-inositol and sorbitol were both synthesised from the same glucose-6P pool in processed coffee seeds. The myo-inositol depletion observed in processed seeds could be due to the decrease of its turnover from glucose-6P in favour of sorbitol biosynthesis. However, the sorbitol biosynthetic pathway in coffee seed remains to be characterised at the molecular level as no candidate gene has been found for S6PDH and aldose reductase in coffee EST databases. From this point of view, it is worth mentioning that sorbitol was also shown to transiently accumulate during coffee seed development (Joët et al., 2009). This transient rise in polyol content was concomitant with the peak of expression of a gene encoding a sorbitol dehydrogenase (SDH), an enzyme that catalyses the reversible oxidation of sorbitol to fructose. This enzyme could be also involved in sorbitol biosynthesis (Ohta, Moriguchi, Kanahama, Yamaki, & Kanayama, 2005). We thus suggest that the accumulation of sorbitol during wet processing could be related to the induction of stress-related metabolism induced under the hypoxic and highly reductive conditions caused by flooding. Sorbitol and other polyols play important roles as osmoprotectants. Many previous reports indicated that marginal accumulation of polyols increases stress tolerance, likely through the stabilisation of macromolecular structures (Tarczynski, Jensen, & Bohnert, 1993). Alternatively, the reduction of glucose to sorbitol could act as a safety redox valve, consuming NAD(P)H and supporting the storage of reducing power under the highly reductive conditions encountered during flooding.

Our results also revealed a clear negative relationship between variations in sucrose content during wet processing and variations in CWP. This trade-off can be easily interpreted by considering the roles played by sucrose synthase (SUSY), a key enzyme controlling carbon partitioning in sink tissues. SUSY catalyses the reversible interconversion of sucrose to UDP-glucose and fructose. A membrane-bound isoform of SUSY is directly involved in CWP synthesis by channelling UDP-glucose to cellulose synthase (Amor, Haigler, Johnson, Wainscott, & Delmer, 1995). Interestingly, SUSY was shown to be regulated at both the transcriptional and post-transcriptional levels by oxygen depletion caused by flooding (Dejardin, Sokolov, & Kleczkowski, 1999).

5. Conclusions

Using samples from 16 plots with considerable variations in their climatic characteristics, the present work established for the first time the effects of temperature on the final composition of the coffee seed. Similarly, we demonstrated the influence of wet processing on the chemical composition of beans and its interactions with the metabolic status of seeds at harvest. This study also highlighted the fact that most changes can be interpreted by physiological processes decrypted in other plants with regard to the effects of temperature during seed development and of hypoxic conditions during wet processing. One of the most important outcomes of this study is therefore to support the development of approaches coupling genomics and metabolomics to improve our understanding of the influence of the environment on coffee bean 'quality'.

However, despite the very wide range of metabolites covered, it seems unlikely that any of them explains to a large extent the better flavour and aroma of high-altitude coffees. Indeed, among compounds exhibiting a significant correlation with temperature, none showed an absolute variation high enough to be involved in the considerable quality differences reported elsewhere between low- and high-altitude Arabica coffees. Similarly, none of the variations revealed during wet processing are likely to play a major role in the generation of aroma and flavour. Obviously, future chemical targets of metabolomics approaches cannot be the compounds that are classically reported in the coffee literature (chlorogenic acids, caffeine, soluble sugars, fatty acids, etc.). Instead, we suggest focusing such studies on other compounds whose content is non-negligible (diterpenes, amino acids, organic acids) and on volatile molecules that could be more directly involved in beverage quality attributes.

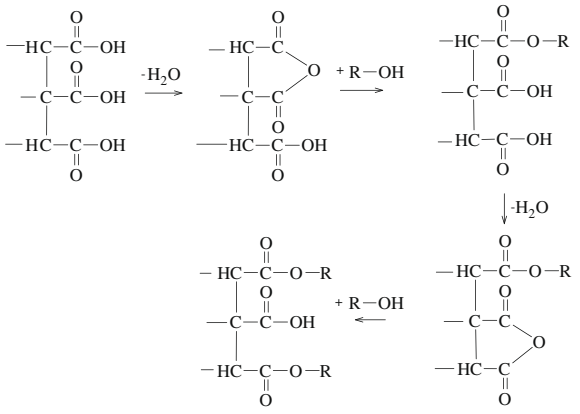

Scheme 1. Mechanism of the conventional dry cross-linking of cellulose using carboxylic acids in the presence of acid catalysts. R represents cellulose (Yang & Wang, 1996; Yang et al., 1997).

antibacterial and acidulant effects of citric acid. It was reported that adding citric acid decreased the strength of the starch–PVA film but provided better strength than glycerol-added starch–PVA films. The better strength of the citric acid-added starch–PVA film compared to glycerol-added starch–PVA films was attributed to the better hydrogen bonding between citric acid and starch–PVA molecules compared to glycerol and starch–PVA molecules (Yoon, Chough, & Park, 2006, 2007).

In this research, we show that citric acid can cross-link starch and improve the mechanical properties and decrease dissolution of starch in water and formic acid. The effect of various amounts of citric acid and glycerol used on the mechanical properties of the films and changes in the morphology and physical structure, thermal stability, water vapour permeability, and colour and stability of the films in water and formic acid has been studied.

2. Materials and methods

2.1. General

Commercially-available corn starch was purchased from American Maize Products Co., Hammond, IN). Glycerol, citric acid, sodium hypophosphite, sodium hydroxide and acetic acid were reagent-grade chemicals purchased from VWR International, Bristol, CT.

2.2. Preparing starch films

Starch films were prepared by dispersing 3% (w/w) starch in water. The starch dispersion was heated on a hot plate to 90 °C and held at that temperature for 20 min. The heated starch solution was cooled to about 65 °C and the required amount of glycerol was added to the starch solution. The starch solution was then poured onto Teflon-coated glass plates. The cast starch films were allowed to air dry for about 48 h before peeling them from the plates.

2.3. Cross-linking starch films

A specified amount of citric acid and the catalyst sodium hypophosphite (50% w/w, on weight of citric acid used) was dissolved in the starch solution. The starch solution containing the cross-linking agent and catalyst was heated to 90 °C, held at that temperature for 20 min, then cooled to 65 °C and poured onto Teflon-coated glass plates. The cast films were allowed to air dry for about 48 h and later peeled from the plates. The starch films were then treated in a hot air oven at 165 °C for various periods of time for the cross-linking reaction to occur. After heating, the films were immediately transferred to a conditioning chamber maintained at 23 °C and 50% relative humidity.

2.4. Tensile properties

The tensile properties of the starch films were determined on an MTS tensile tester (QTest 10; MTS, Eden Prairie, MN) according to ASTM standard D 882-02. Testing was done on five samples each measuring 10 cm × 1 cm randomly cut from the cast films. Two replications were done for a total of 10 tests for each condition. Before testing, all samples were conditioned for at least 40 h in a conditioning chamber maintained at 23 ± 0.5 °C and 50 ± 1% relative humidity.

2.5. Fourier-transform infrared

FTIR spectra were collected from the non-cross-linked and cross-linked starch films on an attenuated total reflectance ATR spectrophotometer (Nicolet 380; Thermo-Fisher, Waltham, MA). The samples were thoroughly washed in water to remove unattached citric acid and catalysts. The washed samples were placed on a germanium plate and 128 scans were collected for each sample.

2.6. Thermal analysis

A differential scanning calorimeter (DSC 822; Mettler-Toledo Inc., Columbus, OH) and a thermogravimetric analyzer (Leco TGA 701; Leco, St Joseph, MI) were used to study the thermal behaviour of the starch films before and after cross-linking. DSC curves were obtained by heating the samples at a rate of 20 °C per minute and holding at 50 °C for 3 min to remove moisture and then to 250 °C at 20 °C per minute. The samples were then cooled to 25 °C and a second heating cycle was performed by heating the samples again to 250 °C at 20 °C per minute. Thermogravimetric analysis was performed by heating the sample at a rate of 15 °C per minute.

2.7. Morphological structure

The surface features of the non-cross-linked and cross-linked films were observed using a scanning electron microscope (Hitachi Model S3000N Variable Pressure SEM; Hitachi Ltd., Tokyo, Japan). The samples were sputter coated with gold palladium and observed under the SEM at a voltage of 15 kV.

2.8. Water vapour permeability

The water vapour permeability of the control and cross-linked starch films was determined according to ASTM standard E96/E96M-05. Three replications were done for the control and cross-linked films and the average water vapour permeability is reported along with ± one standard deviation.

2.9. X-ray diffraction

A Rigaku D-max/BΘ2Θ X-ray diffractometer (Rigaku Americas, Woodlands, TX) with Bragg–Brentano parafocusing geometry, a diffracted beam monochromator, and a copper target X-ray tube set to 40 kV and 30 mA was used to observe the diffraction pattern of the control and cross-linked starch films. The diffraction patterns were recorded for 2θ values ranging from 5° to 40° on samples measuring 2 cm × 2 cm.

2.10. Changes in colour

The changes in the colour of the starch films due to cross-linking were measured in terms of the yellowness index (*YI*) using a spectrophotometer (Hunter Lab, Model: Ultra scan XE; Hunter Associates Laboratory Inc., Reston, VA) with a 1-inch opening and D65/10° observer. The film samples conditioned in the standard testing atmosphere were folded in the middle and the two layers were used for measurement. Three readings were taken from three different places in each film and the measurements were repeated on three films that were cast separately. The average and standard deviations of the *YI* are reported.

2.11. Weight loss in water under various pH conditions

The control and cross-linked starch films were treated in phosphate-buffered saline water (pH 7.2) at 50 °C for 3–35 days. About 0.5 g of the films were put in water (1:5 film to water ratio) and taken out after a specified time. The samples taken out were rinsed in distilled water and allowed to dry in a standard conditioning chamber maintained at 23 ± 0.5 °C and 50 ± 1% relative humidity. The weight of the conditioned specimen after treating in water was used to determine the % weight loss of the films in water.

2.12. Weight loss in formic acid

The weight loss of the non-cross-linked and cross-linked starch films in formic acid was studied at two temperatures (20 and 50 °C). Precisely 0.2 g of the films were put in 5 g of formic acid in glass vials and sealed. The vials were kept at 20 °C for 24 h and at 50 °C for 5 h. After the treatment, the formic acid was removed and the remaining starch was thoroughly washed in distilled water. The dry weight of the samples after formic acid treatment was recorded to calculate the % weight loss. Two replications were repeated for each condition and the average and standard deviation are reported.

3. Results and discussion

3.1. Effect of adding glycerol

The effect of adding glycerol on the tensile strength and elongation of the cross-linked starch films is shown in Fig. 1. Both the control and cross-linked films with less than 10% glycerol became brittle after curing and were not considered for further studies. Increasing the concentration of glycerol to 15% from 10% increases the tensile strength and elongation and provides flexible films. Further increase in glycerol concentration above 15% increased the elongation but considerably decreased the tensile strength of the films. A glycerol concentration of 15% provided the highest tensile strength to the films and was used for all further studies. At low concentrations of glycerol (<10%), there is not enough plasticising effect and the starch molecules become brittle. At concentrations above 15% the plasticising effect is too pronounced and makes the starch molecules move easily, leading to high elongation but decrease in tensile strength. The amount of glycerol to be added should be decided based on the tensile strength and elongation required for a particular application.

3.2. Effect of curing time

The effect of curing time on the tensile strength of the citric acid cross-linked films is shown in Fig. 2. As seen from the figure, there is a narrow range of curing time (3–5 min) that provides the optimum tensile strength to the films. Further increase in curing time substantially decreases the tensile strength of the films at this curing temperature. Curing time is one of the most important factors determining the efficiency of carboxylic acid cross-linking and hence the properties of the cross-linked materials. Sufficient curing time is necessary for the cross-linking reaction to occur but excess curing will damage the starch molecules, leading to decrease in tensile strength and unwanted changes in the colour of the films. An optimum curing time of about 5 min at about 165–170 °C was also reported for citric acid cross-linking of cotton fabrics. Although longer curing times may be suitable, if lower curing temperatures are used, it is more preferable to have shorter curing times for large-scale processing of films, due to economic and technical reasons. Since the citric acid cross-linking of starch occurs at high temperatures, a one-step cross-linking process may be possible, in order to develop cross-linked starch products by extrusion.

3.3. Effect of citric acid concentration

Cross-linking starch films with citric acid improved the tensile strength of the films by more than 150%, as seen from Fig. 3. However, there is an optimum amount of citric acid that is necessary to obtain good increase in the tensile strength of the films. Concentrations of citric acid less than 5% provided relatively low

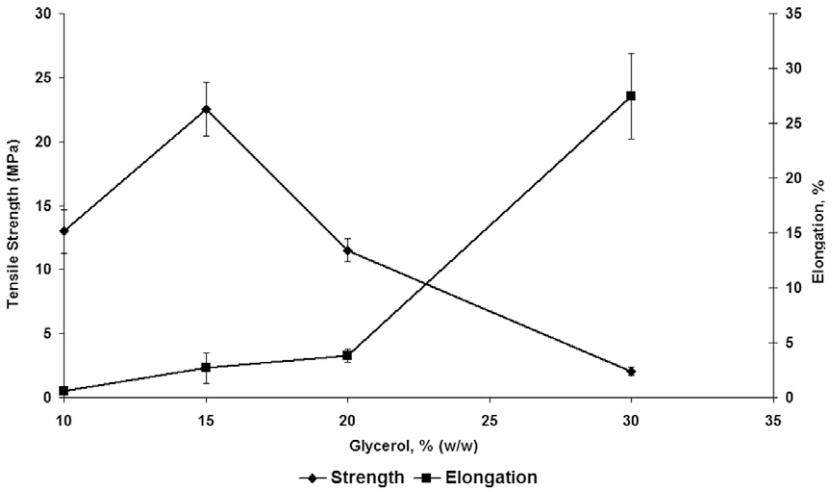

Fig. 1. Effect of adding glycerol on the strength and elongation of cross-linked starch films. Films were cast from 3% starch and cross-linked using 5% (w/w) citric acid and cured at 165 °C for 5 min.

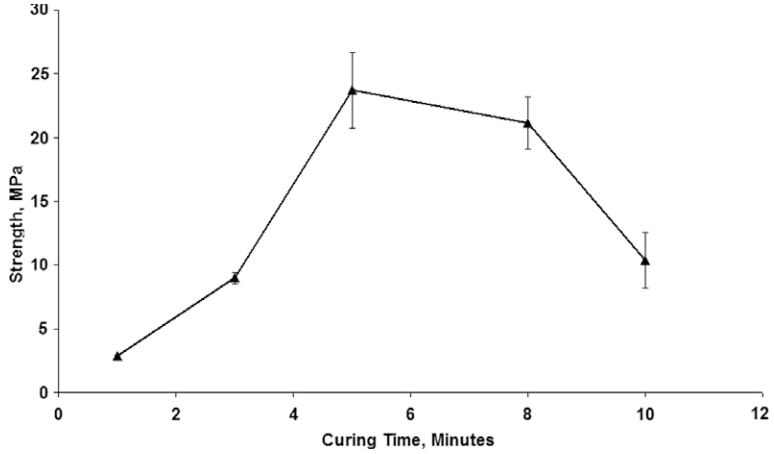

Fig. 2. Effect of curing time on the strength of cross-linked starch films. Films were cast from 3% starch and cross-linked using 5% (w/w) citric acid.

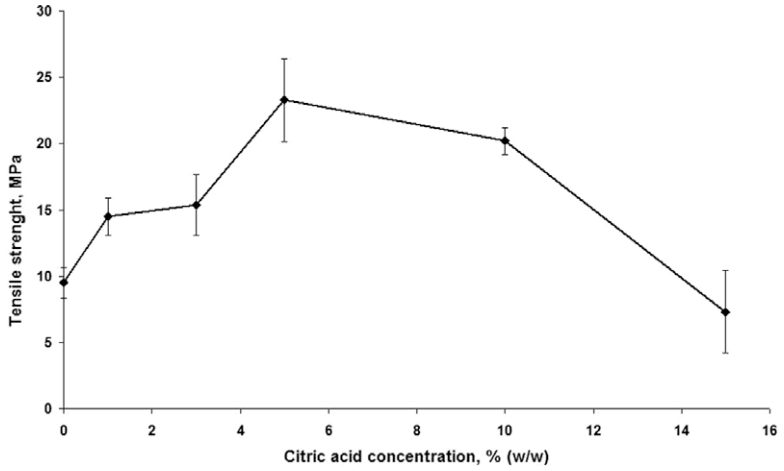

Fig. 3. Effect of increasing citric acid concentration on the strength of cross-linked starch films. Films were cast from 3% starch with 15% glycerol and cured at 165 °C for 5 min.

improvement in tensile strength and concentrations above 5% decreased the tensile strength of the films. Cross-linking interconnects the starch molecules in the film, which could increase the molecular weight of the starch and also provides better intermolecular interactions between molecules, leading to better tensile strength, compared to the non-cross-linked starch films. At low concentrations of citric acid, there is not enough cross-linking between the starch molecules to improve the tensile strength of the films. At high concentrations, however, there is excess cross-linking that limits the mobility of the starch molecules, leading to lower tensile strength (Yang et al., 1996, 1997).

Previously, high amylose starch films cross-linked with epichlorohydrin (6%) had tensile strength of about 38 MPa, higher than the strength of the films obtained in this research but normal starch was used to produce the films in this research (Rioux, Ispas-Szabo, Ait-Kadi, Mateescu, & Juhasz, 2002). Apart from the report on cross-linking high amylose starch films, to the best of our knowledge, there is no literature available on cross-linking pure starch films. Most of the cross-linked starch films reported in the literature are blends of cross-linked starch with synthetic polymers. Films made using epichlorohydrin-cross-linked starch and polyethylene (1:1 ratio) had strength ranging from 12 to 15 MPa with varying amounts of epichlorohydrin (0.1–2%), compared to 24 MPa for the 5% citric acid cross-linked films (Kim & Lee, 2002). Similarly, starch–polyethylene films cross-linked with boric acid (0.5–2.5%) had tensile strength ranging from 8.9 to 10.1 MPa and the breaking elongation decreased from 60% to 8% after cross-linking (Yin, Li, Liu, & Li, 2005). However, starch–polyvinyl alcohol films cross-linked with hexamethoxymethylmelamine had tensile strength ranging from 50 to 65 MPa, and the non-cross-linked films also had high strengths, ranging from 45 to 55 MPa (Chen, Imam, Gordon, & Greene, 1997). In another report, starch–LDPE films made using epichlorohydrin cross-linked and/or glycerol modified starch had strength ranging from 5 to 14 MPa (Garg & Jana, 2007). Using high amylose starch or other poly(carboxylic acids) may be two approaches to further increase the strength of the starch films developed in this research.

