
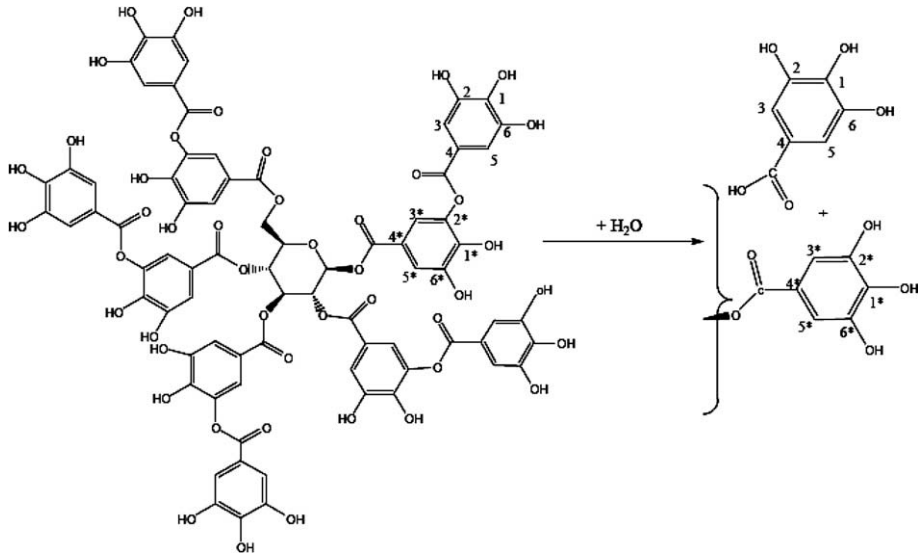

Fig. 2. The hydrolysis of tannic acid at an ester linkage between two gallic groups.

2. Materials and methods

2.1. Thermal processing of tannic acid

To prepare processed tannic acid (PTA, 30% w/v), fresh tannic acid (FTA, 30% w/v) (Sigma–Aldrich, Saint Louis, MO) was diluted in deionised water (pH 6.5). The FTA (5 ml) solution was placed in a glass bottle and hermetically sealed with a cap, and then autoclaved (121 °C, 103.4 kPa) in an autoclave (Market Forge Industries, Inc., Everett, MA) up to 60 min.

2.2. Measurement of lipid oxidation in soybean oil

The induction period (IP) measured volatile products such as aldehydes, acids, and alcohols that occur during the secondary phase of soybean oil treated with FTA and PTA at various concentrations (250, 500, 1000, 2000 and 3000 ppm). A Metrohm Rancimat® apparatus (743 Rancimat®, Brinkmann Instruments, Inc., Westbury, NY) was used to determine IP. Air flow was circulated at 10 ± 0.2 l/h through three gram samples at 110 ± 0.2 °C. Air was then passed through deionised water and the conductivity of

the water was measured. The IP was measured as the intersection of the tangent lines (first derivative) using the software provided with the instrument.

2.3. HPLC analysis of gallic acid in fresh and processed tannic acid

HPLC was used to separate and quantify gallic acid in tannic acid, as described by Kim et al. (2008), with the following modifications. The tannic acid sample was centrifuged at 16,000 *g* for 5 min and the supernatant was filtered through a 0.45 μm syringe filter and 10 μl was injected into a Gemini C18, 250 × 4.6 mm, C18 column at 25 °C. The mobile phases were 0.01 N H_2SO_4/acetonitrile (90:10, v/v) with the flow rate of 1.0 ml/min. Peaks were detected at 215 nm. The peak corresponding to gallic acid was identified, based on retention time of standard gallic acid and quantified using a calibration curve.

2.4. Effects of tannic acids processed for different processing time on lipid oxidation

Tannic acid (30%) was autoclaved at different processing times (0, 1, 5, 10, 15, 30 and 60 min). Autoclave condition was the same as described above. The processed tannic acids (300 ppm) with different processing times were added in soybean oil to measure the induction points. Fresh tannic acid (FTA) at 300 ppm was used as an unprocessed control. The concentration of gallic acid was also measured in processed tannic aid (PTA) by HPLC as described above. To determine the gallic acid effect in soybean oil, the same amount of gallic acid formed in processed tannic acid was added to soybean oil with FTA (300 ppm).

2.5. Bacterial strains

E. coli O157:H7 (ATCC 43890, 43895 and 35150), *Salmonella enterica* serovar Typhimurium (ATCC 19585 and 14028), *Salmonella typhi* (ATCC 6539), *L. monocytogenes* (ATCC 7694 and Δ*inl*AB) and *Enterobacter sakazakii* were used for this study. *E. sakazakii* Fec39 and *E. sakazakii* MSDH were kindly provided by Dr. Yoshen Chen (Department of Food Science and Technology, Mississippi State University). *E. sakazakii* Fec39 were clinically isolated by Dr. Römling (Microbiology and Tumorbiology Center, Sweden) (Zogaj, Bokranz, Nimtz, & Römling, 2003) and *E. sakazakii* MSDH by Mississippi State Department of Health, USA. An internalin A and B negative mutant (Δ*inl*AB) of *L. monocytogenes* was kindly provided with Dr. Pascale Cossart (*Département de Biologie Cellulaire et Infection*, France). All stock cultures were kept at −65 °C in tryptic soy broth (TSB, Becton Dickinson, Sparks, MD) containing 10% glycerol. The cultures were thawed and reactivated by subculture in TSB. Reactivated cells were maintained on tryptic soy agar (TSA, Becton Dickinson, Sparks, MD) slant.

2.6. Antimicrobial test

The antimicrobial test was carried out according to a disc diffusion test (Ali-Shtayeh, Yaghmour, Faidi, Salem, & Al-Nuri, 1998; Mau, Chen, & Hsieh, 2001). Each microbial culture was activated by transferring a loopful of the TSA slant culture into an Erlenmeyer flask with a cotton cap containing TSB (20 ml/flask), incubating at 37 °C for 18 h, and adjusting the cell numbers to 5 log CFU/ml with peptone (Becton Dickinson, Sparks, MD) water prior to use in tests. Each bacterial culture was uniformly streaked on Mueller–Hinton agar (Becton Dickinson, Sparks, MD), as described by O'Bryan, Crandall, Chalova, and Ricke (2008). Two sterile filter papers (Whatman GF/D, diameter = 7.5 mm) were aseptically placed on the agar. Fresh (FTA) and processed (PTA) tannic acid solutions (30%, w/v) were aseptically pipetted onto the discs (50 μl/disc). After 20 min, the agar plate was inverted and incubated at 37 °C for 24 and 48 h. Diameters of zones of inhibition were measured in mm and recorded. Analyses were performed a total of three times per strain.

2.7. ^{13}C NMR spectra of tannic acid samples

^{13}C NMR spectra of FTA and PTA solutions (30% w/v) were obtained on a Techmag 100 MHz NMR spectrometer (Spectral Data Services, Inc., Champaign, IL) at ambient temperature using a 12-μs pulse-width and 10-s delay for maximum quantification results with a 340 scan accumulation. Peaks were integrated and the integral values of the two spectra were compared to estimate the characteristics of the FTA and PTA samples.

2.8. Statistical analysis

A completely randomised design with three replications was used for antimicrobial and antioxidant studies. Analysis of variance and means were computed using the Statistical Analysis System (SAS, 2001). Fisher's least significant difference test ($p \leqslant 0.05$) was used to determine differences between treatment means. A value $p \leqslant 0.05$ was considered statistically significant.

3. Results

3.1. Antioxidant effect of fresh and processed tannic acid in soybean oil

The oxidative stability of soybean oil increased by 5–43% (from 5.93 to 6.23–8.48 h) for FTA and by 35–147% (to 7.98–14.68 h) for PTA (Fig. 3A and B). The induction time (IP) increased ($p < 0.05$) with increasing concentration of FTA or PTA. While there was no difference ($p \geqslant 0.05$) in IP between the control and soybean oil treated with FTA (500 ppm), the addition of PTA (250 ppm) to soybean oil increased ($p < 0.05$) induction time up to 7.98 h, comparable to the value of FTA at 3000 ppm (Fig. 3B). In all concentrations tested, PTA showed much stronger ($p < 0.05$) antioxidant capacity in soybean oil than FTA (Fig. 3B).

3.2. Effects of processing time of tannic acid and the combination of gallic acid and fresh tannic acid on soybean oil oxidation

Gallic acid was investigated as a possible hydrolysed product of tannic acid by thermal processing (Fig. 2). HPLC was used to quantify gallic acid for both FTA (control) and PTA at 300 ppm. As the processing time of PTA was increased from 1 to 15 min, the induction point and gallic acid were also increased ($p < 0.05$) up to 1.24 h and 1.26 μg/100 ml (Fig. 4). However, there were no changes ($p \geqslant 0.05$) beyond 15 min processing. Adding gallic acid at the same concentration found in PTA to fresh tannic acid increased the induction point of soybean oil oxidation, implying that the enhanced antioxidant capacity of processed tannic acid could be due to the galloyl group newly formed by thermal processing (Fig. 4).

3.3. Antimicrobial effect of fresh and processed tannic acid

Ten species of foodborne pathogens were used to evaluate the antimicrobial effect of fresh and processed tannic acid. An inhibition zone of 12 mm was considered as an effective indicator for good inhibitory effect (Mau et al., 2001). Processed tannic acid (PTA) possessed ($p < 0.05$) a broad antimicrobial activity on all tested microorganisms at days 1 and 2 whereas fresh tannic acid (FTA) showed good antimicrobial activity on only two strains, *S. enterica* serovar Typhimurium (ATCC 14028) and *E. sakazakii* MSDH (Table 1). At day 2, cell growth of the tested organisms was ob-

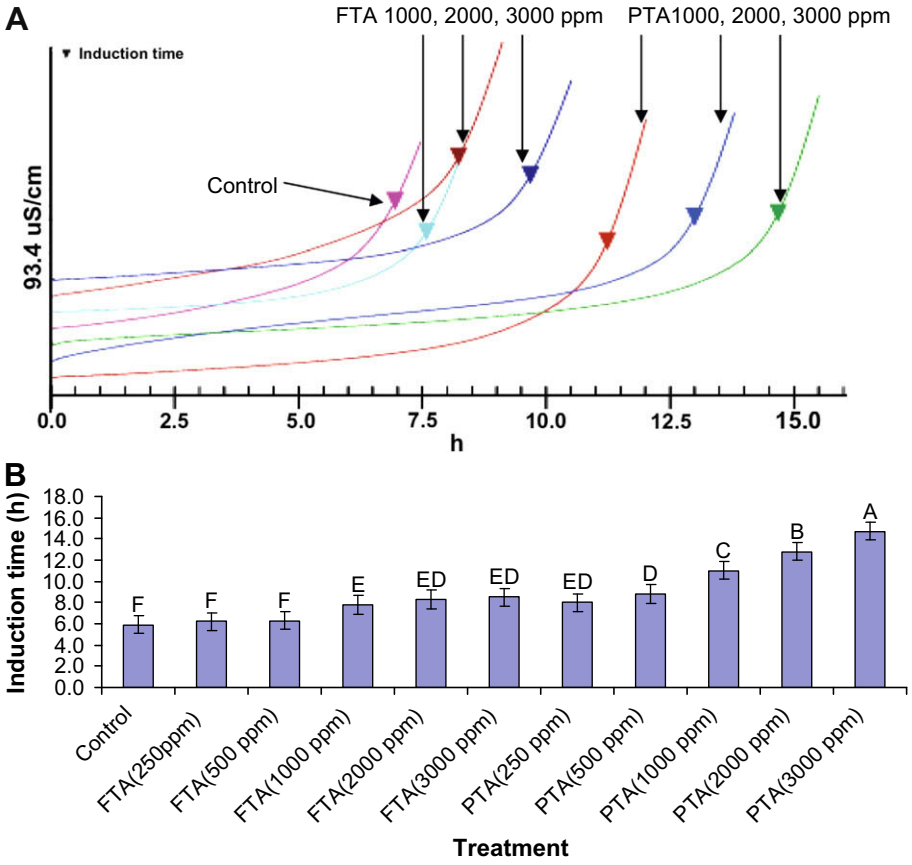

Fig. 3. (A) Induction curve of soybean oil treated with different concentrations of fresh (FTA) and processed tannic acid (PTA). (B) Induction time of soybean oil treated with different concentrations of fresh (FTA) and processed tannic acid (PTA).

served on FTA, which showed a slight decreased inhibition zone, while the cells on PTA did not show growth in the same time period.

3.4. ^{13}C NMR spectra of fresh and processed tannic acids

^{13}C NMR spectroscopy was used to see whether thermal processing causes a structural rearrangement of tannic acid. ^{13}C NMR spectral integration was carried out with different chemical shift scales for 200–100 and 100–0 ppm ranges. For the data interpretation, the chemical structure of tannic acid used in this study is shown in Fig. 3. The ^{13}C NMR spectra (Fig. 5) indicated the presence of unknown impurity peaks at 176, 36, and 20 ppm and also the presence of hydrolysed forms of tannic acid was apparent at 169–170 ppm for the aromatic carboxylic acid groups (Table 2). Thus, about 17% of ester groups of processed tannic acid were in the hydrolysed form in the PTA which showed more hydrolysation than FTA. By comparing with ^{13}C NMR spectra of pyrogallol, gallic acid, *n*-propyl gallate, and D-glucose (Stothers, 1972), other peaks were assigned as follows: aromatic acid ester carbons at 164–

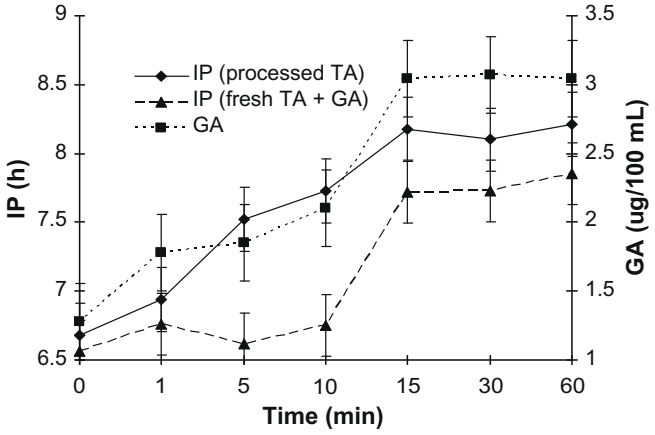

Fig. 4. Effects of processing time of tannic acid (TA) on induction point (IP, time) of soybean oil (solid diamond), their production of gallic acid (GA) (solid square), and the combination of GA and fresh TA on IP (solid triangle).

168 ppm; 2, 6 and 2′, 6′ aromatic carbons at 139–137 ppm; 1 and 1′ aromatic carbons at 146–140 ppm; 4 and 4′ aromatic carbons at 121–117.5 ppm; 3, 5 and 3′, 5′ aromatic carbons at 117.5–108 ppm; anomeric carbons of glucose at 96–90 ppm; and remaining glucose carbons at 77–60 ppm. The overall quantification of the integration values appears to be reasonable in that the carboxylic acid carbons (10.4 groups) are only slightly higher than the theoretical value of 10 based on the aromatic carbon value of 60 for untreated tannic acid. The aromatic carbons also showed small differences from theoretical values. These levels of variation are common in ^{13}C NMR quantitation analyses (Levy & Nelson, 1972). For glucose carbons, the ratio of the anomeric vs. other carbons is 0.7:5.3, in somewhat poor agreement with the theoretical ratio of 1:5. These differences could arise from the inherent nature of the ^{13}C NMR technique, but it is also possible that they might arise from the chemical structural changes, such as from oxidation or reduction reactions, involving the carbon groups.

4. Discussion

Tannic acid is present in many different plant species and foods including tea, cocoa beans, grapes, strawberry and persimmon and is considered as a 'generally recognised as safe' (GRAS) food substance and also as an officinal in Europe and North America (Akiyama et al., 2001; Shi, 1983). Since tannic acid showed strong antioxidant capacity to quench lipid peroxidation, prevent DNA oxidative damage, and scavenge hydroxyl radicals (·OH) (Andrade et al., 2005; Khan et al., 2000), the Rancimat® method was used to evaluate the antioxidant effects of fresh and processed tannic acid on soybean oil. While Reynhout (1991) previously reported no increased induction time (~6.5 h) of soybean oil fortified with butylated hydroxyanisole (BHA, 200 ppm), butylated hydroxytoluene (BHT, 200 ppm), tocopherol (400 ppm) or rosemary extract (400 ppm), our results showed that both soybean oils treated with PTA (8.0 h at 250 ppm) and FTA (7.8 h at 1000 ppm) had much

higher induction times than the control (5.9 h) (Fig. 3A and B). These findings are in agreement with the findings of Sanchez-Moreno, Larrauri, and Saura-Calixto (1999). They reported that tannic acid showed much stronger activity in the inhibition of lipid oxidation than BHA, quercetin, DL-α-tocopherol, and caffeic acid. As compared to FTA, PTA at the same concentration dramatically increased the induction time of soybean oil oxidation. Our results also showed that increasing thermal processing time of PTA up to 15 min increased oxidation stability of soybean oil. Heat treatment of plant materials such as *Hibiscus syriacus* had better antioxidant activity than the non-treated control. The increased antioxidant activity could be due to hydroxyl groups such as phenolic acids, flavonoids, and tocopherol formed by heat treatment (Kwon, Hong, Kim, & Ahn, 2003). Our results also showed that the addition of gallic acid and fresh tannic acid to soybean oil increased the induction point on oil oxidation, though they are not as effective as processed tannic acid, which implies that enhanced antioxidant capacity of processed tannic acid could be explained by hydrolysed gallic acid and the hydroxyl groups newly formed on the galloyl group as a result of thermal hydrolysis. Khan et al. (2000) reported that the antioxidant property appears to be related to the number of hydroxyls on the tannic acid while gallic acid and its structural analogues were found to be non-inhibitory or partially inhibitory on hydroxyl radical and singlet oxygen mediated cleavage of plasmid DNA. They also showed that the highest antioxidant efficiency is exhibited by flavonoids such as myricetin having there hydroxyl groups in the B ring.

Numerous studies have shown a broad antimicrobial activity of tannic acid on *H. pylori* (Funatogawa et al., 2004), *S. aureus* (Akiyama et al., 2001), enterotoxigenic *E. coli* (Taguri et al., 2004), *L. monocytogenes* Scott A and *Salmonella enteritidis* (Chung et al., 1993). The antimicrobial mechanism of tannic acid could be iron deprivation which may work like a siderophore to chelate essential iron from the medium and make its iron unavailable to the microorganisms (Chung et al., 1998). This activity appears to depend on the structure of the plant polyphenols, i.e., the presence of a galloyl group (3,4,5-trihydroxybenzoyl group) (Taguri et al., 2004). Puupponen-Pimiä et al. (2005) have reported that polyphenol compounds that contain three hydroxyl groups in the B ring such as flavonol myricetin have more active antimicrobial activity than other flavonols which have less hydroxyl groups in the B ring. When tannic acid, a mixture of polygalloyl glucopyranose is hydrolysed, the hydrolysis ends up forming one more gallic acid and other galloyl groups on gallotanins which could enhance tannic acid's antimicrobial activity. Since tannic acid is highly water-soluble and relatively rigid and spherical (Taguri et al., 2004), thermal processing could breakdown the ester bonds of a polygalloyls and enhance hydrolysis of tannic acid. Even though gallic acid is known to be a less effective antimicrobial than tannic acid, it is well known that both tannic and gallic acids also bind to and precipitate proteins and enzymes. This mechanism could be explained by hydrogen binding of polygalloyl glucopyranose and hydrophobic interactions by gallic acid with surface proteins on bacteria cells. Yang, Wei, Zhang, Chen, and Chen (2006) have shown that, in certain cancer tissues, tannic acid was bound to the ATP binding pockets of tyrosine kinases through unique hydrogen and hydrophobic interactions between the amino acids of tyrosine kinases and groups of tannic acid. Labieniec and Gabryelak (2006) proved that there is a direct interaction between tannic and gallic acids and DNA or bovine serum albumin (BSA) and this interaction causes the conformational changes in DNA and BSA. Kawamato, Mizutani, and Nakatsubo (1997) also showed that a sufficient number of galloyl groups are needed to form a strong binding between ligand and BSA in a polyphenol molecule. Even though gallic acid is not as effective as tannic acid (Akiyama et al., 2001; Labieniec & Gabryelak, 2006), an increased number of hydrolysed gallic acid and galloyl groups on PTA could enhance the antimicrobial activity by increasing their protein binding capacity (Kawamato et al., 1997). Sterilisation of utensils and equipment is usually conducted at 121 °C for 15 min. This process is sufficient to even kill any spores in these materials. This process is also sufficient to induce hydrolysis, including tannic acid. Thus, additional heating (time) does not provide any effect.

5. Conclusions

Thermal processed tannic acid showed stronger antioxidant capacity and antibacterial activity than fresh tannic acid. Addition of thermally processed tannic acid (up to 15 min) also increased oxidation stability of soybean oil. The thermal process enhanced the hydrolysis of tannic acid, producing one free gallic acid and a galloyl group on the remaining gallotanins, which are responsible for biological activity.

treated with 0.1% polyethyleneimine to precipitate nucleotides. The resulting pellet was discarded and supernatant brought to 65% saturation with ammonium sulphate. The pellet was dissolved in 20 mM Tris buffer, pH 7.4 (NH_4SO_4 extract). The NH_4SO_4 extract (21 mg) was loaded onto a Sephadex G-75 column (14 × 73 cm), pre-equilibrated and eluted with 20 mM Tris buffer, pH 7.4, at a flow rate of 1.5 ml/5 min. Protein elution was monitored at 280 nm using a spectrophotometer. The antibacterial activities of eluted samples were tested by agar diffusion method on nutrient agar. Active peak II (8 mg), pooled and lyophilised was further fractionated on a Sephadex G-75 column by eluting with 20 mM Tris buffer, pH 7.4, to give a homogenous preparation, APC, which showed antibacterial activity.

2.2. Antibacterial activity of APC

Antibacterial activity was evaluated by the well diffusion method on nutrient agar medium (Forbes, Sahm, Weissfeld, & Trevino, 1990). This was confirmed by the inhibitory effect on bacterial growth as reflected by the inhibition zone, compared to that of known antibiotics. The sterile nutrient agar medium (20 ml) in Petri dishes was uniformly smeared using sterile cotton swabs with test pure cultures of human pathogenic bacteria *S. aureus, B. subtilis, E. coli, S. typhi, V. cholerae, K. pneumoniae* and *S. paratyphi.* The nutrient agar media was prepared by dissolving 0.3% beef extract, 0.3% yeast extract, 0.5% peptone, 0.5% NaCl and 1.5% agar in 1 l of distilled water. The wells of 5 mm diameter were made using a sterile cork borer in each petri dish and the buffer extract (0–100 μg), NH_4SO_4 extract (0–74 μg), G-75 eluted samples (0–50 μg) and isolated APC (0–24 μg) were added; a blank well loaded without test compound was regarded as control. For each treatment 10 replicates were prepared. The plates were incubated at 37 °C for 24 h and the resulting zone of inhibition was measured by comparing control and the standard antibiotic.

2.3. Determination of minimum inhibitory concentration (MIC)

The minimum inhibitory concentration of isolated APC were determined by serial dilution in the nutrient agar, with concentrations ranging from 5, 10, 20, 25, 50, 75 and 100 μg/ml. The inoculum was prepared from fresh overnight broth culture in nutrient broth. Plates were incubated for 24 h at 37 °C. *MIC* was recorded as the lowest extract concentration demonstrating no visible growth in the broth (Prescot, Harley, & Klein, 1996).

2.4. Estimation of protein

The protein estimation was determined by Bradford's method (Bradford, 1976) using bovine serum albumin as standard.

2.5. Assay for ribonuclease activity

The ribonuclease activity of APC was estimated according to the method of Lam and Ng (2001), by measuring the production of acid-soluble, UV-absorbing species. Briefly, yeast tRNA (200 μg) was incubated with the APC (0–100 μg) in 150 μl 100 mM MES buffer (pH 6.0) at 37 °C for 15 min. The reaction was terminated by adding 350 μl of ice-cold 3.4% (v/v) perchloric acid. After standing on ice for 15 min, the mixture was centrifuged at 15,000*g* for 15 min at 4 °C. The absorbance of the supernatant, after suitable dilution, was measured at 260 nm. One unit of ribonuclease activity is defined as the amount of ribonuclease that produces an absorbance increase at 260 nm of 1 min^{-1} in the acid-soluble fraction per ml of reaction mixture under the specified conditions.

2.6. Assay for deoxyribonuclease activity

The deoxyribonuclease activity of APC was estimated according to the method of Wang and Ng (2001). Briefly, sperm DNA (1 mg) in 0.2 ml of ammonium acetate buffer (0.1 M), pH 5.5, and 100 μl of APC (0–100 μg) were incubated at 25 °C for 15 min. The reaction was terminated by adding 0.3 ml of ice-cold 20 mM lanthanum nitrate in 1.2% (v/v) perchloric acid, and incubated for 20 min at room temperature. Then, samples were centrifuged at 3000*g* for 5 min at 0 °C. The supernatant was diluted three-fold with water and the optical density was read at 260 nm against a blank without APC. One unit of enzymatic activity is defined as the amount of enzyme required to increase the absorbance at 260 nm of 0.001 min^{-1} ml^{-1} at pH 5.5 and 37 °C using sperm DNA.

2.7. Assay of protease activity

Proteolytic activity was assayed according to the method of Murata, Satake, and Suzuki (1963), using 2% fat-free casein in Tris–HCl buffer pH 8.5 as substrate. APC sample (0–100 μg) was incubated with casein substrate (0.5 ml) for 120 min at 37 °C. Adding 1 ml of 0.44 M trichloroacetic acid terminated the reaction. After standing for 30 min the mixture was then centrifuged. Sodium carbonate (5 ml, 0.4 M) and Folin–Ciocalteu's reagent (0.5 ml diluted to 1/3 of its original strength) were added to 1 ml of supernatant and the absorbance read at 660 nm. One unit of enzyme activity is defined as the amount of enzyme required to cause an increase per min in OD of 0.01 at 660 nm. Enzyme activity is expressed in terms of specific activity.

2.8. Haemolytic activity assay

Haemolytic (direct/indirect) activity of APC was determined according to the method of Boman and Kaletta (1957), using packed human erythrocytes (blood group A). The direct and indirect haemolytic assays were carried out using washed erythrocytes. For the direct haemolytic assay, packed erythrocytes (1 ml) were suspended in nine volumes of phosphate-buffered saline (PBS), which formed the stock. The stock (1 ml) was incubated with various concentrations of APC (0–250 μg) for 30 min at 37 °C. For the indirect haemolytic assay, stock was prepared by mixing packed erythrocytes (1 ml), egg yolk (1 ml) and phosphate-buffered saline (8 ml). One millilitre of suspension from stock was incubated with various concentrations of APC (0–250 μg) for 30 min at 37 °C. The reaction was terminated by adding 10 ml of ice-cold PBS and then centrifuged at 4 °C and 800*g*. The amount of haemoglobin released in the supernatant was measured at 540 nm. One millilitre of stock erythrocytes with 10 ml ice-cold PBS alone was considered as 0% lysis.

Table 1
Total protein yield and antibacterial activities of fractions from different chromatographic steps of isolation procedure.

Chromatographic fraction	Yield (%)	Antibacterial activity
1. Buffer extract	100	+
2. 65% $(NH_4)_2SO_4$ Precipitation	53 ± 4	+
3. Gel filtration on Sephadex G-75		
Peak I	25 ± 3	–
Peak II	22 ± 2	+
Peak III	14 ± 2	–
4. Rechromatography on Sephadex G-75		
APC	17 ± 2	+

The symbols + and – denote the presence and absence of antibacterial activity, respectively.

2.9. Cytotoxicity assay

Cytotoxicity was determined according to the method of Chwetzoff, Tsunasawa, Sakiyama, and Ménez (1989). EAT cells were suspended in Tyrode's solution (5×10^6 cells/2 ml) and incubated with APC (0–250 μg) for 30 min. Trypan blue saline (1%, 100 μl) solution was then added, and unstained (viable) cells were counted using a haemocytometer. The percentage of viable cells was determined by comparing with the number of viable cells in the control (designated as 100%).

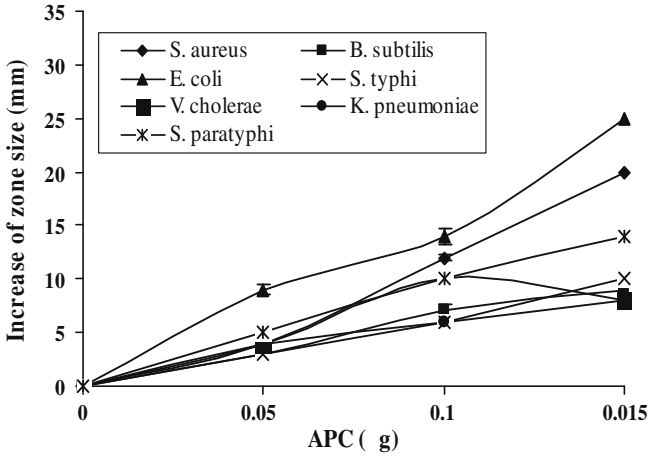

Fig. 1. Dose-dependent antibacterial activity of APC against different human pathogenic strains in agar diffusion assays. The diameter of the clear zone was measured and plotted after subtracting the diameter of the well (5 mm). Results are mean ± SD for three independent assays each performed in triplicate.

Table 2
Antibacterial activity of APC from curry leaves and antibiotics[a,b].

Microorganisms	Diameter of inhibition zone (mm)			
	APC	G	Cp	Sm
Staphylococcus aureus	25 ± 3	18 ± 1	21 ± 2	26 ± 3
Bacillus subtilis	14 ± 1	18 ± 2	17 ± 3	30 ± 2
Escherichia coli	30 ± 3	18 ± 1	17 ± 1	26 ± 3
Salmonella typhi	15 ± 1	16 ± 1	18 ± 1	24 ± 1
Vibrio cholerae	13 ± 1	16 ± 2	18 ± 1	23 ± 3
Klebsiella pneumoniae	13 ± 2	16 ± 2	18 ± 2	21 ± 1
Salmonella paratyphi	19 ± 3	18 ± 2	18 ± 2	20 ± 2

[a] The results are mean ± SD ($n = 6$).
[b] G, gentamycin; Cp, chloramphenicol; Sm, streptomycin.

Table 3
Minimum inhibitory concentrations (*MIC*) of APC and antibiotics[a,b] in serial dilution method.

Microorganisms	*MIC* (μg/ml)			
	APC	G	Cp	Sm
Staphylococcus aureus	24.5 ± 3	20.8 ± 0.7	14.4 ± 0.3	13.6 ± 0.4
Bacillus subtilis	25.2 ± 3	20.8 ± 0.4	14.4 ± 0.5	16.8 ± 0.3
Escherichia coli	14.7 ± 1	24.2v0.1	14.4 ± 0.3	16.3 ± 0.7
Salmonella typhi	15.2 ± 1	19.2 ± 0.4	12.8 ± 0.7	14.4 ± 0.5
Vibrio cholerae	13.6 ± 1	18.4 ± 0.3	12.8 ± 0.5	14.4 ± 0.3
Klebsiella pneumoniae	13.3 ± 2	16.8 ± 0.1	12.8 ± 0.6	14.4 ± 0.4
Salmonella paratyphi	19.2 ± 3	16.2 ± 0.2	12.4 ± 0.4	11.2 ± 0.4

[a] Values are expressed as mean ± SD ($n = 10$).
[b] G, gentamycin; Cp, chloramphenicol; Sm, streptomycin.

2.10. Statistical analysis

Statistical analysis was done using SPSS (Windows version 10.0.1; SPSS Inc., Chicago, IL) using a one-way student's *t*-test; $p < 0.05$ was considered as statistically significant, when comparing with relevant controls. All results refer to mean ± SD.

3. Results and discussion

Murraya koenigii is a common plant with medicinal properties. In our study, when the aqueous extract of *M. koenigii* was tested for antibacterial activity against human pathogenic bacteria, it showed inhibition of bacterial growth. This initial observation prompted us to systematically evaluate the active principle.

The Tris buffer extract (39 mg) of curry leaves upon 65% ammonium sulphate saturation yielded 21 mg of protein with antibacterial activity. The ammonium sulphate extract was fractionated with Sephadex G-75 column chromatography, into three peaks (Peaks I, II and III), amongst which peak II showed antibacterial activity. Peak II upon rechromatography on Sephadex G-75 column resulted in homogenous preparation with antibacterial activity referred to as antioxidant protein from curry leaves (APC) (Table 1). The preparation was homogeneous with a single peak with molecular mass of ~35 kDa according to mass spectrometry (Ningappa & Srinivas, 2008). Antimicrobial protein WSG isolated from *W. sominifera* has a molecular mass of ~28 kDa (Girish et al., 2006). An antimicrobial protein of about 10 kDa, called Ace-AMP1, was isolated from onion (*A. cepa* L.) seeds (Cammue et al., 1995). Recently, hevein, a small (4.7 kDa) cysteine-rich protein with antibacterial activity was isolated from latex of *H. brasiliensis* (Kanokwiroon et al., 2008). The observed molecular mass of ~35 kDa is well within the range of antibacterial proteins reported.

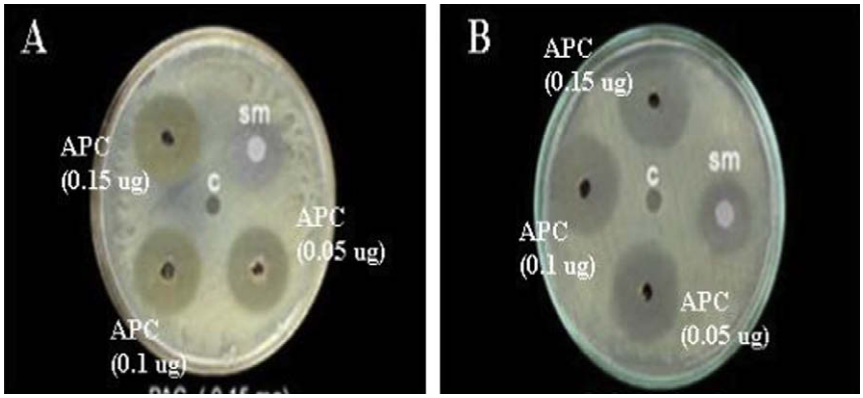

Fig. 2. Agar diffusion assay. Effect of APC on growth of (A) *Escherichia coli* and (B) *Staphylococcus aureus*. Sm, 20 μg streptomycin (positive control); C, 10 mM Tris–HCl buffer (negative control).

The dose-dependent antibacterial activity of APC against human pathogenic bacteria is shown in Fig. 1. APC showed a broad spectrum of very significant antibacterial activity by producing a clear zone of inhibition (20–25 mm) against *E. coli* and *S. aureus* (Table 2). *V. cholerae*, *K. pneumoniae, S. typhi and B. subtilis* were found to be moderately sensitive to APC, which showed an inhibition zone of 12–16 mm of (Table 2). It was interesting to observe that inhibition was comparable to that of the standards; chloramphenicol, streptomycin and gentamycin. Fig. 2 shows inhibition of *E. coli* and *S. aureus* growth by APC at 0.15 μg as studied by agar diffusion method. These results are well comparable with the antibacterial proteins listed earlier.

When APC was tested, using the agar dilution assay for determining minimum inhibitory concentration (*MIC*), it was observed that it inhibited bacterial growth, with *MIC* values ranging from 13 to 24 μg/ml APC. APC showed comparable *MIC* values with standard antibiotics, which ranged from 11.2 to 20 μg/ml (Table 3). Thus APC is as potent as standard antibiotics in inhibiting the growth of bacterial strains.

It is known that some ribonucleases/deoxyribonucleases/proteases exhibit antibacterial activity (Girish et al., 2006; Lam & Ng, 2001; Ng, 2004a; Wang & Ng, 2001). In order to know which class APC belongs to, it was screened for different enzyme activities. The results indicated that APC was devoid of ribonuclease, deoxyribonuclease and protease activity when tested at 50 and 100 μg amounts. This observation ruled out the possibility that APC is a ribonuclease, deoxyribonuclease or protease.

In our study we also investigated the toxicity of APC using EAT cells. It was interesting to observe that there was no decrease in the number of viable cells when APC was added. Further, no haemolysis occurred, either directly or indirectly, when APC was added to human erythrocytes up to 0.25 mg. These results clearly indicate that APC is a non-toxic protein having antibacterial activity. Similarly, antimicrobial protein WSG isolated from *W. sominifera,* is also reported to be non-toxic (Girish et al., 2006). Further studies on the mechanism of action by which APC exhibits antibacterial activity are in progress.

In conclusion, the ~35 kDa APC isolated from *M. koenigii* exhibited a broad spectrum of antibacterial activity against human pathogenic bacteria, comparable to commercial antibiotics. As it is non-toxic, it appears to be a promising candidate for development of an effective antioxidant antibiotic.

Acknowledgements

The authors acknowledge the Adichunchanagiri Mahasamstana Mutt and Shikshana Trust for providing facilities in the Adichunchanagiri Biotechnology and Cancer Research Institute (ABCRI) and Adichunchanagiri Institute of Technology (AIT) for providing continuous Internet facilities for carrying out this work. We acknowledge microbiology department, Adichunchanagiri Institute of Medical Sciences (AIMS), B.G. Nagara, Karnataka, India for providing bacterial strains.

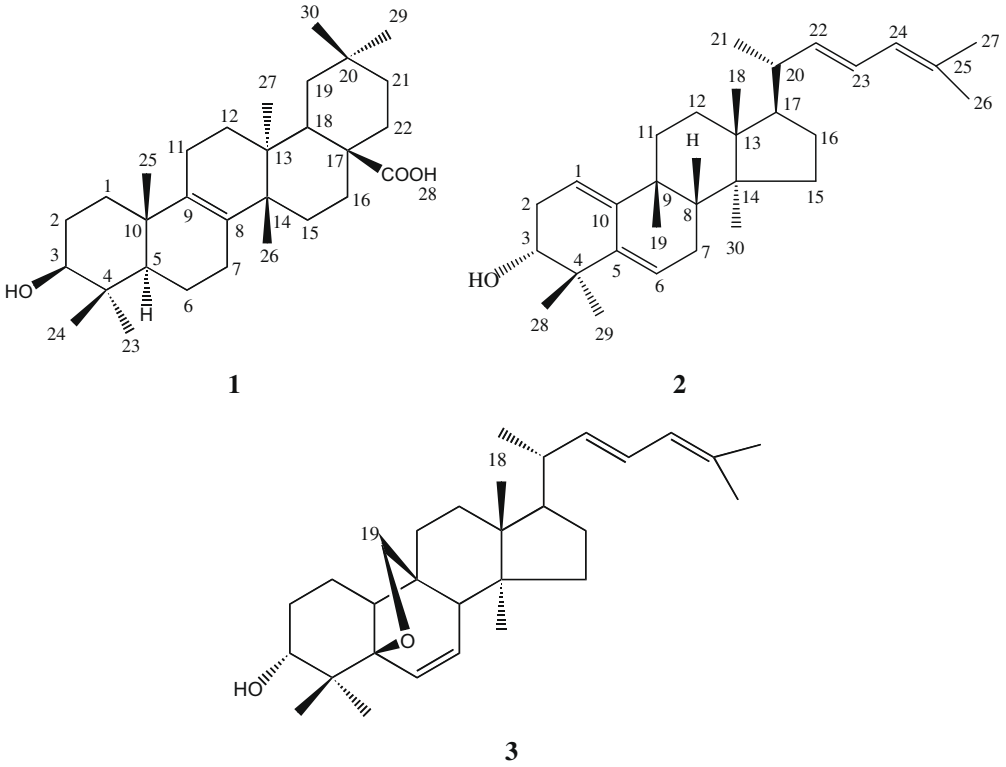

Fig. 1. Structures of triterpenoids.

2. Materials and methods

Instruments: Optical rotations were recorded with a JASCO-370 polarimeter, UV spectra on a Jasco UV–vis spectrophotometer, IR spectra on a Hitachi 260–30 spectrometer, ^{1}H (400 MHz) and ^{13}C NMR (100 MHz) spectra and ^{1}H–^{1}H COSY, NOESY, HMQC and HMBC experiments on a Varian Unity-400 NMR spectrometer and MS on a JMS-HX-100 mass spectrometer. Silica gel (Merck), particle size 15–40 μm, was used for column chromatography. Silica gel 60 F254 precoated aluminium sheets (0.2 mm, Merck) were employed for TLC. All solvents were HPLC grade. Xanthine, xanthine oxidase, and allopurinol were purchased from Sigma Chemicals.

2.1. Plant material

The stems of *M. charantia* (460 g) were collected at Hualien Hsien, Taiwan, March, 2006 and a voucher specimen (2006-1) has been deposited in the Department of Medicinal Chemistry, Kaohsiung Medical University.

2.2. Extraction and Isolation

The air-dried stems of *M. charantia* (460 g) were extracted with MeOH (Akihisa et al., 2007). The MeOH extract was concentrated under reduced pressure to give a dark brown residue (140 g), which was suspended in H_2O and then partitioned between H_2O and $CHCl_3$, H_2O and EtOAc and H_2O and *n*-BuOH, respectively. The $CHCl_3$ extract (40 g) was chromatographied on silica gel (1000 g), eluted successively with solvents of increasing polarity (*n*-hexane–EtOAc, 4:1 (3.0 l), 3:2 (2.5 l), 2:3 (2.0 l), 1:4 (2.0 l); EtOAc–MeOH, 9:1 (3.0 l), 6:1 (2.5 l), 3:1 (2.0 l), 2:1 (5.0 l), afforded 28 fractions. Fraction 12 was subjected to repeated chromatography on silica gel and eluated with CH_2Cl_2–EtOAc (1:2) to give **1** (25 mg). Fraction 6 was subjected to repeated chromatography on silica gel and eluted with *n*-hexane–CH_2Cl_2 (1:1) to give **2** (16 mg) and **3** (14 mg), respectively.

2.3. Spectral measurements

3β-Hydroxymultiflora-8-en-17-oic acid (**1**): white powder; $[\alpha]_D^{25}$ 70 (*c* 0.05, MeOH); IR ν_{max} (KBr): 3446, 1680 cm^{-1}; ^{1}H NMR and ^{13}C NMR see Table 1; ESIMS: 479 ([M+Na]$^+$), 381; HRESIMS: 479.3504 [M+Na]$^+$, $C_{30}H_{48}O_3Na$; calc. 479.3501.

Cucurbita-1(10),5,22,24-tetraen-3α-ol (**2**): yellow oil; $[\alpha]_D^{25}$ 82 (*c* 0.1, $CHCl_3$); UV (MeOH) λ_{max} (log ε): 240 (4.01) nm; IR ν_{max} (KBr): 3433, 1684 cm^{-1}; ^{1}H NMR and ^{13}C NMR see Table 1; ESIMS: 445 [M+Na]$^+$; HRESIMS: 445.3449 [M+Na]$^+$, $C_{30}H_{46}ONa$; calc. 445.3446.

5β,19β-Epoxycucurbita-6,22,24-trien-3α-ol (**3**): yellow oil; $[\alpha]_D^{25}$ −3 (*c* 0.1, $CHCl_3$); UV (MeOH) λ_{max} (log ε): 240 (4.02) nm; IR ν_{max} (KBr): 3469, 1685 cm^{-1}; ^{1}H NMR and ^{13}C NMR see Table 1; EIMS: (probe) 70 eV, *m/z* (rel. int.): 438 [M]$^+$ (19), 390 [M–H_2O–CH_2O]$^+$ (4), 281 (390-side chain) (100), 109 (81); HREIMS: 438.3498 [M]$^+$, $C_{30}H_{46}O_2$; calc. 438.3497.

2.4. Free radical scavenging activity

Radical scavenging activity of **1**–**3** and tocopherol (TOC) was determined using 1,1-diphenyl-2-picrylhydrazyl (DPPH) as a reagent (Kabouche, Kabouche, Öztürk, Kolak, & Topcu, 2007) with modification by using 96-well plates. A 0.1 mM solution of DPPH radical in MeOH was prepared and then 150 μl of this solution was mixed with 50 μl of sample solution. The mixture were incubated for 30 min in a dark room at room temperature. Scavenging capacity was read spectrophotometrically by monitoring the decrease in absorbance at 490 nm using a MRX Microplate Reader (Dynex MRX II, Dynex Technologies, 14340 Sullyfield Circle, Chantility VA 20151-1683, USA). TOC was used as standard. The percentage DPPH scavenging effect was calculated using the following equation:

Table 1
^{1}H and ^{13}C NMR spectroscopic data (δ in ppm, J in Hz) of **1** and **2** (in $CDCl_3$) and **3** (in pyridine-d_5).

$$\text{DPPH scavenging effect } (\%) = [1 - (S - SB)/(C - CB)] \times 100\%$$

where S, SB, C and CB are the absorbencies of the sample, the blank sample, the control and the blank control, respectively (Kabouche et al., 2007).

2.5. Determination of ABTS radical cation scavenging capacity

The radical scavenging activity of the isolated compounds was carried out using an improved ABTS decolourisation assay with some modification (Han, Weng, & Bi, 2008). The ABTS radical cation ($ABTS^{\cdot+}$) was produced by reacting 7 mM stock solution of ABTS with 2.45 mM potassium persulfate (final concentration) and allowing the mixture to stand in the dark at room temperature for 12–16 h before use. The $ABTS^{\cdot+}$ solution was diluted with ethanol, to an absorbance of 0.7 ± 0.02 at 630 nm. An ethanolic solution (30 μl) of the samples at various concentrations was mixed with 170 μl diluted $ABTS^{\cdot+}$ solution. After reaction at room temperature for 20 min, the absorbance at 630 nm was measured. A lower absorbance of the reaction mixture indicates higher $ABTS^{\cdot+}$ scavenging activity. The capability to scavenge the $ABTS^{\cdot+}$ was calculated using the formula given below:

$$ABTS^{\cdot+}\text{scavenging activity } (\%) = [1 - (S - SB)/(C - CB)] \times 100\%$$

where S, SB, C and CB are the absorbencies of the sample, the blank sample, the control, and the blank control, respectively.

2.6. Assay of xanthine oxidase

The xanthine oxidase activity with xanthine as the substrate was measured at 25 °C, according to the protocol of Kong and others (Kong, Zhang, Pan, Tan, & Cheng, 2000) with modification. The assay mixture consisting of 50 μl of test solution, 60 μl of 70 mM phosphate buffer (pH 7.5) and 30 μl of enzyme solution [0.1 units/ml in 70 mM phosphate buffer (pH 7.5)] was prepared immediately before use. After preincubation at 25 °C for 15 min, the reaction was initiated by the addition of 60 μl of substrate solution (150 μM xanthine in the same buffer). The reaction was monitored for 5 min at 295 nm. The xanthine oxidase activity was expressed as micromoles of uric acid per minute.

2.7. Statistical analysis

Data were expressed as the mean ± SD. Statistical analysis were performed using the Bonferroni t-test method after ANOVA for multigroup comparison and the student's t-test method for two group comparison. $p < 0.05$ was considered to be statistically significant. Analysis of linear regression (at least three data within 20–80% inhibition) was used to calculated IC_{50} values.

3. Results and discussion

Compound **1** was obtained as a white powder, $[\alpha]_D^{25}$ 70 (c = 0.05, MeOH). Its IR spectrum showed absorption bands for hydroxyl (3446 cm^{-1}) and carboxylic acid (1680 cm^{-1}). The molecular formula of **1** was determined to be $C_{30}H_{48}O_3$ on the basis of its HRESIMS ($[M+Na]^+$, 479.3504, Δ−0.0003 mmu), which was consistent with its ^{1}H and ^{13}C NMR data. The ^{1}H and ^{13}C NMR spectra of **1** (Table 1) revealed the presence of 7 methyls, 11 methylenes, 3 methines including one oxymethine and 9 quaternary carbons including a carboxylic quaternary carbon. Analysis of ^{1}H–^{1}H COSY and HMQC experiments for **1** established the connectivities of eight ^{1}H–^{1}H and ^{1}H–^{13}C spin systems presented as bold lines (Fig. 2). The HMBC and NOESY correlations (Fig. 2) indicated that the Me-23 and Me-24, Me-29 and Me-30 and C-28–COOH located at C-4, C-20 and C-17, respectively, and the connectivities between C-4/C-3 and C-5, C-10/C-1, C-10/C-5 and C-9, C-9/C-11, C-8/C-7, C-9 and C-14, C-13/C-12, C-18 and C-14, C-14/C-15, C-17/C-18

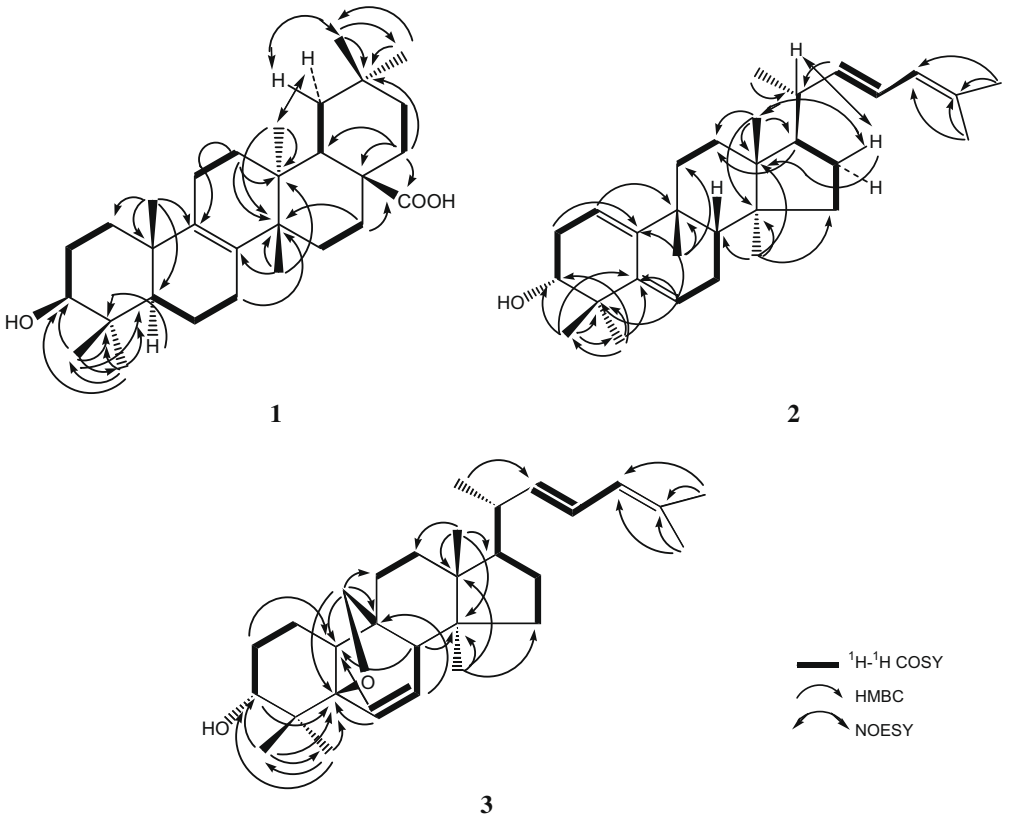

Fig. 2. Key ^{1}H–^{1}H COSY, HMBC and NOESY correlations of compounds **1**–**3**.

and C-28 and C-20/C-19 and C-21. The above result indicated that the structure of **1** was elucidated as shown **1**. The NOESY correlations of H_α-2/H-3 and Me-23, Me-23/H-5, Me-27/H_α-19 and Hβ-19/Me-30 suggested H-3, Me-23, H-5, Me-27 and Me-29 are α-oriented and that Me-24 and Me-30 are β-oriented. The NOESY correlations of Hβ-1/Me-25 and H_β-15/Me-26 suggested Me-25 and Me-26 are β-oriented. In addition, the comparison of carbon signals at C-16, C-17, C-18 and C-20 of **1** with those of reported data (Biemann, 1989a; Biemann, 1989b; Shan, Hu, & Chen, 2001; Wu et al., 2005) supported the C-28–COOH is β-oriented. Thus the structure of **1** was characterised as 3β-hydroxymultiflora-8-en-17-oic acid (**1**).

Compound **2** was assigned a molecular formula of $C_{30}H_{46}O$, as determined from its HRESIMS ([M+Na]$^+$, 445.3449, Δ−0.0003 mmu). The UV spectrum showed the presence of a heteroannular or an acyclic diene moiety (Scott, 1964). The IR absorption of **2** implied the presence of OH (3433 cm^{-1}) and *trans*-form of C=C (1684 cm^{-1}) (Biemann, 1989a; Biemann, 1989b) functionalities. The ^{1}H and ^{13}C NMR spectra of **2** (Table 1) showed the presence of eight methyls, six methylenes, nine methines including an oxymethine and seven quaternary carbons. Analysis of ^{1}H–^{1}H COSY and HMQC experiments for **2** established the connectivities of nine ^{1}H–^{1}H and ^{1}H–^{13}C spin systems presented as bold lines (Fig. 2). The HMBC correlations (Fig. 2) suggested that **2** possesses a cucurbitane skeleton. The HMBC correlations of Me-28 and Me-29/C-3 and C-4, H-1/C-9, H-2/C-10, H-6/C-5, C-4 and C-10, Me-26 and Me-27/C-24 and C-25 and H-22/C-20 suggested that **2** is a cucurbita-1(10),5,22,24-tetraen-3-ol. The NOESY correlations of H_β-2/H-3 and H-3/Me-28, H_β-16/Me-18, Me-18/H-8, H-8/Me-19 suggested that H-3, Me-28, H-8, Me-19 and Me-18 are β-oriented. The NOESY correlations of Me-30/H_α-15 and H-20/H_β-16 and H-23 suggested that Me-21 and Me-30 are α-oriented. Thus, compound **2** is characterised as cucurbita-1(10),5,22, 24-tetraen-3α-ol (**2**).

Compound **3** exhibited a [M]$^+$ at *m/z* 438.3498, Δ−0.0001 mmu, in the HREIMS, compatible with the formula, $C_{30}H_{46}$ O_2. The UV spectrum was similar to that of **2**. The IR absorption of **3** exhibited absorption bands for hydroxy (3469 cm^{-1}) and *trans*-form of C=C (1684 cm^{-1}) (Biemann, 1989a; Biemann, 1989b) moieties. The structure of **3** was identified by a combination of one- and two-dimensional NMR methods. Its ^{1}H and ^{13}C NMR spectra of **3** (Table 1) showed the presence of seven methyls, seven methylenes including an oxygenated methylene, 10 methines including an oxymethine and six quaternary carbons including an oxygenated quaternary carbon. ^{1}H–^{1}H COSY and HMQC spectra established the connectivities of ten ^{1}H–^{1}H and ^{1}H–^{13}C spin systems represented as bold lines (Fig. 2). The HMBC as shown in Fig. 2 supported that **3** was a cucurbitane triterpenoid. The HMBC correlations of H-6/C-5 and C-10, H-19/C-5, C-10, C-9 and C-11 established an epoxy moiety linked between C-5 and C-19. The ^{1}H–^{1}H COSY correlations between C-6/C-7 and C-22/C-23 and HMBC correlations between Me-26 and Me-27/C-25 and C-24 established three double bonds located between C-6/C-7, C-22/C-23 and C-24/C-25. The NOESY correlations between H_α-19/H-10, H-10/Me-28 and H_α-11/Me-30, and Me-29/H-3, Me-18/H_β-11 and H_β-19/H_β-11 suggested that H-10, Me-28, Me-30 and H-3, Me-18, Me-29 and the linkage between C-19/C-9 are on α and β-side of **3**, respectively. The relative configurations at C-5 and C-19 was established by the fact that the bridge C-5 and C-19 can only exist in the cis form (Winkelmann, Heilmann, Zerbe, Rali, & Sticher, 2000). The above result suggested that the structure of **3** was elucidated as 5β,19β -epoxycucurbita-6,22,24-trien-3α-ol (**3**).

The presence of significant peaks at *m/z* 390 [M–H_2O–CH_2O]$^+$ and 281 [390-side chain]$^+$ (base peak) also supported the characterization of **3**. The above result indicated that constituents isolated from the stems of *M. charantia* collected at Hualien Hsien,

Taiwan were different from that of collected at Pingtung County Taiwan (Chang et al., 2008).

A recent study demonstrated that the water extracts of *M. charantia* have a significant antioxidant effect (Kubola & Siriamornpun, 2008). For evaluating the antioxidant effects of isolated constituents, we used several methods, namely, 1,1-diphenyl-2-picrylhydrazl (DPPH) radical-scavenging activity, 2,2′-azinobis (3-ethylbenzothiazoline-6-sulphonic acid) (ABTS) radical cation scavenging activity and inhibition of XO activity.

The effect of antioxidant on DPPH· is thought to be due to their hydrogen donating activity (Mathew & Abraham, 2006). Compounds **2** and **3** with inhibitory effect of XO showed weak DPPH·-scavenging activity with 10.1 ± 10.9% and 13.6 ± 4.2% inhibition at 200 μM while **1** also a XO inhibitor did not show DPPH·-scavenging activity. The positive control TOC showed DPPH·-scavenging activity with 81.9 ± 1.2% inhibition at 200 μM. The relative antioxidant ability to scavenge the radical $ABTS^{\cdot+}$ has been compared to positive control TOC and is an excellent method for determining the antioxidant activity of hydrogen donating antioxidants and of chain breaking antioxidants. As shown in Fig. 3, compounds **1**, **2**, **3** and positive control TOC indicated ABTS radical cation scavenging activity in a concentration-dependent manner with IC_{50} values of 268.5 ± 7.9, 352.1 ± 11.5, 458.9 ± 13.0 and 79.9 ± 2.9 μM, respectively. It clearly showed that 1 with a hydroxyl and a carboxylic acid group displayed stronger ABTS radical cation scavenging activity.

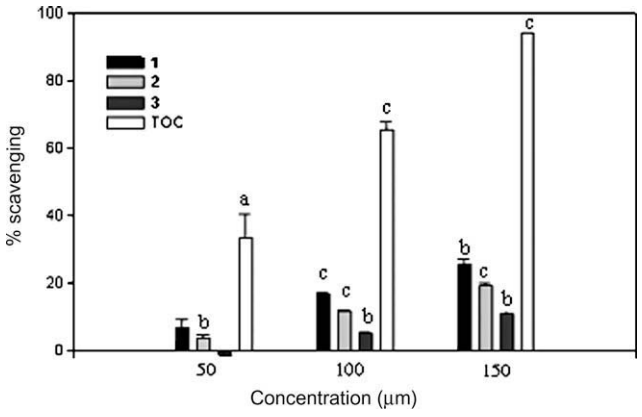

Fig. 3. ABTS radical scavenging activity of various concentrations of **1**–**3** and TOC. Values are means ± S.D., $n = 3$. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ compared to the control value, respectively.

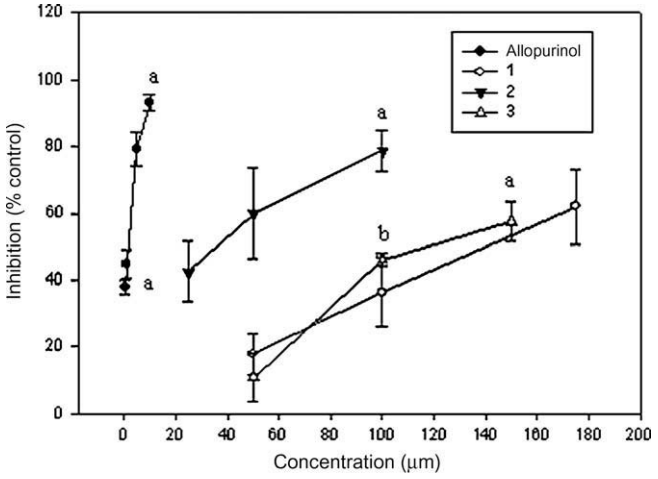

Fig. 4. Dose-dependent inhibition of XO by **1**–**3** and allopurinol. Data as means ± SD $n = 3$. $^{a}P < 0.05$, $^{b}P < 0.01$ compared to the control value, respectively.

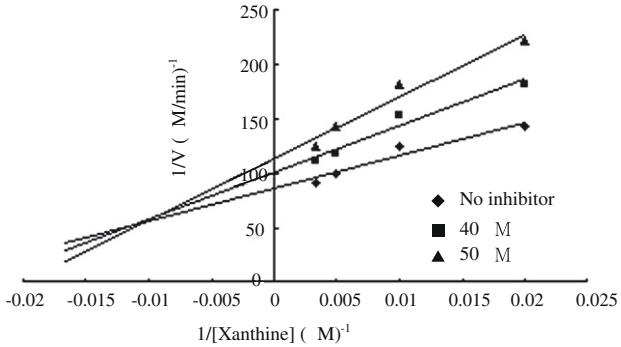

Fig. 5. Lineweaver–Burk plot of XO inhibition of **2** with various concentrations of xanthine. Lineweaver–Burk transformed data were plotted and followed by line regression of the points. Data represent the average of triplicated experiments.

As shown in Fig. 4, compound **2** was identified as a stronger XO inhibitor than those of the same chemical skeleton such as **3**. It indicated that an epoxy moiety linked between C-5 and C-19 such as **3** attenuated the inhibitory effect on XO activity.The multiflorane triterpenoid such as **1** did not show a stronger inhibitory effect on XO activity than those of cucurbitane triterpenoids. As shown in Fig. 5. selective compound **2** was established to be a competitive-noncompetitive inhibitor. It revealed that **2** could be bound to the free enzyme and the enzyme–substrate complex. Biochemically, the enzyme inhibition is associated with hydrogen binding of phenolic hydroxyls and/or carbonyls of substrate with the amide carbonyls and/or amino groups in the peptide chain of enzyme (Jiao, Ge, Shi, & Tan, 2006). Therefore, in addition to chemical skeleton and conformation of compound, the alcoholic hydroxyl in **1**–**3** may interfere with the interaction between enzyme and enzyme–substrate complex.

4. Conclusion

Two new cucurbitane triterpenoids and a new multiflorane triterpenoid were isolated from the stems of *M. charantia*. Compounds **2** and **3**, and **1**–**3** showed weak DPPH·-scavenging and ABTS radical cation scavenging activities, respectively. Compound **2** also showed a significant inhibitory effect on XO activity. Multiflorane triterpenoids have been isolated and reported from *M. cochinchinensis*, *Trichosanthes kiriloroii*, *Polypodium niponicum* and *P. formosanum* (Ageta & Arai, 1983; Shan et al., 2001; Wu et al., 2005). This is the first report of a multiflorane triterpenoid being isolated from this plant and the first report of cucurbitane triterpenoid and multiflorane triterpenoid as antioxidants. These compounds may serve as antioxidant agents for the treatment of reactive oxygen species (ROS) induced diseases.

2. Materials and methods

2.1. Plant materials

The ripe fruits of Chinese quince (*Pseudocydonia sinensis* Schneider var. Toukarin) were obtained from a local orchard in Nagano Prefecture, Japan.

2.2. Chemicals and reagents

(−)-Epicatechin, vanillic acid, 4-hydroxybenzoic acid, β-glucuronidase type H-2 (including sulfatase), and 2,4,6-tri(2-pyridyl)-s-triazine (TPTZ) were purchased from Sigma–Aldrich, Ltd. (St. Louis, MO, USA). Cyanidin chloride was purchased from Funakoshi Co. (Tokyo, Japan). Salicylic acid, protocatechuic acid, hippuric acid, citric acid were purchased from Nacalai Tesque, Inc. (Kyoto, Japan). 3-Hydroxyphenylacetic acid was purchased from Alfa Aesar (Karlsruhe, Germany). Solvents were purchased from Nacalai Tesque. Folin–Ciocalteu reagent was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Procyanidin B2 was purchased from Funakoshi Co., Ltd. (Tokyo, Japan). The other dimers (B1, B3 and B4) were chemically synthesised from catechin and epicatechin (Mohri et al., 2007).

2.3. Extraction of crude polyphenols (CP) from Chinese quince fruit

The semi-purified Chinese quince polyphenols were prepared using the procedure described in a previous report (Hamauzu et al., 2007). The freeze–dried powder of the flesh (30 g) was washed with 300 ml of petroleum ether to remove lipids and then the polyphenols were extracted with 60% aqueous acetone (300 ml, three times), rotary evaporated, and semi-purified using a Sep-Pak Vac 20 cm^3 (5 g) C18 cartridge (Waters Co., Milford, MA). The end result was approx. 3.0 g of freeze–dried crude polyphenols (CP) in powder form.

2.4. Breakdown of CP by heating with citric acid (preparation of CPT)

An aqueous solution of CP (final conc. of 0.1%, w/v, as epicatechin equivalent) was heated in the presence of citric acid (final conc. of 2.0%, w/v) in a screw-capped test tube for 0, 2, 4, 8, or 12 h using a dry bath incubator (GENIUS two block, Nippon Genetics Co., Ltd., Tokyo, Japan) at 95 °C. For the *in vivo* experiment, CP subjected to the same heat treatment for 0 h (CPT-0 = CP plus citric acid), 2 h (CPT-2) and 8 h (CPT-8) were prepared for administration to the rats.

2.5. Total phenolic assay

The experimental procedure was adapted from that of Hamauzu et al. (2007). About 2 ml of sample solution were mixed with 2 ml of diluted Folin–Ciocalteu reagent (1 N) in a test tube. After 3 min, 2 ml of Na_2CO_3 (10 g/100 ml) were added and the mixture was incubated for 60 min at room temperature. The absorbance was measured at 700 nm with a Shimadzu UV-1200 spectrophotometer (Tokyo, Japan) against a blank (2 ml of deionized water, plus reagents) in the reference cell. (−)-Epicatechin was used as the standard (r = 0.99975).

2.6. Reversed phase HPLC

Chromatographic separation was carried out on a Luna 5μ C18 column (150 × 4.6 mm, Phenomenex, Inc., Torrance, CA., USA) with a security guard cartridge (3.0 × 4.6 mm) at 40 °C. Solvents were 0.1% trifluoroacetic acid (A) and 0.1% trifluoroacetic acid in acetonitrile (B). The gradient program began with 5% B and was changed to obtain 15% B at 30 min, 32% B at 35 min, 40% B at 45 min, and 75% B at 50 min. The 75% B was maintained until 65 min. The flow rate was 1.0 ml/min and the injection volume was 20 μl. Detection was performed at 280 nm for flavan-3-ols and 325 nm for hydroxycinnamic derivatives on a Shimadzu SPD-M10Avp photodiode array detector. For the detection of reddish coloured substances, 458 nm and 525 nm were also used. Peaks were identified by comparing retention times and UV–visible spectra with those of standards. Polymeric and oligomeric procyanidins were identified by comparing the absorption spectra with that of (−)-epicatechin, and the denaturation of them was confirmed by thioacidolysis (Hamauzu et al., 2007) as well as the spectral changes. The presence of protocatechuic and vanillic acids in the Chinese quince polyphenols subjected to heat treatment was also checked by retention time and absorption spectra of peaks on the HPLC chromatogram.

2.7. Animals

Male Wistar rats weighing 230–270 g were conditioned in standard boxes for 3 days before the experiments. They were fed a standard laboratory diet (CE-2, CLEA Japan, Inc.), provided with water ad libitum and kept on a 12/12 h light–dark cycle. The animals were fasted 24 h before the experiment but allowed free access to water. Use of animals for the experiment was approved by the Ethics Committee of Shinshu University.

2.8. Oral administration of polyphenols and blood sampling

Each rat received (oral administration) approx. 40 mg of CP or CPT (containing 20 mg of polyphenols as (−)-epicatechin equivalent estimated by the Folin–Ciocalteu method) suspended in 2 ml of water. Each sample destined for heat treatment (CPT-2 and CPT-8) had its (−)-epicatechin equivalent (20 mg) confirmed before heat treatment because the estimation of phenolic content by the Folin–Ciocalteu method is affected by heating. Control rats were given 2 ml of water. Two hours after administration, rats were anaesthetized with diethylether, the abdominal wall was opened, and blood was collected from the abdominal aorta into heparinised tubes. The plasma was separated from the blood solids by centrifugation (800×g for 5 min at 4 °C).

2.9. The FRAP assay in rats

The experimental procedure for the FRAP (ferric reducing ability of plasma) method basically followed that of Benzie and Strain (1996) with minor modifications. The FRAP method reagent was prepared as a mixture of 10 ml of 300 mM acetate buffer (pH 3.6), 1 ml of 10 mM TPTZ–40 mM hydrochloric solution, and 1 ml of 20 mM $FeCl_3$ solution. The FRAP reagent, once prepared, was immediately incubated for 10 min at 37 °C, then 1.5 ml of the reagent was added to 50 μl of the plasma sample. The reaction mixture was incubated for 4 min at room temperature and the absorbance at 593 nm was measured using a UV-1200 spectrophotometer.

2.10. Analysis of aromatic acid metabolites

Plasma (2 ml) was added to 1.05 ml of 0.58 mM acetic acid to obtain a pH of 4.9, and 1000 U of β-glucuronidase Type H-2 containing 50 U of sulfatase was added and then incubated at 37 °C for 45 min. After acidification to pH 2 with 6 M HCl (46 μl), the solution was then extracted twice with ethyl acetate (4 ml) and centrifuged at 2400×g, 4 °C for 10 min. The resulting supernatant was evaporated under an N_2 gas stream and then re-dissolved in

500 μl of 25% (v/v) methanol. A 200 μl sample of the solution was added to 1800 μl of 10 μM salicylic acid as an internal standard and analysed by Waters LC-electrospray ionisation (ESI)-MS/MS system (Quattro Micro API, Micromass, UK). For the quantitative analysis of aromatic acid metabolites, a single ion monitoring (SIR) mode was used. The MS/MS mode was also used for qualitative analysis by monitoring the product ions.

2.11. LC-ESI-MS conditions

The column was a Luna 5μ C18 column (150 × 4.6 mm) with a security guard cartridge (3.0 × 4.6 mm) and the mobile phases consisted of 5% acetonitrile in 0.1% aqueous formic acid (solvent A) and 50% acetonitrile in 0.1% aqueous formic acid (solvent B). The flow rate was 0.3 ml/min. The following gradient was applied: 0–40 min, linear gradient from 25% B to 50% B; 40–60 min, from 50% B to 100% B; 60–65 min, 100% B. Detection was carried out using ESI conducted in negative mode with a capillary voltage of −3 kV. A cone voltage of −20 V was applied for the detection of aromatic acids and −40 V for catechin metabolites. A source temperature of 120 °C and a desolvation temperature of 350 °C were applied. The cone gas and desolvation gas flow were 50 and 600 L/h, respectively. MS data collected were processed using MassLynx v.4.0.

2.12. LC-ESI-MS/MS conditions

The peaks in the total ion chromatogram (TIC) obtained by MS scan or SIR mode were further confirmed using the same LC-ESI-MS/MS system described above. Argon gas was used as a collision gas, and the potential change defining the collision energy was optimised in the range of 10–20 V as appropriate for both parent and product ions. Aromatic acid metabolites and salicylic acid (internal standard) were detected according to the respective *m/z* values of their parent and product ions: 4-hydroxybenzoic acid (137/93), protocatechuic acid (153/109), vanillic acid (167/123), 3-hydroxyphenylacetic acid (151/107), hippuric acid (178/134) and salicylic acid (137/93).

2.13. Statistics

Data are expressed as means ± SE. Means were compared by one-way ANOVAs followed by Tukey–Kramer tests using Excel 2004 with the add-in software Statcel 2 (OMS, Tokyo, Japan). Differences with $P < 0.05$ were considered significant.

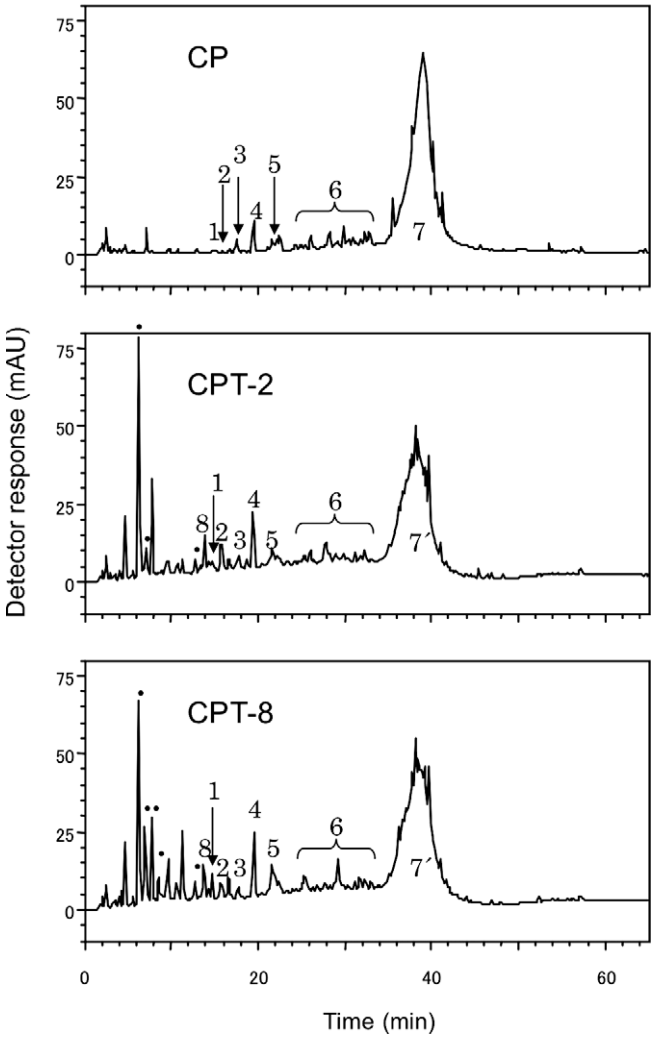

Fig. 1. RP-HPLC profiles of Chinese quince phenolics (CP) and CP subjected to heating for 2 h (CPT-2) and 8 h (CPT-8) in the presence of citric acid. 1, procyanidin B3; 2, (+)-catechin; 3, procyanidin B4; 4, procyanidin B2; 5, (−)-epicatechin; 6, oligomeric procyanidins; 7, clump of polymeric procyanidins; 7′, clump of polymeric components including procyanidin polymers and denatured polyphenols. Peaks indicated with '•' are new peaks with absorption spectra were similar to that of catechin.

3. Results and discussion

3.1. Changes in polyphenolic profile during heat treatment

During 12 h of the heat treatment, the CP solution turned reddish, and the colour intensity (measured at 458 nm) increased linearly as described previously (Hamauzu et al., 2007). During the treatment, increases in (+)-catechin, (−)-epicatechin, procyanidin dimers (B1–B4) and other oligomeric procyanidins were observed (Figs. 1 and 2). The increase in monomeric catechins (catechin plus epicatechin) and in dimers was considerable in the first 2 h. Monomers increased such that their concentrations were approx. 4 times the initial concentration after 2 h of heating, and they reached 5.4 times the initial value at 12 h after the treatment. The (+)-Catechin that was not detected in the initial solution rapidly increased during 2 h of heating and slightly decreased thereafter. Meanwhile, (−)-epicatechin increased continuously over 12 h of heating and reached 3.8 times its initial concentration. The pattern of change in total dimers was similar to that of monomers; it increased to be 3 times the initial concentration after the first 2 h and slightly increased thereafter to be 4 times the initial concentration.