3.4. FTIR

The FTIR spectra of the non-cross-linked films and films cross-linked with 5% citric acid are shown in Fig. 4. Both the films have similar peaks, except for the additional peak in the cross-linked film at 1724 cm^{-1}. The band at 1724 cm^{-1} (indicated by an arrow in Fig. 4) is ascribed to the carboxyl and ester carbonyl bands (Yang et al., 1991). Since the films were thoroughly washed to remove the unbound citric acid and catalyst, the presence of the carbonyl peak confirms the chemical linkages between citric acid and starch.

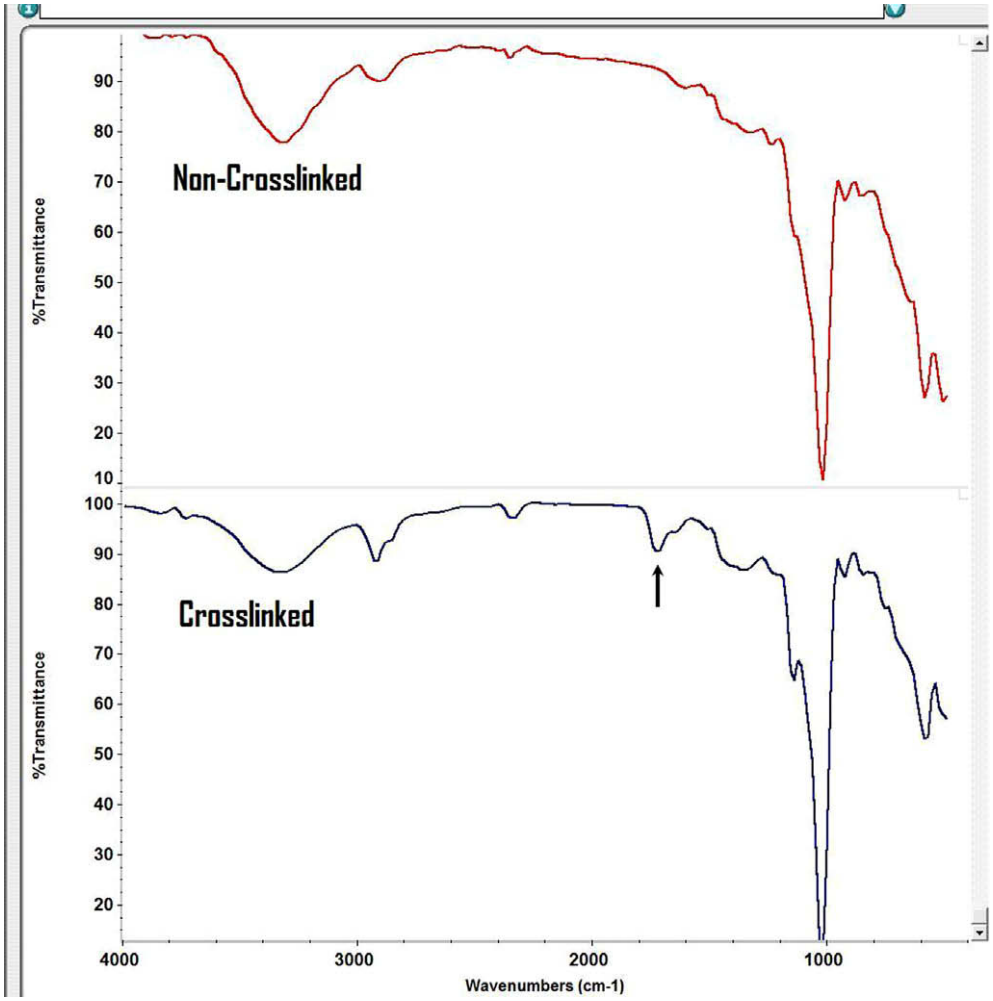

Fig. 4. FTIR spectra of the non-cross-linked starch films and starch films cross-linked with 5% citric acid.

3.5. Thermal analysis

The DSC thermograms of the non-cross-linked films and films cross-linked with 5% citric acid are shown in Fig. 5a and b. Fig. 5a is the DSC thermogram of the films collected during the first heating cycle. The thermogram of the non-cross-linked film (5a) show a endothermic curve that peaks at about 100 °C, whereas the thermogram of the cross-linked film has an endothermic curve that peaks at about 150 °C. The peak in both the non-cross-linked and cross-linked films disappears after the second heating cycle of the same sample, as shown in Fig. 5b. The disappearance of the peaks seen during the first heating cycle indicates that the peaks are most likely due to the presence of moisture in the films. The shift of the water evaporation peak to the higher temperature for the cross-linked films indicated the cross-linkages made water evaporation more difficult than from non-cross-linked film.

The thermal degradation of the starch films can be observed in Fig. 6. Overall, the cross-linked starch films have about 20% lower weight loss than the non-cross-linked films after heating the films to 600 °C, indicating much improved resistance to thermal degradation, due to cross-linkages. The non-cross-linked films begin to show weight loss at about 70 °C, whereas the weight loss of the cross-linked films starts at about 100 °C. The first main increase in weight loss of both the films initiated at about 120 °C, with the non-cross-linked films showing slightly more weight loss than the cross-linked films. The lower weight loss of the cross-linked films between 120 and 220 °C should be due to the higher thermal stability of the starch molecules after cross-linking. However, the cross-linked films showed a higher weight loss than the non-cross-linked films between 220 and 320 °C. This is probably due to the degradation of some of the starch molecules in the cross-linked films when they were cured at high temperatures for the cross-linking reaction to occur. The cross-linked films have much higher thermal stability than the non-cross-linked films above 320 °C, due to the cross-linking of the starch molecules.

3.6. Morphological structure

Scanning electron microscope pictures of the control and cross-linked films do not show any appreciable change in surface morphology due to cross-linking, as seen from Fig. 7a and b, respectively. The films are homogenous without pores or cracks and the starch molecules have been well dispersed without the many granules that were observed in films made from epichlorohydrin cross-linked starch mixed with low-density polyethylene (Garg & Jana, 2007).

3.7. Physical structure

X-ray diffraction patterns of the cross-linked and non-cross-linked starch are similar, with two prominent peaks at about 17° and 22°, as seen from Fig. 8. However, typical starch peaks seen at about 5° and 14° were not seen in either cross-linked or non-cross-linked film, indicating changes in crystallinity and/or the crystal structure. The control and cross-linked starch films had

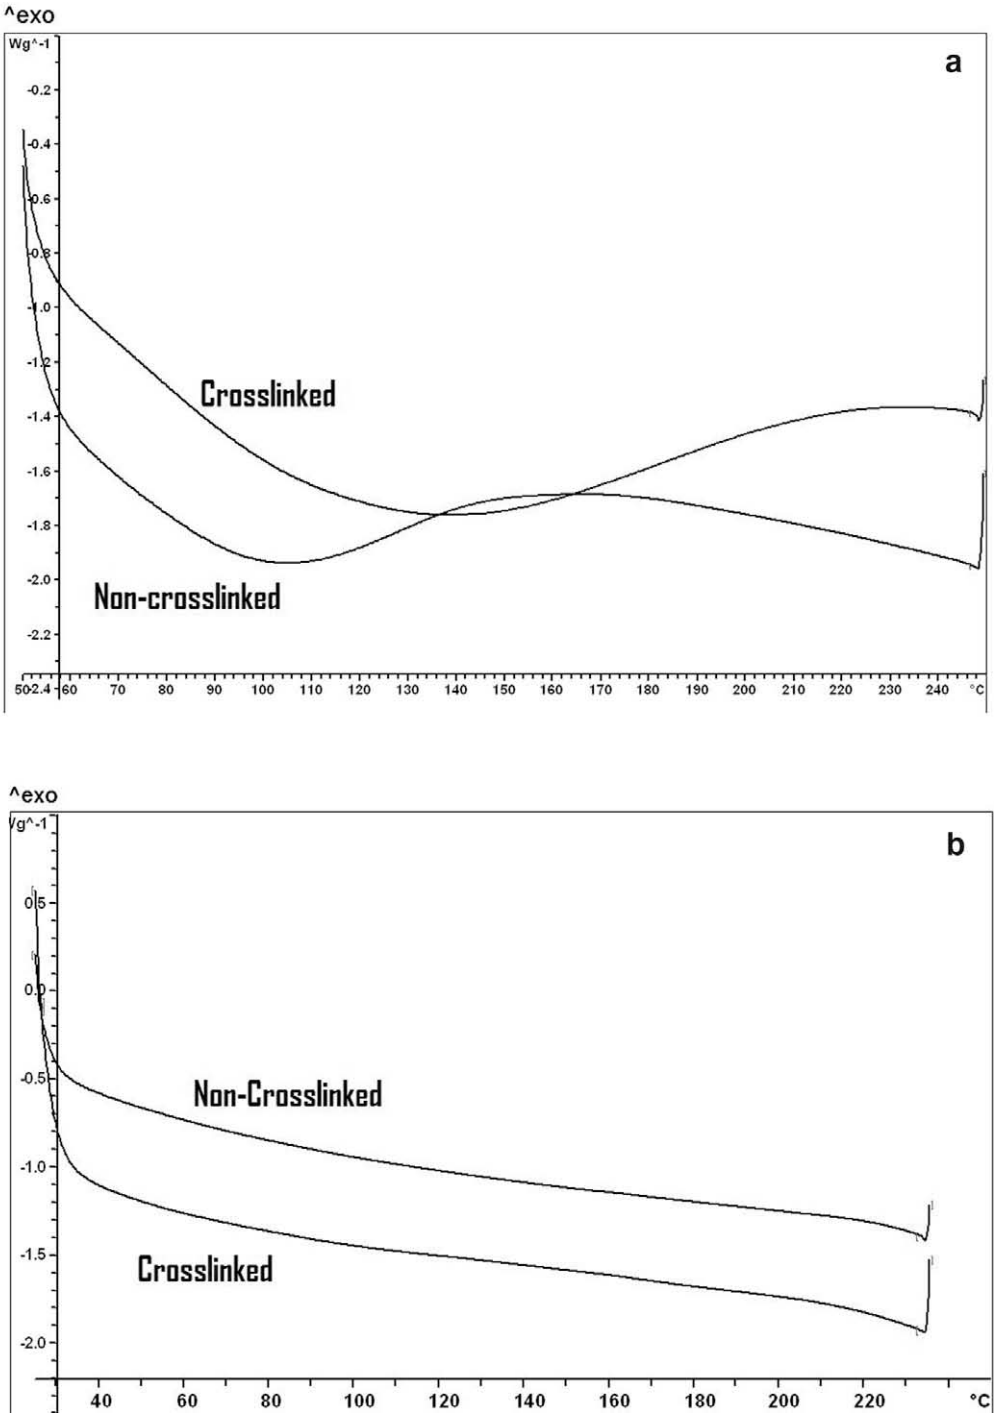

Fig. 5. DSC thermograms of the non-cross-linked starch films and starch films cross-linked with 5% citric acid during the first (a) and second (b) heating cycles.

similar % crystallinity of about 17% and 14%, respectively. Epichlorohydrin cross-linked starch films also did not show any change in % crystallinity or peak positions, compared to native starch (Garg & Jana, 2007; Kim & Lee, 2002). The increase in the diffraction intensity of the cross-linked starch films but decrease in the % crystallinity suggests that some of the amorphous regions may be better oriented after cross-linking.

3.8. Water vapour permeability

Citric acid cross-linked films have slightly lower water vapour permeability, compared to the non-cross-linked films. The control and cross-linked films had a water vapour permeability of 33 ± 0.5 and 31 ± 0.8 g h^{-1} m^{-2}, respectively. The formation of a more tight structure after cross-linking prevents the swelling of starch and also restricts the movement of molecules, leading to a decrease in the water vapour permeability.

3.9. Colour change

Citric acid cross-linking is reported to cause yellowing, especially in proteins when cured at high temperatures and/or long periods of time (Schramm, Vukusic, & Katovic, 2002; Yang et al., 1996). The changes in the *YI* of the starch films before and after

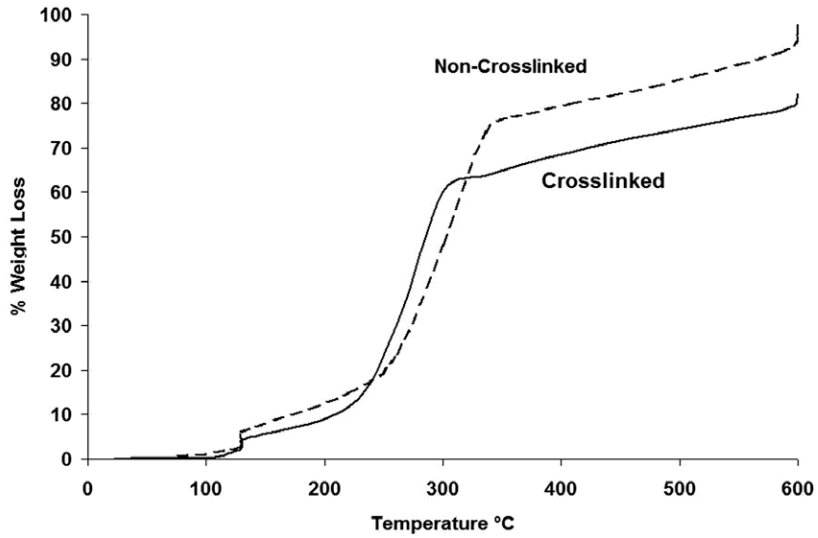

Fig. 6. Weight-loss (%) of the non-cross-linked starch films and starch films cross-linked with 5% citric acid in a thermogravimetric analyser.

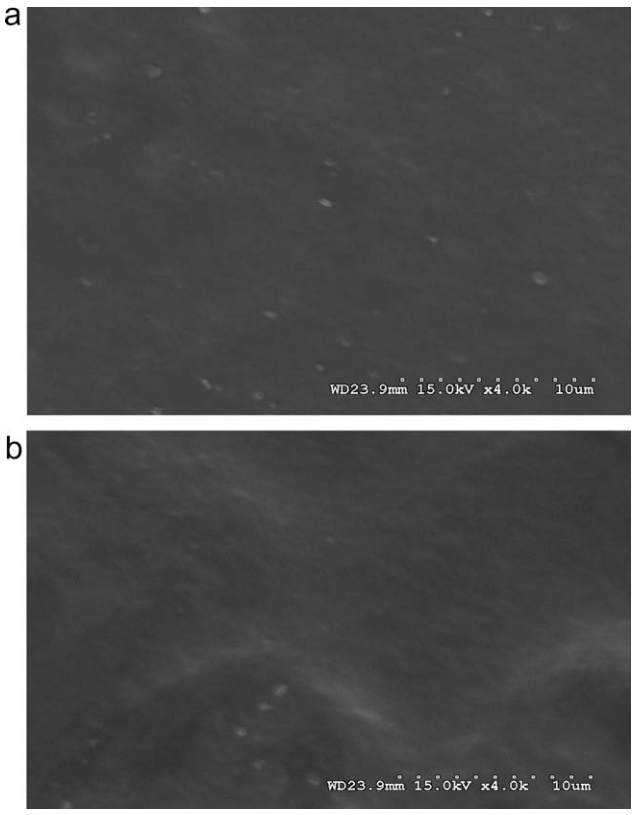

Fig. 7. SEM pictures of cross-linked (a) and control films (b) magnified 4000×. The films are homogenous without any pores or cracks.

curing are shown in Fig. 9. There is no change in the *YI* of the starch films with various amounts of citric acid before curing. After curing at 165 °C for 5 min, the films turn slightly yellow, with the *YI* increasing with increasing amount of citric acid in the films. The non-cross-linked films also show a slight increase in *YI* after curing. Films cross-linked with 1%, 3% and 5% citric acid have similar *YI*, about 10% higher than their corresponding *YI* before curing. The *YI* of the films treated with 10% citric acid increases substantially after curing and those treated with 20% citric acid have nearly 13 times higher *YI* than that of the non-cross-linked films after curing. The discoloration of the films after curing at high temperatures is mainly due to the dehydration of citric acid that leads to the formation of an unsaturated acid that imparts colour to the films (Andrews & Welch, 1989). The higher the amount of citric acid in the films is, the higher the quantities of unsaturated acids formed, leading to more yellowness. In addition to the formation of the unsaturated acids, starch will also degrade to a certain extent at high temperatures, leading to discoloration, as seen from the higher *YI* of the non-cross-linked films after curing, compared to the *YI* of the non-cross-linked films before curing.

3.10. Weight loss in water

The cross-linked starch films had only about 25% weight loss, even after being in pH 7.2 water at 50 °C for 35 days, whereas the non-cross-linked fibres lost about 75% of their weight, as seen from Fig. 10. After 3 days in water, both the cross-linked and non-cross-linked fibres lose about 25% of their weight. On further treatment in water, the cross-linked fibres do not show any considerable loss in weight but the weight loss of the non-cross-linked films increases to about 70% after 10 days in water. The non-cross-linked fibres do not experience much weight loss on further treatment in water for up to 35 days. Cross-linking not only increases the strength of the films but also creates a more dense structure. This prevents the swelling of starch and decreases the accessible regions, leading to an improvement in the resistance to dissolution, compared to the non-cross-linked films.

3.11. Weight loss in formic acid

The weight loss of starch films in formic acid decreases considerably after cross-linking, as seen from Fig. 11. The non-cross-linked starch films lose about 50% of their weight after being in formic acid for 24 h at 20 °C. Films cross-linked with 1% and 3% formic acid have weight loss of about 25% and those cross-linked with 5% and 10% citric acid have weight loss of 17% and 15%, respectively, when treated in formic acid for 24 h at 20 °C. The non-cross-linked and films cross-linked with 1% citric acid completely dissolved in formic acid when treated with formic acid at 50 °C for 5 h. Films cross-linked with higher amounts of citric acid showed substantial decrease in weight loss in formic acid at 50 °C. Starch films cross-linked with 3% and 5% citric acid had weight loss of 53% and 36%,

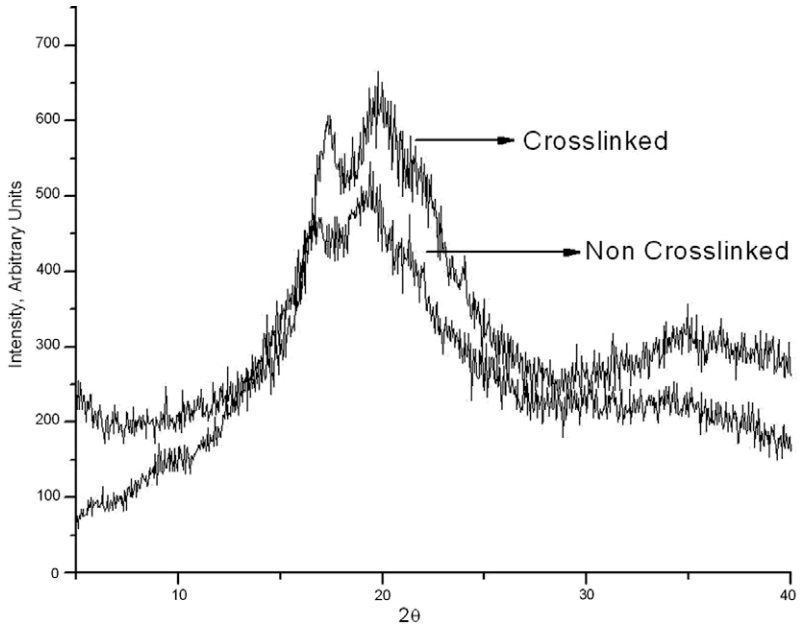

Fig. 8. Diffraction patterns of cross-linked and non-cross-linked starch films show similar diffraction peaks and intensities without any considerable change in the starch crystals due to cross-linking.

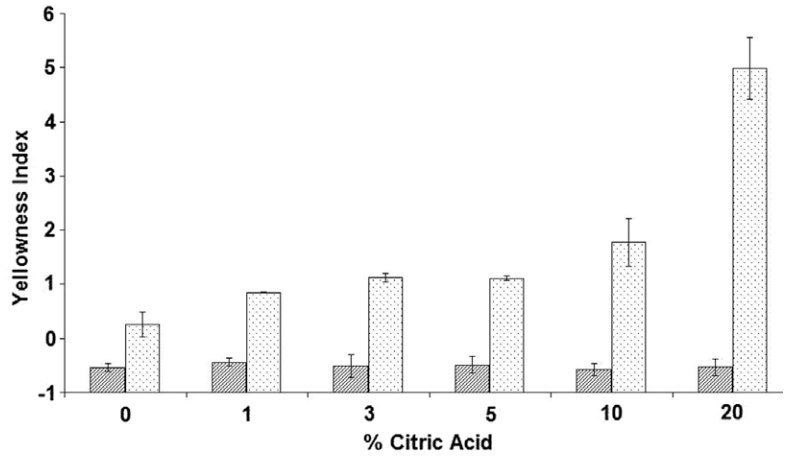

Fig. 9. Changes in the yellowness index of the starch films before and after curing at 165 °C for 5 min with various amounts of citric acid.

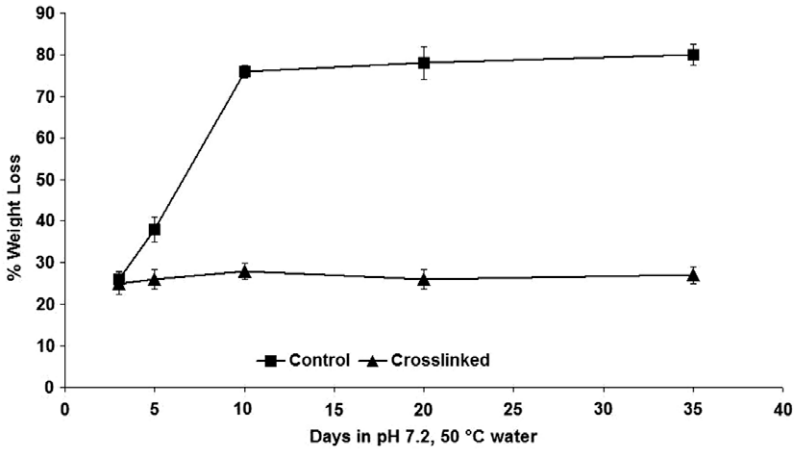

Fig. 10. Weight-loss (%) of the non-cross-linked and cross-linked starch films after treating in pH 7.2 water at 50 °C for various periods of time.

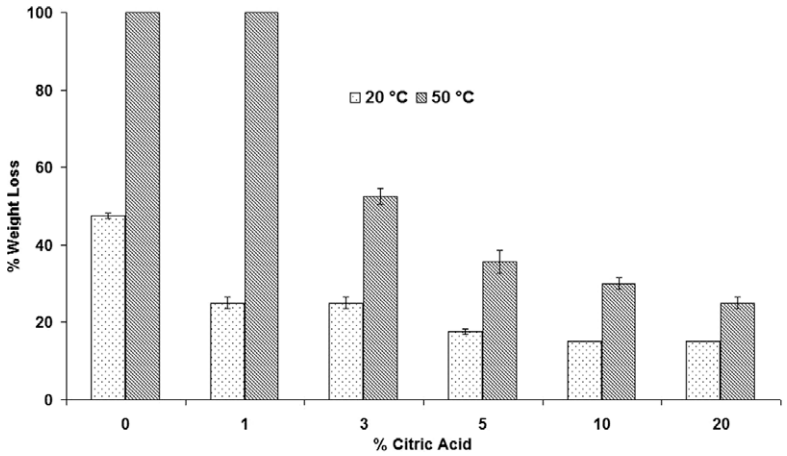

Fig. 11. Weight-loss (%) of the starch films after treating in formic acid at 20 °C for 24 h and 50 °C for 5 h.

respectively whereas 10% and 20% citric acid cross-linked films lost only 30% and 25% of their weight after being in formic acid for 5 h at 50 °C. The higher strength of the starch films and less swelling of the starch molecules after cross-linking should be the major reasons for the better stability of the cross-linked films in formic acid, compared to the non-cross-linked films. Although the 10% and 20% cross-linked starch films have lower strength than the 5% citric acid cross-linked films, the higher amounts of citric acid would prevent the dissolution of the starch in the 10% and 20% films, leading to better resistance to dissolution. The extent of citric acid to be used for cross-linking should therefore be selected based on the end use requirements for the films.

3.12. Advantages of citric acid cross-linking

Citric acid is preferable for starch cross-linking since low levels (5% or less) are required for cross-linking; it can be derived from fermentation and could therefore be considered as a green chemical. Citric acid also has price advantages over a few other compounds commonly used to cross-link starch. Based on reagent-grade chemicals for laboratory purchase, citric acid costs about $0.05 per gram, compared to $0.09, $0.04, $0.08 and $0.07 for glutaraldehyde, epichlorohydrin, boric acid and sodium trimetaphosphate, respectively. From MSDS ratings, citric acid, boric acid and sodium trimetaphosphate have health hazard rating of 1, whereas glutaraldehyde is rated 2 and epichlorohydrin is rated 3. Sodium hypophosphite is reported to be hazardous to the environment. In addition to citric acid, other poly(carboxylic acids) may also be suitable for cross-linking starch films.

4. Conclusions

Citric acid effectively cross-links starch and improves the strength and considerably decreases the weight loss of the films in water and formic acid. Cross-linked starch films have about 150% higher strength than non-cross-linked films and also better strength than most cross-linked and/or synthetic polymer blended starch films previously developed. Cross-linked starch films show a broad melting peak and have considerably higher thermal stability (lower weight loss) compared to the non-cross-linked samples at temperatures between 320 and 600 °C. Citric acid cross-linking slightly decreases the water vapour permeability and colour (*YI*) of the films but the morphology and % crystallinity of the films are not adversely affected. Starch films cross-linked with 3–20% of citric acid have only about 15–25% weight loss, whereas the non-cross-linked films immediately dissolved in formic acid.

more than 50% protein, whilst the depleted starch phase showed less than 2% protein. These values were obtained at constant process conditions (rotational speed, temperature and moisture content); no attempts were made yet to investigate the influence of these parameters on separation behaviour. The gluten obtained from shear induced separation showed higher R_{max} (maximum resistance to extension) and area under curve (energy for extension) in large-strain uniaxial extension tests as compared to commercial gluten. In this paper, we elaborate on separation principles based on differences in rheology between the starch and gluten phase using simple shear flow.

The main mechanism that contributes to the separation of gluten is shear-induced segregation or demixing of gluten and starch. Gluten with its visco-elastic characteristic and starch with dilatant characteristics undergoes segregation (Kieffer & Stein, 1999). This phenomenon is in accordance with the reported segregation behaviour of polymeric systems under shear flow, which is a known effect for synthetic (non-food) polymer blends or polymeric suspensions (Hobbie, Lin-Gibson, Wang, Pathak, & Kim, 2004; Olmsted, 1999; Vermant, 2001).

However, for using this separation principle more information is needed about the driving forces in the system and how the driving forces are influenced by process conditions. Therefore, the objective of the study reported here was to investigate the influence of the process conditions (rotational speed, temperature and shearing time) on the separation behaviour of gluten and starch.

2.1. Materials

Flour of Soissons (single French wheat cultivar) was kindly obtained from Top Institute Food and Nutrition (TIFN), Wageningen, The Netherlands. Protein, GMP wet weight, moisture and ash contents for flour used were 10.65 (%db), 188 (g/100 g dry matter of the flour), 12.7% and 0.48 (%db), respectively. The Farinograph characteristics of this flour are: water absorption 54% (based on 14% flour moisture), arrival time 10.5 min, time to peak 15 min, stability 21 min and time to breakdown 31.5 min.

2.2. Preparation of starting material for shear experiments

Non-developed or "Zero developed" (ZD) dough was prepared according to the method of Campos, Steffe, and Ng (1996) with modifications described by Peighambardoust, van der Goot, van Vliet, Hamer, and Boom (2006). ZD dough is a "zero mechanical energy input" developed dough which is completely hydrated prior to processing. NaCl at a concentration of 2% (w/w flour basis), and moisture content of 49% (5% lower than Farinograph water absorption) was used in preparation of the ZD doughs. A comparison between characteristics of ZD dough and flour–water mixture has been reported earlier (Peighambardoust, van der Goot, Boom, & Hamer, 2006).

Based on previous experiences, for running a successful shear experiment one has to reduce dough moisture content to a level 5% lower than flour's Farinograph water requirement (Peighambardoust, van Brenk, van der Goot, Hamer, & Boom, 2007; Peighambardoust, van der Goot, van Vliet, et al., 2006; Peressini, Peighambardoust, Hamer, Sensidoni, & van der Goot, 2008). Doughs prepared at a high moisture content become sticky upon long processing leading to difficulties in handling and sampling of the processed dough. Previous results showed that shearing of the dough (at Farinograph moisture content) at 120 min led to re-distribution of the separated gluten phase throughout the product (Peighambardoust et al., 2008). Therefore, in the present study a moisture content of 5% lower than Farinograph water absorption was used in the preparation of the ZD doughs.

2.3. Shearing process

We used the same apparatus and methods for the shearing trials as described previously (Peighambardoust et al., 2008). Increasing rotational speeds of 2–6 rpm, 10–20 rpm, 20–30 rpm, 30–40 rpm and 40–50 rpm for different trials were used to ensure a good (non-slippage) shearing conditions. Process temperature set of 5, 15, 20, 30 and 40 °C and processing time of 50, 80, 90, 120 and 180 min were used.

A schematic drawing of the shear cell geometry was shown previously (Peighambardoust et al., 2008). The shear rate in the device can be calculated using the following equation:

$$\dot{\gamma} = \frac{\frac{2\pi N}{60} R\cos(\alpha)}{\delta + R\tan(\theta)\cos(\alpha)} \quad (1)$$

In this equation, $\dot{\gamma}$ is the shear rate (s^{-1}), N is the rotational speed (rpm), R is the distance (in m) from the centre of the cone, δ is the distance between the two cones in the centre (in m), α and θ are the angles of the external and internal cones (in degree), respectively (see also Fig. 1), when δ is zero, the shear rate has the same value throughout the system; however when it is larger, the shear rate will be larger away from the centre of the cones.

2.4. Sampling of dough for subsequent analysis

After stopping the process and disassembling the cell, four or five regions (rings) of dough from top to bottom were sampled using a razor blade. The reason for selecting five samples in some experiments was to see whether or not there is any difference in the composition of the gluten phase (in terms of glutenin macropolymer) separated exactly at the tip part of the cone, where the gluten concentration reaches to its maximum. The sampling time before the dough is frozen in the liquid nitrogen was about 5 min and this was kept constant for all trials. The samples from top to bottom were encoded as 1–4 or 1–5 depending on the conditions for some experiments. The samples were immediately frozen in liquid nitrogen and freeze-dried overnight to an average moisture content of 4% and kept in sealed plastic containers at ambient temperature until further analysis.

2.5. Measurement of protein

The protein contents ($N \times 5.7$) of freeze-dried dough samples were determined by the Dumas method (Sebecic & Balenovic, 2001) using an NA2100 Nitrogen and Protein Analyzer (Thermo-Quest-CE Instruments, Rodeno, Italy). Methionine was used as a standard.

2.6. Measurement of GMP wet weight

Freeze-dried dough sample was weighed (1.55 g) in an ultra-centrifuge tube of approximately 33 ml. The tube was then placed on a Vortex mixer. Whilst rigorous vortexing, 9.125 ml demi-water was added with a calibrated dispensor. Vortexing was continued for about 10–15 s till a homogenous and lump-free suspension was obtained. Immediately after suspending, 3.875 ml 12% (w/v) SDS solution was added, followed by the addition of two portions of 9 ml demi water with a dispensor to reach a final concentration of 1.5% (w/v) SDS. The tubes were then ultra-centrifuged (Graveland, Bosveld, Lichtendonk, Moonen, & Scheepstra, 1982) (80,000g, 30 min at 20 °C) in a Kontron Ultracentrifuge. The supernatant (SUP) was decanted and the gel-like layer found on top of the starch sediment (called GMP) was weighed immediately as GMP wet

weight. This amount was expressed as grams of gel per 100 g of sample (db). The measurements of GMP wet weight were performed at least in triplicate.

3. Results

3.1. Effect of rotational speed

3.1.1. Visual inspection of dough after processing

The sheared doughs showed accumulation of the gluten phase at the apex of the cones for all rotational speed regimes used. Nevertheless, doughs sheared at higher rotational speeds (>30 rpm) appeared to be softer, whilst still giving reasonable gluten accumulation in the apex of the cone. Low rotational speed treatments led to the appearance of gluten domains in the form of strands in the middle regions of the cone (samples 2 and 3). This effect disappeared at higher shear rates.

3.1.2. Changes in protein concentration

Table 1 shows the protein content in the sheared dough as a function of the rotational speed at different locations in the shearing device. The amount of protein at the apex of the cone was at least 32.6% at low rotational speeds of 2–6 rpm. Increasing the rotational speed to 30–40 rpm led to a significant increase in the protein content of the gluten at the apex (sample 5). An additional increase to 40–50 rpm did not increase the protein content of sample 5.

At rotational speeds of more than 30 rpm, there was a significant increase in the protein content of samples in region 3. This was in parallel with protein accumulation at the apex of those trials. In total, increasing rotational speed (>30 rpm) led to an increase in the protein content of the bottom half of the cone (samples 3–5, which comprises 31.8% of total dough weight, see Table 1). In contrast with this, the upper half of the cone (samples 1–2, which comprise 68.2% of total dough weight) stays protein-depleted (<4% protein).

At all rotational speeds, the upper regions of the cone (layers 1 and 2, which comprise 68% of the total dough weight) became protein-depleted (and therefore starch-enriched). In general, it seems that the rotational speed did not have a large influence on the extent of protein separation.

3.1.3. Changes in GMP wet weight

Table 1 also shows the influence of the rotational speed on the GMP wet weight (in non-rested dough or gluten). Increasing the rotational speed from 2–6 to 10–20 rpm led to a decrease in the GMP wet weight of samples 4 and 5. Upper samples (1 and 2) showed increased GMP wet weights at rotational speed of 10–20 rpm. When the rotational speed increased from 10–20 to 20–30 rpm, GMP wet weight decreased in all zones in the cell. This decrease might be related to the breakdown of glutenin particles at higher shear rates. Especially at 20 rpm, a large peak in the torque was observed, which could account for the gluten breakdown. However, a further increase in speed (>30 rpm) did not result in a further decrease in the GMP wet weight of the separated gluten.

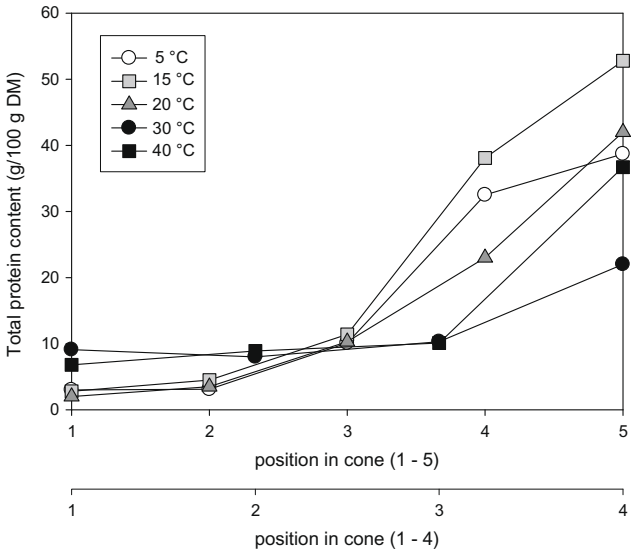

Fig. 1. Effect of temperature on total protein content of dough as function of sampling locations (1–5). Rotational speed regimes for 5, 15, 20, 30 and 40 °C experiments were 10–20, 5–15, 5–10, 5–15 and 5–30 rpm, respectively. Processing times for all experiments were 60 min, except for 40 °C for which a processing time of 40 min was used. Error bars are not shown as they were of a similar size to the symbols used.

3.2. Effect of temperature

3.2.1. Visual inspection of dough

The sheared doughs yielded gluten separation at a temperature of 15 °C. Upon increasing the shearing temperature, accumulation of the gluten phase at the apex of the cone became less. Large gluten domains in the form of long fibres in the middle part of the cone (regions 2 and 3) were observed at a temperature of 20 °C. Shearing at 30 °C showed only minor gluten separation, and shearing at 40 °C resulted in only small gluten domains at the apex of the cone. At this temperature, the rest of dough was soft and sticky.

3.2.2. Changes in protein concentration

The total protein content as a function of sampling position and temperature is shown in Fig. 1. A cold shearing regime (5 °C) gave a protein enrichment of up to 39% at the apex of the cone. Increasing the temperature to 15 °C resulted in a considerable increase in the separation of total protein content. A further increase in temperature did not further increase the separation. At higher temperatures, especially at 30 °C, the enrichment of protein became lower. Shearing at 40 °C, however, led to a slight increase in the to-

Table 1
Effect of rotational speed on total protein content and GMP wet weight of the dough at different sampling locations (1–5). Processing temperature and time were 5–7 °C and 60 min, respectively. Please note that for 2–6 rpm, the four-segmented sampling scheme was used, whilst for the other runs the five-segmented sampling scheme was used.

	Samples	2–6 rpm	10–20 rpm	20–30 rpm	30–40 rpm	40–50 rpm

tal protein content of the material at the apex of the cone, probably due to increased interactions in the gluten phase. It is remarkable that the protein depletion in the starch-rich regions is severely reduced at higher temperatures.