In addition, some compounds having an absorption maximum at 280 nm (with a spectrum shape similar to that of catechin) appeared as peaks on the RP-HPLC chromatogram at early retention times. Small amounts of protocatechuic acid were detected in Chinese quince polyphenols before heating and the amount seemed to increase with long-term heating because a clear absorption spectra peculiar to protocatechuic acid was observed in a peak of CPT-12. However, this was unclear in the same peak of CPT-2 and CPT-8 because the peak was not separated from another peak that appeared with heat treatment. Meanwhile, vanillic acid was not detected in any polyphenolic samples with or without heat treatment. In the chromatogram, a peak of cyanidin and two peaks having an absorption maximum at 458 nm were observed as well as those from the previous report (Hamauzu et al., 2007) (data not shown). The unseparated clump of polymeric procyanidins decreased (approx. 30%) after 2 h of heating, and increased thereafter (Fig. 2). However, the increase was accompanied by the increase of visible absorbency (around 400–550 nm) indicating that polymeric

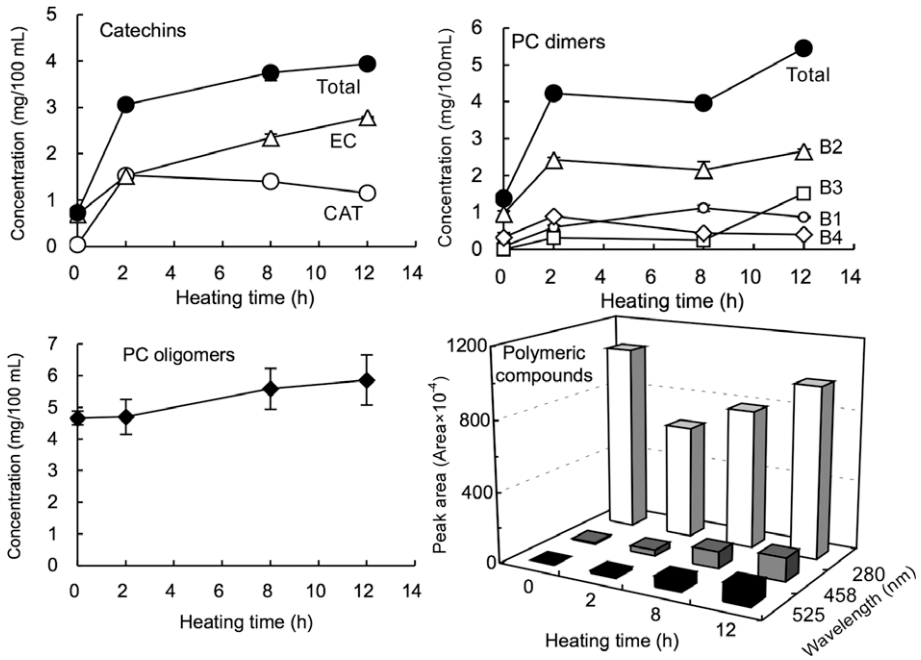

Fig. 2. Change in catechin and procyanidin concentrations and the area of polymeric compounds detected at 280, 458 and 525 nm during the heating of the Chinese quince phenolic solution in the presence of citric acid. Bars indicate SE (n = 3). EC, (−)-epicatechin; CAT, (+)-catechin; PC, procyanidin; B1–B4, procyanidin B1–B4.

procyanidins had been denatured and then re-polymerised to novel polyphenols during heat treatment.

The changes in the *in vitro* antioxidant properties and metal reducing ability were confirmed and the same trend was observed as that described previously (Hamauzu et al., 2007); they markedly increased during the first 2 h of heat treatment and the high levels were maintained until the end of the treatment (data not shown).

From the results, Chinese quince polyphenols heated with 2% citric acid seem to change from having features characteristic of more highly polymerised molecules to those characteristic of relatively less polymerised molecules as a result of the breakdown of polymerised procyanidins during the treatment. These phenomena have already been documented in our previous report (Hamauzu et al., 2007), but that experiment was conducted with 5% of citric acid. It is well known that procyanidins are transformed to cyanidin when broken down by heating with mineral acids (Porter, Hrstich, & Chan, 1986; Santos-Buelga & Scalbert, 2000). However, it has also been shown that, even with HCl, epicatechin monomers and dimers can be produced from oligomers if experimental conditions are pH 2.0 and 37 °C (Spencer et al., 2000). In the current experiment with citric acid, the conditions seemed to be moderate, so that the procyanidins were partially transformed to cyanidin and their breakdown to (−)-epicatechin and dimer B2 occurred. According to Spencer et al. (2000), the procyanidin dimer seems to be more stable than other oligomers and this is supported by our observation that the (−)-epicatechin and procyanidin B2 levels increased during heat treatment.

Protocatechuic acid was detected clearly in the samples subjected to long heating (CPT-12) times, indicating that the heat treatment decomposed polyphenols not only to the levels of monomers but also to smaller molecules such as phenolic acids. It has been known that protocatechuic acid results from the thermal processing of flavonols (Buchner, Krumbein, Rohn, & Kroh, 2006) or from cyanidin (Sadilova, Stintzing, & Carle, 2006). Sadilova et al. (2006) reported that protocatechuic acid concentration was found to increase in purified anthocyanin isolates from some plant materials after heat exposure at 95 °C and pH 1. In the current experiment, protocatechuic acid observed especially in a long-heated sample may be a result of cleavage of cyanidin that derived from 'extention units' of procyanidins.

The clump of polymeric procyanidins partially decreased during 2 h of heat treatment but it increased as denatured forms thereafter with increasing heating time. Because the absorbance increased in the visible light range, elongation of the conjugated diene seems to have occurred. In addition, new components appeared with an absorption maximum of 458 nm after heat treatment. From the shape of their absorption spectra, it is likely that those components have a xanthylium structure. It has been reported that procyanidins or catechins produce xanthylium pigments by polymerisation in the presence of an organic acid (Jurd & Somers, 1970; Labrouche, Clark, Prenzler, & Scollary, 2005).

The increase in the antioxidant properties of Chinese quince polyphenols during heat treatment seemed to be due to changes in their composition and proportions, such as would occur through the lowering of the degree of polymerisation and re-polymerisation to form new components. The antioxidant properties of oligomeric procyanidins have been reported to be superior to those of polymers (Lu & Foo, 2000).

3.2. In Vivo antioxidant activity and aromatic acids in rat plasma

The antioxidant activity of rat plasma as assessed by the FRAP method tended to increase after oral administration of CP, and the tendency was stronger in rats given CP with citric acid (CPT-0) (Fig. 3). The FRAP was also higher in rats given CPT-2 or CPT-8 than in the plasma of the controls, and in rats given CPT-2, the increase was significant ($P < 0.05$).

Aromatic acids detected in rat plasma 2 h after the administration of Chinese quince polyphenols were 3-hydroxyphenylacetic acid, protocatechuic acid, 4-hydroxybenzoic acid, vanillic acid, and hippuric acid (Fig. 4). An additional peak (m/z 209, peak 7) was also detected, indicating a possible metabolite that may have been 3,4-dihydroxyvaleric acid. However, we could not confirm this using its product ions. Although these aromatic acids were also detected in the controls' plasma, protocatechuic acid increased in the plasma of all rats after the administration of polyphenols

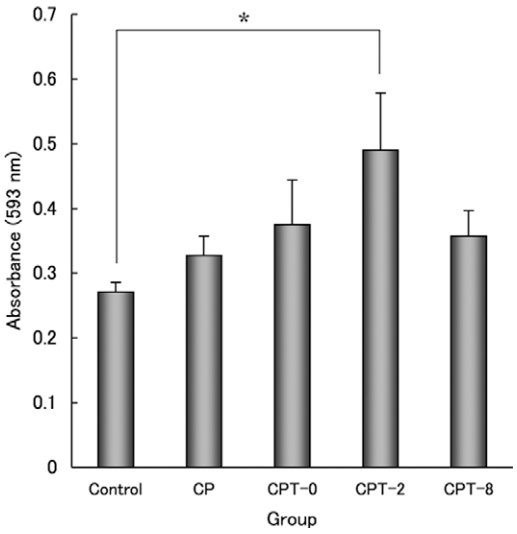

Fig. 3. Ferric reducing ability of the plasma (FRAP) of control rats and rats administered Chinese quince phenolics, some of which were subjected to heat treatment (see text for explanation of group codes). Bars indicate SE ($n = 10$ for control and CP group; $n = 4–5$ for CPT group). $^{*}P < 0.05$ (by Tukey–Kramer test).

(Fig. 5). Moreover, vanillic acid levels increased significantly in the plasma of rats administered CPT-2 and CPT-8, being 4.7 μM and 3.1 μM, respectively (4.7 and 3.1 times, respectively, that of the control or CP group (1.0 μM)). Because it has been reported that vanillic acid is transformed from protocatechuic acid by catechol-*O*-methyl transferase (COMT) in the liver (Gonthier et al., 2003b), the total amount of those two compounds (PCA + VA) was also compared in Fig. 5. The concentration of PCA + VA in the CPT-2 group (5.8 μM) was significantly higher ($P < 0.05$) than that of other groups and it was approx. 4 , 2.5 and 2 times that of the control, CP and CPT-0 groups, respectively. Levels of hippuric acid tended to be higher in rats administered CPT than those of the control or CP group. However, they did not seem to reflect the administration of polyphenols; rather they seemed to be related to the citric acid administered with polyphenols. The plasma levels of two other aromatic acids, 3-hydroxyphenylacetic acid and 4-hydroxybenzoic acid, did not show any particular trends, with a concentration of 7.0–12 μM in the former and 60–82 μM in the latter.

These results suggested that polyphenols from Chinese quince fruit might raise the antioxidant activity of plasma after intake, and that heating the polyphenols in the presence of an organic acid could improve the effect by increasing the plasma concentrations of vanillic acid. Administration of CPT-2 resulted in the most effective increase in the FRAP, which might be explained by the fact that CPT-2 had the lowest proportion of polymeric components and the highest proportion of monomers, dimers and oligomers. It has been thought that procyanidins that are larger than trimers are unlikely to be absorbed in the small intestine in their native forms (Manach, Scalbert, Morand, Rémésy, and Jiménez, 2004) and that, therefore, polymeric procyanidins may not contribute to an increase in the antioxidant activity of plasma in their intact forms. However, they can be absorbed once they reach the colon and are subjected to metabolism by the microflora there into various aromatic acids (Santos-Buelga & Scalbert, 2000; Déprez et al., 2000; Gonthier et al., 2003a), and act as functional compounds. The yields of aromatic acids of microbial origin have been reported to decrease with an increase in the degree of polymerisation of procyanidins (Gonthier et al., 2003b). Therefore, breakdown of procyanidins into smaller polymers by 2 h of heating in the presence of 2% citric acid seemed to be an effective method of bringing about a high yield of aromatic acids by the acceleration of microbial metabolism. The highest concentration of vanillic acid was detected in the plasma of rats that had received CPT-2, indicating that metabolism of the polyphenols into aromatic acids and the intestinal absorption of those metabolites were most active in rats given CPT-2.

Because protocatechuic acid was detected in Chinese quince polyphenols especially in samples heated for a long time, this compound detected in rat plasma seems to be partly the result of direct absorption from the samples administered. However, the plasma concentration of protocatechuic acid (and vanillic acid, the metabolite of protocatechuic acid) did not reflect the tendency of the efficacy of heating time. Therefore, the action of the intestinal flora of rats might also be important in increasing the plasma concentration of these phenolic acids. 3-Hydroxyphenylacetic acid, protocatechuic acid and 4-hydroxybenzoic acid have been reported to be produced from the metabolism of (+)-catechin, (−)-epicatechin or procyanidins by the intestinal microflora, whereas vanillic acid might have been transformed from protocatechuic acid by COMT in the liver (Gonthier et al., 2003b). Among these aromatic metabolites, only protocatechuic and vanillic acids reflected the effect of administration of CP or heat-treated CP; the other aromatic acids might have been derived from other ingested items such as pre-fasting food components or the citric acid administered with the polyphenols. Protocatechuic acid increased in the plasma of all rats given Chinese quince polyphenols and vanillic acid increased in the plasma of rats given CPT-2 and CPT-8, reflecting a positive effect of heat treatment. Since vanillic acid exists as protocatechuic acid before transformation by COMT in the liver, the total concentration of protocatechuic acid and vanillic acid seemed to reflect the total amount of the incorporated protocatechuic acid. This incorporation may have occurred in two ways: (1) direct incorporation from breakdown products of Chinese quince polyphenols; (2) indirect incorporation after the heated polyphenols were subjected to decomposition by intestinal microflora. Since heat treatment must have advantages for both type of incorporation, these two compounds in the plasma could be useful as indicators for the intake of Chinese quince polyphenols and especially for the effect of the heat treatment on them.

It has been reported that protocatechuic acid and vanillic acid have antioxidant activity (Mansouri, Makris, & Kefalas, 2005; Guan, Bao, Jiang, & An, 2006; Shyamala, Naidu, Sulochanamma, & Srinivas, 2007). Therefore, these compounds might contribute to an increase in the FRAP of rats given Chinese quince polyphenols. In fact, the difference of the FRAP between the groups seemed to reflect the plasma PCA + VA level of them, although the actual FRAP value cannot be explained just from the concentration of aromatic acids detected.

Not only increased antioxidant activity but also other beneficial properties have been reported for those two aromatic acids. Protocatechuic acid has been reported to have an inhibitory effect on histamine release from rat mast cells (Osawa et al., 1999), anti-inflammatory activity (Fernández, Sáenz, & García, 1998) and an anti-cancer effect on TPA-induced tumour promotion (Tseng et al., 1998). In addition, recent reports have shown that protocatechuic acid could inhibit the formation of H_2O_2-induced reactive oxygen species at the cytosolic level and also could inhibit H_2O_2-induced apoptotic events, such as the loss of mitochondrial functioning and DNA fragmentation (Tarozzi et al., 2007). Vanillic acid has been reported to have antimicrobial activity (De Moura, Pereira, Januário, França, and Dias, 2004), inhibitory effects on platelet aggregation (Yasuda, Takasawa, Nakazawa, Ueda, & Ohsawa, 2003) and a stimulatory effect on the expression of human endothelial NO synthase (Wallerath, Li, Gödtel-Ambrust, Schwarz, & Förstermann, 2005). Therefore, a heat treatment-induced increase in the plasma concentration of these aromatic acids may confer health benefits through their effects on the circulatory system.

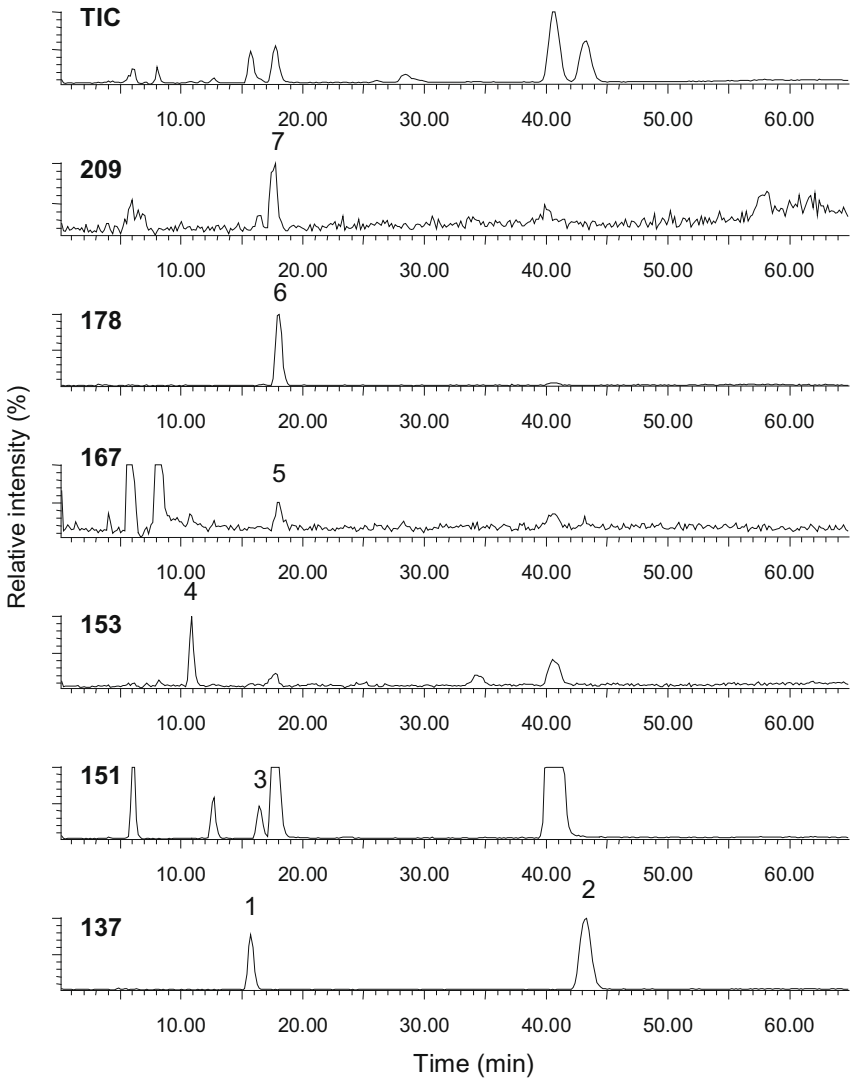

Fig. 4. LC/MS single ion recording (SIR) mass chromatogram profile of representative rat plasma after the administration of Chinese quince phenolics. Peaks: 1 = 4-hydroxybenzoic acid; 2 = salicylic acid (IS); 3 = 3-hydroxyphenylacetic acid; 4 = protocatechuic acid; 5 = vanillic acid; 6 = hippuric acid; 7 = 3,4-dihydroxyphenylvaleric acid (?).

There are some additional advantages to the breakdown of Chinese quince polyphenols by heat treatment in the presence of citric acids. The treatment can increase their bioavailability, as indicated by the observed increase in monomers such as (−)-epicatechin (which can be absorbed in their intact forms) (Manach et al., 2004). In the current experiment, however, this compound could not be detected in any of the rat plasma samples. The proportion of monomers in the polyphenolic samples given to rats was too small for monomers to be detected in the plasma after administration, even CPT-2 (it contained only 3% of total polyphenols). Moreover, using citric acid might have an additional effect on the intestinal absorption of polyphenols. The FRAP and PCA + VA concentration were both higher in the plasma of rats given CPT-0 than in the rats given CP, although the difference was not significant, suggesting that the presence of citric acid might affect the absorption of polyphenols. Yamashita et al. (2002) reported that tartaric acid enhanced the absorption of catechin in rats. Another beneficial aspect of the breakdown of Chinese quince polyphenols by heat treatment is a decreased amount of highly polymerised procyanidins. Highly polymerised procyanidins are the main component of Chinese quince polyphenols, and by having strong tannic activity, they are associated with some food problems such as astringency and may be related to some types of iron deficiency (Santos-Buelga & Scalbert, 2000). Thus, the heat-induced breakdown of polymeric procyanidins is beneficial because of the decrease in astringency and increase in functionality although polymeric procyanidins themselves may also have some beneficial functions such as antioxidant activity, anti-ulcerative activity, anti-influenza viral activity (Hamauzu et al., 2005; Hamauzu et al., 2006) and anti-proliferative activity (Miura et al., 2008). Polymeric procyanidins may have important functions in the digestive tract rather than in the circulatory system.

In conclusion, the breakdown of Chinese quince polyphenols by heating in the presence of citric acid seems to be an effective method to improve their biological activity through the increasing of lower molecular compounds and the *in vivo* production of aromatic acids such as protocatechuic and vanillic acids. The treatment could lower the proportion of polymeric procyanidins and increase the proportion of smaller molecules, such as dimers, monomers and protocatechuic acid. Thus, their ability to be absorbed in the small intestine and susceptibility to metabolism by microflora increases and the plasma concentration of aromatic acids of microbial origin will also increase. However, the results also suggest that heating for too long a period may decrease the efficiency of

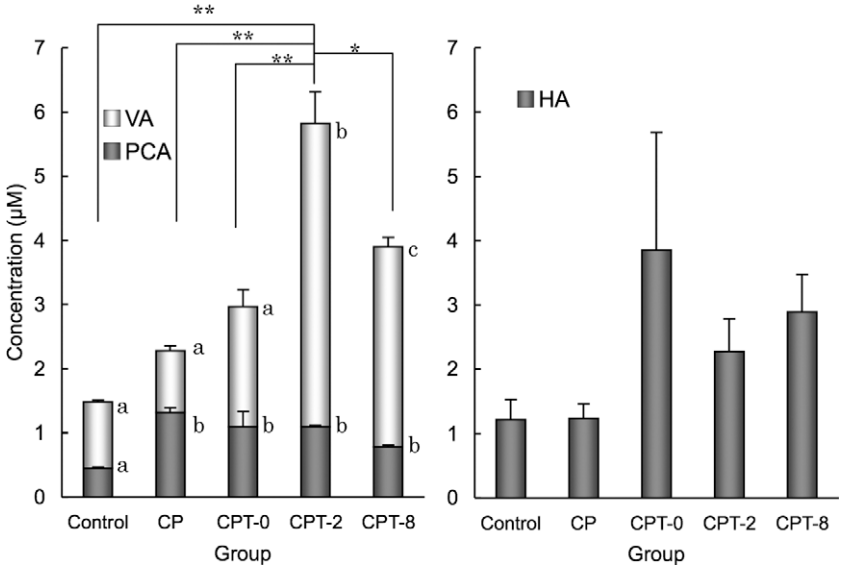

Fig. 5. Aromatic acid concentrations in the plasma of control and trial rats 2 h after the administration of Chinese quince phenolics, some of which were subjected to heat treatment (see text for explanation of group codes). the treatment. The appropriate conditions to improve the health-promoting properties of Chinese quince polyphenols are under investigation.

Information depicting a comparative analysis of the fatty acid profiles of wild and reared perch, that so far originate from one source, demonstrate the impact of geographic source, rearing system and the domestication process on the fatty acid composition of muscle lipids (Mairesse, Thomas, Gardeur, & Brun-Bellut, 2006; Mairesse, Thomas, Gardeur, & Brun-Bellut, 2007). The presented work describes a study undertaken in order to determine fatty acid composition of various body parts of European perch originating from natural aquifers and reared in the intensive system in a closed circuit and fed an artificial feed mixture.

2. Materials and methods

2.1. Experimental material

The experimental material was perch from intensive fattening with an artificial feed mixture and wild fish of that species. The reared fish originated from the "Dgał" Experimental Stocking Station belonging to the Institute of Inland Fisheries in Olsztyn, Poland. Larval fish obtained as a result of artificial reproduction were pre-reared in tanks with a volume of 1 m^3, in a recirculating cycle. Afterwards, the material was transferred into tanks with a volume of 2 m^3. The fish were fed with excess Nutra Classic trout pellets by Trouvit; Trouw, Fontaine-les-vervins, France. In the final 6 months of fattening, the feed mixture was changed into T-2P Classic (Nutreco; Amersfoort, The Netherlands) with the following composition: protein 45%, fat 16%, carbohydrates 20.8%, ash 8.5%, fibre 1.7%, total phosphorus 1.2%; vitamin A 10,000 u/kg, vitamin D3 1500 u/kg and vitamin E 150 u/kg. Digestible energy accounted for 18.8 MJ/kg, and the size of pellets was 4.0 mm. The feed mixture (a daily dose of 0.3–0.5% of stock biomass) was administered by means of automatic feeders 24 h a day. In the last 2 months, the stock density reached 30–60 kg m^{-3}. In the fattening period, the temperature of water ranged from 17.9 to 22.8 °C. The content of oxygen at the outlet did not drop below 5.1 mg O_2/l. The water reaction accounted for 7.79–8.43, whereas the concentration of total ammonia nitrogen (TAN = NH_4 + NH_3) accounted for 0.08–0.52 mg TAN/l, and that of nitrites for 0.019–0.236 mg NO_2–N/l.

In mid-November, 18 fish from the tank rearing (age 1+) and 18 wild fish (age 3+) were caught. The latter were obtained as a result of a net catch at Dgał Wielki Lake (Mazurian Lake District, Northern Poland). The fish were selected so as to provide the same number of males and females in each group and so that the mean body mass of reared (119.3 g) and wild (116.0 g) perches was alike. Immediately after the catch, the fish were killed and kept in ice for 24 h. Fillets, liver and mesenteric fat obtained after fish dissections served as an analytical material for assays of the fatty acid profile. In each group, analyses were conducted on 18 fish.

2.2. Fatty acid profile

The quantitative and qualitative analysis of fatty acid composition was conducted after the cold extraction of lipids (Folch, Less, & Stanley, 1957). Fatty acids were methylated with the use of a chloroform:methanol:sulphuric acid mixture (100:100:1) (Peisker, 1964). Chromatographic separation was conducted on a gas chromatograph (Agilent Technologies 6890N), with flame ionisation detector, and a capillary column (30 m × 0.32 mm i.d.). The liquid phase used was Supelcowax 10, and film thickness was 0.25 μm. The carrier gas was helium at a flow rate of 1 ml/min. The detector temperature was 250 °C, that of the injector was 225 °C, and that of the column was 180 °C. The detector signal was recorded by means of a Philips recorder with a 1 mV scale at a tape feed of 10 mm/min. Individual acids were identified by comparing their retention times with those of standards by Supelco (Bellefonte, PA).

2.3. Atherogenic and thrombogenicity indices

Lipid quality indices, i.e., atherogenic index (AI) and thrombogenicity index (TI), were calculated according to Ulbricht and Southgate (1991). AI = [12:0 + (4 × 14:0) + 16:0]/[(PUFA $n-6$ + $n-3$) + 18:1 + other MUFA]; TI = [14:0 + 16:0 + 18:0]/[0.5 × 18:1 + 0.5 × other MUFA + 0.5 × $n-6$ PUFA + 3 × $n-3$ PUFA + ($n-3$ PUFA/$n-6$ PUFA)].

2.4. Statistical analysis

Differences between mean values were computed using a one-way analysis of variance (ANOVA). Use was also made of Duncan's test, statistically significant differences were demonstrated at $p \leqslant 0.01$. All calculations were performed by means of Statistica 6.0 PL software (StatSoft Inc., Tulsa, OK).

3. Results

Data referring to the fatty acid composition of the artificial feed mixture and natural feed show that the content of unsaturated fatty acids (UFA) was lower by 6.11% in the natural feed. It was due to a lower (by 9.92%) content of monoenoic fatty acids (MUFA), whilst the content of polyenoic fatty acids (PUFA) was higher by 3.81% as compared to the artificial feed mixture. The greatest differences in contents of individual fatty acids were observed for 16:1 (palmitoleic) and 20:4 $n-6$ (AA, arachidonic), the concentrations of which were higher in the natural feed, and for *cis*18:1 $n-9$ (oleic), 18:2 $n-6$ (LA, linoleic), and 20:1 $n-9$ (erucic) occurring in higher amounts in the artificial feed mixture (Table 1).

Table 1
Fatty acid composition (% of total fatty acids) in an artificial feed mixture and natural feed.

Fatty acid	Artificial feed mixture	Natural feed

∑$n-6$ PUFA	12.20	15.90

The fatty acid compositions of the total lipids of the analysed body parts of perch are presented in Tables 2 and 3. Out of 48 fatty acids detected, 28 were identified as fitting in a range from C14:0 to C22:6 $n-3$.

The qualitative composition of muscle fatty acids of perch from both groups was identical, except for 16:4 acid, occurring exclusively in muscles, liver and mesenteric fat of the reared fish. Out of the three acids predominating in the muscles in terms of relative content, two, namely 16:0 (palmitic) and DHA, occurred at similar concentrations. The content of the third acid, i.e., oleic, was higher in perch fed the artificial feed mixture. Analyses demonstrated higher concentrations of such fatty acids as: 14:0, 18:4, 20:1 $n-9$ and 22:1 $n-11$ and a lower concentration of 18:0, *cis*18:1 $n-11$, 18:3 $n-3$, 20:4 $n-6$ and 22:5 $n-6$ in the reared fish. In addition, the study showed no differences in the contents of SFA and UFA as well as a relatively higher content of MUFA and a lower content of PUFA in the reared perch. The meat of the latter was additionally found to contain less $n-6$ PUFA. However, $n-3$ PUFA occurred in similar quantities in both groups of perch.

Liver lipids of the reared perch were characterised by a higher content of oleic, a lower content of DHA and a similar concentration of 16:0. Differences were also observed in the concentrations of 14:0, 16:1, 18:2 $n-6$, 18:4 and 20:1 $n-9$ acids (higher in the reared fished) as well as in those of 18:0, *cis*18:1 $n-11$, 20:4 $n-6$ and 22:5 $n-6$ acids (lower in the reared fish). In turn, no differences were found in the total contents of SFA and UFA, however, a higher content of MUFA and a lower content of PUFA, including both $n-6$ PUFA and $n-3$ PUFA, were demonstrated in the fish from intensive rearing.

In the mesenteric fat of the reared perch, analyses demonstrated a higher content of oleic, a lower content of DHA and a similar content of 16:0, as compared to the wild fish. Differences

SFA contain 14:0, 15:0, 16:0, 18:0 and 20:0.
UFA contain 14:1, 16:1, 16:4, 17:1, 18:1cis9, 18:1cis11, 18:2 $n-6$, 18:3 $n-3$, 18:4, 20:1 $n-7$, 20:1 $n-9$, 20:2, 20:3 $n-3$, 20:3 $n-6$, 20:4 $n-3$, 20:4 $n-6$, 20:5 $n-3$, 21:5, 22:1 $n-9$, 22:1 $n-11$, 22:5 $n-3$, 22:5 $n-6$ and 22:6 $n-3$.
MUFA contain 14:1, 16:1, 17:1, 18:1cis9, 18:1cis11, 20:1 $n-7$, 20:1 $n-9$, 22:1 $n-9$ and 22:1 $n-11$.
PUFA contain 16:4, 18:2 $n-6$, 18:3 $n-3$, 18:4, 20:2, 20:3 $n-3$, 20:3 $n-6$, 20:4 $n-3$, 20:4 $n-6$, 20:5 $n-3$, 21:5, 22:5 $n-3$, 22:5 $n-6$ and 22:6 $n-3$.
$n-3$ PUFA contain 18:3 $n-3$, 20:3 $n-3$, 20:4 $n-3$, 20:5 $n-3$, 22:5 $n-3$ and 22:6 $n-3$.
$n-6$ PUFA contain 18:2 $n-6$, 20:3 $n-6$, 20:4 $n-6$ and 22:5 $n-6$.
Mean values denoted with various letters in the same row for a given body part are statistically significantly different ($p \leqslant 0.01$).

between the groups examined were also observed for such fatty acids as: 14:0, 16:1, 18:4, 20:1 $n-9$, 22:1 $n-11$ and 22:5 $n-3$ occurring in a higher relative quantity in the reared fish, as well as for 18:0, *cis*18:1 $n-11$, 18:3 $n-3$, 20:4 $n-6$ and EPA whose concentrations in that group of fish appeared to be lower. The total content of SFA and UFA was alike in both groups of fish, whereas the total content of MUFA was higher and that of PUFA was lower in the fish from intensive rearing. Additional differences were observed in the total $n-6$ PUFA and $n-3$ PUFA whose content was higher in the mesenteric fat of wild perch.

4. Discussion

The above-presented results pointed to an identical dependency referring to the total content of SFA and UFA in muscles, liver and mesenteric fat of wild and reared perch. Quantities of those groups of fatty acids were similar. Lipids of the examined body parts of perch from both groups were also characterised by the same tendency in respect of contents of MUFA and PUFA, i.e., the wild fish contained less MUFA and more PUFA. The total content of $n-3$ PUFA was similar only in muscles, whereas the total content of $n-6$ PUFA turned out to be different in muscles, liver and mesenteric fat; its higher values were determined in the wild perch.

Thus, the differences observed between both groups of perch, resulting from different ratio of MUFA and PUFA, corresponded to a relationship determined between the artificial feed mixture and natural feed. The higher content of MUFA in the artificial feed mixture was manifested in their higher content in the reared perch. Analogously, the higher content of PUFA in natural feed corresponded to their higher concentration in the wild fish. An identical dependency referring to MUFA and PUFA was demonstrated in a study by Mairesse et al. (2007) conducted on wild and reared perch as well as in other predatory fish (Alasavar, Taylor, Zubcov, Shahidi, & Alexis, 2002; Jankowska, Zakęś, Żmijewski, & Szczepkowski, 2008; Periago et al., 2005; Yildiz & Şener, 2004).

The higher content of MUFA in muscles, liver and mesenteric fat of the reared perch was due to higher concentrations of *cis*18:1 $n-9$ and 20:1 $n-9$, as well as 22:1 $n-11$ in muscles and omental fat. However, the content of *cis*18:1 $n-9$ in all body parts of both wild and reared perch was lower than that determined in feed; hence it may be speculated that this acid was utilised as a source of metabolic energy. Differences in the contents of the other two MUFA resulted from the type of diet. High concentrations of 20:1 $n-9$ and 22:1 $n-11$ are typical of fish meal in which Atlantic herring or that originating from the North Sea as well as other sea fish are constituents (Aidos, van der Padt, Luten, & Boom, 2002; Ratnayake & Ackman, 1979). In freshwater wild fish, the content of both of those fatty acids is low (Ahlgren, Blomqvist, Boberg, & Gustafsson, 1994; Linko, Rajasilta, & Hiltunen, 1992a, 1992b). Likewise, in the wild perch, the content of both those fatty acids was lower as compared to the reared perch fed an artificial feed mixture containing fish meals.

The total content of $n-3$ PUFA in the artificial feed mixture and natural feed was similar. The same observations were made for those acids in muscles, yet their concentrations in live mesenteric fat were different and in both organs were higher in the wild perch. This was mostly due to DHA, the content of which was similar in muscles but different in the two other tissues. The same relationship between muscles and liver as well as internal fat was demonstrated by Rueda et al. (2001) for wild and reared sharpsnout sea brea (*Diplodus puntazzo*). It should also be noted that the mesenteric fat of both groups of perch contained about half the DHA as compared to muscles and liver. Likewise, according to Jezierska, Hazel, and Gerking (1982) in rainbow trout (*Oncorhynchus mykiss* Walb.*i*) the mesenteric fat accumulates less DHA than the fat of muscles or liver. Such a dependency may be linked with the fact that this fatty acid is the major component of phosphoglycerols of cellular biomembranes in fish (Henderson & Tocher, 1987).

In addition, it should be added that the content of DHA, and the resultant total content of $n-3$ PUFA, in the wild and reared perch was usually higher than that determined in the natural feed and artificial feed mixture. This could have been due to the selective retention of that fatty acid or transformation of fatty acids of the $n-3$ family, with a shorter carbon chain and a lower number of double bonds in their long-chain derivatives with a higher degree of unsaturation. The process of bioconversion of $n-3$ fatty acids in that species of fish has been confirmed by Xu and Kestemont (2002), as well as by Xu, Fontaine, Mélard, and Kestemont (2001) using reared perch fed a diet with the addition of various vegetable oils and a diet with various contents of fat. These authors point to the high activity of desaturases $\Delta5$ and $\Delta6$ in fish of that species and to 18:3 $n-3$ as a preferred reaction substrate.

A reference to the findings of the above-cited authors may also be found in the case of $n-6$ PUFA. The study demonstrated that the differences in the content of predominating AA between the wild and reared perch were very similar to those determined between the artificial feed mixture and natural feed. In addition, it is common knowledge that fatty acids of the $n-3$ and $n-6$ families compete for desaturating enzymes and that desaturases $\Delta6$ and $\Delta4$ more readily utilise PUFA $n-3$ than PUFA $n-6$ (Henderson, 1996). It may be speculated, thus, that the content of AA was determined, most of all, by the type of feed and not by bioconversion of its precursor, i.e., LA. Hence, as a result of substantially higher content of AA in the natural feed, the content of that acid in the wild perch was repeatedly higher as compared to the reared fish.

Owing to their predominating quantity, two fatty acids, namely DHA and AA, were responsible to the greatest extent for changes in the essential fatty acid ratio ($n-3/n-6$), a reliable indicator that enables a comparison of the relative nutritive value of lipids. According to Valfré, Caprino, and Turchini (2003), in freshwater fish the $n-3/n-6$ ratio fluctuates between 1 and 4. Values determined for muscles, liver and mesenteric fat were also within that range, however in the case of the wild perch they were lower as compared to the same tissues and organs of the reared perch. This was mostly due to the higher concentration of AA and, consequently, of $n-6$ PUFA in the wild perch. The higher value of the $n-3/n-6$ ratio increases the nutritive value of the reared perch. The $n-3/n-6$ ratio shown in the study is consistent with that determined between wild and reared gilthead sea bream (*Sparus aurata*) and pike (*Esox lucius*) (Jankowska et al., 2008; Orban, Nevigato, Di Lena, Casini, & Marzetti, 2003), but differs from that determined for Atlantic salmon (*Salmo salar*), rainbow trout and European eel (*Anguilla anguilla* L.) as well as sea bass (*Dicentrarchus labrax* L.), indicating the lower $n-3/n-6$ value in reared fish (Krajnovic-Ozretic, Najdek, & Ozretic, 1994; van Vliet & Katan, 1990).

Human health is additionally affected by saturated, monoenoic and polyenoic fatty acids, other than $n-3$ PUFA. Lipid quality indicators that depend on the relative contents of particular groups of fatty acids are the atherogenic index (AI) and thrombogenicity index (TI), which indicate the global dietetic quality of lipids and their potential effect on the development of coronary disease (Ulbricht et al., 1991). In the current study, the wild and reared perch were found not to differ in the values of those indices except for IA of liver and omental fat lipids. Thus, it may be stated that relationships between pro-atherogenic and anti-atherogenic fatty acids of perch muscles were not determined by its origin. No differences between the groups were either observed in comparing dependencies between pro- and anti-thrombogenic fatty acids of all body parts of both wild and reared perch.

In summarising the results obtained, it may be concluded that the intensive rearing of perch in recirculating cycles produces fish whose muscle lipids do not diverge from those of wild fish in terms of contents of EPA and DHA acids, the most valuable to a consumer, or in the values of such indicators of the nutritional quality of lipids as AI and TI. Hence, in this respect the reared perch is not inferior to the wild one. Nevertheless, the contents of fatty acids in liver (DHA) and mesenteric fat (EPA, DHA) of both groups of perch are still different. Fish of this species display a high bioconversion efficiency of $n-3$ fatty acids, which results in a higher concentration of DHA in muscles, liver and mesenteric fat of the fish compared to their diet.

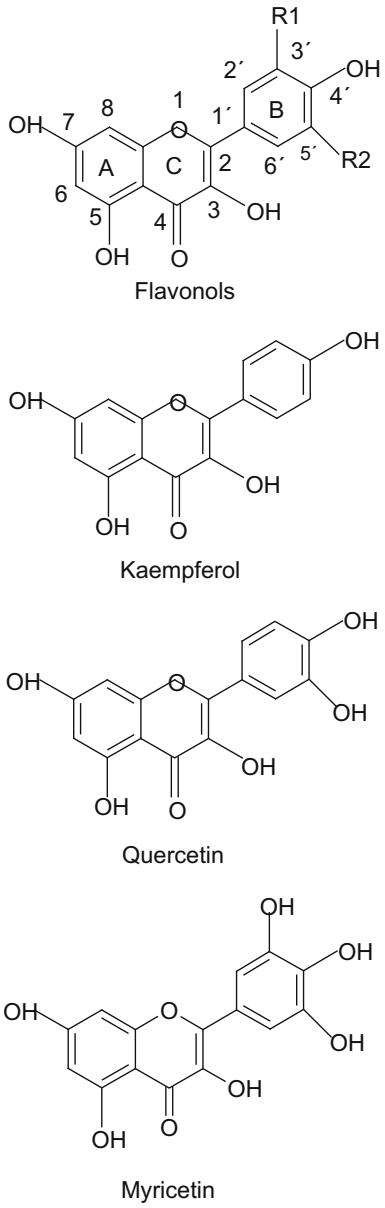

Fig. 1. Flavonols structures.

as drugs, vitamins and food colourants, increasing the solubility, stability and bioavailability of the guest molecule (Buschmann & Schollmayer, 2002; Loftsson & Brewster, 1996).

The ability of CDs to form inclusion complexes with guest molecules depends on the relative size of the internal cavity of CD to the size of the guest molecule or certain key functional groups within the guest. While the height of the CD cavity is the same for all types (7.9 Å), the number of glucose units determines the internal diameter of the cavity and its volume. Based on these dimensions β-CDs (cavity diameter 6–6.5 Å) will complex mainly aromatics and heterocycles (Martín Del Valle, 2004).

As recently described by our group, CDs can be used as flavonoids complexation agents, not only to increase the total flavonoid concentration in aqueous solutions, while the free flavonoids concentration remains constant, but also to decrease the free flavonoid concentration in aqueous solution, while the total concentration remains constant (Lucas-Abellán, Fortea, López-Nicolás, & Núñez-Delicado, 2007). In all cases, CDs acts as substrate reservoir in a dosage-controlled manner. In the case of resveratrol, its complexation with hydroxypropyl-β-cyclodextrins (HP-β-CDs) led to an increase not only in its aqueous solubility but also in its antioxidant activity due to its protection towards free radical attack (Lucas-Abellán et al., 2008).

The complexation of myricetin and quercetin in CDs has been described by our group and their complexation constants (K_c) were calculated by using both solubility and enzymatic methods (Lucas-Abellán, Fortea, Gabaldón, & Núñez-Delicado, 2008). However, it is still unknown whether entrapment in the internal cavity of CDs affects the antioxidant capacity of those flavonols.

Based on the statement described above and tacking into account radial distances, flavonols could be entrapped by β-CDs via phenoxyl group of ring A (C6–C8 = 2.68 Å) or ring B having one (C3′–C5′ = 2.68 Å), two (–OHC4′–OH–C5′ = 3.09 Å) or three OH groups (OH–C3′–OH–C5′ = 5.27 Å) (Fig. 1).

As continuing research examines the effect of antioxidants on health, the testing for antioxidant protection has become focus of attention in the dietary and natural products industry. Researchers associated with the natural product industry have pushed for a standardised method for measuring antioxidant capacity in natural products (Honzel et al., 2008). A large number of methods have been developed to evaluate the antioxidant capacity in foods, one of the most popular and best standardised chemical antioxidant methods being the oxygen radical absorbance capacity (ORAC) test (Ou, Huang, Hampsch-Woodill, & Prior, 2001). The ORAC method is based on the inhibition of the peroxyl-radical-induced oxidation initiated by thermal decomposition of azo-compounds, like 2,2′-azobis(2-amidino-propane) dihydrochloride (AAPH), and it is the only method that combines inhibition time and inhibition degree into a single quantity. This test is widely used for the evaluation and comparison of the antioxidant capacity of natural food products and plasma (Prior et al., 2007).

In the present paper, the effect of the complexation of three flavonols kaempferol, quercetin and myricetin, with HP-β-CDs on their antioxidant capacity against reactive oxygen species (ROS) has been studied by means of ORAC-fluorescein (ORAC-FL) assay (Ou et al., 2001). The antioxidant capacity of myricetin, quercetin and kaempferol in aqueous solution in the absence and presence of CDs is studied for the first time, using the ORAC-FL assay adapted to manual handling, and a conventional fluorescence plate reader.

2. Material and methods

2.1. Chemicals

FL, AAPH, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox C), myricetin, quercetin and kaempferol were purchased from Sigma (Madrid, Spain). HP-β-CDs were from TCI (Europe). All other chemicals used were of analytical grade.

A FL stock solution (4 μM) was made in 75 mM sodium phosphate buffer (pH 7.4) and was stored at −20 °C for 4 weeks. The FL solution was prepared daily in 75 mM sodium phosphate buffer (pH 7.4) by diluting the FL stock to a final concentration of 6 nM. Solutions of 0.25 mM Trolox C and 15 μM myricetin, quercetin and kaempferol in 75 mM sodium phosphate buffer (pH 7.4) were prepared and aliquoted into small vials for storage at −80 °C until use. A 127 mM AAPH solution in 75 mM sodium phosphate buffer (pH 7.4) was prepared daily.

2.2. ORAC-FL assay

The ORAC analyses were carried out on a Synergy HT multi-detection microplate reader, from Bio-Tek Instruments, Inc. (Winooski, USA), using 96-well polystyrene microplates with black

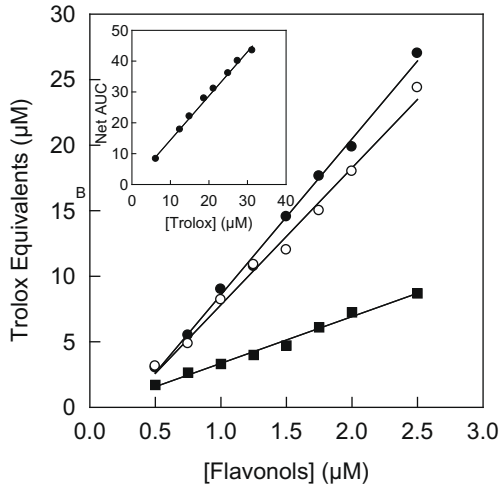

Fig. 2. Regression of μM Trolox equivalents of kaempferol (●), quercetin (○) and myricetin (■) at different concentrations. *Inset:* regression of net AUC of Trolox C on different concentrations of Trolox C. The net AUC = $AUC_{sample} - AUC_{blank}$.

sides and clear bottom, purchased from Nalge Nunc International. Fluorescence was read through the clear bottom, with an excitation wavelength of 485/20 nm and an emission filter of 528/20 nm. The plate reader was controlled by KC4, version 3.4, software. The oxygen radical absorbance capacity was determined as described by Dávalos, Gómez-Cordovés, and Bartolomé (2004), with slight modifications. The reaction was carried out in 75 mM sodium phosphate buffer (pH 7.4), and the final reaction mixture was 200 μL. FL (100 μL; 3 nM, final concentration) and myricetin, quercetin, or kaempferol in the absence or presence of β-CDs or HP-β-CDs (70 μL) solutions, were placed in the wells of the microplate. The mixture was preincubated for 30 min at 37 °C, before rapidly adding the AAPH solution (30 μL; 19 mM, final concentration) using a multichannel pipette. The microplate was immediately placed in the reader and the fluorescence recorded every 1.14 min for 120 min. The microplate was automatically shaken prior to each reading. A blank with FL and AAPH using sodium phosphate buffer instead of the antioxidant solution and eight calibration solutions using Trolox C (6.25, 12.5, 15.0, 18.75, 21.25, 25, 27.5 and 31.25 μM) as antioxidant were also used in each assay. The inhibition capacity was expressed as Trolox equivalents (mM), and is quantified by integrating of the area under the curve (AUC). All reaction mixtures were prepared in triplicate and at least three independent assays were performed for each sample. In order to avoid a temperature effect, only the inner 60 wells were used for experimental purposes, while the outer wells were filled with 200 μL of distilled water.

The results were expressed as μM Trolox equivalents by using the calibration curve of Trolox C ($y = 0.12 + 1.43x$) (Fig. 2, insert). The area under the fluorescence decay curve (AUC) was calculated by the following equation:

$$AUC = 1 + \sum_{i=1.14}^{i=120} f_i/f_0 \quad (1)$$

where f_0 is the initial fluorescence read at 0 min and f_i is the fluorescence read at time i. The net AUC corresponding to the sample was calculated by subtracting the AUC corresponding to the blank. Data processing was performed using Sigmaplot software package 9.0 (Jandel Scientific, Germany).

3. Results and discussion

Synthetic antioxidants such as butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT) and tertbutylhydroquinone (TBHQ) have been widely used as antioxidants in foods, but concerns over their safety have led to increased interest in natural antioxidants (Wanasundara & Shahidi, 1998). Synthetic antioxidants have in many cases been substituted by phenolic compounds and much research effect has been directed at these natural antioxidants, in particular flavonoids (Martínez-Valverde, Periago, Provan, & Chesson, 2002).

In the present paper, the effect of including of myricetin, quercetin and kaempferol in CDs on their antioxidant activity is studied by using the ORAC-FL method in the presence of increasing concentrations of CDs. These three flavonols were selected for study become of their on chemical structure characteristics, availability and prevalence in plants foods.

Fig. 2 presents the concentration-dependent data of antioxidant activity obtained for each flavonol tested: myricetin (filled square), quercetin (open circle) and kaempferol (filled circle). Least squares regression lines were computed between flavonols concentration and antioxidant activity (expressed as μM Trolox equivalents). As can be seen in Fig. 2, the regression analysis showed linear relation between each flavonol concentration and μM Trolox equivalents, yielding the equations: $y = -3.3 + 11.9x$; $y = -2.6 + 10.45x$ and $y = -0.2 + 3.56x$ for kaempferol, quercetin and myricetin, respectively. Considering that a slope of 1.0 in the lines of Fig. 2 would mean that the ORAC activity of 1 μM of the tested flavonol is equivalent to 1 μM Trolox, kaempferol (slope 11.9), quercetin (slope 10.45) and myricetin (slope 3.56) had ORAC activities from 3–12-fold greater than Trolox. These results agree with those presented by Tabart, Kevers, Pincemail, Defraigne, and Dommes (2009), in which the antioxidant activity of the same three flavonols was determined by several methods, including ORAC assay.

In general, the antioxidant activity of flavonoids depends on the structure and substitution pattern of their hydroxyl groups. As stated in other papers the presence of 3-OH group, which provides a catechol-like structure in ring C, is beneficial for the antioxidant activity of flavonoids. Additional hydroxyl groups at positions C5 and C7 of the A ring appear to be less important. The presence of the C2–C3 double bond with a 4-keto arrangement is known to be responsible for electron delocalisation from ring B, which it increases the radical-scavenging activity. The flavonols tested in this work have a different number of OH in ring B. We observed (Fig. 2) the antioxidant activity to be as follows: kaempferol > quercetin > myricetin, which is inversely proportional to the number of hydroxyl groups in the B ring. Kaempferol, which had only one OH group in position C4′ of ring B, showed a slightly higher antioxidant activity than quercetin (with a catechol moiety). Both flavonols appeared to be much better antioxidants than myricetin, which has a galloyl structure in ring B.

Once the antioxidant activity of each flavonol had been established, our purpose was to demonstrate the effect of the inclusion of kaempferol, quercetin and myricetin in HP-β-CDs on the antioxidant activity of the flavonols using the ORAC-FL assay.

The respective areas, under the curve, when the FL decay curves obtained in the presence of kaempferol (Fig. 3, insert), quercetin or myricetin (0.5 or 0.75 μM) (*data not shown*) in the absence of HP-β-CDs were smaller than those obtained in the presence of 1.75 mM HP-β-CDs. Because ORAC assay data combines inhibition time and inhibition degree in a single datum, it is important to note that any increase in the inhibition time and decrease in the inhibition degree of the FL decay curve was greater in the presence of flavonols–CD complexes in all cases than in the presence of flavonols alone (Fig. 3, insert).

When increasing concentrations of HP-β-CDs were added to the reaction medium at too flavonoid concentrations (0.5 or 0.75 μM), a clear increase in the antioxidant activity was observed in all cases (Figs. 3–5). It was not possible to measure the net AUC of kaempferol, quercetin and myricetin at concentrations higher than

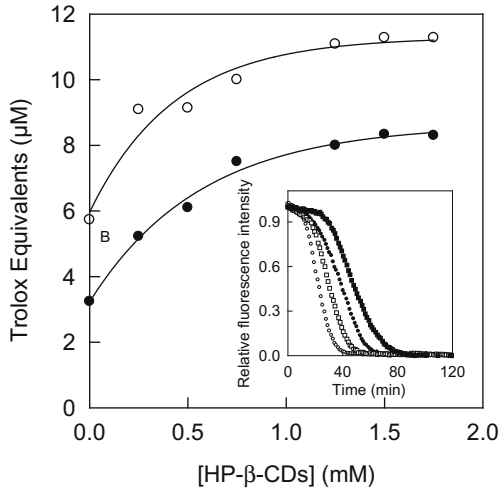

Fig. 3. Effect of HP-β-CDs concentration on the μM Trolox equivalents of kaempferol 0.5 μM (●) and 0.75 μM (○). *Inset:* FL fluorescence decay curves induced by AAPH in the presence of kaempferol alone (0.5 μM (○) and 0.75 μM (□)) and with HP-β-CDs 1.75 mM (kaempferol 0.5 μM (●) and 0.75 μM (■)).

0.75 μM in the presence of CDs, because the measuring times exceeded 2 h, which was established as optimum for the ORAC assay (Lucas-Abellán et al., 2008).

When the concentration of HP-β-CDs increased, the μM Trolox equivalents of flavonols also increased reaching saturation level at approximately 1 mM of HP-β-CDs in all cases. At the saturation level, flavonols showed approximately double the antioxidant activity in the presence than in the absence of CDs in all the cases studied (Figs. 3–5). This effect on antioxidant activity may have been due to the formation of inclusion complexes between these flavonoids and HP-β-CDs.

In order to corroborate that those three flavonols were complexed by HP-β-CDs in 75 mM sodium phosphate buffer (pH 7.4), their complexation constants, K_c were calculated by constructing phase solubility diagrams (*data not shown*). The K_c values obtained for kaempferol, quercetin and myricetin were 1411, 900 and 850 M^{-1}, respectively (Table 1). Kaempferol showed the highest K_c, whereas quercetin and myricetin had lower (and very similar) values.

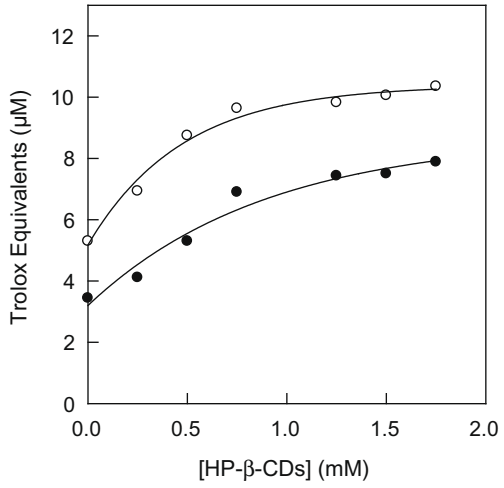

Fig. 4. Effect of HP-β-CDs concentration on the μM Trolox equivalents of quercetin 0.5 μM (●) and 0.75 μM (○).

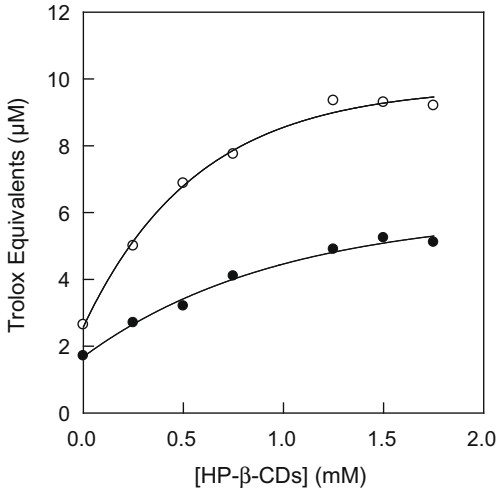

Fig. 5. Effect of HP-β-CDs concentration on the μM Trolox equivalents of myricetin 0.5 μM (●) and 0.75 μM (○).

As can be seen in Fig. 6, at an HP-β-CDs concentration of 1.75 mM, the concentration at which almost all flavonols were complexed, kaempferol presented the highest antioxidant activity (Fig. 6, black bars) and myricetin the lowest, as in the absence of HP-β-CDs. It is important to note that there was little difference between the antioxidant activities observed for the tree flavonols when all of them were totally complexed in HP-β-CDs. However,

Table 1
Complexation constant (K_c), aqueous solubility (S_0), free flavonol ([flavonol]$_f$) and antioxidant activity (AA) normalised with respect to the Trolox measurement.

Flavonol	K_c (M^{-1})	S_0 (μM)	[Flavonol]$_f$ (μM)			AA normalised respect to Trolox (μM TE/μM flavonol)	
			0 mM HP-β-CDs	0.25 mM HP-β-CDs	1.75 mM HP-β-CDs	0 mM HP-β-CDs	1.75 mM HP-β-CDs
Kaempferol	1411	4	0.75	0.556	0.217	11.9	15.1
Quecetin	900	26	0.75	0.612	0.291	10.4	13.5
Myricetin	850	62	0.75	0.619	0.3	3.6	11.2

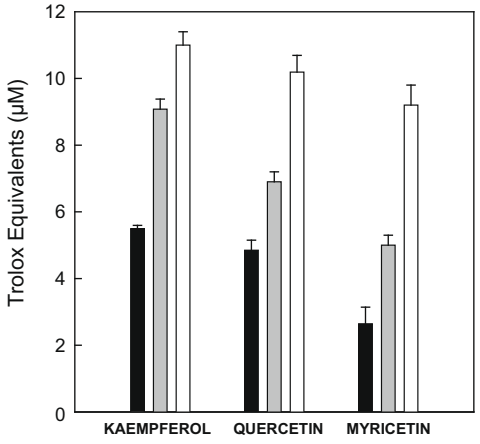

Fig. 6. Effect of HP-β-CDs concentration in the μM Trolox equivalents of kaempferol, quercetin and myricetin alone, 0.75 μM (black bars) and in the presence of HP-β-CDs 0.25 mM (grey bar) or HP-β-CDs 1.75 mM (white bars).

at 0.25 mM HP-β-CDs, a concentration at which not all the flavonol is complexed, the differences between the antioxidant activities of three flavonols were greater (Fig. 6, grey bars). As can be seen in Fig. 6, the increase in antioxidant activity at 0.25 mM HP-β-CDs was close to the increase observed at 1.75 mM in the case of kaempferol, while in the case of quercetin and myricetin, the antioxidant activity at 0.25 mM HP-β-CDs was much lower than at 1.75 mM. This can be explained taking by the higher K_c of kaempferol is compared with quercetin or myricetin.

At flavonol concentrations studied in this paper (up to 0.75 μM), kampferol, quercetin and myricetin were soluble in the reaction medium (Table 1). Therefore, the increase in μM Trolox equivalent observed in Figs. 3–5 when increasing CDs concentration were added to the reaction medium, cannot be attributed to the solubilisation of flavonols, as has been previously described for lycopen (Bangalore, McGlynn, & Scott, 2005) and α-tocopherol (Huang, Ou, Hampsch-Woodill, Flanagan, & Deemer, 2002). In all cases, when the flavonols were complexed, HP-β-CDs acted as a reservoir of controlled substrate dosage protecting flavonols against their rapid oxidation by AAPH radical. So, their antioxidant activity was prolonged and only reached a maximum when all the flavonols had been complexed (a minimum quantity of free flavonols was always present because the complexation phenomenon is a dynamic equilibrium).

To complete the study, an experiment was carried out in which increasing concentrations of each flavonol were added to the reaction medium at a fixed HP-β-CDs concentration (1.75 mM). In this case, the values of antioxidant activity normalised with respect to Trolox increased in all cases (Table 1).

In order to clarify whether the increase in antioxidant activity of flavonols was due to the protection afforded by HP-β-CDs, the free flavonol concentrations ($[\text{flavonols}]_f$) at each bar of Fig. 6, were calculated using the K_c value previously obtained for each flavonol (Table 1) and the following Eq. (2) (Lucas-Abellán et al., 2008):

$$[\text{flavonols}]_f = (-([\text{CD}]_t K_c - [\text{flavonols}]_t K_c + 1) + \sqrt{([\text{CD}]_t K_c - [\text{flavonols}]_t K_c + 1)^2 + 4K_c[\text{flavonols}]_t})/2K_c \quad (2)$$

where $[\text{flavonols}]_t$ is total flavonol and $[\text{CD}]_t$ is total CD.

As can be seen in Table 1, in the absence of HP-β-CDs, the concentration of free flavonol was the same in all cases. However, as shown in Fig. 6, kaempferol presented the highest antioxidant activity, due to its chemical structure. Moreover, as HP-β-CDs concentration increased, free flavonol concentration decreased in all cases, kaempferol being the most complexed flavonol, due to its higher K_c (Table 1). Due to the similar K_c value for quercetin and myricetin, both flavonols presented similar free concentrations at a fixed HP-β-CDs concentration, (Table 1). However, as can be seen in Fig. 6, quercetin presented greater antioxidant activity, as in the absence of HP-β-CDs, due to its chemical structure.

In summary, the antioxidant activity of kaempferol, quercetin and myricetin increased when as they are complexed in HP-β-CDs. Kaempferol presented the highest antioxidant activity both in the absence and presence of HP-β-CDs, while myricetin showed the lowest antioxidant activity.

information is available on the effect of 1-MCP treatment on physiological and biochemical responses, towards, for example, antioxidant enzymes and lipid peroxidation, as well as the alteration of nutritional quality in broccoli florets. To date, there are no reports on the effect of 1-MCP treatment on glucosinolates of products including broccoli florets. The objective of the present study was to investigate the effect of treatment of broccoli florets with 2.5 μl/l 1-MCP on shelf life, visual quality, physiological and biochemical responses and health-promoting compounds during storage at 20 °C.

2. Materials and methods

2.1. Plant material

Broccoli heads (*Br. oleracea* var. *italica* cv. Lvxiong) of prime quality were harvested in the early morning from the greenhouse of Zhejiang University (Hangzhou, China), top-iced and then transported to the Postharvest Laboratory of Vegetable Institute, Zhejiang University within 10 min. Broccoli heads with a diameter ranging from 15 to 20 cm were chosen, and the inner branches (with florets having stalks of approximately 2 cm) were then cut from these heads for experimentation. The florets were surface-sterilised by washing with a solution of 50 mg/kg NaOCl for 1 min and dried using a household model spin drier for 2 min. The florets were then randomly distributed into the required number of treatment units.

2.2. 1-MCP and storage treatments

Broccoli florets were treated with air (control), 0.1, 1, 2.5, 5 and 10 μl/l 1-MCP for 6 h at 20 °C. The broccoli florets were placed in plastic bags and 1-MCP was injected, then the injection pore of the bags was immediately sealed and the samples were stored for 6 h at 20 °C. After treatment, all experimental units were stored according to randomised complete block design in incubation chamber with 95% RH at 20 °C. The shelf life was then determined. The concentration of 2.5 μl/l 1-MCP was selected for further study.

There were three replicates per treatment with 200 g of broccoli florets per replicate. Shelf life, visual quality and visual colour scale rating were made in replicates of 10 florets taken daily. The treated broccoli florets were used for determination of chlorophyll, antioxidant enzymes, polyphenol oxidase (PPO, EC 1.14.18.1), lipoxygenase (LOX, EC 1.13.11.12), malondialdehyde (MDA), ascorbic acid, total carotenoids and glucosinolates.

2.3. Determination of shelf life

Shelf life was determined according to previous reports (Ku & Wills, 1999; Xu, Guo, Yuan, Yuan, & Wang, 2006). The time for quality to decline to 30% yellowing in florets was assigned as their shelf life.

2.4. Determination of visual colour rating scale and visual quality

Visual quality was determined as previously described (Jia et al., 2009). Visual quality of florets was scored on a 1–9 scale, where 9 refers to excellent and fresh appearance, 7 to good, 5 to fair (limit of marketability), 3 to fair (useable but not saleable), and 1 to unusable. Intermediate numbers were assigned where appropriate. Colour of broccoli florets was visually rated using colour rating scales 1–5, as described by Rangkadilok et al. (2002), where 1 refers to dark green, 2 to trace yellow (10% yellow), 3 to slightly yellow (25% yellow), 4 to medium yellow (50% yellow), and 5 to completely yellow (100%).

2.5. Determination of chlorophyll content

Florets (0.5 g) were ground and extracted in 10 ml of 80% acetone, centrifuged at 3000 rpm for 10 min at room temperature, and then residue was removed. Total chlorophyll content was determined by reading the absorbance at 652 nm with a spectrophotometer. Total chlorophyll content was estimated as mg/g fresh weight (FW).

2.6. Enzyme assay

Broccoli florets (0.5 g) were homogenised with 5 ml, 50 mM phosphate buffer (pH 7.8) in an ice-water bath, and then centrifuged at 8000 rpm for 20 min at 4 °C. The supernatant was collected and used for enzyme assay.

Total superoxide dismutase (SOD, EC 1.15.1.1), catalase (CAT, EC 1.11.1.6) and peroxidase (POD, EC 1.11.1.7) activities were assayed according to the method of Toivonen and Sweeney (1998). SOD activity was determined based on the ability of SOD to inhibit the reduction of nitroblue tetrazolium. The absorbance was monitored at 560 nm. One unit of SOD is the amount of extract that gives 50% inhibition of the reduction rate of NBT. CAT activity was determined by monitoring the enzyme-catalysed decomposition of H_2O_2 by potassium permanganate. One unit of CAT activity was defined as the amount of H_2O_2 (μmol) depleted per min at 240 nm. POD activity was measured based on the determination of guaiacol oxidation at 470 nm by H_2O_2. The change in absorbance at 470 nm was followed every 30 s by spectrophotometer. PPO activity was assayed by measuring the increase in absorbance at 420 nm with 100 mM catechol solution as substrate, according to Kumar, Mohan, and Murugan (2008). One unit of enzyme activity was defined as the amount of enzyme that caused an increase in absorbance of 0.001 min^{-1}. LOX activity was determined according to the method of Anese and Sovrano (2006) with minor changes. The substrate solution was prepared by mixing 20 μl of linoleic acid, 48 ml of H_2O, 2 ml of 0.1 N NaOH and 10 μl of Tween 20. Each test contained 0.1 ml enzymatic extracts, 0.15 ml substrate solution and 1.25 ml phosphate buffer (pH 5.7). One unit of LOX is defined as the amount of enzyme which caused an increase in absorption at 234 nm of 0.1 min^{-1} (3 min period).

The SOD, CAT, POD, PPO and LOX activities were estimated by units/mg protein. Protein content of samples was determined by using Folin phenol reagent (Lowry, Rosebrough, Farr, & Randall, 1951).

2.7. Malondialdehyde (MDA) determination

MDA was measured by 2-thiobarbituric acid reaction. One gram fresh weight of broccoli florets sample was homogenised in 5 ml of 0.1% (w/v) TCA. The homogenate was centrifuged at 12,500 rpm for 20 min. One millilitre of supernatant was precipitated with 4 ml 20% TCA containing 0.5% (w/v) 2-thiobarbituric acid. The mixture was heated in a water-bath shaker at 95 °C for 30 min and quickly cooled in an ice-bath. The absorbance was read at 532 nm after centrifugation at 3000 rpm for 10 min and the value for non-specific absorption at 600 nm was subtracted. The MDA content was calculated using its extinction coefficient of 155 mM^{-1} cm^{-1}. The amount of MDA was estimated as μmol/g FW.

2.8. Total carotenoids determination

Five grams of florets were ground and extracted with a mixture of acetone and petroleum ether (1:1, v/v) repeatedly using the mortar and pestle until a colourless residue was obtained. After washing several times with water, the upper phase was collected and combined as crude extract. The extracts were made up to a

known volume with petroleum ether. Total carotenoids content was determined by reading the absorbance at 451 nm with a spectrophotometer. Total carotenoids content was estimated as mg/100 g FW.

2.9. Ascorbic acid determination

Twenty grams of frozen broccoli florets were ground to a fine powder at liquid nitrogen temperature, extracted twice with 20 ml of 1.0% (w/v) oxalic acid and centrifuged for 20 min at 3000 rpm. The combined aqueous extract was filtered under vacuum in a volumetric flask. Each sample was filtered through a 0.45 μm cellulose acetate filter prior to injection. HPLC analysis of ascorbic acid was carried out using a Shimadzu (Tokyo, Japan) mode VP liquid chromatograph with a dual-wavelength spectrophotometer. Samples (5 μl) were separated at room temperature on a Waters Spherisorb C18 column (150 × 4.6 mm id; 5 μm particle size) (Milford, MA) using a solution of 0.05 M KH_2PO_4 at a flow rate of 1.0 ml/min. The amount of ascorbic acid was calculated from absorbance at 254 nm, using ascorbic acid as a standard. Results were expressed as mg/100 g FW.

2.10. Glucosinolate assay

Freshly harvested and stored broccoli florets were frozen in liquid N_2 and kept in polyethylene bags at −70 °C until freeze-drying. Freeze-dried broccoli samples were stored in sealed polyethylene bags at 4 °C until analysis. Glucosinolates were extracted and analysed as previously described with minor modifications (Wang, Grubb, & Abel, 2002; Xu et al., 2006). Freeze-dried samples (25 mg) were boiled in 1 ml water for 10 min. After recovery of the liquid, the residues were washed with water (1 ml), and the combined aqueous extract was applied to a DEAE-Sephadex A-25 (40 mg) column (pyridine acetate form) (GE Healthcare, Piscataway, NJ). The column was washed three times with 20 mM pyridine acetate and twice with water. The glucosinolates were converted into their desulfo analogues by overnight treatment with 100 μl of 0.1% (1.4 units) aryl sulfatase, and the desulfoglucosinolates were eluted with 2 × 0.5 ml water. HPLC analysis of desulfoglucosinolates was carried out using a Shimadzu mode VP liquid chromatograph with a dual-wavelength spectrophotometer. Samples (100 μl) were separated at 30 °C on a Waters Spherisorb C18 column (150 × 4.6 mm id; 5 μm particle size) using acetonitrile and water at a flow rate of 1.0 ml/min. The procedure employed isocratic elution with 1.5% acetonitrile for the first 5 min; a linear gradient to 20% acetonitrile over the next 15 min, followed by isocratic elution with 20% acetonitrile for the final 10 min. Absorbance was measured at 226 nm and 280 nm. *ortho*-Nitrophenyl-β-D-galactopyranoside (Sigma) was used as an internal standard for HPLC analysis. Concentrations of individual glucosinolates were determined according to published response factors. The integrated area of the desulfo-4-methylsulfinylbutyl glucosinolate peak was converted to a molar amount under the assumption that this compound has a molar extinction coefficient at 226 nm equal to that of sinigrin.

2.11. Statistical analyses

Statistical analysis was performed using the SPSS package program version 11.5 (SPSS Inc., Chicago, IL). Data was analysed by analysis of variance (ANOVA model one-way). Sources of variation were storage duration and treatments. The means were compared by the least significant differences (LSD) test at a significance level of 0.05. The values are reported as means with their standard deviations for all results.

3. Results

3.1. Effect of 1-MCP treatment on shelf life

All 1-MCP treatments greatly extended the shelf life of broccoli florets, the most significant being broccoli florets treated with 2.5 μl/l 1-MCP (Fig. 1). The shelf life of broccoli florets treated with 2.5 μl/l 1-MCP was extended to two times that of control florets (2.5 days at 20 °C). Based on the results of shelf life studies, 1-MCP at a dose of 2.5 μl/l was selected, to analyse the effect of 1-MCP treatment on visual and nutritional quality of broccoli florets.

3.2. Effect of 1-MCP treatment on colour, visual quality and chlorophyll degradation

There was yellowing and rapid loss in visual quality occurred in control florets during storage at 20 °C. 1-MCP treatment effectively inhibited this yellowing and visual quality deterioration of broccoli florets. A significant difference in colour and visual quality between 1-MCP treatment and control was observed after 1 days storage at 20 °C (Fig. 2). Chlorophyll content decreased in both control and 1-MCP-treated broccoli florets during storage. However, chlorophyll degradation rate was significantly lower in treated broccoli florets than in control florets (Fig. 2). After storage at 20 °C for 5 days, 1-MCP-treated broccoli florets contained 67% of the initial chlorophyll content, while control florets contained only 24% of initial value.

3.3. Effect of 1-MCP treatment on SOD, CAT, POD and PPO activities

SOD activity in both the control and treatment declined during the first 3 days of storage, significantly increased during the following day and then fell again at the 5th day. CAT activity in both the control and treatment showed the same trend as SOD during the first 3 days of storage, and then increased steadily to the 5th day. 1-MCP treatment significantly improved the SOD and CAT activities, which made the SOD and CAT activities always higher in the treatment than in control across the whole storage period (Fig. 3). POD activity increased in both control and 1-MCP treatment during the first day, decreased over the next 3 days and then

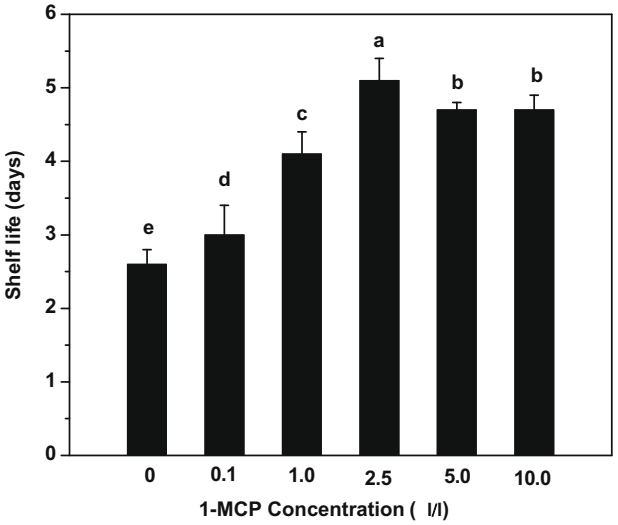

Fig. 1. Shelf life of broccoli florets treated with different concentrations of 1-MCP during storage at 20 °C. Each data is the mean of three replicate samples. Values not sharing a common letter are significantly different at $p < 0.05$.

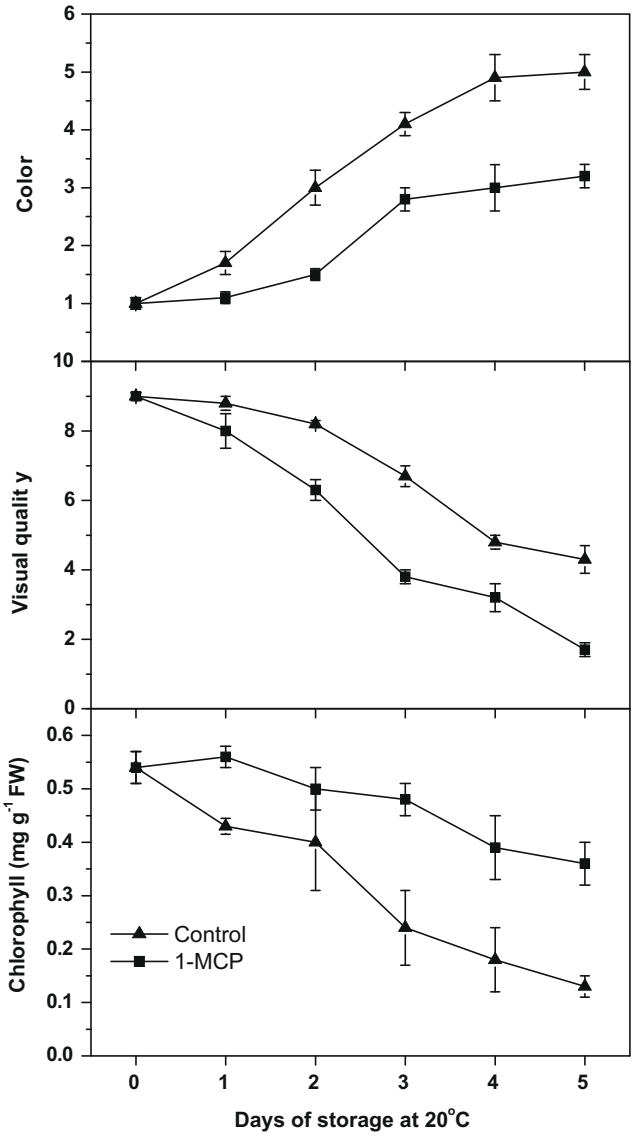

Fig. 2. Changes of colour, visual quality and chlorophyll content in broccoli florets. Florets were treated with air (control) and 2.5 μl/l 1-MCP for 6 h at 20 °C. Florets were stored at 20 °C for 5 days. Each data point is the mean of three replicate samples. Vertical bars represent standard deviation of the mean.

increased again. The activity of POD in treated broccoli florets was significantly higher than in the control florets during 5 days storage at 20 °C (Fig. 3). PPO activity in both control and treatment markedly increased during the initial 4 days of storage and then decreased at day 5. However, the florets treated with 1-MCP possessed relatively lower PPO activity in comparison with the control florets during storage (Fig. 3).

3.4. Effect of 1-MCP treatment on MDA content and LOX activity

The initial content of MDA was 1.54 μmol/g FW, and no significant difference in MDA content was observed between control and 1-MCP treatment during the first day of storage; subsequently a larger rise in MDA content was found in control florets than in florets treated with 2.5 μl/l 1-MCP from the second day at 20 °C (Fig. 4). The results indicated that 1-MCP treatment could inhibit the rise of MDA content. Similarly, the rise of LOX activity during storage was inhibited by the 1-MCP treatment (Fig. 4).

3.5. Effect of 1-MCP treatment on the contents of ascorbic acid and total carotenoids

The contents of ascorbic acid and total carotenoids in both control and 1-MCP treated broccoli florets declined progressively, with a higher level of both in 1-MCP treated florets than in the control after 5 days of storage at 20 °C. The loss of ascorbic acid and total carotenoids were 19.4% and 30.0%, respectively, in 1-MCP-treated florets, while losses of as much as 57.8% and 50.0% occurred, respectively, in control florets over 5 days of storage at 20 °C. The contents of ascorbic acid and total carotenoids were 2-fold and 1.3-fold higher, respectively, in 1-MCP treatment florets than in control florets on the 5th day (see Fig. 5).

3.6. Effect of 1-MCP treatment on total and individual glucosinolates

The total glucosinolate content as well as the individual aliphatic (methylsulfinylalkyl: glucoiberin, glucoraphanin and progoitrin) and indole (glucobrassicin, neoglucobrassicin and 4-methoxyglucobrassicin) glucosinolate contents were quantitatively determined in broccoli florets over 5 days of storage (Fig. 6). The predominant aliphatic glucosinolates in broccoli florets were 4-methylsulfinylbutyl glucosinolate (glucoraphanin), followed by 3-methylsulfinylpropyl glucosinolate (glucoiberin), while the predominant indole glucosinolates were 3-indolylmethyl glucosinolate (glucobrassicin) and 1-methoxy-3-indolymethyl glucosinolate (neoglucobrassicin).

The change of the total aliphatic glucosinolates content was not significant in both control and 1-MCP treatment over the first two days storage, then a rapid decrease of total aliphatic glucosinolates content was observed in florets of control and 1-MCP treatment. However, the decrease rate in treated florets was significantly lower than in control florets. The total aliphatic glucosinolates was reduced by 71.2% after 5 days of storage at 20 °C in control florets, but only reduced by 51.3% in florets treated with 2.5 μl/l 1-MCP (Fig. 6). Amongst the individual aliphatic glucosinolates, glucoraphanin, progoitrin and glucoiberin showed similar trends to total aliphatic glucosinolates in both control and treatment during 5 days of storage at 20 °C. The loss rates of glucoraphanin, progoitrin and glucoiberin in broccoli florets treated with 1-MCP (56.4%, 23.6% and 32.4%, respectively) were much lower than those in control florets (77.7%, 48.6% and 42.7%, respectively) at the end of the 5 days storage period (Fig. 6).

The total indole glucosinolates content decreased during 5 days storage at 20 °C, although lower losses of indole glucosinolates than aliphatic glucosinolates in both control and treatment were detected. The total indole glucosinolates decreased by 37.0% in the control, but only 23.7% in the treatment (Fig. 6). The decrease in total indole glucosinolates was predominantly due to the progressive degradation of glucobrassicin and neoglucobrassicin in both control and treatment. However, the decrease rate of glucobrassicin and neoglucobrassicin in the treatment (26.7% and 20.6%, respectively) was lower than in the control (41.5% and 33.2%, respectively) (Fig. 6).

4. Discussion

The effect of 1-MCP treatment on shelf life, visual quality, antioxidant enzymes and health-promoting compounds in broccoli florets was investigated in the present study. The results showed that the shelf life of broccoli florets treated with various concentrations of 1-MCP was significantly improved. This is consistent with the findings of Ku and Wills (1999), Fan and Mattheis (2000), Able, Wong, Prasad and O'Hare (2002), and Forney, Song, Fan, Hildebrand, and Jordan (2003). However, Ku and Wills (1999) found that

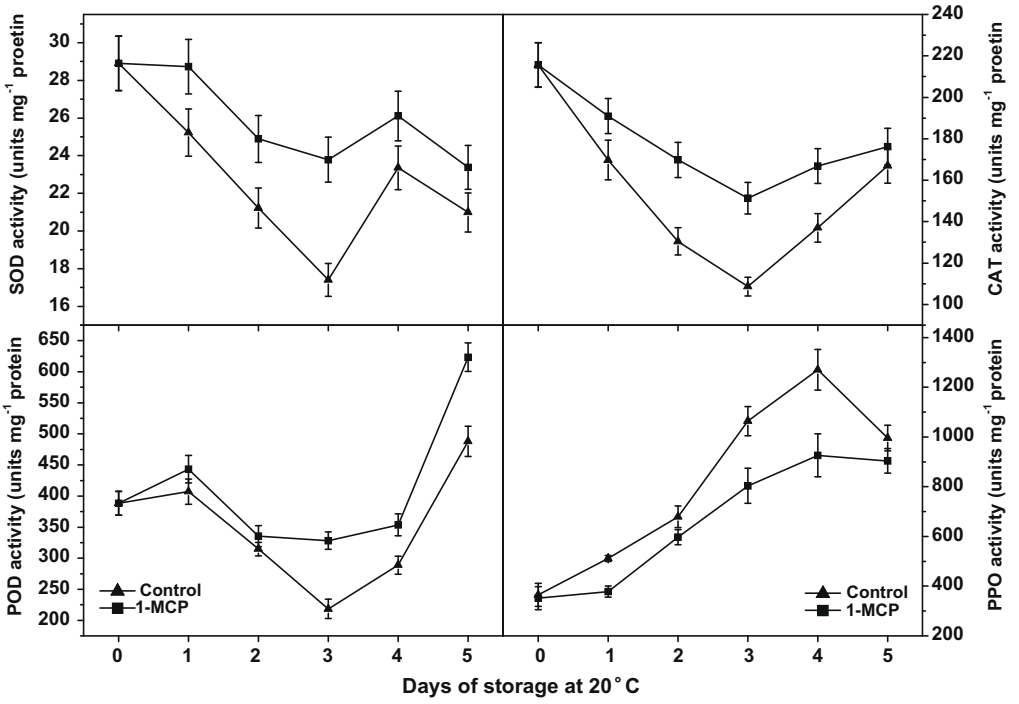

Fig. 3. Changes of superoxide dismutase (SOD), peroxidase (POD), catalase (CAT) and polyphenol oxidase (PPO) activities in broccoli florets. Florets were treated with air (control) and 2.5 μl/l 1-MCP for 6 h at 20 °C. Florets were stored at 20 °C for 5 days. Each data point is the mean of three replicate samples. Vertical bars represent standard deviation of the mean.

the higher the concentration of 1-MCP was (ranging from 0.02 to 50 μl/l), the greater was the storage life of broccoli florets, but also suggested that a lower concentration range (1–10 μl/l) needs to be used to avoid toxicity. Able et al. (2002) showed that a concentration of 12 μl/l 1-MCP was considered optimal for extension of the shelf life of broccoli florets. Our study showed that the extension of shelf life was most significant in broccoli florets treated with 2.5 μl/l 1-MCP. This discrepancy could be due to different cultivars and temperatures used.

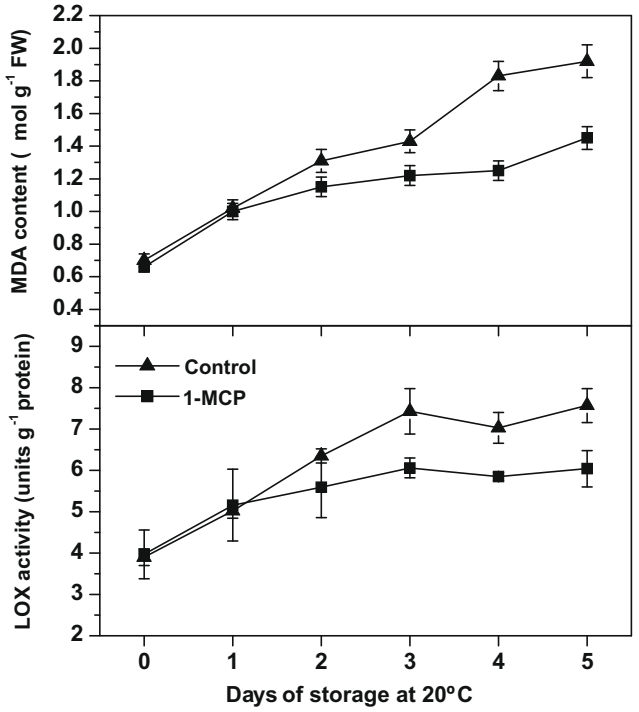

Fig. 4. Change of malondialdehyde (MDA) content and lipoxygenase (LOX) activity in broccoli florets. Florets were treated with air (control) and 2.5 μl/l 1-MCP for 6 h at 20 °C. Florets were stored at 20 °C for 5 days. Each data point is the mean of three replicate samples. Vertical bars represent standard deviation of the mean.

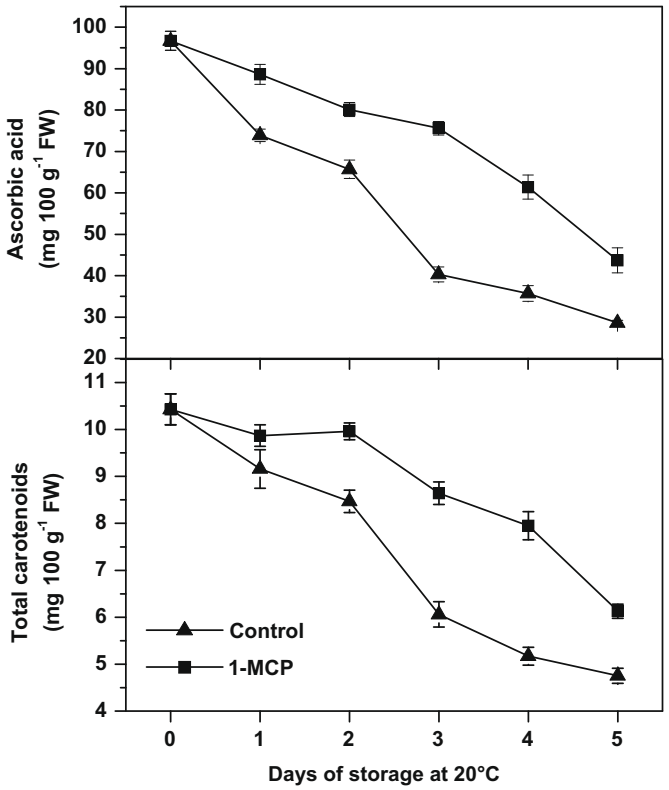

Fig. 5. Changes of ascorbic acid and total carotenoids in broccoli florets. Florets were treated with air (control) and 2.5 μl/l 1-MCP for 6 h at 20 °C. Florets were stored at 20 °C for 5 days. Each data point is the mean of three replicate samples. Vertical bars represent standard deviation of the mean.

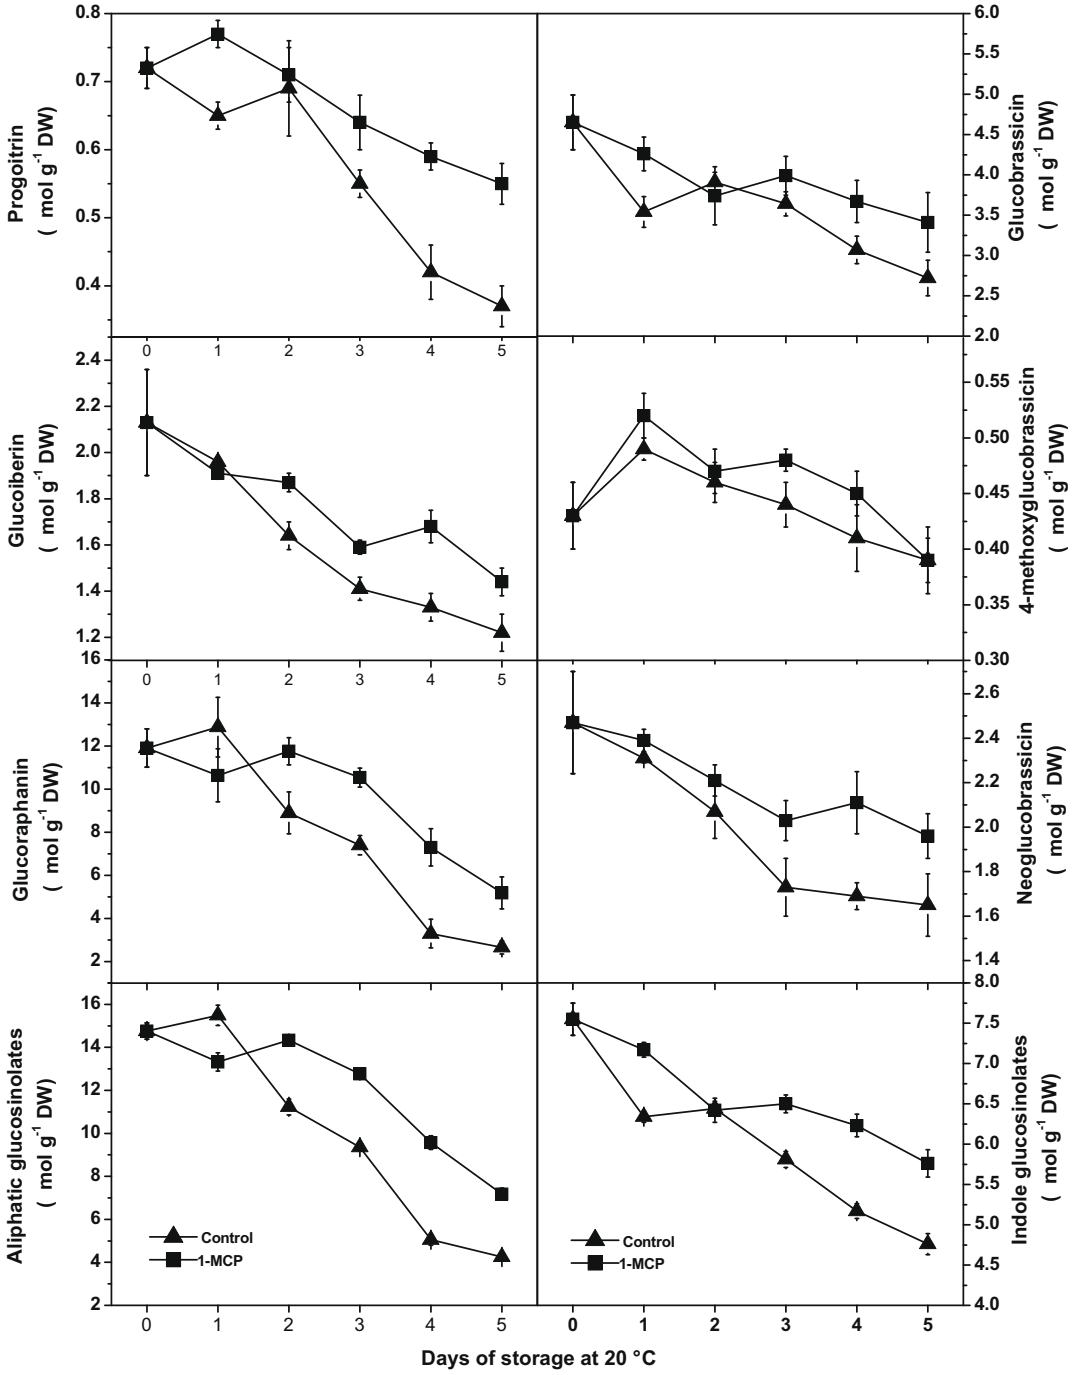

Fig. 6. Changes of total aliphatic, total indole and individual glucosinolates in broccoli florets. Florets were treated with air (control) and 2.5 μl/l 1-MCP for 6 h at 20 °C. Florets were stored at 20 °C for 5 days. Each data point is the mean of three replicate samples. Vertical bars represent standard deviation of the mean.

The green colour of broccoli is an important commercial quality index. Degreening of broccoli after harvest occurs rapidly during storage at 20 °C (Wang, 1977). Treatment of broccoli with 1-MCP resulted in delayed loss of green colour and delayed onset of yellowing (Fan & Mattheis, 2000; Gong & Mattheis, 2003; Ku & Wills, 1999). Our study supported the evidence that treatment of broccoli florets with 2.5 μl/l 1-MCP inhibited chlorophyll degradation, yellowing and quality deterioration.

Senescence is considered to be associated with the defence system, including antioxidant enzymes and antioxidants. Antioxidant enzymes (SOD, CAT and POD) are considered to be important in the oxy-radical detoxification process in plant tissues (Han et al., 2006; Mittler, 2002). Toivonen and Sweeney (1998) reported that antioxidant protection offered by SOD and POD is important for the retention of green colour in broccoli flower buds, and the increases in SOD, POD and CAT were likely responses to the increases in oxygen radical production in broccoli, which could subsequently lead to yellowing. Postharvest treatment could change the activity of antioxidant enzymes in vegetables and fruits. Ethanol vapour treatment leads to higher activities of SOD, POD and CAT in broccoli florets during storage, as compared with the control (Han et al., 2006). 1-MCP treatment has also been shown to increase the activities of antioxidant enzymes in mango (Singh & Dwivedi, 2008) and *Yali* pear (Fu, Cao, Li, Lin, & Jiang, 2007). In our study,

it was found that SOD, CAT and POD activities were consistently higher in the 1-MCP treatment than in the control during 5 days storage at 20 °C. It was suggested that the increases in the activities of SOD, CAT and POD were generally a consequence of the system ability to delay senescence (Toivonen & Sweeney, 1998). From the results of our study, it can be hypothesised that 1-MCP might delay the senescence of broccoli florets by means of regulating the antioxidant enzymes system. The specific mechanism of 1-MCP in delaying the senescence of broccoli florets and its relationship with the antioxidant enzymes still remain to be further investigated. PPO represents a marker compound for the extent of oxidation and is responsible for browning in fresh-cut fruits and vegetables. 1-MCP treatment has been shown to reduce browning, which was associated with reduced PPO activity in avocados (Watkins, 2006). It is suggested in the present study that 1-MCP treatment could reduced the browning of broccoli florets by reduction of PPO activity.

The thiobarbituric acid-reactive substance MDA is the product of membrane peroxidation and has been used as a direct indicator of membrane injury. According to Zhuang, Hildebrand, and Barth (1995, 1997), postharvest senescence of broccoli is correlated with lipid peroxidation (MDA content), leading to cell-membrane disintegration. LOX are regarded to be responsible for membrane degradation because they catalyse the peroxidation of polyunsaturated fatty acids, producing hydroperoxy fatty acids (Macri, Braidot, Petrusa, & Vianello, 1994). It was found in our study that 1-MCP treatment could inhibit the increase of lipid peroxidation (MDA content) and LOX activity in broccoli florets, compared with control florets, during postharvest storage.

Vitamin C is one of the most important nutritional components in broccoli, as well as in many other horticultural crops, and has many biological activities in the human body. The concentration of vitamin C/ascorbic acid (the predominant form of vitamin C) in broccoli generally decreased during storage and the loss rate during storage could be lowered by postharvest handling (Serrano et al., 2006; Vallejo et al., 2003). In our study, the control florets lost more than half of their initial ascorbic acid after 5 days of storage, while these losses were minimised in those florets treated with 1-MCP. The present study showed that 1-MCP treatment resulted in significantly better retention of ascorbic acid during postharvest storage. Carotenoids have been extensively studied for their potential protection against numerous cancers. However, limited information is available on the effect of postharvest handling on carotenoids in broccoli. In the present work, total carotenoids in both control and treated florets decreased during 5 days of storage. However, treatment of broccoli florets with 2.5 μl/l 1-MCP significantly lowered the magnitude of total carotenoids loss during postharvest storage.

Glucosinolates are among the most important health-promoting natural products in broccoli florets. They are known to contribute to the anticarcinogenic activity of broccoli. Several hydrolysis products of methylsulfinyl aliphatic glucosinolates, such as glucoraphanin, in broccoli are considered to reduce the risk of cancers. Sulforaphane (derived from glucoraphanin) is the most potent, naturally-occurring inducer of Phase 2 enzymes that detoxify carcinogens (Brown et al., 2002). The same is true for breakdown products of indole glucosinolates, notably glucobrassicin (Weng, Tsai, Kulp, & Chen, 2008). However, higher losses of glucoraphanin (or sulforaphane) and other glucosinolates have been reported after harvesting (Cieslik, Leszczynska, Filipiak-Florkiewicz, Sikora, & Pisulewski, 2007; Jia et al., 2009; Rangkadilok et al., 2002; Vallejo et al., 2003). In fact, control florets lost over half of their initial glucosinolates after 5 days storage at 20 °C (Fig. 6). Broccoli florets suffer a series of stresses after harvest (washing/pre-cutting) and during storage, which might trigger complex metabolism of glucosinolates. Cutting of broccoli heads to broccoli florets brings myrosinase in contact with glucosinolates, which might lead to a high degree of glucosinolate hydrolysis. On the other hand, it might also induce the biosynthesis of glucosinolates during 1-MCP treatment and storage. The glucosinolate level of stored broccoli florets is a reflection of two opposing mechanisms, hydrolysis of glucosinolates by myrosinase and induction of glucosinolate biosynthesis by an unknown mechanism. The elevated level of some individual glucosinolates (progoitrin, glucoraphanin, and 4-methoxyglucobrassicin) in broccoli florets during the first day of storage under control or 1-MCP treatment was observed in our study (Fig. 6). The predominance of the induction of biosynthesis of these glucosinolates might be the cause of the increase of the content under these cases during storage, though the specific mechanism involved remains to be further elucidated.

Postharvest handing is required to maintain glucosinolate content in broccoli florets and low temperature and high relative humidity are effective conditions (Jia et al., 2009; Jones et al., 2006; Rodrigues & Rosa, 1999). The present study showed that 1-MCP treatment leads to better retention of glucosinolates, in comparison with the control, during storage at 20 °C, which suggested that 1-MCP treatment is also an effective method to maintain glucosinolate content. To the best of our knowledge, this is the first report on the effect of 1-MCP treatment on the glucosinolate content of foods. The mechanism by which broccoli florets treated with 2.5 μl/l 1-MCP inhibited the decrease rate of glucosinolate content compared with the control is not clear. However, previous studies and the data from the current study could provide possible explanations. Firstly, as mentioned above, 1-MCP treatment inhibited the increase of MDA as compared with the control. MDA is the product of membrane peroxidation, and could damage the structure and integrity of membrane during the senescence of broccoli florets. Thus, it can be hypothesised that 1-MCP could inhibit probable loss of membrane integrity and mixing of glucosinolates with myrosinase, leading to less glucosinolates hydrolysis. Furthermore, the biosynthesis of secondary metabolites, such as glucosinolates, is thought to be part of the plant defensive mechanism, and ethylene seems to play a role in this process (Mikkelsen et al., 2003). On the other hand, 1-MCP is well-known as an ethylene inhibitor and ethylene production was decreased by 1-MCP treatment. It is possible that the blockage of ethylene action by 1-MCP treatment favoured the biosynthesis of glucosinolates or inhibited some ethylene-related degradative pathways. Further studies are warranted to provide a clearer understanding of the effect of 1-MCP treatment on glucosinolate content.

It was reported that aliphatic glucosinolates were generally more stable than indole glucosinolates during storage and processing of Brassica vegetables (Jia et al., 2009; Rungapamestry, Duncan, Fuller, & Ratcliffe, 2007). Boiling of these vegetables leads to inactivation of myrosinase and partial decomposition of thermolabile glucosinolates, especially indole glucosinolates (Cieslik et al., 2007). The observation that indole glucosinolates were preserved better than aliphatic glucosinolates under 1-MCP treatment in the current study suggests that 1-MCP treatment might have different effects on the stability of myrosinase and individual glucosinolates metabolites, though the mechanism involved remains to be further investigated.

Previous studies have found that glucoraphanin, the predominant glucosinolate in broccoli, dramatically decreased at room temperature (Rodrigues & Rosa, 1999). Our current study showed similar results. On the other hand, 1-MCP treatment significantly inhibited the loss rate of glucoraphanin and glucobrassicin. In this regard, it is likely that broccoli florets treated with 1-MCP will be preferable for human consumption than control broccoli florets.

As high temperatures are often encountered during the handling, transportation and retail marketing of broccoli, they have become the main cause of postharvest loss of broccoli, especially in developing countries. The use of 1-MCP can reduce the require-

ment for low temperature while still extending the shelf life, and reducing the loss of visual and nutritional quality. It has tremendous potential for maintaining broccoli florets quality during storage at relatively higher temperature.

In conclusion, 2.5 μl/l 1-MCP treatment significantly extended the shelf life, reduced the postharvest deterioration, retarded the chlorophyll degradation and inhibited the increase of MDA content and the activities of PPO and LOX of broccoli florets. The activities of SDO, POD and CAT in florets treated with 1-MCP were higher than those in control florets. 1-MCP treatment reduced the losses of total carotenoids, ascorbic acid and total aliphatic, total indole and individual glucosinolates in broccoli florets when compared to those in the control. These results indicated that 1-MCP treatment could be a good candidate for extending shelf life, maintaining the visual quality and reducing the loss of health-promoting compounds, particularly chemopreventive glucosinolates in broccoli florets stored at 20 °C.

extracts (~6–10% of coffee composition) but not in roasted (~0.01% of coffee composition) (Farah, Monteiro, Calado, Franca, & Trugo, 2006) was not considered. Furthermore, a few natural active substances in coffee of low molecular weight such as trigonelline, caffeic acid and 5-caffeoylquinic acid (139, 180 and 354 Da, respectively) have shown activity against the growth of *Legionella pneumophila* (Furuhata, Dogasaki, Hara, & Fukuyama, 2002), Enterobacteria (Almeida et al., 2006) and *S. mutans* (Almeida et al., 2004).

In view of existing contradictory results and of the persistent need for new strategies for caries control, the aim of the present study was to verify if natural coffee compounds contribute to the antibacterial activity against *S. mutans*, correlating results of minimum inhibitory concentration (MIC), minimum bactericidal concentration (MBC), biofilm inhibition concentration and biofilm reduction concentration assays with the concentration of major bioactive compounds in various coffee extracts with different chemical composition. Additionally, this study aimed at investigating the effect of species, decaffeination and roasting on such antibacterial effect.

2. Materials and methods

2.1. Coffee chemical compounds

5-Caffeoylquinic acid (chlorogenic acid, 5-CQA), caffeic acid, ferulic acid, trigonelline, nicotinic acid and caffeine (Sigma–Aldrich, St. Louis, MO, USA) solutions at 1 mg/mL were prepared using Milli-Q purified water (Millipore Corporation, Billerica, MA, USA). All standard solutions were filtered through sterile filter paper discs (TPP, 0.22 μm membrane, Zurich, Switzerland) prior to microbiological tests.

2.2. Coffee samples and aqueous extracts

Regular *C. arabica* cv. Yellow Bourbon and *C. canephora* cv. Conillon beans were harvested, respectively, in Minas Gerais and Espírito Santo, Brazil (Group 1). One blend of *C. arabica* harvested in São Paulo and a second sample of *C. canephora* cv. Conillon harvested in Espírito Santo were used in both regular and decaffeinated forms (Group 2). Decaffeination was performed using water and dichloromethane (Cocam, Brazil). Samples from Group 2 were of inferior quality comparing to those of Group 1.

Samples were roasted in a commercial spouted bed roaster (I-Roast, Gumee, IL, USA), operating at a maximum temperature of 220 °C, for 6, 7, 8, 13 and 15 min. The Roast Colour Classification system (Agtron-SCAA, Reno, NV; 1995), the percent weight loss values on a wet basis (Farah et al., 2005, 2006) and the instrumental colour (Colourgap 1A, Leogap-Probat, Brazil) were used as tools for roasting degree determination. Green and roasted coffee beans were ground in a laboratory-scale mill to pass through a 0.46 mm sieve.

Coffee extracts at 10% were obtained by a coffee brewing procedure commonly used in Brazil, percolating 100 mL of pre-boiling (95 °C) Milli-Q purified water through 10 g of green or roasted coffee samples. The extracts were filtered through Whatman #1 qualitative filter paper (Whatman, Maidstone, UK). Prior to microbiological tests, all coffee extracts were re-filtered through sterile filter papers (TPP, 0.22 μm membrane) and aliquots of the filtered extracts were reserved for chromatographic analyses.

2.3. Chemical characterisation of coffee extracts

The pH of the extracts was obtained by means of a pH metre (DM20 Digimed, Santo Amaro, SP, Brazil). The contents of caffeic, ferulic and chlorogenic acids (3-, 4- and 5-caffeoylquinic acids – 3-, 4- and 5-CQA; 3-, 4- and 5-feruloylquinic acids – 3-, 4- and 5-FQA; 3-, 4- and 5-coumaroylquinic acids – 3-, 4- and 5-CoQA; 3,4-, 3,5- and 4,5-dicaffeoylquinic acids – 3,4-, 3,5- and 4,5-diCQA; caffeoylferuloylquinic acids – CFQA), their respective 1,5-quinolactones (3- and 4-caffeoylquinide – 3- and 4-CQL; 3- and 4-feruloylquinide – 3- and 4-FQL; 3,4-dicaffeoylquinide – 3,4-diCQL) were determined by gradient LC-DAD-ESI-MS according to Farah et al. (2006), using a Magic C30 column (150 × 2.0 mm, 5 μm, 100 Å, Michrom Bioresources, Inc., Auburn, CA). The contents of caffeine, trigonelline, nicotinic acid and sucrose were determined by LC-ESI-MS according to Perrone, Donangelo, and Farah (2008), using a Spherisorb® S5 ODS2 Microbore column (150 × 2.0 mm, 5 μm, Waters, Milford, MA, USA). The LC equipment (Shimadzu, Kyoto, Japan) comprised a LC-10AD*vp* quaternary pump, a CTO-10AS*vp* column oven, an 8125 manual injector (Rheodyne) with a 5 μL loop and a SPD-M10A*vp* diode array detector. This LC system was interfaced with a LC–MS 2010 mass spectrometer (Shimadzu, Kyoto, Japan).

For sample clarification prior to the chromatographic analyses of phenolic compounds, 500 μL of each coffee extract were mixed with 500 μL of each Carrez solution and the volume was made up to 50 mL with Milli-Q water. For the determination of trigonelline, nicotinic acid, caffeine and sucrose Carrez solutions were replaced by 1 mL of saturated basic lead acetate solution (Farah et al., 2006). The mixtures were shaken, let rest for 10 min and filtered through a Whatman #1 qualitative filter paper and a 0.22 μm membrane (Millipore). The filtrates were used directly for chromatography. Chemical analyses were performed in triplicate.

2.4. Bacterial strains and culture

The bacterial strain used was from the American Type Culture Collection (ATCC): *S. mutans* ATCC 25175. Bacteria were kept at −20 °C in Tryptic Soy Broth [TSB] (Oxoid, Hampshire, England) with 20% glycerol and activated by transfer into blood agar, and incubation at 36.5 ± 1.0 °C, in anaerobic conditions, for 48 h in a candle jar. Bacterial cells were suspended, according to the McFarland protocol (1907), in saline solution to produce a suspension of about 1.5×10^8 CFU/mL. Three-hundred microlitres of this suspension were mixed with 9.7 mL of Mueller–Hinton bacterial broth medium (Difco, Sparks, USA), resulting in an inoculum with $4–5 \times 10^6$ CFU/mL.

2.5. Minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) determination

MIC was evaluated by the dilution method in Mueller–Hinton broth medium (Difco) according to Clinical and Laboratory Standards Institute (CSLI, formerly NCCLS) guidelines (NCCLS, 2003), with concentrations ranging from 1 to 10 mg/mL of the 10% coffee extracts. The concentrations varied from 1 to 1000 μg/mL for the standard solutions. The inoculum was added to each tube and the MIC value was evaluated after 24 h of incubation at 36.5 ± 1.0 °C, as the lowest concentration that completely inhibited the formation of visible growth. The MBC determination was used to assess if the inhibitory effect observed in MIC determinations was through a lethal (bactericidal) action. Samples from tubes where the MIC results showed no bacterial growth were removed with a loop, inoculated onto a blood agar plate, and incubated at 36.5 ± 1.0 °C, for 48 h in a candle jar. MBC was considered to be the concentration at which microorganisms were totally unable to grow. In the cases where the referred samples showed no bactericidal activity, the number of colonies formed (colony-forming units – CFU) on that plate was calculated at the inhibitory concentrations (no presence of turbidity). The controls included an inocu-

lated Mueller–Hinton broth medium (Difco) without the test compounds. Experiments were performed three times in duplicate.

2.6. Ethanol test

Based on the fact that ethanol has been used as a vehicle for chemical compounds or as an extraction solvent for plant extracts in various antibacterial studies (Almeida et al., 2004; Dall'Agnol et al., 2003; Xiao et al., 2007), and in order to choose a solution vehicle eliminating the possibility of false-positive results, ethanol alone was tested – in replacement of standard solution or coffee extracts – for *S. mutans* growth inhibition. HPLC grade ethanol (0.4 mL) (Tedia, Brazil) at 5%, 10% and 20% was added to test tubes containing 3.6 mL inoculated Mueller–Hinton broth medium. Experiment was performed in duplicate.

2.7. Sucrose supplemented medium test

The *S. mutans* inoculum was made as described above in Section 2.4. Three-hundred microlitres of the inoculum were transferred to two test tubes, one containing only 9.7 mL of Mueller–Hinton broth medium (control) and one containing the same amount of medium supplemented with 5.06 mg of sucrose. After incubation at 36.5 ± 1 °C for 6 h, diluted samples from the tubes were inoculated onto a blood agar plate and incubated at the same temperature for 48 h in a candle jar. The number of CFU was calculated. The experiment was performed in duplicate.

2.8. Biofilm susceptibility assay

The standard solutions and extracts showing better performance in relation to the cell-growth inhibition (MIC and MBC results) were selected for this assay. All 6 min roasted coffee extracts were tested. The effect of 5-CQA, trigonelline and selected extracts on *S. mutans* biofilm formation was examined by microdilution method. Twofold serial dilutions of extracts were prepared in 96-well polystyrene tissue culture plates (TPP, Zellkultur Testplatte 96 F) containing brain–heart infusion growth supplemented with 2% sucrose (BHIS, Difco, 200 μL/well) with final concentrations of 1.25, 2.5, 5.0, 50 and 90 mg/mL of the 10% selected coffee extracts. The selected standard solutions were tested at the concentration of 0.8 mg/mL. Chlorhexidine (0.05%, w/v) was used as the positive control; the medium without the tested agents was used as the non-treated control and the medium alone as the blank control. Aliquots (20 μL) of *S. mutans* ATCC 25175 cell suspension (final concentration of cells 5×10^7 CFU/mL) were inoculated in the wells of the polystyrene tissue culture plate except in the wells with the cell culture media alone as the blank control. After incubation in an anaerobic incubator (10% CO_2, 80% N_2, 10% H_2, 37 °C, 24 h), absorbance at 570 nm was recorded to assess the culture growth. Culture supernatants from each well were then decanted and planktonic cells were removed by washing with PBS, pH 7.2. The biofilm was air-dried (room temperature), stained (1 h) with 0.1% (w/v) Crystal Violet (Sigma) and rinsed thoroughly with water until control wells appeared colourless. Biofilm formation was quantified by the addition of 200 μL of 80% ethanol and 20% acetone to each Crystal Violet-stained well. The absorbance at 570 nm (A_{570}) was determined using a microplate reader (model 550 – Bio Rade Microplate Reader, Marnes – La-Coquete, France). The percentage of inhibition was calculated using the equation $(1 - A_{570}$ of the test$/A_{570}$ of non-treated control$) \times 100$ (Wei, Campagna, & Bobek, 2006).

To examine the effects of the selected chemical compounds and coffee extracts, *S. mutans* ATCC 25175 cells (20 μL aliquots of 5×10^7 CFU/mL) were inoculated into the wells of a polystyrene microtitre plate containing BHIS at a volume of 200 μL/well. Following incubation in an anaerobic incubator (10% CO_2, 80% N_2, 10% H_2, 37 °C, 24 h), the culture supernatant from each well was decanted and planktonic cells were removed by washing with PBS. BHIS containing the test samples, prepared in another microtitre plate, was then transferred to the one-day biofilm plate, and the plates were further incubated at 37 °C for 24 h under anaerobic conditions. Following, the cell growth was assessed by measurement of the absorbance at 570 nm, and the biofilm was fixed, stained and quantified as described above. The biofilm assays were performed in quadruplicate.

2.9. Statistical analysis

The association between chemical composition and number of colonies formed on the plate surface results was investigated using Pearson correlation analysis. CFU and biofilm results were analysed using Student's *t* test. SSPS software, version 11.0 was used for all statistical analysis. A 5% significance level was considered.

3. Results and discussion

In the present study, six bioactive compounds and 36 coffee extracts with distinct chemical composition were tested for *S. mutans* growth inhibition. For those compounds and coffee extracts showing growth inhibition in any of the tested concentrations, MIC was determined. Additionally, the coffee extracts showing the best performances in these assays were tested for biofilm inhibition and reduction.

3.1. Ethanol test

All tubes containing ethanol inhibited the growth of *S. mutans*, compared to the control with Milli-Q purified water. Therefore, for the evaluation of antibacterial activity Milli-Q water was chosen as the vehicle for selected chemical compounds and for coffee extracts preparation.

3.2. Selected coffee compounds

5-CQA, caffeic acid and trigonelline were able to inhibit the growth of *S. mutans*, with MIC of 0.8 mg/mL (bacteriostatic activity). No bactericidal activity was observed at this concentration. Nicotinic acid, caffeine and ferulic acid did not show bacteriostatic activity against *S. mutans* at tested concentrations. Although it is possible that at higher concentrations nicotinic acid, caffeine and ferulic acid would show bacteriostatic activity and 5-CQA, caffeic acid and trigonelline would show bactericidal activity, this test was not performed because we opted for testing concentrations that would mimic those found in coffee or other food sources.

The number of CFU from the tube containing trigonelline (0.1×10^2) was significantly lower than those containing 5-CQA and caffeic acid (0.3×10^2 and 0.5×10^2, respectively) ($p < 0.01$), evidencing a stronger antibacterial activity of trigonelline against *S. mutans* compared with those of the tested phenolic compounds. Among the phenolic compounds, 5-CQA showed the highest inhibitory performance. These results are in accordance with previous studies investigating the antibacterial activity of coffee compounds against *S. mutans* and other bacteria (Almeida et al., 2004; Almeida et al., 2006; Furuhata et al., 2002). Furuhata et al. (2002) reported antibacterial activity of caffeic and 5-CQA against a strain of *L. pneumophila*, while Almeida et al. (2006), Almeida et al. (2004) described antibacterial effects of trigonelline, 5-CQA and caffeic acid on the growth of Enterobacteria and *S. mutans*, respectively, using the agar diffusion method. To our knowledge, the antibacterial activity of ferulic and nicotinic acids against *S. mutans* had not been

tested until the present study. Despite the inhibitory effect of 5-CQA and trigonelline on *S. mutans* cell-growth, these compounds did not exert inhibition or reduction of the bacteria biofilm formation at the tested concentration (correspondent to MIC result). This is not surprising, given that biofilm is less susceptible to antimicrobial agents compared with planktonic cells (Wei et al., 2006).

The colour characterisation, percent weight loss on a wet basis during roasting and pH of the tested coffee extracts from Groups 1 and 2 are presented in Table 1. Sucrose, caffeine, trigonelline and nicotinic acid concentrations in the coffee extracts are presented in Table 2. Phenolic compounds concentrations are presented in Table 3.

3.3. Coffee extracts from Group 1

In Group 1 regular coffee samples of different species (*C. arabica* cv. Yellow Bourbon and *C. canephora* cv. Conillon) were tested before and after 6, 7, 8, 13 and 15 min of roasting. Both species inhibited *S. mutans* growth when roasted for 6, 7 and 8 min, with MIC of 5.0 mg/mL. The extracts obtained from green beans and at 13 and 15 min of roasting did not show inhibitory activity at tested concentrations. Inoculation of positive tubes onto a blood agar plate showed that at tested concentrations (5 and 10 mg/mL), the lighter the roasting degree the higher was the inhibitory activity (Table 4). Daglia et al. (1998) observed higher antibacterial activity in acidic fractions of coffee extracts. In our study, samples showing higher inhibitory activity (lighter samples) also showed lower pH compared to darker samples (Table 1).

Our MIC results are also in agreement with those obtained in the tests with isolated compounds. Trigonelline and 5-CQA are thermo-labile compounds and therefore the darker the roasting degree the lower their concentration (Tables 2 and 3). Trigonelline is a *N*-metyl-betaine (Farah et al., 2006) and 5-CQA is an ester of caffeic acid with quinic acid (Farah et al., 2006). During roasting, trigonelline is demethylated to form nicotinic acid or degraded into low molecular weight compounds (Farah et al., 2006), while chlorogenic acids may be isomerised, epimerised, lactonised and also degraded to low molecular weight compounds (Farah et al., 2006).

[a] Results are shown as mean of triplicate of analysis, expressed in μg/mL. Analyses' coefficient of variation was <5%.
[b] No ferulic acid was observed in any of the analysed samples from both groups.
[c] CA, caffeic acid; CQA, cafeoylquinic acids; FQA, feruloylquinic acids; *p*-CoQA, *p*-coumaruloylquinic acids; diCQA, dicaffeoylquinic acids; CFQA, cafeoylferuloylquinic acids; CGA, chlorogenic acids; CQL, caffeoylquinide; FQL, feruloylquinide; diCQL, dicaffeoylquinide; CGL, chlorogenic acids lactones.

Like 5-CQA, other CQA and diCQA isomers are also formed from caffeic and quinic acid, and it is very possible that all these compounds, which together are responsible for more than 90% of the chlorogenic acids content in the coffee extracts, exert antibacterial activity. On the other hand, since ferulic acid did not show activity against *S. mutans*, it is possible that feruloylquinic acids and their lactones do not exert such activity. The mechanisms of growth inhibition of chlorogenic acids and trigonelline are not clear, but according to Cowan (1999) the causes for phenolic toxicity to microorganisms may include enzymatic inhibition by oxidised compounds, possibly through reaction with sulfidryl groups or also through more nonspecific interactions with proteins.

Although the contents of 5-CQA and trigonelline in the coffee extracts were similar to those of the standard solutions with bacteriostatic activity (Tables 2 and 3), other non-bacteriostatic compounds such as polysaccharides and aminoacids that are also part of coffee composition may have contributed to increase the MIC of coffee extract compared to those of the isolated compounds.

Despite caffeic acid inhibitory activity, the amount of this phenolic acid in its non-esterified form in coffee is generally very low, especially in the roasted beans (Farah et al., 2005). In the present study, we only identified caffeic acid in the green coffee extracts (Table 3). Although the high concentrations of chlorogenic acids, trigonelline and caffeic acid were found in the green coffee extracts (4.0 and 7.0 mg/mL altogether in *C. arabica* and *C canephora*, respectively) (Tables 2 and 3), sucrose concentration in these extracts was quite high (10.2 and 4.8 mg/mL, respectively), being equivalent to 2.6 and 0.7 times those of the sum of the tested antibacterial compounds in *C. arabica* and *C. canephora*, respectively (Table 2). The majority of the oral microbiota depends on sugar as energy source (McNeill & Hamilton, 2004). Although glucose is the preferred sugar for bacterial growth, bacteria may use a large variety of sugars such as sucrose, maltose and lactose as alternative sources of energy (Wen, Browngardt, & Burne, 2001). Therefore, it is most likely that sucrose has promoted the growth of the referred bacteria, counteracting the inhibitory effect of trigonelline and chlorogenic acids in the green coffee extracts.

The present results are in accordance with Daglia et al. (1998, 2007) who did not observe inhibitory activity in green coffee extracts. However, one of these studies (Daglia et al., 2007) reported

[a] Results are shown in $\log_{10}$ scale for better comparison.

that due to the lack of antibacterial activity of green coffee, along with a positive activity of dark roasted coffee, the compounds with inhibitory activity could not be naturally present in coffee, being formed by Maillard reaction during roasting process. The study went further identifying α-dycarbonil compounds as the main coffee agents with inhibitory activity (Daglia et al., 2007). Nevertheless, such compounds are present in very low concentrations in commonly consumed aqueous coffee extracts (Daglia et al., 2007). Furthermore, even though the medium roasted coffee extract evaluated by Daglia et al. (2007) was about six times more concentrated than the light roasted extracts (6 and 7 min of roasting) used in the present study, all extracts exhibited similar MIC results. This indicates that the antibacterial effect of the referred α-dycarbonil compounds may be lower than those of natural coffee compounds such as 5-CQA, trigonelline, caffeic acid and possibly other compounds that are more abundant in lighter roasted coffees, although results from the present study and from Daglia et al. (2007) cannot be directly compared. This matter should be investigated in future studies.

In order to confirm our hypotheses that the high concentration of sucrose present in green coffee beans was counteracting the antibacterial effect of natural coffee compounds, we performed an additional experiment incubating the *S. mutans* inoculum in test tubes containing plain medium (control) or the same medium supplemented with sucrose. The concentration of sucrose used in this test was similar to that found in the *C. canephora* sample from Group 1. The number of CFU from the control tube was 1.2×10^6, while the number of CFU of the supplemented medium tube was 5.3×10^6, 4.4 times higher than in non-supplemented media. This result increases evidence that sucrose may counteract the antibacterial effect of natural occurring compounds in green coffee beans.

Regarding differences between both investigated species, *C. arabica* cv. Yellow Bourbon extracts showed similar inhibitory activity on the growth of *S. mutans* when compared to *C. canephora* cv. Conillon. No significant difference was observed between the numbers of CFU of both species (Table 4). In the biofilm formation assays, however, while *C. arabica* cv. Yellow Bourbon extract did not inhibit the biofilm formation at tested concentrations, *C. canephora* cv. Conillon showed an inhibition of 39.6% (compared to 91.7% of the positive control chlorhexidine) at 90 mg/mL, a concentration similar to that commonly used in Brazil and other countries for coffee preparation (100 mg/mL). As far as we know, this is the first study evaluating the inhibitory activity of coffee on biofilm formation, but it is possible that the anti-adhesive property reported for coffee (Daglia et al., 2002) is related to this activity. Considering that the contribution of caffeine for the anti-adhesive property of coffee has previously been discarded (Daglia et al., 2002), the possible involvement of chlorogenic acids and their lactones in such activity should be investigated, since the amount of both classes of compounds in the active *C. canephora* extract (6 min roasted) was about 27% and 73% higher than in *C. arabica*, respectively.

Regarding the biofilm reduction assay, *C. canephora* extract of Group 1 showed a low biofilm viability reduction (6.6%) at 90 mg/mL (against 20.6% by chlorhexidine), while *C. arabica* did not show reduction at tested concentrations. The low reduction of mature biofilm when compared to the inhibition of biofilm formation was expected, since in a biofilm, bacteria are invariably less susceptible to antimicrobial agents than their planktonic counterparts (Wilson, 1996). Nonetheless, the inhibition of early biofilm formation is more important than the reduction of mature biofilm because once the formation of biofilm is inhibited, mature biofilm existence may be prevented.

3.4. Coffee extracts from Group 2

With the intention to confirm the results from Group 1 and because decaffeination process may considerably change coffee chemical composition (Farah et al., 2006; Toci, Farah, & Trugo, 2006), a group of green and roasted regular and decaffeinated *C. arabica* and *C. canephora* samples from the same lot was tested. As in Group 1, all regular coffee extracts roasted for 6, 7 and 8 min inhibited the growth of *S. mutans*, with a MIC of 5 mg/mL. No activity was observed in extracts roasted for 13 and 15 min. No significant difference was observed between the numbers of CFU of both species (Table 4). Also, as in Group 1, regular *C. canephora* showed biofilm formation inhibition (18.3% inhibition at 90 mg/mL), while regular *C. arabica* did not exhibit inhibitory activity at tested concentrations.

Only *C. arabica* and *C. canephora* extracts prepared from beans roasted for 6 and 7 min inhibited the bacterial growth (MIC of 5 mg/mL). Differently from the regular samples, extracts from decaffeinated beans roasted for 8 min did not show inhibitory activity. Additionally, none of the decaffeinated extracts inhibited the biofilm formation. Although in the present study caffeine alone did not exert inhibitory activity on the growth of *S. mutans*, studies performed by Daglia et al. (2007) and Almeida et al. (2004) observed that at concentrations of 5.0 and 2.0 mg/mL, respectively, caffeine provided antimicrobial activity against *S. mutans*. These authors also showed that caffeine was able to enhance the inhibi-

tory effect of coffee compounds. This could explain why decaffeinated coffee roasted for 8 min did not show inhibitory effect. Furthermore, other possibly inhibitory compounds may have been washed out by water and dichloromethane during decaffeination process. As in regular samples, a significant inverse correlation was found between roasting degree and inhibitory activity among decaffeinated samples (Table 4). Group 2 samples did not show biofilm reduction at tested concentrations.

Regular samples from Group 1 showed a tendency ($p = 0.08$) to exhibit better antibacterial performance than those from Group 2. Additionally, regular *C. canephora* samples from Group 1 showed better inhibitory performance of biofilm formation than those from Group 2. This could probably be explained by the inferior quality of samples from Group 2, which contained a higher number of fermented defective beans such as black and sour (Farah et al., 2006; Toci & Farah, 2008) possibly presenting unknown substances that could counteract the antibacterial effects of natural coffee components.

In conclusion, this study showed that 5-CQA, trigonelline, and caffeic acid from coffee exert inhibitory activity against the growth of *S. mutans*; that such activity is enhanced by the presence of caffeine and/or other compounds extracted by decaffeination; that *C. canephora* extracts seems to exert better performance in relation to inhibition of biofilm formation than those of *C. arabica* and that roasting degree is inversely associated with antibacterial activity against *S. mutans*.

Coffee is a natural ingredient that may be obtained in large quantities at low cost. Furthermore, the advantage of coffee as an antibacterial beverage is that it is consumed in a concentrated form (6–10%) as opposed to various medicinal infusions that have shown such effect *in vitro* and are usually consumed at 1–2% (Bravo, Goya, & Lecumberri, 2007). So, the fact that the coffee derived extract used in this study exhibited antibacterial activity against *S. mutans* cell-growth and against *S. mutans* biofilm formation supports the hypothesis that it may be highly beneficial as an anticariogenic ingredient, when consumed without sucrose addition. However, in the *in vivo* situation, *S. mutans* does not occur in monoculture, but rather in a complex ecosystem biofilm. As the *in vitro* tests employed in this study are essentially preliminary screenings, further investigation – especially *in vivo* – should be performed to verify the effect of regular light roasted *C. canephora* and *C. arabica* extracts and their components in the prevention of dental caries.

Acknowledgments

The authors would like to thank Professor José Mauro Costa Monteiro (Minas Gerais, Brazil) and Mr. Robert Machtans Junior from Cocam Cia. de Café Solúvel e Derivados (São Paulo, Brazil) for generously providing the coffee samples. The financial support of the National Council for Technological Development (CNPq), Consórcio Brasileiro de Pesquisa e Desenvolvimento do Café (CBP&D)/EMBRAPA (Brazil) and Fundação Carlos Chagas Filho de Amparo à Pesquisa do Estado do Rio de Janeiro (FAPERJ) is acknowledged.

Blacnchard, 1994). There are several ways available to study the properties of a gel and the mechanism of their formation e.g. employing the two main rheological studies available, namely small strain and large strain testing. The combination of these measurements can give valuable information on gel properties and qualities. Small strain testing is a study where a sample is deformed without breaking the structure. Heating and cooling of a gel, using low frequency and small strain oscillatory experiments, is one of the best suited methods to follow changes in physical properties relating molecular properties of a gel (Hamman, 1991; Hamman & MacDonald, 1992). Large strain testing is when a sample is deformed until the structure is permanently broken. Large strain testing, such as torsion estimates fundamental properties of a gel and has shown to correlate with sensory. The torsion test is a typical method to test the hardness (shear stress) and elasticity (shear strain) of surimi gels.

The overall objective of this study was to evaluate the quality of gels prepared using muscle proteins isolated from tilapia white muscle using the acid and alkali-aided processes and compare to gels prepared using washed tilapia muscle which simulates surimi without added cryoprotectants.

2. Materials and methods

2.1. Raw material

Tilapia fillets (170–200 g) were obtained fresh from a local supplier (Rain Forest Aquaculture, Sunrise, FL). The fillets were processed immediately after fish were killed and transported in Styrofoam boxes on ice to the laboratory and stored in a cold room at 4 °C until processed (within 24 h from the time of filleting). Red muscle was manually excised from the white muscle and discarded. The remaining white muscle was ground using a Scoville grinder (Hamilton Beach, Washington, NC) with 6 mm holes. All sample preparation was performed in a cold room at 4 °C or on ice when applicable to maintain temperature below 5 °C.

2.2. Preparation of washed muscle

Ground muscle was mixed with cold DI water (1:3, w/w) and allowed to sit for 15 min, stirring every few minutes with a plastic spatula. The slurry was poured into a strainer covered with double layer of cheesecloth and the water manually squeezed out. This was repeated 2×, with the last wash water containing 0.2% NaCl to aid in the dewatering of the tilapia white muscle proteins. The washed muscle was placed in a zip-lock bag and stored overnight on ice in a cold room at 4 °C before gel preparation.

2.3. Preparation of protein isolates

Ground muscle was mixed with cold DI water (1:9, w/w), homogenised for 60 s (2 × 30s) using a Waring blender (Waring Products Division, New Hartford, CT) at 40% electrical output and carefully poured (to avoid foaming) into a plastic beaker on ice. The homogenates were adjusted to pH 2.5, 2.9, 11.0 or 11.2 to solubilise the proteins, using 2 M HCl or 2 M NaOH. The adjusted homogenate was poured into centrifuge bottles and centrifuged at 10,000*g* for 20 min in a Sorvall RC-5B using a GS-3 rotor. Centrifugation resulted in the formation of three layers. The supernatant was separated from the top layer and the sediment by pouring the contents of the centrifuge bottles through a strainer covered with two layers of cheesecloth. The collected supernatant was subjected to isoelectric precipitation by adjusting the pH to 5.5, following centrifugation at 10,000*g* for 20 min. The sediment (protein isolate) was placed in a zip-lock bag and stored on ice in a cold room at 4 °C over night.

2.4. Moisture content

To determine moisture content of the protein isolates and washed muscle a ~5 g sample was placed in a Cenco moisture balance (CSC Scientific Company, Inc., Fairfax, VA). Prior to sample preparation for rheological measurements moisture content of protein isolate and washed muscle was adjusted to 90% by adding cold DI water based on the following formula:

$$g\ H_2O = \frac{X\ g_{\text{sample}}\left(X_{\text{moisture of sample}} - X_{\text{desired moisture}}\right)}{X_{\text{desired moisture}} - 1}. \quad (1)$$

For gel quality analysis the protein isolates were adjusted to 83% moisture content by squeezing the water out manually. The washed muscle required centrifugation at 10,000*g* for 20 min in a RC-5B centrifuge using a GS-3 rotor to reach the desired moisture content.

2.5. Rheology

Samples for rheology measurements were prepared by placing ~25 or 30 g of the protein isolate/washed muscle (90% moisture) in a 100 mL plastic beaker. The isolate/washed muscle was homogenised with a hand held Tissue Tearor (Biospec Products, Inc., Bartlesville, OK) for 1 min on speed six, then 25 mM of sodium phosphate dibasic (pulverised with a mortar and pestle to reduce particle size) was added and the paste homogenised again for 2 min on same speed for thorough mixing. Finally 2% NaCl was added (when applicable) and mixed well with a stainless steel spatula. The pH of the paste was adjusted to pH 7.1–7.2 with 2 M NaOH followed by mixing with a stainless steel spatula. After the pH adjustment the beaker was covered with parafilm and the paste was kept on ice for 30 min before rheological measurements. Sample preparation time including the 30 min setting time was ~50–60 min.

Viscoelastic changes on heating and cooling were determined using single gap geometry in an AR2000 Advanced Rheometer (TA Instruments, New Castle, DE). Approximately 20 g of sample (prepared as previously described) was placed in the sample chamber at 5 °C and the head set to a specified gap (4950 μm). After reaching the gap, excess sample was removed with a stainless steel spatula and a layer of mineral oil was placed on top of the sample to prevent evaporation on heating. The opening was covered with a metal moisture trap to prevent evaporation. The samples were heated from 5 to 80 °C at a rate of 2 °C/min and cooled from 80 to 5 °C at the same rate and measurement conducted using a oscillatory mode with constant frequency set at 0.1 Hz and maximum strain at 0.01 (Kristinsson & Hultin, 2003b).

2.6. Gel quality

Approximately 130 g of isolate/washed muscle were accurately weighed and placed in a Mini Chopper (Sunbeam Products Inc., Boca Raton, FL) with 25 mM sodium phosphate dibasic buffer added after blending for 20 s, and after ~1 min 2% NaCl was added when applicable. The pH was adjusted to 7.1–7.2 by adding 2 M NaOH drop wise. The paste was mixed for a total of 4 min with all steps performed in a cold room at 4 °C. The paste was then manually stuffed into steel tubes (diameter 19 mm) and the ends sealed with a rubber cap and fastened with a hose clamp. The paste was cooked for 30 min at 80 °C in a Precision water bath (Precision Scientific, Winchester, VA) and cooled in ice water for 15 min. Gels were removed from stainless steel tubes and placed in zip-lock bags and stored in a cold room at 4 °C for 48 h prior to testing.

After storing the gels at 4 °C for 48 h they were cut into 28.7 mm long samples using a cutting motive. After reaching room temperature (~40 min) the gels were milled into dumbbell shape with a minimum centre diameter of 1.0 cm. Gels were tested using

a modified Brookfield DV-II viscometer (Gel Consultants, Raleigh, NC) and the gels twisted at 2.5 rpm until structure failed. Shear stress (resistance to breakage) and shear strain (distance until breakage) of the gels were obtained using computer software linked to the viscometer.

2.7. Folding

Folding test was performed within 60 h of storage at 4 °C, according to the method of Kudo, Okada, and Miyauchi (1973). Approximately 3 mm slices were cut and folded by hand at room temperature. The ability of the gels to fold was graded using a five point system.

2.8. Water-holding capacity

Water-holding capacity of the gels on pressing was determined using the method of Feng and Hultin (2001) where pressing loss is defined as the water loss of a 3 mm thick slice under 3000 g pressure (using a 3 L beaker full of water) for 1 min. The sample was sandwiched between 5 layers of Whatman filter paper (Whatman Inc., Clifton, NJ) which absorbed the expressible water. Weight before and after pressing was recorded and moisture content was determined by drying the samples overnight at 106 °C in a moisture oven.

2.9. Sulphydryl content

Total sulphydryl (SH) content was determined on the protein paste before cooking and on the gels after cooking by using the method of Choi and Park (2002) with slight modifications. The pastes and gels were diluted 100× to give a protein concentration between 1 and 2 mg/mL. A 0.25 mL sample of the protein solution was added to 2.5 mL of 8 M urea, 2% sodium dodecylsulphate (SDS) and 10 mM EDTA in 0.2 M Tris–HCl buffer at pH 7.1. To this solution 50 uL of 10 mM Ellman's reagent (10 mM 5,5′-dithiobis(2-nitrobenzoic acid) was added, mixed and heated in a water bath at 40 °C for 15 min. After the reaction the absorbance of the solution was measured at 420 nm using an Agilent 8453 UV–VIS spectrophotometer (Agilent Technologies, Palo Alto, CA) and total SH content was calculated using a molar extinction coefficient of 13,600 mol/cm.

2.10. Statistics

Analysis of variance (ANOVA) was used to determine significant differences between treatments. All results were analysed by using the Statistical Analysis System (SAS). Results are expressed as means ± SD.

3. Results and discussions

Gel forming ability of tilapia white muscle protein isolates prepared with the acid and alkali-aided processes were determined and compared to gel forming ability of washed tilapia white muscle (analogue to conventional lab scale surimi without added cryoprotectants). Gel characteristics were evaluated by using small strain (viscoelastic changes) and large strain (torsion) testing, folding and water-holding capacity. Gels were prepared with or without addition of 2% NaCl (w/w) and the paste was adjusted to pH 7.1–7.2 which are common conditions for gelation of fish muscle.

3.1. Torsion

Shear stress (i.e. resistance to breakage) of gels prepared using 2% NaCl (w/w) was significantly higher ($p < 0.01$) than that seen for gels without added NaCl, except for gels prepared from washed muscle (Fig. 1a). For gels with 2% added salt, the lowest shear stress, thus least resistance to breakage, was obtained for gels prepared from washed muscle, 32.1 ± 4.3 kPa. Gels from protein isolates prepared by solubilising the proteins at pH 2.5, 11.0 and 11.2 gave the highest shear stress values, ranging from 80 to 84 kPa. There was however no significant difference between these gels ($p > 0.05$). For gels without added salt, the highest stress value, 69.1 ± 12.0 kPa, was obtained for the isolates prepared using pH 11.0 while the lowest stress value was obtained for the isolates prepared using pH 2.9 and the washing procedure, 30.4 ± 7.0 and 26.0 ± 2.0 kPa, respectively.

Resistance of gels to deformation or shear strain (Fig. 1b) showed that the addition of 2% NaCl (w/w) resulted in significantly higher ($p < 0.01$) strain values for all treatments compared to gels without added NaCl. For samples without added salt, isolates prepared using pH 11.0 and 11.2 gave significantly ($p < 0.05$) higher strain values (1.6 ± 0.1 and 1.5 ± 0.2, respectively) compared to acid treated proteins and washed muscle. On the other hand, the isolate prepared using pH 2.9 and the washed muscle had the lowest shear strain values (1.1 ± 0.1 and 1.2 ± 0.1, respectively), which is in line with the results seen for shear stress. If isolates prepared using low pH treatment are compared it is clear that pH 2.5 treatment with and without 2% NaCl (w/w) gave significantly ($p < 0.01$) higher strain values than the pH 2.9 treatment, thus being significantly more elastic.

The strain values obtained for the treatments were lower or borderline for the ideal shear strain values for surimi from fish muscle, which are expected to be between 2 and 3. The reason for lower values could be explained by the absence of cryoprotectants and setting which are used in surimi production. Bakir, Hultin, and Kelleher (1994) had similar findings for gels prepared from Atlantic mackerel and Bluefish.

Shear stress and strain values were significantly higher for samples with 2% added NaCl (w/w). Salt is believed to improve gelation ability and water retention by solubilising myofibrillar proteins (Xiong, 1997). Addition of salt above 300 mM (~1%) solubilises the myofibrillar proteins by breaking up the interactions between myosin in the thick filament and actin in the thin filaments, along with other cytoskeletal proteins (Lanier, 2000). In a concentrated gel paste (prior to gelation), the osmotic pressure is probably too high to obtain complete solubilisation of the myofibrillar proteins. Uniform dispersion of partially solubilised or unravelled proteins is likely to be more important in a gel paste. Addition of salt is also believed to contribute to a more elastic gel by dispersing the proteins more evenly, which is a consequence of partial or full solubilisation.

It was interesting to note the difference between the two low pH treatments. A difference in gel performance between different low pH treatments has been seen with other species. A study performed by Kim, Park, and Choi (2003) on Pacific whiting showed by using a puncture test that deformation of gels containing 1.5% beef plasma protein was higher for proteins treated at pH 2.0 compared to pH 3.0 which was in part explained by increased hydrophobicity of the proteins at low pH. Davenport, Theodore, and Kristinsson (2004) also found a significant difference in gel forming ability between three different low pH treatments which could on the other hand not be explained by hydrophobicity changes or changes in protein conformation using tryptophan as a structural probe.

The pH 2.9 treatment in particular resulted in the formation of weak gels. During isoelectric precipitation of proteins solubilised at pH 2.9 it was observed that the proteins seemed to form larger aggregates compared to proteins at pH 2.5 and 11.0. Larger aggregates do not form as ordered three dimensional structures and thus form a weaker gel. Hermansson (1978) reported that denaturation of proteins prior to aggregation results in a finer gel structure,

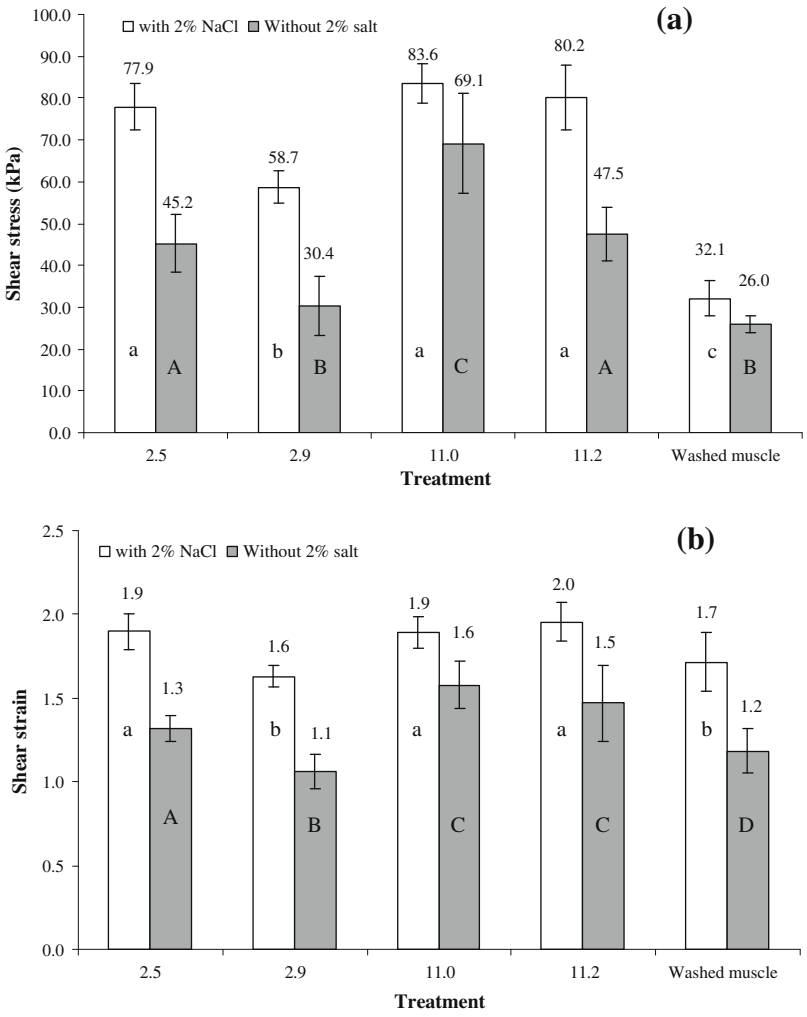

Fig. 1. Shear stress (kPa) (a) and shear strain (b) of gels produced from proteins extracted from tilapia white muscle. Low and high solubilisation pH treatment was compared to a three cycle washing treatment (control). Different capital letters indicate significant difference ($p < 0.01$) for treatments without 2% NaCl. Different small letters indicate a significant difference for treatments with 2% NaCl.

exhibiting greater elasticity than if random aggregation occurs prior to denaturation. Too many protein–protein interactions might result in a hard and inelastic gel whereas too many protein–water interactions might result in a soft and fragile gel (Cortes-Ruiz, Pacheco-Aguilar, Garcia-Sanches, & Lugo-Sanches, 2001). Hydrolysis of the myosin heavy chain was observed for isolates produced with the acid process (Kristinsson & Ingadottir, 2006), which could in part explain their reduced gel forming abilities. This is in agreement with results by Undeland et al. (2002) who suggested that reduced amount of myosin heavy chain (possibly due to proteolysis) contributed to lower stress values at acidic conditions. It is interesting to note however that the pH 2.5 treatment with tilapia proteins was better than the pH 2.9 treatment. It is possible the proteases in question were more active at pH 2.9 than pH 2.5. Differences in protein conformation between the two treatments may also be causing the difference, as discussed above.

Kristinsson and Ingadottir (2006) reported that washed muscle, acid isolates and alkali isolates have different protein compositions, which may contribute to the different gel forming ability of these treatments. Interestingly the alkali process and the washing process removed similar proteins but had significantly different gel forming abilities. The very low stress values obtained for the washed muscle compared to the acid and alkali treated proteins indicate that conformational differences of proteins contribute to variations in gelation properties.

3.2. Folding

The fold test is a common test used in the surimi industry for a quick evaluation of gel quality. All treatments with 2% added NaCl exhibited excellent folding ability and received the highest score available, or 5 (Table 1). Gels prepared using alkali treated proteins without 2% NaCl (w/w) exhibited excellent folding ability and were double folded without breaking. The salt free gels prepared using acid treated proteins and washed muscle performed very poorly. The lowest folding score was obtained for gels prepared from isolates made with pH 2.9 treatment which split in two during the first fold (score 1). Gels prepared from washed muscle and pH 2.5 cracked without splitting during the first fold and received a score of 2.

3.3. Rheology

Small strain oscillatory rheological testing was used to follow changes in viscoelastic properties of gels during heating and cooling. Initial and final storage modulus (G') during gelation was determined for all treatments (Fig. 2a). All treatments exhibited

Table 1
Quality of protein gels as assessed by the fold test. Gel quality was estimated by folding ~3 mm thick gel slices by hand at room temperature and graded by using a five point system (Kudo et al., 1973).

Added NaCl (%)	Treatment				
	pH 2.5	pH 2.9	pH 11	pH 11.2	Washed muscle
2	$5.0 \pm 0.0^{a,1}$	$5.0 \pm 0.0^{a,1}$	$5.0 \pm 0.0^{a,1}$	$5.0 \pm 0.0^{a,1}$	$5.0 \pm 0.0^{a,1}$
0	$2.0 \pm 1.5^{b,1}$	$1.0 \pm 0.0^{b,2}$	$5.0 \pm 0.0^{a,3}$	$5.0 \pm 0.0^{a,3}$	$2.0 \pm 1.2^{b,1}$

Different letters within each column indicate significant difference ($p < 0.05$). Different numbers within each row indicate significant difference ($p < 0.05$).

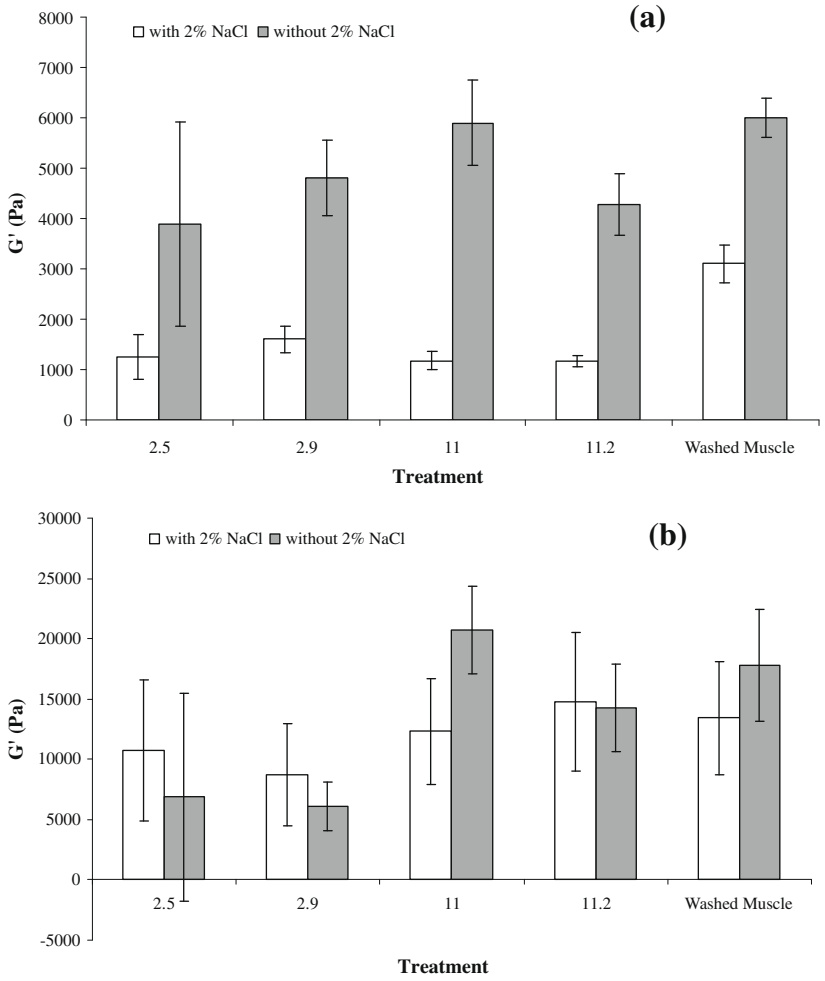

Fig. 2. Storage modulus (G') of protein pastes at 5 °C before thermal gelation (a) and at 5 °C after thermal gelation (b). Samples (~10% protein (w/w)) were adjusted to pH 7.1–7.2. Samples measured at 5 °C before gelation were allowed to sit for 30 min on ice prior to recording G'.

higher initial G' (Pa) in the absence of NaCl (Fig. 2a) compared to samples with 2% NaCl (w/w). A higher G' translates to a more rigid system. The protein paste was adjusted to pH 7.1–7.2 which would give the muscle proteins a substantial negative charge (Feng & Hultin, 1997). This negative charge creates strong repulsive forces between the proteins, creating more space for water to enter giving a more expanded and rigid system. When 2% NaCl (w/w) is added the ions screen some of the repulsive forces bringing the proteins closer together and thus decreasing the space available for water to enter (Kristinsson & Hultin, 2003c) and therefore decrease hydration and leads to less expansion of the system. Differences in initial G' between treatments were observed. Washed muscle showed the highest value among the samples that contained salt. This is likely due to more structure in the washed muscle, since some of the myofibrils would still be intact for that system and many of the myofibrillar proteins would still be part of their native structural elements.