3.2.3. Changes in the GMP wet weight

The effect of the shearing temperature on the GMP wet weight (in non-rested dough) was investigated. Fig. 2 demonstrates GMP wet weight variations as function of shearing temperature. At all temperatures, GMP data showed significantly higher values at the apex of the cone (sample 4) compared to other sampling locations, indicating separation in terms of glutenin macro-polymer. In terms of the effect of shearing temperature, the GMP wet weights followed the trend in the total protein content (in Fig. 1), except for the 5 °C experiment, which showed lower GMP values in samples 4 and 5. There is an optimum in the enrichment of the glutenin macro-polymer at shearing temperatures of 15 and 20 °C. No clear difference was seen between GMP wet weight values of sheared doughs at 15 or 20 °C. Increasing the temperature from 20 to 30 °C led to a decrease in the GMP wet weight.

3.3. Influence of shearing time

3.3.1. Visual inspection of sheared dough

Regardless of small differences in terms of rotational speed and processing temperatures, separation of gluten and starch was observed for all shearing runs. Shearing for 50 min already gave a reasonable separation. At the moisture content used in this study, a shearing time of 120 min gave the most complete separation, as judged visually. Prolonged shearing (for 180 min) exhausted the dough, leading to a smaller volume of the gluten phase in the apex of the cone. This dough was sticky and appeared over-processed.

3.3.2. Changes in protein concentration

Fig. 3 shows that the apex of the cone is enriched in protein for all shearing times, whilst the top of the cone was depleted of protein (<4%), thus rich in starch. Especially after 120 min, a low protein content was found in the starch phase. There was no clear difference in protein content of samples in the same locations and sheared for 50–80 min. The highest level of protein enrichment (43–49%) was found for shearing times of 90–120 min. Further shearing for 180 decreased the protein content in zones 4 and 5.

3.3.3. Changes in the GMP wet weight

Fig. 4 shows the GMP wet weights as a function of the shearing time. Shearing for 50 min already led to an increase in the GMP wet weight at the apex of the cone. Changes in GMP wet weight paralleled changes in the total protein content of the dough upon differ-

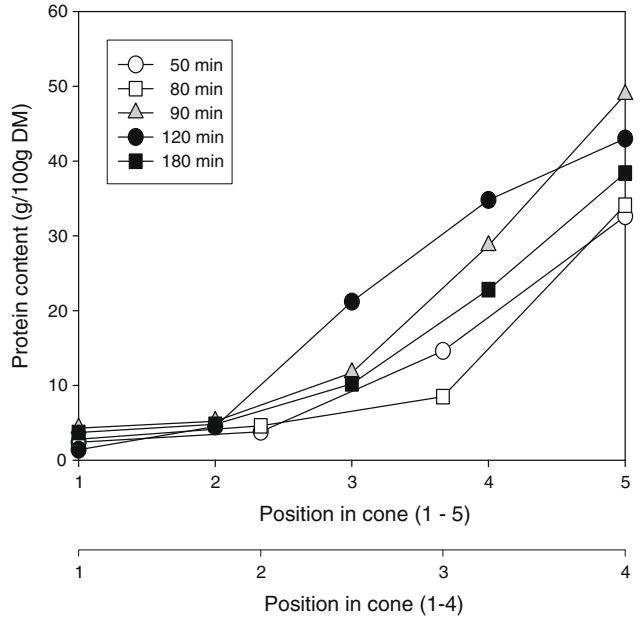

Fig. 3. Effect of shearing time on total protein content of dough as function of sampling locations (1–5). The shearing runs of 50 min and 180 min were carried out at a temperature of 5 °C. Temperature for shear runs of 90 and 120 min was 15 and 10 °C, respectively. Rotational speed regimes for shearing times of 50, 90, 120 and 180 min were 2–6, 5–20, 5–15 and 4–15 rpm, respectively. Error bars are not shown as they were of a similar size to the symbols used.

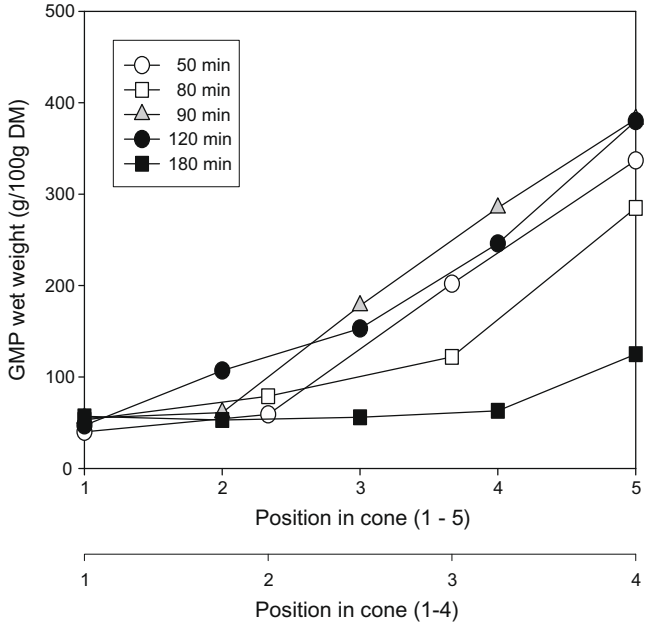

Fig. 4. Effect of shearing time on GMP wet weight (in non-rested dough) at different sampling locations (1–5). Processing temperature and rotational speed was mentioned in Fig. 3. Error bars are not shown as they were of a similar size to the symbols used.

ent shearing times (Fig. 3), except that upon prolonged shearing (180 min) GMP wet weight of gluten samples (at the apex) were considerably lower (125 g) than its amount in other shearing times. Similarly with the total protein content, an optimum for separation was observed in terms of GMP wet weight for shearing times of 90–120 min.

4. Discussion

We previously reported that the separation of wheat dough into gluten-rich and gluten-poor fractions occurs through a two-stage mechanism (Peighambardoust et al., 2008). The first stage leads to the formation of gluten domains. The size of these local gluten domains decreases with increasing shear rate (Peressini et al., 2008) that was explained by a rupture of those domains due to the shear forces. The second stage comprises of the migration of local gluten domains to the centre part of the shear cell. As this is an exchange (binary transfer) process, the gluten migration is accompanied by migration of starch particles to the outer part of the cell.

There are numerous publications on the effect of simple shear on the migration of polymers (MacDonald & Muller, 1996; Shelby & Caflisch, 2004) and macromolecules (Agarwal, Dutta, & Mashelkar, 1994; Ponche & Dupuis, 2005). Shelby and Caflisch (2004) mentioned that a gradient in shear rate causes a gradient in the elastic strain energy for HMW molecules. As a result, they diffuse away from the wall and towards the centreline in order to reduce their potential energy. Consequently, the smaller particles would migrate toward the wall surface. Carrying this thought further and considering that dough comprises of a visco-elastic gluten phase and inert starch particles (Kieffer & Stein, 1999), we think that the migration in the cell is due to the visco-elastic nature of the gluten. Because starch particles are unlikely to deform upon the shear field applied due to their rigid nature, they will not store elastic strain energy. Therefore, starch particle will not experience a driving force for migration towards the apex of the cone. This leads us to the conclusion that inward migration is induced by the gluten phase. Nevertheless, a number of studies report on migration phenomena in particle containing, viscous and visco-elastic media (Highgate, 1966; Ponche & Dupuis, 2005). Shear-induced normal stresses in cone-and-plate systems can lead to outward migration of particles (Feng & Joseph, 1996; Morris & Boulay, 1999). If this effect is also present when shearing dough, there will be an active driving force for starch particles to migrate away from the apex of the cone. Unfortunately, we are not able to indicate which of the two migration effects is dominant in the experiments reported at this stage.

Dill (1979) and Agarwal et al. (1994) derived an equation describing the migration of a DNA macromolecule in a cone and plate shear field. They assumed that the DNA molecule is a random coil that behaves as a Hookean spring when stretched. This gives rise to a migration velocity towards the centre of the cell:

$$v_m \cong -\frac{\eta_c \dot{\gamma}^2(R)}{R k_B T} r_0^5 \tag{2}$$

where η_c is the viscosity of the continuous phase, R is the radial position, $\dot{\gamma}$ is the shear rate, k_B the Boltzman constant, T the temperature and r_0 the undisturbed radius of the macromolecule. Here we interpret that r_0 is the size of the gluten domain at rest. Combining equations 1 and 2 leads to:

$$v_m \cong \frac{\eta_c R}{k_B T}\left(\frac{2\pi N \cos(\alpha)}{\delta + R\tan(\theta)\cos(\alpha)}\right)^2 r_0^5 \tag{3}$$

It is clear that a single DNA molecule in water behaves differently than a gluten domain in dough. Nevertheless, we think that the driving force for migration is similar, namely elongation of an elastic particle. Since, the elongation is elastic, it leads to an inward migration. In qualitative terms, the equation seems therefore useful for the first and initial explanations in our observation in the dough systems.

Eq. (3) indicates that the size of the gluten domains strongly determines the radial migration velocity of the gluten. Thus, the gluten domains need to have a minimum size before migration can become significant. Furthermore, the visco-elastic nature of the gluten seems to be important in the second step.

4.1. Influence of moisture content

We previously (Peighambardoust et al., 2008) reported on the separation of gluten and starch under shear field at a moisture content of 54% (according to Farinograph moisture absorption of the flour). In the present study, a lower moisture content (49%) was used. The results shown for shearing time (Section 3.3) indicated that at a low moisture content, it takes longer (>60 min) to reach an optimum time for separation. In the previous study we showed that a shearing time of 40 min already gave enhanced separation followed by the disappearance of a separated phase at a longer time (120 min). The higher dough viscosity might play a role here, because a positive correlation has been reported between the radial migration velocity and the viscosity of the medium (Agarwal et al., 1994). This is all in agreement with Eq. (3). The increased viscosity induces the stretching of the gluten domains, enhancing the radial force on these gluten domains. Nevertheless, local aggregation of gluten is probably less at low moisture contents, most likely due to a smaller volume of the gluten phase at lower moisture contents. Thus, a longer shearing time is necessary to obtain local gluten domains that are large enough to induce radial migration. Therefore, the total effect of the moisture content on the separation rate is difficult to predict, though the experiments showed that a lower moisture content leads to a slower separation. Compared to our previous study, it seems that a lower moisture content had a positive effect on gluten stability, as it was possible to shear the dough for 120 min without re-dispersion of the gluten throughout the dough.

4.2. Effect of rotational speed

The migration velocity is proportional to the square of the rotational speed (via the shear rate – see Eq. (2)) (Agarwal et al., 1994; Dill, 1979). This faster migration is however counteracted by the fact that gluten domains become more susceptible to breaking at higher shear rates (Peressini et al., 2008). Thus, their radius will be smaller on average. Furthermore, an increased rotational speed also reduces the dough viscosity (Data not shown). Though the migration of gluten domains is positively effected by an increased shear rate, the lower viscosity reduces this positive effect.

Visual inspection of the processed dough revealed the presence of strongly elongated gluten domains at low speeds. Higher speeds led to softer dough, but still gluten migration could be obtained. However, this gluten contained less GMP (see Table 1), suggesting a reduced gluten vitality. Therefore, a low rotational speed in the range of 10 to 20 rpm seems to work best in the shearing device used here.

4.3. Effect of temperature

The process temperature has a significant effect on the dough viscosity. At higher temperatures the hydrophobic interactions become more important (Fasina, Walter, Fleming, & Simunovic, 2003) as a result of the fact that formation of gluten domains are favoured. Thus, an increased temperature would have a positive ef-

fect on step 1. However, the increased hydrophobic interaction will exhaust the dough more quickly, as a result of which over-processing can occur. The lower average GMP-values at 40 °C hints in this direction. Step 2 is negatively influence by the temperature as shown by Eq. (3). In addition, the dough viscosity will be lowered, which reduces the driving force for migration even further.

4.4. Outlook towards industrial application

Wheat flour can be separated into a gluten-rich and gluten-poor phase using a broad range of process conditions. The separation is not influenced strongly by the process conditions, which can be explained by the multitude of the effects that play a role. Overall, a low rotational speed in combination with a moderate temperature seems to work best because those conditions minimise gluten damage. The shear separation process could also benefit starch quality, since the process does not apply multiple washing steps for separation or purification of the starch, and therefore the loss of suspending small starch granules in the water is restricted.

Since the experiments reported here were not optimised to yield the highest possible protein content, it is relevant to consider whether one could further increase the protein content (e.g. by changing device geometry and dough formulation). In our previous study, we showed that the remaining gluten is present in small domains in the starch-enriched phase (in other words it is not dispersed throughout the starch phase as it is in an over-mixed dough). Also the starch particles are clustered in the gluten-rich phase. The formation of those gluten domains and starch clusters indicate that further purification should be possible. Eq. (3) suggests that a modification of the shear rate profile might lead to enhanced purification. The distance between the cones and possibly the shape of the cones could be modified. Furthermore, since the separation mechanism has two distinct stages, it might be beneficial to separate both stages into isolated process steps, which can then both be optimised. Many changes in conditions yield opposing effects results in stages 1 and 2, which may be avoided in a two stage process. Nevertheless, we think that the use of differences in rheological behaviour of dough constituents is a challenging new principle, which merits further exploration.

It is clear that for industrial application, dedicated and new equipment has to be developed, in which the shear rate and absolute velocities are key design parameters. The development of new separation equipment faces many challenges. We still need a better understanding of the driving forces present in this system in order to optimise the process conditions. It is not clear yet, how the separation principle presented here can be translated to a continuous set-up. Finally, it can be mentioned that the long shearing times lead to large energy inputs, which should be reduced to make this process industrially feasible.

5. Conclusions

The influence of process conditions on the separation of starch and gluten in a cone-cone shearing device was reported. Separation of the dough into a starch-rich and a gluten-rich region was clearly observed under all experimental conditions tested. The migration of gluten was not strongly influenced through variations in the process conditions. A possible explanation is that the two stages in the mechanism (formation of local small gluten domains followed by macroscopic radial migration) respond oppositely to most changes in process conditions. Nevertheless, the experiments described in this paper showed that a low rotational speed combined with a moderate temperature seem most favourable. A higher shear rate at lower temperature, prolonged shearing, and a higher process temperature all lead to certain extent of gluten damage, thereby softening the dough and reducing the driving force for separation.

Acknowledgements

Financial support of Cargill (Bergen op Zoom, The Netherlands) in performing this study is gratefully acknowledged. The helpful discussions given by Rob Hamer (Top Institute Food and Nutrition, TIFN, Wageningen, The Netherlands) and Remko Boom (Food Process Engineering Group, Wageningen University, The Netherlands) during this study is highly appreciated. We thank the mechanical and electronic workshops of Wageningen University (Wageningen, the Netherlands) for constructing the shear cell.

were taken. The fruits were washed, cut into four equal pieces (rinds) parallel to the major axis, then ground after the removal of seeds. HPLC-grade methanol, acetonitrile, glacial acetic acid, and hydrochloric acid were procured from Merck India Ltd., Mumbai. C18 Sep-Pak cartridges and Sephadex LH-20 were procured from Waters India Private Ltd., Bangalore and from Sigma Chemicals, Bangalore, respectively. All the other chemicals used were of analytical grade. A consolidated experimental plan has been presented in Fig. 1.

2.2. Extraction of anthocyanins

The pulp, thus obtained as described in Section 2.1, was mixed in a 1:2 ratio with acidified water (0.1% hydrochloric acid). The mixture was subjected to hydraulic press (M/s B. Sen & Berry, New Delhi, India). The extract was filtered using muslin cloth and stored in a cold room at 4–5 °C and used for experiments as and when required.

2.3. Monomeric anthocyanin content

Monomeric anthocyanin content in the whole extract was determined using pH differential method (Wrolstad et al., 2005). All the experiments were carried out in triplicate and average values were reported.

2.4. Purification of anthocyanins

The aqueous extract of *kokum* was passed through a 500 mg sorbent C-18 Sep-Pak cartridge (Waters Associates, Milford, MA) which was previously activated with methanol followed by 0.01% aqueous HCl. Anthocyanins were adsorbed onto the cartridge, whereas sugars, organic acids and other water soluble compounds were washed off the cartridge with 0.01% aqueous hydrochloric acid. Anthocyanins were eluted using acidified methanol (0.01%, v/v HCl). Methanol was evaporated using a rotary evaporator at 35 °C and pigments were dissolved in double distilled water containing 0.01% HCl. These partially purified concentrated anthocyanins were loaded (0.8 ml) onto a Sephadex LH20 column (1.0 × 60 cm) and eluted with a mixture of methanol/water/trifluoroacetic acid at a ratio of 20:79.5:0.5 (Wrolstad et al., 2005). Separated fractions from the Sephadex LH20 column were pooled and were concentrated using a lyophiliser (ThermoLab, UK) separately and subjected to NMR spectroscopy.

2.5. Thin-layer chromatography

Partially purified anthocyanins were streaked on cellulose-based thin-layer chromatography plates. Mobile phase was acetic acid:HCl:water in the ratio of 15:3:82 (Krishnamurthy, 1984). The solvent was allowed a run time of 6 h. Subsequently, the thin layer chromatography plate was dried and retention factors of separated components were determined.

2.6. High-performance liquid chromatography

The anthocyanins sample was diluted accordingly with methanol, filtered through a 0.45-μm membrane filter type HA (Millipore, Billerica, MA) and analysed by high-performance liquid chromatography (HPLC), with a photodiode array detector. The detection was carried out at 520 nm. The flow rate was maintained at 1.0 ml/min. A C-18 ODS column (250 mm × 4.6 mm; SGE, Ringwood, Australia) having a particle size of 5.0 μm was used for HPLC analysis of anthocyanins. A gradient mobile phase was used for elution: eluant **A** was acetonitrile and **B** was 3.0% acetic acid/5.0% acetonitrile/1.0% phosphoric acid in water. The elution profile has been described by Wrolstad et al. (2005).