The final G' represents samples that have undergone thermally induced gelation along with setting on cooling (Fig. 2b). The results for final G' showed significant variations for the acid treated samples which could be attributed to the procedures used, the isolate or the raw material. There is evidence that the acid process may lead to larger variations in gelation when using small strain oscillatory testing compared to the alkali process (Theodore, Kristinsson, & Crynen, 2003). The reason for this is unknown, but is hypothesised to be due to unstable structural protein conformations that can form at low pH, thus leading to many different refolded structures at pH 5.5, where the proteins are precipitated. Although variations were large, the results indicate that the proteins from the alkali process have the ability to form stronger gels

compared to the proteins from the acid process, which partly agrees with the torsion results.

In contrast to the torsion results where samples containing 2% NaCl (w/w) exhibited better gelling ability, samples without salt seemed to form better gels, except for the isolates made at pH 2.9. The small strain oscillatory testing and the torsion testing are not necessarily expected to go hand in hand, since they are different tests done at different protein concentrations. The small strain oscillatory testing gives more insight into the gel forming mechanism and protein–protein interaction potential of the muscle proteins at lower concentrations, while the torsion test measures the final gel strength and quality at high protein concentration. It is interesting to note the higher G' for the isolates from the alkaline process, suggesting they have substantially more protein–protein interactions and higher gel forming potential at lower protein concentrations than higher concentrations compared to the isolates from acid process which performed poorer at lower concentrations compared to higher concentrations. The rheology results also indicated that the washed muscle performs better relative to the alkali isolates, at low compared to high protein concentrations.

Fig. 3a–d shows the changes in G' during heating and cooling for the acid and alkali treated proteins, respectively, compared to the washed tilapia white muscle. These graphs allow us to gain an insight into possible differences in gel forming mechanisms between the samples. Washed tilapia muscle with 2% (w/w) added NaCl (Fig. 3a) had a stable G', from 5 to 38 °C, where it started to increase until peaking at ~44 °C and then declining down to a minimum of 53 °C. The G' then rose steadily until 80 °C was reached. A similar curve for heating was observed by Klesk, Yongsawatdigul, Park, Viratchakul, and Virulhakul (2000b) which studied the effect of state of rigor on the gel forming ability of washed tilapia muscle. The increase up to 44 °C has been attributed to cross-linking of myosin and the drop in G' after that to denaturation of light meromyosin, leading to increased fluidity. The second increase in G' has been attributed to the formation of permanent cross-linked myosin filaments (Xiong, 1997). A rapid increase in G' was observed during cooling of the gel indicating formation of a firm gel structure.

Myofibrillar proteins, especially myosin and actin are believed to be largely responsible for gelation. Therefore, gelation of myosin, actin and their complex actomyosin has been the subject of many studies. For myosin, the heavy chain is believed to be the main subunit involved in gelation. The role of the light chain seems to depend on ionic strength where at high ionic strength they may be less important than at low ionic strength. At low ionic strength, removal of the light chains substantially lowered the rigidity of myosin gels (Xiong, 1997). Results from studies on key isolated muscle proteins have been used to try to elucidate gelation mechanism of complex mixture of myofibrillar proteins (Xiong, 1997). The increase in G' that was observed for the washed muscle on heating may be attributed to dissociation of light chains from the heavy chains resulting in conformational changes to the molecule. Cross-linking of myosin is also believed to be responsible for the

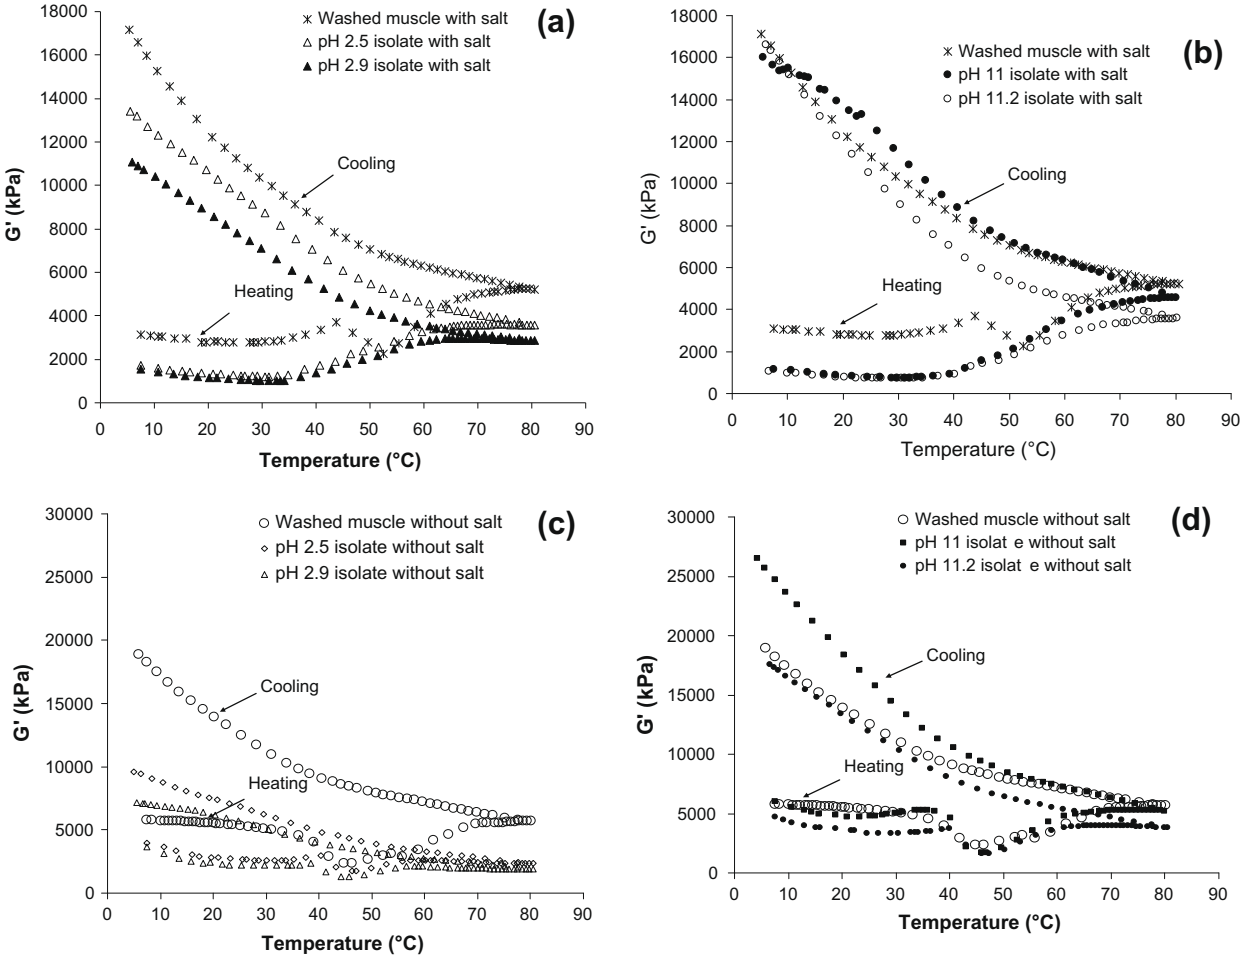

Fig. 3. Rheograms of washed tilapia muscle and protein isolates with 2% NaCl (w/w) added (a) and (b), and with no NaCl added (c) and (d). The rheograms show storage modulus (G') development during heating at 5–80 °C followed by cooling from 80 to 5 °C at 2 °C/min. Samples (~10% protein (w/w)) were adjusted to pH 7.1–7.2 were allowed to sit for 30 min on ice prior to thermal gelation.

increase in G' since it forms a strong elastic network. The subsequent drop is postulated to relate to dissociation of the actin–myosin complex and unfolding of the alpha-helix portion of the myosin rod (Xiong & Blacnchard, 1994). This transformation leads to a large increase in fluidity and might disrupt some protein networks that have already formed (Xiong & Blacnchard, 1994). All these structural changes lead to rapid aggregation and formation of gel networks resulting in a steady increase in G' (Xiong, 1997).

Acid treated proteins with 2% NaCl (w/w) behaved quite differently from the washed muscle. The pH 2.5 treated proteins showed a continuous increase in G' which started around 36 °C and leveled off at ~65 °C (Fig. 3a). A similar pattern was observed for the heating phase of the pH 2.9 treatment (Fig. 3a). The onset of gelation was thus at a significantly lower temperature that that seen for washed tilapia muscle. This could be due to a more unfolded structure of the acid treated proteins, thus requiring a lower temperature to further unfold and interact on heating. The same was seen for cod muscle proteins by Kristinsson and Hultin (2003b). The large difference observed between replicates of the acid treated proteins has been discussed in the previous section and may be attributed to unstable protein structures at low pH leading to different refolded structures which can affect the gelation properties.

The alkali treated proteins showed a similar viscoelastic curve on heating in the presence of 2% NaCl (w/w) as the acid treated proteins (Fig. 3b). The G' started to gradually increase around 40 °C but as presented previously had a larger final G' indicating the formation of a firmer gel compared to the acid treated proteins (Fig. 3a). The slightly higher onset temperature of gelation for the alkali treated proteins compared to acid treated proteins may suggest that they are more refolded than the acid treated proteins. The protein composition differences between the two isolates (Kristinsson & Ingadottir, 2006), might also partly account for the differences in temperature sensitivity.

The acid and alkali treated proteins with added 2% NaCl (w/w) did not show the same transitions as were observed for washed muscle likely due to denaturation and dissociation of the muscle proteins during processing. It has been found that major changes occur with myosin on acid and alkali treatment (Kristinsson & Hultin, 2003b). It was for example found that acid treatment led to complete dissociation of cod myosin while alkaline treatment only led to the dissociation of the light chains from the myosin head. As a result the proteins had different viscoelastic behaviour on heating and cooling compared to a washed cod muscle (Kristinsson & Hultin, 2003b). It was believed that the absence of light chains led to protein aggregation and cross-linking at lower temperatures due to a more exposed myosin head group. Yongsawatdigul and Park (2004) also observed that acid and alkali treated proteins from rockfish were denatured during treatment while still retaining ability to form gels. The lower gelation ability of the acid treated proteins compared to the alkali treated could be due to different conformational changes in part due to loss of myosin heavy chain during processing or the presence of unfavourable conformation of the proteins during acidic treatments, e.g. too many hydrophobic groups leading to bigger aggregates and a less ordered gel. Another explanation for the poor gelling ability of the acid treated proteins could be the presence of denatured sarcoplasmic proteins, many which were retained in the acid process but not in the alkali and washed process (Kristinsson, Theodore, Demir, & Ingadottir, 2005). Crynen and Kristinsson (2003) demonstrated with catfish proteins that the acid process not only negatively affects the myofibrillar proteins but also leads to changes in the sarcoplasmic proteins that, when mixed with the myofibrillar proteins, have a very detrimental effect on gelation. These authors however found that when sarcoplasmic proteins were subjected to alkaline pH treatment they in many cases increased the gel forming ability of the myofibrillar proteins.

Washed muscle without 2% added NaCl (Fig. 3c) exhibited different viscoelastic behaviour on heating compared to the washed muscle containing salt. Initial G' was higher and decreased with increasing temperature until it reached a minimum at 46 °C, which was 7 °C lower than the minimum observed for washed muscle with 2% NaCl (w/w). This decrease suggests that protein complexes may have dissociated instead of forming cross-links as in the system with salt. A steady increase, similar to the one seen for the proteins in salt, was then observed with increasing heating excluding a small bump at ~56 °C. The increase in G' on cooling was similar for both washed muscle in the presence and absence of salt, so differences between the two systems were only seen during the heating/denaturation part of the rheology experiments.

When the viscoelastic curves for isolates without added NaCl were compared to isolates with 2% NaCl (w/w) they were quite different and resembled the curves for washed tilapia muscle. The acid treated proteins (pH 2.5) showed a slight decrease in G' on heating until they reached approximately 40 °C, where the G' dropped down to a minimum at 47 °C (Fig. 3c). The G' then increased again and leveled off at higher temperatures. Protein isolates made with the pH 2.9 treatment showed a very similar trend, however with a lower final G' (Fig. 3c). The alkali treated proteins without added salt showed the same trend as the acid treated proteins except for a higher final G' (Fig. 3d).

Not many gelation studies have been performed with fish proteins in the absence of salt, in part due to the long held believe that salt was necessary for gelation. The results here show that gels can form in the absence of salt, and higher final G' values were in most cases seen in the absence of salt. The absence of salt leads to more electrostatic repulsion between the proteins at pH 7.1–7.2 compared to samples with salt, which may explain the higher G'. The onset of thermal gelation was also different for samples in the absence of salt. For example the rheological curve of washed muscle without salt exhibited a similar pattern reaching a minimum 7 °C lower than compared with salt. Another observation was that the rheology curves for acid and alkali treated proteins without salt exhibited all similar drop in G' around 40 °C. This drop could be explained by a breakup of protein aggregates with higher temperatures, and the subsequent increase in G' due to proteins denaturing and forming permanent cross-links at higher temperatures. Washed muscle consists mainly of myofibrillar proteins because much of the sarcoplasmic proteins are removed during the washing step (Park & Lanier, 2000). The acid produced protein isolate contains on the other hand sizable amount of sarcoplasmic proteins while the alkali isolate had significantly less of the sarcoplasmic proteins. The types of proteins recovered therefore do not seem to explain this similar behaviour of the acid and alkali isolates on heating. The above emphasises that the differences between the two systems are far from trivial and more investigation is needed to understand the underlying mechanisms for gelation in salt and no salt.

3.4. Water-holding capacity

Good water-holding capacity is an important factor in muscle protein gels as it not only affects the economics of their production but also their quality. Same gels as were tested with the Torsion Gelometer were analysed for water loss on pressing (Fig. 4). Gels with no added salt lost from about 5% to 14% water on pressing. Addition of 2% NaCl (w/w) significantly reduced ($p < 0.05$) water loss for protein isolates, while the difference was not significant ($p > 0.05$) for the washed muscle. The range of water loss, ~4.5–6%, for gels with salt was also smaller than that of gels with no salt. Most water loss, or ~14%, was observed for gels with no added NaCl from isolated made from pH 2.9 treated proteins, while the gels with added salt from the isolate made from pH 11 treated proteins had least water loss, or ~4.5%.

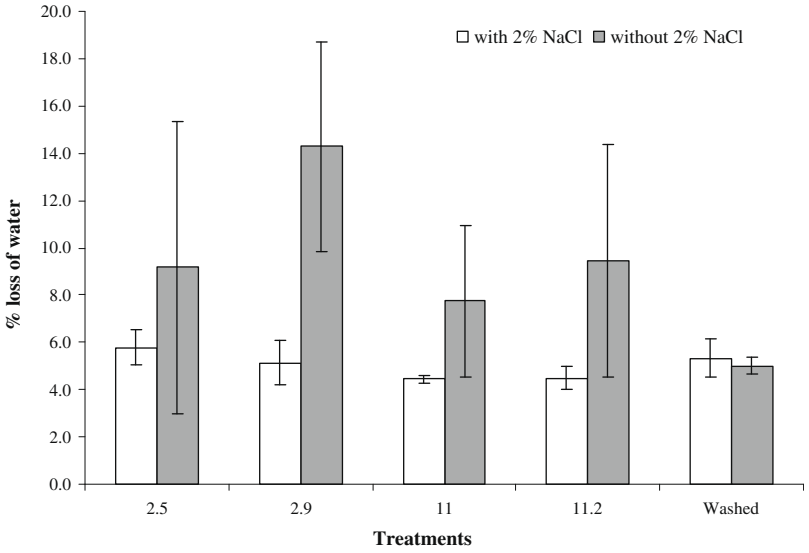

Fig. 4. Water loss of heat-induced tilapia protein isolates and washed muscle gel slices (3 mm) under pressure (3 kg). Samples contained either 2% added NaCl and no added NaCl.

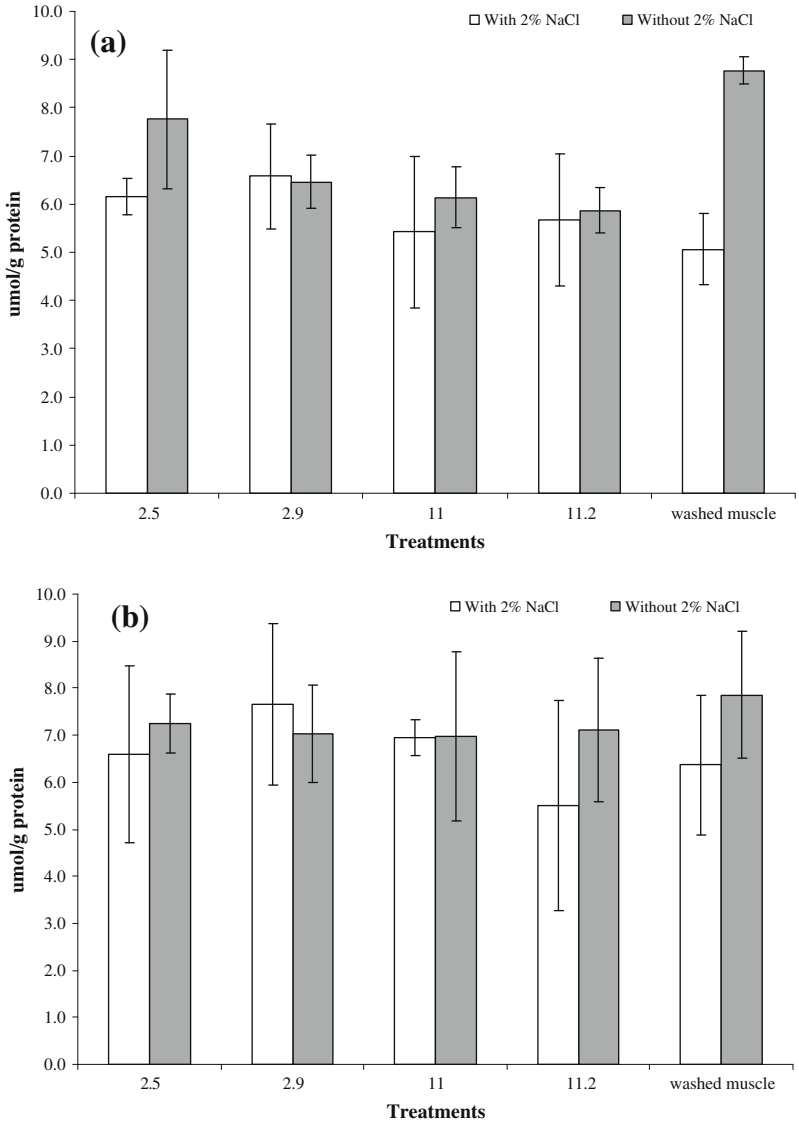

Fig. 5. Level of total sulphydryl groups (μmol/g protein) in tilapia protein isolates and washed muscle before (a) and after (b) thermal gelation (20 min at 80 °C).

Gel structure is believed to greatly influence the ability of a gel to hold water. In a well ordered gel, movement of water might be restricted compared to a less ordered structure (Hamman & MacDonald, 1992). This is partly due to strong capillary forces within the ordered structure and also high gel pressure if water is being held due to strong repulsive forces between negative charges in the protein matrix (Kristinsson & Hultin, 2003c). Between pH 7.1 and 7.2 there are strong repulsive forces between muscle proteins and these repulsive forces strengthen even more in the absence of salt (Kristinsson & Hultin, 2003c). The water-holding results agree with the gelation results, in that the weaker and more brittle gels had lower water-holding capacity. Feng and Hultin (2001) reported that gels with an evenly distributed gel structure showed improved WHC whereas a poor gel matrix can lead to syneresis, i.e. a discharge of water from the gel. Formation of localised aggregates is believed to contribute to lower gel forming ability (Feng & Hultin, 2001) and a correlation between a gel elasticity and water-holding capacity has been seen for chicken-breast gels (Kristinsson & Hultin, 2003c). For example the gels from the pH 2.9 treatment had the poorest gel forming ability (especially in the absence of salt), thus having a poorer gel structure, and also had the least ability to hold water than any of the other treatments. The salt free gels in general had poorer gel forming ability than the gels with salt, and these did also have worse water-holding ability. The addition of salt to the proteins thus appears to have led to a better ordered structure than the absence of salt. The salt is able to partially "solubilise" the muscle proteins, and this could have been important for the formation of an ordered structure since proteins would have been dispersed better prior to gelation.

3.5. SH-content

Changes in free sulphydryl (SH) groups and disulphide bonds (S–S) are often associated with gelation of muscle proteins. It is also known that SH-groups become more reactive at the high pH values representative of the alkaline process (Yongsawatdigul & Park, 2004). Washed muscle exhibited the highest total SH content before cooking for samples without added NaCl, whereas washed muscle with 2% NaCl (w/w) had significantly lower ($p < 0.05$) total SH content (Fig. 5a). There were no significant differences ($p > 0.05$) between pastes with no added salt and added salt between acid or alkali isolates. There was also no significant difference ($p > 0.05$) in total SH-groups after cooking between treatments and salt concentrations (Fig. 5b). It was also interesting to see that there were no significant ($p > 0.05$) difference in total SH-groups before and after gel formation.

A reduction in total SH-groups indicates the formation of S–S bonds between proteins, and has been found on many occasions when gelation of muscle proteins is studied (Lanier, 2000). A significant difference in SH group between the low and high pH treatments was not found. Other studies with the acid and alkali processes have either reported differences or no differences in reactive and total SH-groups. Kristinsson and Hultin (2003a) showed that alkali treated myosin had more reactive SH-groups than acid treated myosin, and also had better gel forming ability. A study by Yongsawatdigul and Park (2004) performed on rockfish muscle showed that washed muscle had lower content of total SH compared to unwashed muscle. These authors observed a higher amount of total SH-groups in proteins made with the alkaline process compared to acid process, thus suggesting S–S bonds formed during the acid process. Rockfish proteins made with the alkali process had the largest decrease in SH-groups, suggesting that more S–S bonds were formed during gelation for that treatment compared to other treatments. This was not seen with the tilapia muscle proteins. Another study performed on Pacific whiting showed a significantly higher total SH content of isolates made at low pH compared to high pH, suggesting SH-groups became more reactive on alkali treatment. Even though differences were seen in SH-groups with Pacific whiting proteins there were no link between these and gel forming ability. A study performed on threadfin bream showed that total sulphydryl groups were stable up to 30 °C but decreased from 40 to 80 °C which indicates formation of disulphide linkages during heating (Yongsawatdigul & Park, 2003). Again, the data with the tilapia proteins indicate that no significant S–S bonds were formed on heating and thus differences in SH-groups could not explain the different functionality of the proteins.

4. Conclusions

Gel forming ability of the acid and alkali treated proteins was determined and compared to washed tilapia muscle. Large strain testing (torsion) showed that gels with 2% added NaCl were stronger and more elastic compared to samples without 2% NaCl. The alkali treated proteins also gave better results when compared to acid treated proteins and washed muscle. The use of small strain oscillatory testing gave interesting results. Samples without 2% NaCl performed in some cases better than samples with 2% NaCl. Variability at low pH was high possibly due to a more unstable structure of the proteins. The small and large strain testing are however not necessarily expected to go hand in hand. Levels of total sulphydryl groups before and after thermal gelation did not explain differences in gel forming ability or gel quality. More investigation is needed to understand the underlying mechanism and the molecular properties involved in gelation of tilapia muscle proteins. The overall findings from this research indicate that alkali treated tilapia muscle proteins can form strong and elastic gels upon heating.

2. Materials and methods

2.1. Materials

Chufa [*Eleocharis tuberosa* (Roxb.) Roem. et Schult. cv. Guilin] corms were purchased from a commercial market in Nanning of China. The healthy corms with uniform size were selected, washed, peeled and then cut into small pieces using a sharp stainless steel knife. These fresh-cut samples were stored at −20 °C until further extraction and analysis.

2.2. Chemicals and reagents

Standards (−)-gallocatechin gallate, (−)-epicatechin gallate and (+)-catechin gallate were purchased from Sigma–Aldrich (St. Louis, MO, USA). Acetonitrile was HPLC grade and obtained from Merck (Darmstadt, Germany). Other reagents were analytical grade.

2.3. Partial purification and activity determination of PPO

PPO was extracted by the modified methods of Jiang, Giora, and Yoram (1997). At 4 °C, 30 g of corm samples were homogenised in 200 ml of 0.1 M sodium phosphate buffer (pH 6.8) containing 2 g of polyvinyl pyrrolidone (PVP) and 1.0% (v/v) Triton X-100. After filtration of the homogenate through cheesecloth, the filtrate was centrifuged at 10,000 rpm for 15 min. The supernatant was collected and fractionated with solid ammonium sulfate (30–80% saturation). The precipitate was collected by centrifugation at 10,000 rpm for 15 min, which was further re-dissolved in a small volume of 10 mM sodium phosphate buffer (pH 6.8). After overnight dialysis against the same buffer, the dialysed solution was collected as the partially purified PPO to analyse its biochemical properties. PPO activity was spectrophotometrically assayed according to the modified method of Jiang (1999) with catechol as an exogenous substrate. The enzyme solution (0.2 ml) was rapidly added into 2.8 ml of 10 mM catechol solution (prepared in 10 mM sodium phosphate buffer, pH 6.8). The increase in absorbance at 400 nm at 25 °C was recorded automatically for 3 min using a UV-1700 spectrophotometer (Shimadzu, Kyoto, Japan). One unit of PPO activity was defined as the amount of the enzyme that caused a change of 0.001 in absorbance per minute. Relative activity described enzymatic activity as the percentage of the activity expressed as $(A/A_{max}) \times 100$, where A indicated the increase in optical density per minute (Montero, Ávalos, & Pérez-Mateos, 2001). Protein content was determined by the dye-binding method of Bradford (1976).

2.4. Effects of pH and temperature on PPO properties

PPO activity was assayed in a pH range of 4–6 in 50 mM citric acid–phosphate buffer and 7–9 in 50 mM Tris–HCl buffer using catechol as the substrate. To determine the optimal pH values of chufa PPO, 1 ml of 10 mM catechol and 1.9 ml of buffer solution were mixed at 25 °C prior to adding 0.1 ml of enzyme solution. On the other hand, the PPO activity was measured in a temperature range of 20–60 °C using a water bath. A total of 2.8 ml of 10 mM catechol was pre-warmed to the corresponding temperatures. Then, 0.2 ml of enzyme solution was added. To determine the effects of high temperature, the enzyme solution was incubated in water bath at 70, 80 and 90 °C for 4 min. Every one minute, 0.2 ml of enzyme solution was transferred into 2.8 ml of 10 mM catechol to assay the enzyme stability. The relative activities were compared by the method described above.

2.5. Effects of inhibitors and metal ions on PPO properties

To determine the effects of inhibitors on PPO activity, 2.9 ml of 10 mM catechol and 25 μl of 0.1 M inhibitor solutions were mixed immediately at 25 °C prior to adding 75 μl of enzyme solution. To determine the effects of metal ions, 2 ml of 10 mM catechol and 1 ml of 2 mg/ml metal compounds were mixed before adding 0.5 ml of enzyme solution. The control was the substrate–enzyme reaction system without any inhibitor or metal compounds.

2.6. Determination of kinetic parameters

The enzyme kinetic parameters (Doğan & Doğan, 2004), Michaelis–Menten constant (K_m) and maximal reaction velocity (V_{max}) for chufa PPO were determined at 25 °C when using catechol as the substrate. The assay cuvette (3 ml) contained 2.8 ml of catechol solution with gradient concentration (from 0.002 to 0.01 M) and 0.2 ml of the enzyme solution. The kinetic parameters were estimated by linear regression analysis using the following equation.

$$v = \frac{V_{max} \cdot [S]}{K_m + [S]}, \quad (1)$$

where [S] corresponds to the substrate concentration. The data were plotted as $1/v$ vs $1/[S]$. K_m and V_{max} were determined as the reciprocal absolute values of the intercepts on the x- and y-axes of the regression curve (Lineweaver & Burk, 1934).

2.7. Identification and estimation of endogenous PPO substrates

Polyphenols in plants are often considered as PPO substrates. The identification of polyphenols in chufa corms were performed by high performance liquid chromatography using a Waters 2695 HPLC system (Waters, Milford, MA, USA) with a dual wavelength absorbance detector. The separation was carried out on a 250 × 4.6 mm i.d., 5 μm Pinnacle C_{18} column (Restek, Bellafonte, PA, USA). The mobile phase consisted of acetonitrile (A) and acidified water containing 2% acetic acid (B). The linear gradient program was as follows: 0 min, 1% A; 4 min, 1% A; 38 min, 50% A; 42 min, 80% A and then held for 3 min before returning to the initial conditions. The flow rate was 1 ml/min and the injection volume was 20 μl. The monitoring wavelength was at 280 nm. The recognition of phenolic compositions was achieved by comparison with retention times (Rt) and ultraviolet spectra of standards. HPLC profile ranged from 5 to 30 min, in which the obvious peaks appeared, was obtained by Waters Empower software.

2.8. Data analysis

In the present study, all experiments were performed in triplicate ($n = 3$), and the results represented mean ± standard deviations (SD) of three replicated determinations.

3. Results and discussion

3.1. Protein content and PPO activity

During the extraction of chufa PPO, an undesirable reaction between the natural phenols and PPO was prevented by adding PVP, which could extract phenols by a well-postulated hydrogen bonding of the ionisable hydrogens of phenol to the oxygens of polyvinylpyrrolidone (Andersen & Sowers, 1968). The addition of Triton X-100 during extraction might improve the PPO activity because this surfactant could extract enzymatic proteins in plasma membranes (Broothaerts et al., 2000; Sun et al., 2008). Using the dye-

binding method, the calibration curve was linear in a protein content range of 10–100 μg, with $R^2 > 0.99$ and the calibration curve equation was $y = 0.0074x - 0.0422$. Based on this equation, the protein content of the dialysed PPO enzyme solution in the present study was around 52.7 μg protein/ml with a total activity of 45 units/ml when catechol as the substrate.

3.2. Optimal pH and temperature

In general, PPO shows maximum activity at or near neutral pH values. However, the optimum pH has been found to vary with the enzymatic source and the substrate over a relatively wide range of values, including in alkaline medium (Cestari, Vieira, Nascimento, Santos Filha, & Airoldi, 2002). The pH profile for the oxidation of catechol by chufa PPO is shown in Fig. 1A. At 25 °C, the highest peak for relative enzyme activity was observed at pH 5, which indicated that the optimal pH for chufa PPO activity was pH 5. From Fig. 1A, the enzyme activity only slightly decreased between pH 5 and 6. However, it steeply declined under pH 5 and above pH 6. At pH 3 and 9, the PPO activities were only about 52.9% and 17.6% of the maximal activity. Plant PPO is suggested to contain Cu^{2+} in its active site (Kuwabara & Katoh, 1999), and Cu^{2+} will depart from the active site in the acidic or alkaline pH range, leading to the loss in PPO activity (Huang, Zhang, & Wang, 2005). This is the possible reason for steep decrease of chufa PPO activity under pH 5 and above pH 6 in the present study.

In addition, when using catechol as the substrate, the optimal temperature for chufa PPO activity was shown in Fig. 1B. The temperature has a two-sided influence on enzymatic activity, i.e. increasing incubation temperature enhances enzymatic reaction velocity but simultaneously results in denaturalisation of the enzyme. The optimal temperature depends on the effect of the two-sided equilibrium (Sun et al., 2008). From Fig. 1B, chufa PPO activity exhibited a gradually increasing trend in a temperature range of 20–45 °C, and then rapidly decreased above 45 °C due to the denaturalisation of the enzyme. The optimal temperature for chufa PPO activity was at 45 °C. The PPO in plant tissues is relatively heat labile and high temperatures can inactivate it. Thermal inactivation of PPO usually increases with increasing temperature and follows first-order kinetics, which has been reported in many studies (Chutintrasri & Noomhorm, 2006; Lee & Smith, 1979; Rapeanu, Loey, Smout, & Hendrickx, 2006; Schweiggert, Schieber, & Carle, 2005). The effects of high temperatures on chufa PPO are shown in Fig. 1C. The PPO was relatively stable at 70 °C but unstable at 80 and 90 °C. After heating for 4 min at 70 °C, the relative PPO activity were similar to that of heating for 0 min. While heating PPO at 80 and 90 °C, its relative activities remained at 79.4% and 61.8% after 4 min. The above results indicated that chufa PPO activity would obviously decline when heating it above 70 °C, which owes to the degradation of PPO at higher temperatures.

3.3. Effects of various inhibitors and metal ions

The effects of various inhibitors and metal ions on chufa PPO activity are listed in Table 1. Compared with the control, ethylenediaminetetraacetic acid disodium salt (EDTA-2Na) and L-cysteine had no inhibiting effects on the PPO activity. Contrarily, both compounds somewhat improved the enzymatic reaction between the PPO and catechol. Adding ascorbic acid, sodium thiosulfate pentahydrate ($Na_2S_2O_3{\cdot}5H_2O$) and anhydrous sodium sulfite (Na_2SO_3) into the substrate–enzyme system reduced the PPO activity. Amongst three inhibitors, $Na_2S_2O_3{\cdot}5H_2O$ exhibited the strongest inhibiting effect, followed by ascorbic acid and Na_2SO_3. The mechanism of inhibition differs, depending on the compound used. Ascorbic acid, owing to its nontoxic nature at the levels employed, is widely used to inhibit the activity of PPO in vegetable or fruit tissues. Ascorbic acid may act more as an antioxidant than as an enzyme inhibitor because it reduces the initial quinone formed by PPO to the original diphenol before it undergoes the browning reaction (Aydemir, 2004). On the other hand, ascorbic acid can also reduce Cu^{2+} of PPO into Cu^{+} (Hsu, Shieh, Bills, & White, 1988). Na_2-

Table 1
Effects of various inhibitors and metal compounds on chufa PPO activity.

Compounds	Concentration	A/A_{max} (%)
Inhibitors[*]		
Control	0.1 M	76.5 ± 0.7
EDTA-2Na	0.1 M	80.4 ± 0.6
Ascorbic acid	0.1 M	45.1 ± 1.2
$Na_2S_2O_3{\cdot}5H_2O$	0.1 M	41.2 ± 1.1
Na_2SO_3	0.1 M	64.7 ± 0.7
L-Cysteine	0.1 M	100 ± 0.0
Metal compounds[**]		
Control	2 mg/ml	37.3 ± 0.2
NaCl	2 mg/ml	44.1 ± 0.8
KCl	2 mg/ml	36.3 ± 1.4
$ZnSO_4{\cdot}7H_2O$	2 mg/ml	100 ± 0.0
$CaCl_2$	2 mg/ml	71.6 ± 3.5
$CuSO_4{\cdot}5H_2O$	2 mg/ml	87.3 ± 1.7
$FeSO_4{\cdot}7H_2O$	2 mg/ml	50.0 ± 2.2
$FeCl_3{\cdot}6H_2O$	2 mg/ml	74.5 ± 1.0

[*] Enzyme reaction system: 2.9 ml of 10 mM catechol (prepared in 10 mM sodium phosphate buffer, pH 6.8) + 25 μl of inhibitor + 75 μl of enzyme solution.
[**] Enzyme reaction system: 2 ml of 10 mM catechol (prepared in 10 mM sodium phosphate buffer, pH 6.8) + 1 ml of metal compounds + 0.5 ml of enzyme solution.

$S_2O_3{\cdot}5H_2O$ and Na_2SO_3 are the good reducing agents of *o*-quinone. Both may react directly with sulfhydryl groups, resulting in the reduction of *o*-quinone and formation of colourless complexes with *o*-quinone (Sun et al., 2008). Sulfites are effective in inhibiting PPO activity but they are subject to regulatory restrictions due to adverse effects on human health.

Generally speaking, adding 2 mg/ml metal compounds into the substrate–enzyme system had considerable influences on the PPO activity. Except for K^+, other metal ions accelerated the enzymatic reaction between the PPO and catechol. Amongst them, Zn^{2+} exhibited the strongest accelerating effect and the PPO activity increased most after adding it. Cu^{2+}, Fe^{3+} and Ca^{2+} also improved this enzymatic reaction. Furthermore, adding Fe^{2+} and Na^+ into the substrate–enzyme system weakly increased the PPO activity. Plant PPO is suggested to have one binuclear Cu site per protein molecule for the reaction centre (Kuwabara & Katoh, 1999), and various metal ions may affect the substrate combining this reaction centre so as to alter the PPO activity. Some metal ions that increase PPO activity have already found by other researchers who suggested that the effect of metal ions on PPO activity was concentration-dependent or pH-dependent. Chu, Yeh, and Shaw (1993) reported that Cu^{2+} activated banana leaf PPO activity at concentrations lower than 0.6 mM but inhibited it at higher concentrations. Using a kinetic study on the effect of sodium chloride on latent grape PPO activity, Valero and García-Carmona (1998) observed that this metal compound showed a strongly pH-dependent inhibitory effect at pH values lower than 5 but acted as an activator at higher values. Whether the effect of metal ions on chufa PPO activity is dependent on concentration and pH value needs further study.

3.4. Kinetic study

A Lineweaver–Burk double reciprocal plot (Fig. 2) showed a correlation coefficient of $R^2 = 0.9635$, and the regression curve equation was $y = 0.1307x + 12.125$. The K_m and V_{max} values of chufa PPO for catechol were calculated from above equation. The results showed that the apparent K_m and V_{max} values of the present enzymatic reaction were about 10.77 mM and 82 units/ml min at 25 °C, respectively.

3.5. Evaluation of potential endogenous PPO substrates

By HPLC analysis, three major polyphenols isolated from chufa corms were identified as (−)-gallocatechin gallate (Rt = 18.4 min),

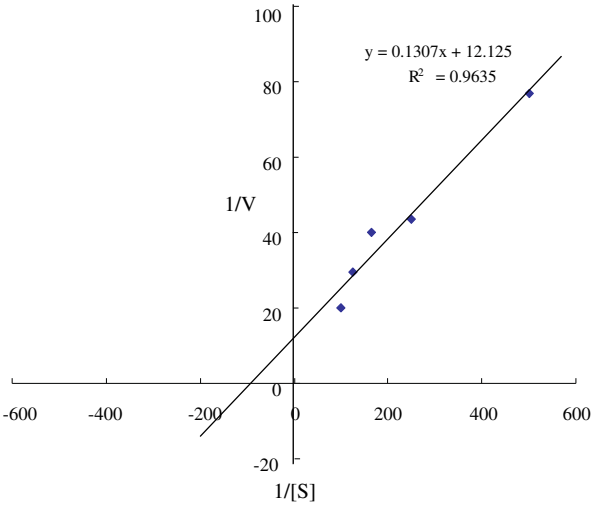

Fig. 2. Lineweaver–Burk double reciprocal plot of chufa PPO. The substrate concentrations were 0.002, 0.004, 0.006, 0.008 and 0.01 M, respectively.

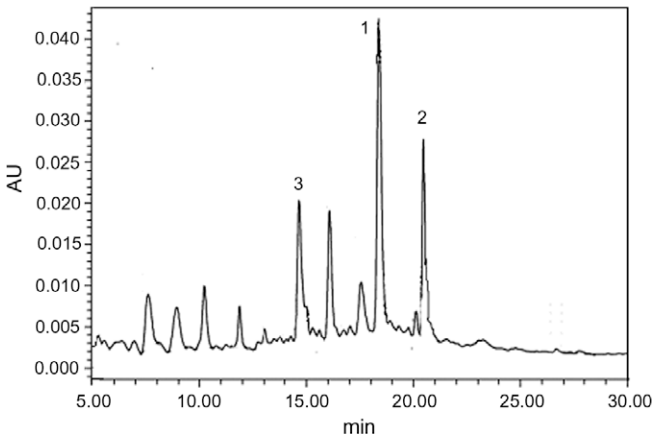

Fig. 3. HPLC–chromatogram of polyphenol components extracted from chufa corms ($\lambda = 280$ nm). Peak 1: (−)-gallocatechin gallate; peak 2: (−)-epicatechin gallate; and peak 3: (+)-catechin gallate.

(−)-epicatechin gallate (Rt = 20.5 min) and (+)-catechin gallate (Rt = 14.7 min) (Fig. 3). These three polyphenols possessed similar chemical structures to catechol, i.e. the *ortho*-diphenolic or pyrogallolic hydroxyls, which were the locations of enzymatic action of PPO (Jiang, 1999; Martinez & Whitaker, 1995; Sun et al., 2006). A wide range of compounds with *ortho*-dihydroxyphenolic or pyrogallolic structures are substrates for the PPO in higher plants because of the presence of oxidisable OH groups (i.e. those phenolic OHs that are adjacent to each other) (Martinez & Whitaker, 1995). Therefore, just like catechol which served as substrate of chufa PPO, these three polyphenols (as the potential endogenous substrates) might also be catalysed by chufa PPO in the presence of oxygen and finally polymerised into the yellow or brown coloured by-products, causing the browning of corm tissues after fresh-cut processing. In chufa corms, the phenolic compositions catalysed by PPO and the PPO properties when reacting with endogenous substrates will be investigated in further studies. These studies will be necessary for exactly elucidating enzyme-catalysed browning mechanism of fresh-cut chufa corms.

sensory attributes (especially focusing on the umami-taste attribute) according to their grades.

2. Materials and methods

2.1. Pine-mushroom

Pine-mushrooms of four grades cultivated in Inje-eup, Gangwon-do, Republic of Korea, in 2006 were used in this study. Fresh pine-mushrooms were wrapped in LLD-PE (low-level-density-polyethylene) film and stored at −70 °C in a deep freezer until use. Then they were thawed at 4 °C in a refrigerator for 3 h before sliced using a cutter (model SFS-102, Shinomura, Sanjo, Niigata, Japan). Then the pine-mushrooms were freeze-dried for the analysis of free amino acids and 5′-nucleotides.

2.2. Free amino acids assay

Free amino acids were extracted and analysed using EZ:faast-free amino acid analysis kit (Phenomenex, Torrance, CA) combined by gas chromatograph-flame ionisation detector (GC-FID) as described by Elmore, Koutsidis, Dodson, Mottram, and Wedzicha (2005). Freeze-dried pine-mushroom powder (1 g) was extracted with 15 ml of methanol at 75 °C for 25 min and cooled to room temperature. Then 15 ml of water and 17 ml of chloroform were added and this was centrifuged at 3000 rpm for 10 min. The supernatant was used as an extract sample for EZ:faast analysis. The preparation of a sample for GC-FID began with the addition of 20 nmol of novaline internal standard, followed by a solid phase extraction and then two derivatisation steps at room temperature. The derivatised amino acids were extracted into isooctane/chloroform (100 μl) and analysed by an HP 6890 GC-FID (Hewlett–Packard, Palo Alto, CA).

An aliquot of the derivatised amino acid solution (2 μl) was injected at 250 °C in split mode (1:15) onto a ZB AAA capillary column (60 m length × 0.25 mm i.d. × 0.25 mm film thickness, Phenomenex). The oven temperature was held at 110 °C for 1 min, then increased to 320 °C at 32 °C/min, and then held at 320 °C for 2 min. The carrier gas was helium at a constant flow rate of 1.5 ml/min. Each free amino acid was identified by matching its retention time with that of EZ:faast standard in GC chromatogram and quantified using its respective calibration curve.

2.3. 5′-Nucleotides

5′-Nucleotides were extracted and analysed as described by Taylor, Hershey, Levine, Coy, and Olivelle (1981). Freeze-dried pine-mushroom powder (500 mg) was extracted with 25 ml of deionised water. This suspension was heated to boil for 1 min, cooled, and then centrifuged at 3000 rpm for 15 min. The extraction was repeated twice. The combined supernatants were then evaporated, and filtered using a 0.45 μm PVDF filter (26 mm, Phenomenex) prior to HPLC analysis.

HPLC analysis was carried out using a HP series 1100 ultra performance liquid chromatograph (UPLC) system equipped with a G1311A quaternary pump, variable wavelength detector, and auto sampler (Hewlett–Packard). 5′-Nucleotides were separated by Sunfire C18 column (4.6 × 250 mm, 5 μl) (Waters Co., Milford, MA) using an isocratic mobile phase of 0.5 M potassium phosphate (pH 4.0 with phosphoric acid) at a flow rate of 1 ml/min and UV detection at 254 nm. Each 5′-nucleotide was identified by matching its retention time with that of an authentic standard in HPLC chromatogram and quantified using its respective calibration curve.

2.4. Equivalent umami concentration (EUC)

EUC (g MSG/100 g) is the concentration of MSG equivalent to the umami intensity given by a mixture of MSG and 5′-nucleotides and is represented by the following addition equation (Yamaguchi, Yoshikawa, Ikeda, & Ninomiya, 1971):

$$Y = \Sigma a_i b_i + 1218(\Sigma a_i b_i)(\Sigma a_j b_j)$$

where Y is the EUC of the mixture in terms of g MSG/100 g; a_i is the concentration (g/100 g) of each umami amino acid [aspartic acid (Asp) or glutamic acid (Glu)]; a_j is the concentration (g/100 g) of each 5′-nucleotide [5′-IMP, 5′-GMP, 5′-XMP, 5′-AMP]; b_i is the relative umami concentration (RUC) for each umami amino acid to MSG (Glu, 1 and Asp, 0.077); b_j is the RUC for each umami 5′-nucleotide to 5′-IMP (5′-IMP, 1; 5′-GMP, 2.3; 5′-XMP, 0.61 and 5′-AMP, 0.18); and 1218 is a synergistic constant based on the concentration (g/100 g) used.

2.5. Statistical analysis

Analysis of variance (ANOVA) was performed using the general line model (GLM) procedure to determine significant differences in the amounts of free amino acids and 5′-nucleotides of pine-mushrooms according to their grades. Duncan's multi-range test was conducted when the samples exhibited a significance difference between samples, with the level of significance set at $P < 0.05$. Both ANOVA and Duncan's multiple range test were performed with SPSS (version 10.1, Chicago, IL).

3. Results and discussion

The quality of mushrooms depends on various factors such as their aroma, taste, texture, and colour, with the aroma and taste being the most important. Pine-mushrooms have been classified according to their appearance by the Korean National Forestry Cooperatives Federation (http://www.koreanforest.com), which is affected mostly by their ripening stages and cultivating conditions. Our previous studies demonstrated that the flavour characteristics of pine-mushrooms vary distinctively with their grades, with the intensities of most sensory flavour attributes being either strongest or weakest in pine-mushrooms of the highest grade. A total of 15 sensory attributes, such as sweet, salty, sour, bitter, umami, piny, floral, alcohol-like, meaty, moldy, wet soil-like, fishy, fermented, metallic, and astringent properties, in pine-mushrooms, were described by eight trained panelists. The intensities of sweet, piny, floral, and meaty attributes were strongest in pine-mushrooms of the highest grade, whereas those of sour, bitter, alcohol-like, moldy, wet soil-like, fermented, metallic, and astringent attributes were highest in pine-mushrooms of the lowest grade, both ones being decreased or increased according to their grades. However, it was noteworthy that the umami-taste was strongest in pine-mushrooms of second grade (7.84), followed by third grade (6.56), fourth grade (5.84), and first grade (5.00), respectively (Cho et al., 2007).

As indicated in Table 1, 23 amino acids were identified in the two parts of the four grades of pine-mushrooms, with ANOVA their mean contents differed significantly with part and grade ($P < 0.05$). Free amino acids were grouped according to Komata (1969) into the following four classes of taste components: MSG-like, sweet, bitter, and tasteless. Chen (1986) found that sweet components (alanine, glycine, and threonine) and MSG-like components (aspartic and glutamic acids) were taste-active amino acids in mushrooms. In the present study, the content of glutamic acid decreased in the order of second grade > third grade > fourth grade > first grade. Also, the content of aspartic acid was highest in

[a] Each values are expressed as mean ± SD ($n = 3$) are significant differences ($P < 0.05$) among pine-mushrooms using Ducan's multiple comparison test between the samples having the different letter in a row.
[b] Umami-taste active amino acids, aspartic acid + glutamic acid.
[c] 5′-AMP, 5′-adenosine monophosphate.
[d] 5′-CMP, 5′-cytosine monophosphate.
[e] 5′-GMP, 5′-guanosine monophosphate.
[f] 5′-UMP, 5′-uridine monophosphate.
[g] Flavor 5′-nucleotides, 5′-GMP + 5′-IMP + 5′-XMP.
[h] Calculated based on the equation: $Y = \Sigma a_i b_i + 1218(\Sigma a_i b_i)(\Sigma a_j b_j)$ (Yamaguchi, Yoshikawa, Ikeda, & Ninomiya, 1971) where Y is the EUC of the mixture in terms of g MSG/100 g; a_i is the concentration (g/100 g) of each umami amino acid [aspartic acid (Asp) or glutamic acid (Glu)]; a_j is the concentration (g/100 g) of each 5′-nucleotide [5′-IMP, 5′-GMP, 5′-XMP, 5′-AMP]; b_i is the relative umami concentration (RUC) for each umami amino acid to MSG (Glu, 1 and Asp, 0.077); b_j is the RUC for each umami 5′-nucleotide to 5′-IMP (5′-IMP, 1; 5′-GMP, 2.3; 5′-XMP, 0.61 and 5′-AMP, 0.18); and 1218 is a synergistic constant based on the concentration (g/100 g) used.

pine-mushrooms of second grade, followed by those of third, first, and fourth grades. The contents of both aspartic and glutamic acids were higher in the pileus than in the stipe, irrespective of the grade. Moreover, as for the umami-taste, the total contents of aspartic and glutamic acids were highest and lowest in pine-mushrooms of second and first grades, respectively, which is consistent with the sensory results in our previous study (Cho et al., 2007).

Yamaguchi et al. (1971) reported that four of the six 5′-nucleotides (5′-AMP, 5′-IMP, 5′-GMP, and 5′-XMP) normally detected in mushrooms contribute to umami-taste. Table 1 lists the contents of the 5′-nucleotides (5′-AMP, 5′-CMP, 5′-GMP, and 5′-UMP) identified in the pileus and stipe of pine-mushrooms of the four grades. The contents of 5′-AMP and 5′-GMP exhibiting umami-taste decreased in the order of second grade > third grade > fourth grade > first grade. As for the umami-taste active free amino acids, the contents of 5′-AMP and 5′-GMP were higher in the pileus than in the stipe.

Yamaguchi et al. (1971) suggested that the combination of umami amino acids and umami 5′-nucleotides would synergistically increase the umami-taste of mushrooms. The EUC value of 100% indicates that the umami intensity of mushrooms per 1 g dry matter is equivalent to the umami intensity of 1 g of MSG; in other words, 1 g MSG/g dry matter. The EUC values of pine-mushrooms varied widely, ranging from 204.26% in the pileus of second grade mushrooms to 13.26% in the stipe of first grade mushrooms. Mau (2005) grouped the EUC values into four levels: (1) >1000 g, (2) 100–1000 g, (3) 10–100 g, and (4) <10 g per 100 g of dry matter, corresponding to >10, 1–10, 0.1–1, and <0.1 g MSG/g, respectively. Therefore, the EUC values of our tested pine-mushrooms were in the second level. On the other hand, it was noteworthy that the EUC values and umami sensory intensities exhibited the same patterns in pine-mushrooms of different grades. Also, the EUC values were higher in the pileus than in the stipe.

In conclusion, the total contents of umami-taste active free amino acids and 5′-nucleotides were highest and lowest in pine-mushrooms of second and first grades, respectively. Also, the EUC value, which could express the synergistic effect between umami-taste components, decreased in the order of second grade > third grade > four grade > first grade. All of these results are highly consistent with those of the sensory tests performed in our previous study (Cho et al., 2007), showing that amino acids (e.g., aspartic acid and glutamic acid) and 5′-nucleotides (e.g., 5′-AMP and 5′-

GMP) are key umami-taste components of pine-mushrooms. Moreover, the contents of umami-taste active free amino acids and 5′-nucleotides and the EUC values were higher in the pileus than in the stipe in all four grades of pine-mushrooms.

pH of soy milk from 7.5 to 6.0 (Nsofor & Maduako, 1992). Pasteurised soy milks were fortified with Ca, followed by serial concentrations of potassium citrate (used as CA) and SHMP, to compare their effectiveness in the study of Yazici et al. (1997). They found that heat stability of soy milks with SHMP were lower than for potassium citrate. They discussed that this might be because the final pH attained with potassium citrate was higher than that of SHMP and also might be due to conformational changes in protein structure due to specific reactions of CA.

There has been no report on the effect of pasteurisation on the properties of Ca-fortified soy milk, which would be useful for their manufacture. The objective of the present study is to investigate [Ca^{2+}], pH, absolute viscosity, particle diameter and dry sediment content of Ca-fortified soy milk incorporating SHMP, DSHP, TSC or EDTA-Na_2, before and after pasteurisation.

2. Materials and methods

2.1. Materials

Dried soybeans, *Glycine max*, (product of Canada) were purchased from a supermarket in Reading, UK.

The following CAs was used: SHMP ($(NaPO_3)_6$, Fisher Scientific Ltd., Loughborough, UK), DSHP ($Na_2HPO_4{\cdot}2H_2O$, Fisher Scientific Ltd., Loughborough, UK), TSC ($Na_3C_6H_5O_7{\cdot}2H_2O$, Fisher Scientific Ltd., Loughborough, UK) and EDTA-Na_2 ($C_{10}H_{14}N_2Na_2O_8{\cdot}2H_2O$, BDH Laboratory Supplies, Poole, UK). Ca chloride ($CaCl_2{\cdot}2H_2O$) was obtained from VWR International Ltd., Poole, UK.

2.2. Preparation of soy milk

Soybeans (100 g) were washed in de-ionised water. The cleaned beans were soaked in 1 kg of water for 14 h at 4 °C. The swollen soybeans were drained and blended with 1 kg of boiling water in a blender (Model A707A, Kenwood MFG, Surrey, UK) at low speed for 5 min. The slurry was heated for 10 min at 80 °C. The hot mixture was filtered through four layers of cheese cloth and the filtrate (~850 g) was collected. The soy milk was cooled to room temperature and then kept at 4 °C.

2.3. Preparation of samples

Soy milk (700 g) was heated to 45 °C on a heated magnetic stirrer, and SHMP, DSHP, TSC or EDTA-Na_2 was added at concentrations of 0.5% or 1.0%. The mixtures were stirred on a heated magnetic stirrer for 10 min at 45 °C. The soy milks (600 ml) containing chelating agents were warmed to 45 °C and Ca chloride was added at a concentration of 25 mM, followed by stirring under the same conditions. Each sample of Ca-fortified soy milk was divided into two, and one was pasteurised at 72 °C for 15 s in a glass bottle (500 ml capacity) in a water bath, with the temperature controlled at 75 °C, and subsequently cooled to room temperature. The remaining portions of Ca-fortified soy milks were not pasteurised. Control samples before and after pasteurisation were prepared without addition of CAs. All samples were allowed to equilibrate at 4 °C for 2 h. Preparation of samples was carried out in triplicate.

2.4. Analysis of samples

2.4.1. Ionic Ca concentration

Ionic Ca concentration was measured using a Ca^{2+}/pH analyser (Model 634, Ciba Corning Diagnostics, Essex, UK), described by Lin, Lewis, and Grandison (2006). The mV value for standards and samples was obtained directly from the analyser. Five ionic Ca standards (0.1–11 mM) were used to produce a calibration curve (log [Ca^{2+}] versus mV) on each day of analysis.

2.4.2. pH

A pH meter (Model SA 720, Orion Research Inc., Massachusetts, USA) was used to measure pH of samples at 25 °C.

2.4.3. Absolute viscosity

Kinematic viscosity of samples at 25 °C was measured with an Ostwald U-tube as described by Lewis (1996). The density of samples at 25 °C was analysed using specific gravity bottles (Lewis, 1996). Absolute viscosity was calculated according to Eq. (1)

$$\text{Absolute viscosity} = \text{kinematic viscosity} \times \text{density} \quad (1)$$

2.4.4. Particle diameter

Particle diameters of diluted samples (100 μl samples in 3 ml de-ionised water) were measured with a Zetamaster (Model ZEM 5002, Malvern Instruments Ltd., Malvern, UK).

2.4.5. Dry sediment

An accurately weighed (A, g) sample (approximately 23 g) was added to a centrifuge tube. The tube was then centrifuged at 4200 rpm for 30 min (2760 G) in a centrifuge (Model Centaur 2, Fisons, Loughborough, UK). The supernatant was discarded. The pellet was transferred to a moisture dish and dried in a hot air oven at 105 °C to constant weight (B, g). The equation below was applied to find% dry sediment

$$\%\ \text{Dry sediment} = \left(\frac{B}{A}\right) \times 100 \quad (2)$$

2.5. Statistical analysis

Statistical analysis of data for effects of CA and pasteurisation on properties of soy milk was performed by one-way ANOVA using SPSS 15.0 for Windows. Mean differences were analysed using Duncan's multiple-range test at $p \leqslant 0.05$.

3. Results and discussion

3.1. Effect of CA and pasteurisation on [Ca^{2+}]

Table 1 shows how [Ca^{2+}] of Ca-fortified soy milks is affected by addition of four types of CA. Control samples (with no addition of CA) before and after pasteurisation had the highest [Ca^{2+}]. Adding 25 mM Ca chloride clearly precipitated soybean protein in the control samples. This Ca level was within the range (10–100 mM) reported necessary to form a good curd in soy milk (Wang & Hesseltine, 1982). Soybean curd was found at the bottom of the bottle and clear whey formed the top layer. In a previous study, it was found that [Ca^{2+}] in soy milk was very low (<0.02 mM) Pathomrungsiyounggul et al. (2007). Thus, most of the [Ca^{2+}] (0.28–8.55 mM) in Table 1 was derived from the added Ca chloride.

[Ca^{2+}] in the pasteurised control sample in the present study (8.38 mM) was slightly higher than that produced in the previous study (7.66 mM) (Pathomrungsiyounggul et al., 2007). Note that different batches of soybeans were used to make the soy milks. It was found that approximately one third of the added Ca dissociated to Ca ion in the control samples. The remainder would be either undissociated or bound to the proteins. It is known that Ca does bind to soy protein. The two main storage proteins of soybean, 7S and 11S globulin are both involved in soy curd formation (Saio, Kamiya, & Watanabe, 1969). The binding sites are on the side-chain carboxyl groups of the aspartic and glutamic acid resi-

No significant effect of pasteurisation on $[Ca^{2+}]$ of samples.

dues, as well as on the imidazole group of histidine (Kroll, 1984). Besides binding with protein, Ca ions also bind with phytate in soy milk (Torikata, Ishihara, & Yano, 1986).

As well as in the control samples, coagulation also occurred in the pasteurised sample containing 0.5% SHMP; and in both unheated and heated soy milks with 0.5% added TSC, and for all samples with added EDTA-Na_2.

Addition of all types of CA led to a significant ($p \leqslant 0.05$) reduction in $[Ca^{2+}]$ of both unheated and pasteurised soy milks, compared to their controls. They function by reducing the chemical activity of metal ions, forming complexes with their unshared electron pair (Lindsay, 1996; Martell & Motekaitis, 2002). Higher additions of added CA resulted in significantly lower $[Ca^{2+}]$ levels in the samples, ($p \leqslant 0.05$).

Similar results have been found in other drinks. A model nutritional beverage, (soybean oil-in-water emulsion stabilised by whey protein isolate) containing Ca chloride, had lower $[Ca^{2+}]$ when EDTA-Na_2 or TSC were added (Keowmaneechai & McClements, 2002). Tsioulpas (2005) found that increasing levels of SHMP, DSHP or TSC caused a significant drop of $[Ca^{2+}]$ in raw cows' milk. For all types of CA, the reduction of $[Ca^{2+}]$, measured in mM of added CA, was higher for 0.5% addition compared to 1% addition (Table 1).

Pasteurisation did not significantly change $[Ca^{2+}]$ (Table 1). Tessier and Rose (1958) reported a similar finding for skim milk pasteurised at 66 °C for 30 min, although heating milk at 82 °C for 30 min lowered $[Ca^{2+}]$. In the study of May and Smith (1998), a 7.3% decrease in $[Ca^{2+}]$ was found in milk after pasteurisation at 72.8 °C for 15 s and this supported the previous findings that Ca transferred from the soluble to the colloidal state.

It was noted for non-pasteurised samples that non-coagulated samples contained lower $[Ca^{2+}]$ than coagulated samples. The contents of Ca ions were generally in a range of 0.28–0.82 mM for non-coagulated and 0.91–8.55 mM for coagulated samples, respectively. However, the sample with 0.5% added DSHP showed no coagulation although its $[Ca^{2+}]$ was 1.11 mM.

3.2. Effect of CA and pasteurisation on pH

Table 2 shows the pH of Ca-fortified soy milk with various CAs before and after pasteurisation. Soy milk fortified with Ca had a pH of 5.66 and 5.65, before and after pasteurisation. It has been reported that the pH of soy milk (pH 6.7) was reduced to ~5.8 when 14 mM Ca were added (using Ca chloride) (Shun-Tang, Ono, & Mikami, 1999). It is expected that pH of soy milks with added Ca would be lower, as hydrogen ions are released. The hydrogen ions compete with Ca ions for the same binding sites on the protein molecule (Kroll, 1984) and these hydrogen ions should dissociate from protein molecules because of Ca ions binding to protein.

Adding 0.5% SHMP reduced the pH of control samples. This reduction was not significant for non-pasteurised samples but became significant ($p \leqslant 0.05$) for pasteurised samples. Adding 1% SHMP significantly increased ($p \leqslant 0.05$) the pH of control samples. The reduction of pH when adding low levels of SHMP might have arisen because hydrogen ions were released through the binding of protein with sodium ions from SHMP. Salts of Ca and magnesium have been used to bind to protein in the preparation of tofu resulting in a reduction in its pH (Prabhakaran, Perera, & Valiyaveettil, 2005). Adding 0.3% and 0.5% SHMP was previously found to decrease the pH of the 25 mM Ca-fortified soy milk but 0.7–1.2% addition raised its pH (Pathomrungsiyounggul et al., 2007). A drop in pH was observed when 0.3–1.5% SHMP were added to stabilise the Ca-fortified soy milk (Yazici et al., 1997). A slight increase of pH was reported in raw cows milk when 0.05–0.2% SHMP was added (Tsioulpas, 2005). These data indicate that using SHMP to stabilise beverages causes variable effects, sometimes decreasing and sometimes increasing the pH.

Addition of 0.5% and 1% DSHP significantly ($p \leqslant 0.05$) increased the pH of control samples; a higher concentration of added DSHP led to a higher pH. The same trend was found in raw cow milk (Tsioulpas, 2005). The pH of 1% DSHP solution was 9.14 (Table 2), forming an alkaline solution in water, leading to an increase of pH when added to soy milk.

Tri-sodium citrate caused similar, although less marked, pH changes to DSHP. A 1% TSC solution had a pH of 8.28 (Table 2), again contributing to this pH increase. At the 1% level of addition, TSC increased pH by less than DSHP. It was noted that the pH of a 1% TSC was lower than that of a 1% DSHP solution. The greater ability of DSHP to raise pH might be due to its higher molar concentration (at same % addition). The increase in pH of samples when adding a greater concentration of TSC in the present study was in agreement with its effects on cows' milk in the study of Tsioulpas (2005). Moreover, the addition of 0.3–1.5% potassium citrate as stabiliser in Ca-fortified soy milk caused an increase in pH, (Yazici et al., 1997).

All samples prepared with EDTA-Na_2 had much lower pH values (pH 4.33–4.69) compared with control samples (pH 5.65–5.66). The pH decreased significantly ($p \leqslant 0.05$) as the concentration of EDTA-Na_2 increased. Addition of EDTA-Na_2 as its disodium salt results in a reduction in pH of the system. For example, the pH of the

1% EDTA-Na_2 solution was as low as 4.57 (Table 2), because weakly acidic acetic acid is released into water. The isoelectric point (p*I*) of soy protein is about 4.2 (Liu et al., 2004). Protein molecules have a minimum solubility at their p*I* and are often seen to precipitate. Coagulation occurred in all samples treated with EDTA-Na_2, probably because their pH was lower, approaching the p*I*.

It was reported that soy protein in soy milk began to coagulate when the pH was reduced to about 6.0 regardless of the type of Ca salts, and that pH, rather than Ca ions is the most important factor for the precipitation of soy protein (Lu, Carter, & Chung, 1980). All samples showing coagulation in Table 2 had pH's near to or less than 6.0. Non-coagulated samples following the addition of DSHP and TSC had pH's higher than 6.0 but those using SHMP had pH's lower than 6.0.

Overall, most of the measured changes in pH following pasteurisation were not significant. In the case of the control and soy milk with added phosphates (SHMP and DSHP), pH decreased slightly after pasteurisation, and there were two samples (addition of 0.5% DSHP and 1% SHMP) in which the pH dropped significantly ($p \leqslant 0.05$) after pasteurisation. However, for soy milk with added TSC and EDTA-Na_2, the trend was for pasteurisation to increase the pH, although these changes were not statistically significant. Pasteurisation of skim milk at 66 °C for 30 min brought about a slight reduction of pH, from 6.79 to 6.72 in a previous study (Tessier & Rose, 1958). Sterilisation caused a small reduction in the pH of soy milks which were fortified with Ca using mixtures of Ca citrate and tri-Ca phosphate (Weingartner, Nelson, & Erdman, 1983). In contrast, a much larger reduction of pH after sterilisation was found in soy milks produced from blanched soybean (from 7.5 to 6.0), sprouted-blanched soybean (from 7.5 to 6.2) and sprouted-unblanched soybean (from 6.5 to 5.8) (Nsofor & Maduako, 1992).

3.3. Effect of CA and pasteurisation on absolute viscosity

Absolute viscosities of samples before and after pasteurisation are shown in Table 3. Viscosity will affect consumer acceptability of Ca-fortified soy milk. Some coagulated samples could not be measured because their curd blocked the capillary tube of the smaller diameter viscometer whereas flow times were too quick (<100 s) in the larger diameter viscometer. Flow times between 100 and 500 s offer accurate and reproducible results (Lewis, 1996). In the case of SHMP, DSHP and TSC, reductions of absolute viscosity were observed when their concentration was increased from 0.5% to 1%. Similar trends were reported previously in Ca-fortified soy milk. Adding 0.35–1% SHMP reduced absolute viscosity from 140 to 30 cp (Yazici et al., 1997). The viscosity dropped from 6.5 to 4.4 cp when TSC was increased from 0.2% to 0.7% TSC (Prabharaksa et al., 1989). Absolute viscosity is affected by total solids as well as the suspended matter, which usually increases the viscosity (Bourne, 2002). When Ca ions bind to the protein molecules, the

hydrophobic interaction of the neutralised proteins becomes more predominant and induces the aggregation (Kohyama et al., 1995). The aggregates of soy protein might influence the viscosity of samples in the same way as suspended matter. At lower concentration of CA, more Ca ions might bind with protein resulting in more aggregates in the samples, leading to higher absolute viscosities.

However, there was an increase in absolute viscosity when the concentration of EDTA-Na_2 increased from 0.5% to 1%. As mentioned, all samples with added EDTA-Na_2 coagulated. Therefore the higher solute concentration in the samples from high concentration of EDTA-Na_2 might increase the absolute viscosity of the samples. The relationship between the concentration of a solute and viscosity is a direct non-linear function (Bourne, 2002).

For samples prior to pasteurisation, the absolute viscosity of samples containing 1% SHMP, DSHP and TSC was low, in the range of 3.5–3.7 cp. Pasteurised samples which had not coagulated had absolute viscosities in a range of 3.79–8.42 cp. For more severe heat treatment of Ca lactate fortified soy milk by sterilisation containing 0.1–0.4% TSC, decreased the viscosity of samples about 3–4 times (Prabharaksa et al., 1989). They observed that viscosities of samples before and after sterilisation were 8.98–12.49 cp and 3.00–3.50 cp, respectively. Weingartner et al. (1983) reported that pasteurised soy beverages, containing 25 mM Ca using the mixtures of Ca citrate and tri-Ca phosphate, were acceptable to sensory panels and indistinguishable from the control (pasteurised soy milk no added Ca) and their viscosities were in the range 4.9–5.7 cp. Prabharaksa et al. (1989) found that Ca soy milk formulated for infants and young children by adding 0.45% Ca lactate and 0.3% TSC had a viscosity of 3.12 cp. Thus in comparison with this data, it should be possible to prepare the pasteurised-Ca-fortified soy milk with the desired viscosity by addition of 1% of either DSHP or TSC.

3.4. Effect of Ca and pasteurisation on particle diameter

The effects of different CAs and pasteurisation on the particle diameter are summarised in Table 4. In control samples, their particle sizes were bigger than 1000 nm. In the case of adding SHMP, particle size dropped following the addition of SHMP, with higher concentrations of SHMP giving a significantly smaller particle size. These results were in agreement with published data (Pathomrungsiyounggul et al., 2007). The reduction of particle diameter when Ca ions were bound by CA might be because the binding caused the repulsive force of negatively charged protein molecules to become predominant and protein molecules were less likely to aggregate. This drop of particle diameter in the present study contrasted with the results reported by Tsioulpas (2005), who added various concentrations of SHMP (from 0.8 to 3.2 mM) to unheated milks and sterilised them. His results showed that unheated milks and heated milks had larger casein micelles when increasing the concentration of SHMP.

For DSHP, it also reduced the particle diameter compared to control samples. A slightly larger particle diameter was found in non-pasteurised samples when increasing DSHP concentration from 0.5% to 1%, but a reduction in particle size was observed in pasteurised samples. Tsioulpas (2005) found that adding DSHP from 3.5 to 14 mM in milk, led to an unpredictable trend of casein micelle size in non-heated milk, whereas increase of casein micelle size was found in sterilised milk.

Samples containing 1% TSC had a smaller particle diameter than those containing 0.5% TSC. At 0.5%, TSC was less effective than other CAs in retarding aggregation but at 1% addition, it was able to reduce the size of samples to as low as ~487 and 509 nm for non-heated and heated samples, respectively. Keowmaneechai and McClements (2002) reported that sequestering of ionic Ca with TSC prevented droplets from aggregating and retarded the formation of larger flocs of the whey protein-stabilised oil-in-water emulsions. Their study showed that particle diameter of the beverage became smaller when TSC was added at 2.5 to 10 mM. In milk, addition of 2–8 mM TSC caused increase in size of casein micelles in non-sterilised and sterilised milk (Tsioulpas, 2005).

Particle diameter of samples containing 0.5% EDTA-Na_2 was smaller than control samples. Raising the EDTA-Na_2 concentration from 0.5% to 1% led to an increase in the particle diameter. Samples with 1% added EDTA-Na_2 had particle size >1000 nm which had been observed in control samples. This enlargement of particle diameter resulted possibly from the acidic function of EDTA-Na_2 (Table 2) on p*I* of protein molecules as mentioned. Keowmaneechai and McClements (2002) found the decrease and the increase of particle diameter of the whey protein-stabilised oil-in-water emulsions containing 10 mM Ca when increasing the concentration of EDTA-Na_2. Particle size of their sample was found to decrease when 2.5–10 mM EDTA-Na_2 were used and attributed to chelating free ionic Ca with EDTA. However, the particle size increased when the EDTA-Na_2 concentrations were used at 20–40 mM. They suggested that this was probably due to the ability of free sodium cation and EDTA anion to increase the ionic strength of the aqueous phase resulting in the reduction of the electrostatic repulsion between the droplets.

At a concentration of 0.5%, TSC was less effective in reducing the particle diameter than EDTA-Na_2. Even so, TSC gave a greater reduction in the particle diameter than EDTA-Na_2, at a concentra-

tion of 1%. TSC was shown previously to be somewhat less effective than EDTA-Na_2 at preventing flocculation at a low concentration in the whey protein-stabilised oil-in-water emulsion (Keowmaneechai & McClements, 2002).

Overall, all CAs improved the stability of control samples as a result of lowering particle diameter. The smallest particle diameter among pasteurised samples was observed in the sample containing 1% TSC. The particle sizes of three commercial soy milks were 380–440 nm according to a report by Saeseaw et al., (2005). It should be noted that the smallest size of pasteurised sample in this study was not as small as the particle size in the previous study.

Prior to pasteurisation, non-coagulated samples had a particle diameter of 468–596 nm. Pasteurisation increased their particle diameter but this was not significant ($p > 0.05$). For milk with added SHMP, DSHP and TSC at 0.05–0.2%, high heat treatment by sterilisation increased their casein micelle size by approximately 100–200 nm (Tsioulpas, 2005).

3.5. Effect of CA and pasteurisation on dry sediment

The dry sediment content is used to indicate the solids sedimented by applying a centrifugal force (Table 5). Control samples had dry sediment levels of 4.42% and 4.35%, before and after pasteurisation. There were significant ($p < 0.05$) reductions in dry sediment of samples with added SHMP, DSHP and TSC. However, in the case of addition of EDTA-Na_2, there was a small but non significant increase in dry sediment. These high levels of sediment are unacceptable.

Within the non-pasteurised group, all samples which had coagulated had a higher dry sediment content than that of control sample. The same result was also found among the pasteurised samples. For the non-pasteurised sample with 0.5% SHMP, although it did not show coagulation after 2 h, it contained higher dry sediment than the control sample. For the other non-coagulated samples addition of SHMP, DSHP and TSC reduced the dry sediment content when compared with their control samples, both before and after pasteurisation. The higher the level of CA, the lower the content of dry sediment.

Pasteurisation influenced significantly ($p \leqslant 0.05$) the dry sediment of the sample with 1% added SHMP. Its dry sediment content increased about three times following pasteurisation. For the remaining treatments, pasteurisation did not significantly change the dry sediment content of samples. The effect of soy milk temperature (60, 70 and 80 °C) at the time of adding $CaCl_2$ on total solid mass of samples was studied (Wang & Hesseltine, 1982). They found that the total solids mass remained about the same.

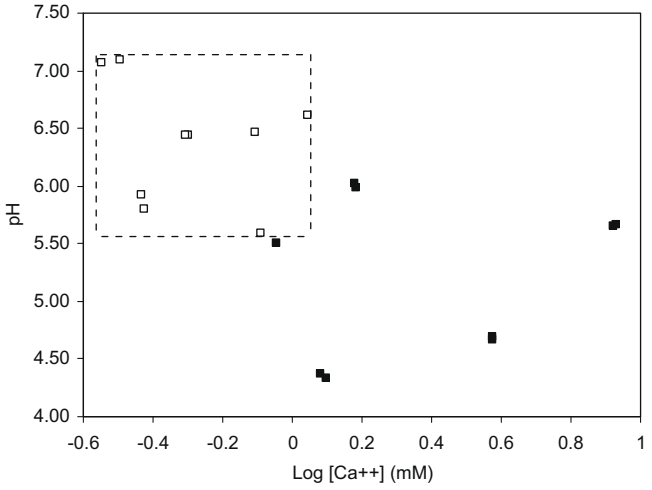

Fig. 1. Relationship between log [Ca^{2+}] and pH (□ non-coagulated and ■ coagulated sample).