2.7. Alkaline hydrolysis of anthocyanins

Purified pigments (1.0 ml) were hydrolysed (saponified) in a screw-cap test tube with 10 ml of 10% aqueous KOH for 8 to 10 min at room temperature in the dark as described by Wrolstad et al. (2005). The solution was neutralised using 2 N HCl, and

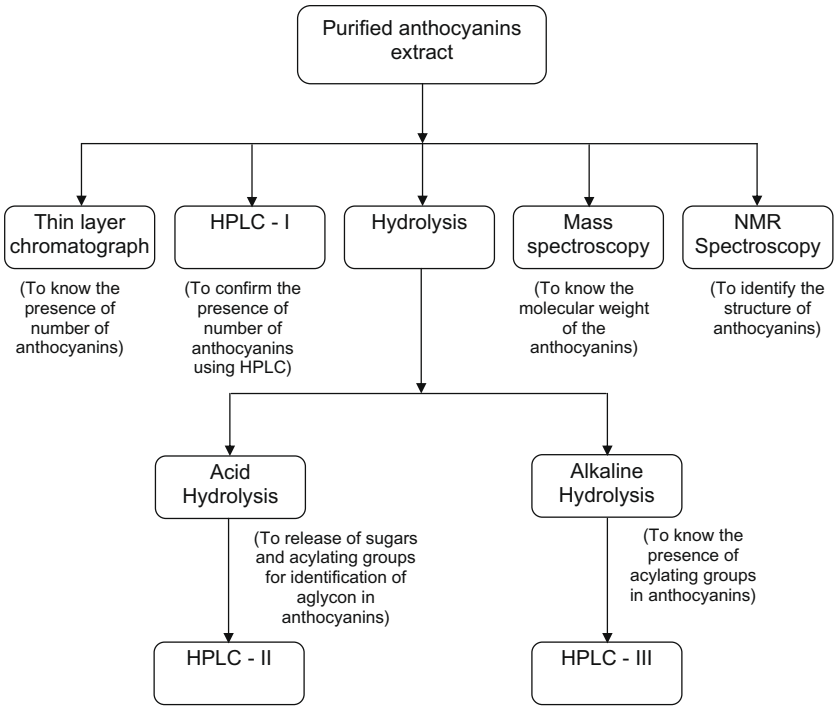

Fig. 1. Experimental plan of work for the characterisation of anthocyanins from *Garcinia indica* Choisy.

Kokum	*Garcinia indica* Choisy	1000–2400	Present work

saponified anthocyanins were purified by subjecting to C18 Sep-Pak cartridge as previously described in Section 2.4, and concentrated using a rotary evaporator.

2.8. Acid hydrolysis of anthocyanins

Ten millilitres of 2 N HCl was added to the pigment (1.0 ml) in a screw-cap test tube, which was flushed with nitrogen gas and capped. The pigment was hydrolysed for 1 h at 100 °C, and then cooled in an ice bath. Anthocyanins after hydrolysis were purified using a C18 Sep-Pak cartridge, as described in Section 2.4.

2.9. Electrospray ionisation mass spectroscopy of anthocyanins

Partially purified as well as purified sample collected from Sephadex LH-20 was diluted with methanol and analysed by ESI-MS. Q-TOF Ultima ™ mass spectrometer, with electrospray ionisation (ESI-MS) interface (Waters Corporation, Milford, MA) and loop injection. A 5.0-μl sample of purified anthocyanin extracts was injected into the system. Samples were analysed in duplicate. Posi-

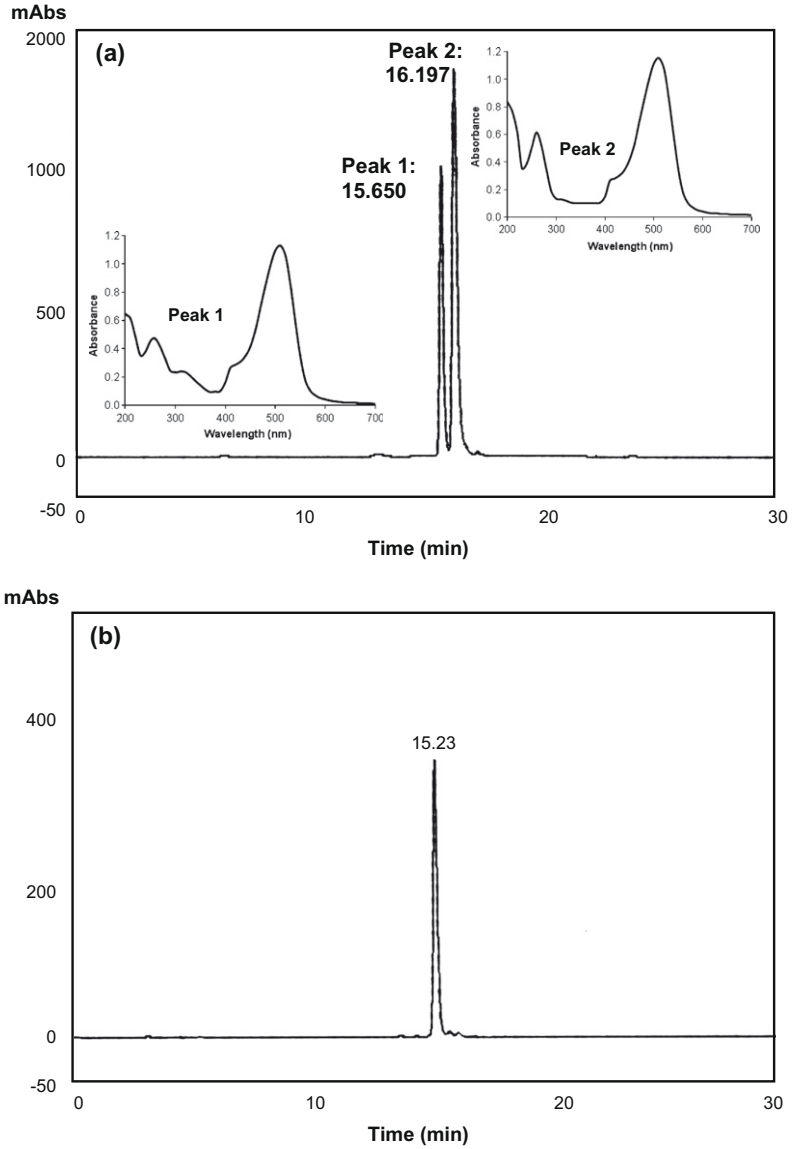

Fig. 2. HPLC chromatogram at 520 nm corresponding to (a) purified anthocyanins of *kokum*, (b) purified extract of acid-hydrolysed anthocyanins of *kokum*.

tive ion spectra of the column eluate were recorded in the range of *m/z* 250–1000 at a scan rate of 2.0 s/cycle under the following conditions: collision energy 10.0; capillary voltage 35 V; cone voltage 100 kV; source temperature 30 °C; desolvation temperature 300 °C; cone gas flow 0.8 l/min; desolvation gas flow (8.3 l/min). Argon was used as a collision gas. Data acquisition and processing were performed using MassLynxTM 4.0 SP4 software (Veigas, Narayan, Laxman, & Bhagyalakshmi, 2007).

2.10. NMR spectroscopy

Purified anthocyanin compounds were analysed by ^{1}H and ^{13}C NMR on a Bruker Avance 500 instrument. Sample (10.0 mg) was dissolved in 0.5 ml deuterated methanol for recording ^{1}H and ^{13}C spectra. Chemical shifts and coupling constants were expressed in δ and Hz, respectively (Kucharska & Oszmianski, 2002).

3. Results and discussion

The extraction of anthocyanins from *kokum* rinds yielded 2400 mg of monomeric anthocyanins/100 g of fresh fruit on a dry weight basis. This anthocyanins content was higher than the one reported for banana bracts, red radish, strawberry, capulin cherry, black raspberries, roselle hibiscus, berries and corn cobs (Table 1).

3.1. Thin-layer chromatography of anthocyanins

Thin-layer chromatography of the extract indicated two distinct red bands with retention factors of 0.26 and 0.52, which showed presence of two anthocyanins in the *kokum* extract. Krishnamurthy (1984) reported similar results.

3.2. High-performance liquid chromatography separation of kokum anthocyanins

HPLC chromatograms of *kokum* showed the presence of two major peaks with a concentration of 36% and 64% of the total peak area at 520 nm with retention times of 15.65 and 16.20 min, respectively (Fig. 2a). Individual anthocyanins (anthocyanindins) from *kokum* were isolated by HPLC. Absorbance spectra of the individual peaks (Fig. 2a) showed that the maxima of both the peaks were at 512 nm, which indicated the presence of the same anthocyanindin (Giusti & Jing, 2008, chap. 6.3). Further, absorbance spectra of anthocyanins provide information with respect to position of

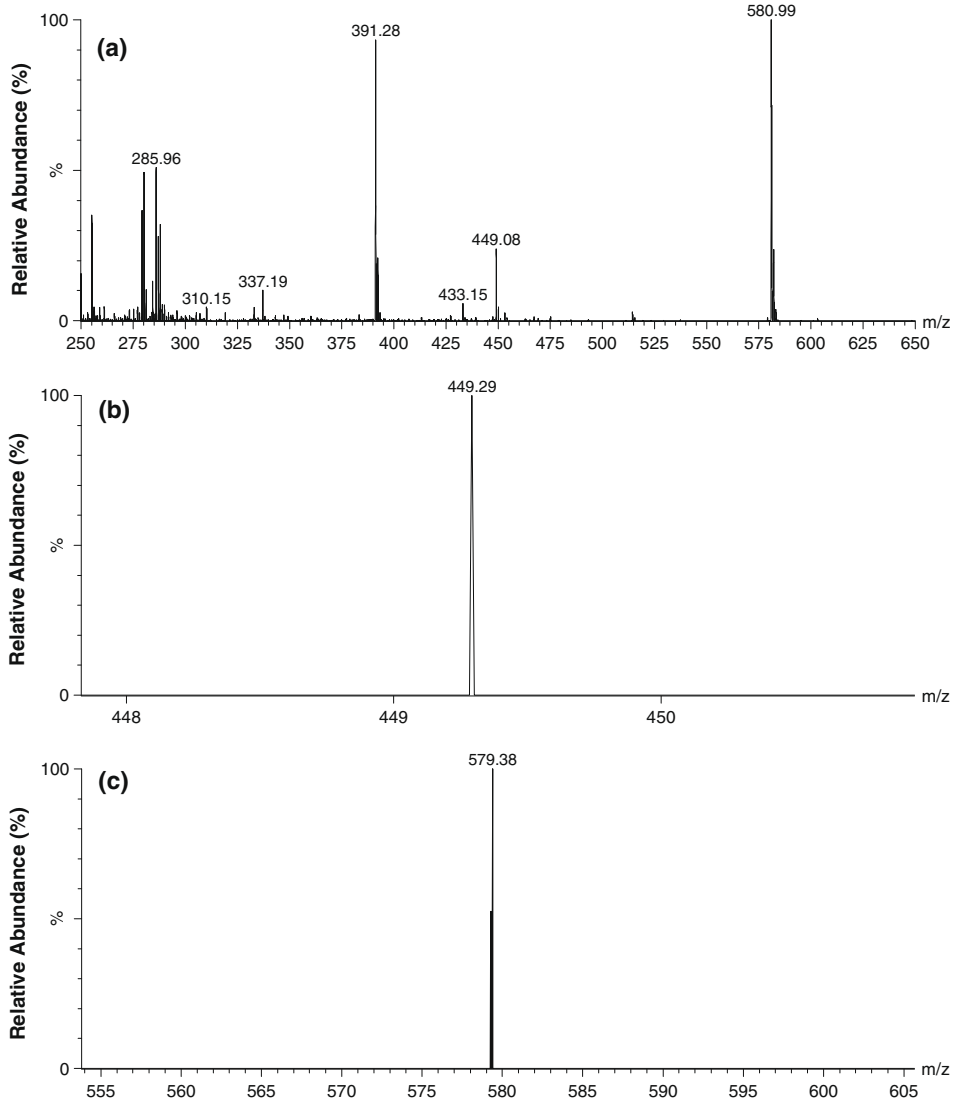

Fig. 3. Electrospray mass spectrum of (a) crude *kokum* (b) peak 1 of the HPLC (c) peak 2 of the HPLC.

glycosylation as well as the presence of acylating groups. The ratio of absorbance at 440 nm to the absorbance at visible maximum wave length ($A_{440nm}/A_{\lambda max}$ ratio) for peaks 1 and 2 were found to be 0.29 and 0.31, respectively, which indicated the possibility of glycosylation at the C-3 position of anthocyanin for both the compounds (Giusti & Jing, 2008, chap. 6.3; Longo & Vasapollo, 2006). The absence of peaks in the absorption spectra (Fig. 2a) in the region from 300 to 350 nm indicated that the pigment was not acylated (Giusti & Jing, 2008, chap. 6.3).

Acid hydrolysis of anthocyanins results in the release of sugars and acylating groups to form the aglycone, without affecting its structure. The *kokum* anthocyanins after acid hydrolysis yielded a single peak with a retention time of 15.23 min (Fig. 2b), which corresponded to cyanidin aglycone, as confirmed by comparing the results with grape anthocyanins. Wrolstad et al. (2005) demonstrated that grape anthocyanins can be used a standard for the purpose of comparison and identification. Similarly, Chiang and Wrolstad (2005) compared their results with blackberries for identification of anthocyanins.

Alkaline hydrolysis does not affect the glycosidic bond, but it will break ester linkages of acylating groups, if any are present (Giusti & Jing, 2008, chap. 6.3; Hong & Wrolstad, 1990). The chromatographic profile of alkaline-hydrolysed *kokum* anthocyanins was found to be same as that of unsaponified extract, as shown in Fig. 2a, which indicated that the anthocyanins of *kokum* were not acylated. Ordaz-Galindo, Wesche-Ebeling, Wrolstad, Rodriguez-Saona, and Argaiz-Jamet (1999) and Veigas et al. (2007) reported that there was no difference in chromatographic profiles of saponified and unsaponified fractions in the case of anthocyanins obtained from *Syzygium cumini* and capulin fruits. These results conclusively showed that anthocyanins in both cases were not acylated.

3.3. Mass spectroscopy

The mass spectrum for partially purified anthocyanin pigments shows strong ion peaks at *m/z* 286, 391, 449 and 581 (Fig. 3a). The precursor ion scan demonstrated that an ion peak at *m/z* 286 corresponding with cyanidin molecule, as the aglycone moiety (Tian, Giusti, Stoner, & Schwartz, 2006). The component corresponding to an ion peak at *m/z* 391 could not be identified in the present work. Bhaskaran and Mehta (2006) have also obtained ion peak at *m/z* 391 and regarded it as an error in the mass spectroscopy. The ion peaks at *m/z* 581 and 449 indicated the presence of anthocyanins.

Mass spectra of the peaks collected from HPLC are shown in Fig. 3b and c. The component corresponding to the ion peak at *m/z* 449 (Fig. 3b) coincided with cyanidin 3-glucoside ($C_{21}H_{21}O_{11}$) (Ordaz-Galindo et al., 1999; Zhang, Xuequn, Yang, Ji, & Jiang, 2004). The ion peak at *m/z* 581 (Fig. 3c) showed that the molecular weight of the major anthocyanin in *kokum* coincided with cyanidin 3-sambubioside ($C_{26}H_{28}O_{15}$) (Tian et al., 2006).

3.4. ^{1}H and ^{13}C NMR spectroscopy

^{1}H spectra data of compounds, corresponding to peaks 1 and 2 (Fig. 2a) isolated by chromatography exhibited signals characteristic of cyanidin aglycone moiety (Table 2a, Fig. 4). Compound corresponding to peak 1 showed a singlet at 9.03, with doublets at 6.68 and 6.93 corresponding to protons 4, 6 and 8, respectively, in the flavone group. Two doublets at 8.07 and 7.05 are observed with coupling constants of 2 and 8.5 Hz corresponding to 2′ and 5′ aromatic protons respectively. The 6′ aromatic proton appears in the spectrum at 8.27 as a double doublet with *J* values of 2 and 8.5 Hz. The doublet at 5.32 corresponds to the anomeric proton of the sugar portion with a β-configuration. Other protons corresponding to the sugar moiety appear at 3.93 (dd, 1H), 3.69–3.75 (m, 2H), 3.56–3.60 (m, 2H) and 3.47 (d). Corresponding ^{13}C spectra show fifteen carbons for the cyanidin moiety and six carbons for the glycoside portion and the spectral assignments are presented in Table 2b. These data along with the molecular mass of [449 (M^+)] indicate the compound to be cyanidin β-3-glucoside (I). This anthocyanidin was reported in black raspberries, hibiscus flowers and elderberry (Chiang & Wrolstad 2005; Nakamura, Hidaka,

Table 2a
^{1}H spectral assignments for cyanidin 3-glucoside and cyanidin 3-sambubioside.

Protons	Cyanidin β-3-glucoside	Cyanidin β-3-sambubioside
Cyanidn (Aglycone)		
4	9.03 (1H, s)	8.96 (1H, s)
6	6.68 (1H, d, J = 1.5 Hz)	6.67 (1H, d, J = 1.5 Hz)
8	6.93 (1H, d, J = 1.5 Hz)	6.92 (1H, d, J = 1.5 Hz)
2'	8.07 (1H, d, J = 2 Hz)	8.05 (1H, d, J = 2 Hz)

2	168.24	168.72
3	135.29	143.52
4	128.44	134.56
5	163.52	162.52
6	111.75	111.56
7	169.82	170.25
8	93.47	93.40
9	157.53	157.51
10	113.18	116.89
1′	126.51	126.85
2′	115.76	115.69
3′	143.88	145.70
4′	151.35	154.02
5′	116.83	115.44
6′	119.58	119.55
Sugar moiety		
1-O-β-glucoside		
1″	101.99	101.76
2″	70.37	76.95
3″	76.36	76.07
4″	68.17	73.95
5″	77.04	69.06
6″	60.64	60.52
2-O- β-xylanoyl		
1‴	–	103.95
2‴	–	79.99
3‴	–	76.41
4‴	–	69.23
5‴	–	65.40

Masaki, Seto, & Uozumi, 1990; Watanabe, Yamamoto, Nagai, & Terabe, 1998).

Similarly, compound corresponding to peak 2 showed singlet at 8.96 and doublets at 6.67 and 6.92 for the flavone aromatic protons 4, 6 and 8, respectively. The aromatic protons 2′, 5′ and 6′ are seen as two doublets and a double doublet at 8.05, 7.04 and 8.28, respectively, with *J* values of 2.5 and 9 Hz. The anomeric sugar protons at 5.46 and 4.77 appear as doublets with $J = 8$ Hz, indicating it to be a diglycoside with β-configuration at the anomeric positions. Other protons corresponding to the glycoside group appeared as four triplets at 3.80, 3.52, 3.18 and 3.06, corresponding to one, one, two and two protons respectively. The spectrum also contained two doublets at 3.74 and 3.67, along with a double doublet at 3.71. Two multiplets were seen in the spectrum at 3.60 and 3.42. A total of thirteen protons were seen for the glycoside moiety showing it to consist of a disaccharide comprising an aldohexose and an aldopentose. ^{13}C spectral data (Table 2b) clearly show fifteen carbons for the cyanidin aglycone portion and thirteen carbons for the sugar moiety. The molecular mass of [580 (M^+)] along with NMR spectral data agreed well with literature values (Watanabe et al., 1998) of cyanidin β-3-sambubioside (II).