It is desirable to minimise sediment formation. After pasteurisation, the sample with 1.0% added TSC contained the minimum amount of sediment content (1.26%). However, its level was higher than that of 25 mM Ca-fortified soy milk with 1.2% added SHMP, which was 0.76% (Pathomrungsiyounggul et al., 2007).

3.6. Relationship between [Ca^{2+}] and pH

It was found that increase in log [Ca^{2+}] led to a decrease in pH of samples (Fig. 1) This was similar to the observation of Pathomrungsiyounggul et al. (2007). To prepare Ca-fortified soy milk without coagulation, its Ca^{2+} and pH needs to be adjusted with values in the area indicated in Fig. 1. These were within the ranges log [Ca^{2+}] between −0.55 and 0.05 mM (i.e. 0.28–1.12 mM) and pH 5.6–7.1.

3.7. Relationship between [Ca^{2+}] and dry sediment

Fig. 2 indicates that the dry sediment of non-coagulated samples increase very quickly when [Ca^{2+}] is slightly higher whereas

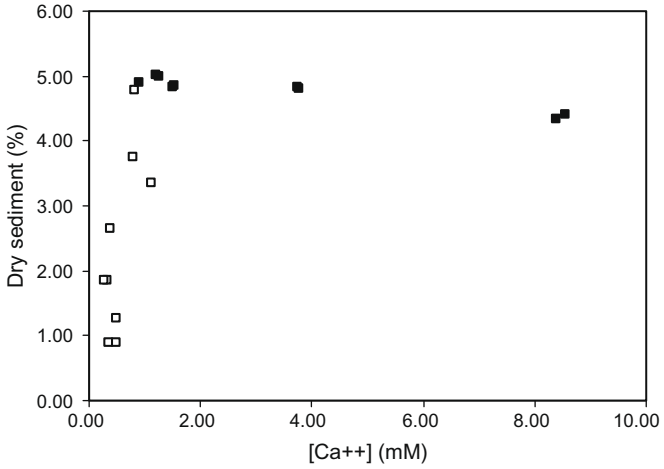

Fig. 2. Relationship between log [Ca^{2+}] and dry sediment (□ non-coagulated and ■ coagulated sample).

those of the coagulated samples were almost the same (~4.4–5.0%). The result in the present study agrees with the previous work in Ca-fortified soy milk (Pathomrungsiyounggul et al., 2007).

4. General discussion

Ca chloride is not the best salt for Ca fortification of soy milk, as the pH is reduced and ionic Ca is increased. The negative effects these factors have on heat stability are shown in Fig. 1. However, this can be corrected by the addition of stabilisers, and those which tend to work best are those which increase pH and decrease ionic Ca. Therefore, measuring pH and ionic Ca provides an effective method to monitor the effects of stabiliser addition. For soy milk, this has not been routinely reported. Since pH and ionic Ca provide good indicators of the susceptibility of sediment formation, this needs to be evaluated at higher temperatures, to evaluate heat stability during UHT processing and in-container sterilisation.

It is interesting to compare and contrast heat stability and sediment formation in milk of animal origin (e.g. cows' milk) and vegetable origin (e.g. soy milk).

On-Nom (2007) have found that when milk is heated, its pH falls and ionic Ca decreases, but that this is largely reversible on cooling. They measured pH and ionic Ca in milk at temperatures between 80 and 120 °C using dialysis. It has been argued that in order to evaluate heat stability, it is important be able to measure pH and ionic Ca at the pasteurisation and sterilisation conditions, although there is no reported data on how these properties change with temperature in soy milk.

EDTA-Na_2 is an interesting salt, as it chelates Ca in soy milk but also reduces pH and thus does not improve heat stability. An alternative chelating agent would be the tetra sodium salt, which when added to milk has been found to decrease ionic Ca and also increase pH. This is currently being investigated further.

However, the genetic basis of the aroma formation in melon is still unknown. One strategy to gain knowledge and improve aroma volatiles is the identification of genes or quantitative trait loci (QTLs) associated with certain compounds of the melon aroma profile. This strategy would help to implement quality-oriented breeding programme in order to design fruit with new or improved aroma.

The goal of the present work is to characterize the aroma profile of a collection of NILs that, with PI 161375 introgressions, encompassed many of the twelve linkage groups (LG) of the melon genome. Secondarily, some QTLs associated with aroma volatiles are reported and non-climacteric behaviour verified.

2. Material and methods

2.1. Plant material

The set of 25 melon near-isogenic lines (NILs) developed by introgressing Korean accession 'Shongwan Charmi' PI 161375 (SC; Group Conomon) genomic regions into 'Piel de sapo' (PS) [*C. melo* var. inodorus H. Jacq. (Group Inodorus)] genome (Eduardo, Arús, & Monforte, 2005) used in this study was described by Eduardo et al. (2007). Eighteen NILs contained a single molecular marker-defined introgression from SC into the PS genetic background (Eduardo et al., 2007), and the rest had two or more. The introgressions from SC presented in this set of NILs covered at least 85% of melon genome. In the present study the NIL SC3–5 was not used because of its evident climacteric behaviour (Obando-Ulloa et al., 2008). NILs were coded with the prefix "SC" followed by *x*–*y* numbers and, in some cases, one or two *z* letters (SC*x*–*y z*, for example SC3–5*ab*): the first *x* number indicates the linkage group (LG), and the second number *y* indicates the number of the NIL within the LG. The letters indicates additional genetic facts: "*a*", there is more than one introgression; "*b*" the NIL has an introgression slightly different from the introgression of the NIL with the same number described in Eduardo et al. (2005), although it covers the same genomic region; "*h*", the introgression is heterozygous and "*d*", part of the introgression is heterozygous (Eduardo et al., 2007). Although the mapping resolution of this population is not very high, it is sufficient for focusing research effort.

2.2. Experimental design

Crop management, harvesting practices, and harvesting indices have been previously described (Obando et al., 2008). Nine samples for the parental PS and 86 more for the NILs were analyzed. Only two replicates of NILs SC8–3, SC11–2*hab*, SC12–4*hb* and SC11–4*d* were available for analysis, while three samples of the remaining 21 NILs were analyzed (Table 1).

2.3. Fruit respiration rate

To confirm climacteric or non-climacteric behaviour, the fruit respiration rate in the NILs of interest was monitored over a period of 14*d* at 18.6 ± 1.1 °C and 68 ± 9% relative humidity. Nine NILs and PS were tested according to the static method (Fernández-Trujillo et al., 2008; Obando-Ulloa et al., 2008). The NILs were chosen based on the suspicion of climacteric behaviour in the field.

2.4. Juice sampling for aroma volatile analysis

Juice samples were obtained according to Obando-Ulloa et al. (2008) and stored at –60 °C until analysis. Juice was squeezed with a Simplex Super metal juicer (Italy) using 20 mm long and 15 mm diameter flesh cylinders obtained with an apple cork borer from the middle of one of the longitudinal sections of every fruit. Samples were taken by filtering juice through a powder funnel and four-layer cheesecloth. After 3 min, 4 ml of a saturated calcium chloride solution were added to 10 ml of juice and the mixture was homogenized, according to Baldwin, Goodner, Plotto, Pritchett, and Einstein (2004). A 1.33-ml mixture aliquot was poured into 4-ml glass vials for chromatography analysis. These samples were stored in a freezer at −70 °C until transportation for eight hours by car to the laboratory in Cáceres (Spain) in a 10 mm-thick polystyrene icebox with eight dry-CO_2 tablets of 100 g, and then stored at −80 °C until analysis.

2.5. Volatile analysis: headspace formation, solid-phase microextraction (SPME), gas chromatography–mass spectrometry (GC–MS) analysis

The methodology for gas chromatography–mass spectrometry (GC–MS) analysis of the samples was based on Ruiz, Ventanas, Cava, Andrés, and García (1999) and García-Esteban, Ansorena, Astiasarán, Martín, and Ruiz (2004), taking into account the information supplied by Kourkoutas et al. (2006). The method was described in a previous publication (Obando-Ulloa et al., 2008), but was slightly modified as a result of manual operation. The 4-ml vials were heated at 37 °C in a stirred shaken water bath for 30 min until equilibrium, and then aroma volatiles were extracted from the headspace for 30 min with a SPME fibre (StableFlex Divinylbenzene/Carboxen/polydimethyl siloxane 50/30 μm or DVD/CAR/PDMS) with 1 cm long standard needle for manual operation (Supelco Ref. 57328-U, Bellefonte, PA, USA), which was previously preconditioned at 280 °C for 50 min in the gas chromatography injection port.

After extraction, the fibre was manually introduced in the split/split-less injector at 280 °C in order to desorb the aroma volatile compounds during three minutes. The injector was mounted on a HP-6890 gas chromatograph (Agilent Technol., Wilmington, DEL) coupled to a selective single quadrupole mass spectrometer (HP-5973 Network, Agilent Technol.). For the split/split-less injector, the liner used had a 0.75 mm diameter (Supelco, Bellefonte, PA). The volatiles were separated into a 30 m × 0.25 mm internal diameter with 5% phenyl–methylsiloxane as stationary phase (HP-5MS, Agilent Technol.). The injection port was in split-less mode and the temperature was isothermal for 10 min at 40 °C, rising to 200 °C at 5 °C min^{-1}, and holding for 5 min. The transfer line to the mass spectrum was maintained at 280 °C.

The mass spectra were obtained by electronic impact at 70 eV, a multiplier voltage of 1756 V and collecting data at a rate of 1 scan·s^{-1} over the *m/z* range of 30–500 AMU. Compounds were tentatively identified by comparing their mass spectra with those included in the National Institute for Standards and Technology (NIST98, search version 2.0) data bank and by comparison of Kovats indices with those reported in the literature (Kondjoyan & Berdagué, 1996). The retention times from a series of straight-chain alkanes (C8–C20) supplied by Fluka were used under identical conditions to calculate the Kovats indices for all the identified volatile compounds (Kondjoyan & Berdagué, 1996; for "DB-5 like" phases). C6 and C7 were calculated from compounds present in our chromatograms. In addition, the Chemical Abstract Service (CAS) numbers of the volatiles reported in the NIST98 database also found in the website http://webbook.nist.gov/chemistry/name-ser.html (Table 2), were used to obtain their corresponding IUPAC names by checking the website http://www.chemindustry.com/apps/chemicals (Obando-Ulloa et al., 2008). The results of the volatile analyzes were expressed as percentage of total chromatographic area of the 28 volatile compounds of the profile reported in Table 2 (Muriel, Antequera, Petrón, Andrés, & Ruiz, 2004). These compounds were recovered and positively identified within the run time (Beaulieu, 2005, 2006; Muriel et al., 2004).

Table 1
Mean relative content of the probable aromatic compounds identified in the headspace of the fruit of the collection of near-isogenic lines (NILs) of melon and the parental line 'Piel de sapo' (PS). Mean physiological activities at harvest of the fruit analyzed are also reported. NIL means within rows highlighted with * showed statistical differences from PS data, according to a Dunnett's test at $P = 0.05$.

2.6. Statistical analysis

Data were subjected to a one-way ANOVA using general linear model procedures, with pedigree as factor in JMP® v5.1.2 for Windows (SAS Institute Inc., NC). If significant differences were found by ANOVA using pedigree, the differences between NILs and PS were evaluated by Dunnett's test at $P = 0.05$, using JMP, according to Obando et al. (2008).

Aroma data were also subjected to principal components analysis (PCA), using JMP. This analysis was used to identify the volatiles that explain the most part of the volatile differences among NILs and to group the NILs according their aroma profile. The NIL PC values of all the compounds were analyzed by ANOVA with pedigree as factor and Dunnett's test in JMP. The PCA graph was split into two graphs (score and loading plots, respectively) in order to clarify the analysis due to the high number of samples and volatiles considered in this study. Otherwise, the PCA figure with the score plot overlapping the loading plot would be a cloud of data with no sense. The score plot was performed with the mean component value (prin) obtained for each PC, while the loading plot was reached with the eigenvectors greater than 0.20 for the aroma volatile compounds that better define the orientation of each PC axis.

3. Results

3.1. Respiration rate

The PS showed a non-climacteric pattern, while four NILs showed a similar non-climacteric behaviour (Fig. 1). Compared with the respiration rate levels of PS, SC8–4 and SC9–2*a* showed slightly higher levels, while SC2–3*d* showed slightly lower levels. The NIL SC3–3 was classified as having a slightly climacteric behaviour (Fig. 1). Other NILs checked at harvest (Table 1) or in other experiments, such as SC10–2, also showed the levels of non-climacteric PS or a typical non-climacteric pattern (data not shown).

3.2. Definition of the aroma profile

About 206 aroma volatile compounds were tentatively identified in the headspace of the NILs analyzed, although only 48 compounds were preliminarily identified in most of the NILs and in PS. The definition of the aroma profile was based on the number of samples in which the compound was detected. So, in cases in which there were two NIL samples and the compound was detected in only one of them, the compound was not considered for the profile. On the other hand, if there were three samples and the compound was identified in two of the three or in all three samples, it was considered for the profile. That is why only 24 compounds defined the probable aroma profile in the whole collection and PS (Table 1). The profile was composed of six aldehydes, three esters, three branched alkanes, three aromatic branched hydrocarbons, two terpenes, two ketones and five compounds from other groups (Tables 1 and 2).

It was also found that (*Z*,*Z*)-3,6 nonadienal was only detected in NIL SC8–1, with a relative content levels of around 0.51%.

3.3. Principal component analysis of the aroma volatile data

PCA transformed a number of possibly correlated variables of single aroma volatiles into a smaller number of uncorrelated variables called principal components. Principal components were obtained as linear combinations of the original variables, so the first principal component has maximum possible variance, the second principal component is orthogonal to the first principal component and has the maximum possible variance and so on. PC components explain better the melon aroma than single compounds individually. The first three PCs contributed to 57% of the total variance (30%, 15% and 12%, respectively). Fig. 2A depicts PC1 versus PC2. The parental line PS was located close to the centre of the graph. The NIL SC12–1*ab* showed the higher PC1 levels, significantly higher than PS, according to the Dunnett's test (Table 1; data not shown). NILs SC4–3*b*, SC11–2*hab* showed higher PC2 values than PS, while SC7–2 showed lower PC2 values according to Dunnett's tests (Fig. 2A; data not shown).

PC1, representing 30% of the total variance, was mostly affected by the relative concentrations of 2-methylpentane, 3-methylpentane, ethylbenzene, 1,4-dimethylbenzene, 1,2-dimethylbenzene and 5,5,6-trimethyl-, endo-bicyclo[2.2.1]-2-heptanone in the positive direction, while pentanal, hexanal, and heptanal defined the negative orientation of the PC1 axis (Fig. 2B). PC2, representing 15% of the total variance, was affected by relative concentrations of methanethiol, ethanol, ethyl ether, methylcyclopentane, which defined its negative orientation, while its positive orientation was defined by 1-methoxypropan-2-yl acetate, 6-methyl-5-heptene-2-one, octanal and decanal. The third component PC3, representing 12% of the total variance, was mainly affected in its negative orientation by the relative concentration of butyl acetate, a non-identified terpene and 1,7,7-trimethylnorbornan-2-one (camphor) (data not shown).

3.4. Univariate analysis of the compounds identified in the aroma profile

Three compounds of the profile [hexanal, 1,7,7-trimethylnorbornan-2-one (camphor), and methanethiol] showed noticeably higher levels than the rest of the compounds but with no significant pedigree effect.

However, compounds with lower relative content were more affected by the pedigree factor. Some of them, such as the 3-hydroxy-2,4,4-trimethylpentyl 2-methylpropanoate, showed a higher relative content compared with PS (29–148% in the NILs SC4–3*b*, SC4–4 and SC11–4*d*). On the other hand, octanal showed a 11.3% lower level in the NIL SC8–1 than PS (Table 1).

3.5. QTL mapping

Only three QTLs were associated with the aroma profile of these NILs. Two of them increased the ester 3-hydroxy-2,4,4-trimethylpentyl 2-methylpropanoate (2 QTLs in LG IV and XI), while other in LG VIII reduced the relative content of octanal. Additionally, another QTL in LG VIII was responsible for the cucumber-like aroma [(*Z*,*Z*)-3,6 nonadienal], characteristic of NIL SC8–1, as mentioned above.

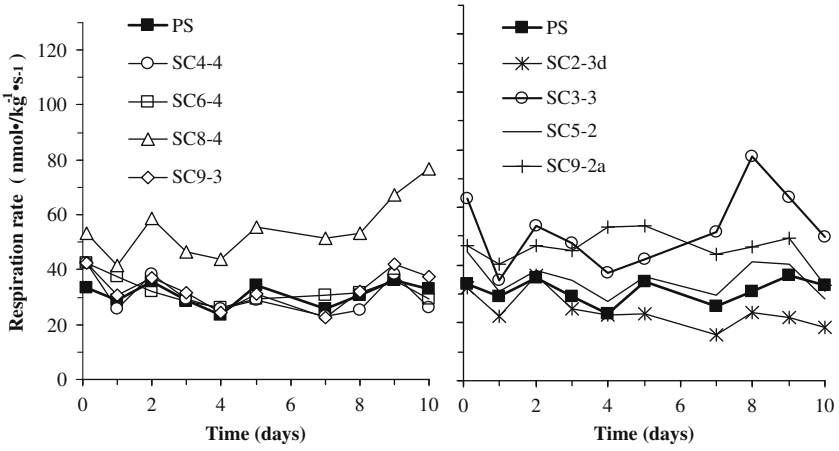

Fig. 1. Respiration rate (mean of representative fruit, $n = 3–5$) in the parental line 'Piel de Sapo' (PS) and five selected near-isogenic lines (NILs) of melon measured over 10 d at 18.6 °C.

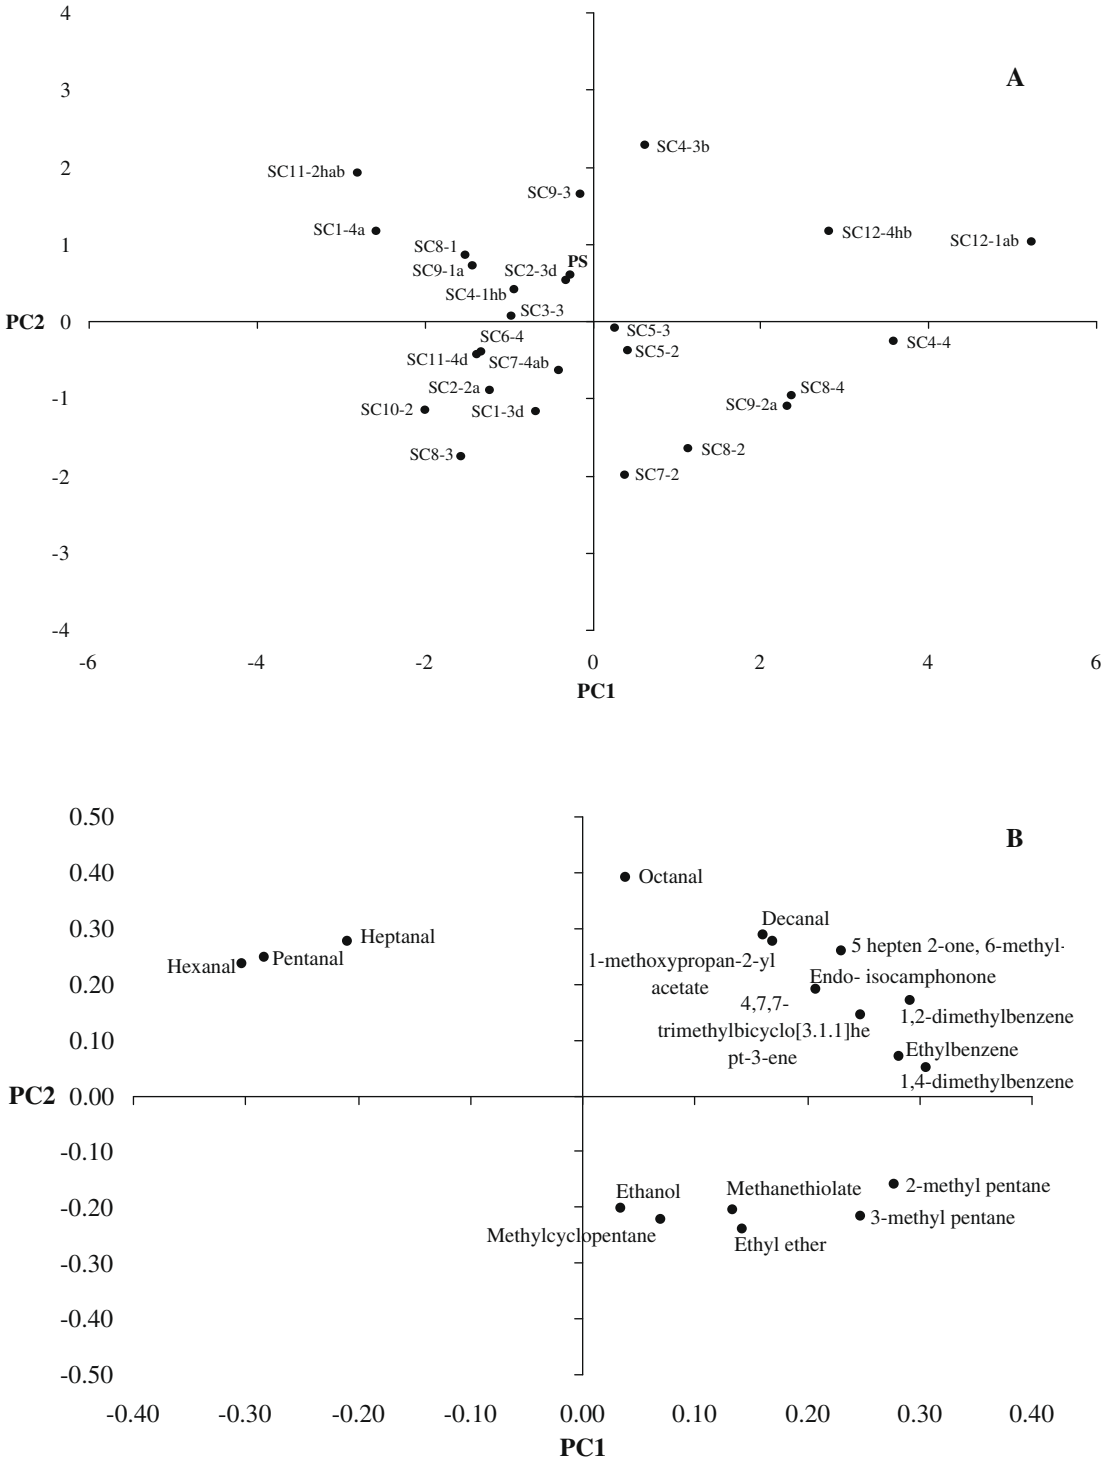

Fig. 2. Plot of the centroids of scores (A) and loading plots (B) of the the two main principal component analyzes (PCA) of the aroma volatiles identified in the collection of near-isogenic lines (NILs) of melon at harvest. The loading plots higher than 0.20% allowed the orientation of the PC axis to be defined. The first two PC's explained 30% and 15% of the total variance, respectively. The biplot was divided in two figures in order to provide a clearer graph for a better understanding of the results.

4. Discussion

Overall, PI 161375 did not really affect the physiological behaviour of the NILs studied, which showed a non-climacteric behaviour, except NIL SC8–4 with its respiration rate that seemed to be higher and showed a trend to increase (Fig. 1), and the NIL SC3–5 previously studied (Moreno et al., 2008; Obando-Ulloa et al., 2008; data not shown). The aroma profile of non-climacteric *Inodorous* melons has received little attention in the literature (Kourkoutas et al., 2006), but these melons have great interest as intact, fresh-cut or processed fruit due to their longer shelf-life than the climacteric ones (Beaulieu & Baldwin, 2002; Fernández-Trujillo et al., 2008; Oms-Oliu, Odriozola-Serrano, Soliva-Fortuny, & Martin-Belloso, 2008).

Usually, ethylene burst aroma biosynthesis is easy to detect by the human nose, while in non-climacteric fruit the external aroma is scarcely detected except when the fruit become senescent or rotten (Obando-Ulloa et al., 2009). The non-climacteric PS type, how-

ever, shows many aroma compounds, most of them aldehydes (Table 1). Even though some aldehydes are not easily detectable by the human nose, others have a low human detection threshold (Baldwin, 2002; Beaulieu & Baldwin, 2002; Canoles, Beaudry, Li, & Howe, 2006), and are important for the flavour of tomato, cucumber, peppers and other vegetables (Baldwin, 2002; Canoles et al., 2006). Aldehydes with low molecular weight are associated with immature stages in climacteric Cantaloupe melons (Beaulieu & Grimm, 2001). However, most aldehydes are present at high levels or increase markedly during early growth stages and then decrease with increasing harvest maturity (Beaulieu & Grimm, 2001). In this collection, aldehydes are present in between 15–40% relative levels of the total aroma of the profile, and hexanal shows the highest relative content with respect to other aldehydes, in agreement with previous results working with PS and other non-climacteric NILs with introgression in LG III (Obando-Ulloa et al., 2008). Hexanal is considered to contribute to green notes and, secondarily, to melon aroma, and benzaldehyde has been defined as a pleasant aroma for Cantaloupe type melons (Beaulieu, 2006; Beaulieu & Grimm, 2001), and high concentrations are usually associated with a high degree of melon ripening (Beaulieu & Grimm, 2001). Also, it is not unlikely that the unsaturated aldehyde fraction and, particularly, hexanal, may be due to lipid peroxidation during sampling and freezing (Ma et al., 2007). It has also been reported that hexanal increases with increasing harvest maturity, which could lead to development of off-flavours in stored melon and fresh-cut products (Beaulieu & Grimm, 2001) and in tomato (Canoles et al., 2006). However, hexanal slightly changes during PS senescence compared with other NILs (Obando-Ulloa et al., 2009).

The rest of the main compounds of the profile have previously been reported as aroma components in other foods. For example, methanethiolate has been associated with food heating and/or cooking, and is also an essential compound for the flavour of cured ham (Ruiz et al., 1999). However, the high concentrations in some NILs and reference cultivars seem to contribute to the *musky* notes of the aroma (Obando-Ulloa et al., 2008).

On the other hand, 1,7,7-trimethylnorbornan-2-one (camphor) have also been reported in other melon cultivars (Lamikanra & Richard, 2002), and in NILs with introgression of the melon LG III (Obando-Ulloa et al., 2008). The three QTLs mapped for three different compounds and LG's can be used as a good model for melons to study the relationship between aroma biosynthesis and aroma precursors (Baldwin, 2002). Octanal is an aldehyde previously reported as a major component (12.7% v/v) in orange flavourings (Muñoz-Aguirre, Yoshino, Nakamoto, & Morizumi, 2007), but also reported in the flesh of Queen Ann's pocket melons (Aubert & Pitrat, 2006), fresh-cut Cantaloupe melons (Beaulieu & Lancaster, 2007), in and in seedless watermelon juice (Beaulieu & Lea, 2006).

The compound 3-hydroxy-2,4,4-trimethylpentyl 2-methylpropanoate is a complex ester not previously reported in PS or the NILs studied with introgression in LG III (Obando-Ulloa et al., 2008). This compound has been found in green tea (Hattori, 2006) and as a minor compound of the extracellular secretion from living brown algae (Shibata, Hama, Miyasaki, Ito, & Nakamura, 2006).

The compound (*Z,Z*)-3,6-nonadienal is one of the precursors of the cucumber-like aroma which is produced from fatty acid oxidation (Ma et al., 2007). The pleasant odour in cucumber has been attributed to (*E,Z*)-2,6-nonadienal, while two unsaturated aldehydes (2-hexenal and 2-nonenal) and three saturated aldehydes (ethanal, propanal and hexanal) were considered to contribute secondarily to overall flavour (Beaulieu and Baldwin, 2002; Beaulieu, 2005; Beaulieu & Grimm, 2001; Palma-Harris, McFeeters, & Fleming, 2002), but (*Z,Z*)-3,6-nonadienal was not recovered in Cantaloupe melons (Beaulieu & Grimm, 2001). The NIL SC8–1 can be used as a model to avoid cucumber-like aroma in melons or to study the biosynthetic pathways of C6 and C9 unsaturated aldehydes and alcohols from linolenic precursors (Ma et al., 2007). Hydroxyperoxide lyases (HPL) cleave these C9 aldehydes (Tijet, Schneider, Muller, & Brash, 2001). HPL form very unstable hemiacetals from hydroperoxides (HPO) generated by lipoxygenases from the polyunsaturated fatty acids, leading to the generation of aldehydes and aldehyde enols by spontaneous dissociation (Pech et al., 2008, chap. 13). The compound (*E,Z*)-2,6-nonadienal is a muskmelon-like or musky aroma and and (*Z,Z*)-3,6-nonadien-1-ol is a grassy boiled leaf-like aroma (Kourkoutas et al., 2006), Due to the reasons mentioned above, the former compounds can be easily obtained from (*Z,Z*)-3,6-nonadienal by isomerisation.

This aroma profile has multiple uses for the characterization of melon cultivars of the Inodorus Group, particularly of the 'Piel de sapo' type. For example, this profile can be used for present or future European protected geographical indications (PGI). Additionally, the compounds can be used to train and establish melon test panel and sensorial protocols, or to correlate sensory and instrumental parameters, for new or traditional melon cultivars (Pardo et al., 2000). Finally, the profile is useful for standardizing or developing new natural melon flavours and fragances; for the on-line control using the right sensors of fresh or processed melon products (Muñoz-Aguirre et al., 2007), such as fresh-cut halves, slices or cubes; or cremogenates, soups, canning balls, etc. This profile is also useful for developing new melon fruit spirits and distillates (Hernández-Gomez, Ubeda, & Briones, 2003) with aroma volatiles closer to the fresh fruit aroma.

5. Conclusions

The aroma profile of this collection was composed of 24 compounds with predominance of aldehydes in non-climacteric melons, particularly hexanal and methanethiolate. The introgressions of PI 161375 studied also had higher levels of one ester and lower levels of octanal with no significant effects on the rest of the compounds of the profile. Three QTLs associated with ester and aldehyde biosynthesis were mapped, while another QTL was associated with the cucumber-like aroma [(*Z,Z*)-3,6 nonadienal].

were washed thoroughly with tap water, dried by forced air circulation and pulverised in a blender. Algal powder (270 g) was depigmented using sequential extraction with petroleum ether (24 h) and acetone (24 h) as solvent in a Soxhlet apparatus. The unextracted material was placed in a plastic beaker and air dried to yield depigmented algal powder (DAP; 173 g).

2.1.2. Extraction with acid

Extractions of DAP (3 g) with 0.1 M HCl (w/v::1:100) were conducted at 30–35 °C for 12 h under constant stirring (twice). Separation of the residue from the extract was performed by filtration through a glass filter (G-2). The residue was washed with additional 0.1 M HCl and the wash was collected to maximise polysaccharide recovery. The extracts were combined, dialysed and lyophilised to give fraction A (yield, 8.8%).

2.1.3. Extraction with alkali

The acid insoluble residue was extracted with 3% Na_2CO_3 (w/v::1:100) at 45–50 °C for 4 h under constant stirring (twice). The extract was carefully acidified with concentrated HCl to pH ~1, the precipitate formed was collected by centrifugation, washed with 0.1 M HCl, suspended in water and dissolved by careful addition of NaOH. The slightly alkaline solution was dialysed and diluted with 4.0 M $CaCl_2$ solution to make a final concentration of 2% $CaCl_2$. The precipitate formed at this stage was isolated by centrifugation, washed with water and treated with 0.1 M HCl (4 × 50 ml, stirring at room temperature for ~2 h). Then the precipitate was dissolved in dilute NaOH as above, the solution dialysed and finally lyophilised to yield sodium alginate (B, yield, 22.6%).

2.1.4. Extraction with water

The residue left after extraction with alkali was once again extracted with water at 80 °C (twice) and the combined extract (C) dialysed. Then 4.0 M $CaCl_2$ solution was added to the extract to make a final concentration of 2% $CaCl_2$, and the suspension kept at 5–9 °C overnight. After separating the precipitate (C2) by centrifugation the supernatant dialysed, concentrated and lyophilised to give fraction C1 (yield, 6.2%).

The resulting insoluble residue was dialysed against distilled water and finally lyophilised (INS).

2.1.5. Anion exchange chromatography (AEC)

A solution (20 ml) of dilute acid extracted polymer (fraction A) in 50 mM sodium acetate (pH 5.5) was applied to a column (2.6 × 25 cm) of DEAE-Sepharose FF (AcO^-). Thereafter, the column was eluted (0.6 ml min^{-1}) successively with 0.05 M (fraction AF1), 0.7 M (fraction AF2) and 2.0 M (fraction AF3) NaOAc buffer in a stepwise manner. Appropriate fractions were pooled, dialysed and lyophilised.

2.1.6. Size exclusion chromatography (SEC)

System A: Size exclusion chromatography of fraction C1 on Superdex-30 column (2.6 × 50 cm; Amersham Biosciences AB) was carried out using 0.5 M sodium acetate buffer (pH 5.0) as solvent. Fractions (5 ml) were collected and analysed for neutral sugar content by phenol–sulphuric acid method (Dubois, Gilles, Hamilton, Rebers, & Smith, 1956). Appropriate fractions (namely, C1F1 and C1F2) were pooled, dialysed and lyophilised.

System B: Apparent molecular mass of the fucoidan fraction (AF3) was determined by size exclusion chromatography on Sephacryl S-200 column (2.6 × 90 cm, Amersham Biosciences AB) using standard dextrans (M_w range 1000–5,00,000 Da), as described previously (Adhikari et al., 2006).

2.2. General methods

Chemicals used were analytical grade or best available. All experiments were conducted at least in duplicate, the mean and standard deviation was directly calculated from the functions present in excel program. Evaporations were performed under diminished pressure at ~45 °C (bath) and small volume of aqueous solutions was lyophilised. Dialysis against distilled water was performed with continuous stirring, toluene being added to inhibit microbial growth. Moisture was determined by drying ground material in an air-circulated oven at 110 °C for 3 h. Gas liquid chromatography (GLC) was carried out on a Shimadzu GC-17A (Shimadzu, Kyoto, Japan) gas chromatograph equipped with FID, and nitrogen was used as a carrier gas. Gas liquid chromatography–mass spectrometry (GLC–MS) analysis was carried out on a Shimadzu QP 5050 A, Shimadzu, and the ionisation potential was 70 eV.

2.3. Sugar analysis

Total sugars and uronic acids were determined by the phenol–sulphuric acid (Dubois et al., 1956) and *m*-hydroxydiphenyl (Ahmed & Labavitch, 1977) assay, respectively. All fractions were hydrolysed with 2 M trifluoro acetic acid (2 h, 100 °C) for measurement of individual neutral sugar. Sugars were reduced, acetylated and analysed as their alditol acetate by GLC (Blakeney, Harris, Henry, & Bruce, 1983) on columns of 3% SP-2340 on Supelcoport 100–120 mesh, and DB-225 (JW) and by GLC-MS. Myo-inositol was used as an internal standard. Sugars in the acid hydrolysate were also analysed by thin layer chromatography as described elsewhere (Adhikari et al., 2006). DAP was hydrolysed with 2 M trifluoro acetic acid (2 h at 100 °C) for soluble substances. For insoluble residues, this hydrolysis was followed by a treatment of the residue with 72% (w/w) H_2SO_4 for 1 h at room temperature and then with 1 M H_2SO_4 for 2 h at 100 °C. Alternatively, trimethylsilyl (TMS) derivatives of methyl glycosides were analysed by gas chromatography.

2.4. Sulphate estimation and desulphation

Estimation of sulphate by modified barium chloride method and FT-IR spectroscopy and solvolytic desulphation were carried out as described (Mandal et al., 2007).

2.4.1. Methylation analysis

The laminaran fraction (C1F2), the fucoidan (AF3) and its desulphated (AF3-D) derivatives (~2 mg of each) were subjected to two rounds of methylation (Blakeney & Stone, 1985). The methylated polysaccharides were hydrolysed, and the liberated glycoses converted into their partially methylated alditol acetates and analysed by GLC and GLC/MS.

2.4.2. Fourier transform infra red spectroscopy (FT-IR)

Recording of IR spectra were carried out as described previously (Adhikari et al., 2006).

2.4.3. Nuclear magnetic resonance spectroscopy (NMR)

The ^1H NMR spectra were recorded on a Bruker 500 spectrometer (Bruker Biospin AG, Fallanden, Switzerland) operating at 500 MHz, respectively, for ^1H.

The samples (~10 mg of each) was heated (at 80 °C for 30 min) with water (1 ml), centrifuged and the resulting supernatant lyophilised. The freeze-dried sample was deuterium-exchanged by lyophilisation with D_2O and then examined in 99.9% D_2O.

2.4.4. Ferric ion reducing/antioxidant power (FRAP) assay

The FRAP assay was conducted according to Benzie and Strain (1996) as modified by Pulido, Bravo, and Saura-Calixto (2000).

Briefly, the oxidant was prepared by mixing 2.5 ml of a 10 mM TPTZ [2,4,6-tri(2-pyridyl-5-triazine) Fluka Chemicals, Madrid, Spain] solution in 40 mM HCl with 25 ml of 0.3 M acetate buffer (pH 3.6) and 2.5 ml of 20 mM $FeCl_3 \cdot 6H_2O$. The final solution has Fe(III) of 1.67 mM and TPTZ of 0.83 mM. To measure FRAP value, 900 μl of freshly prepared FRAP reagent was warmed to 37 °C and a reagent blank reading was taken at 593 nm; then 30 μl of test sample and 90 μl of distilled water were added. Absorbance readings were taken after 0.5 s and every 15 s until 30 min using a Shimadzu UV-1601 (PC) Spectrophotometer. The change of absorbance ($\Delta A = A_{30\ min} - A_{0\ min}$) was calculated and related to ΔA of an Fe(II) standard solution. Aqueous solutions of known Fe(II) concentrations (100–2000 μM $FeSO_4 \cdot 7H_2O$) were used for calibration.

2.4.5. Scavenging capability for 1,1-diphenyl-2-picrylhydrazyl (DPPH) radicals

The method reported by Shimada, Fujikawa, Yahara, and Nakamura (1992) was adopted for measurement of free radical scavenging capability. To each 4 ml of sample solution, 1 ml of freshly prepared methanolic DMSO solution of DPPH (0.5 mM) was added, mixed well and then let stand for 30 min at room temperature in the dark. The absorbance of the resulting was recorded at 517 nm. Butylated hydroxyanisole (BHA) was used as reference compound. The capability to scavenge the DPPH radical was calculated using the following equation:

$$\text{Scavenging effect}\ (\%) = \left[1 - \frac{\text{absorbance of sample at 517 nm}}{\text{absorbance of control at 517 nm}}\right] \times 100$$

3. Results and discussion

3.1. General

The central goal of this study was to determine the classes of polysaccharides present in brown alga *T. conoides*. For this sugar composition of depigmented algal powder (DAP) was determined. It contained 35% 2 M TFA hydrolysable sugars of which about seventh were uronic acids. The main neutral sugar was fucose and it also contained other sugar including glucose, galactose and xylose (Table 1). The sequential extraction procedure as shown in Fig. 1 was based on the different solubility, molecular mass and charge distribution of polysaccharides from brown seaweeds. Laminarans are soluble in warm waters and therefore extracted at 80 °C. Fucans were extracted with diluted hydrochloric acid, whereas alginates were extracted with sodium carbonate. Alginates form insoluble precipitates with bivalent calcium and at acid pH, and are stable in solution between pH 6 and 9.

3.2. Chemical characterisation of the fucoidan from Turbinaria conoides

3.2.1. General

Sugar compositional analysis revealed that fraction A consist mainly of fucose as the major neutral sugar together with smaller amount of galactose and xylose units (Table 1). The uronide content of this fraction was 6% and it also contained sulphate groups.

Anion exchange chromatography on a DEAE-Sepharose column separated fraction C into three components (AF1, AF2 and AF3). AF1, which accounted for 11% of the total polymers recovered from the anion exchanger, was the minor component of A fraction. It consisted mostly of fucose together with smaller amount of galactose, xylose and glucose residues (Table 1). The second fraction AF2, eluted at the beginning of the salt gradient, is the second largest fraction. AF3 was the major fraction, amounting to 51% of the total polymers recovered from the column. Sugar compositional analyses revealed that AF3 consists mainly of fucose together with smaller amount of galactose and xylose units (Table 1). Thin layer chromatographic analysis of the monosaccharides present in the hydrolysate indicates the presence of an uronic acid with an R_f value similar to that of glucuronic acid. GLC analysis of the TMS derivatives of the derived methyl glycosides confirmed this result. The presence of glucuronic acid has already been reported in fucoidan from brown seaweeds (Adhikari et al., 2006; Mandal et al., 2007). Therefore, AF3 is essentially a fucoidan that might contain a high number of sulphate groups, as indicated by its late elution. Indeed, the high charge density of this polysaccharide was confirmed by its sulphate content (4%, w/w). The FT-IR spectrum (Supplementary Fig. 1) of AF3 showed an absorption band at 1252 cm^{-1} related to a >S=O stretching vibration of the sulphate group. An additional sulphate absorption band at 848 cm^{-1} (C–O–S, secondary axial sulphate) indicated that the sulphate group is located at position 4 of the fucopyranosyl residue (Patankar, Oehninger, Barnett, Williams & Clark, 1993). Solvolytic desulphation of the purified (AF3) fucoidan (as pyridinium salt) produces a desulphated derivative (AF3D). Preliminary experiments (data not shown) showed a higher recovery with this method compared to methanol–HCl and

auto-desulphation methods. In the IR spectrum of desulphated derivative (AF3D) absorbances at 1252 cm^{-1} and 848 cm^{-1} become weak, demonstrating that they were associated with sulphate groups. This purified fucoidan had negative specific rotation $[\alpha]_D^{33}$ − 109° (*c* 0.2, H_2O), revealing that fucose in AF3 belongs to the L-series, like other fucoidan from brown seaweeds (Adhikari et al., 2006; Kariya et al., 2004; Mandal et al., 2007).

3.2.2. Molecular mass

AF3 was subjected to further chemical analysis. First, the apparent molecular mass was determined by size exclusion chromatography. The elution profile of this macromolecule on Sephacryl S-200 suggests that this polymer is homogeneous (Supplementary Fig. 2). Based on calibration with standard dextrans, the apparent molecular mass of AF3 would be 50 kDa.

3.2.3. Glycosidic linkages

Table 2 shows that the desulphated fucoidan yielded partially methylated alditol acetates corresponding to (1 → 2)-Xyl_p (xylopyranose), (1 → 3)-linked Fuc_p, and (1 → 3)- and (1 → 2,3)-linked Gal_p residues, consistent with the presence of fucoidan. The presence of large quantities of T-Xyl_p (terminal xylopyranose) and T-Fuc_p residues suggest that this polymer is highly branched with 29 terminals for every 71 residues in the main chain. Interestingly, 33–34% of the total fucose residues are terminal, 27–28% are (1 → 3)-linked, 21–22% are branched points (Table 2). Small amount of (1 → 4)- and (1 → 2)-linked Fuc_p residues were also present. So far, fucose residues in algal fucoidans are either (1 → 3)- or (1 → 3)- and (1 → 4)-linked (Cumashi et al., 2007; Pomin & Mourão, 2008). Linkage analysis of the native fucan sulphate AF3 yielded a variety of monomethylated, dimethylated and trimethylated products (Table 2) indicating that the structure of this polymer is highly complex. The amount of sulphate groups in the native polysaccharide as calculated from methylation was not in good agreement with the experimentally determined sulphate. But, methylation of sulphated polysaccharides does not always yield reliable proportions of methylated alditol acetates (Adhikari et al., 2006; Pereira, Mulloy, & Mourao, 1999;). 2-*O*-methyl fucitol, and unmethylated fucitol were amongst the abundant products of methylation analysis of the native polymer. The increase in the proportions of 2,4-di-*O*-methyl fucitol after desulphation, as a consequence of decreased proportions of 2-*O*-methyl fucitol residues, suggests that sulphate groups, when present, are located at position 4 of the (1 → 3)-linked fucosyl residues. This result also confirms the prediction made by IR analysis regarding the position of sulphate group.

Table 2
Partially methylated alditol acetates derived from the fucoidan (AF3) of *Turbinaria conoides* and its desulphated derivative (AF3D).

3.2.4. NMR spectroscopy

We employed ^1H NMR spectroscopy to determine the anomeric configuration and the sulphation pattern of the fucoidan AF3. The native polysaccharide has a very complex ^1H NMR spectrum (Fig. 2). A number of separate spin systems ranging from 5.02 to 5.43 ppm attributable to anomeric protons of α-fucose residues were distinguishable in the spectrum of the pure fucoidan (Kariya et al., 2004; Mandal et al., 2007; Mourao et al., 1996). The appearance of large number of anomeric signals suggest that the environment of the fucose residues are different and this may arise from varied sulphation pattern, different glycosidic linkage positions and/or diverse sequence of monosaccharide residues. This spectrum also included resonances characteristic of fucoidan, such as signals from ring protons (H-2 to H-5) between 3.34 and 4.34 ppm, and intense signals from the methyl protons H-6 at ~1.02–1.28 ppm. This later envelope of signals confirms the presence of different types of fucosyl residues. The signals between 4.45 and 4.90 ppm were attributed to anomeric protons of β-linked sugars. The high proportion of xylose and galactose residues must be responsible for these signals in the spectrum, but was not possible to assign any particular signals to these residues. Therefore, it is apparent that the NMR spectrum of this polysaccharide is complex as observed for fucoidan from other marine brown algae (Adhikari et al., 2006; Mandal et al., 2007; Mourao et al., 1996; Pereira et al., 1999).

3.3. Structural features of the laminaran and alginic acid rich fractions from Turbinaria

Laminarans are soluble, but their water solubility depends on the branching level: the higher the branching degree, the higher the solubility. The less branched laminarans are soluble only in warm water (60–80 °C). The alginic acid (C2) present in the hot water extract (C) was removed by taking advantage of the insolubility of Ca-alginate in water. The molecular mass of laminarans is small (5–

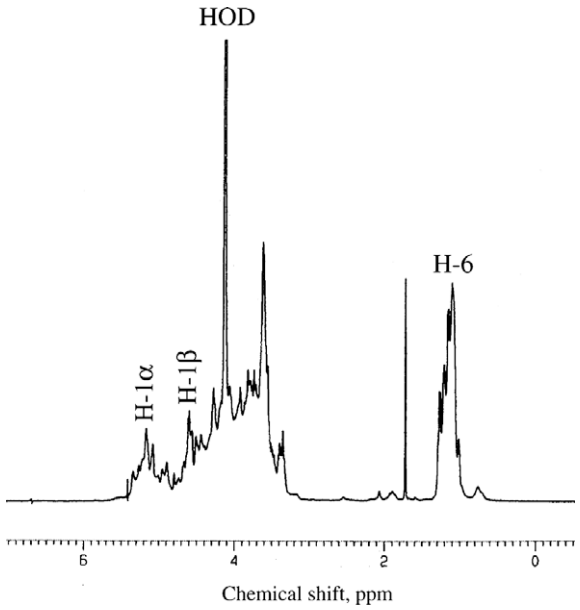

Fig. 2. ^1H NMR spectrum at 500 MHz of the fucoidan (AF3) of *Turbinaria conoides*. The spectrum was recorded at 80 °C for sample in D_2O solution. H-1α, H-1β and H-6 refer to anomeric signals of α-linked fucose, β-linked sugars and methyl protons of fucose residues, respectively. The signal for the residual water was designated as HOD.

10 kDa). Therefore, attempts have been made to separate them from fucoidan fraction by size exclusion chromatography. Indeed, SEC on Superdex-30 separates C1 into two fractions C1F1 and C1F2 (Supplementary Fig. 3). The minor fraction, C1F2, which accounted for 35% of the total sugar recovered from the column consisted of mainly glucose as neutral sugar. Based on calibration with standard dextrans, the apparent molecular weight of this glucan would be 5 kDa. This glucan containing fraction (C1F2) does not produce blue colouration with iodine. Moreover ^{1}H NMR spectrum of this polymer clearly shows the presence of only one anomeric signal at 4.827 ppm indicative of β-configuration. Finally, methylation analysis of this glucan revealed the presence of 1,3,5-tri-*O*-acetyl-2,4,6-tri-*O*-methylglucitol (98%) and 1,5-di-*O*-acetyl-2,3,4,6-tera-*O*-methylglucitol (2%) residues. On the basis of the glycosidic linkage and ^{1}H NMR analysis it may be concluded that the glucan of *T. conoides* is a linear polysaccharide and contained β-(1 → 3)-linked glucopyranosyl residues.

Sodium alginates form insoluble precipitates at acid pH and with calcium salts, but they are stable in solution between pH 6 and 9. Therefore, these macromolecules were extracted with Na_2CO_3. The fractional product (B) was analysed using FT-IR and ^{1}H NMR spectroscopy. The FT-IR spectrum of this fraction contains band at 3400 (OH stretching), 2925 (CH stretching), 1675 and 1420 (COO stretching) cm^{-1} characteristic of alginate. Moreover two bands at approximately 1100 and 1025 cm^{-1} responsible for mannuronic (M) and guluronic (G) units, respectively, were also observed (Supplementary Fig. 4).

To evaluate the content of G, M and G–G linkage, we have investigated the ^{1}H NMR spectrum (Fig. 3) of sodium alginate using procedures as described previously (Grasdalen, 1983; Matsushima et al., 2005). The relative areas of anomeric protons G-1 (H-1 of G) and M-1 (H-1 of M) correspond to the mole fractions of G and M, respectively. The peak areas of G-5 (H-5 resonances of G) give the distribution of G in G-block and GM-block, and the algebraic sum of their intensities accounts for the total G content, i.e., the relative area of G-5 is equal to that of G-1. From the measurement

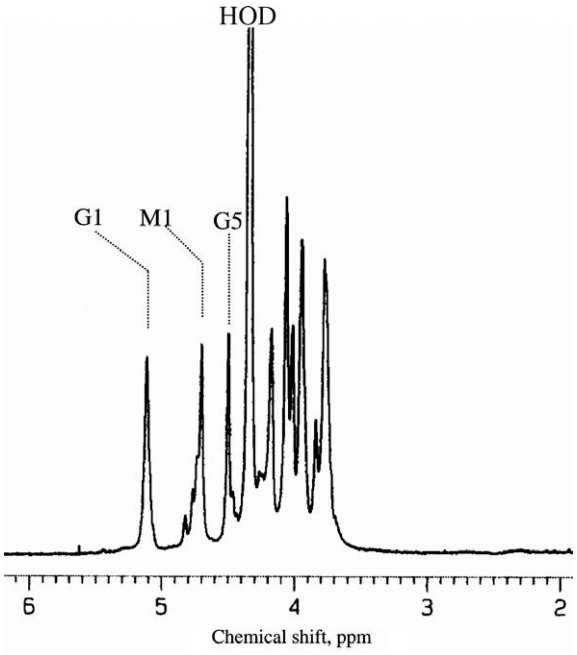

Fig. 3. ^{1}H NMR spectrum at 500 MHz of the alginic acid containing fraction (B) isolated from the brown seaweed *Tubinaria conoides*. G1 and M1 are the anomeric signals of guluronic acid and mannuronic acid, respectively, and G5 is the signals of the H-5 proton of guluronic acid residue. The spectrum was recorded at 80 °C for sample in D_2O solution. The signal for the residual water was designated as HOD.

of peak areas of A (δ_H 5.13 (G-1)), B (δ_H 4.72–4.84 (G-5 in GM-block and M-1)) and C (δ_H 4.45–4.52 (G-5 in G-block)), the guluronic acid content (G%) and G–G diad frequency (GG%) were calculated using Eqs. (1) and (2), and the calculated values are 46.19 and 42.12, respectively

$$G\%(\%) = \frac{\text{area of } A}{(\text{area of } B) + (\text{area of } C)} \times 100 \quad (1)$$

$$GG\%(\%) = \frac{\text{area of } C}{(\text{area of } B) + (\text{area of } C)} \times 100 \quad (2)$$

3.4. Antioxidant activity of polysaccharides

3.4.1. Frap assay

In recent years many different methods are being used to evaluate antioxidant capacity of foods and biological samples (Huang, Ou, & Prior, 2005). In some of these protocols, antioxidant assays were performed in alcoholic solutions, but in this condition polysaccharide would precipitate. Therefore, the antioxidant capacity of sulphated polysaccharides (AF3, B and C1F2) from *Turbanaria* was determined by the FRAP assay. This assay in which a ferric salt $Fe(III)(TPTZ)_2Cl_3$ (TPTZ = 2,4,6-tripyridyl-s-triazine) is used as oxidant (Benzie & Strain, 1996) takes advantage of electron transfer reactions (Huang et al., 2005). FRAP values increased considerably from 4 to 30 min, as it has been described for other vegetable and seaweed samples (Ruperez et al., 2002).

Regarding antioxidant capacity of the polysaccharides of present study it is clear that the fucoidan (AF3) showed the highest reducing power at 4 and 30 min (165 and 190 mol Fe(II) per g sample dry weight, respectively). This is followed by alginic acid and laminaran (Table 3). Results are expressed as mol Fe(II) per g sample dry weight. For comparison of potencies, values are also calculated as mol Trolox/g sample dry weight from regression equations as described by Pulido et al. (2000) of Trolox at 4 and 30 min of reaction with the FRAP reagent.

3.4.2. Scavenging effect on1,1-diphenyl-2-picrylhydrazyl (DPPH) radicals

For further insight into the activation mechanism, we examined whether the protective effect was associated with DPPH radicals. The proton radical scavenging action is known to be one of the various mechanisms for antioxidation. DPPH is one of the compounds that possess a proton free radical and shows a characteristic absorption at 517 nm (purple) (Matsukawa et al., 1997). When DPPH encounters proton radical scavengers, its purple colour would fade rapidly (Yamaguchi, Takamura, Matoba, & Terao, 1998). An excellent scavenging capability on DPPH radicals at a dosage of 1 mg/ml (61%) was found with the fucoidan fraction AF3 as compared with the control BHA (100%) regarding the low dosage ranges used (Fig. 4). More significant and effective radical scavenging capability (90%) was also found with the fraction AF3 at a higher dosage (5 mg/ml). Comparable results with the fraction

Table 3

	4 min		30 min	
	μmol Trolox/g	μmol Fe(II)/g	μmol Fe(II)/g	μmol Trolox/g
AF3[b]	165	79	190	96
B[b]	92	53	137	85
C1F2[b]	72	38	82	43

[a] Results are expressed as equivalent of Fe(II) or Trolox per gram dry weight of fractions in aqueous solution. Each value, which is given to its nearest whole number, was the mean of two replicates.
[b] For a description of fractions obtained see Section 2.

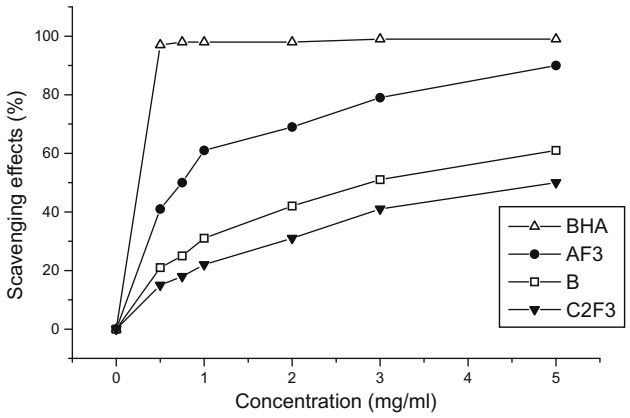

Fig. 4. Scavenging effect of polysaccharides isolated from the brown seaweed *Tubinaria conoides* on DPPH radicals. BHA: Butylated hydroxyanisole. AF3: The fucoidan rich fraction. B: The alginic acid containing fraction. C2F3: The laminaran rich fraction.

AF3 were found to be 62% at the dosages of 5.0 mg/ml for the alginate rich fraction B (Fig. 4). In contrast, the laminaran fraction C2F3 obtained from demonstrated least scavenging capability (50%) among three fractions at the concentration of 5.0 mg/ml. Moreover, the marked inhibitory effect of these polysaccharides on DPPH radicals was found to be concentration dependent (Fig. 4), though the activities were low. These results reveal that the polysaccharides of present study are potent scavenger and their antioxidative activity may be attributed to their proton-donating ability (Shimada et al., 1992). Probably, these fractions might contain a higher amount of reductone which could react with radicals to stabilise and terminate radical chain reaction. Whether the structures can be related to scavenging capacity for DPPH radicals remains to be determined in future studies. However, our preliminary results suggest that different bioactivities of these fractions apparently may be, in some respects, linked to their different molecular structures.

Most of earlier data on antioxidant of foods and biological samples were on phenolic compounds and many researchers have been reported positive correlation between free radical scavenging activity and total phenolic compound. But this correlation between structure and activity is not always valid. For example, selected enzymatic extracts of seaweeds (*Ecklonia cava* and *Sargassum coreanum*) did not possess antioxidant activity, although they contained as much phenolic compounds as the other extracts of *E. cava*. Feruloyl oligosaccharides showed a higher antioxidant capacity than free ferulic acid (Yuan, Wang, Yao, & Chen, 2005). Moreover, the former showed greater antioxidant capacity in vivo than in vitro when compared with vitamin C (Ou et al., 2007). Therefore, it is believed that other materials in seaweed extracts, such as small molecular weight polysaccharides, pigments, proteins or peptides, may influence the activity. Indeed, recent data showed that a number of polysaccharide containing fractions isolated from various sources such as medicinal mushrooms (Jiang et al., 2008; Shimada et al., 1992), higher plants (Aguirre, Isaacs, Matsuhiro, Mendoza, & Zúñiga, 2009), marine algae (Rocha de Souza et al., 2007; Ruperez et al., 2002; Wang, Zhang, Duan & Li, 2009; Wang et al., 2008) and even some enzymatic extracts (Je et al., 2009) possess antioxidant activity. Our results are in agreement with these studies. In addition, the polysaccharides used in this study were purified and, therefore, conclusively prove their antioxidant potency.

Literature data also shows that some polysaccharides have higher antioxidative potency than the others. For example, the antioxidant potential of sulphated polysaccharides from the brown seaweed *Fucus vesiculosus* was higher than that of agar-like sulphated galactans from the red seaweed Nori (Ruperez, 2001). In a more recent study this group (Ruperez et al., 2002) found that antioxidant potency of fucoidan containing fraction from the brown alga *Fucus vesiculosus* was higher than that of laminaran and alginic acid containing fractions. The laminaran (C1F2) and alginate (B) rich fractions of present study exhibited lower antioxidant potentials than the fucoidan containing fraction AF3 (Table 3). This result is in agreement with that of Ruperez et al. (2002) except that the antioxidant potency of the purified polysaccharides of present study is lower.

Although the antioxidant capacity of polysaccharide has been proven, the relationships between structure and antioxidative capacity have not yet been elucidated. This is primarily due to the interplay of two important factors. Firstly, the huge structural diversity of these polysaccharides has given a major hindrance in the structure–activity relationship establishment. However, on the basis of the accumulated data several common structural motifs emerge that are important for activity. Secondly, many of the hitherto used sulphated polysaccharides contained a number of other molecules. These later molecules may have their own activities, and or at least dilute the efficacy of the sulphated polymer itself. However, the polysaccharides described in this work are purified and therefore, conclusively proves their antioxidant activities.

4. Conclusions

In this study, we found that the soluble polysaccharides of *T. conoides* can be an excellent antioxidant. The fucoidan (40 kDa) exhibit more potency than the laminaran (5 kDa) and, therefore, this potency may be directly related with the molecular mass of these polysaccharides. These differences can as well be attributed to the differences in structure and perhaps to the actual availability of the functionality in each individual structure. The antioxidative activity of *Turbinaria* polysaccharides may be attributed to their proton-donating activity as evidenced through DPPH radical scavenging results.

Because the polysaccharides tested in this study was basically prepared without toxic chemical reagents, it can be assumed to be potentially useful as a safe antioxidant in food processing industries. Furthermore, as the isolation of these polysaccharides involves a few inexpensive and easy steps it will be of an added advantage.

emulsions, their ability to inhibit lipid oxidation could increase (Heins, McPhail, Sokolowski, Stockmann, & Schwarz, 2007).

Most free radical scavenging antioxidants in food systems contain active hydroxyl groups that can donate hydrogen to lipid radicals. These hydroxyl groups are most commonly associated with phenolic compounds. Many phenolic compounds are surface active (e.g., accumulate at water–lipid interfaces) since they contain both oxygen and hydrocarbon ring structures (Chaiyasit, Elias, McClements, & Decker, 2007). Unfortunately, phenolic compounds are not strongly surface active and sometimes contain other functional groups such as carboxylic acids that can make them very water soluble. If phenolic acids could be made more surface active by esterifying them with hydrocarbon chains, this would potentially increase their concentration at water–lipid interfaces in oil-in-water emulsions where they could potentially be more effective at inhibiting lipid oxidation.

Previous work in our lab looked at the ability of free or esterified (butyl or dodecyl groups) *p*-hydroxyphenylacetic acid (HPA) to inhibit lipid oxidation in oil-in-water emulsions (Yuji et al., 2007). Unexpectedly, free HPA was a more effective antioxidant than its more surface active butyl and dodecyl conjugates in menhaden oil-in-water emulsions as determined by both lipid hydroperoxides and thiobarbituric acid reactive substances. One potential reason for this discrepancy could be that the esterification of the butyl and dodecyl groups onto HPA resulted in compounds with different free radical scavenging activity.

The objective of this work was to determine if the esterification of chlorogenic acid (CGA) to hydrocarbon chains would improve its ability to inhibit lipid oxidation in oil-in-water emulsions. Chlorogenic acid, a commonly occurring polyphenol found in plants, is widely recognised to be an active free radical scavenger (Clifford, 1999). Since esterification of hydrocarbons onto phenolic acids can alter their antioxidant activity, the free CGA and CGA esters (C_4, C_8, or C_{12}) were added to oil-in-water emulsions at equal free radical scavenging activities.

2. Materials and methods

2.1. Materials

Menhaden oil was donated by Omega Protein (Houston, TX). 2,2-Azobis (2-methylpropionamidine) dihydrochloride (AAPH), fluorescein, hexadecane, and ethylenediaminetetraacetic acid (EDTA) were obtained from Sigma–Aldrich (St. Louis, MO). Brij 35 was purchased from Acros Organics (Morris Plains, NJ). All other chemicals were reagent grade or purer and were obtained from Fisher Scientific (Pittsburgh, PA). Double distilled water was used throughout the experiments.

2.2. Methods

2.2.1. Enzymatic synthesis of chlorogenic acid conjugates

The chemo-enzymatic synthesis of chlorogenate fatty esters was carried out from methyl chlorogenate following the procedure described by Lopez Giraldo et al. (2007). Typically, methyl chlorogenate (5 mmol) was added to 375 ml of desired fatty alcohol and the mixtures were then placed in sealed flasks, and stirred on an orbital shaker (250 rpm, 55 °C) until complete dissolution of methyl chlorogenate. *Candida antarctica* B lipase 5% w/w (calculated from the total weight of both substrates) was added to start the reaction. The mixture then stirred at 55 °C for 96 h under a nitrogen flow. The final lipophilised esters were then purified using a two step liquid–liquid extraction procedure as described by Lopez Giraldo et al. (2007). All recovered esters were characterised by mass spectrometry.

2.2.2. Preparation of emulsion

Oil-in-water emulsions were prepared by mixing menhaden oil with an emulsifier solution (17 mM Brij 35 in 10 mM phosphate buffer, pH 7.0) to achieve a final lipid concentration of 20% (w/w) lipid. A coarse emulsion was produced first by homogenising at high speed for 2 min with a Bio-homogenizer (Tekmar Company, Cincinnati, OH). Emulsion droplet size was then further reduced with an ultrasonicator (Fisher Sonic Dismembrator 500, Pittsburgh, PA) at 4 °C for 3 min at 70% power and 0.5 s duty cycles. A laser light scattering instrument (Mastersizer, Malvern Instruments, Ltd., Worcestershire, UK) was used to measure the particle size distribution. The mean particle size of the emulsion was reported as the volume–surface mean diameter (d_{32}). The mean particle diameter in all emulsions ranged from 0.35 to 0.45 μm and did not change during the storage studies.

2.2.3. Removal of continuous phase surfactant

Excess Brij 35 in the continuous phase of the emulsion was removed because surfactants not absorbed to the emulsion droplets have been shown to form micelles and change the physical location of antioxidants (Richards, Chaiyasit, McClements, & Decker, 2002). To remove excess Brij 35, emulsions were divided into centrifuge tubes (Sorvall 75 ml, Asheville, NC) and centrifuged at 30,000 rpm at 4 °C for 40 min. After centrifugation, the aqueous phase (lower layer) was removed with a syringe and discarded and fresh buffer was added. The emulsion was redispersed by vortexing for 5 min. This procedure of centrifugation, removal of continuous phase and reconstitution of emulsion droplets was repeated a total of three times (Elias, McClements, & Decker, 2007). Following the final wash, the total lipid content of the creamed emulsion (1.0 g) was determined gravimetrically after extracting the lipid using a modified method of Folch, Lees, and Stanley (1957). After determination of lipid content of the creamed emulsion, the creamed layer was diluted into fresh 10 mM phosphate buffer (pH 7.0) to a final lipid concentration of 2% (w/w). Antioxidants dissolved in 10 mM phosphate buffer (pH 7.0) were then added to the emulsion at final antioxidant concentrations ranging from 47 to 120 μM.

2.2.4. Measurement of antioxidants concentration in continuous phase of the oil-in-water emulsions

To determine the concentration of antioxidants in the continuous phase, fresh menhaden oil-in-water emulsions containing 50 μM of antioxidants were put into centrifuge tubes (Sorvall 9.8 ml, Asheville, NC) and centrifuged at 30,000 rpm at 4 °C for 40 min. After centrifugation, the aqueous phase (lower layer) was withdrawn with a syringe and filtered through a 0.22 μm syringe filter (Millex-GS, Bedford, MA). The concentration of each antioxidant in the continuous phase was measured at 285 nm using a UV–VIS scanning spectrophotometer (UV-2010PC, Shimazu, Kyoto, Japan). The concentration of the antioxidants was determined using a standard curve prepared with each antioxidant over the concentration range of 1–50.0 μM. Limit of detection was 0.5 μM.

2.2.5. Interfacial tensiometry

The surface activity of antioxidants was determined by interfacial tensiometry using a drop shape analyzer (DSA 10; Kruss USA, Charlotte, NC). Antioxidants were dissolved in hexadecane at 0–500 μM. Hexadecane was used as a non-oxidisable lipid to prevent oxidation of the antioxidants during analysis. The mixture was loaded in a syringe and ejected to form a droplet at the inverted tip of a hypodermic needle that was submerged in double distilled water. The tip of the needle was positioned on an optical bench between a light source and a high speed charge couple device (CCD) camera. The CCD camera was connected to a video frame-grabber board to record the image onto the hard drive of a computer at a speed of one frame per 1 min. The shape of pendent

drops was determined through numerical analysis of the entire drop shape. The interfacial tension was calculated from the drop shape using the Young–Laplace equation of capillarity (Nicole, Kristianto, Osman, & Michael, 2005). This methodology requires accurate determination of solution densities, which were measured using a digital density metre (DMA 35 N; Anton Paar USA, Ashland, VA). All interfacial tension measurements were carried out after 1 h of equilibrium.

2.2.6. Free radical scavenging activity as determined by the oxygen radical absorbance capacity (ORAC) assay

The ability of the free and esterified CGA to scavenge peroxyl radicals was determined using the ORAC assay (Huang, Ou, Hampsch-Woodill, Flanagan, & Deemer, 2002; Ou, Hampsch-Woodill, & Prior, 2001; Prior, Wu, & Schaich, 2005). Chlorogenic acid and its conjugates were dissolved in acetone/water mixture (50:50, v/v) to a final concentration of 1 mM. A 300 mM solution of 2,2′-azobis (2-methylpropionamidine) dihydrochloride (AAPH) and 50 nM solution of fluorescein in 75 mM potassium phosphate buffer at pH 7.0 were prepared and kept on ice. Fluorescein was held at 37 °C in a water bath for 15 min and then brought to a final concentration of 45 nM in a cuvette with 0–10 μM antioxidant, 0.1 mM EDTA, and 20 mM AAPH in 75 mM phosphate buffer (pH 7.0). Analyses were performed on a Fluorolog fluorometer (Photon Technology International Inc., Birmingham, NJ) set at an excitation wavelength of 493 nm and an emission wavelength of 515 nm with the temperature being maintained at 37 °C. Fluorescence was recorded every minute for 40 min and the fluorescence relative to the fluorescence at time zero (F/F_0) was calculated from the fluorescence decay curve. The area under the curve (AUC) was obtained by subtracting the AUC of the blank from that of the sample. AUC was calculated using PeakFit v4.12 (SeaSolve Software Inc.). Data were expressed as micromoles of Trolox equivalents (TE) per gram of sample as determined from a Trolox standard curve over the range of 1.0–20 μM.

2.2.7. Lipid oxidation measurements

Emulsion samples (1 ml) were placed into 10 ml headspace vials and sealed with polytetrafluoroethylene (PTFE)/butyl rubber septa and allowed to oxidise in the absence of light at 20 °C for up to 7 days. Headspace propanol was measured using a Shimazu GC-2014 gas chromatograph equipped with a solid phase microextraction (SPME) AOC-5000 auto injector (Shimazu, Kyoto, Japan) according to the method described by Yuji et al. (2007). The SPME head space conditions were as follows: sample incubation temperature, 45 °C; sample incubation time, 15 min; extraction time, 2 min; injection time, 3 min. A 50/30 μm DVB/Carboxen/PDMS SPME fibre was used for extraction (Supelco, Bellefonte, PA). The GC operating conditions were as follows: samples were injected in split mode (5:1); oven temperature program was 40 °C for 4 min followed by an increase of 10 °C/min to 110 °C, then an increase of 20 °C/min to a final temperature of 250 °C held for 2 min; injector was 250 °C; flame ionisation detector was 250 °C. The aldehydes were separated on a Supelco (Equity™-1) fused silica capillary column (30 m, 0.32 mm i.d., 1.0 μm film thickness). Concentrations were determined from peak area using a standard curve made from authentic propanol over the range of 0.025–1.0 mM.

Following headspace analysis, vials were opened and emulsion samples were used for lipid hydroperoxide measurements. Lipid hydroperoxides were measured using a modified method from Shantha and Decker (1994). Emulsions (0.3 ml) were mixed with 1.5 ml of isooctane/isopropanol (3:1, v/v) by vortexing (10 s, three times) and centrifuged at 1000*g* for 2 min. The upper layer (0.2 ml total volume containing 0.02–0.2 ml of lipid extract) was added to 2.8 ml of methanol/butanol (2:1, v/v), followed by 15 μl of 3.94 M ammonium thiocyanate and 15 μl of ferrous iron solution (prepared by adding equal amounts of 0.132 M $BaCl_2$ and 0.144 M $FeSO_4$). After 20 min, the absorbance of the solutions was measured at a wavelength of 510 nm using a UV–visible spectrophotometer (Genesys 20; Thermo Fisher Scientific Inc., Waltham, MA). Lipid hydroperoxide concentrations were determined using a standard curve prepared with cumene hydroperoxides over the range of 0.03–50 mM.

2.2.8. Statistical analysis

All experiments were performed in triplicate. Differences between means were determined with the least-squares means procedure at $p < 0.05$ (Snedecor & Cochran, 1989).

3. Results and discussion

To determine if the esterification of hydrocarbon chains onto CGA altered its physical properties, continuous phase concentrations in the menhaden oil-in-water emulsions and surface activity of the free and esterified antioxidants was determined. As expected, hydrocarbon chain esterification was able to change the partitioning behaviour of chlorogenic acid in the oil-in-water emulsions. The concentration of antioxidants in the aqueous phase of the menhaden oil-in-water emulsions was in the order of CGA > butyl CGA > octyl CGA > dodecyl CGA (Fig. 1). The concentration of CGA in the aqueous phase was more than 80% compared to dodecyl CGA which was 16%. These results indicate that esterification of CGA to hydrocarbon chains resulted in a greater retention of antioxidant in the lipid droplets of the emulsion.

To determine if the esterification also would increase the ability of CGA to concentrate at the oil–water interface of emulsion droplets where oxidation is thought to be most prevalent (McClements & Decker, 2000), the surface activity of CGA and its esters was determined. Fig. 2 shows that CGA and butyl CGA were not able to decrease the interfacial tension in a hexadecane–water system over a concentration range of 0–500 μM. In contrast, both octyl and dodecyl CGA were surface active decreasing interfacial tension by 20% and 60% at a concentration of 500 μM, respectively, compared to the control (no added chlorogenic acid). The greater reduction of interfacial tension by dodecyl than octyl CGA indicated that increasing the hydrocarbon chain from 8 to 12 carbons

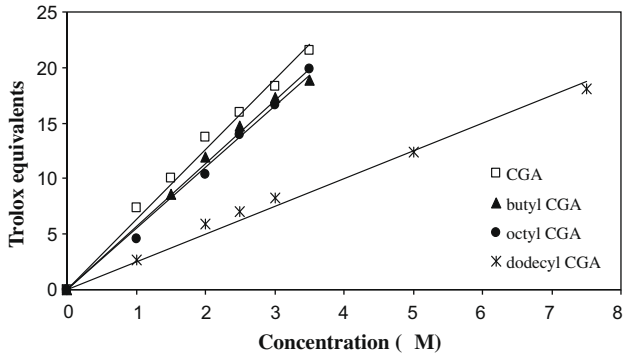

Fig. 3. The Trolox equivalents of chlorogenic acid (CGA), butyl CGA, octyl CGA, and dodecyl CGA at different concentrations as determined by the oxygen radical absorbance capacity (ORAC).

would increased the ability of dodecyl CGA to concentrate at the oil–water interface instead of partitioning into the lipid core of the emulsion droplet.

Previous research showed that the esterification of hydrocarbon chains onto *p*-hydroxyphenylacetic acid decreased its ability to scavenge peroxyl radicals (Yuji et al., 2007). Therefore, prior to conducting experiments on the ability of the CGA esters to inhibit lipid oxidation in oil-in-water emulsions, their peroxyl radical scavenging activity was determined using the ORAC assay. Fig. 3 shows the linear response between the concentration and the radical scavenging capacity, expressed as Trolox equivalents, for CGA and each of its derivatives. Peroxyl radical scavenging activity was in the order of CGA > butyl CGA = octyl CGA > dodecyl CGA. The peroxyl radical scavenging activity of the dodecyl CGA esters was about 50% less than that of the other antioxidants. As in our previous work, the free *p*-hydroxyphenylacetic acid was also the most effective free radical scavenger (Yuji et al., 2007). However, unlike CGA, the *p*-hydroxyphenylacetic acid dodecyl ester was a more effective free radical scavenger than the butyl ester.

The ability of CGA and its esters to inhibit lipid oxidation in oil-in-water emulsions would be expected to be a function of both their physical location and free radical scavenging activity. To control for the differences in free radical scavenging activity between CGA and its esters, the antioxidants were added at equal free radical scavenging activities. This was done by calculating the concentration of CGA and its esters that would give a Trolox equivalent of 7.2 as determined by the standard curves in Fig. 3. The resulting concentrations of antioxidants added to the menhaden oil-in-water emulsions are shown in Table 1.