4. Conclusion

Monomeric anthocyanin content of *kokum* was 2400 mg/100 g of fresh fruits, which was quite high as compared to other fruits and vegetables. Acid and alkaline hydrolysis of *kokum* pigment indicated that the *kokum* anthocyanin consisted of single aglycone and did not contain any acylation. Pure anthocyanin compounds were isolated in high purity and analysed by mass spectrophotometry, ^{1}H and ^{13}C NMR Spectroscopy. The pigments were characterised as cyanidin 3-glucoside and cyanidin 3-sambubioside.

different families, A, B, X, and Y (Friedberg, Feaver, & Gerlach, 2000). Family A includes mitochondrial pol γ, and pol θ, family B includes three replicative pols (α, δ, and ε) and pol ζ, family X includes pols β, λ, μ, and TdT, and family Y includes pols η, ι, κ, and REV1. Pols are not only essential for DNA replication, repair and recombination, but are also involved in cell division. Selective inhibitors of pol are considered to be a group of potentially useful anticancer and antiparasitic agents, because some inhibitors suppress human cancer cell proliferation and have cytotoxicity (Sakaguchi, Sugawara, & Mizushina, 2002).

This paper described the structural elucidation of chemical constituents in the chloroform-soluble phase of the root of *M. citrifolia*, which inhibited the activities of mammalian pols. Furthermore, we focused on the anticancer effect of the isolated anthraquinones (i.e., compounds **1**–**10**, Fig. 1) from the chloroform extract, and investigated the chemical constituents which inhibited the activities of mammalian pol families and colon cancer cell line, HCT116, proliferation.

2. Materials and methods

2.1. Materials

Roots of the tropical plant "Noni" (*M. citrifolia*) were collected in Okinawa in August 2004. Nucleotides and chemically synthesised template-primers, such as poly(dA), oligo(dT)$_{12-18}$, and [^{3}H]-dTTP (2′-deoxythymidine 5′-triphosphate) (43 Ci/mmol), were purchased from GE Healthcare Bio-Sciences (Little Chalfont, UK). All other reagents were of analytical grade and purchased from Nacalai Tesque Inc. (Kyoto, Japan).

2.2. Enzymes

Pol α was purified from calf thymus by immuno-affinity column chromatography, as described by Tamai et al. (1988). Recombinant rat pol β was purified from *Escherichia coli* JMpβ5, as described by Date et al. (1988). The human pol γ catalytic gene was cloned into pFastBac. The histidine-tagged enzyme was expressed using the BAC-TO-BAC HT Baculovirus Expression System according to the supplier's manual (Life Technologies, MD, USA) and purified using ProBoundresin (Invitrogen Japan, Tokyo, Japan) (Umeda et al., 2000). Human pols δ and ε were purified by the nuclear fractionation of human peripheral blood cancer cells (Molt-4) using the second subunit of pols δ and ε-conjugated affinity column chromatography, respectively (Oshige, Takeuchi, Ruike, Kuroda, & Sakaguchi, 2004). A truncated form of human pol η (residues 1–511) tagged with His6 at its C-terminal was expressed in *E. coli* cells and purified as described previously (Kusumoto, Masutani, Shimmyo, Iwai, & Hanaoka, 2004). A recombinant mouse pol ι tagged with His$_6$ at its C-terminal was expressed and purified by Ni-NTA column chromatography. A truncated form of pol κ (residues 1–560) with 6 × His-tags attached at the C-terminus was overproduced in *E. coli* and purified as described previously (Ohashi et al., 2004). Recombinant human His-pol λ was overexpressed and purified according to a method described previously (Shimazaki et al., 2002). Fish pol δ was purified from the testis of cherry salmon (*Oncorhynchus masou*) (Yamaguchi et al., 2006). Fruit fly pols α, δ and ε were purified from early embryos of *Drosophila melanogaster*, as described previously (Aoyagi, Matsuoka, Furunobu, Matsukage, & Sakaguchi, 1994; Aoyagi et al., 1997). Pol α from a higher plant, cauliflower inflorescence, was purified according to the methods outlined by Sakaguchi, Hotta, and Stern (1980). Calf thymus TdT and bovine pancreas deoxyribonuclease I (DNase I) were obtained from Stratagene Cloning Systems (La Jolla, CA, USA). Human immunodeficiency virus type-1 (HIV-1) reverse transcriptase (recombinant) and the Klenow fragment of pol I from *E. coli* were purchased from Worthington Biochemical Corp. (Freehold, NJ, USA). T4 pol, *Taq* pol, T7 RNA polymerase and T4 polynucleotide kinase were purchased from Takara Bio (Tokyo, Japan). Recombinant mouse inosine 5′-monophosphate (IMP) dehydrogenase (type II) was overexpressed using *E. coli* and purified according to the method described previously (Mizushina et al., 2007).

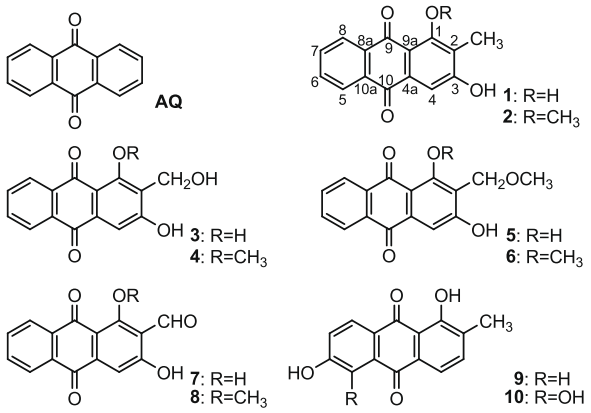

Fig. 1. Isolated anthraquinones (compounds **1**–**10**) from the chloroform-soluble phase of *M. citrifolia* root. Anthraquinone (AQ), rubiadin (**1**), rubiadin 1-methyl ether (**2**), lucidin (**3**), damnacanthol (**4**), 1,3-dihydroxy-2-methoxymethylanthraquinone (**5**), 3-hydroxy-1-methoxy-2-methoxymethylanthraquinone (**6**), nordamnacanthal (**7**), damnacanthal (**8**), sorandidiol (**9**) and morindone (**10**).

2.3. DNA polymerase assays

The reaction mixtures for pol α, pol β, plant pol α and prokaryotic pols were described previously (Mizushina et al., 1996; Mizushina, Yoshida, Matsukage, & Sakaguchi, 1997), and those for pol γ, and pols δ and ε were as described by Ogawa, Murate, Suzuki, Nimura, and Yoshida (1998) and Umeda et al. (2000), respectively. The reaction mixtures for pols η, ι and κ were the same as for pol α, and the reaction mixture for pol λ was the same as for pol β. For pols, poly(dA)/oligo(dT)$_{12-18}$ (A/T = 2/1) and dTTP were used as the DNA template-primer and nucleotide (i.e., dNTP) substrate, respectively. For HIV-1 reverse transcriptase, poly(rA)/oligo(dT)$_{12-18}$ (A/T = 2/1) and dTTP were used as the template-primer and nucleotide substrate, respectively. For TdT, oligo(dT)$_{12-18}$ (3′-OH) and dTTP were used as the DNA primer and nucleotide substrate, respectively.

The compounds were dissolved in distilled dimethyl sulfoxide (DMSO) at various concentrations and sonicated for 30 s. Aliquots of 4 μl sonicated samples were mixed with 16 μl of each enzyme (final amount 0.05 units) in 50 mM Tris–HCl (pH 7.5) containing 1 mM dithiothreitol, 50% glycerol and 0.1 mM EDTA, and kept at 0 °C for 10 min. These inhibitor-enzyme mixtures (8 μl) were added to 16 μl of each enzyme standard reaction mixture, and incubation was carried out at 37 °C for 60 min, except for *Taq* pol, which was incubated at 74 °C for 60 min. Activity without the inhibitor was considered 100%, and the remaining activity at each concentration of the inhibitor was determined relative to this value. One unit of pol activity was defined as the amount of enzyme that catalysed the incorporation of 1 nmol dNTP (i.e., dTTP) into synthetic DNA template-primers in 60 min at 37 °C under the normal reaction conditions for each enzyme (Mizushina et al., 1996, 1997).

2.4. Other DNA metabolic enzymes assays

The activities of calf primase of pol α, T7 RNA polymerase, mouse IMP dehydrogenase, T4 polynucleotide kinase and bovine DNase I were measured in standard assays according to the manu-

facturer's specifications, as described by Lu and Sakaguchi (1991), Mizushina et al. (2007), Nakayama and Saneyoshi (1985), Soltis and Uhlenbeck (1982), and Tamiya-Koizumi et al. (1997), respectively.

2.5. Cell growth assay of cultured human cancer cell line

Human colon carcinoma cell line, HCT116, was a kind gift from Dr. Bert Vogelstein (Johns Hopkins University, Baltimore, MO, USA). HCT116 cells were trypsinised and resuspended in McCoy's 5A medium with 10% FBS, and 5×10^3 cells were seeded in 96-well tissue culture plates for 24 h. The cells were then stimulated with the isolated compounds **1**–**10** for 24 h. After treatment, the survival rate was determined by MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide) assay (Mosmann, 1983).

3. Results and discussion

3.1. Isolation and structure determination of anthraquinones from M. citrifolia root

Since the chloroform-soluble phase of the root of tropical plant "Noni" (*M. citrifolia*) had inhibitory activity of mammalian pols, the chloroform extract (122 g) was chromatographed on Sephadex LH-20 using $CHCl_3$–MeOH (1:1) to give an anthraquinone-containing fraction. This fraction was subjected to repeated SiO_2 column chromatography using a *n*-hexane–$CHCl_3$ solvent system and was finally purified by preparative TLC using a $CHCl_3$–MeOH solvent system to afford compounds **1**–**10**.

HPLC was performed with a Diol column (Inertsil Diol 5 mm, 4.6 × 250 mm, GL Sciences). The detection wavelength was 254 nm. Elution was carried out with *n*-hexane:$CHCl_3$ (A, 25:75), (B, 50:50) and (C, 75:25) at a flow rate of 1 ml/min. The injection volume was 10 μl (1.0 mg/ml, chloroform-soluble phase in $CHCl_3$). Compounds **1**–**10** contained in the chloroform-soluble phase could be separated by HPLC using three solvent systems (Fig. 2). The yields of 10 compounds from the dried root were (**1**: 0.009%), (**2**: 0.094%), (**3**: 0.011%), (**4**: 0.186%), (**5**: 0.051%), (**6**: 0.012%), (**7**: 0.086%), (**8**: 0.434%), (**9**: 0.015%) and (**10**: 0.105%). The purified compounds **1**–**10** were analysed by IR, UV, ^1H and ^{13}C NMR spectra, and the chemical structures of the isolated anthraquinones (**1**–**10**) are shown in Fig. 1.

*Rubiadin (**1**):* Yellow amorphous powder; IR ν_{max}^{KBr} cm^{-1}: 3396, 1660, 1623, 1588, 1484, 1430, 1339, 1313, 1294, 1121; UV λ_{max} (MeOH) nm (log ε): 410 (3.75), 278 (4.40), 245 (4.33), 206 (4.38); ^1H NMR (400 MHz, DMSO-d_6) δ: 13.05 (1H, s, 1-OH), 7.19 (1H, s, H-4), 8.08 (1H, dd, J = 7.0, 2.1 Hz, H-5), 7.84 (1H, td, J = 7.0, 1.7 Hz, H-6), 7.87 (1H, td, J = 7.2, 2.1 Hz, H-7), 8.14 (1H, dd, J = 7.2, 1.7 Hz, H-8), 2.03 (3H, s, H-11); ^{13}C NMR (100 MHz, DMSO-d_6) δ: 162.39 (C-1), 117.26 (C-2), 162.87 (C-3), 107.35 (C-4), 131.64 (C-4a), 126.64 (C-5), 134.34 (C-6), 134.35 (C-7), 126.31 (C-8), 132.94 (C-8a), 186.10 (C-9), 108.85 (C-9a), 181.72 (C-10), 132.82 (C-10a), 8.06 (C-11).

*Rubiadin 1-methyl ether (**2**):* Yellow needles; IR ν_{max}^{KBr} cm^{-1}: 3300, 2945, 1672, 1651, 1580, 1566, 1448, 1410, 1337, 1300, 1281, 1121; UV λ_{max} (MeOH) nm (log ε): 279 (4.57), 238 (4.22), 203 (4.46); ^1H NMR (400 MHz, DMSO-d_6) δ: 7.51 (1H, s, H-4), 8.10 (1H, dd, J = 7.4, 1.4 Hz, H-5), 7.83 (1H, td, J = 7.4, 1.4 Hz, H-6), 7.89 (1H, td, J = 7.5, 1.4 Hz, H-7), 8.15 (1H, dd, J = 7.5, 1.4 Hz, H-8), 2.16 (3H, s, H-11), 3.79 (3H, s, 1-OCH_3); ^{13}C NMR (100 MHz, DMSO-d_6) δ: 161.09 (C-1), 126.63 (C-2), 162.26 (C-3), 109.51 (C-4), 135.00 (C-4a), 126.51 (C-5), 133.82 (C-6), 134.21 (C-7), 127.11 (C-8), 134.98 (C-8a), 180.64 (C-9), 118.35 (C-9a), 183.09 (C-10), 132.54 (C-10a), 9.50 (C-11), 61.07 (1-OCH_3).

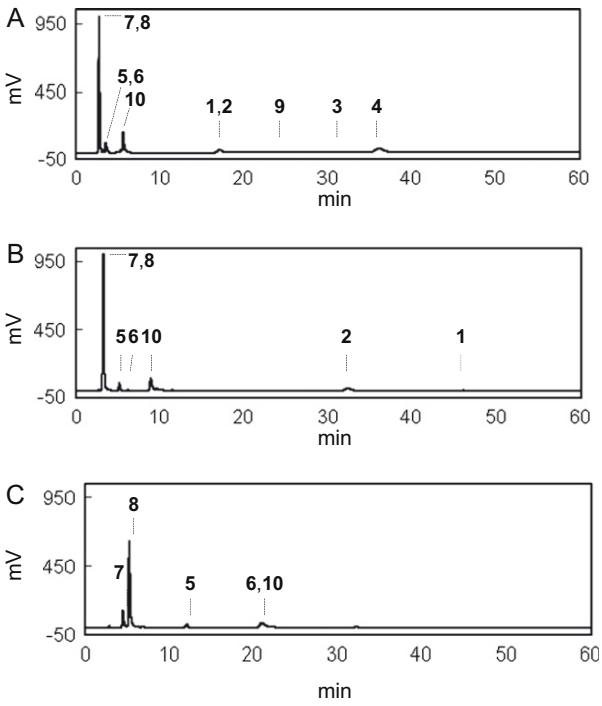

Fig. 2. HPLC profiles of chloroform-soluble phase of *M. citrifolia* root. Elution was carried out with *n*-hexane:chloroform = 25:75 (A), 50:50 (B) and 75:25 (C).

*Lucidin (**3**):* Yellow amorphous powder; IR ν_{max}^{KBr} cm^{-1}: 3413, 2945, 1660, 1615, 1590, 1439, 1413, 1333, 1307, 1284, 1008, 985; UV λ_{max} (MeOH) nm (log ε): 411 (3.69), 279 (4.23), 245 (4.24), 204 (4.27); ^1H NMR (400 MHz, DMSO-d_6) δ: 13.20 (1H, s, 1-OH), 7.26 (1H, s, H-4), 8.15 (1H, dd, J = 7.4, 1.8 Hz, H-5), 7.89 (1H, td, J = 7.4, 1.7 Hz, H-6), 7.93 (1H, td, J = 7.4, 1.8 Hz, H-7), 8.22 (1H, dd, J = 7.4, 1.7 Hz, H-8), 4.54 (2H, s, H-11); ^{13}C NMR (100 MHz, DMSO-d_6) δ: 161.09 (C-1), 126.63 (C-2), 162.26 (C-3), 109.51 (C-4), 135.00 (C-4a), 126.51 (C-5), 133.82 (C-6), 134.21 (C-7), 127.11 (C-8), 134.98 (C-8a), 180.64 (C-9), 118.35 (C-9a), 183.09 (C-10), 132.54 (C-10a), 51.18 (C-11).

*Damnacanthol (**4**):* Yellow needles; IR ν_{max}^{KBr} cm^{-1}: 3300, 2851, 1672, 1651, 1566, 1450, 1423, 1331, 1281, 1119, 968; UV λ_{max} (MeOH) nm (log ε): 277 (4.54), 239 (4.30), 203 (4.49); ^1H NMR (400 MHz, DMSO-d_6) δ: 7.52 (1H, s, H-4), 8.11 (1H, dd, J = 7.5, 1.5 Hz, H-5), 7.83 (1H, td, J = 7.5, 1.4 Hz, H-6), 7.89 (1H, td, J = 7.5, 1.5 Hz, H-7), 8.16 (1H, dd, J = 7.5, 1.4 Hz, H-8), 4.57 (2H, s, H-11), 3.87 (3H, s, 1-OCH_3); ^{13}C NMR (100 MHz, DMSO-d_6) δ: 161.66 (C-1), 128.80 (C-2), 162.17 (C-3), 109.80 (C-4), 135.37 (C-4a), 126.10 (C-5), 133.36 (C-6), 134.56 (C-7), 126.57 (C-8), 134.60 (C-8a), 179.98 (C-9), 117.85 (C-9a), 182.56 (C-10), 132.03 (C-10a), 52.15 (C-11), 62.40 (1-OCH_3).

*1,3-Dihydroxy-2-methoxymethylanthraquinone (**5**):* Yellow amorphous powder; IR ν_{max}^{KBr} cm^{-1}: 3300, 2922, 2850, 1674, 1626, 1580, 1556, 1368, 1277, 1159, 1097, 935; UV λ_{max} (MeOH) nm (log ε): 411 (3.66), 281 (4.27), 245 (4.31), 205 (4.31); ^1H NMR (400 MHz, DMSO-d_6) δ: 13.22 (1H, s, 1-OH), 7.21 (1H, s, H-4), 8.08 (1H, dd, J = 7.1, 1.4 Hz, H-5), 7.85 (1H, td, J = 7.1, 1.4 Hz, H-6), 7.88 (1H, td, J = 7.1, 1.4 Hz, H-7), 8.15 (1H, dd, J = 7.1, 1.4 Hz, H-8), 4.40 (2H, s, H-11), 3.25 (3H, s, 11-OCH_3); ^{13}C NMR (100 MHz, DMSO-d_6) δ: 163.78 (C-1), 116.60 (C-2), 164.71 (C-3), 107.92 (C-4), 133.82 (C-4a), 126.70 (C-5), 134.36 (C-6), 134.59 (C-7), 126.31 (C-8), 133.02 (C-8a), 185.88 (C-9), 106.69 (C-9a), 181.77 (C-10), 132.76 (C-10a), 57.58 (C-11), 61.07 (11-OCH_3).