Table 1
The concentrations of chlorogenic acid (CGA) and its esters that produced an equivalent oxygen radical absorbance capacity (ORAC) value (expressed as μmol of Trolox equivalents (TE) and concentration of antioxidants added to an the oil-in-water emulsion lipid oxidation test so that all antioxidants were added at equal free radical scavenging activity.

Sample	Conc. at ORAC = 7.2 TE	Conc. in oxidation test (μM)
CGA	2.37	47.4
Butyl CGA	2.67	53.3
Octyl CGA	2.71	54.2
Dodecyl CGA	6.00	120.0

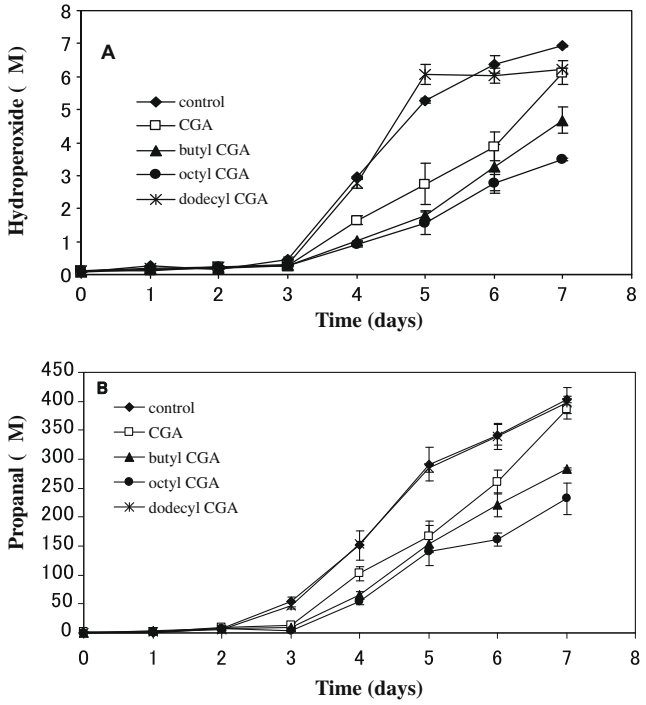

Fig. 4. Ability of chlorogenic acid (CGA), butyl CGA, octyl CGA and dodecyl CGA to inhibit formation of (A) lipid hydroperoxides and (B) propanol in a 2% menhaden oil-in-water emulsions (pH 7.0) stored at 20 °C. Data points represent means ($n = 3$) ± standard deviations (some error bars may lie within the data points).

Surfactants are normally used to stabilize oil-in-water emulsions against flocculation and coalescence by changing the physical properties of the emulsion droplet interface. However, after homogenisation there are often significant quantities of non-adsorbed surfactant molecules present in the aqueous phase of emulsions. Above a critical micelle concentration (CMC), the non-adsorbed surfactant will form micelles. Surfactant micelles are capable of incorporating molecules such as antioxidants within their hydrophobic core. In previous studies we found that excess surfactant will increase the solubilisation of antioxidants into the aqueous phase of oil-in-water emulsions (Richards et al., 2002). Therefore, in all experiments we used an emulsion to which excess surfactant was removed by a repeated washing procedure as described in the methods section.

Fig. 4 shows the results of lipid oxidation measurements. All antioxidants, except dodecyl CGA, inhibited lipid hydroperoxide formation up to 4 days of storage ($p < 0.05$) and propanol formation up to 3 days of storage ($p < 0.05$). Dodecyl CGA was not able to inhibit either lipid hydroperoxide or propanol formation compared to the control. Lipid hydroperoxide formation was inhibited 44% by CGA, 66% by butyl CGA and 70% by octyl CGA when compared to the control at 4 days storage. Propanol formation was inhibited 32% by CGA, 57% by butyl CGA, and 65% by octyl CGA

compared to the control at 4 days of storage. In general, as the chain length increased, antioxidant activity was increased compare to CGA with the exception of dodecyl CGA. However, little differences in antioxidant activity were observed between butyl CGA and octyl CGA.

Dodecyl CGA had higher lipid partitioning and surface activity than CGA, butyl CGA and octyl CGA. According to the antioxidant polar paradox hypothesis, non-polar antioxidants which are retained in the oil phase of oil-in-water emulsions should be more effective than antioxidants which tend to partition more into the aqueous phase (Frankel, 2005). Some investigators have also suggested that increasing the surface activity of an antioxidant would also increase its ability to inhibit lipid oxidation since it would concentrate at the oil–water interface where oxidation is most prevalent (Heins et al., 2007).

The results of this research suggest that neither retention in the lipid phase concentration nor surface activity were good predictors of antioxidant activity in oil-in-water emulsions. Increasing the size of the hydrocarbon chain esterified to chlorogenic acid increased both lipid partitioning in oil-in-water emulsion droplets (Fig. 1) and surface activity (Fig. 2). However, the esters with the highest lipid partitioning and surface activity were not an effective antioxidant when CGA and its esters were added at equal free radical scavenging activities. In addition, dodecyl CGA which had greater lipid partitioning and surface activity than butyl CGA (Figs. 1 and 2) did not have substantially greater ability to inhibit lipid hydroperoxide and propanol formation compared to butyl CGA (Fig. 4). Similar results were also reported by Yuji and coworkers (2007).

In this research all antioxidants were added at equal free radical scavenging activity to minimise differences in the ability of the different antioxidants to scavenge free radicals that could be caused by the esterification of a hydrocarbon chain onto the chlorogenic acid. However, in addition to free radical scavenging, chlorogenic acid can also inhibit lipid oxidation by chelating prooxidant metals (Andjelkovic et al., 2006). Since transition metals such as iron are major prooxidants in oil-in-water emulsions (Mancuso et al., 1999), it is possible that CGA and its derivates are inhibiting lipid oxidation by a combination of both free radical scavenging and metal chelation. This could mean that partitioning of the CGA esters into the lipid phase could decrease their ability to chelate aqueous phase prooxidative metals while simultaneously increasing their ability to scavenge free radicals in the lipid phase. If loss of chelating activity in the aqueous phase of the emulsions was important in the overall antioxidant activity of the tested compounds than increasing antioxidant concentration in the lipid phase my not result in an increase in antioxidant activity.

The ability of CGA and its esters to inhibit lipid oxidation in oil-in-water emulsions could also be influenced by interactions with other antioxidants. Antioxidant interactions such as the ability of ascorbic acid to regenerate oxidised α-tocopherol to reactivate α-tocopherol in biological membranes (Buettner, 1993; Porter, 1993) have been used to explain why antioxidant combination can work better than single antioxidants. Since the oil used in these experiments would contain α-tocopherol, it is possible that it or other lipid soluble antioxidants endogenous to the oil could be regenerated at the oil–water interface of the emulsion droplets by an antioxidant in the aqueous phase. Therefore, the CGA esters could also become less effective at regenerating antioxidants at the lipid–water interface as their partitioning into the lipid phase increased.

Interestingly, the dodecyl CGA had little to no antioxidant activity in the oil-in-water emulsion when added at equal free radical scavenging activity even though it had the highest lipid partitioning and surface activity. Since the dodecyl CGA had approximately one half the free radical scavenging activity as the other CGA derivatives, it was added at approximately twice the concentrations. At high concentrations, antioxidants can promote lipid oxidation through pathways such as transition metal reduction (Mei, McClements, & Decker, 1999) which could help explain why dodecyl CGA did not inhibit lipid oxidation.

4. Conclusions

The antioxidant polar paradox hypothesis states that antioxidants that are retained in lipid droplets are better antioxidants in oil-in-water emulsions. To test this hypothesis, chlorogenic acid was esterified with hydrocarbon chains to alter its physical properties. Esterification of chlorogenic acid resulted in increase lipid solubility and surface activity as the number of carbons on the hydrocarbon chains increased. Esterification of chlorogenic acid did not change its ability to scavenge free radicals with the exception of the dodecyl ester which had approximately half the free radical scavenging activity as free CGA and the other CGA esters. Since the antioxidant polar paradox hypothesis was developed for free radical scavenging antioxidants, CGA and its esters were added to oil-in-water emulsions at equal free radical scavenging activity. Even though the CGA esters had greater lipid partitioning and surface activity than free CGA, their ability to inhibit lipid oxidation did not increase. This suggests that the presence of CGA in the aqueous phase of oil-in-water emulsions could also contribute to total antioxidant activity possibly by chelating prooxidants metals or regeneration of antioxidants within the emulsion droplet.

2. Materials and methods

2.1. Plant material

Seeds of *L. bipinnata* were collected from Asangihal village in Sindagi taluk of Bijapur district, India, in October 2007 and grown in the botanical garden, Department of Botany, Karnatak University, Dharwad, India. The species was identified by Dr. M. Jayaraj, and a voucher specimen was prepared and deposited in the Department of Botany, Karnatak University, Dharwad, India.

2.2. Isolation procedure

The dried leaves were extracted using a soxhlet apparatus for 8 h in petroleum ether (40–60 °C). The essential oil obtained was dried under vacuum and stored at 4–6 °C before analysis.

2.3. Gas chromatography–mass spectrometry (GC–MS)

The analysis was carried out on a Shimadzu-GCMS-QP2010S fitted with a 30 m × 0.25 mm × 0.25 μm Rtx-5ms capillary column. The oven temperature was programmed as follows: from 60 to 180 °C at 3 °C/min and isothermally held for 15 min. Helium was used as carrier gas at 1 ml/min and 1 μl of sample was injected for analysis.

2.4. Identification of constituents

The identifications of the components were based on the comparison of their mass spectra with those of reference spectra in the computer library, as well as by comparison of their retention indices with literature values and our data are in accordance with those previously reported (Alberto et al., 2006).

2.5. Antimicrobial activity

2.5.1. Microbial strains

The antimicrobial activity of the essential oils samples was tested towards 11 different microorganisms. Three gram-negative bacteria, namely *Escherichia coli* ATCC 25922, *Pseudomonas aeruginosa* ATCC 27853, *Shigella dysentery*. Five gram positive bacteria namely *Enterococcus faecalis* ATCC 29212, *Staphylococcus aureus* ATCC 29213, *Vancomycin resistant enterococcus* ATCC 51299, *Bacillus subtilis, Micrococcus. Aspergillus niger, Penicillium notatum* and *Candida albicans* were the three fungi used for the study.

2.5.2. Determination of antimicrobial activity and minimum inhibitory concentration (MIC)

Antibacterial activity of essential oils of *L. bipinnata* was tested by the paper disc diffusion method according to the slightly modified National Committee for Clinical Laboratory Standards Guidelines (National Committee for Clinical Laboratory Standard, 2001), using 100 μl of suspension of the tested microorganisms, containing 2.0×10^6 colony forming units (cfu/ml) for inoculating the plates (William, 1977). A test oil solution was prepared in dimethyl sulphoxide (DMSO) and loaded (10 μl) onto sterile filter paper discs (6 mm diameter, HiMedia Laboratories Pvt. Limited, India), which finally contained 300 μg/μl of the compound per disc. Since the essential oil was dissolved in DMSO, it was used as a control. Impregnated disks were then dried for 1 h and placed on inoculated plates. The seeded plates were incubated at 37 °C for 24 h and 25 °C for 72 h for bacteria and fungi, respectively. The diameters of the inhibition zones were measured in millimetres. Studies were performed in triplicate, and the developing inhibition zones were compared with those of reference discs. Antibiotic streptomycin was used as a reference for bacteria and nystatin for fungi. The minimal inhibitory concentration of essential oil was determined by a micro dilution assay. The essential oil was twofold serially diluted with DMSO containing 0.125–8 μg/μl of oil. The MIC of the essential oil was defined, as the lowest concentration at which there was 100% inhibition of growth compared with the growth for a drug free control. In order to ensure that the solvent had no effect on fungal growth, a control test was also performed containing broth supplemented with only DMSO at the same dilution used in the assay. Each experiment for the antibacterial assay and MIC was repeated thrice.

3. Results and discussion

The essential oil of *L. bipinnata* obtained on extraction was analysed by gas chromatography–mass spectrometry (GC–MS). Twenty-nine components, representing 72.38% of the total essential oil, were identified (see Table 1). The constituents identified by GC–MS analysis, their retention indices and area percentages (concentrations) are summarised in Table 1. The essential oil was dominated by terpenes and alcohols which accounted for 34.44% and 28.03% of the essential oil, respectively. The major terpenes were pulegone (8.45%) and camphor (7.09%) while the alcohols consisted mainly of transcarveol (18.93%) and menthol (5.89%). Other terpenes present in appreciable amounts are caryophyllene oxide (3.68%), linalyl acetate (3.37%), bicyclogermacrene (3.09%) and thymol (2.35%) as mentioned in Table 1. The chemical composition of the essential oil was, however, different from that observed from other *Lavandula* species. Carveol and pulegone are used as a fragrance in cosmetics and flavour additive in food industry, pulegone is also used in aromatherapy. Camphor and menthol are readily absorbed through skin and produces a felling of cooling and acts as a slight local anaesthetic and antimicrobial substance. There are anti-itch gel and cooling gels with camphor and menthol

Table 1
The essential oil components of leaves of *L. bipinnata* (data were obtained using GC–MS analysis).

Compound	Retention index	Area (%)
α-Pinene	939	1.01
Camphene	964	0.35

Table 2
The zone of inhibition (mm) and minimum inhibitory concentration (MIC) values (μg/μl) of the essential oil of *L. bipinnata* and standard streptomycin against bacteria.

No.	Bacteria	Zone of inhibition (mm)		MIC (μg/μl)	MIC (μg/μl)
		L. bipinnata oil	Streptomycin	*L. bipinnata* oil	Streptomycin
1.	*E. coli* ATCC 25922	10	24	⩽0.5	⩽0.005
2.	*P. aeruginosa* ATCC 27853	07	15	⩽2.0	⩽0.010
3.	*Sh. dysentery*	11	17	⩽1.0	⩽0.020
4.	*E. faecalis* ATCC 29212	10		⩽2.0	⩽0.010
5.	*S. aureus* ATCC 29213	13	29	⩽1.0	⩽0.005
6.	*VRE* ATCC 51299	11	21	⩽2.0	⩽0.010
7.	*B. subtilis*	13	23	⩽1.0	⩽0.010
8.	*Micrococcus*	12	32	⩽0.5	⩽0.005

as the active ingredients. The essential oil of *L. bipinnata* is rich in transcarveol, pulegone, camphor and menthol and hence it can be used as a source of these components.

The essential oil was evaluated for antimicrobial activity against gram positive (*E. faecalis* ATCC 29212, *S. aureus* ATCC 29213, *VRE* ATCC 51299, *B. subtilis*, *Micrococcus*), gram-negative (*E. coli* ATCC 25922, *P. aeruginosa* ATCC 27853, *Sh. dysentery*) bacteria and fungi (*A. niger*, *P. notatum* and *C. albicans*). It was found to be active against all the microbes used for the activity. The essential oil was very active against *B. subtilis*, *S. aureus*, *Micrococcus*, *A. niger*, Moderately active against *E. coli*, *Sh. dysentery*, *E. feacalis*, *VRE*, *C. albicans* and low activity against *P. aureginosa and P. notatum* (see Tables 2 and 3). The minimum inhibiting concentration (MIC) of essential oil ranged from 0.5 to 2.0 μg/μl and 2 to 4 μg/μl for bacteria and fungi respectively. The MIC values for the standard ranged from 0.005 to 0.02 μg/μl and 0.04 to 0.16 μg/μl for streptomycin and nystatin, respectively. In general, the essential oil showed better antibacterial activity than antifungal activity (see Tables 2 and 3). The gram positive bacterium is more susceptible to the antimicrobial properties of essential oils than gram-negative bacteria and it is considered to be due to its outer membrane (Cox et al., 2001). The activity of the essential oil varies with its concentration and kind of bacteria. These differences in the susceptibility of the test organisms to essential oil could be attributed to a variation in the rate of the essential oil constituent's penetration through the cell wall and cell membrane structures. The ability of essential oil to disrupt the permeability barrier of cell membrane structures and the accompanying loss of chemiosmotic control are the most likely reasons for its lethal action (Cox et al., 2001). Although the concentrations of the essential oil were generally about 100 times more than those of the standard antibiotic (streptomycin and nystatin), they showed marked antibacterial and antifungal activities, as evidenced by their zones of inhibition (see Table 2). This difference between concentrations of the essential oil and the standard antibiotic can be explained in terms of the fact that the active components in the essential oil comprise only a fraction of the oil used. Therefore, the concentration of the active components could be much lower than the standard antibiotics used. It is important to note that, if the active components were isolated and purified, they would probably show higher antimicrobial activities than those observed here.

The increasing antibiotic resistance of pathogens associated with infectious disease as well as undesirable side effects of antibiotics suggested the use of natural products such as essential oils as antibiotics or its components as alternatives to antibiotics. However further research is required to evaluate the practical values of therapeutic application.

Mass spectral data of six major compounds are as follows

Camphor (152): 152 [M^+], 135, 123, 108, 95, 81, 69. 152 is the molecular ion peak corresponding to molecular weight of the compound and 95 is the base peak.
Menthol (156): 152 [M^+], 138, 123, 109, 95, 81, 71, 55, 53. 156 is the molecular ion peak corresponding to the molecular weight of the compound and 71 is the base peak.
Transcarveol (152): 152 [M^+], 137, 119, 109, 91, 84, 77. 152 is the molecular ion peak corresponding to molecular weight of the compound and 109 is the base peak.
Pulegone (152): 152 [M^+], 137, 123, 109, 95, 81, 67, 53. 152 is the molecular ion peak corresponding to molecular weight of the compound and 81 is the base peak.
Piperitone (152): 152 [M^+], 137, 124, 111, 95, 82, 67, 54. 152 is the molecular ion peak corresponding to molecular weight of the compound and 82 is the base peak.
Caryophyllene oxide (220): 220 [M^+], 205, 187, 177, 161, 145, 131, 121, 107, 93, 79, 69, 55, 43, 41. 220 is the molecular ion peak corresponding to molecular weight of the compound and 41 is the base peak.

Table 3
The zone of inhibition (mm) and minimum inhibitory concentration (MIC) values (μg/μl) of the essential oil of *L. bipinnata* and standard nystatin against fungi.

		Zone of inhibition (mm)		MIC (μg/μl)	MIC (μg/μl)
		L. bipinnata oil	Nystatin	*L. bipinnata* oil	Nystatin
1.	*A. niger*	13	21	⩽2.0	⩽0.040
2.	*P. notatum*	09	13	⩽4.0	⩽0.160
3.	*C. albicans*	10	23	⩽4.0	⩽0.160

4. Conclusions

Our results demonstrated that transcarveol, pulegone, camphor and menthol were the main constituents of essential oil of *L. bipinnata*. Since, these constituents are used as flavouring agents in cosmetic and food industry, the essential oil of *L. bipinnata* can be used as a source of these constituents. The essential oil of *L. bipinnata* showed antimicrobial activity against both bacteria and fungi, therefore it can be used as an herbal medicine. The plant is not known to be toxic because it has been consumed by mankind for centuries without showing any signs of toxicity.

two yellow rock sugars (*gula batu*) from cane; two palm sugars (*gula anau* and *gula Melaka*); and three fancy sugars, varieties of rock honey sugar, also from cane (see Table 1). One of these fancy sugars, china rock honey sugar, listed dried chrysanthemum flowers amongst its contents.

Sugars were dissolved in phosphate buffer (50 mM, pH 6.2). The raw sugar and the soft brown sugar were both light brown, granulated, sugars coloured and flavoured by coating with caramel or molasses. The red sugars were refined, granulated, sugars whose crystals were coloured artificially. All the rock sugars were refined, lightly coloured, sugars in large lumps or crystals. The palm sugars were unrefined: the *gula Melaka* was a single piece of solid sugar, and the *gula anau* was a viscous liquid. The lump sugars were crushed in a mortar with a pestle in order to aid dissolution. Each sugar was tested over a concentration range from 0.1% to 50% (w/v). Each individual sample concentration was tested twice, and each individual sugar was tested at least three times.

2.2. Chrysanthemum flowers

Dried chrysanthemum flowers are used in traditional Chinese medicines and were obtained from a Chinese apothecary. The dried petals were infused with hot, double-distilled, water, just off the boil at room temperature (25 °C) for 15 min at a concentration of 1% (w/v). This infusion was diluted further in phosphate buffer to produce solutions of 0.1–50% v/v stock/buffer.

2.3. Cyclic voltammetry

Cyclic voltammetry was performed using an eDAQ system (www.eDAQ.com), consisting of an E190 potentiostat connected to an e-corder which inputted to eChem software (running on a PC using Microsoft Windows Vista platform). The working electrode was a 3 mm diameter glassy carbon electrode; the reference electrode was Ag/AgCl in 3 M NaCl (+207 mV *vs*. standard hydrogen electrode); the auxiliary electrode was a 0.25 mm diameter Pt wire. The working electrode was polished for at least 4 min before individual cycles of voltammetry. Unless otherwise stated, applied potentials ranged from −200 to +800 mV, and the scan rate was 200 mV s^{-1}. The volume of the voltammetric cell was approximately 15 ml.

Vitamin C (ascorbic acid) was used as a standard antioxidant for comparison of the sugars. Cyclic voltammograms were constructed for vitamin C at concentrations from 5.1 μM to 2.6 mM. Vitamin C (Krüger GmbH & Co., Germany) was dissolved freshly at the start of the experiments. All solutions were prepared using double-distilled water.

2.4. Diffusion coefficients

According to the Randles–Ševcik equation (Randles, 1948):

$$I_{pa} = kn^{3/2}AD^{1/2}C.v^{1/2}$$

where I_{pa} = peak anodic current; k = Randles–Ševcik constant (2.69×10^5 A.s.$V^{-1/2}$ mol^{-1}) at 25 °C; n = electron stoichiometry (i.e., the number of electrons transferred to the substrate molecule); A = exposed surface area of the electrode (cm^2); D = diffusion coefficient of the substrate molecule (cm^2 s^{-1}); C = concentration of the substrate molecule (mol cm^{-3}); v = scan rate (V s^{-1}).

Thus, if the concentration of the substrate is kept constant, a plot of I_{pa} *vs.* $v^{½}$ will yield a straight line whose slope can be used to determine the diffusion coefficient. Samples of sugars were scanned at rates from 50 to 3200 V s^{-1}, in steps of $\log_2$ units.

2.5. Redox potentials and peak potentials

In cases where the oxidation of compounds was, at least partially, reversible, the redox potential was calculated form $(E_{pa} + E_{pc})/2$ and the peak potential was calculated from $(E_{pc} - E_{pa})$, where E_{pa} and E_{pc} were the potentials at which the peak anodic and peak cathodic currents (I_{pa} and I_{pc}, respectively) were recorded.

3. Results

3.1. Vitamin C standards

Over a range of 5.1 μM to 2.6 mM, vitamin C produced a concentration-dependent peak anodic current (I_{pa}) (Figs. 1 and 2).

Table 1
Peak anodic currents per unit concentration.

Gula Melaka	–	–

Values for $C.D^{0.5}$ (±standard error) were calculated from the slopes of the regressions of I_{pa} on (scan rate)$^{0.5}$, as shown in Fig. 10, constraining the line to pass through the origin; the correlation coefficient (r^2) is given within parentheses. The values of $C.D^{0.5}$ for vitamin C (mol.cm^{-2} $s^{-0.5}$ × 10^{-6}) were: 38.9 ± 0.58 (0.999), 21.3 ± 0.53 (0.996) and 3.3 ± 0.04 (0.999) at concentrations of 0.51, 0.26 mM and 51.1 μM, respectively. For chrysanthemum flower infusion (10% v/v buffer) the slope was 10.8 ± 0.73 × 10^{-6} mol cm^{-2} $s^{-0.5}$ (r^2 = 0.973). All data are for 7 d.f.

[a] Current constants were obtained form the slope of the regression of I_{pa}^{-1} on [analyte]$^{-1}$, constraining the regression to pass through the origin. The regressions are drawn in Fig. 8; values are slope ± s.e. slope, with the correlation coefficient (r^2) and degrees of freedom given within parentheses. The units of concentration for all the sugars is *g*% (w/v) phosphate buffer.

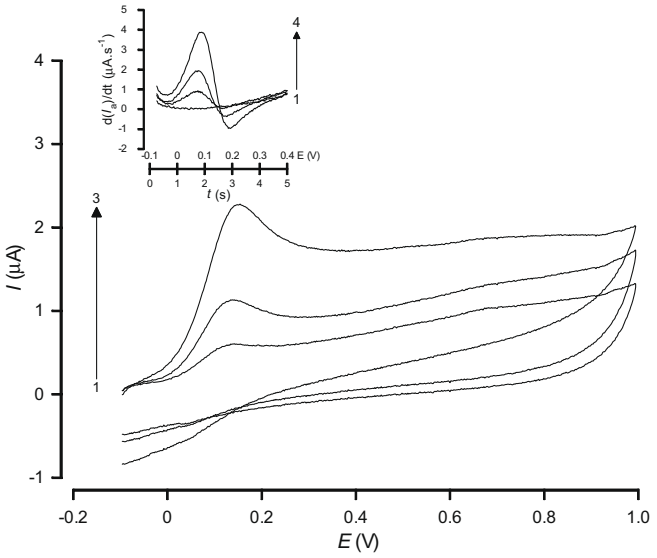

Fig. 1. Vitamin C. Cyclic voltammograms for vitamin C in 0.1 M phosphate buffer, pH 6.2. The numbers 1 → 3 correspond to concentrations of 0.010, 0.026 and 0.051 mM vitamin C in phosphate buffer. Inset are differentiated recordings, with the numbers 1 → 4 corresponding to concentrations of 0, 0.010, 0.026 and 0.051 mM vitamin C in phosphate buffer.

The potential (E_{pa}) at which I_{pa} occurred was 168–218 mV for concentrations from 5.1 μM to 2.6 mM (Fig. 2). There were no observable peak cathodic currents (I_{pc}).

The relationship between I_{pa} and concentration of vitamin C appeared to be linear over the concentration range of 5.1 μM to 2.6 mM (Fig. 2A). When both the ordinate and abscissa were plotted on reciprocal scales the regression was also linear (Fig. 2B). The slope of this transformation, 0.03 ± 0.007 mM μA^{-1}, gives the concentration of vitamin C per unit I_{pa} which was termed the "current constant".

The voltammograms were subjected to first order differentiation with respect to time (using eChem software). The resulting transformed voltammograms give $d(I_a)/dt$ with a peak corresponding to the fastest rate of increase of the I_{pa} (Fig. 1 inset). In other words, the differentiated traces give the rate of oxidation of vitamin C. There was a linear correlation between the amplitude of the signal produced by vitamin C and the rate of increase of that signal (Fig. 2C).

When the concentration of vitamin C was kept fixed at either 0.05, 0.25 or 0.51 mM, the I_{pa} was linearly dependent upon the scan rate for a range from 50 to 3200 mV s^{-1} (Fig. 2D). Using the slope of this regression and the Randles–Ševcik equation, the diffusion coefficient of vitamin C was calculated and found to be $1.89 \times 10^{-6} \pm 2.67 \times 10^{-7}$ (mean ± s.e. mean, of the three different concentrations of vitamin C, three different samples each measured in duplicate using two different recording electrodes). The negative logarithm of this, i.e. the p*D*, is 5.74 ± 0.064 ($n = 3$).

3.2. Sugars

Refined white granulated sugar, up to 50% w/v buffer, gave a signal no different from the phosphate buffer alone. No signal was found for two of the three red sugars (Nabila *gula merah* and STM *gula merah*), nor for the white or yellow rock sugars, nor for *gula Melaka* palm sugar, nor for the two Luo Han Guo mixed sugars. No peaks were observed in the anodic or cathodic directions of the cyclic voltammograms, nor were any peaks identified on the differentiated traces. Potentials were applied from −200 to +1200 mV.

In contrast, anodic current peaks were found in four refined cane sugars (SIS raw sugar, Nazri soft brown sugar, China rock honey sugar and *gula merah*) and one unrefined palm sugar (*gula anau*) (Figs. 3–7, respectively). The cyclic voltammograms for SIS raw sugar, soft brown sugar and China rock honey sugar had more than one peak, however the smaller peaks tended to be obscured by the main peak; it was often easier to discern that there was a second or third compound present from the differentiated recording (Figs. 3–5).

The relationship between the I_{pa} amplitude and the concentration was similar for all the five positive sugars, in that for low level signals the relationship looked linear but at higher level signals (higher concentrations) the relationship deviated from linearity as if to plateau. Using double-reciprocal plots, the graphs were

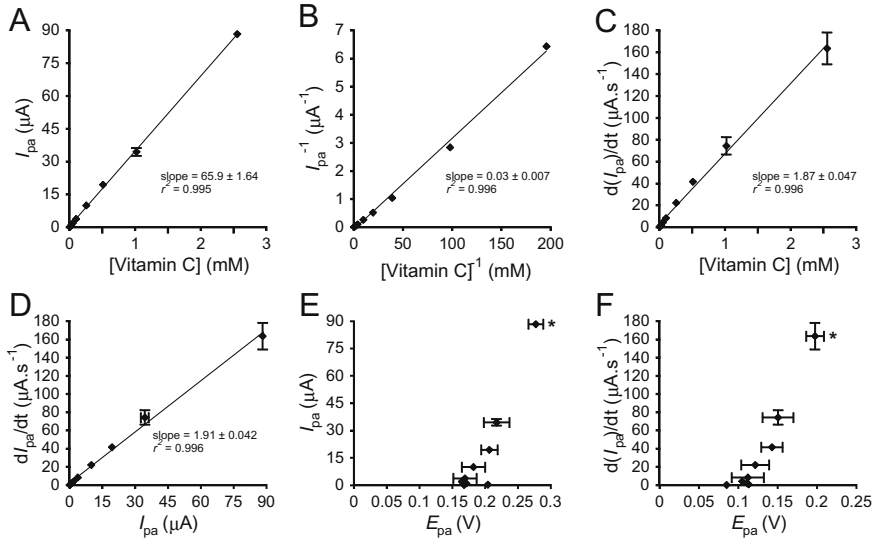

Fig. 2. Characteristics of vitamin C by voltammetry. (A) Vitamin C produces a concentration-dependent linear increase in peak anodic current (I_{pa}). (B) The double reciprocal plot of I_{pa}^{-1} on concentration^{-1} is linear. (C) The first order derivative of the I_{pa} also has a linear dependency on concentration. (D) The first order derivative has a linear relation with the I_{pa}. (E) From 5.11 μM to 1.02 mM there was no significant change in the potential (E_{pa}) at which the I_{pa} occurred, only at the highest concentration tested (∗, 2.56 mM) does the E_{pa} lie significantly more positive (two-way ANOVA and *post hoc t*-test). (F). For dI_{pa}/dt, there was no significant shift in E_{pa} over a concentration range from 5.11 μM to 1.02 mM, but at 2.56 mM (∗) the rightward shift is statistically significant ($p < 0.01$) two-way ANOVA and *post hoc t*-test).

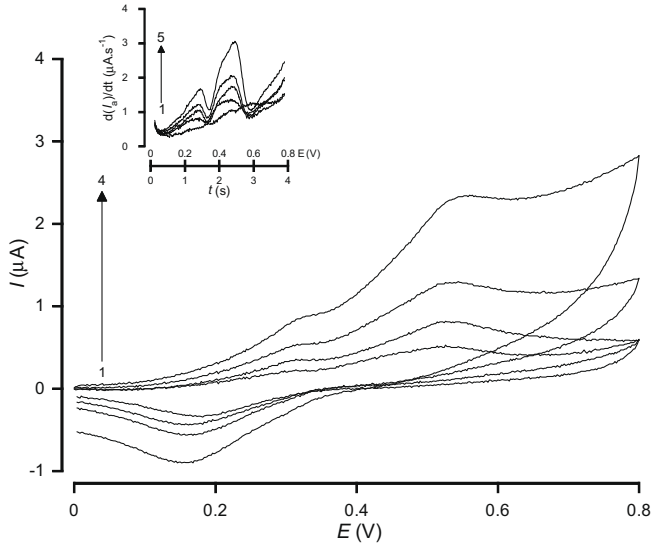

Fig. 3. SIS raw sugar. Cyclic voltammograms for SIS raw sugar in 0.1 M phosphate buffer, pH 6.2. The numbers 1 → 4 correspond to concentrations of 3%, 6%, 12% and 25% (w/v) sugar in phosphate buffer. Inset are differentiated recordings, with the numbers 1 → 5 corresponding to concentrations of 0%, 3%, 6%, 12% and 25% (w/v) sugar in phosphate buffer.

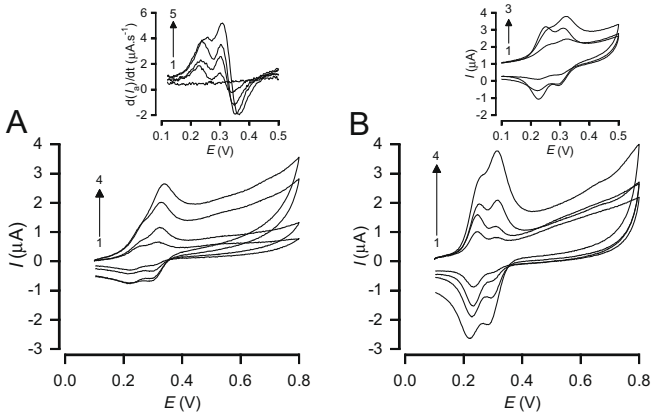

Fig. 5. China rock honey sugar and chrysanthemum flowers infusion. Cyclic voltammograms for: (A) China rock honey sugar in 0.1 M phosphate buffer, pH 6.2. The numbers 1 → 4 correspond to concentrations of 3%, 6%, 12% and 25% (w/v) sugar. Inset are differentiated recordings, with the numbers 1 → 5 corresponding to concentrations of 0%, 3%, 6%, 12% and 25% (w/v) sugar in phosphate buffer; (B) chrysanthemum flower infusion in phosphate buffer, pH 6.2. The background (phosphate buffer alone) has been subtracted. The numbers 1 → 4 correspond to concentrations of 0.5%, 1%, 2% and 5% (v/v) infusion. Inset are current recordings, with the numbers 1 → 3 corresponding to concentrations of 6.25% (w/v) China rock honey sugar in phosphate buffer, chrysanthemum flowers infusion 2% (v/v) in phosphate buffer, and an equal volume mixture of these two.

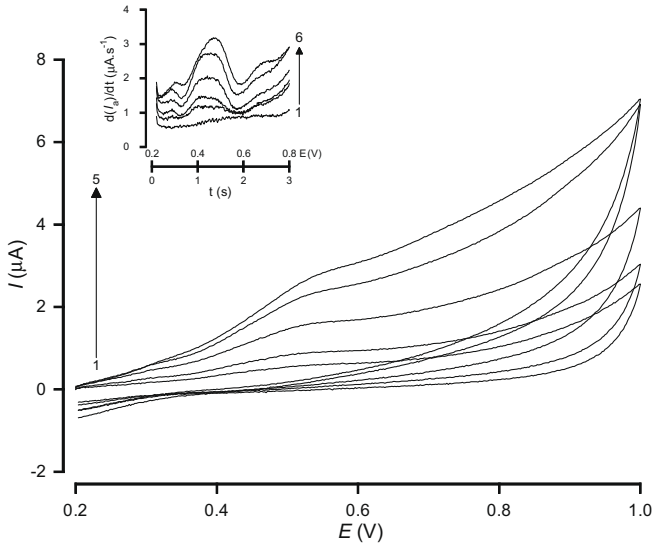

Fig. 4. Soft brown sugar. Cyclic voltammograms for soft brown sugar in 0.1 M phosphate buffer, pH 6.2. The numbers 1 → 5 correspond to concentrations of 1%, 3%, 6%, 12% and 25% (w/v) sugar in phosphate buffer. Inset are differentiated recordings, with the numbers 1 → 6 corresponding to concentrations of 0, 1, 3, 6, 12 and 25% (w/v) sugar in phosphate buffer.

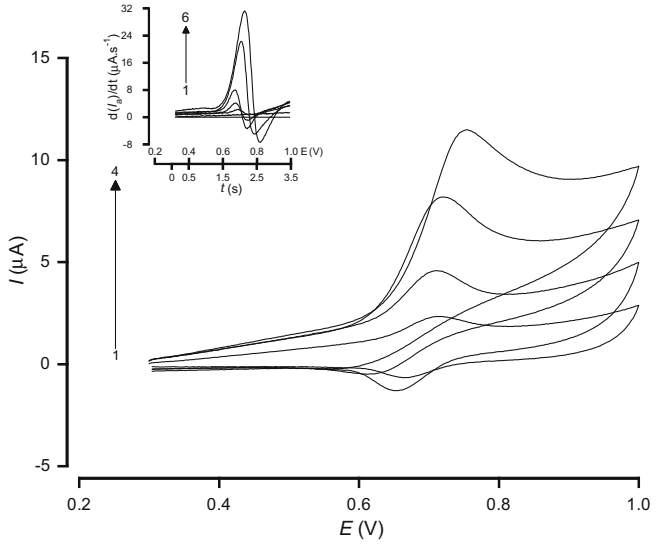

Fig. 6. *Gula merah*. Cyclic voltammograms for *gula merah* in 0.1 M phosphate buffer, pH 6.2. The numbers 1 → 4 correspond to concentrations of 1.5%, 3%, 6%, and 12% (w/v) sugar in phosphate buffer. Inset are differentiated recordings, with the numbers 1 → 6 corresponding to concentrations of 0%, 1%, 3%, 6%, 12% and 25% (w/v) sugar in phosphate buffer.

linearised (Fig. 8); as for vitamin C, the slope of this transformation gave the concentration of analyte per unit I_{pa}, or current constant (Table 1), and allows a direct comparison between the sugars and vitamin C. Assuming that the I_{pa} reflects antioxidant activity, comparing these values with vitamin C gives a rank order of antioxidant activity of the five sugars: *gula anau* > *gula merah* > China rock honey sugar > soft brown sugar > SIS raw sugar.

The red sugar, sunflower *gula merah*, was certainly red in colour. When it was being dissolved it was noticeable that the red colour came away from the sugar crystals so that in the early stages of dissolution there was a reddish coloured liquid with white crystals on the bottom of the beaker. The same was true for the two negative red sugars, Nabilah *gula merah* and STM *gula merah*.

The two refined brown sugars and the China rock honey sugar contained compounds whose oxidation appeared to be at least partially reversible, because the cathodic current traces in the cyclic voltamograms also displayed peaks (I_{pc}) (Figs. 3–5).

For the China rock honey sugar, for the first peak, which was due to a substance with a redox potential of 258 ± 8.4 mV (n = 5), the I_{pa}/I_{pc} ratio was 1.1 ± 0.18 (n = 5) and the peak potential was 44.7 ± 5.28 mV (n = 5). This peak was only measurable at a concentration of 3.13% (w/v) buffer because otherwise it merged into the peak for a second substance. This second peak was due to a substance with a redox potential of 302 ± 6.7 mV (n = 6, at five concentrations from 3.13% to 50% w/v buffer); the I_{pa}/I_{pc} ratio was 2.3 ± 0.26 and the peak potential was 54.6 ± 3.80 mV.

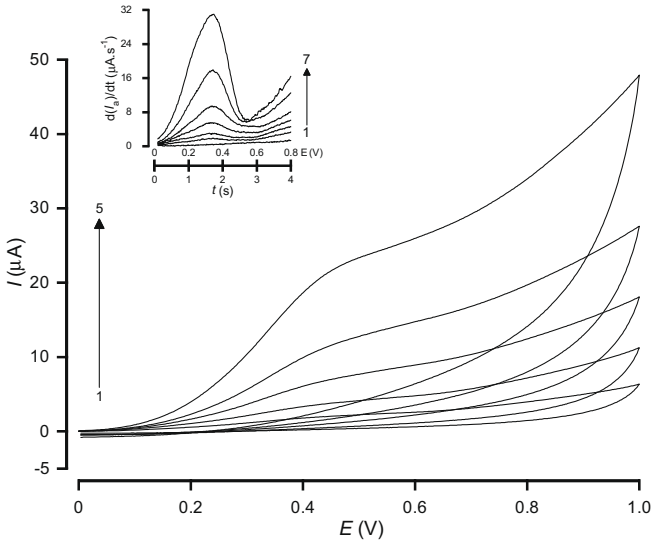

Fig. 7. *Gula anau*. Cyclic voltammograms for *gula anau* in 0.1 M phosphate buffer, pH 6.2. The numbers 1 → 5 correspond to concentrations of 1%, 2%, 5%, 10% and 20% (w/v) sugar in phosphate buffer. Inset are differentiated recordings, with the numbers 1 → 7 corresponding to concentrations of 0%, 1%, 2%, 5%, 10%, 20% and 50% (w/v) sugar in phosphate buffer.

3.3. Chrysanthemum flowers

The solutions of infused dried chrysanthemum flowers yielded multiple peaks in the cyclic voltammograms. Two prominent peaks were discernible below 400 mV and occurred close together (Fig. 5). The potentials at which these peaks occurred were similar to those observed in the China rock honey sugar, and when the China rock honey sugar (6.25%) was mixed with an equal volume of the chrysanthemum infusion (2%), there were still only two peaks in either the anodic or cathodic current traces (Fig. 5). Furthermore, on the differentiated traces, no additional peaks were seen. The first peak, was due to a substance with a redox potential of 238 ± 1.3 mV (n = 5); the I_{pa}/I_{pc} ratio was 1.0 ± 0.04 (n = 5) and the peak potential was 38.4 ± 17.7 mV (n = 5). This peak was measurable only at concentrations from 0.1% to 2% (w/v) buffer because otherwise it merged into the second peak. The second peak was due to a substance with a redox potential of 284 ± 5.3 mV (n = 7), at concentrations from 0.5% to 50% w/v buffer; the I_{pa}/I_{pc} ratio was 1.9 ± 0.37 and the peak potential was 52.9 ± 18.3 mV. The peak potentials for both the first and second peaks were not significantly different from those for the corresponding peaks in the China rock honey sugar (unpaired Student's t-tests). Likewise, the peak ratios did not significantly differ between the flower infusion and the sugar, nor did the redox potentials (unpaired t-tests, $p > 0.05$).

3.4. Peak anodic current potentials

Of all the compounds tested, vitamin C had the lowest E_{pa}, at approximately 200 mV (Fig. 9). None of the sugars had compounds with an oxidation potential in this region. The main antioxidant in the China rock honey sugar, the raw sugar (peak1), the soft brown sugar (peak1) and the chrysanthemum infusion all had values for E_{pa} in the region of 300–400 mV. The antioxidant compounds in *gula anau* and in the second peaks of the refined raw sugar and the soft brown sugar had potentials that were similar at 500–650 mV. The compound in *gula merah,* that yielded an anodic current peak, had a very high potential, greater than 700 mV. Furthermore, the peak potential of this compound became more positive, in a concentration-dependent fashion (Fig. 8), up to 900 mV at the highest concentration tested (50% w/v).

3.5. Diffusion coefficients

For the five positive sugars, vitamin C and the chrysanthemum flower infusion, the plots of I_{pa} against the square root of the scan

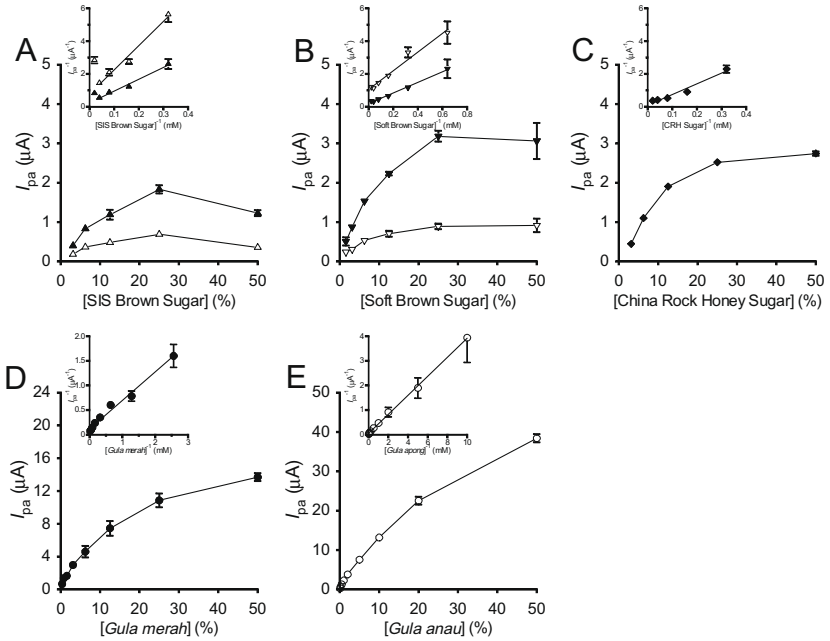

Fig. 8. Sugars displaying peak anodic currents (I_{pa}). (A) SIS raw sugar peak1 (open upward triangle); SIS raw sugar peak2 (closed upward triangle). (B) Soft brown sugar peak1 (open downward triangle); soft brown sugar peak2 (closed downward triangle). (C) China rock honey sugar (closed diamond). (D) *Gula merah* (closed circle). (E) *Gula anau* (open circle). Concentrations are given as w/v phosphate buffer. Graphs show concentration dependency of I_{pa}, insets show double-reciprocal plots of I_{pa}^{-1} *versus* concentration^{-1}. Regression slopes and correlation coefficients are given in Table 1 (N.B. For SIS brown sugar, the points at a concentration of 50% were not included in the regression). Points show mean ± s.e. mean, unless occluded by symbol.

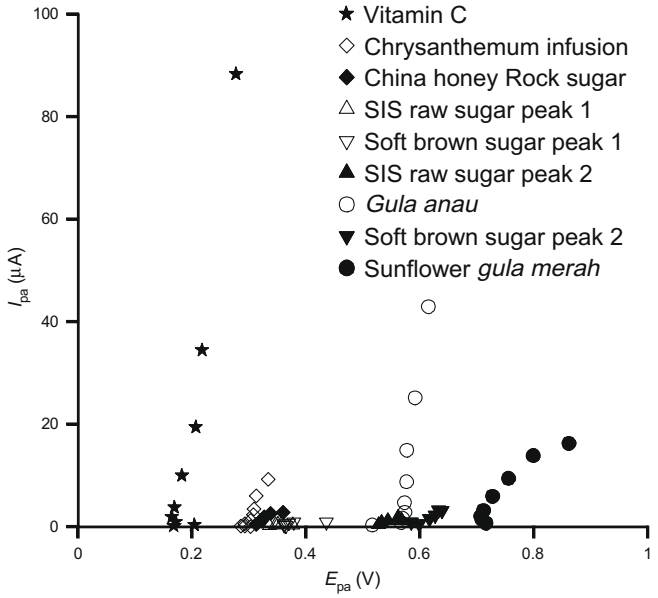

Fig. 9. Relationships between peak anodic currents (I_{pa}) and oxidation potentials (E_{pa}). Vitamin C (closed star), chrysanthemum flowers infusion (open diamond), China rock honey sugar (closed diamond), SIS raw sugar peak1 (open upward triangle), soft brown sugar peak1 (open downward triangle, occluding open upward triangles), *gula anau* (open circle), SIS raw sugar peak2 (closed upward triangle), soft brown sugar peak2 (closed downward triangle) and *gula merah* (closed circle). The highest concentrations tested, and the highest I_{pa} for each analyte, were: vitamin C, 2.6 mM; chrysanthemum flower infusion 50% v/v buffer; all sugars, 50% w/v buffer.

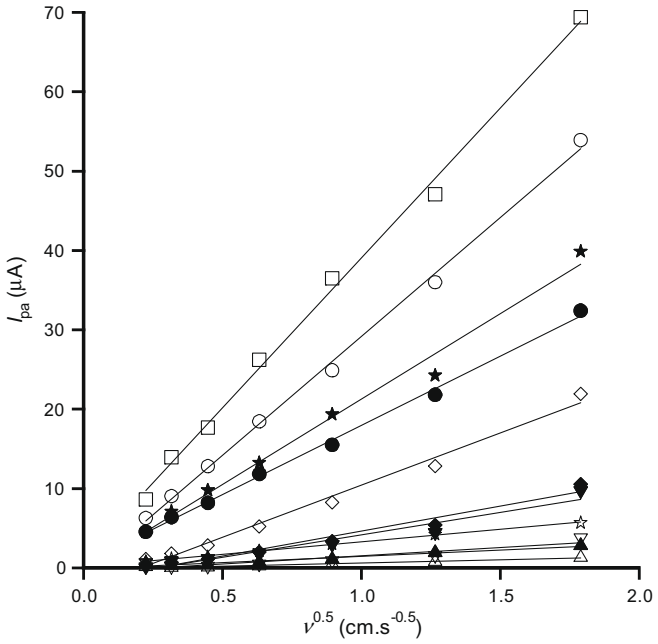

Fig. 10. Regressions of peak anodic currents (I_{pa}) on the square root of the scan rate ($v^{0.5}$). Vitamin C (10%, open square; 5% closed star; 1% open star), chrysanthemum flowers infusion (open diamond), China rock honey sugar (closed diamond), SIS raw sugar peak1 (open upward triangle), soft brown sugar peak1 (open downward triangle), *gula anau* (open circle), SIS raw sugar peak2 (closed upward triangle), soft brown sugar peak2 (closed downward triangle) and *gula merah* (closed circle). All the sugars were tested at concentrations of 10% w/v buffer; the chrysanthemum flower infusion was tested at 10% v/v buffer.

rate are shown in Fig. 10. In each case, the regression of I_{pa} on the square root of the scan rate was linear (least-squares regression); the regression lines were constrained to passing through the origin and their slopes are given in Table 1 together with their correlation coefficients. For the China honey rock sugar, and for the infusion of chrysanthemum flowers, there was not a clear enough separation of the two peaks to allow separate analysis, and data for the I_{pa} that occurred around 300 mV in both cases are shown. The slope of the regression is the value $C.D^{0.5}$ (from the Randles–Ševcik equation), but the diffusion coefficients for compounds contained in the sugars could not be calculated, because their concentration is unknown.

4. Discussion

The results show that some refined and unrefined sugars do contain antioxidants. Previous studies relating the redox potential of a compound to a lipid peroxidation assay showed that compounds with a redox potential below 450 mV were antioxidant, and that compounds with a redox potential of 490 mV or above were pro-oxidant (Simic, Manojlovic, Šegan, & Todorovic, 2007). The highest levels of antioxidant activity appeared to be found in the palm sugar *gula anau*. This sugar had an antioxidant activity equivalent to 1.7 mg of vitamin C per 1 g of *gula anau*. The nature of the antioxidant has not been described, but it is unlikely to be vitamin C itself because, even though the diffusion coefficient of this compound was close to that of authentic vitamin C, the potential at which the peak anodic currents occurred was approximately 100 mV more positive than that of authentic vitamin C.

A red sugar, *gula merah*, also contained a substance in appreciable amount that was oxidisable, however, the potential at which the peak anodic current arose were very high, around 700 mV. This means that this substance is not a powerful antioxidant (Simic et al., 2007). Because the colour readily came away from the sugar crystals during dissolution, and also because the red colour of this product did not look like that of any other sugar, there is some doubt as to the origin of this antioxidant. No further information has been supplied by the manufacturer.

The mixed sugar, China rock honey sugar, had a comparatively low level of antioxidant activity. This is almost certainly entirely due to its chrysanthemum flower content. The two peaks of anodic current, that were present in this mixed sugar, were also present in aqueous extracts of dried chrysanthemum petals alone. When samples of the sugar and flowers were mixed, there were still only the two anodic peaks. Furthermore, the I_{pa}/I_{pc} ratios, the redox potentials and the peak potentials for the two substances did not significantly differ between the two samples. Finally, the predominant peaks in these two substances also had similar diffusion coefficients. Two other mixed sugars with similar or identical contents apart from the chrysanthemum flowers had no discernible antioxidant activity. Therefore, it is probable that any antioxidant activity present in the China rock honey sugar is due to the dried chrysanthemum flowers.

The refined SIS raw sugar and the Nazri soft brown sugar both had low levels of antioxidant activity from two compounds. From the current constants, assuming that the compounds in the two sugars are the same, the concentrations of both compounds in the soft brown sugar were just over double (2.25 and 2.22 times great for peaks 1 and 2, respectively) those in the raw sugar; the oxidation potentials for the compounds were the same. When this difference in concentration is taken into account, the diffusion coefficients for the compound of peak1 become almost identical, while those for peak2 become very close. The main difference between these two products appeared to be particle size; the raw sugar was composed of larger crystals.

From the potentials at which the anodic current peaks arose, it would appear that the antioxidant in the refined raw and soft

brown sugars could be the same as that in the unrefined palm sugar. From the values of the current constants, the amount present in the *gula anau* was 20 times greater than that in the raw sugar. Correcting the value of $C.D^{0.5}$ to reflect this 20-fold difference, gives a compound with the same diffusion coefficient in the two sugars (the corrected $C.D^{0.5}$ for gula anau becomes 1.47 μmol $cm^{-2}.s^{-0.5}$ c.f. 1.5 μmol cm^{-2} $s^{-0.5}$ for the raw sugar).

The antioxidants in the chrysanthemum petals and the China rock honey sugar were the most powerful amongst the sugars, arising at potentials approximately 100 mV lower than any other. As noted above, it was not always possible to resolve the peaks for these compounds because they merged into each other. Antioxidant activity has been reported in chrysanthemum flower buds from three different species (Woo et al., 2008), and at least 17 polyphenol compounds which may have antioxidant activity can be extracted from *Chrysanthemum morifolium* flowers (Lai et al., 2007).

The calculated diffusion coefficient for vitamin C (1.89×10^{-6} cm s^{-1}) is in agreement with values in the literature obtained using modified carbon paste electrodes (5.7×10^{-6} cm s^{-1}, Marian, Sandulescu, & Bonciocat, 2000) or glassy carbon electrodes (3.2×10^{-6} cm s^{-1}, Sabzi & Pournaghi-Azar, 2005).

The cyclic voltammograms for *gula anau* show a remarkable similarity to those for vanillic acid. Simic et al. (2007) showed that vanillic acid (1 mM) has a single broad-based peak at a potential of 0.73 mV, with a linear relationship between I_{pa} and the square root of the scan rate. The voltammograms also showed no peak on the reduction curve. These authors also used a glassy carbon electrode with a Ag/AgCl reference electrode. Vanillic acid is among several antioxidant compounds found in refined or coated brown sugars from sugarcane (Payet, Sing, & Smadja, 2005).

Using a colourimetric assay which determined the total amount of antioxidants in a sample, Halvorsen et al. (2006) showed that raw cane sugar had nearly twice the antioxidant capacity of turbinado sugar, and that the level of antioxidant activity in refined granulated sugar was approximately 80 times less than that in the raw cane sugar. Using cyclic voltammetry, antioxidant activity was not detected in any of the white or yellow sugars that were tested.

In conclusion, it is evident that most types of refined sugars on the market do not contain any antioxidants. Very low levels of antioxidant activity were found in the refined raw and brown cane sugars. Higher levels were found in a rock honey sugar (also refined) which also contained chrysanthemum flowers, and the activity was due to the flowers.

An oxidisable substance was found at appreciable levels in the unrefined palm sugar, *gula anau*, however whether or not this functions as an antioxidant remains to be determined. If it is, then *gula anau*, should be promoted as the sweetener of choice because of its antioxidant content.

problems of different nature as to heart and circulatory, or complications in the immunization system. Other researchers, however, when developing some experiments concerning the influence of injected caffeine on the urinary excretion of some metal ions, e.g. potassium, sodium, magnesium, calcium, zinc, copper, in rats, conclude that the urinary excretion of zinc and copper were found to be unaffected by caffeine (YeH et al., 1986).

Whilst earlier data on diffusion coefficients of copper chloride in aqueous solutions at 25 °C and 37 °C over the concentration range from 0.001 to 0.05 mol dm^{-3} have been reviewed (Ribeiro et al., 2005), no data on mutual diffusion coefficients of Cu(II) salts in the presence of caffeine at 25 °C and 37 °C – relevant data for *in vivo* pharmaceutical applications- have been published, as far as careful literature searches have shown. This paper reports experimental data for differential ternary mutual diffusion coefficients (D_{11}, D_{22}, D_{12} and D_{21}) of copper chloride in aqueous solutions at carrier concentrations from (0.000 to 0.020 mol dm^{-3}), for each solute, respectively, in the presence of caffeine at different concentrations (that is from 0.000 to 0.020 mol dm^{-3}) using the Taylor dispersion equipment for aqueous solutions of $CuCl_2$-caffeine at 25 °C and 37 °C.

2. Experimental

2.1. Reagents and solutions

Copper chloride (Sigma–Aldrich, *pro analysi* > 99.9%) and caffeine (Sigma, *pro analysi* > 98.5%) were used as supplied, without further purification. All the solutions were freshly prepared before each experiment (concentration uncertainty less than ± 0.1%). They were prepared in calibrated volumetric flasks using bi-distilled water and de-aerated during 30 min, approximately, before use.

2.2. Equipment and procedure for diffusion measurements

The theory of the Taylor dispersion technique is well described in literature (Barthel, Gores, Lohr, & Seidl, 1996; Callendar & Leaist, 2006; Vitagliano, 1991), and therefore, we only indicate some relevant points concerning this method on the experimental determination of ternary diffusion coefficients, D_{11}, D_{22}, D_{12} and D_{21}, respectively.

The above dispersion method is based on the dispersion of small amounts of solution injected into laminar carrier streams of solvent or solution of different composition, flowing through a long capillary tube. The length of the Teflon dispersion tube used in the present study was measured directly by stretching the tube in a large hall and using two high quality theodolytes and appropriate mirrors to accurately focus on the tube ends. This technique gave a tube length of 3.2799 (±0.0001) × 10^4 mm, in agreement with less-precise control measurements using a good-quality measuring tape. The radius of the tube, 0.5570 (±0.00003) mm, was calculated from the tube volume obtained by accurately weighing (resolution 0.1 mg) the tube when empty and when filled with distilled water of known density.

At the start of each run, a 6-port Teflon injection valve (Rheodyne, model 5020) was used to introduce 0.063 mL of solution into the laminar carrier stream of slightly different composition. A flow rate of 0.17 mL min^{-1} was maintained by a metering pump (Gilson model Minipuls 3) to give retention times of about 1.1 × 10^4 s. The dispersion tube and the injection valve were kept at 298.15 K and 303.15 K (±0.01 K) in an air thermostat.

Dispersion of the injected samples was monitored using a differential refractometer (Waters model 2410) at the outlet of the dispersion tube. Detector voltages, $V(t)$, were measured at accurately 5 s time intervals with a digital voltmeter (Agilent 34401A) with an IEEE interface. Binary diffusion coefficients, D, were evaluated by fitting the dispersion equation

$$V(t) = V_0 + V_1 t + V_{\max}(t_R/t)^{1/2} \exp\left[-12D(t - t_R)^2/r^2 t\right] \quad (1)$$

to the detector voltages. The additional fitting parameters were the mean sample retention time t_R, peak height $V_{\max}$, baseline voltage V_0, and baseline slope V_1.

Diffusion in a ternary solution is described by the diffusion equations

$$-(J_1) = (D_{11})_v \frac{\partial c_1}{\partial x} + (D_{12})_v \frac{\partial c_2}{\partial x} \quad (2)$$

$$-(J_2) = (D_{21})_v \frac{\partial c_1}{\partial x} + (D_{22})_v \frac{\partial c_2}{\partial x} \quad (3)$$

where J_1, J_2, $\frac{\partial c_1}{\partial x}$ and $\frac{\partial c_2}{\partial x}$ are the molar fluxes and the gradients in the concentrations of solutes 1 and 2, respectively. Main diffusion coefficients, D_{11} and D_{22}, give the flux of each solute produced by its own concentration gradient. Cross diffusion coefficients D_{12} and D_{21} give the coupled flux of each solute driven by a concentration gradient in the other solute. A positive D_{ik} cross- coefficient ($i \neq k$) indicates co-current coupled transport of solute i from regions of higher concentration of solute k to regions of lower concentration of solute k. However, a negative D_{ik} coefficient indicates counter-current coupled transport of solute i from regions of lower to higher concentration of solute k.

Extensions of the Taylor technique have been used to measure ternary mutual diffusion coefficients (D_{11}, D_{22}, D_{12} and D_{21}) for multicomponent solutions. These coefficients were evaluated by fitting the ternary dispersion equation (Eq. (4)) to two or more replicate pairs of peaks for each carrier-stream.

$$V(t) = V_0 + V_1 t + V_{\max}(t_R/t)^{1/2} \quad (4)$$

$$\left[W_1 \exp\left(-\frac{12D_1(t - t_R)^2}{r^2 t}\right) + (1 - W_1)\exp\left(-\frac{12D_2(t - t_R)^2}{r^2 t}\right)\right] \quad (5)$$

Two pairs of refractive-index profiles, D_1 and D_2, are the eigenvalues of the matrix of the ternary D_{ik} coefficients.

In these experiments, small volumes of ΔV of solution, of composition $\bar{c}_1 + \overline{\Delta c}_1$, $\bar{c}_2 + \overline{\Delta c}_2$ are injected into carrier solutions of composition, $\bar{c}_1$, $\bar{c}_2$ at time $t = 0$.

3. Results and discussion

The diffusion coefficients values for the ternary system $CuCl_2$ + caffeine + water at 25 °C and 37 °C, D_{11}, D_{12}, D_{21} and D_{22}, are summarised in Tables 1 and 2. These results are the average of 4 experiments. Good reproducibility was observed, as seen by the small standard deviations of the mean, S_{Dav}. Previous papers (Ribeiro, Leaist, et al., 2006; Ribeiro, Valente, et al., 2007; Ribeiro et al., 2008) reporting data obtained with this technique have shown that the error limits of our results should be close to the imprecision, therefore, giving an experimental uncertainty of 1–3%.

These results are compared with those obtained for binary systems at same temperature and same technique (Tables 1 and 2), that is, for $CuCl_2$ and caffeine in aqueous solutions, respectively.

From the above results, it is evident that caffeine molecules exert a significant influence on the diffusion of $CuCl_2$ in aqueous solution (that is, in general, for [caffeine]/[$CuCl_2$] ratio values $\geqslant 1$, increasing this effect with the increase of these ratios, and with increase of the concentrations but for the same ratio). Main coefficients D_{11} and D_{22} give the molar fluxes of the $CuCl_2$ (1) and caffeine (2) components driven by their own concentration

gradient. In general, these coefficients are lower than the binary diffusion coefficients of aqueous $CuCl_2$ and caffeine for both temperatures (deviations between 1% and 10%). However, in general, at the concentrations used in this study, we verify that added $CuCl_2$ produces relatively minor changes in D_{22} for caffeine, whilst added caffeine produces major chances in D_{11} for $CuCl_2$. Some copper ions can be present in solution as complexes 1:1 Cu(II):caffeine, as indicated in the literature (Franska, 2008). Consequently, they will have less mobility and, consequently, they can be responsible for relatively large decreases in D_{11}. This effect is less accentuated when we consider the effect of $CuCl_2$ on transport of caffeine, probably due to the similarity of the mobilities of caffeine free species and eventual aggregates of $CuCl_2$ and caffeine (Spiro et al., 1989).

The limiting values for infinitesimal concentration of cross-coefficients D_{12} and D_{21} should be zero within experimental error. However, at finite concentrations, the cross-coefficients D_{12} and D_{21} values different from zero may be used to understand the influence of these solutes in diffusion of solution components. In our case, the gradient in the concentration of $CuCl_2$ produces co-current coupled flows of caffeine. Considering that D_{12}/D_{22} gives the number of moles of $CuCl_2$ co-transported per mole of caffeine, we may say that, at the concentrations used, a mole of diffusing caffeine co-transports at most 0.02 mol of $CuCl_2$, increasing the co-transport with the increase of its concentration. Through D_{21}/D_{11} values, at the same concentrations, we can expect that a mole of diffusing $CuCl_2$ counter transports at most 0.01 mol of caffeine.

At 310.15 K, the of $CuCl_2$ co-transported per mole of caffeine, $D_{12}/D_{22,}$ is about 0.001 mol, whilst the number of moles of caffeine transported per mole of copper chloride, D_{21}/D_{11}, and their direction strongly depend on the concentration of the caffeine (that is, for concentrations of caffeine for the concentration range 0.001–0.020 M, the number of moles of this component can change between 0.002 and 0.084, as well as their direction).

These interactions can be explained with basis in electrostatic mechanism (Callendar & Leaist, 2006; Leaist, 1986). In binary solutions of $CuCl_2$, the condition of electroneutrality requires that Cu^{2+} and Cl^- ions diffuse at the same rate, even though the mobility of Cl^- is approximately two times larger than the mobility of Cu^{2+}. In fact, the electrical field produced by the flow of the $CuCl_2$ slows down Cl^- and speeds up Cu^{2+}, so that they travel at the same rate and thereby preventing charge separation. If caffeine is added, amounts of copper and chloride can be transported as complexes 1:1 Cu(II):caffeine and, in that situation, most the free copper is consumed by formation of these complexes. As a result, the gradi-

ent in $CuCl_2$ produces a gradient with opposite sign in the concentration of Cu^{2+} species. As these species diffuses toward the region of higher copper chloride concentration, as electric field is induced to slow Cl^- migration and maintain electroneutrality. The electric field pulls the caffeine (as a mixture of monomer caffeine molecules, and of a significant fraction of dimmers and higher caffeine multimers species, as shown as by dimerisation constant, K_D = 6.8 kg mol^{-1} at 25 °C Spiro et al., 1989) along with Cl^-, counter-current to the main flow of copper chloride, and resulting, hence, negative values of D_{21}. However, with the increase of the temperature (Table 2), we obtain, for some concentrations, values of D_{21} and D_{12} lower, indicating us that eventual interactions present in those systems are less accentuated at physiological temperature, (37 °C). The contribution of all species for the influence on this transport property may eventually be difficult to make. In fact, clarifying the nature of these interactions is not an easy task. However, we could say that what eventually can be more important for some areas of interest (e.g. pharmaceutical applications) is the thermodynamic behaviour of the involved species, not so much the complex question of the nature of their internal binding forces.

4. Conclusions

Based on these ternary diffusion measurements, we may conclude that in the concentration range studied, for each solute, caffeine plays a role on the behaviour of the diffusion copper chloride in aqueous solutions. In fact, we can see that the diffusion of $CuCl_2$ in aqueous solutions at both temperatures, 25 °C and 37 °C, may be affected by the eventual presence of new different species resulting from various equilibria (e.g. dimmers and higher caffeine multimers, different complexes as 1:1 Cu(II):caffeine, and monomers of protonated caffeine).

In conclusion, diffusion coefficients measured for aqueous solutions of $CuCl_2$ and caffeine provide transport data necessary to model diffusion in practical applications.

It is well known that post-harvest processing has pronounced effects on the chemical composition of coffee seeds, specially in water-soluble components like sugars, caffeine, trigonelline and chlorogenic acids (Smith, 1985). Despite the considerable availability of studies comparing coffees processed by dry and wet methods in the literature (Balylaya & Clifford, 1995; Clifford & Ramirez-Martinez, 1991; Guyot, Guele, Assemar, Tchana, & Pomathios, 1995; Knopp, Bytof, & Selmar, 2006; Leloup et al., 2004; Mazzafera & Padilha-Purcino, 2004), data on the chemical composition of coffees processed by semi-dry methods are still scarce.

Chlorogenic acids (CGA), a major family of phenolic compounds that represent 6–12% of coffee constituents in mass (Farah, DePaulis, Trugo, & Martin, 2005), are known to be responsible for coffee pigmentation and astringency (Farah & Donangelo, 2006). The thermal degradation of chlorogenic acids during roasting will result in formation of phenolic substances that contribute to bitterness (Clifford, 1985a) and aromatic compounds like phenols, which are undesirable to cup quality (Toci & Farah, 2008). Additionally, CGA participates in colour formation through its incorporation into the backbone of melanoidins (Farah & Donangelo, 2006). The major CGA classes in coffee are the caffeoylquinic acids (CQA), feruloylquinic acids (FQA) and dicaffeoylquinic acids (diCQA), with at least three isomers per class (Clifford, 2000). Caffeine is a xanthine derivative that gives a bitter characteristic taste to coffee (Farah, DePaulis, Moreira, Trugo, & Martin, 2006). Trigonelline is a pyridine derivative known to contribute indirectly to the formation of desirable and undesirable aroma compounds during roasting (Macrae, 1985; Moreira, Trugo, & Maria, 2000). Trigonelline content has also been correlated to good cup quality (Farah, Monteiro, Calado, Franca, & Trugo, 2006). Sugars, particularly sucrose, which is the most abundant simple carbohydrate in coffee, act as aroma precursor, originating several volatile substances during roasting such as furans, aldehydes and carboxylic acids (Farah, DePaulis et al., 2006; Farah, Monteiro et al., 2006; Teixeira et al., 1995). In the last few years, CGA, caffeine and trigonelline have also been the subject of several investigations in view of their potentially positive biological effects in humans.

The aim of this study was to compare the composition of the nine main chlorogenic acids, caffeine, trigonelline and sucrose in Brazilian green coffee seeds produced by wet and semi-dry post-harvesting methods.

2. Materials and methods

2.1. Samples

Seventeen coffee samples were used in this study, being four Arabica cultivars (Red Catuaí; Rubi; Yellow Bourbon and Topázio) and 11 hybrids, 10 from the crossing of *C. arabica* cv. Yellow Catuaí with Timor Hybrid (numbers 1–11) and two from the crossing of cv. Red Caturra with Timor Hybrid (numbers 12 and 13). The coffee fruits were produced in a farm located in Paula Cândido, Minas Gerais, Brazil. After harvesting, fruits were processed by wet and semi-dry methods.

2.1.1. Post-harvesting treatments

The ripe coffee cherries were harvested by hand picking, followed by wet or semi-dry processing. For wet processing, coffee fruits were quickly washed, manually pulped, followed by 8 h soaking for fermentation and mucilage removal. After soaking, parchment coffees were washed and de-hulled. The semi-dry processed seeds, were quickly washed and manually pulped, followed by washing and de-hulling, without mucilage removal. After wet or semi-dry processing, coffee seeds were stored in plastic bags under −20 °C until chemical analysis.

2.2. Extractions for chromatographic analyses

Prior to extraction, all seeds were milled to pass a 0.46 mm sieve. CGA were extracted with aqueous methanol (40%) and clarified with Carrez solutions according to Trugo and Macrae (1984), also described in Farah et al. (2005). Caffeine and trigonelline were extracted with 95 °C distilled water and clarified with aqueous plumb acetate (20%) (Farah, DePaulis et al., 2006; Farah, Monteiro et al., 2006; Trugo & Macrae, 1984). For sucrose evaluation, green coffee seeds were extracted with aqueous methanol (40%) and clarified with acetonitrile (Trugo, Farah, & Cabral, 1995). Extractions were performed in duplicates.

2.2.1. HPLC analyses

2.2.1.1. Chlorogenic acids. CGA were analysed, using a HPLC gradient system with a high-precision pump (Shimadzu model LC-10-AD, Kyoto, Japan), a UV detector (Shimadzu model LC-10-AD) operating at 325 nm, and a ODS-C18 column (Rexchrom: 5 μm, 250 × 4.6 nm, Regis Technologies, Morton Grove, IL) coupled with a guard column (Rexchrom: 5 μm, 10 × 3 nm, Regis Technologies). Chromatographic data was recorded and integrated in the Class VP computer software (Shimadzu). A gradient using 10 mM citric acid solution and methanol was performed (Farah et al., 2005). The identity of CGA was confirmed by LC–MS analyses as described by Farah, DePaulis et al. (2006) and Farah, Monteiro et al. (2006). In this work, the authors used IUPAC numbering system for CGA. When citing other authors, their numbering has been changed when necessary for consistency.

2.2.1.2. Caffeine and trigonelline. Caffeine and trigonelline analyses were performed according to Trugo and Macrae (1984), also described in Farah, DePaulis et al. (2006) and Farah, Monteiro et al. (2006). Analyses were performed by an isocratic system consisting of pump (Knauer, Model 64, Germany), integrator (Shimadzu, Model C-R6A) and UV detector (Shimadzu, model SPD-1-AV) operating at 272 nm for caffeine and 264 nm for trigonelline. A reversal phase column (ODS C-18 Merck, Darmstadt, Germany) was used with 40% methanol as mobile phase for caffeine and with 5% methanol for trigonelline. Flow rate was 1 mL/min.

2.2.1.3. Sucrose. Sucrose analyses were performed according to Trugo et al. (1995), adapted. A pump (Knauer, model 64) with a 20 μL Rheodyne fixed loop injector (Oak Harbor, WA, USA), Spherisorb NH_2 column (Supelco, Bellefonte, PA, USA), RI detector (Waters, Milford, MA, USA) and integrator (Hewllet Packard, model) were used. A mobile phase with acetonitrile 80%, at 1 mL/min was used.

2.3. Water content

In order to express the results in dry matter basis (dm), the water content of all samples was determined according to AOAC procedures (2000).

2.4. Statistical analysis

HPLC results were tested for differences by GraphPad Prism® software, version 4.0 (San Diego, CA, USA), using paired *t*-test method and considered significant when $p \leqslant 0.05$.

3. Results and discussion

3.1. Chlorogenic acids

The levels of CQA, FQA and diCQA in green coffee seeds processed by wet and semi-dry post-harvesting methods are

presented in Tables 1 and 2, respectively. For the first time, the distribution and content of nine CGA (3-CQA; 4-CQA; 5-CQA; 3-FQA; 4-FQA; 5-FQA; 3,4-diCQA; 3,5-diCQA; 4,5-diCQA) are compared in Brazilian coffees processed by wet and semi-dry methods. The CGA contents observed in this work are consistent with previous data for coffee in general (Farah & Donangelo, 2006). In the wet method, the average contents of CQA, di-CQA and FQA were, respectively, 4.94 ± 0.41; 0.94 ± 0.05 and 0.32 ± 0.02 g/100 g (dm), representing 81.3%, 13.3% and 5.3% of total CGA content (6.08 ± 0.44 g/100 g, dm). In this group, the sample with highest level of CGA was hybrid **1** (7.4 ± 0.21 g/100 g, dm), while the one with the lowest level was *C. arabica* cv. Topázio (5.2 ± 0.57 g/100 g, dm).

In the semi-dry method, the mean levels of CQA were 4.70 ± 0.37 g/100 g (dm), followed by diCQAs with 0.98 ± 0.02 g/100 g (dm) and FQA with 0.30 ± 0.01 g/100 g (dm). These classes accounted for 81.0%, 14.0% and 5.1% of total CGA levels (5.8 ± 0.38 g/100 g, dm), respectively. The highest content of total CGA was observed in hybrid **2** (6.7 ± 0.58 g/100 g, dm), mainly due to higher contents of 5-CQA and, to a lesser extent, 3,5-diCQA. The lowest content was observed in hybrid **3** (5.4 ± 0.25 g/100 g, dm). The highest and lowest CGA contents present in hybrids **2** and **3**, respectively, may result from different genetic inheritance of *C. arabica* and *C. canephora*, since Timor hybrid samples were produced by crossing of these two species. The higher CGA content in *C. canephora* comparing to *C. arabica* has been extensively reported (Clifford & Ramirez-Martinez, 1991; Farah & Donangelo, 2006).

Although the distribution profile of CGA classes in samples treated by the semi-dry method was similar to those treated by the wet method, on average, coffees processed by the wet method presented significantly higher total CGA content ($p = 0.02$) than those processed by the semi-dry method. This difference was observed in all CGA classes, except for the diCQA.

No data on CGA composition of semi-dry method is available in the literature. However, literature has reported a higher CGA content in wet processed Robusta seeds than in dry processed seeds. This difference in CGA contents has been attributed to losses of other water-soluble components by lixiviation and fermentation in the wet method (Wootton, 1974), in addition to slight degradation of such components in dry processed seeds exposed to sun heat. In this work, it is possible to observe that the CGA composition of semi-dry seeds are intermediate to those of dry and wet processed seeds, being more comparable to results obtained for dry processed seeds. This result is coherent, since semi-dry pro-

cessed seeds do not undergo soaking and fermentation like wet processed seeds. Moreover, it is noteworthy to point that this difference between the chemical composition of semi-dry and wet processed seeds may be considerably amplified if soaking time is increased in the wet method. While in this work, seeds have been soaked for 8 h, soaking time may be increased to up to 48 h (Teixeira et al., 1995).

Considering the similarity of dry and semi-dry methods, the present results are in agreement with results from Balylaya and Clifford (1995), using three dry and wet-processed *C. canephora* cv. Robusta samples and Leloup et al. (2004) for six Robusta samples. On the other hand, in Balylaya and Clifford (1995), wet-processed Arabica seeds ($n = 3$) showed lower levels of total chlorogenic acids compared to dry processed seeds. In this work, when only Arabica seeds ($n = 4$) were compared statistically, no significant difference was observed between wet and semi-dry methods. Therefore, the difference observed between both methods ($p = 0.02$) is attributed to the hybrid samples ($n = 13$), which presented a similar behaviour to Robusta samples. This difference between the results obtained for Arabica and Robusta/hybrids samples may be attributed to differences in their cell-wall constitutions (Toci & Farah, 2008).

3.2. Caffeine

In the coffee seeds processed by the wet method, the contents ranged from 1.05 ± 0.02 to 1.53 ± 0.01 g/100 g (dm) while in those seeds processed by semi-dry method, caffeine contents ranged from 1.12 ± 0.02 to 1.54 ± 0.02 g/100 g (dm) of coffee (Table 3). These results are in agreement with literature reports (Farah, DePaulis et al., 2006; Farah, Monteiro et al., 2006; Macrae, 1985). No significant difference between both methods was observed regarding caffeine contents. This is in agreement with results from Balylaya and Clifford (1995) and Leloup et al. (2004) for dry and wet processed seeds, and may be possibly due to the thermo-stability and the lower contents of caffeine in coffee compared to CGA.

3.3. Trigonelline

Trigonelline contents in seeds processed by the wet method ranged from 0.80 ± 0.02 to 1.40 ± 0.01 g/100 g (dm) with average of 0.90 ± 0.01 g/100 g (dm), while in seeds processed by semi-dry method, trigonelline contents ranged from 0.64 ± 0.01 to 0.92 ± 0.01 g/100 g (dm) with average of 0.81 ± 0.02 g/100 g (dm) (Table 3). These contents are in agreement with general coffee data (Farah, DePaulis et al., 2006; Farah; Martín, Pablo, & Gonzaléz, 1998; Monteiro et al., 2006). As with CGA, the relative increase in trigonelline content of coffee seeds processed by wet method compared to semi-dry method ($p < 0.0001$) may be due to loss of other components with higher water solubility by lixiviation and thermal degradation.

3.4. Sucrose

The content of sucrose in coffee treated by the wet method ranged from 8.0 ± 0.02 to 10.8 ± 0.05 g/100 g (dm), with average of 9.0 ± 0.03 g/100 g (dm) (Table 3). Sucrose content in seeds treated by the semi-dry method ranged from 7.10 ± 0.02 g/100 g to 14.5 ± 0.05 g/100 g (dm) with average of 12.3 ± 0.07 g/100 g (dm) (Table 3). These contents are generally in agreement with reports by Farah, DePaulis et al. (2006), Farah, Monteiro et al. (2006) and Knopp et al. (2006). Sucrose content in coffee seeds processed by the semi-dry method was significantly higher than in those processed by the wet method ($p = 0.02$) when including hybrids and Arabica samples. However, when evaluating only Arabica samples, no differences were found between semi-dry and wet methods. These results are also in agreement with those by Knopp et al. (2006).

In contrast with our results, Leloup et al. (2004) did not find differences when comparing sugar contents in dry and wet Robusta samples. However, our results are comparable to results from Guyot et al. (1995) who evaluated samples of *C. canephora* cv. Robusta treated by dry and wet methods.

As stated above, differently from the wet method, in the semi-dry method the mucilage is kept on the bean. According to Avallone, Guiraud, Guyot, Olguin, and Brillouet (2001), the mucilage is composed mostly by cell well polysaccharides, pectic substances and monosaccharides. Sucrose is not present in a dominant proportion in the mucilage when compared with other sugars. The authors state that this disaccharide is present mostly inside the coffee bean. Thus, it would not be possible to easily conclude that coffees produced by semi-dry methods have more sucrose than those produced by the wet method. Therefore, sucrose losses observed in our wet processed hybrid seeds are possibly mostly due to the high water solubility of this compound during washing and soaking and due to its use as a substrate for fermentation (Wootton, 1974). As with the CGA, the difference between the results obtained for Arabica and hybrids from Robusta samples might

Table 3

be attributed to differences in their cell-wall constitutions (Toci & Farah, 2008) but should be thoroughly investigated.

4. Conclusions

For the first time, the contents of nine chlorogenic acids, caffeine, trigonelline and sucrose were evaluated together in Brazilian Arabica coffee cultivars and hybrids treated by wet and semi-dry post-harvesting methods. The wet method produced an increase in chlorogenic acids and trigonelline contents and a small loss in sucrose contents comparing to semi-dry method. However, since the soaking period in the wet method is largely variable, more dramatic changes may be observed in these coffee components when seeds are soaked for longer periods of time. Sensorial analysis should be carried out in order to correlate the chemical differences observed between both post-harvesting methods with cup quality.

Acknowledgements

The authors would like to thank Henrique Theodoro Martins Peixoto, Dartanhan Augusto Fernandes Lima and José Carlos Silva Guimarães for assistance with coffee production, harvesting and processing; and to Carolina Castro Borges for technical assistance with trigonelline analysis. The financial support of CBPandD/Café-EMBRAPA; CNPq and FAPERJ is greatly acknowledged.

The characterisation of the animal origin of raw materials used for production of gelatin is now of concern for both manufacturers and consumers. This paper describes the potential utilisation of FTIR spectroscopy as a rapid method to differentiate and authenticate the source of gelatin.

2. Materials and methods

2.1. Sample preparation

Two different gelatin samples from porcine and bovine sources were obtained from Sigma and Merck, respectively (Table 1). Gelatin jellies were prepared by dissolving gelatins in deionized water and the mixtures were placed in a sonicator at 50 °C for 10 min until a clear solution was acquired. The jellies were poured into aluminum foil moulds (68 mm × 8 mm × 5 mm) and allowed to set for 1 h at 16–20 °C. The jellies were then cut into 68 mm × 8 mm × 3 mm according to ATR surface area. In this study, a total of 19 samples of porcine and bovine jellies were prepared, the concentrations of which were between 2% w/v and 16% w/v. The concentrations were chosen to be similar to those found in typical desserts and pastilles.

2.2. FTIR measurement

A Nicolet 6700 spectrometer model (Thermo-Nicolet, USA) with a DTGS-KBR detector was used in the measurements. An ATR accessory equipped with ZnSe cell was used. All spectra were recorded within a range of 4000–650 cm^{-1} with a 4 cm^{-1} resolution and 32 scans. Two replicate spectra were obtained from two independent experiments and the average spectrum was taken for further investigation. All measurements were performed in a dry atmosphere at room temperature (25 ± 0.5 °C). A single beam spectrum was obtained for all samples. These spectrums were subtracted against a background air spectrum and the results were presented in absorbance units.

ATR is a technique whereby the sample is placed in contact with ATR element (ZnSe crystal, 45° ends) and a spectrum is recorded because of that contact. This sampling technique allows radiation through the sample without transmission and only small amount of sample is sufficient to allow transmission of the incident radiation provided the sample is sufficient to cover the entire ATR surface (Griffiths & Haseth, 2007).

2.3. Acquisition of infrared spectra and data

All data were subjected to discriminant analysis (DA) using TQ Analyst software (Thermo-Nicolet, Madison, WI, USA). DA was performed for the wavenumber ranges between 3300–3280 cm^{-1} and 1660–1217 cm^{-1}. Constant pathlength was used for calculations. There are six principal components used for calculation to reduce spectral information. The Mahalanobis distance was used to formulate a distance between clusters. It was made on the variables of the study with the aim to determine which of these variables best discriminated according to the right sources of gelatin as well as establishing a mathematical model for this purpose. The distance is measured in terms of standard deviations from the mean of the training samples.

2.4. Discriminant analysis

In the TQ Analyst Software, the validation needs to be carried out by splitting the spectrum into two groups. One group for calibration and the other one for validation. Only three to four spectra were selected as validation spectra. The rest were performed as calibration spectra. When all validation spectra lay inside their cluster, the modules is consider correct.

3. Results and discussion

3.1. Spectral for gelatins

The frequencies at which major peaks occurred are shown in Fig. 1. Gelatins derived from porcine exhibited spectra very similar to those for gelatins derived from bovine. Four regions involves are 3600–2300 cm^{-1} (Amide A), 1656–1644 cm^{-1} (Amide I), 1560–1335 cm^{-1} (Amide II) and 1240–670 cm^{-1} (Amide III). These peaks were identified to be similar with those reported by Muyonga et al. (2004).

A typical gelatin spectrum showed low intensities of Amides I and II bands, with the Amide III band almost non-existent. This is consistent with changes expected because of denaturation of collagen to gelatin. A very low intensity showed for Amide III region is associated with loss of triple helix state during high temperature gelatin extraction (Muyonga et al., 2004). The 3290–3280 cm^{-1} region is donated by N–H bond-stretching mode of hydrogen bonded amide groups. The absorption is polarised parallel to N–H bond, which is parallel to the helix axis in α-helical structures and perpendicular to the polypeptide chain in β-sheets. The band might be shifted to lower frequency when the hydrogen bonding strength increases (Krimm & Bandekar, 1986).

The carbonyl C=O double bond-stretching mode, with contributions from in-phase bending of the N–H bond and stretching of the C–N bond, occurs in frequency range 1660–1620 cm^{-1} region which is often referred to as Amide I band. The frequency range 1660–1650 cm^{-1} was known as α-helical and 1640–1620 cm^{-1} as β-sheets structures. The frequency range of 1550–1520 cm^{-1} is due to Amide II with α-helical structure between 1550–1540 cm^{-1} and β-sheets at 1525–1520 cm^{-1}. The Amide II vibration is caused by deformation of the N–H bonds. Fischer, Cao, Cox, and Francis (2005) and Lagant, Vergoten, Loucheux-Lefebvre, and Fleury (1983) attributed 1500–1200 cm^{-1} to CH_2 deformation. It is known that this region contains vibrations corresponding to groups present in fatty acids, proteins, polysaccharides and phosphate derivatives.

Table 1
General description of gelatin samples employed in this study.

Gelatin type	Company name	Batch no.	Gelatine type	Bloom value
Gelatin bovine skin	Sigma	115K0144	Type B	~225
Gelatin bovine skin	Sigma	047K0005	Type B	~225
Gelatin bovine skin	Sigma	126K0053	Type B	~225
Gelatin porcine skin	Sigma	087K0125	Cell culture tested	–[a]
Gelatin porcine skin	Sigma	084K0211	Cell culture tested	–[a]
Gelatin porcine skin	Sigma	047K00061	Cell culture tested	–[a]
Gelatin powder (bovine)	Merck	K37294478719	Type B	80–120
Gelatin sheet (porcine)	Merck	K35519572612	Type A	160–240

[a] Not stated.

Table 2
Performance index (PI) and principal component spectra diagnostic of the analysis region contribution.

Day	Performance index	PC1	PC2
1	91.6	94.81	99.56
2	91.2	90.28	99.24
3	89.9	98.93	99.33
Mean ± SD	90.9 ± 0.89		

PC1 – Principal component 1.
PC2 – Principal component 2.

The FTIR spectra obtained from porcine and bovine gelatin show wide and overlapping absorption bands since it covers multitude of functional groups that contain more information than that offered by all the chemical components considered individually. As illustrated in Fig. 2, samples with different concentration of gelatin showed different spectra and all of them follow the correct sequences according to the concentrations. The spectrum showed the sensitivity of FTIR and its capability of discriminating between sample concentrations.

3.2. Discriminant analysis and characterisation of FTIR spectrum of standard gelatin

A multivariate DA based on criterion groups formed by cluster analysis was performed to determine the extent to which the groups were separated by the cluster solution (Duckworth, 1998). It can be performed as follow-up procedure where the results can be used as the predictor to form the groups in the cluster phase.

Even though both porcine and bovine gelatins have a very similar spectrum to each other, the discrimination was made by focusing on protein and polypeptides since these are the main components which in turn determine its function in food systems. Infrared spectra of these are affected by coupling of the vibrations of neighbouring peptide groups (Brauner, Dugan, & Mendelsohn 2000; Brauner, Flach, & Mendelsohn 2005; Krimm & Bandekar 1986). The maximum differences among gelatins spectra were found in two main windows (3290–3280 cm^{-1} and 1660–1200 cm^{-1}) of the complete spectral range. These window were specified through analysis using differences of variance between spectrum of bovine gelatin and porcine gelatin (Fig. 3).

Principal component analysis (PCA) was performed using TQ Analyst software to find out spectral features that had significant influence on spectral variance. Table 2 showed performance index (PI) and principal component spectra diagnostic of the analysis region contribution. The PI signifies how well the calibrated method can classify the validation standards where the higher value of PI indicates the closer of standard to its class. For the three different days of analysis, the average of PI values is 90.9 ± 0.89, showing the ability of this method to produce good repeatability results. The

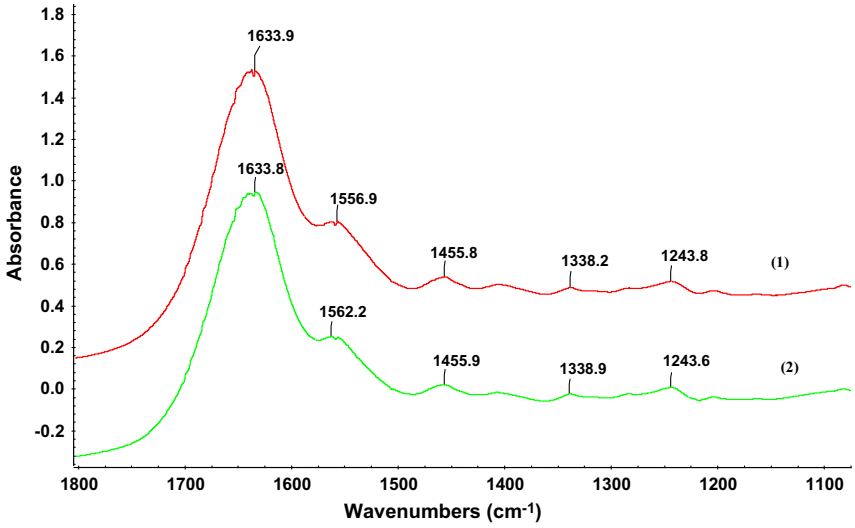

Fig. 4. Component peak location FTIR for average of three spectra of bovine gelatins (1) and average of three spectra of porcine gelatins (2).

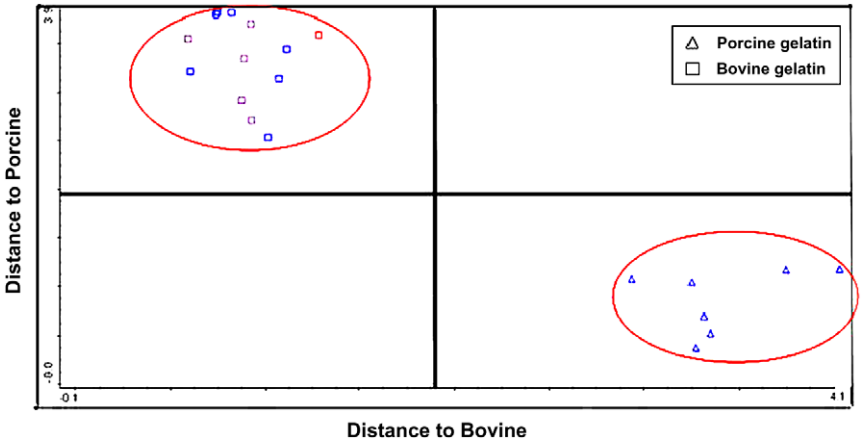

Fig. 5. Cooman's plot for two classes of gelatin: porcine gelatin and bovine gelatin.

principal component spectra diagnostic elaborate more on the spectral information in a calibration set which is determined by the principal component. It also described the amount of total spectra variation for each principal component.

Muyonga et al. (2004) have shown that the secondary structure of gelatin can be analysed at absorption band between 1600 and 1700 cm^{-1}. However, the spectra of both porcine and bovine gelatin samples were found to be indistinguishable when analysed at a resolution of 2 cm^{-1} (Fig. 4). However, when the comparison was done based on the intensity of the spectra, a slight difference was obtained to enable the results to be clustered using the discriminant analysis technique.

Infrared spectra of all sample of gelatins were used to perform the discriminant analysis using TQ Analyst software. The results obtained from discriminant analysis is best visualise using Cooman's plot that were obtained using Mahalanobis distance value of the FTIR spectrum of standard bovine and porcine gelatin (Pettersen, Svartengren, & Lundstedt, 1998). The axes are the distance to the models and the coordinates are calculated OMNIC distance (sample standard deviation). The distances to the principal component models for the porcine gelatins and bovine gelatins are plotted in Fig. 5. Both samples were successfully classified according to their respective group.

4. Conclusion

The FTIR spectroscopic techniques can be used for rapid classification of gelatin. In order to determine unknown gelatin sources, the deformation of N–H bonds found in the range 3290–3280 cm^{-1} and 1660–1200 cm^{-1} were analysed using discriminant analysis. These regions were found to give information about the origin of the gelatin. Cooman's plot proved to be useful for visualising the discriminant analysis approach for the classification. This qualitative method may provide a rapid determination of gelatin source for application in food, pharmaceutical and photographic applications. Two independent PCA models were calculated defining two separate classes of samples. A future use of such a qualitative approach may be established by the food industry as well as second derivative study of FTIR spectrum can be done to alleviate any doubts about the gelatin source as to whether it is porcine or bovine.

Acknowledgements

We would like to thank the Ministry of Science, Technology and Innovation Malaysia (MOSTI) for funding this study (Science Fund No. 05-01-04-SF0625 awarded to Prof. Dr. Yaakob B. Che Man).

natural flavours, while maintaining inhibition of bacterial and enzymatic degradation. Mild heat treatment would be sufficient enough to destroy vegetative microorganisms, removing that requirement from the irradiation process, without strongly impacting flavour. The application of irradiation was hypothesised to offer other benefits, such as improved texture, additional protection from spore-forming organisms, and better retained nutrients.

Minimal literature reports exist on irradiation of juices. Papaya juice has been shown to quench hydroxyl free radicals formed during exposure to gamma rays (Gray & Mower, 1991). Glucose, fructose and sucrose were found to primarily absorb the rays, with malonaldehyde and other sugar derivatives being formed. Niemand, den Drijver, Pretorius, Holzapfel, and van der Linde (1983) reported that irradiation of sugar solutions resulted in mutagenic compounds; these mutagenic compounds did not form in irradiated mango juice. Organic acids and phenols contributed to 85% of the protective effect. These results would likely apply to papaya as well, since the sugar, organic acid and phenol contents are similar (Luximon-Ramma et al., 2003). A WHO Technical Report (1997) also concluded there were no safety concerns with high (>10 kGy) doses of irradiation.

In designing a process for preparing papaya pulp, pasteurisation was first explored (Brekke, Chan, & Cavaletto, 1973). However, cooked flavour development in papaya occurs to a much greater degree than in other pasteurised fruit products (Argaiz & Lopez-Malo, 1995). As a result, products have been developed that mix papaya with other components in an effort to minimise off-flavours produced from papaya heat treatment (Mostafa, Abd El Hady, & Askar, 1997; Tiwari, 2000). Producing a papaya beverage where the primary flavours come from papaya requires different processing approaches to avoid off-flavours produced by heat treatment. A combination of moderate irradiation and mild heat should decrease the need for flavour masking, and allow a higher percentage of the flavour to come from papaya.

The purpose of this research was to evaluate irradiation and mild heat treatment together as a viable alternative to heat treatment alone. Also, the aim was to minimise required processing as much as possible to maximise nutrient retention. It was hypothesised that a combination treatment using both irradiation and mild heat would result in a safe product that retained flavour and a nutritional profile more similar to fresh papaya than pasteurised pulp. This would make possible a wider acceptability of a fruit pulp with superior nutrient density.

2. Materials and methods

2.1. Materials

Carica papaya L. var.'s *Rainbow* and *SunUp* were donated by the Hawaiian Papaya Industry Association and the Hawaii Department of Agriculture. They were harvested when approximately 25% yellow and vapour-heat treated to eliminate fruit fly infestation (by heating to 47 °C over at least 4 h at 90% humidity, then cooling for 1 h) in Hawaii before shipment (second day air). Fruit were stored at 23 °C for 3–5 days until at least 80% yellow before pulping.

Escherichia coli K12 was provided by Dr. Scott Martin from the University of Illinois and cultured in Luria-Bertani (LB) broth. *Listeria innocua* (ATCC, Manassas, VA) was received freeze-dried and cultured in Brain Heart Infusion medium (Fisher Scientific, Fairlawn, NJ). *Salmonella typhimurium* (Carolina Biological Supply, Burlington, NC) was received in MicroKwik nutrient agar and cultured in LB broth. *Clostridium sporogenes* (Carolina Biological Supply) was received in thioglycollate medium in a MicroKwik vial and cultured using reinforced Clostridium medium (Fisher Scientific). AAPH (2,2′-azobis(2-amidino-propane)dihydrochloride) was obtained from Wako Chemical (Richmond, VA). Trolox, ascorbic acid, ferrous sulphate and EDTA were purchased from Fisher Scientific. Fluorescein, α-(4-pyridyl-1-oxide)-*N*-*tert*-butylnitrone (POBN), quercetin and pectin were acquired from Sigma Chemical (St. Louis, MO).

2.2. Sample preparation

Papaya was divided into sets (5 fruit per set) which were washed, dried, halved, and the seeds were removed. The pulp was transferred into a KitchenAid K5SS with a pulper attachment (Hobart Corporation, Troy, OH) and collected. Brix was measured using a Westover Scientific (Mill Creek, WA) RHB-32ATC hand held refractometer and papaya pulp was diluted with double distilled H_2O (ddH_2O) to 8 °Brix. Diluted pulp was separated into glass containers labelled for the following treatments and frozen (−20 °C): control (C), heated to 80 °C for 5 min (H), 5 kGy irradiation (5), 7.5 kGy (7.5), 5 kGy + heat (5H), 7.5 kGy + heat (7.5H). Samples were irradiated in triplicate while frozen in a Gammacell 220 Excel with a cobalt-60 source (MDS Nordion, Ottawa, ON, Canada). Combination treatments were irradiated prior to heat treatment.

2.3. Titratable acidity

Titratable acidity was performed according to a modified AOAC (2002, chapter 11) method, conducted as follows: the pH of 5 g diluted papaya was measured after addition of 125 ml ddH_2O. This solution was quickly titrated with 0.02 N NaOH to reach a final pH 8.2. The volume of NaOH consumed was used to calculate citric acid equivalents.

2.4. Viscometry

Freshly thawed papaya samples were centrifuged (to remove pulp) and transferred onto the Advanced Rheometric Expansion System Rheometric Fluid Spectrometer III (ARES RFS III) with an attached SR5 Peltier Circulator (TA Instruments, New Castle, DE). It was connected to TA Orchestrator Software Version 8.03 (TA Instruments) with the gap set at 0.5 mm and a temperature of 5 °C. Treatment samples were run in triplicate and ddH_2O was used as a standard for calibration. Values are reported as shear rate/shear stress (s^{-1} Pa^{-1}).

2.5. Colourimetry

Papaya samples were poured into a glass container, placed on the reading area of the HunterLab LabScan II 0/45 (Hunter Associates Laboratory Inc., Reston, VA), and covered. Measurements were analysed with HunterLab Universal Software™ Version 3.8. After automatic standardisation, samples were analysed in triplicate. Each treatment was compared to the control with respect to differences in L, a, b, and ΔE values.

2.6. Microbiology

Four non-pathogenic or opportunistic organisms were selected to represent a variety of potential contaminating organisms (Busta et al., 2003). Frozen *E. coli* K12 cultures were thawed and added to LB media. Cultures were incubated (24 h, 37 °C) with rotation. Thawed *Rainbow* and *SunUp* papaya pulp samples were spiked with sufficient *E. coli* K12 culture to result in 10^{10} CFU of *E. coli* added per container. Inoculated papaya pulp was frozen overnight and treated the following day, after which inoculated papaya was plated on LB plates in duplicate. The plates were then incubated (24 h, 37 °C). Observations for *S. typhimurium* were conducted in

a similar fashion. Growth and bacterial counts were verified before papaya spiking began. *L. innocua* was prepared in a similar fashion to *E. coli* with the following exceptions: it was cultured in and grown on Brain Heart Infusion broth and plates, respectively. *C. sporogenes* starter culture was added to reinforced Clostridial media in a Type A Anaerobic Chamber 7000000 (Coy Laboratory Products Inc.; Grass Lake, MI) maintained at 37 °C with a gas mixture of 5% carbon dioxide, 5% hydrogen, and nitrogen to balance and incubated (24 h). Inoculation and plating for *C. sporogenes* spiked papaya was conducted similar to *E. coli* K12, except for the use of Clostridial media plates and incubation (24 h, 37 °C) in the anaerobic chamber. After incubation of duplicate plates for all four organisms, colonies were counted. Values are reported as number of colonies per 1.0 ml diluted (8 °Brix) papaya pulp plus spike.

2.7. Pectinesterase (PE) activity

Pectinesterase activity was determined by the method of Kertesz (1955), with minor alterations. A 1% pectin solution was adjusted to pH 7.5, found to be optimal by Chang, Morita, and Yamamoto (1965) and maintained at 30 °C. Diluted papaya and 1.7 M NaCl were mixed and vortexed for 30 s. The optimum NaCl concentration of 0.2 M (Chang et al., 1965; Lourenco & Catutani, 1984) was achieved upon addition of the papaya/NaCl solution to the 1% pectin solution. The pH was readjusted with 0.02 N NaOH to 7.5 before beginning the trial. For 7 min, the pH was maintained at 7.5 with titration of 0.02 N NaOH. Trials were performed in triplicate for each treatment. The baseline for methyl de-esterification of pectin was determined in the absence of papaya, under the same conditions as above and subtracted from all trials. One unit of pectinesterase activity (PEU) is expressed as mmol NaOH consumed per min per g fresh undiluted papaya.

2.8. Consistometry

Papaya pulp samples were placed in the closed reservoir of a level Bostwick Consistometer (Fairfax, VA). Trials (30 s) began once the gate was released allowing treatments to flow. The minimum and maximum flow was recorded and averaged. Remaining puree in the weighing boats was subtracted from the initial weight to determine actual treatment weight. Pulp samples in the consistometer were returned to their containers and stored in the refrigerator. Measurements were continued daily or every other day over a 10-day period or until the sample had gelled such that it flowed 6 cm or less (*Rainbow* variety) or 4 cm or less (*SunUp* variety).

2.9. High performance liquid chromatography (HPLC)

2.9.1. Phenolics extraction

Papaya samples were weighed into 15 ml plastic tubes and centrifuged (17,000*g*, 1 min). The supernatant was collected in a round bottom flask. Pulp extractions began with the addition of 5 ml 100% warm MeOH (~40 °C), vortexing (30 s), sonication (2 min, 40 °C), and centrifugation (17,000*g*, 1 min). The supernatant was added to the round bottom flask and the extraction was repeated three times. Combined extracts were dried (37 °C) in a Brinkmann Büchi RE 111 Rotavapor (New Castle, DE). Dried extracts were reconstituted with warm MeOH and continuous mild heat to ensure complete extraction. The supernatant was placed in a test tube, followed by additional extractions until the dried extract was pale yellow. The MeOH extracts were dried continuously under N_2 at 37 °C to 1 ml. The resulting volume was centrifuged (17,000*g*, 5 min) and the supernatant was poured into a new tube. One last extraction (as above) was performed on the pulp remaining in the tube using warm MeOH. After drying to 1 ml, the extract was filtered (0.45 μm) and injected onto the HPLC. Quercetin was added to the original pulp to monitor phenolic recovery using this extraction protocol.

2.9.2. HPLC phenolic measurements

A Waters Corp. 2695 separations module and autosampler (Millford, MA) and Hewlett Packard 1050 diode array detector model G1306A (Agilent Technologies Inc., Santa Clara, CA) was used with simultaneous detection at 260, 280, 320 and 360 nm using Chemstation software (Agilent Technologies, Palo Alto, CA). Absorption spectra were recorded from 190 to 600 nm for all peaks. Peak separation was accomplished with a Waters Xterra RP18 (5 μm) 3.1 × 150 mm column preceded by a guard column containing Sepralyte C18 (10 μm, Analytichem Intl., Harbor City, CA). Solvent A consisted of 0.1% H_3PO_4 in ddH_2O and solvent B was 0.1% H_3PO_4 in 95% acetonitrile. At a flow rate of 1 ml/min, the elution program followed a linear gradient from 0% B to 50% B in 20 min, from 50% back to 40% in 0.1 min, holding at 40% for 10 min, from 40% to 95% in 15 min, from 95% to 0% in 3 min, and holding 10 min (Franke, Custer, Arakaki, & Murphy, 2004). Treatment peak areas were calculated from a quercetin standard curve. Samples were analysed in triplicate.

2.9.3. Ascorbic acid extraction

Extraction was performed according to Lee and Coates (1999). Papaya pulp samples were diluted to 1 ml with dithiothreitol (DTT) (4.2 mM in 0.1 M K_2HPO_4, pH 7.0) and vortexed. An aliquot of this mixture was added to freshly prepared 4.5% *m*-phosphoric acid (*m*-PA) in a new tube. Treatments were mixed, spin filtered (0.45 μm), and injected onto the HPLC column.

2.9.4. HPLC-ascorbic acid measurements

A Waters Xterra column and guard column were used as above. Solvent A consisted of 0.1% H_3PO_4 in ddH_2O and solvent B was 100% methanol. At a flow rate of 0.8 ml/min, the elution program followed a linear gradient from 0% to 30% B over 8 min, back to 0% B in 3 min and held for 6 min. Peak detection was at 240 nm. An external ascorbic acid standard curve with three different concentrations was used to quantify the results. The ascorbic acid standard was also treated with DTT and *m*-PA solutions. Samples were analysed in triplicate.

2.10. Electron paramagnetic resonance (EPR)

2.10.1. Extraction of papaya samples

Frozen papaya pulp samples were thawed at RT. Samples (1 g) were carefully weighed into Eppendorf tubes and centrifuged in a tabletop microfuge (max speed, 1 min). The supernatant was transferred to 2 ml vials. The papaya pellet was resuspended by addition of 500 μl 100% MeOH and vortexing; the suspension was sonicated (2 min with intermittent shaking) and centrifuged (max speed, 1 min). The resulting supernatant was added to the 2 ml vial to complete the first extraction. The above MeOH extraction was repeated with a final centrifugation of 2 min. Combined supernatants were centrifuged (max speed, 1 min) a final time to remove residual pulp. Remaining papaya pulp from the original 2 ml freezer vials was also centrifuged (max speed, 2 min) and the resulting supernatant was used as a water extract.

2.10.2. EPR

The EPR protocol and solution preparation was performed according to Falchi et al. (2006). A quartz flat cell (SP Industries Inc., Wilmad-LabGlass, Buena, NJ) was used. Scans began 3 min after the addition of H_2O_2. Spectra were recorded at X-band (~9.5 GHz) on a Varian E-122 spectrometer with a TE102 cavity (Palo Alto, CA). Other parameters: frequency, ~9.51 GHz; field centre, 3390; gain, 3200; number of scans, 5; scan range, 80; scan

time, 30 s; 2 s between each scan; modulation amplitude, 1; time constant, 0.032 s; and power, 20 mW (10 db). Fenton controls were subtracted from control and treated papaya samples and the values adjusted to a scale that placed the control papaya at a value of 100 arbitrary units. Samples were run in triplicate.

2.11. Oxygen radical absorbance capacity (ORAC)

2.11.1. Fruit extractions

Extractions followed the procedure of Wu et al. (2004), with minor adjustments: papaya samples (1 g) were added to 15 ml Corning polypropylene tubes (Corning Inc., Corning, NY). Extractions began with the addition of 10 ml 70:29.5:0.5 acetone:water:acetic acid (AWA) to papaya samples followed by the Wu et al. (2004) extraction method. The extract was then further diluted (1:5) with AWA to fit the Trolox standard curve used in the assay.

2.11.2. $ORAC_{FL}$ analysis

$ORAC_{FL}$ assays were conducted according to Davalos, Gomez-Cordoves, and Bartolome (2004) in a preheated (37 °C) BioTek FLx600 fluorometer (BioTek Instruments Inc., Winooski, VT) using 96-well black side with clear bottom plates (Corning Inc., Corning, NY). Data were collected using KC4 software (BioTek Instruments Inc.). Parameters: emission wavelength, 515 nm (530/25); excitation wavelength, 493 nm (485/15); reading every minute for 80 min with shaking for 3 s at intensity 3 before each reading. Reagent concentrations and plate organisation were as described in Davalos et al. (2004).

2.12. Statistics

Data were compiled using Microsoft Excel (Microsoft Corporation, Redmond, WA). Treatments were compared within each variety as well as among varieties using analysis of variance (Tukey's HSD, $p < 0.05$, SAS statistical software, SAS Institute Inc., Cary, NC). The Tukey adjustment was utilised to control experiment wise errors across papaya varieties. Consistometry was measured using analysis of variance repeated measures ($p < 0.05$).

3. Results and discussion

3.1. Processing conditions

It was the goal of this study to produce a shelf stable processed pulp-based papaya beverage, similar in consistency to tomato juice (a drinkable, commercially available pulp-containing nectar), while maintaining product quality, nutritional value and flavour. If irradiation alone were to be used to create a shelf-stable pulp, this would require 48 kGy to guarantee destruction of *C. botulinum* (WHO Technical Report, 1997). This high dosage would be cost prohibitive and unfeasible due to the extremely long process required. Less than 10 kGy is sufficient to destroy vegetative cells, depending on the food product being examined; this would however require refrigeration of the product to account for *C. botulinum* risk. No guidelines have yet been issued for irradiation of the pulp or juice of papaya.

In addition to microbiological concerns, papaya processing would also have to address inactivation of the enzyme pectin methylesterase (PE, further discussed below), which causes papaya pulp to gel (Chang et al., 1973). Fresh (non-processed) diluted pulp was demonstrated to undergo rapid gel formation (within 1–2 days) as indicated by consistometry (Figs. 1 and 2) and visual observation. Thus, it was necessary to modify processing to include enzymatic inactivation. Doses of irradiation up to 7.5 kGy applied

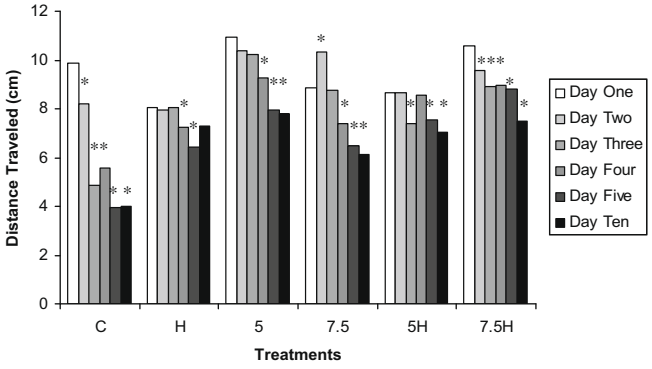

Fig. 1. Consistency of *Rainbow* papaya over 10 days. Each bar represents the distance the papaya sample travelled in the consistometer. *Significant at 0.05 level compared to day 1 for each sample using repeated measures analysis of variance. C, control; H, heat (80 °C, 5 min); 5, 5 kGy; 7.5, 7.5 kGy; 5H, 5 kGy + heat; and 7.5H, 7.5 kGy + heat ($n = 3$).

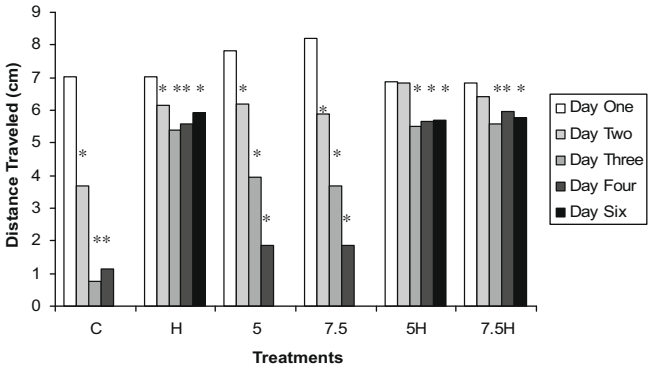

Fig. 2. Consistency of *SunUp* papaya over 6 days. Each bar represents the distance the papaya sample travelled in the consistometer. *Significant at 0.05 level compared to day 1 for each sample using repeated measures analysis of variance. C, control; H, heat (80 °C, 5 min); 5, 5 kGy; 7.5, 7.5 kGy; 5H, 5 kGy + heat; and 7.5H, 7.5 kGy + heat ($n = 3$).

in this study did not affect PE activity (Fig. 3). Though we did not test PE activity on samples irradiated at higher doses, others have demonstrated that up to 48 kGy did not have a significant impact on elimination of destructive enzyme activity (Wilkinson & Gould, 1996). This necessitated the use of mild heat treatment to reduce PE activity to acceptable levels.

Preliminary indications of aroma and flavour of the irradiated product indicated that favourable flavour and aroma could be obtained with irradiation dosages between 5 and 15 kGy. Although 10 and 15 kGy were preferred by a few tasters during informal

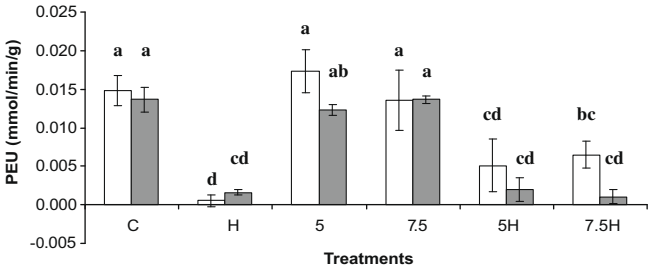

Fig. 3. Pectinesterase activity units (PEU) of *Rainbow* (white bars) and *SunUp* (grey bars) papaya. Values are reported as mean ± SD. Bars not sharing the same lowercase letter are significantly different ($p < 0.05$). C, control; H, heat (80 °C, 5 min); 5, 5 kGy; 7.5, 7.5 kGy; 5H, 5 kGy + heat; and 7.5H, 7.5 kGy + heat ($n = 3$).

testing (~8 students and faculty in the laboratory evaluated 5, 7.5, 10 and 15 kGy papaya treatments), the longer time required for irradiation and potential cost were problematic. Thus, 5 and 7.5 kGy were selected. More than one dose was included to quantify the independent effects on microbiological organisms, particularly in combination with heat, as well as any differences in impact on nutrient content.

Heat treatment temperature and time were chosen based on the work of Magalhães, Tosello, and de Massaguer (1996). Our results were within the ranges of residual pectin methylesterase activities found by Castaldo et al. (1997) in thermally processed fruit preparations. When administered before heat treatment, both selected doses resulted in a greater destruction of *C. sporogenes* (see Section 3.6 below) and improved flavour and texture compared to heat followed by irradiation. The pulp texture was smoother, with fewer clumps.

3.2. pH and °Brix

For *Rainbow* variety samples, the pH of heat treatment alone was the only value significantly higher than the control (Table 1). The pH was not significantly different than the control for any treatments applied to the *SunUp* variety samples, nor were the pH values significantly different from each other across varieties. Others have reported various varieties of papaya to have a pH between 4.9 and 5.1 (Ahmed & Ramaswamy, 2004; Brekke et al., 1973; Penteado & Leitão, 2004). Significant changes from control values were noted in °Brix for the 5H treatment for *Rainbow* papaya; Brix did not change for the *SunUp* variety (Table 1). Across varieties, only the 5H treatments were significantly different from one another. By informal testing it was noted that all irradiated samples tasted sweeter than control samples. Preliminary sugar compositional analysis of our treatments resulted in no significant change in carbohydrates (data not shown, Hawaiian Agricultural Research Center, Oahu, HI). Thus, perceived changes in sweetness were likely due to changes in other components, such as flavour compounds, which can mask sweetness levels (Bakker, 1995). These flavour components may change during food processing and thus change sweetness perception.

3.3. Titratable acidity

Titratable acidity was conducted to quantify the amount of citric acid, the most predominant organic acid, within each variety of papaya (Table 1). Within each papaya variety there were no significant differences between the control and any of the five treatments. However, there were significant differences between *Rainbow* and *SunUp* varieties between controls and 5H samples. This is likely due to varietal differences.

3.4. Viscometry

The juices of each treatment (pulp removed) were analysed for viscosity compared to the control within that variety (Table 1). For the *Rainbow* papaya samples, all treatments were significantly different from the control, but not from each other. For the *SunUp* papaya samples, there were no significant differences from the control, though 5H was significantly less viscous than 7.5. It is unclear how the latter should be interpreted. Though controls were not significantly different from one another across varieties, many of the other treatments were. It was hypothesised that differences may be due to different varietal responses to treatments. The results may also help explain why the *SunUp* papaya was thicker in general (see consistometry results below). We chose to measure the viscometry of the fluid portion of the papaya pulp to determine if our processing conditions would result in any immediate effects

Table 1
Effects of papaya variety and treatment on pH, °Brix, viscometry, and titratable acidity.[A]

C, control; H, heat (80 °C, 5 min); 5, 5 kGy; 7.5, 7.5 kGy; 5H, 5 kGy + heat; and 7.5H, 7.5 kGy + heat (n = 3).

[A] Values not sharing the same letter within each row are significantly different ($p < 0.05$) and are reported as mean ± SD.

[B] Values are reported as shear/stress (s^{-1} Pa^{-1}).

[C] Values are reported as g/100 ml citric acid.

on the viscosity of the juice. Consistometry measurements would determine thickening of the entire pulp, thus allowing us to separate where changes, if any, were occurring. If we observed an increased viscosity, further dilution might be necessary, as consumer preference decreases for a product that is more viscous than expected (Grigelmo-Miguel & Martín-Belloso, 1999). All significant changes that occurred after our treatments resulted in a less viscous juice.

Comparison of an untreated fresh sample of *SunUp* papaya to a frozen (then thawed) untreated *SunUp* papaya sample indicated no significant viscosity differences between fresh and frozen samples (data for fresh samples found in Table 1; frozen data not shown). This supported the decision to freeze samples rather than add citric acid to avoid gelation. Tomato juice was compared to the *Rainbow* papaya control sample, as our papaya samples were diluted to the same °Brix as tomato juice (~8% dissolved solids). Papaya juice is significantly more viscous than tomato juice ($p < 0.05$, data not shown). This suggests that °Brix is not the only contributor to viscosity in papaya.

3.5. Colourimetry

In *Rainbow* papaya samples the only significant colour differences from the control were localised to '*a*' values, losing some of its redness when heated with or without irradiation (H, 5H, and 7.5H; Table 2). Significant changes in the '*a*' values resulted in a significant change in the overall ΔE values as well. For *SunUp* papaya, significant differences from the control were also found only in the '*a*' measurements. However, values were only significantly less red for H and 7.5H. Surprisingly, 7.5 was significantly more red than the control. None of the ΔE values were significantly different from the control for this variety. These results suggest that, in *SunUp* samples, heat resulted in loss of red colour while irradiation resulted in enhanced red colour. Overall, the two treatments work in opposition, resulting, for the *SunUp* variety, in combination treatments having a colour similar to that of the control. The same did not seem to occur, at least not significantly, in the *Rainbow* variety. *SunUp* papaya gets its red colour from lycopene, a carotenoid not produced in *Rainbow* papaya. This gives *SunUp* papaya an increased overall carotenoid content (Yamamoto, 1964) and its distinct red colour. Carotenoids are easily destroyed by heat (Beyers & Thomas, 1979) but have the ability to absorb high energy radicals, such as singlet oxygen (Lee, Koo, & Min, 2004). Heat resulted in a loss of red colour, and thus carotenoids, in both varieties of papaya. Irradiation may have changed the structure or ratios of the carotenoids, and thus the apparent colour, depending on their concentrations and/or ability to absorb free radicals produced during irradiation. In a side-by-side comparison of papaya pulp, the colour difference between control and heat treated *Rainbow* samples is visible, with heat treated samples having a slightly more pale yellow colour. No colour difference was visually apparent between control and treated *SunUp* papaya. The overall darker red colour likely masked the colour changes resulting from our treatments.

3.6. Microbiology

Before treatment, the final concentration of the organisms in the papaya pulp was as follows: 4.65×10^8 CFU/ml for *E. coli*; 5.58×10^8 CFU/ml for *S. typhimurium*; 5.63×10^8 CFU/ml for *L. innocua*; 4.21×10^6 CFU/ml for *C. sporogenes.* Administration of heat, whether alone or in combination with irradiation, was sufficient to eliminate all growth of *E. coli* and *S. typhimurium*. All *E. coli* was also destroyed with 7.5 kGy, while 530 CFU/ml (*Rainbow*) and 930 CFU/ml (*SunUp*) remained after 5 kGy. Neither irradiation treatment alone was sufficient to destroy *S. typhimurium* (plates were confluent or uncountable). For *L. innocua*, in *Rainbow* and

[B] L measures lightness on a scale of $L = 0$ (black) to $L = 100$ (white); a measures the degree of red (+a) or green (−a) present in a sample; b indicates the degree of yellow (+b) or blue (−b) present in the sample; and ΔE combines all three values.

SunUp papaya, respectively, 50 and 20 CFU/ml remained after heat alone, 60 and 3890 after 5 kGy, and no colonies survived after 7.5 kGy or either or the combination treatments. For *C. sporogenes*, heat alone left 370 and 710 CFU/ml, 5 and 7.5 kGy resulted in a distinguishable but uncountable number of colonies (for both varieties), 5H left 90 and 140 CFU/ml and 7.5H left 320 and 130 CFU/ml.

To completely eliminate *C. sporogenes* and *L. innocua* by heat treatment alone, higher temperatures would be necessary; however, this would lead to detrimental changes in flavour, odour, colour, and texture of papaya pulp (Argaiz & Lopez-Malo, 1995). The combination treatment of irradiation followed by heat produced a stronger elimination of all organisms tested, while minimising detrimental changes. The 5H and 7.5H treatments were effective at eliminating growth of all bacteria tested except *C. sporogenes* in both varieties of papaya. *C. sporogenes* is a resilient spore-forming bacterium that can survive harsh conditions to a greater degree than organisms that do not form spores; yet its viability was reduced to countable colonies by both combination treatments applied in this study. While this is an encouraging result, our combination treatments did not completely eliminate the spore-forming bacteria. Use of our processing method will require that the product be refrigerated to ensure it is safe for consumption. Almost no *Clostridium* species will grow at refrigeration temperatures (Hauschild, 1989).

3.7. Pectinesterase (PE) activity

PE is responsible for demethylation of methyl ester groups on the alpha-galacturonic acid residues of pectin polymers (Powell, Morris, Gidley, & Rees, 1982). This results in a greater number of carboxylic acid groups available to interact with divalent cations present in the pulp. Many of these cations will bind to adjacent pectin molecules, resulting in less fluidity and subsequent gel formation in the fresh papaya pulp. A significant reduction in PE activity (from the control) was achieved in both varieties of papaya with heat treatment, whether or not it was combined with irradiation (Fig. 3). Irradiation alone did not significantly reduce PE activity for either variety. Results were not significantly different between varieties for any of the treatments.

3.8. Consistometry

Initially, *Rainbow* papaya pulp had a longer flow distance, indicating lower viscosity, than *SunUp* papaya; however, it did not decrease as dramatically over time (Figs. 1 and 2). Irradiated *Rainbow* papaya did not gel as quickly as the *SunUp* variety despite similar PE activities. The *SunUp* irradiated samples gelled much more similarly to the control than irradiated *Rainbow* samples. For both varieties, all treatments decreased significantly from the control within a few days. It is unclear how much of this is due to enzyme activity. Since there was a reduction in the enzymatic activity of PE after heat treatment, it was expected that there would only be significant differences over time in control or irradiated samples. Though there were significant drops in flow distance for all samples, heat treated samples maintained the lowest flow distance over a number of days. Control and irradiated samples flowed shorter distances with time.

Because of the small but significant decrease in flow distance in all samples, the goal was to confirm that the change was not due to PE activity increasing with time. Some of the stable form of PE may have only been partially denatured and may have regained activity over time (Magalhães et al., 1996). A follow-up PE assay was performed after consistometry measurements were completed. PE values were very similar to the PE values obtained before the consistometry measurement began (data not shown). Thus, slight thickening of the pulp of both varieties after a few days of measurements must be due to some other factor yet to be determined.

3.9. HPLC-flavonoids

Extractions of both varieties were performed multiple times with various solvent mixtures. No flavonoids were detected after any of the extractions attempted. Even after preparation of a 10× concentrated papaya sample, no flavonoids were detected for either *Rainbow* or *SunUp* varieties. A quercetin spike was added to the method described above to confirm the quality of the extraction/concentration process (80% recovery). Other researchers (Franke et al., 2004) also reported undetectable levels of flavonoids in papaya.

3.10. HPLC-ascorbic acid

The ascorbic acid concentration significantly decreased after both doses of irradiation in the *Rainbow* variety compared to control (Fig. 4); however, combination treatments were not significantly different from the control. In the *SunUp* variety, 7.5 and combination treatments were significantly lower than the control. Comparing varieties, H, 5H, and 7.5H were significantly different from one another. This suggests that *SunUp* papaya ascorbic acid may be more susceptible to heat or that *Rainbow* papaya may not be as susceptible to it. Overall, irradiation was more detrimental to ascorbic acid than the mild heat treatment applied, and in the *Rainbow* variety, combination treatments significantly removed the negative effects of irradiation on ascorbic acid content. This may be due to decompartmentalisation of ascorbic acid in the pulp. Other researchers (Wilkinson & Gould, 1996) have found an 8–20% reduction of ascorbic acid content after irradiation at 3 kGy. For comparison, ascorbic acid loss in this study after 5 kGy was 18% in *Rainbow* papaya samples and 11% in *SunUp* papaya samples.

3.11. EPR analysis

EPR provided a unique method to evaluate papaya's response to hydroxyl radicals (Rødtjer, Skibsted, & Andersen, 2006). Two different extraction methods were employed to evaluate the antioxidant capacity of both *SunUp* and *Rainbow* papaya varieties and to determine if any differences were apparent due to extraction method (Figs. 5 and 6). There were no significant differences observed between any samples for either extraction method, though the trends were similar to the results of ascorbic acid analysis. Other researchers (Tzika, Papadimitriou, Sotiroudis, & Xenakis, 2008) have also recently applied this methodology to a number of fruit and vegetables juices.

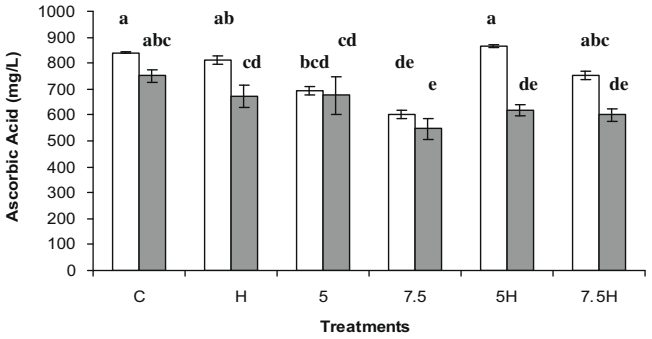

Fig. 4. Ascorbic acid content of *Rainbow* (white bars) and *SunUp* (grey bars) papaya. Values are reported as mean ± SD. Bars not sharing the same lowercase letter are significantly different ($p < 0.05$). C, control; H, heat (80 °C, 5 min); 5, 5 kGy; 7.5, 7.5 kGy; 5H, 5 kGy + heat; and 7.5H, 7.5 kGy + heat ($n = 3$).

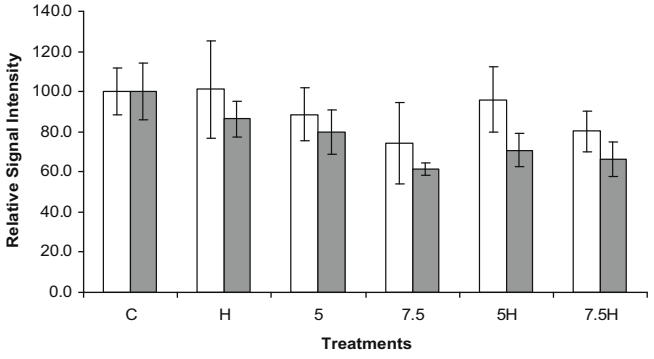

Fig. 5. EPR signal intensity of water extracts of *Rainbow* (white bars) and *SunUp* (grey bars) papaya. For ease of comparison, the average control EPR signal was adjusted to a value of 100 with other subsequent treatments shown relative to the control. Values are reported as mean ± SD. No treatments were significantly different ($p < 0.05$). C, control; H, heat (80 °C, 5 min); 5, 5 kGy; 7.5, 7.5 kGy; 5H, 5 kGy + heat; and 7.5H, 7.5 kGy + heat ($n = 3$).

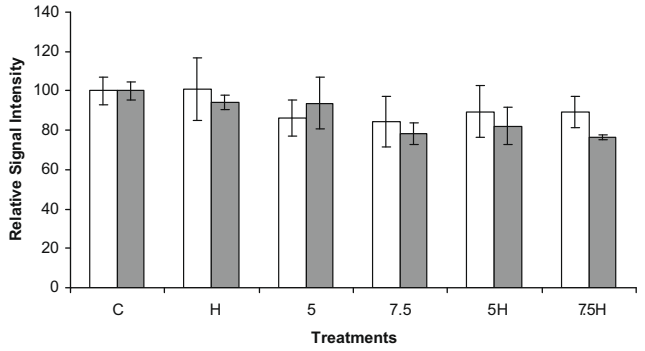

Fig. 6. EPR signal intensity of methanolic extracts of *Rainbow* (white bars) and *SunUp* (grey bars) papaya. For ease of comparison, the average control EPR signal was adjusted to a value of 100 with other subsequent treatments shown relative to the control. Values are reported as mean ± SD. No treatments were significantly different ($p < 0.05$). C, control; H, heat (80 °C, 5 min); 5, 5 kGy; 7.5, 7.5 kGy; 5H, 5 kGy + heat; and 7.5H, 7.5 kGy + heat ($n = 3$).

3.12. ORAC analysis

No significant antioxidant capacity differences were observed between controls and any treatments for either variety of papaya (Fig. 7). However, the antioxidant capacity of the 5H treatment in *Rainbow* samples was significantly higher than that of either irradiation treatment alone. There were no significant differences between the two papaya varieties for control or treated samples. Comparing these results with EPR and ascorbic acid results, it is likely that the decrease in ORAC after irradiation is primarily due to loss of ascorbic acid. Though *Rainbow* and *SunUp* papaya contain undetectable levels of flavonoids, papaya does contain phenolic compounds (total phenolics assayed by Luximon-Ramma et al. (2003); individual papaya phenolics have not been quantified). However, as no differences were seen between the water and methanol extracts in the EPR assay, either most of the phenolic compounds are water-soluble or irradiation does not have a large effect on the phenolic content. The latter is most likely, as papaya sugars have been shown to be primarily responsible for quenching gamma ray-produced radicals (Gray & Mower, 1991).

With an average ORAC value of 5 μmol TE/g (undiluted papaya), papaya has a higher ORAC value than cantaloupe or watermelon, but lower than grapes, carrots or apples (Wu et al., 2004). To our knowledge, no other researchers have explored the impact of ionising radiation on ORAC values at the doses applied in this study.

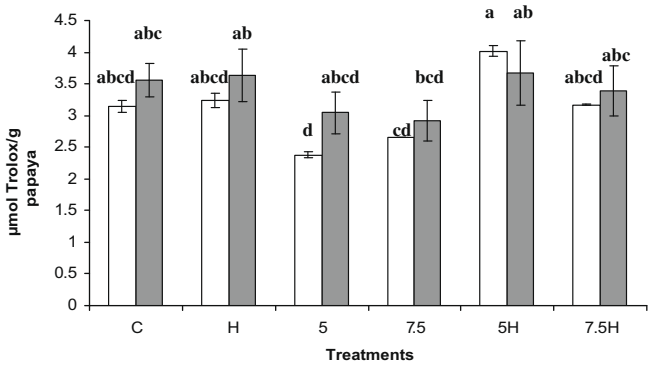

Fig. 7. ORAC values of *Rainbow* (white bars) and *SunUp* (grey bars) papaya (diluted to 8 °Brix). Values are reported as mean ± SD. Bars not sharing the same lowercase letter are significantly different ($p < 0.05$). C, control; H, heat (80 °C, 5 min); 5, 5 kGy; 7.5, 7.5 kGy; 5H, 5 kGy + heat; and 7.5H, 7.5 kGy + heat ($n = 3$).

Reyes and Cisneros-Cevallos (2007) found no change in ORAC value on whole mangoes at doses of up to 3 kGy. Due to the significant decrease in ascorbic acid after irradiation described above, it would be expected that higher doses of irradiation would result in a significant reduction of ORAC value. The trend toward a decreased ORAC value at the doses used in this study support this hypothesis. It would be of interest to explore the rate of change in ORAC value at doses of irradiation that would be expected to oxidise all of the ascorbic acid, and attempt to determine what other compounds in papaya would be subsequent targets. Niemand et al. (1983) found that phenols and organic acids accounted for most of the protection from mutagen formation in mango juice. Their contribution to ORAC value should be further explored.

A combination of moderate irradiation and mild heat resulted in a microbiologically safe (if refrigerated), enzyme inactive, and nutritionally optimised papaya pulp. Irradiation resulted in a sweeter papaya flavour, though there was no significant change in sugar profiles. Drinkable consistency is maintained for at least 10 days. Colour changed slightly in the *Rainbow* variety, though was not as important as aroma and flavour in informal tasting. Ascorbic acid was significantly reduced after irradiation in both varieties, but was similar to controls after heat treatment in the *Rainbow* variety samples. Neither EPR nor ORAC antioxidant analyses of treatments were significantly different from controls, though the results were patterned similarly to ascorbic acid results. This suggests that in diluted papaya pulp, the antioxidant primarily affected by irradiation is ascorbic acid. Challenges to the implementation of this process include the requirement for refrigeration, consumer resistance to irradiation, and potential costs of irradiation. If implemented, processed papaya pulp will retain more of its fresh flavour and nutritional qualities, increasing papaya marketability.

Support

Funding for this research was provided by a grant from the Hawaiian Farm Bureau. Papaya was provided by the Hawaiian Papaya Industry Association by arrangement through the Hawaii Department of Agriculture. Support for T. Parker and S. Esgro was provided by a Jonathan Baldwin Turner Fellowship (University of Illinois at Urbana-Champaign).

Acknowledgements

We would like to thank the following from the University of Illinois at Urbana-Champaign for use of their equipment: Dr. Stoyan Toshkov for use of the Gammacell irradiator; Dr. William Helferich

for the use of the fluorometer; Dr. Mark Nilges and the EPR centre for the use of their spectrometer; Dr. Shelly Schmidt for use of the viscometer; Dr. Keith Cadwallader and John Jerrell for use of their HPLC equipment; Dr. Susan Brewer for use of the colourimeter; and Dr. Michael Miller for use of the anaerobic chamber.

Among them synthetic peptides hippuryl-L-histidyl-L-leucine (HHL) and furanacryloyl-L-phenylalanylglycyl-glycine (FAPGG) are the most commonly used but other peptides can be used like fluorescent molecules (for example, o-aminobenzoylglycyl-p-nitrophenylalanylproline) for specific detection and quantification (Carmel & Yaron, 1978; Sentandreu & Toldra, 2006).

In most of the previous cited works, the assay used for ACE activity was based on the method developed by Cushman and Cheung (1971). The amount of hippuric acid (HA) formed from HHL by action of ACE is extracted with ethyl acetate and the concentration is determined by a spectrophotometric assay. Different modifications of this method have been reported in which the ethyl acetate extraction was replaced by a specific binding of His-Leu with 2,4,6-trinitrobenzene sulphonate (TNBS) (Matsui, Matsufuji, & Osajima, 1992) or a specific reaction of HA with benzene sulfonyl chloride (Li, Liu, Shi, & Le, 2005). Although this assay has been very useful during decades, it has some limitations such as the required extraction of the product from the reaction mixture with an organic solvent which is an additional source of error.

Another method was described by Holmquist, Bünning, and Riordan (1979) using FAPGG as substrate. This method, consisting in the measurement of the absorbance decrease due to the substrate hydrolysis by action of ACE, was adopted for testing ACE-inhibitory activity of peptides (Vermeirssen, Van Camp, & Verstraete, 2002). Different modifications were also reported with fixed time conditions (Murray, Walsh, & FitzGeralg, 2004), using 96-wells microtiter plate (Otte et al., 2007) or HPLC determination (Anzenbacherová, Anzenbacher, Macek, & Květina, 2001). Shalaby, Zakora, and Otte (2006) have compared the performance of the ACE inhibition assays using FAPGG and HHL as substrates.

Both methods showed similar performance but HHL substrate in solution seemed to be less stable than FAPGG substrate and the assay with FAPGG consumed less chemicals per sample. It was also pointed out that ACE preparation showed various activities. So, it is important to control the ACE-activity in the assays or to use the same enzyme preparation to compare the ACE-inhibitory activity of different samples.

In the present study, the objective was to determine the antihypertensive activity of a fish hydrolysate produced industrially from by-products normally discarded in the process of fish manufacture. Different methods have been tested and adapted. A HPLC method using FAPGG as substrate was finally selected and optimised. The determination of Hill coefficient allowed us to confirm the number of ACE active sites corresponding to low-molecular inhibitory peptides.

2. Materials and methods

2.1. Chemicals and reagents

Fish by-products hydrolysate was produced by ID.MER (Lorient, France). ACE (angiotensin-converting enzyme, EC 3.4.15.1) from rabbit lung, Captopril, HHL (Hippuryl-His-Leu), FAPGG (N-(3-[2-furylacryloyl)-Phe-Gly-Gly) and all other reagents were purchased from Sigma. Water and acetonitrile were HPLC grade.

2.2. Preparation of ACE working solution

Commercial angiotensin I-converting enzyme (Unit) was diluted in buffer (50 mM Tris–HCl pH 7.5 containing 0.3 M NaCl) to obtained a concentration of 100 mU/mL. Aliquots of 250 μL were then stored at −20 °C until use.

2.3. Methods

2.3.1. Determination of ACE inhibition using HHL as substrate

The method used was a HPLC method based on the assay developed by Cushman and Cheung (1971) and Wu, Aluko, & Muir (2002). The substrate HHL was dissolved (5 mM) in 0.1 M sodium-borate buffer (pH 8.3) containing 0.3 M NaCl. The assay was performed by mixing 100 μL of substrate solution with 25 μL of inhibitor solution (or borate buffer for control). After 10 min of incubation at 37 °C, 10 μL of ACE solution (100 mU/mL) were added and the sample was further incubated at 37 °C for 30 min with continuous agitation at 450 rpm. The reaction was stopped by addition of 100 μL of 1 M HCl and the solution was filtered through a 0.45-μm nylon syringe filter before being analyzed by reversed-phase HPLC.

The HPLC analysis was performed on a C18 column (150 × 3.0 mm i.d.), particle size 5 μm with a Varian chromatographic system and analytes were detected at the wavelength of λ = 228 nm. The column was eluted at a flow rate of 0.5 mL min^{-1} with a two solvents system: (A) 0.05% TFA in water and (B) 0.05% TFA in acetonitrile. The gradient consisted 5–60% B in 10 min, maintained for 2 min at 60% B, then returned to 5% B for 1 min. This was followed by isocratic elution for 4 min at 5% B.

2.3.2. Determination of ACE inhibition using FAPGG as substrate

To 125 μL of buffer (50 mM Tris–HCl pH 7.5 containing 0.3 M NaCl), 100 μL of substrate solution (2.5 μM FAPGG in the same buffer) and 50 μL of inhibitor solution were added. The reaction was started by addition of 25 μL of enzyme (100 mU/mL ACE solution) and the mixture was incubated 45 min at 37 °C in a water bath. The reaction was then stopped by addition of 200 μL of methanol and the reaction mixture was then analyzed by HPLC. ACE inhibition was determined by measuring the level of FAP with and without inhibitor, in the same conditions.

The HPLC analysis was performed on a ODS Hypersil column (250 × 4.6 mm i.d.), particle size 5 μm with a Varian chromatographic system. FAP and FAPGG were separated isocratically at room temperature with a mobile phase consisting of a mixture of 0.02 M nonylamine (adjusted to pH 2.4 with H_3PO_4) – acetonitrile (67.5:32.5 v/v). The flow rate was 1 mL min^{-1} and the injection volume was 100 μL. Analytes were detected at the wavelength of λ = 305 nm.

2.3.3. ACE inhibition measurement

The evaluation of ACE inhibition was based on the comparison between the concentration of FAP in presence or not (control sample) of an inhibitor. After injection in HPLC of the control and the assay with inhibitor, the FAP peak areas obtained in the two cases were measured (Fig. 1) and the degree of ACE inhibition (in%) was calculated according to the equation (A):

$$\text{ACE inhibition } (\%) = [1 - (A_{\text{inhibitor}}/A_{\text{control}})] \times 100 \quad \text{(A)}$$

where $A_{\text{inhibitor}}$ and A_{control} are respectively, the relative areas of the FAP peak of the assay with inhibitor and of the control sample without inhibitor.

This protocol was reproduced 15 times with the fish hydrolysate in order to be validated. The retention times were constant and the experimental error for the determination of ACE inhibition was around 3.5%.

The relation previously described supposed a linearity of UV response between the peak area and the FAPGG amount. Known rising amounts of substrate FAPGG were injected in HPLC to determine in which interval the UV response curve was linear. The results obtained showed this relationship was linear until 0.25 nmol of FAPGG but not over. Given that the amount of FAPGG injected during the ACE inhibition measurement was 0.05 nmol,

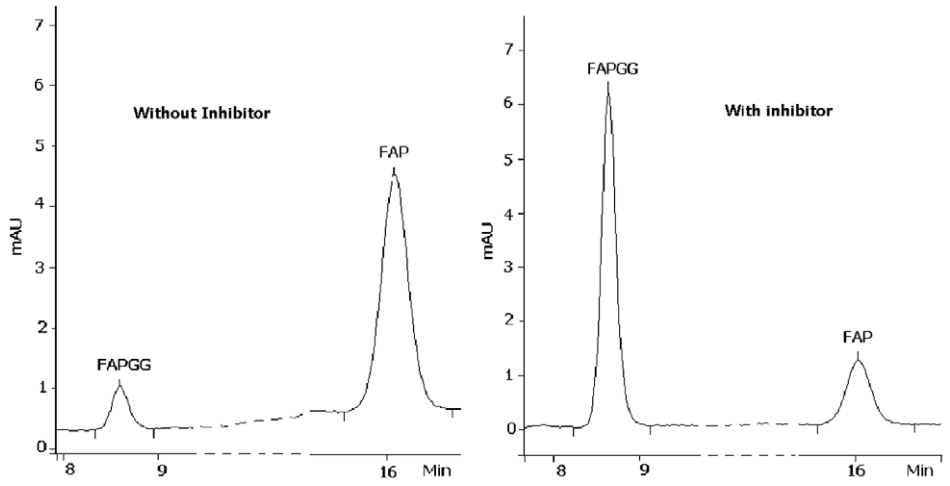

Fig. 1. HPLC profiles of the control sample without inhibitor and the assay sample with inhibitor. Retention times of the substrate FAPGG and the product formed by ACE hydrolysis (FAP) were, respectively of 8.6 and 16.1 min.

the comparison of peak areas could be used to calculate the inhibition.

2.3.4. Determination of Hill coefficient

ACE is known to possess two binding sites for low-molecular weight inhibitors. In order to know if the fish hydrolysate peptides responsible for the ACE inhibition are low-molecular peptides, the Hill coefficient corresponding to the number of binding sites was determined for the fish hydrolysate in comparison to Captopril.

The experimental data were evaluated for fitting with an equation of type Hill equation: $y = a/[1 + (b/x)^n]$, where y was the meaning of the inhibition (I), x was the inhibitor concentration (C), a was the maximum of inhibition (I_{max}), b was the inhibitor concentration corresponding to a 50% inhibition (IC_{50}) and n was the Hill coefficient corresponding to the number of the binding sites of the ACE (steepness of the curves below).

2.3.5. Optimization of the E/S ratio and the incubation time

Before measuring ACE inhibition, the best conditions for the FAPGG hydrolysis by ACE were determined. Different ratios of enzyme/substrate (E/S) were first tested with an incubation time of 30 min (0.4, 4, 8, 10 and 17.5 mU ACE/nmol substrate). Then, various incubation times were assayed using the optimum E/S ratio (15, 30, 45 and 60 min).

2.3.6. Influence of NaCl content in buffer

In the literature, the NaCl concentration in buffer currently used was 300 mM but we noticed in some cases, other concentrations (Jung et al., 2006; Matsui et al., 1992). To evaluate the influence of the NaCl content in buffer on the ACE inhibition, three different buffers were prepared with various amounts of NaCl (5 mM, 300 mM and 1 M). ACE inhibition measurement was performed as described on Section 2.3.2. using the fish hydrolysate as inhibitor. The E/S ratio was 10 mU ACE/nmol substrate and the incubation time was 45 min.

2.3.7. Determination of ACE-inhibitory activity of Captopril

Captopril, an inhibitor of ACE, was used as a reference. The degree of ACE inhibition was measured using different amounts of Captopril from 5 to 100 μL of a 5 ng/mL solution as described in the Section 2.3.1. The IC_{50} value, corresponding to the amount required to inhibit 50% of the ACE activity, was determined from the ACE inhibition curve. Five different inhibition curves were realised to evaluate the IC_{50} standard deviation.

2.3.8. Determination of ACE-inhibitory activity of a fish hydrolysate

As for Captopril, IC_{50} value and standard deviation were determined from five ACE inhibition curves obtained with different amounts of a same batch of fish hydrolysate. Other batches of the fish hydrolysate were then tested in terms of ACE inhibition to evaluate the reproducibility of the process.

2.4. Statistical analysis

The IC_{50} values were calculated from ACE inhibition curves obtained with increasing amounts of inhibitor (Captopril and the fish hydrolysate). The results for each inhibitor were expressed as the mean ± S.D. of five values obtained from five inhibition curves.

3. Results and discussion

3.1. Choice of substrate

In this work, the analyses were carried out by HPLC-UV and HHL and FAPGG were tested. The choice of the substrate was based on (i) the sensitivity (corresponding detection limits have been estimated) and (ii) the cost and more precisely the ACE amounts required for hydrolysis. The chromatographic conditions lead to a good separation of the products HHL and HA with respective retention times of 10.8 and 7.5 min. Nevertheless, the background signal is unstable and disturbs a precise quantification. The corresponding detection limit is high and insufficient for the study: 0.25 nmol of HHL are hardly detected.

FAPGG constitutes a better substrate: 0.05 nmol were easily detected. The substrate and the hydrolysed compound were separated in good conditions with a stable and low background. The retention times were 8.6 and 16.1 min for FAPGG and FAP, respectively.

Moreover, from the point of view of reactant consumption, FAPGG is excellent. With a same enzyme/substrate ratio, the degree of hydrolysis was lower with HHL (33%) while it approaches 90% with FAPGG.

3.2. E/S ratio and incubation time

The results of FAPGG hydrolysis by ACE showed it needed a great amount of enzyme to reach a hydrolysis rate of 50%. As a steady state was obtained from a E/S ratio of 10 mU/nmol, it was decided to go on with this ratio for all measurements (Fig. 2).

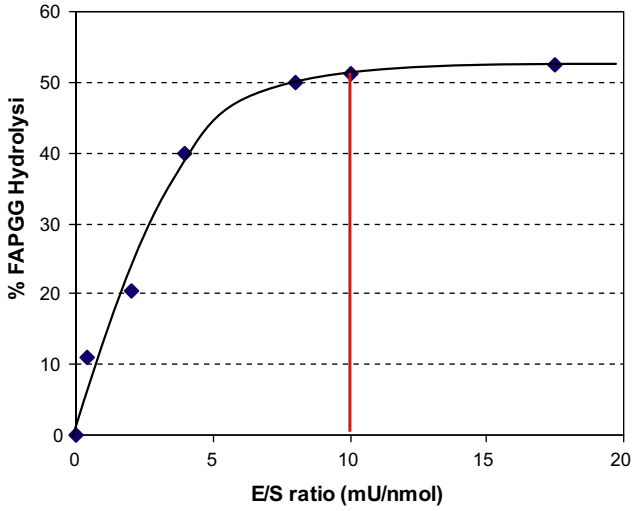

Fig. 2. FAPGG hydrolysis rate obtained with different E/S ratio after 30 min incubation at 37 °C. A steady state was reached from a E/S ratio of 10 mU/nmol.

With regard to the incubation time (Fig. 3), the different assays showed the FAPGG hydrolysis was not optimum after 30 min incubation and began to decrease after 45 min. So, the ACE inhibition measurements were carried out with an incubation time of 45 min.

3.3. Influence of NaCl content in buffer

The ACE inhibition with 5 mM NaCl was the lowest with an IC_{50} of 23.4 μg peptides. In the other hand, there were less differences between 1 M and 300 mM NaCl with IC_{50}, respectively of 15.3 μg and 12.3 μg peptides. However, the ACE inhibition was slightly higher with 300 mM NaCl and, as it was currently described in the literature, we decided to work with this concentration in buffer.