*3-Hydroxy-1-methoxy-2-methoxymethylanthraquinone (**6**):* Yellow amorphous powder; IR ν_{max}^{KBr} cm^{-1}: 3287, 2967, 1672, 1653, 1568, 1423, 1335, 1302, 1284, 1106, 1065, 977; UV λ_{max} (MeOH)

nm (log ε): 277 (4.52), 240 (4.29), 204 (4.42); ^{1}H NMR (400 MHz, DMSO-d_6) δ: 7.51 (1H, s, H-4), 8.05 (1H, dd, *J* = 7.5, 1.1 Hz, H-5), 7.78 (1H, td, *J* = 7.5, 1.1 Hz, H-6), 7.84 (1H, td, *J* = 7.5, 1.1 Hz, H-7), 8.10 (1H, dd, *J* = 7.5, 1.1 Hz, H-8), 4.43 (2H, s, H-11), 3.81 (3H, s, 1-OCH_3), 3.29 (3H, s, 11-OCH_3); ^{13}C NMR (100 MHz, DMSO-d_6) δ: 162.33 (C-1), 125.23 (C-2), 162.89 (C-3), 109.90 (C-4), 135.86 (C-4a), 126.04 (C-5), 133.25 (C-6), 134.52 (C-7), 126.60 (C-8), 134.52 (C-8a), 179.77 (C-9), 117.46 (C-9a), 182.49 (C-10), 131.97 (C-10a), 62.41 (1-OCH_3), 62.23 (11-OCH_3).

*Nordamnacanthal (**7**):* Yellowish-orange needles; IR ν_{max}^{KBr} cm^{-1}: 3075, 1651, 1628, 1600, 1574, 1381, 1331, 1283, 1196, 984; UV λ_{max} (MeOH) nm (log ε): 291 (4.33), 258 (4.40), 207 (4.25); ^{1}H NMR (400 MHz, pyridine-d_5) δ: 7.42 (1H, s, H-4), 8.24 (1H, dd, *J* = 7.1, 1.8 Hz, H-5), 7.68 (1H, td, *J* = 7.1, 1.8 Hz, H-6), 7.71 (1H, td, *J* = 7.1, 1.8 Hz, H-7), 8.28 (1H, dd, *J* = 7.1, 1.8 Hz, H-8), 10.57 (1H, s, H-11); ^{13}C NMR (100 MHz, pyridine-d_5) δ: 168.33 (C-1), 113.14 (C-2), 169.27 (C-3), 109.53 (C-4), 139.45 (C-4a), 127.56 (C-5), 134.78 (C-6), 134.86 (C-7), 127.02 (C-8), 133.58 (C-8a), 186.71 (C-9), 109.36 (C-9a), 181.59 (C-10), 133.63 (C-10a), 192.99 (C-11).

*Damnacanthal (**8**):* Yellow amorphous powder; IR ν_{max}^{KBr} cm^{-1}: 3070, 1668, 1647, 1565, 1344, 1329, 1261, 1132, 980; UV λ_{max} (MeOH) nm (log ε): 283 (4.23), 247 (4.26), 203 (4.12); ^{1}H NMR (400 MHz, pyridine-d_5) δ: 7.77 (1H, s, H-4), 8.24 (1H, dd, *J* = 7.5, 1.3 Hz, H-5), 7.64 (1H, td, *J* = 7.5, 1.2 Hz, H-6), 7.70 (1H, td, *J* = 7.5, 1.3 Hz, H-7), 8.33 (1H, dd, *J* = 7.5, 1.2 Hz, H-8), 10.57 (1H, s, H-11), 4.14 (3H, s, 1-OCH_3); ^{13}C NMR (100 MHz, pyridine-d_5) δ: 166.58 (C-1), 119.51 (C-2), 166.41 (C-3), 112.67 (C-4), 141.58 (C-4a), 126.96 (C-5), 133.67 (C-6), 134.89 (C-7), 127.39 (C-8), 135.41 (C-8a), 180.07 (C-9), 118.21 (C-9a), 182.22 (C-10), 132.92 (C-10a), 194.98 (C-11), 64.31 (1-OCH_3).

*Sorandidiol (**9**):* Yellowish-orange powder; IR ν_{max}^{KBr} cm^{-1}: 3394, 1666, 1634, 1594, 1577, 1474, 1431, 1362, 1300, 1277, 1257, 1032; UV λ_{max} (MeOH) nm (log ε): 411 (3.95), 292 (4.26), 269 (4.53), 220 (4.51); ^{1}H NMR (400 MHz, DMSO-d_6) δ: 13.01 (1H, s, 1-OH), 7.54 (1H, d, *J* = 7.7 Hz, H-3), 7.48 (1H, d, *J* = 7.7 Hz, H-4), 7.39 (1H, d, *J* = 2.3 Hz, H-5), 7.17 (1H, dd, *J* = 8.6, 2.3 Hz, H-7), 8.02 (1H, d, *J* = 8.6 Hz, H-8), 2.22 (3H, s, H-11); ^{13}C NMR (100 MHz, DMSO-d_6) δ: 159.89 (C-1), 134.09 (C-2), 136.69 (C-3), 118.48 (C-4), 130.99 (C-4a), 112.44 (C-5), 163.75 (C-6), 121.32 (C-7), 129.62 (C-8), 124.39 (C-8a), 187.46 (C-9), 114.54 (C-9a), 181.59 (C-10), 135.46 (C-10a), 15.70 (C-11).

As shown in Fig. 1, eight (**1**–**8**) of 10 anthraquinone compounds were 1,2,3-trisubstituted anthraquinones and were classified into four types according to the kind of functional group bonded to the C-2 position of the anthraquinone skeleton. These four types were a methyl group for compounds **1** and **2**, a hydroxymethyl group for compounds **3** and **4**, a methoxymethyl group for compounds **5** and **6**, and an aldehyde group for compounds **7** and **8**. The remaining two compounds (**9** and **10**) contained common 1-hydroxy and 2-methyl groups on the anthraquinone skeleton.

3.2. Effects of isolated anthraquinones (compounds **1**–**10**) on mammalian pols α, β and κ

First, 10 anthraquinones (i.e., compounds **1**–**10**) obtained from the chloroform-soluble phase together with three anthraquinone glycosides and two iridoid glycosides (Fig. 3) previously isolated from the *n*-butanol-soluble phase were tested for their inhibitory activities on pols. In mammalian pols, calf pol α, rat pol β, and human pol κ were used as representative replicative pol (i.e., B-family), repair/recombination-related pol (i.e., X-family), and repair of translation synthesis (TLS) pol (i.e., Y-family), respectively (Bebenek and Kunkel, 2004; Friedberg et al., 2000). Three anthraquinone glycosides and two iridoid glycosides did not influence the activities of these pols (data not shown), but several compounds obtained from the chloroform-soluble phase exhibited inhibitory activities (Fig. 4). These results suggest that the glycoside moiety of the compounds might prevent pol inhibitory activity.

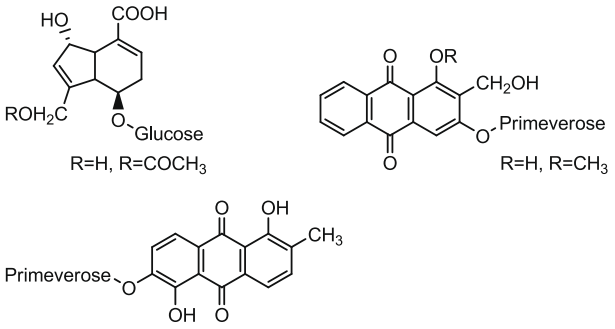

Fig. 3. Iridoid and anthraquinone glycosides isolated from the *n*-butanol-soluble phase of *M. citrifolia* root (Kamiya et al., 2008).

As shown in Fig. 4, anthraquinone (AQ) and the 1,2,3-trisubstituted anthraquinones which possessed 2-methyl or 2-hydroxymethyl groups (i.e., compounds **1**–**4**) did not show prominent inhibitory activities against these pols. 2-Methoxymethyl or 2-aldehyde groups attached to 1,2,3-trisubstituted anthraquinones (i.e., compounds **5**–**8**) exhibited remarkable inhibition against the activities of pols α and κ, but did not affect pol β activity. In anthraquinones that possessed 1-hydroxy and 2-methyl groups on one aromatic ring, compound **9**, which possessed a hydroxyl group at the C-6 position of the other aromatic ring, did not show the same pol inhibitory activity as compound **1**, whereas compound **10**, which had the hydroxyl group at the C-5 position of compound **9**, showed remarkably strong inhibitory activity against pols α and κ.

3.3. Effects of compound **10** on various pols and other DNA metabolic enzymes

Since compound **10** was the strongest inhibitor of mammalian pols α and κ in the anthraquinones (compounds **1**–**10**) investigated (Fig. 4), we focused on compound **10** in this section. As

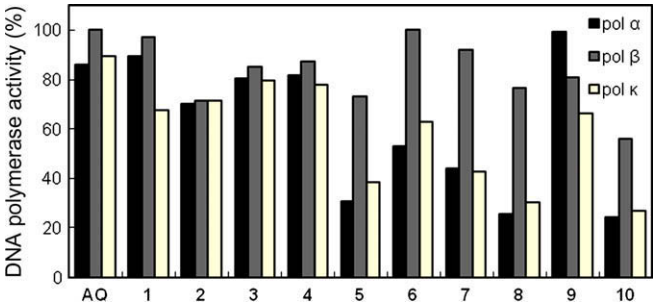

Fig. 4. Effect of anthraquinones (compounds **1**–**10**) on the activities of mammalian pols. Ten micromolar of each compound isolated from *M. citrifolia* root was incubated with calf pol α, rat pol β and human pol κ (0.05 units each). Pol activity in the absence of the compound was taken as 100%. AQ is anthraquinone.

Table 1
IC_{50} values of morindone (compound **10**) on the activities of various DNA polymerases and other DNA metabolic enzymes.

Enzyme	IC_{50} value (μM)
Mammalian DNA polymerases	
[A-family]	
Human DNA polymerase γ	35.9
[B-family]	
Calf DNA polymerase α	28.1
Human DNA polymerase δ	30.7
Human DNA polymerase ε	29.8
[X-family]	
Rat DNA polymerase β	>100
Human DNA polymerase λ	>100
Calf terminal deoxynucleotidyl transferase	>100
[Y-family]	
Human DNA polymerase η	33.3
Mouse DNA polymerase ι	32.5
Human DNA polymerase κ	29.7
Fish DNA polymerases	
Cherry salmon DNA polymerase δ	34.0
Insect DNA polymerases	
Fruit fly DNA polymerase α	28.5
Fruit fly DNA polymerase δ	29.2
Fruit fly DNA polymerase ε	29.6
Plant DNA polymerases	
Cauliflower DNA polymerase α	>100
Prokaryotic DNA polymerases	
E. coli DNA polymerase I (Klenow fragment)	>100
T4 DNA polymerase	>100
Taq DNA polymerase	>100
Other DNA metabolic enzymes	
Calf primase of DNA polymerase α	>100
HIV-1 Reverse transcriptase	>100
T7 RNA polymerase	>100
Mouse IMP dehydrogenase (type II)	>100
T4 polynucleotide kinase	>100
Bovine deoxyribonuclease I	>100

Compound **10** was incubated with each enzyme. Enzymatic activity in the absence of the compound was taken as 100%.

shown in Table 1, this compound inhibited the activities of some mammalian pols, such as A-family of pol γ, B-family of pols α, δ and ε, and Y-family of pols η, ι and κ, and these pols were suppressed to the same extent, with IC_{50} values of 28.1–35.9 μM; however, compound **10** did not inhibit the activities of X-family pols (i.e., pols β, λ and TdT). Furthermore, this compound also inhibited animal pols from fish (cherry salmon) pol δ, and insect (fruit fly) pols α, δ and ε at almost the same concentration as the inhibition of mammalian pols. On the other hand, compound **10** had no significant influence on the activities of pol α from plants (cauliflower) and prokaryotes, such as the Klenow fragment of *E. coli* pol I, *Taq* pol and T4 pol. This compound did not inhibit the activities of the other DNA metabolic enzymes tested, including calf primase of pol α, HIV-1 reverse transcriptase, T7 RNA polymerase, mouse IMP dehydrogenase (type II), T4 polynucleotide kinase and bovine DNase I.

To determine whether the inhibitor resulted in binding to DNA or the enzyme, the interaction of compound **10** with double-stranded DNA (dsDNA) was investigated based on the thermal transition of dsDNA with or without the compound. The Tm of dsDNA with an excess amount of compound **10** (100 μM) was measured using a spectrophotometer equipped with a thermoelectric cell holder. In the concentration range used, thermal transition of Tm was not observed, whereas ethidium bromide used as a positive control, a typical intercalating compound, produced a clear thermal transition. We then investigated whether an excessive amount of nucleic acid (i.e., poly(rC)) or protein (i.e., bovine serum albumin (BSA)) could prevent the inhibitory effect of compound **10** to determine whether the effect resulted from their non-specific adhesion to mammalian pols α and κ, or selective binding to specific sites. Poly(rC) and BSA had little or no influence on the effect of compound **10**, suggesting that the binding to the pols occurs selectively. These observations indicated that compound **10** did not intercalate to DNA as a template-primer, and the compound could directly bind to the enzyme and inhibit its activity.

These results suggested that compound **10** might be a potent and selective inhibitor of animal A-, B- and Y-families of pols.

3.4. Effects of anthraquinones on cultured human cancer cells

Furthermore, the inhibitory effect of the isolated anthraquinones (compounds **1**–**10**) on human colon cancer cells (HCT116 cells) was investigated. As shown in Fig. 5, 100 μM of compounds **5**, **7**, **8** and **10** suppressed cell growth by less than 100 μM of LD_{50} values. The effect of anthraquinone (AQ) and the 10 derivatives on cancer cell growth showed almost the same tendency as the inhibitory effect on pols α and κ (Fig. 4). The cell growth suppression of compound **10** was strongest in the anthraquinones (compounds **1**–**10**) tested, and the LD_{50} value was 32.2 μM. Since the LD_{50} value of compound **10** for cancer cell growth was almost the same as the IC_{50} values for animal pols, such as pol α (Table 1), this compound might be able to penetrate cancer cells and reach the nucleus, inhibiting the activities of A-, B- and Y-families of pols, and inhibition of pol activities by compound **10** might lead to cell growth suppression.

In summary, the presence of a methoxymethyl or aldehyde group at the C-2 position on the anthraquinone skeleton could be important for inhibitory activities against pols and the cell growth suppression of a human colon cancer cell line, HCT116. Furthermore, from the comparison of these bio-activities between compound **1** and compound **10**, a substituent at 3-position was unnecessary, but the hydroxyl group at 5-position was very important.

In animal pol families, the B-family of pols α, δ and ε is a replicative form and is essential for DNA replication during cell proliferation. Biologically active anthraquinones isolated from the root of the healthy tropical plant "Noni" (*M. citrifolia*) are assumed to suppress the proliferation of colon cancer cells by inhibiting DNA replication from the positive correlation between the suppression of HCT116 cell growth and the inhibition of B-family pol activities. The Noni root containing anthraquinones may be used as an anti-cancer functional food based on the inhibitory activities of pols A-, B- and Y-families. The anthraquinones, especially morindone (compound **10**), may be useful in providing valuable information to develop a drug design strategy for anti-cancer chemotherapy agents.

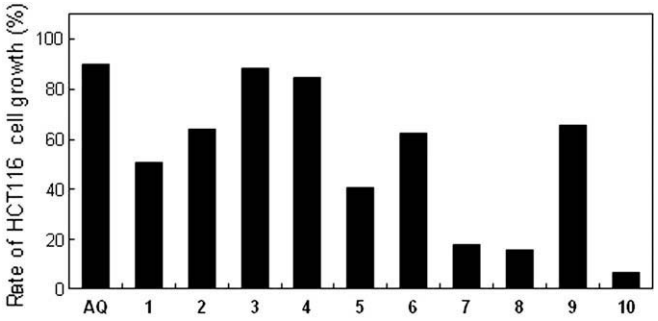

Fig. 5. Effect of anthraquinones (compounds **1**–**10**) on the proliferation of a human colon cancer cell line, HCT116. Each compound (100 μM) was added to the culture of HCT116 cells, and incubated for 24 h. The cell growth rate was determined by MTT assay (Mosmann, 1983). The proliferation of cancer cells in the absence of the compound was taken as 100%. AQ is anthraquinone.

is a collection of statistical and mathematical techniques that have been successfully used in developing, improving and optimising bio-processes (Bandeira, Tininis, Bolzani, & Cavalheiro, 2006; Juntachote, Berghofer, Bauer, & Siebenhandl, 2006; Liyana-Pathirana & Shahidi, 2005; Paz, Vázquez, Riobó, & Franco, 2006; Vázquez, González, & Murado, 2006).

In this study, the optimal conditions for antioxidant extraction from soybeans fermented with *Aspergillus oryzae* were investigated using two complementary and sequential approaches. A factorial design was initially proposed. Kinetic analyses were then performed at the temperature–ethanol concentration points of the design. The parameters obtained from the fits of the kinetic data to a modified first-order model were the dependent variables to formulate the empirical equations of the second-order design. Finally, optimal conditions for a maximum antioxidant extraction were obtained from the response surfaces.

2. Materials and methods

2.1. Microorganism

A. oryzae was originally obtained from soy sauce industry (Wang, Law, & Webb, 2005). A distilled water suspension of the fungi spores was kept at −30 °C until used. The volume of inoculum was 1.5 ml with a cell concentration of 1.2×10^8 cells/ml.

2.2. Soybeans fermentation

Split soybeans (150 g) and 73.5 ml of distilled water were separately placed in 500 ml capped Duran bottles and autoclaved at 121 °C for 20 min. After the soybeans and the distilled water cooled down (at room temperature) they were both mixed with the spore suspension and manually shaken (vertically and horizontally) for 10 min to homogenise the inoculum. The inoculated soybeans were poured into Petri dishes and incubated at 30 °C for 5 days. Soybean samples were crushed with a mortar and pestle before being sealed in plastic bags and store at −30 °C until used.

2.3. Crude phenolic extraction

Detailed extraction conditions of temperature and concentration of ethanol are shown in Table 1. Ground samples (2 g) were extracted with 20 ml of the corresponding aqueous ethanol concentration at the temperature pre-established in the factorial design using a Soxtec System HT (1043 – Tecator). Subsequently, the extract was dehydrated to obtain a dry extract and diluted with ethanol up to 20 mg/ml of extract concentration. After that, the extract was centrifugated at 16,249×*g* for 5 min, and the supernatant was used for the antioxidant determination.

Table 1
Experimental domain and codification of independent variables in the factorial rotatable design.

Coded values	Natural values of temperature (T) and ethanol concentration (E)	
	T (°C)	E (%)
−1.41	40	21
−1	45	32
0	57	60
+1	69	88
+1.41	74	100

Codification: $V_c = (V_n - V_0)/\Delta V_n$; Decodification: $V_n = V_0 + (\Delta V_n \times V_c)$.
V_n = natural value in the centre of the domain.
ΔV_n = increment of V_n per unit of V_c.
Shaded area: values corresponding to the first-order design.

2.4. Determination of total phenolic content

The total phenolic content was determined based on the method of Singleton, Orthofer, and Lamuela-Raventós (1999), using the Folin–Ciocalteu Reagent (FCR) with gallic acid as a standard. Fifty microlitre of sample or blank were added to 3 ml of distilled water in 12 ml test tubes. A volume of FCR (250 μl) was placed into the tube and mixed before adding 750 μl of saturated Na_2CO_3. The final volume of the reaction mixture was adjusted to 5 ml with distilled water. The absorbance at 765 nm was read in 1 cm cuvettes after incubation for 2 h at room temperature, and readings were compared with a standard curve of gallic acid. The total phenolic content was expressed as mg of gallic acid equivalent per gram dry basis of fermented soybeans (mg GAE /g db).

2.5. Determination of DPPH radical scavenging activity

The effect of the extract on the 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical was estimated according to the procedure described by Brand-Williams, Cuvelier, and Berset (1995). The extract (0.1 ml) was added to 3.9 ml of DPPH radical 6×10^{-5} M in methanol which was prepared daily. The decrease in absorbance was determined at 515 nm after incubation for 30 min. A DPPH radical solution without sample was used as a control and the DPPH percentage inhibition was calculated according to the following equation:

$$\text{DPPH radical scavenging effect } (\%) = \left(1 - \frac{\text{absorbance}_{\text{sample}}}{\text{absorbance}_{\text{control}}}\right) \times 100 \quad (1)$$

2.6. Experimental design and statistical analysis

The antioxidant activities (total phenolic content and DPPH radical scavenging capacity) as a function of the extraction time was studied using a rotatable second-order design with quintuple replication in the centre of the experimental domain (Akhnazarova & Kafarov, 1982; Box et al., 2005). The range of independent variables studied, temperature (T) and ethanol concentration (E), is shown in Table 1.

The experiments were planned using two different approaches. The variation of the antioxidant extraction (measured as total phenolic concentration and DPPH radical scavenging activity) with time were fitted to appropriate mathematical models to obtain a group of kinetic parameters that could describe these trends. A rotatable second-order design was then implemented using the kinetic parameters as response.

In the first case, the calculation was carried out using a non linear least-squares (quasi-Newton) method *via* the macro 'Solver' in the Microsoft Excel XP spreadsheet. Later, the Statistica 6.0 program (StatSoft, Inc. 2001) was used to calculate the significance of the estimated parameters (Student t-test, $\alpha = 0.05$) and the robustness of the model (Fisher F-test, $\alpha = 0.05$). Results of the factorial designs were employed to obtain empirical equations that describe the significant parameters as a function of temperature and ethanol concentration. The statistical significance of the coefficients was verified by means of the Student t-test ($\alpha = 0.05$), and the model consistency by the Fisher F-test ($\alpha = 0.05$) using the following mean squares ratios:

	The model is acceptable if
F_1 = model/total error	$F_1 \geqslant F_{\text{den}}^{\text{num}}$
F_2 = (model + lack of fitting)/model	$F_2 \leqslant F_{\text{den}}^{\text{num}}$
F_3 = total error/experimental error	$F_3 \leqslant F_{\text{den}}^{\text{num}}$
F_4 = lack of fitting/experimental error	$F_4 \leqslant F_{\text{den}}^{\text{num}}$

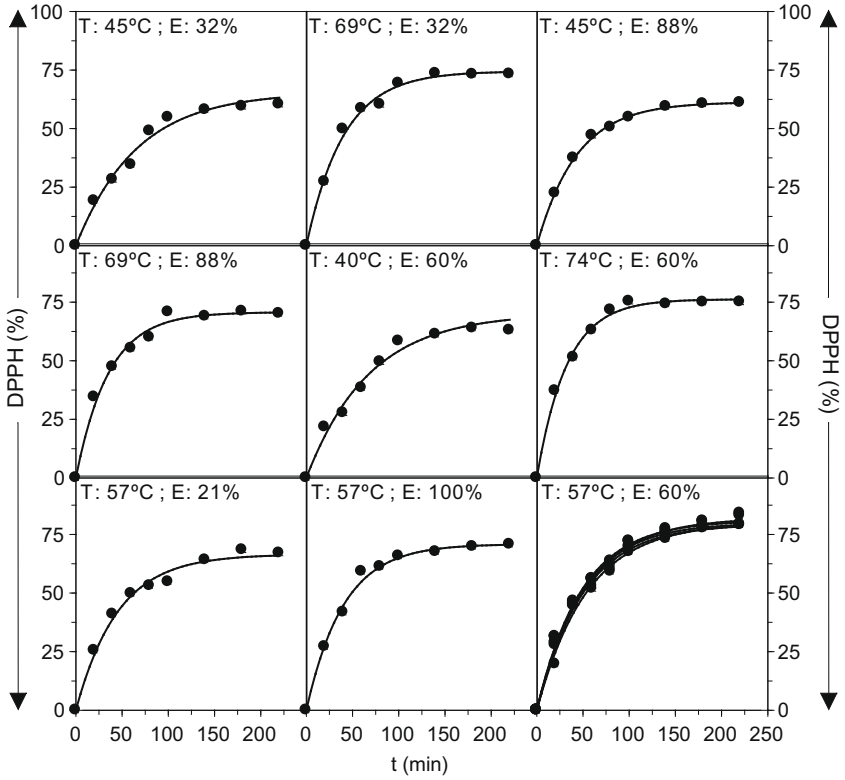

Fig. 2. Kinetics of DPPH radical scavenging activity extracted from soybeans fermented with *Aspergillus oryzae* in each one of the experimental conditions (in natural values) defined in Table 1. The experimental data (symbols) were fitted to the model (3) (continuous line).

3. Results and discussion

Previous experiments using different solvents (acetone, methanol, ethanol, hexane and ethyl acetate) at various concentrations demonstrated that methanol and ethanol were the most efficient compounds in the extraction of antioxidant compounds from fermented soybeans (data not shown). Among these, ethanol was selected since it has less restriction in food applications. The aim of this study was to evaluate the combined effects of extraction temperature and ethanol concentration for the recovery of antioxidant compounds from fermented soybeans.

3.1. Kinetics of antioxidants activities

Kinetics of the antioxidant extraction were firstly performed at the points selected in the factorial design. The results for total phenolic content and DPPH scavenging activity are shown in Figs. 1 and 2. In both cases the experimental data follow hyperbolic curves, and for this reason a modified first-order kinetic model with a final asymptote was chosen to describe the extraction of antioxidants with time

$$P = P_m \cdot (1 - e^{-k_p \cdot t}) \quad (2)$$

where P is the phenolic concentration at time t (mg GAE/g db), P_m is the maximum concentration when time approaches infinite, and k_p is the specific rate of the total phenolic concentration (min^{-1}). Similarly, for the DPPH scavenging capacity

$$D = D_m \cdot (1 - e^{-k_d \cdot t}) \quad (3)$$

where D is the DPPH radical scavenging activity (%), D_m the maximum DPPH radical scavenging activity when time approaches infinite, and k_d is the specific rate of DPPH radical scavenging activity (min^{-1}). The continuous curves in Figs. 1 and 2 represent the models obtained by fitting the experimental data to these equations. The statistical analyses of the kinetic models are summarised in Tables 2 and 3.

In general, the proposed models were statistically robust (Fisher's F-test and p-values < 0.001), and the parametric estimations were significant (Student's t-test $\alpha = 0.05$). The coefficients of linear correlation (r) between predicted and observed values were in all cases higher than 0.964. This indicates that the proposed kinetic models can be used to describe and predict the extraction of antioxidants from fermented soybeans in the range of temperature and ethanol concentration assayed.

Table 2

[c] Specific rates of DPPH radical scavenging activity.
[d] F-Fisher test (df_1 = degrees of freedom of the model; df_2 = degrees of freedom of the error).
[e] Correlation coefficient between observed and predicted data.

From the values of the parameters in the fitted models, it can be concluded that the highest phenolic concentration (P_m) and specific rate of total phenolic content (k_p) are found at the highest temperature studied (74 °C). The highest DPPH scavenging activity (D_m) was achieved at the centre of the experimental domain ($T = 0$, $E = 0$), but the maximum specific rate of DPPH scavenging activity (k_d) is obtained at the point $T = 1.41$ and $E = 0$ (see Table 1).

3.2. Factorial design

As stated before, the second approach was to study the correlation between the kinetic parameters and the combined effects of temperature (T) and ethanol concentration (E). The parameters obtained from the fitted kinetic models were adjusted to the polynomic function

$$R = b_0 + b_1T + b_2E + b_{12}TE + b_{11}T^2 + b_{22}E^2 \quad (4)$$

where R is any of the response variables (D_m, P_m, k_p or k_d).

The best-fit model and the statistical analysis of the rotatable second-order design when R was the maximum total phenolic content (P_m) are shown in Table 4. The statistical analysis indicates that the combined term TE in Eq. (4) was not significant.

The response surfaces obtained from fitting the total phenolic parameters P_m and k_p to Eq. (4) are plotted in Fig. 3. The maximum phenolic content (P_m, left) shows a well defined maximum within the experimental domain. The maximum can be calculated by

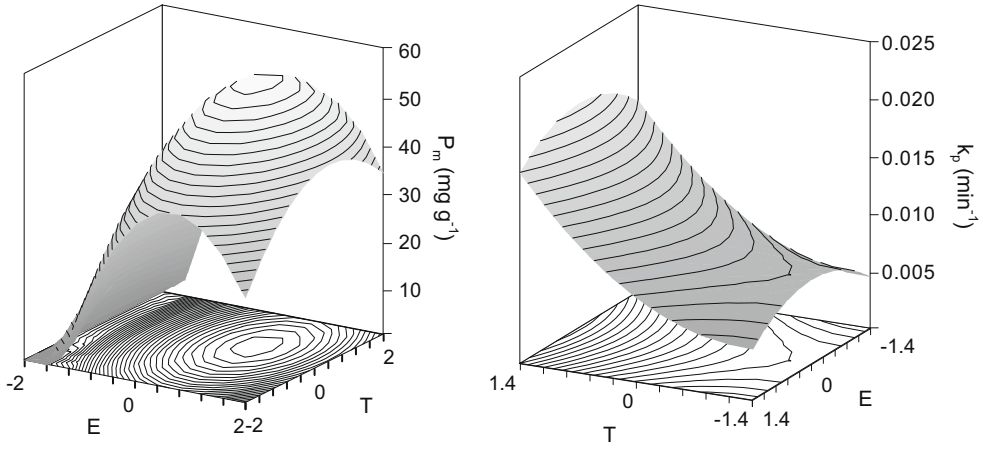

Fig. 3. Response surface corresponding to the joint effect of ethanol (E) and temperature (T) on the maximum total phenolic production (P_m, left) and in the specific rates of total phenolic production (k_p, right) according to the equations described in Tables 4 and 5. Independent variables are expressed in codified values.

deriving the response equation with respect to the independent variables T and E

$$\left.\frac{\partial P_m}{\partial T}\right|_{T=T_m} = 11.915 - 17.32T \quad \text{and} \quad \left.\frac{\partial P_m}{\partial E}\right|_{E=E_m} = 2.937 - 6.29E$$

Since at the maximum both derivatives must be zero, it is possible to calculate the optimum temperature and ethanol concentration for a maximum antioxidant extraction; $T_m = 0.690$ and $E_m = 0.467$ in codified values, equivalent to 65.3 °C and 73.1% ethanol in real values (see Table 1 for codification/decodification). At this point the predicted maximum total phenolic concentration was 56.2 mg GAE/g db.

The best-fit model and the statistical analysis of the rotatable second-order design for the specific rate of the total phenolic concentration (k_p) are shown in Table 5. In this case the statistical analysis indicates that neither the combined term TE nor the E term in Eq. (4) are significant. The response for k_p (Fig. 3, right) is a convex surface with a line of maxima at $E = 0$. An absolute maximum response cannot be obtained within the experimental domain. However, in all cases the specific rate of total phenolic concentration increases with temperature.

The results for maximum DPPH radical scavenging activity (D_m) were similar to those for the total phenolic. Fig. 4 (left) shows the parabolic response surface obtained from the equation in Table 6. Both the E and TE terms in Eq. (4) were not significant. The maximum can be equally calculated deriving the response equation with respect to the independent variables T and E

$$\left.\frac{\partial D_m}{\partial T}\right|_{T=T_m} = 3.35 - 8.70T \quad \text{and} \quad \left.\frac{\partial D_m}{\partial E}\right|_{E=E_m} = -13.24E$$

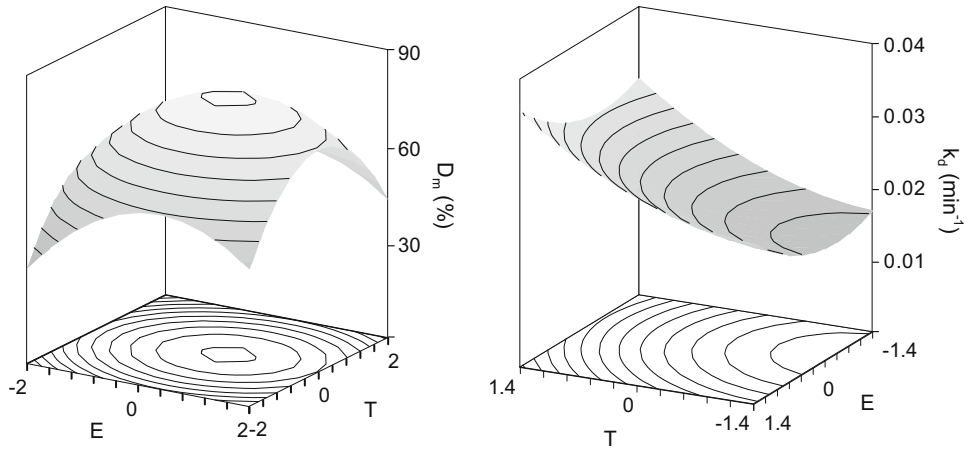

Fig. 4. Response surface corresponding to the joint effect of ethanol (E) and temperature (T) on the maximum DPPH radical scavenging activity (D_m, left) and in the specific rates of DPPH radical scavenging activity (k_d, right) according to the equations described in Tables 6 and 7. Independent variables are expressed in codified values.

The maximum D_m was found at $T_m = 0.385$ (61.6 °C) and $E_m = 0$ (60%). At this point the predicted maximum DPPH scavenging activity was 81.6%.

Table 7 summarises the results of the factorial design for the specific rate of DPPH scavenging activity (k_d) plotted in Fig. 4 (right). Only the combined term *TE* was not significant, and the model defines a concave response surface with a line of maximum slope in the proximity of $E = 0$. As for the k_p model, a maximum response cannot be calculated within the experimental domain, but k_d increases with the temperature.

[a] Experimental values of the specific rates of DPPH radical scavenging activity.
[b] Estimated values of the specific rates of DPPH radical scavenging activity from the adjusted model.
[c] Coefficients for the terms of the adjusted model: *i.t.*, independent term; *E*, ethanol concentration (%); *T*, temperature (°C); NS, not significant coefficient.
[d] SS: sum of squares.
[e] *v*: degrees of freedom.
[f] MS: mean squares.
[g] Mean square ratios: MSM, mean squares of the model; MSE, mean squares for error; MSMLF, mean squares for model lack of fit; MSEe, mean squares for experimental error.

The empirical models obtained show a good fitting and consistency. The correlation with the observed values ($r^2_{adjusted}$) was higher that 0.85 and the experimental variability of the replica in the centre of the experimental domain was considerably low, allowing for construction of highly predictive models.

The improvement of the antioxidant extraction with temperature was probably due to the increasing diffusivity of the solvent in the solid matrix and the solubility of the phenolic compounds in the solvent, which favour the extraction (Cacace & Mazza, 2003; Herrero, Martin-Alvarez, Señoráns, Cifuentes, & Ibáñez, 2005; Juntachote et al., 2006). However, it should be noted that increasing temperature beyond a certain value can lead to decomposition of some phenolic compounds. Rostagno, Palma, and Barroso (2007) reported decomposition of isoflavones in soybean during heat treatments. Malonyl isoflavones also degrade when the extraction is performed between 75 and 100 °C. Extraction between 100 and 125 °C affects acetyl isoflavones and higher temperatures sharply reduced the glucosides concentrations.

It is not surprising to find out that the DPPH results showed a similar trend to the total phenolic concentration. However, the optimum extraction conditions were slightly different for the two assays. This could be due to the fact that each assay measures different kinds of phenolics, and each phenolic compound shows different antioxidant properties, which depends on the chemical structure and substitution position (Pokorny, 2003).

The fit of models to second-order polynomial equations was in agreement with other authors who used temperature, solvent concentration and time as variables in a similar approach using other food matrices. Wettasinghe and Shahidi (1999) studied the antioxidant properties of an ethanol extract of defatted borage seeds, and Herrero et al. (2005) investigated antioxidants from *Spirulina platensis* microalga. Liyana-Pathirana and Shahidi (2005) studied phenolic compounds from wheat, and Juntachote et al. (2006) tested phenolic extracts of lemon grass, galangal, holy basil and rosemary. However, only Herrero et al. (2005) reported that temperature had the strongest influence amongst all variables. In the other studies, the solvent concentration was the main factor affecting antioxidant extraction. These discrepancies highlight the need for appropriate extraction protocols, with suitable solvent polarity, time and temperature for each food matrix, and using multivariable experimental design techniques.

4. Conclusions

A factorial design combined with a kinetic approach was successfully applied to maximise the extraction of antioxidant compounds from soybeans fermented with *A. oryzae*. The highest values of P_m and D_m were obtained close to the centre of the experimental domain studied. Both k_p and k_d showed a marked increase with temperature, but absolute maxima for this parameters were not predicted within the experimental domain. In general, higher temperatures lead to higher yields of total phenolics and DPPH scavenging activity. However, over a certain temperature value decomposition of some phenolic compounds may occur. In this case, the optimal conditions for antioxidant extraction were 65.3 °C and 73.1% ethanol for maximum total phenolic concentration, and 61.6 °C and 60% ethanol for maximum DPPH radical scavenging activity.

Acknowledgements

The authors wish to acknowledge the SPMU-TPSD Diponegoro University (Indonesia) for the Grant awarded to Dyah Hesti Wardhani to do this research (ADB Loan No. 1792-INO). Dr. José Antonio Vázquez has been awarded a postdoctoral Grant (Programa de bolsas para estadías fóra de Galicia, 2008) by the Dirección Xeral de Investigación, Desenvolvemento e Innovación, Xunta de Galicia, Spain.