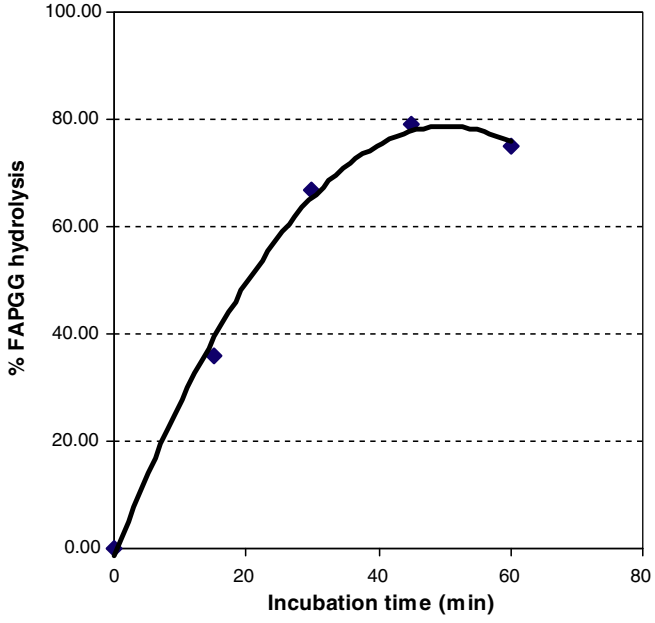

Fig. 3. FAPGG hydrolysis rate obtained with a E/S ratio of 12.5 mU/nmol after different incubation times at 37 °C. The hydrolysis reached an optimum after 45 min of incubation.

3.4. IC_{50} of Captopril

The measurement of ACE inhibition with Captopril allowed us to determine an IC_{50} value of 0.19 ng (±0.09) corresponding to a concentration of 1.75 nM. This value corresponds well with literature where a value of 1.56 nM has been reported by Vermeirssen et al. (2002).The repeated measurements showed also the high sensibility but the low stability of the Captopril solution. Indeed, we noticed a decrease of 28% of the inhibition activity after only 2 days storage at −20 °C. Captopril in aqueous solution is known to undergo oxidative degradation at its thiol function to yield Captopril-disulphide which possesses no ACE inhibiting activity. In solution in Sterile Water for Irrigation, USP, Captopril 1 mg/mL is stable only three days at 5 °C (Anaizi & Swenson, 1993). This explained the important standard deviation of the IC_{50} value (Fig. 4).

3.5. IC_{50} of fish hydrolysate

The IC_{50} value obtained with a same batch of fish hydrolysate was of 43 μg (±5) and the mean value of IC_{50} obtained with four different batches of fish hydrolysate was of 46 μg (±5) (Fig. 5).

Many studies have reported ACE inhibition activity of fish hydrolysates and the IC_{50} values were very different according to the fish species and the purity level of the hydrolysate. Crude hydrolysates showed IC_{50} values of 0.88–0.26 mg/mL (Jung et al., 2006; Matsui et al., 1993) while the value for a purified fraction by RP-HPLC was 0.013 mg/mL (Je, Park, Kwon, & Kim, 2004) and 2.4 μM or 12.2 μM for purified peptides (Fujita & Yoshikawa, 1999; Kawasaki et al., 2000).

Considering those results, our non-purified fish hydrolysate appears to be very interesting and it underlines the interest of the peptides purification and identification.

Furthermore, this fish hydrolysate shows a relatively good stability even after several months of storage at −20 °C. The results show the same standard deviation between the measurements intra- and inter-batches. So, the industrial process of the fish by-products hydrolysis showed a good repeatability and allowed to produce a standardised active product.

3.6. Determination of Hill coefficient

The values of Hill coefficient obtained for Captopril and the fish hydrolysate were about 2 (respectively 1.83 and 1.98) expressing

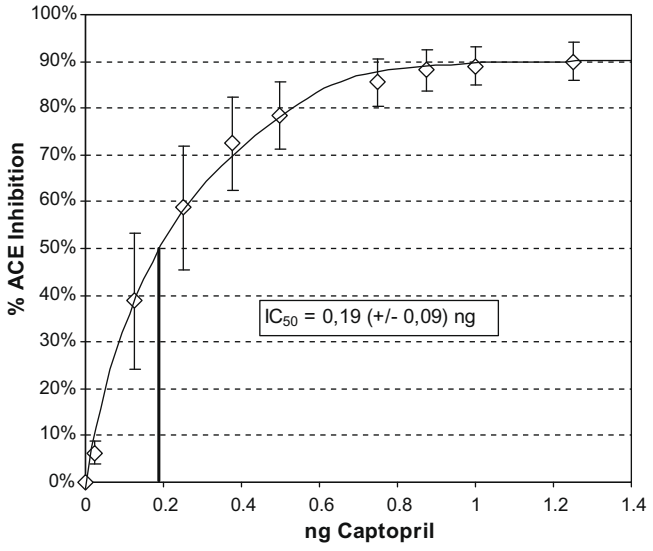

Fig. 4. ACE inhibition curve of Captopril obtained with a E/S ratio of 10 mU/nmol and an incubation time of 45 min.

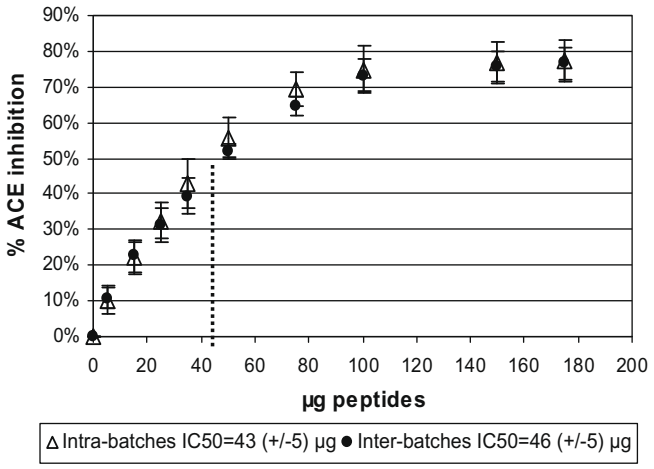

Fig. 5. ACE inhibition curve of a fish hydrolysate obtained with a E/S ratio of 10 mU/nmol and an incubation time of 45 min (intra-batches) and mean curve of ACE inhibition obtained from different fish hydrolysate batches (inter-batches).

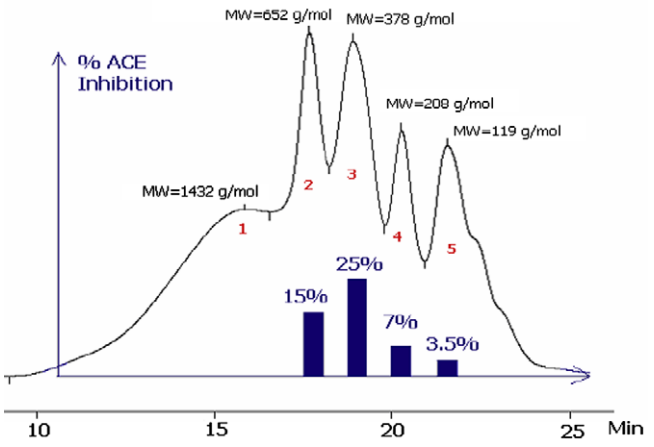

Fig. 6. Gel filtration profile of fish hydrolysate and ACE inhibition activity of the different fractions.

well the property of the ACE to possess two binding sites for low-molecular weight inhibitors. This result confirms the inhibitors present in the fish hydrolysate are low-molecular peptides. Moreover, the first results obtained on the ACE inhibition activity of the fish hydrolysate fractions isolated by gel filtration showed the most active fractions were those with molecular weights less than 600 g/mol (Fig. 6).

All those results pointed out we have to deal with peptides composed of about 2–5 amino acids.

4. Conclusion

After testing different methods for the determination of a fish hydrolysate ACE inhibition activity, we finally opted for a sensitive, extraction-free HPLC method using N-(3-[2-furylacryloyl)-Phe-Gly-Gly (FAPGG) as substrate. By varying the experimental conditions, the optimum enzyme/substrate ratio was defined as 10 mU/nmol. The incubation time was optimised at 45 min and the NaCl concentration at 300 mM.

In this way, IC_{50} values for Captopril and the fish hydrolysate were, respectively of 0.19 ng (±0.09) and 43 µg (±5). Those results allowed to underline the fish hydrolysate produced by ID. Mer had a significant ACE-inhibitory activity with a good repeatability.

The determination of the Hill coefficient and the results obtained on the gel filtration fractions tend to prove that the peptides responsible for this activity are very small molecules (2–5 amino acids). Further analyses are actually in progress to isolate and identify those peptides using different chromatographic and detection methods. The identification of those peptides constitutes the next step of this study because the knowledge of the peptides structure will allow the development of a novel functional food for preventing hypertension.

However, tannin and amino acid levels in tea vary during each manufacturing stage. Young two-leaf flushes are typically chosen for manufacturing the finest tea because theanine accumulates in growing shoots (Chu, Kobayashi, Juneja, & Yamamoto, 1997). During the withering and fermentation processes for Oolong tea and black tea, the composition of polyphenolic compounds changes significantly. Colorless epigallocatechin (EGC) derivates are oxidised, polymerised and transferred into theasinensins and reddish theaflavins in Oolong tea, and finally red-brown thearubigins in black tea (Haslam, 2003). Amino acids also increase during black tea fermentation, a result of protein hydrolysis. Furthermore, the tannin and amino acid contents in tea infusions are influenced by brewing (extraction) conditions, namely, temperature and time. Therefore, a rapid assay for both tannin and total amino acid in tea is essential for quality control, evaluation and classification in tea processing.

High-performance liquid chromatography (HPLC) (Reich et al., 2006; Ying, Ho, Chen, & Wang, 2005; Zhu et al., 2004) and capillary electrophoresis (CE) (Aucamp, Hara, & Apostolides, 2000; Chen et al., 2003; Horie & Kohata, 1998) techniques combined with ultraviolet detection, fluorescent detection and mass spectrometry are commonly utilised for analysing individual tea compounds. However, these separation-based techniques are labour- and time-consuming for quality control purposes. Near infrared reflectance (NIR) spectrometry was recently introduced as a rapid and non-destructive method for evaluating tea quality (Yan, 2005); however, the regression equations were established from a large database, and generating such a database is itself a tedious task.

Due to the requirements of simple sensing principle and equipment, photometric and fluorometric methods are widely used for assessing concentration of tannin and amino acids. These photometry techniques will be increased convenience and usability when flow-injection manifolds are also utilised in these analytical instrumentations. The Folin–Ciocalteau method, the AOAC method for tannin, is based on a redox reaction and prone to interference by reducing agents (Hagerman & Butler, 1989). An alternative method based on the complex-formation, the ferrous tartrate method, is the Japanese standard, and is not be affected by any coexisting reducing agent or ascorbate in Japanese green tea. Nevertheless, the ferrous tartrate method tends to form precipitate that is not compatible with the conventional FIA manifold (Iwasa, 1975). Recently, our research group developed a fluorometric FIA method for tannin based on the quenching effect on fluorescence of 3-aminophthalate (3-APA). The manifold is simple to assemble and the reagent utilised is both limited and eco-friendly (Chen et al., 2005).

For amino acids, chromogenic techniques, such as the ninhydrin method, are well known and extremely popular. However, for sample pretreatments, such as removing polyphenols with polyvinylpolypyrrolidone (PVPP), complicated reagent preparation and incubation procedures make pretreatments inconvenient practically for FIA system development. Although somewhat unstable in the reagent, the fluorogenic reaction of *o*-phthalaldehyde (OPA) is likely the most rapid and convenient amino acid assay (Roth, 1971). The problem in reagent stability can be overcome using a flow system.

In this study, an OPA reagent stream employed for amino acid determination was integrated with the tannin assay FIA manifold (Chen et al., 2005). Both reactions were sequentially monitored in a flow system with the same fluorometric detector fixed at the same excitation and emission wavelength (340/425 nm). The optimal analytical condition for the integrated system was determined, and was then utilised for classifying tea products with different processes. The effects of plucking position of tea leaves in tea plants, withering time and brewing method of infusions of partially fermented tea were investigated using the proposed system. Analytical results for commercial Oolong tea products and their market prices were compared.

2. Materials and methods

2.1. Chemicals and reagents

Tannic acid, *o*-phthalaldehyde and 2-mercaptoethanol were obtained from Wako (Osaka, Japan). Luminol (5-amino-2,3-dihydro-1,4-phthalazinedione), sodium bicarbonate, sodium borate and sodium hydroxide were obtained from Nacalai Tesque (Kyoto, Japan). Glutamic acid, aspartic acid and arginine were obtained from Sigma (St. Louis, MO, USA). Theanine was acquired from LKT Laboratories (St. Paul, MN, USA). All chemicals were analytical-reagent grade and used as received.

Carbonate buffers (pH 9.0–10.0) were prepared by adjusting the sodium bicarbonate aqueous solution with sodium hydroxide to a desired pH and stored at room temperature. Preparations of borax buffers (pH 11.0–12.0) were similar to those for carbonate buffers. Luminol stock solution (10 mM) was prepared by dissolving luminol powders in 0.1 M carbonate buffer (pH 10.0) and stored at 4 °C until use. Luminol reagent (0.4 mM) was prepared by diluting the stock solution with 0.1 M carbonate buffer. The OPA reagent was prepared by mixing 3 mL *o*-phthalaldehyde solution (10 mg mL^{-1} in ethanol) and 1.5 mL 2-mercaptoethanol solution (5 μL mL^{-1} in ethanol) in 100 mL carbonate buffer (0.1 M, pH 10.0). Standard tannic acid and theanine solutions were prepared and diluted prior to use. Deionised water with conductivity <1 μS cm^{-1} was used to prepare buffers and solutions.

2.2. Flow-injection manifold

The proposed system was assembled using conventional flow-injection silicon tubes (inner diameter, 1 mm), Teflon tubes and polypropylene connectors. The carrier (deionised water) and reagent (luminol reagent for tannin or OPA reagent for total amino acid content) were driven at 0.5 mL min^{-1} by a signal-controllable three-channel peristaltic pump (SMP23S, Tokyo Rika Co., Japan). A 100-μL aliquot of sample solution was injected into the carrier stream and merged with the reagent stream. After mixing in a 60-cm coiled tube (mixing coil), the resulting sample plug was delivered through a fluorometric detector (FP-1520, Jasco Co., Japan) for fluorescence monitoring (λ_{ex} = 340 nm; λ_{em} = 425 nm; slit = 10 nm). Fluorescence intensity was converted to a voltage signal and recorded using a chart pen recorder (Model 101, Cole–Parmer Co., USA). Relative outputs of fluorescence intensity were calculated by peak height.

2.3. Manufacture of tea samples from fresh tea leaves

Fresh tea leaves were harvested at the Wen-Shan Branch of the Tea Research and Extension Station, Council of Agriculture, Executive Yuan, Taiwan. Young three-leaf flushes of TTES No. 12 were plucked and dried slightly in hot air (30 °C for 20 min). Following the standard manufacturing process for Pouchong tea, the flushes were placed indoor and withered for 0–24 h. The withered flushes were then pan fired (250 °C for 5 min) and rolled. After rolling, tea-leaves were dried at 90 °C and further dried overnight at 75 °C. For comparison, fresh tea leaves of three species (TTES No. 12, TTES No. 14 and TTES No. 17) harvested with various plucking positions (the first two leaves and the bud, and leaves 3–5) were manufactured using the standard process for Pi-Lo-Chun green tea.

2.4. Preparation of extractions from dried tea leaves

Tea samples were prepared by infusing 3 g of dried tealeaves with 150 mL deionised water. Hot tea infusions were prepared

by brewing tealeaves with boiling water for 5 min. Tea extracts were filtered through standard filter paper (#1 Whatman™) and cooled to room temperature using an ice-water bath (3 min). Cold tea infusions were prepared by brewing tealeaves in water (room temperature) and then stored in a refrigerator at 4 °C. All tea samples were prepared and diluted before use.

3. Results and discussion

3.1. Dose-dependent FIA fluorescent responses

Fig. 1a shows typical response signals for determining tannic acid and theanine concentrations. The high baseline for tannin determination (left part in Fig. 1a) was from the background fluorescence of oxidised luminal, 3-aminophthalate, which was quenched by tannic acid in a dose-dependent manner ($r = 0.994$) (Chen et al., 2005) as predicted by the following modified Stern–Volmer relationship (IUPAC, 1996).

$$\frac{\Delta F}{F} = K_{SV}[Q] \quad (1)$$

where ΔF is the reduction in fluorescence intensity (peak height in the FIAgram); F is the unquenched fluorescence intensity (baseline fluorescence intensity); K_{SV} is the Stern–Volmer bimolecular quenching constant; [Q] is the quencher molecule concentration.

For amino acid determination, the luminol reagent was replaced with the non-fluorescent OPA reagent (the lowered baseline on the right in Fig. 1a). The linearity ($r = 0.999$) of the calibration curve reveals a pseudo first-order kinetics of the OPA-labelling reaction with theanine. The linear dynamic ranges for tannic acid and theanine were 50–250 and 0.1–1.0 μg mL^{-1} (CV < 5%, $n = 3$), respectively. Sample throughout was 20 samples h^{-1} in the proposed FIA system.

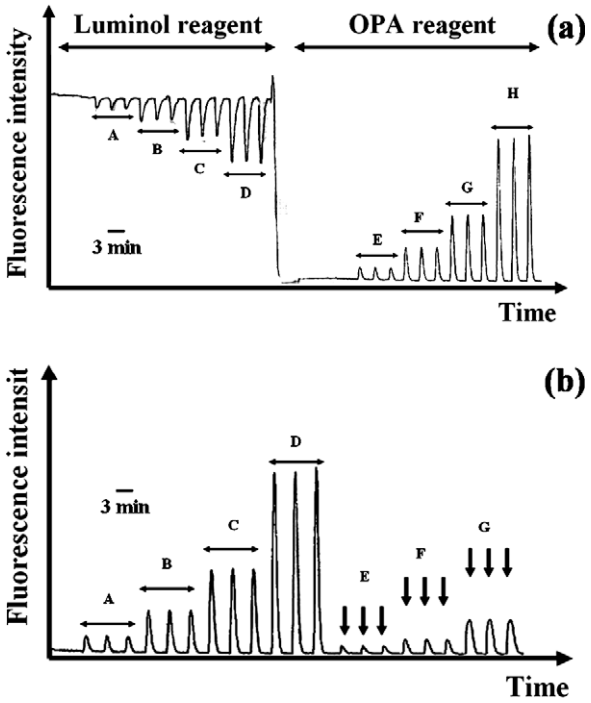

Fig. 1. (a) Dose-dependent FIAgram for calibrations of tannic acid and theanine. (A–D) Tannic acid (50, 100, 200 and 250 μg mL^{-1}). (E–H) Theanine (0.1, 0.2, 0.5 and 1 μg mL^{-1}). Luminol concentration: 0.4 mM. OPA reagent (pH 10.0): 2 mM of OPA and 1 mM of 2-mercaptoethanol. Flow rate, 0.5 mL min^{-1}. The fluorescence intensity was scaled in arbitrary unit; (b) fluorescent responses of tannic acid with OPA reagent. (A–D) Theanine (0.1, 0.2, 0.5 and 1 μg mL^{-1}). (E–G) Tannic acid (50, 100 and 500 μg mL^{-1}). OPA reagent (pH 10.0): OPA, 2 mM of OPA and 1 mM of 2-mercaptoethanol. Flow rate, 0.5 mL min^{-1}.

3.2. Cross-interference of tannin and amino acids

Concentrations of tannin and amino acids in tea infusions are generally 200–500 and 100–500 μg mL^{-1}, respectively. Significant interference occurred when tannic acid solutions of similar concentrations (50–500 μg mL^{-1}) with undiluted tea infusions were injected into the FIA system (left part in Fig. 1b). However, to determine amino acid levels in tea infusions, tea infusions diluted at minimum 100-fold should be utilised to fit the detecting range for amino acid determination. Therefore, the aforementioned interference may be negligible in practical applications.

Conversely, no fluorescence quenching effect existed even when 1000 μg mL^{-1} theanine was injected into the luminol reagent (data not shown). As this system is used in practical applications, cross-interference to both sensing subsystems will be insignificant and can be ignored.

3.3. Relative fluorescent outputs of major amino acids in tea infusions

The fluorogenic reaction of the OPA reagent with primary amines is non-specific (Roth, 1971). Other amino acids that taste sour (such as aspartic acid) or bitter (such as arginine) in tea infusions may also contribute to signal output. To evaluate the relative output from the fluorometric FIA system of major amino acids in tea leaves, treated as a percentage contribution to fluorescence by a particular amino acid in the tea leaves in the proposed OPA sensing system, the fluorescent responses of theanine, glutamic acid, aspartic acid and arginine references were initially determined using the proposed system and the OPA reagent. Fluorescent intensities of 11.8, 15.2, 16.1 and 12.7 mV were measured for 0.5 μg mL^{-1} of theanine, glutamic acid, aspartic acid and arginine, respectively (Hung, 2008). Relative output was then calculated as the product of the relative fluorescent responses and the proportions of the individual amino acids in tea leaves, taken from another study (Lee, Chen, & Matsumoto, 1996). Signal outputs of the four representative amino acids were examined; approximately 70.5% of signal response was associated with the umami-related amino acids, theanine (58.4%) and glutamate (12.1%). This experimental result for response percentage is similar to that obtained by a previous study of green tea (Lee et al., 1996) and a recent report regarding Taiwan red tea (Hsieh & Chen, 2007). Therefore, the proposed amines determination based on OPA-fluorescent was considered as an indicator of umami in tea infusions during the taste assessment.

3.4. System optimisation

The length of the mixing coil (Fig. 2a) for tannin and amino acids determinations was optimised to compromise between reaction time (especially for the OPA fluorogenic reaction) and sample dispersion. A mixing coil 60 cm long was selected based on its high peak height and short baseline reversion time.

The conditions for tannin determination were optimised in a previous study (Chen et al., 2005). For the OPA fluorogenic reaction, OPA and 2-mercaptoethanol concentrations as well as pH value were optimised (Fig. 2b and c) as 2 mM OPA, 1 mM 2-mercaptoethanol and pH 10.0 (carbonate buffer) to maximise the signal with reduced reagent consumption.

3.5. Taste quality assessment of green tea and partially fermented tea

Theanine is the predominant taste compound of umami accumulates in growing shoots (Konishi & Kasai, 1968); therefore,

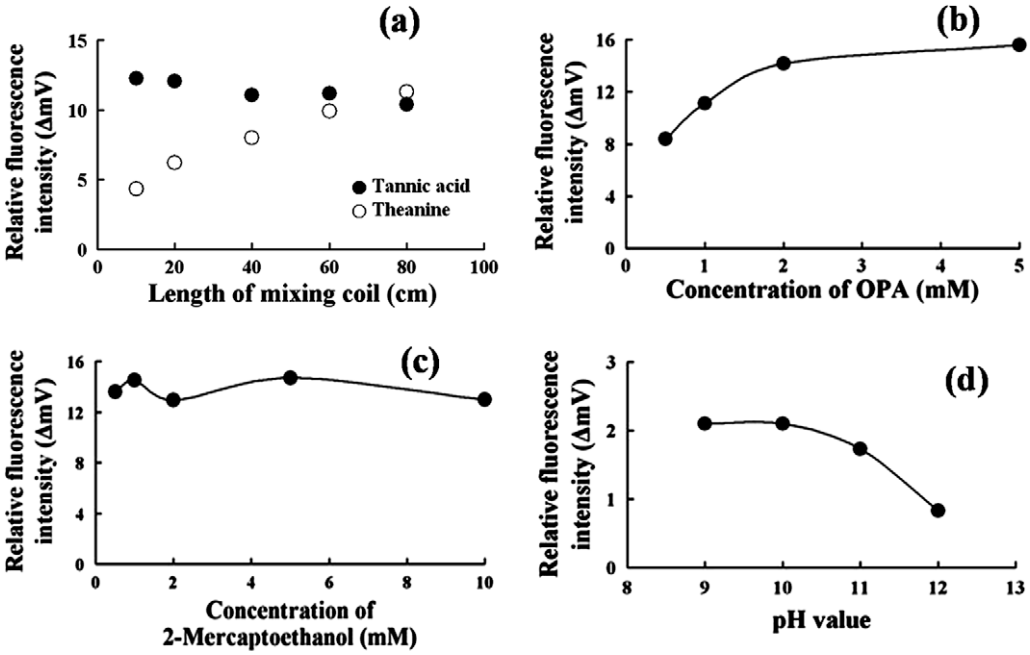

Fig. 2. Effects of the length of mixing coil for fluorescent responses of 100 μg mL^{-1} of tannic acid and 0.5 μg mL^{-1} of theanine (a). Luminol concentration: 0.4 mM. OPA reagent (pH 10.0): 2 mM of OPA and 1 mM of 2-mercaptoethanol. Flow rate, 0.5 mL min^{-1}. Effects of OPA concentration (b), 2-mercaptoethanol concentration (c) and buffer pH value (d) for fluorescent response of 0.5 μg mL^{-1} of theanine to OPA reagent. Flow rate, 0.5 mL min^{-1}. (b) 1 mM of 2-mercaptoethanol, pH value = 10.0. (b and c) 2 mM of OPA, pH value = 10.0. (d) 2 mM of OPA and 1 mM of 2-mercaptoethanol.

superior teas are typically manufactured from the youngest tea shoots. The top bud and first two leaves of tea plants produce the best teas according to tea specialists in Taiwan. The tannin and amino acids concentrations in Pi-Lo-Chun green tea infusions with young shoots and maintenance leaves were analysed using the proposed method and compared (Table 1). Typically, a significant reduction existed in both amino acids and tannin contents in tea manufactured with maintenance leaves; this experimental finding is consistent with that obtained by a free amino acid in the tea study (Nakagawa, Tokumura, Toriumi, & Nagashima, 1957). This preliminary work demonstrates that the proposed system can determine both tannin and amino acids contents in tea infusions of different teas.

According to tea experts, indoor withering time is critical for aroma development of partially fermented tea. This claim was confirmed by an experimental study (Harbowy & Balentine, 1997). Table 2 presents the effects of indoor withering time on tannin and amino acid levels. The content of tannin and amino acids in tea infusions was correlated with withering time when withering time was <24 h. A minor increase in amino acid content is consistent with free amino acids finding obtained by black and green tea study (Nagashima, Nakagawa, Tokumura, & Toriumi, 1957). However, tannin content decreased significantly after 40 h of withering. This experimental data should only be considered as a reference as 40 h of withering time is excessive for partially fermented tea. Furthermore, as diverse polyphenolic compounds are generated during withering, the relative responses of such components for quenching effect must be confirmed in further studies.

Cold water steeping is a new trend in brewing Japanese green tea and Pouchong tea because some heat-labile chemicals are preserved during low-temperature extraction. Moreover, the taste of the tea infusion may be dependant on the kinetics of extracting amino acid (umami) and tannin (astringency) at different water temperatures. As demonstrated by the FIA system, cold water steeping is effective for extracting amino acids, thus, astringency can be suppressed (Table 3). The experimental result is consistent with that obtained by a quality evaluation of green tea study (Horie et al., 1993), which showed that the major components extracted by boiling and cold water differed. This study determined that extraction efficiency for amino acids was better than that for tannin using cold water for <1 h. Therefore, tea prepared using the cold-brew method can generate a superior taste due to the reduction of astringent components (tannin) and increase in umami (amino acids), demonstrating the potential of the proposed system to optimise steeping time.

Finally, the concentrations of amino acids and tannin and local market prices of Oolong tea in Taiwan were compared (Table 4). This table indicates that the result based upon four samples from typical Oolong tea products with various grades from local market. As demonstrated by the proposed system, amino acid content is

the basis for taste quality and Oolong tea prices. Similar trends were also found for Japanese green tea (Horie, Ujihara & Kohata, 2001; Lee et al., 1996). Amino acids content can only be used to differentiate between low- and high-grade Oolong teas, and is relatively less sensitive in discriminating between taste quality and price of high-grade Oolong tea (e.g., Yu-Shan Oolong and Ali-Shan Oolong). Tannin acid content in top-grade product (Ali-Shan Oolong) is significantly lower than that in high-grade (B tea) and medium-grade tea (Yu-Shan) (Table 4). Therefore, the ratio of amino acids to tannin was proposed as an advanced indicator for taste assessment of Oolong tea. This indicator has an increased ability to discriminate between high-grade Oolong teas (the discrimination percentage between Yu-Shan Oolong and Ali-Shan Oolong improved to 56% from 18%). Although, tea prices are determined by taste, labour and transportation costs, and market demand. Experimental results indicated that the proposed system with this indicator (ratio of tannin to amino acids in tea infusions) can be utilised to classify Oolong teas.

4. Conclusion

In conclusion, based on the quenching effect of tea tannin on 3-APA fluorescence and OPA fluorogenic reaction with amino acids, an on-line fluorometric system was proposed that determines the levels of astringency and umami in tea infusions using a single FIA system with the same excitation and emission wavelengths of fluorometry. Without interferences caused by reducing agents and time-consuming pretreatments, the proposed system was preliminarily applied to assess partially fermented Taiwanese teas. Analytical results show the potential of the proposed system for on-line monitoring and classification of tea. Routine analysis of a massive amount of tea samples was completed rapidly (20 samples h^{-1}), accurately (CV < 5%, $n = 3$) and conveniently using the proposed method. This method will be used to verify NIR spectrometry of tealeaves during manufacturing in future work.

ultra-performance liquid chromatography (UPLC). Remarkably shorter separation times are the hallmarks of the technique. This technique has found application in the analysis of aflatoxins (Fu et al., 2008; Ventura et al., 2006).

The incidence of aflatoxins in foods and feeds is relatively high in the tropical and sub-tropical regions due to the warm and humid weather conditions that provide ideal conditions for the growth of the aflatoxigenic moulds. Although studies on the levels of aflatoxins in food items such as corn, peanuts, spices, traditional medicines, etc. have been conducted in Malaysia (Ali, Hashim, & Yoshizawa, 1999; Ali et al., 2005), no recent data on animal feeds have been reported. A survey conducted by the Malaysian Agricultural Research and Development Institute from 1981 to 1984 indicate that 10 of the 14 feed samples were contaminated by aflatoxins (Ali, 2000). Thus, it is the aim of this study to survey the levels of aflatoxins in animal feeds that are readily available on the Malaysian market. There is considerable public concern on the adverse effects of animals consuming mycotoxin-contaminated feeds, as these aflatoxins and/or their metabolites can potentially be passed onto food products such as meat, milk or eggs.

Due to the complexity of the samples, effective sorbent materials for the cleaning-up step must be used. Immunoaffinity column enjoys widespread use due to its good specificity (Giray et al., 2007; O'Riordan & Wilkinson, 2008). However, this sorbent is expensive and commercially available as a single-use format (Calleri, Marrubini, Brusotti, Massolini, & Caccialanza, 2007; Wilson & Romer, 1991). The selective sites are more sensitive to storage conditions, thus have a somewhat shorter shelf-life compared to the more robust C18-based silica sorbent materials. Thus another objective of this work is to evaluate the suitability of multifunctional column for the cleaning-up of the extracts. The multifunctional column is furthermore attractive as it involves fewer manipulation steps, thus minimising the analysis time (Ali et al., 1999; Fu et al., 2008).

2. Experimental

2.1. Chemicals and reagents

Aflatoxin standards and trifluoroacetic acid (TFA) were purchased from Sigma–Aldrich, USA, while acetonitrile, methanol (HPLC grade) and *n*-hexane were purchased from Fisher Scientific (UK), 18 Mohm milliQ water was generated from a TKA Water Treatment System. Isolute Multimode® Columns (1 mL capacity, 100 mg), hereafter referred to as multifunctional column (MFC) were purchased from International Sorbent Technology, UK. Forty-two feed samples were obtained from various outlets in Malaysia. Most of these samples, except for copra meal and palm kernel meal, were imported from different countries.

2.2. Instrumentation and chromatographic conditions

Quantitative analyses of the aflatoxins were carried out using a HPLC unit that consisted of a pump (Jasco PU-1580) and quartenary gradient system (JASCO PU-1580-04). Fluorescence detector was used for the quantitation under the following conditions: 360 nm excitation and 440 nm emission. The analytical column was a Supelco C_{18}, 25 cm × 4.6 mm id, 5 μm particle size. All HPLC analysis were carried out under isocratic conditions using a mobile phase of acetonitrile:methanol:water (8:27:65) and the flow rate was fixed at 1.0 mL min^{-1}. The mixture was filtered using a membrane filter and degassed in an ultrasonic bath for 25 min prior to use. A 20 μL sample loop (Jasco model 7725) was used.

2.3. Preparation of standards

The aflatoxins B1, B2, G1 and G2 standards (1.0 mg of each aflatoxin in capped amber bottles) were purchased from Sigma–Aldrich. The working solutions were prepared according to the AOAC procedure (AOAC, 2000) by injecting 1 mL of acetonitrile into each vial to dissolve the aflatoxins. Working solutions (50–1000 ng g^{-1}) were diluted in acetonitrile and stored at 8 °C. They were evaporated to dryness under nitrogen before being derivatised with TFA according to the procedure describe below.

2.4. Extraction and clean-up

The method as described by Akiyama and co-workers was used with minor modifications (Akiyama, Chen, Miyahara, Toyoda, & Saito, 1996). A 20 g of sample was extracted with 80 mL acetonitrile:water (9:1) mixture for 30 min by shaking under high speed, and then filtering using a No. 4 Whatman filter paper. A 1-mL portion of the filtrate was loaded on the MFC and passed through at a flow rate of 2 mL min^{-1} (the column had previously been preconditioned with 5 mL methanol and 5 mL acetonitrile:water (9:1)). Next, 1 mL of acetonitrile:water (9:1) was applied to the column to ensure all the aflatoxins are collected. This step was repeated five times and the filtrates were combined and evaporated to dryness under nitrogen in amber bottles (5 mL capacity) and the residue was used for the derivatisation.

2.5. Pre-column derivatisation

A 100 μL of the TFA solution and 300 μL of *n*-hexane were added to the residue from the sample extract or to the aflatoxin working standards, vortexed for 30 s, and kept in the dark for 15 min at room temperature. Nine hundred microlitres of acetonitrile:water (1:9) was added to the vial, and vortexed for 30 s. The mixture was left to stand to allow the two layers to be separated. Twenty microlitres of the derivatised product (bottom layer) was injected into the HPLC column.

3. Results and discussion

3.1. Mobile phase selection

Five mobile phases consisting of acetonitrile:methanol:water (8:27:65, 17:0:83, 17:13:70, 8:20:72 and 10:20:70) were tried. Fig. 1 shows the effect of mobile phase compositions on the retention times of the aflatoxins. Aflatoxin G1 standard cannot be detected by the second and the fourth mobile phases. Shorter

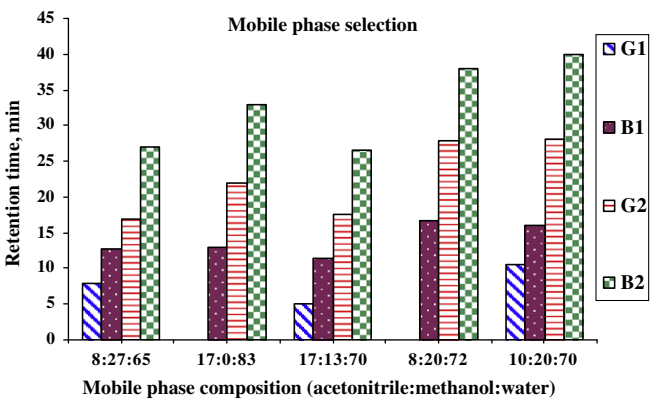

Fig. 1. Effect of mobile phase composition (acetonitrile:methanol:water) on the retention times of aflatoxins.

retention times when the third mobile phase was used, but aflatoxins B1 and B2 lower than 10 ng g^{-1} could not be detected. It appears that the sensitivity decreased when the mobile phase contained more than 70% water (mobile phases 2–4). The first mobile phase was chosen in the present study as it gave not only higher sensitivity but also with shorter retention time. This composition was also used by Akiyama et al. (2001).

3.2. Selection of extraction solvent and multifunctional column

In general, the extraction procedure depends to a great extent on the physicochemical properties of the commodities that are contaminated with aflatoxins. Commodities with high lipid and pigment content require a more selective treatment followed by extensive purification methods than those with lower content of these components. As aflatoxins are soluble in moderately polar solvents, they are normally extracted using a mixture of organic solvents such as acetonitrile, chloroform, or methanol. In earlier work, chloroform was commonly used as the extracting solvent, but has since been replaced by more environmentally-friendly solvents. It was reported that a mixture of methanol:water is more suitable compared to the use of acetonitrile:water (Gilbert & Vargas, 2003).

Different extraction mixtures involving acetonitrile:water and methanol:water was examined for the extraction efficiency of copra meal that had been spiked with 10 ng g^{-1} aflatoxin standards. Of the combinations investigated, using acetonitrile:water (9:1) and methanol:water (8:2) are more suitable than the others (Fig. 2). Using acetonitrile:water (9:1) gave more satisfactory recoveries, all the aflatoxins were at least 85% extracted. This is further supported by the recovery results when 5–30 ng g^{-1} aflatoxins were spiked and next extracted using methanol:water and acetonitrile:water (Fig. 3). Recoveries of aflatoxin G1 is significantly lower when extracted using methanol:water mixture.

Table 1
Recoveries of aflatoxins spiked to feed samples.

Sample, level spiked	% Recovery ± %RSD			
	G1	B1	G2	B2
Copra meal				
5 ng g^{-1}	98.0 ± 5.7	100.0 ± 1.0	94.0 ± 7.0	93.0 ± 1.1
15 ng g^{-1}	84.0 ± 3.9	100.6 ± 0.7	98.0 ± 4.7	95.5 ± 1.2
30 ng g^{-1}	98.0 ± 1.2	92.0 ± 0.4	98.0 ± 1.0	95.0 ± 0.6
Corn meal, 15 ng g^{-1}	95.3 ± 3.1	92.6 ± 4.6	98.6 ± 4.6	99.6 ± 1.0
Wheat bean, 15 ng g^{-1}	80.0 ± 2.7	98.0 ± 2.9	94.6 ± 5.3	86.6 ± 3.6
Mixed feed, 15 ng g^{-1}	70.0 ± 2.7	93.3 ± 6.4	104.6 ± 4.6	83.3 ± 0.4

RSD, relative standard deviation.

MFC is an interesting alternative sorbent that can be used for the cleaning-up of samples. They are designed to retain particular groups of compounds that may interfere in the analytical method but at the same time allow analytes of interest to pass through. The proprietary packing material in MFC contains both lipophilic (non-polar) and charged (polar) active sites. Lipophilic sites are largely responsible for the removal of fats and other non-polar components such as xanthophyll pigments. Charged sites consist of both dipolar and anion-exchange sites that remove proteinaceous compounds, carbohydrate and other polar interfering compounds. Contrary to solid phase extractions (SPE), the MFC procedure does not require washing or elution procedures. SPE procedures require three steps, i.e., retention of analyte on the sorbent column, washing of undesirable compounds, and elution of analyte from the sorbents. Another advantage of the MFC procedure is the elimination

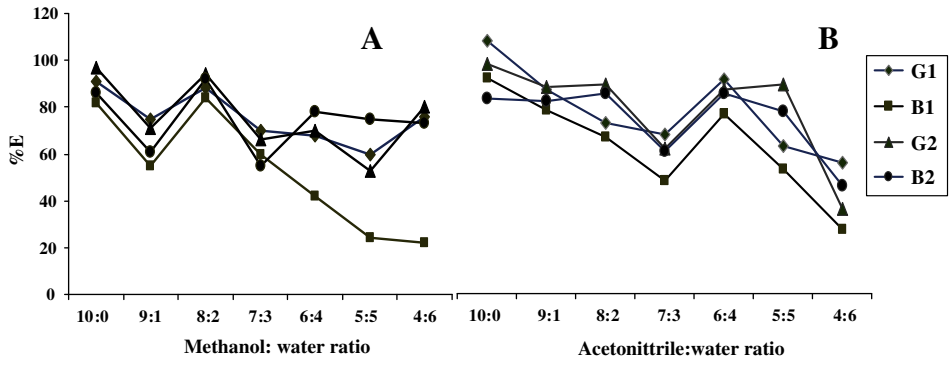

Fig. 2. Effect of extracting solvent mixtures ((A) methanol:water and (B) acetonitrile:water) on the efficiency of extraction (aflatoxins spiked, 10 ppb each).

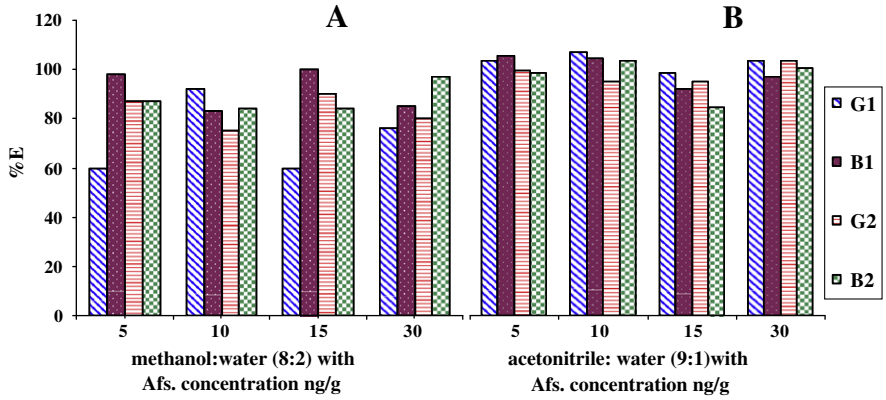

Fig. 3. Recoveries of aflatoxins that were spiked at different levels (5, 15 and 30 ng g^{-1}) when extracted with (A) methanol:water (8:2), and (B) acetonitrile:water (9:1).

of the irreversible adsorption or premature elution of analyte from the sorbent column (Krska, Welzig, Berthiller, Molinelli, & Mizaikoff, 2005; Wilson & Romer, 1991). The total analysis time is about 1 h, and this is comparable to the UPLC method (Fu et al., 2008). A direct comparison with other reports is problematic as the total analysis time is not specified by the authors.

Table 2
Levels of aflatoxins found in aflatoxin-positive feed samples.

Sample no.	Product	Aflatoxin found ng g^{-1}				
		G1	B1	G2	B2	Total
1	Maize	N.D	6.31	0.07	0.13	6.51
2	Copra meal	6.7	13.8	N.D	3.9	24.4
3	Sunflower meal	57.8	37.8	N.D	7.0	101.9
4	Wheat bean	8.6	N.D	N.D	N.D	8.6
5	Corn	6.3	2.3	N.D	N.D	8.6
6	Palm kernel expeller	9.9	N.D	N.D	N.D	9.9
7	Corn germ meal	45.6	N.D	N.D	N.D	45.6
8	Poultry feed	8.5	N.D	N.D	N.D	8.5

N.D, not detected.

3.3. Analytical characteristics

The linearity of the calibration graphs were studied by injecting in duplicate five concentrations (5–35 ng g^{-1}) of standard mixtures of the aflatoxins. Calibration plots were linear for the tested range with correlation coefficients >0.999 for all the aflatoxins. The limit of detection (LOD) was calculated to be 0.10 ng g^{-1} for both aflatoxins G1 and G2 and 0.06 ng g^{-1} for both aflatoxins B1 and B2.

The LOD was obtained by using the equation:

$$\mathrm{LOD} = ks_b/m \quad (1)$$

where m is the calibration sensitivity, s_b is the standard deviation of the blank, 3 was chosen as the factor k while the LOD was based on the signal-to-noise ratio of 3:1. LODs of 0.01 ng g^{-1} and 0.5 ng g^{-1} for each aflatoxin was reported by Ali et al. (2005) and Akiyama et al. (2001), respectively. The repeatability and reproducibility of the method was assessed by injecting five times each of the four

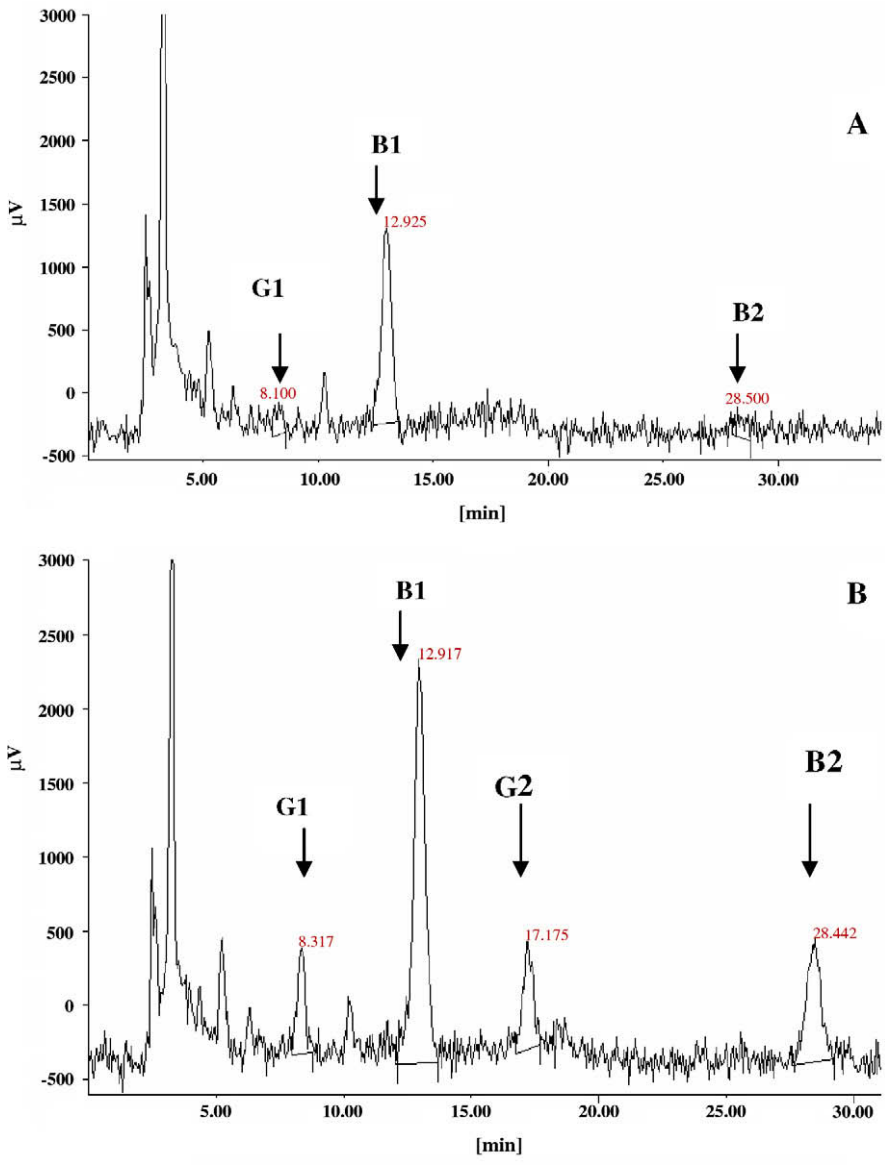

Fig. 4. Typical chromatograms of (A) extract of copra meal (sample 2), and (B) extract of copra meal that was spiked with aflatoxins B1, B2, G1 and G2 (15 ng g^{-1} each).

standard mixtures on the same day (intra-day) and over 6 days (inter-day), respectively. Good reproducibility of both the peak area (RSD $\leqslant$ 3.5%) and retention time (RSD $\leqslant$ 1.0%) were found.

3.4. Analysis of animal feeds

In the analysis of animal feed samples, peak identification was based on the comparison between the retention times of standard compounds and was confirmed by spiking standards to the samples. Quantification was based on the external standard method using calibration curves fitted by linear regression analysis. Under the stated experimental conditions, baseline separation of the aflatoxins was achieved in less than 30 min.

To further evaluate the capability of the method, aflatoxins were spiked to a few types of feed samples and analysed using the proposed method. Satisfactory recoveries, ranging from 70.0% to 104.6% were obtained (Table 1), indicating the suitability of the extracting solvents and MFC used.

Of the 42 feed samples that were tested, eight was found to be contaminated with aflatoxins (Table 2). The total aflatoxins ranged from 6.51 to 101 ng g^{-1}. Some of these samples contain aflatoxins that exceed the legal limits of 20 ng g^{-1} as imposed in many countries (e.g., USA, Austria, India, Argentina, Netherlands and Brazil) (Moss, 2002). The incidence of aflatoxins in copra (24.4 ng g^{-1}) and palm kernel (9.9 ng g^{-1}) clearly indicate that better hygienic practices must be in place in the preparation of these commodities. The traditional method of drying these items on the ground in the open air in poor hygienic conditions promotes the growth of moulds and production of mycotoxins. Surveys from other countries have reported the occurrence of aflatoxins in corn and related products from Turkey (Castells et al., 2008) and China (Li et al., 2001) and the contamination of animal feeds has been reported in Greece, Turkey (Aycicek et al., 2005). Typical chromatogram is shown in Fig. 4. It can be readily seen that all the aflatoxins are well separated from the unwanted components.

4. Conclusion

Forty-two animal feeds, comprising corn, wheat meal, sunflower meal, mixed feed, copra meal, and palm kernel expeller were analysed for the content of the aflatoxins B1, B2, G1 and G2. Three samples were found to contain total aflatoxins greater than 20 ng g^{-1}, exceeding the legal limit imposed in many countries. Cleaning-up of the extracts using the MFC is effective in removing unwanted interfering components, thus can be recommended as alternative clean-up sorbent to the more expensive immunoaffinity columns. Simpler clean-up procedure is also associated with the use of the MFC.

Preface

This Special Edition of Food Chemistry is devoted to the subject of analytical methods for authenticating food. The publication is timely as there have recently a plethora of high profile incidents where food authenticity has been compromised e.g. adulterated vodka in the UK, European frauds concerned with cheese and wine, adulteration of dairy products. The adulteration of food that takes place can sometimes be crude and can have severe implications for public safety. In this respect the recent melamine incident, although a global food safety issue, had its origins in a common food adulteration scenario, i.e. fraudsters trying to seek financial gain through mislabelling of their products, in the melamine case mislabelling the protein content of milk.

In Europe in particular, an ever more discerning consumer is prepared to pay extra for "added value" products. In many cases the products are essentially similar but with particular labelled "quality" attributes. These attributes such as local/regional/country of origin, free range, organic, species, blended or single variety, Protected Denomination of origin, to name but a few, provide food researchers with considerable challenges in terms of providing verification solutions that will satisfy consumers, food industry and control bodies alike. Our job is not helped when we are not only tasked with answering the question "is this product adulterated?" but also the more difficult question "what is the level of adulterant in the authentic product?" It is easy to see why researchers often need sophisticated solutions to authenticate food.

It is against this background that I am pleased that this special edition will present some of the latest research in this area. Approximately half of the papers are derived from research carried out within the framework of the TRACE integrated project (www.trace.eu.org). This largely European funded research programme involves over 50 participants from Europe, South America and China. TRACE has initiated research into the development of methods and systems for verifying geographical origin, species and varietal origin and methods that can verify a food using spectroscopic "fingerprinting". The analytical methods are invariably supported by chemometric interpretation in order to discriminate between the adulterated and authentic products and where possible/appropriate quantify the adulterant.

This Special edition also includes papers detailing research funded through other national and international funding bodies. In many of the manuscripts direct support has been provided by the food industry, not least in the form of highly valued provision of authentic samples and commodity expertise. This close co-operation is valued and essential for method development and validation. In addition to acknowledging the work of researchers involved in producing the manuscripts in the Special Edition we would like to acknowledge all those involved in facilitating the research and in helping through various means to develop methods to ensure the integrity of our food supply.

TRACE is delighted to help support this Special Edition and cordially invites readers to its final conference in Brussels on 2–3 December 2009 (www.trace.eu.org/admin/event/file/TRACE-Leaflet.pdf) where the final outputs from the project on methods for tracing the origin of our food will be presented.

Preface

Today Port is a world-wide reputed wine known to be produced in the specific region of Douro in Portugal according to well-defined wine making-practices. The historical reasons and evolution which led to the product we drink today are probably less known to most of the consumers. At the end of the 17th century difficult political situation between France and England resulted in an increasing importation of Port wine as a replacement of the Claret Bordeaux wine for the British market. The trip on the ocean to England often spoiled the wine; the fortification or addition of distilled grape improved the shipping and preservation of the wine for its journey. This practice was further improved in the mid 19th century to stop fermentation before all the sugar is converted to alcohol, thus creating a sweeter mouth-taste typical of the Port Wines we know today. Increasing demand and high prices also gave rise to fraud and infractions. Consequently, the Portuguese government created in 1756 an institution (Companhia Geral dos Vinhos do Alto Douro) to guarantee the quality of the product. The concept of a register of vines was thus defined and Port wine became the third oldest defined and protected wine region in the world after Tokaji (1730) in Hungary and Chianti (1716) in Italy.

All world-wide reknown food products bearing traditional geographical indication of origin as distinctive signs of quality and reputation have certainly encountered a similar evolution than that of Port wine. After an initial period of commercial success, consortium of producers or government authorities establish rules for delimitation of the geographic area of origin, manufacturing practices and specifications of the finished product.

Geographic indications of products were considered in International treaties such as the Paris Convention for the Protection of Industrial Property in 1883 and the Madrid Agreements on Indications of Source and the International Registration of Marks in 1891. These international treaties and the more recent Lisbon Agreement for the Protection of Appellations of Origin and their International Registration (1958) are now administered by the World Intellectual Property Organization (WIPO), a United Nations Agency. In addition, the Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) deals with the international protection of geographical indications within the framework of the World Trade Organization (WTO). The European Regulation EC Reg. 2081/92 introduced the protection of Geographical Indications (PGIs) and Designations of Origin (PDOs) for agricultural products and foodstuffs in 1992. It is now replaced by the Council Regulation No. 510/2006 which also allows producers from third countries to register their names in the European Union. It should be noted that the wine-sector products (except wine vinegars) and spirits drinks are covered by their own existing Community legislation.

This frame of international agreements and regulations is important to enable the recognition of origin of a product. Food chemists are requested to provide scientific methods and perform measurements that establish the compliance of food products with the regulatory requirements. Food safety aspects are generally easily controlled with official methods determining physico-chemical or biological parameters against well-established specifications and tolerances. The analytical testing for authentication purpose such as recognition of geographic origin, or detection of adulteration is somewhat more complex. The specifications for food with geographic indication are generally based on consolidated traditional practices and often on subjective characteristics such as organoleptic properties. Although physico-chemical parameters were sometimes included in the specifications, they were generally not specific of the geographic origin and did not allow differentiation from other similar products. In this context, it is likely that imitations or adulterated products are present on the market and compete in an unfair manner with the genuine products. It is both in the interest of the consumers, the producers and also of the control bodies to dispose of analytical methods and objective parameters that enable a better control of origin of food products. The isotopic methods have shown to be an efficient tool to fight against adulteration of food products since the beginning of the 90s after the European Council has decided to establish an official European isotopic wine databank for the controls in the wine sector (EC Reg. No. 2048/89). Several European funded research projects further developed these isotopic techniques and also spectroscopic fingerprinting methods on a broader range of food products investigating applications for the control of botanical, animal and geographic origins of food products. The techniques developed in molecular biology have also led to the possibility of characterisation of species. This Special Edition of Food Chemistry illustrates the vivacity of these researches on a broad range of food products. Half of these works are based on the isotopic techniques eventually in combination with trace elements. The fingerprinting techniques are also important tools for the confirmation of origin of many food products provided that reference databank of genuine products can be established. The research works presented in this Special Edition highlight some of the analytical possibilities available today to the food chemist to provide objective physico-chemical parameters helping the recognition of origin of PDO food products and also to detect adulteration or mis-labeling. Much progress has been achieved in the past years, for instance throughout the Integrated Project TRACE.

doi:10.1016/j.foodchem.2009.07.034

However there is still a lot of work ahead for development of new methods, to integrate data and share databanks among official control bodies but also, when possible, with industry and producers within systems of certification at the level of quality control of the production. The strong interest in Europe for authentication and traceability of food products will continue to stimulate the research in that field. Certainly several of these works will naturally find their publication in future issues of Food Chemistry.

to kinetic or thermodynamic isotope effects and, therefore, reflect the circumstances under which physical or (bio-) chemical processes took place. IR of the light elements provide information about climate, distance to the sea, altitude, latitude and agricultural practices.

During the last ten years IR of heavy (geo) elements (Sr, Pb) came into use in said field of application. Regional variations of respective IR are caused by radioactive decay of mother nuclides and radiogenic increase of daughter nuclides and are evolved during geologic processes. Isotopic signatures of the heavy elements in any biogenous tissue are thus inherited from the geologic environment and therefore vary spatially depending on the regional geo-, litho- and pedological situation (Horn, Schaaf, Holbach, Hölzl, & Eschnauer, 1993).

2. Juice samples

From 2002 to 2005 a Project named "Pure Juice" was funded by the European Union and coordinated by SGF International e.V., Nieder-Olm, Germany, during which especially methods using stable isotope analysis had been developed and improved to detect adulterations of fruit juices (see Results of the Pure Juice Project, 2006). One aim of the study was to establish suitable means to identify the geographic origin of fruit juices by building up a multi-element isotope data base and by developing new isotopic techniques for the elements sulphur and strontium and especially the combination of light elements' IR with those of strontium for fruit juice authenticity control. For this purpose we were supplied with numerous authentic juice samples by the SGF, amongst others, around 150 samples of orange juices from major orange cultivating regions of the world.

3. Materials and methods

For the verification of geographical origin of fruit juices the IR of hydrogen, carbon, nitrogen, sulphur and strontium proved useful in most cases.

Results of stable isotope measurement of light elements are always displayed in the delta notation, where the measured value is referred to an international standard:

$$\delta X(‰) = \left(\frac{\left(\frac{X}{Y}\right)_{Sample}}{\left(\frac{X}{Y}\right)_{Standard}} - 1 \right) \times 1000, \quad (1)$$

with X being the heavier and Y being the lighter isotope of an element.

International reference values ("Standard") are: V-SMOW (δ^2H), V-PDB ($\delta^{13}C$), AIR ($\delta^{15}N$), V-CDT ($\delta^{34}S$).

The results of Sr-isotope analyses are normally given as $^{87}Sr/^{86}Sr$ but sometimes, in analogy to those of light stable isotopes, as $\delta^{87}Sr$ with[1]

$$\delta^{87}Sr\ (‰) = \left(\frac{\left(\frac{^{87}Sr}{^{86}Sr}\right)_{Sample}}{0.7093} - 1 \right) \times 1000 \quad (2)$$

δ^2H-values of plant material are directly correlated to the water taken up from soils. Hydrogen isotopic composition of meteoric water provides information about local climatic and geographic conditions like temperature, amount of precipitation, humidity, latitude or altitude. Depending on rooting depth and water supply plants take up water either from ground water or from surface water. Although roots of orange trees can reach depths of 3 m highest root activity is found in the upper soil from 30 cm down to 60 cm; hence, water is supposed to be taken mainly from these depths (Wahid, 2001).

Although experiments have shown that – apart from ^2H-enrichment in leaf water due to evapotranspiration – no fractionation of δ^2H in the bulk plant material occurs upon water uptake (Ehleringer & Dawson, 1992), large fractionation effects caused by biochemical reactions like e.g. carbohydrate metabolism or production of lipids can be recognised within a plant (Schmidt, Werner, & Eisenreich, 2003). However, as the only source of hydrogen in oranges ultimately is meteoric water and strong correlations between δ^2H-values of the water and both plant and plant metabolites can be observed (Luo & Sternberg, 1992; Martin & Martin, 2003; Schmidt et al., 2003) it was expected to obtain useful geographic and environmental information by measuring δ^2H. Pulp turned out to be a particularly suitable material as it contains considerably less exchangeable hydrogen than carbohydrates (the latter even more than 50%).

The main source of carbon for plants is CO_2 taken up from the atmosphere for the production of carbohydrates. During photosynthetic CO_2-fixation isotope effects occur which lead to carbon isotope discrimination depending on the photosynthetic pathway a plant uses. Two pathways can be distinguished depending on the number of C-atoms built in the primary assimilation product, on the one hand the C3- or Calvin-cycle, on the other hand the C4- or the Hatch-Slack pathway (Krueger & Reesman, 1982). Regarding the carbon IR, these processes can be well discriminated as C3-plants (e.g. most species of fruit and vegetable, legumes or domestic cereals) show $\delta^{13}C$-values ranging from −24‰ to −32‰ whereas C4-plants (e.g. corn or cane sugar) display significant higher $\delta^{13}C$-values between −11‰ and −15‰. CAM (crassulacean acid metabolism) plants, like for example pineapple or vanilla can use both kinds of metabolism and consequently show intermediate values between −15‰ and −24‰ (Schmidt, Rossmann, Stöckigt, & Christoph, 2005a). Individual variation ranges are due to climatic conditions like light intensity, changes in soil water content and relative humidity (Francey & Farquhar, 1982). Hence, the distribution of carbon isotopes in plants rather acts as an indicator for different plant-physiological processes than for geographic origin. Nevertheless, in practise there are systematic differences of carbon IR between fruits e.g. coming from Mediterranean countries compared to those from South-America as a result of different growing conditions (temperature, humidity).

$\delta^{15}N$ values of plants are mainly influenced by soil nitrogen. Therefore, N-isotopes cannot directly be linked to a certain region as the main nitrogen sources for soils are fertilizers and manure – i.e. N-isotopes mainly reflect agricultural practices which, however, can be typical for certain regions (Kornexl, Werner, Rossmann, & Schmidt, 1997; Schmidt et al., 2005b).

Sulphur IR of natural compounds are influenced by several factors. On the one hand there are anthropogenic sources like industrial emissions or – though of smaller importance – fertilizers; on the other hand there are natural sources like sea spray (i.e. small drops of sea water blown to land), volcanic emissions or lithological setting of an area. Thus, the variability of $\delta^{34}S$-values is large. For example, the $\delta^{34}S$-value of seawater and that of sea spray lies around +22‰. Although $\delta^{34}S$ of volcanic emissions can vary between −20‰ and +20‰ (Thode, 1991) the average is around +5‰ (Pichlmayer, Schöner, Seibert, Stichler, & Wagenbach, 1998) and $\delta^{34}S$-values of fertilizer sulphate can vary between −6,5‰ and +24,4‰ (Vitoria, Otero, Soler, & Canals, 2004). Experiments with wheat have shown that there is no or very little isotope fractionation during sulphate uptake and transport from roots to plants (Monaghan, Scrimgeour, Stein, Zhao, & Evans, 1999). Hence, sulphur IR are very site-specific and thus can contribute significantly to the identification of geographical provenance.

[1] $^{87}Sr/^{86}Sr = 0.7093$ is an approximation for Sr-IR in (Baltic) seawater.

Like isotopes of the light elements also those of the heavy or trace elements are subject to isotope effects and mass dependent fractionation effects. But these are, according to high nuclide masses and small relative mass differences practically insignificant compared to observed variations. Applications using isotope-ratio measurements of heavy elements (Sr, Pb, Nd, etc.) are utilising variations in isotopic composition due to radioactive decay where one isotope of a given element (parent-nuclide) is transmuted into a stable isotope of another element (daughter-nuclide). The variation of the isotopic composition of strontium is due to the radioactive β-decay of ^{87}Rb with a half-life of 48 Ga resulting in an increase of the radiogenic ^{87}Sr (for further details see also Faure, 1986). For our applications it can be assumed that absolute amounts of the isotopes ^{84}Sr, ^{86}Sr and ^{88}Sr are invariant and thus remain constant in any material. Hence, $^{87}Sr/^{86}Sr$ in soils and the plants growing thereon depend – as a first approximation – on the initial Rb/Sr and the geological age of the underlying rocks. For example, plants growing on young basalts normally have low $^{87}Sr/^{86}Sr$ ratios ($^{87}Sr/^{86}Sr < 0.706$) whereas those on old crystalline rocks, like gneisses or granites display high Sr-IR ($^{87}Sr/^{86}Sr > 0.711$). According to the Sr–seawater curve (Faure, 1986) the vast majority of marine carbonatic sediments lead to intermediate $^{87}Sr/^{86}Sr$-values (0.706–0.709). In clastic sediments usually higher values between 0.709 and 0.711 can be expected as mostly material deriving from magmatic precursors is involved.

According to this, regions with different geologic histories usually show different but site-specific isotopic signatures for Sr which do not alter during (bio-) chemical and physical reactions. The biologically available, i.e. the water soluble fraction of Sr, passes from rock to soil into aerosols and water and from there enters the food chain i.e. tissues of plants, animals and humans without significant fractionation. The variability of Sr-isotopes in nature is rather wide and the concentrations of Sr in most organic materials are in the dimension of hundreds of μg/kg or mg/kg which makes sampling and sample handling easy as no large amounts of material (500 mg–5 g) are required (Horn 2005).

When interpreting Sr-IR of plant material it has to be taken into account that the isotopic composition of plants does not represent exactly that of the underlying whole rock. Several factors may influence Sr IR of organic material to different degrees. Plants take up nutrients (including Sr) from the soil by their roots and due to similar ionic radius and -charge Sr is physiologically incorporated like calcium. Formation of soil (pedogenesis) occurs through weathering of rocks. As rock forming minerals have both different Sr contents, IR and solubilities, soil and soil solution containing the bio-available Sr show either increased (mostly true for more basic rocks) or decreased (mostly true for acidic rocks) Sr IR compared to the parent rocks (Horn, 2005). Sr in soils developed on carbonates more closely resembles – due to the relatively high water solubility of $CaCO_3$ – the isotopic composition of the bulk rocks.

External factors which sometimes may significantly contribute to the Sr budget and composition of vegetation are aerosols, sea spray or fertilizers. The extend to which these sources can seriously influence the isotopic composition of plants has to be evaluated individually.

Precipitation has a mean concentration of dissolved Sr of several μg/l (Åberg, 1995). This is, although completely bio-available to plants, negligible compared to the Sr content of a typical soil which is normally several hundreds of mg/kg. Solid aerosols can strongly contribute to the Sr content of bulk soil. Whereas for example, the ubiquitous Sahara dust plays a minor role for bio-available Sr as mostly consisting of more or less insoluble minerals like mica or quartz, carbonate dust can be an important source of mobile Sr in soils. Sea spray, however, can change Sr IR in organic material significantly. Ocean water has a Sr concentration of about 8 mg/l with a $^{87}Sr/^{86}Sr$ of 0.7092 which has especially to be taken into account when interpreting Sr data of plants growing in coastal areas.

Fertilizers can play an important role for Sr IR of plants when they have both high Sr-concentrations and extreme IR like e.g. some lime or phosphate fertilizers. Nevertheless, it can be presumed that even in such special fertilizers Sr IR of plants can be altered but never falsified completely (Horn, 2005).

Thus, geographic information which can be obtained by analysing Sr IR in orange juices is mainly based on the lithologic or pedologic composition of an area. However, from case to case several different influencing factors have additionally to be taken into account.

4. Sample treatment

Three laboratories were involved in the isotope analyses: stable isotopes of C, N, S were measured at Isolab GmbH, Schweitenkirchen, δ^2H was measured at LGL, Oberschleissheim and Sr-isotope-measurements were carried out at Bavarian States Collection for Palaeontology and Geology, Munich.

Preparation steps for multi-element-isotope measurements on orange juices are schematically displayed in Fig. 1.

4.1. δ^2H, $\delta^{13}C$, $\delta^{15}N$, $\delta^{34}S$

4.1.1. Sample preparation

For the analyses of the light elements pulp, sugar, amino-acids and proteins of the juice samples were prepared. However, the stable isotope-data presented here is restricted to results of pulp as the preparation method is simple and officially accepted (see below), the material is stable and it is the only juice component which can be analysed for all isotope parameters. Pulp, which is the insoluble fraction of a juice, mainly consists of cellulose, hemicellulose, pectines and proteins and is separated from the liquid fraction by centrifugation, followed by washing several times with water and acetone (according to an officially accepted method of CEN prENV 13070, 1998). The dried samples (3–4 mg for $\delta^{13}C$, $\delta^{15}N$, $\delta^{34}S$ and 200 μg for δ^2H, respectively) are weighed into tin capsules for isotope-ratio measurements.

4.1.2. Isotope measurements

The measurements of $\delta^{13}C$, $\delta^{15}N$, $\delta^{34}S$ are carried out on an Elemental Analyser (Vario EL, Elementar, Hanau) coupled with an isotope-ratio mass spectrometer, IRMS (IsoPrime, GV Instruments). In the course of the study a system for the simultaneous determination of C, N, S has been developed and tested for routine work. Only recently a system for the simultaneous determination of H in addition to C, N and S is under development and results are compared to the conventional way of hydrogen analysis (pyrolysis at 1450° C with a Thermo Finnigan High Temperature conversion unit coupled to a Finnigan XL plus IRMS; Thermo Finnigan GmbH, Bremen, FRG) in order to get established into routine work. Detailed information about this EA-IRMS-system as well as data showing the comparability of the two systems can be found in Sieper et al. (2006).

At the beginning of each sequence of measurements six working standards are analysed, then four to six replicates of five samples alternating with six working standards – for samples discussed here this was a casein (assigned values are −23.37‰ for $\delta^{13}C$, 6.15‰ for $\delta^{15}N$, 4.4‰ for $\delta^{34}S$ and −113‰ for δ^2H) which was calibrated in a former EU-project (SMT4-CT2236-1998) by several laboratories (e.g. Camin et al., 2004). As applied since over 15 years the measured values (raw data) are referenced against this working standard. Each sequence additionally includes four to six replicates of an international reference material, e.g. NIST

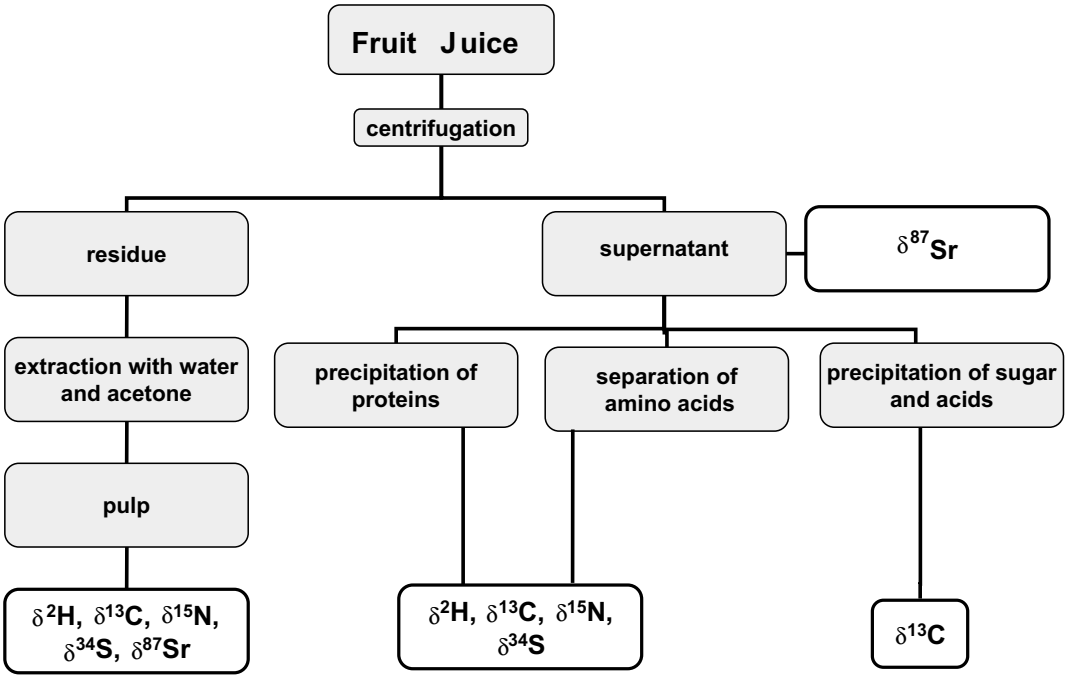

Fig. 1. Sample preparation scheme for isotope analyses in fruit juice samples.

1577b to check the accuracy of the calculation. Achieved uncertainties (1 STD) of measurements are better than ±3.0‰ (δ^{2}H), ±0.1‰ (δ^{13}C), ±0.2‰ (δ^{15}N) and ±0.3‰ (δ^{34}S). Tests for the accuracy of the measurements are regularly performed within interlaboratory round robins or by comparison with data from single-element analysis. Further details and data can be found in Rossmann, Rummel, and Kupka (2003), Camin et al. (2004), (2007) and Sieper et al. (2006).

Supposed possible exchange of hydrogen with water and/or ambient air moisture during and after preparation is corrected for by use of the "comparative equilibration technique" (Wassenaar & Hobson, 2003). The reference material was the casein standard (see above).

4.2. $^{87}Sr/^{86}Sr$

4.2.1. Sample preparation

Juice samples – 100 mg of pulp or 1 mL of bulk juice or liquid fraction – are dried for several hours and afterwards thermally ashed at 800 °C. ^{87}Rb is isobaric to ^{87}Sr and therefore cannot be distinguished by the mass spectrometer. Accordingly, it is very important to remove Rb completely. For this purpose the ashed sample is dissolved in concentrated HNO_3. Sr is then separated from other elements such as Ca, Ba and Rb by ion-chromatography on Sr-spec®, a Sr-specific crown-ether using a method modified after Pin and Bassin (1992). Due to small resin volume (50 μL) and little amounts of chemicals required (2 mL of HNO_3 in total), the usage of only extremely clean reagents (water and acid are cleaned with subboiling distillation) and multiply cleaned quartz- and teflon-beakers and the performance of separations under clean room conditions (class 100 laboratory), total blanks are below 500 pg Sr in any case. In view of a Sr content of 200 ng and more in the sample this is negligible.

4.2.2. Isotope measurement

Isotope analyses of Sr are performed on a thermal ionisation mass spectrometer (TIMS, MAT 261.8, Thermo Finnigan). Tungsten-single-filaments are used for the measurements. As Rb has a significantly – about 300 °C – lower ionisation temperature than Sr any extant Rb is evaporated from the loaded filament through controlled pre-heating before the isotopic composition of Sr is measured. For quality control and to check for proper operation of the mass spectrometer, a certified reference material ($SrCO_3$, NIST SRM 987) is analysed under the same conditions as the samples (60 single scans, $^{87}Sr/^{86}Sr$ mean value: 0.710251 ± 0.000023 (1 STD) with $n = 120$). Isotope mass fractionation during analysis is corrected for by referencing to an invariant $^{88}Sr/^{86}Sr$ value of 8.37521. The achieved precision of strontium-isotope measurements normally is <0.003% (2σm). A combined uncertainty (precision + accuracy) for $^{87}Sr/^{86}Sr$ is <0.005%.

5. Results and discussion

During the EU-project "Pure Juice" approximately 150 authentic orange juices have been analysed. The results are shown in boxplots (Fig. 2).

Samples for this project were taken from juice producing factories and not from single plantations which makes interpretation more difficult as the harvest area of the oranges can exceed several hundreds of square kilometres. Additionally, geographic details of the provenances are not available for all samples. Therefore, measured IR are supposed to reflect a mixture of values from samples grown in different environments. However, this constellation reflects "real-life" because usually laboratories do not obtain fruit juices from one single area for their market control but they will always get a final product for analysis.

Although comparisons of juices and fresh fruits of the same origin lead to corresponding results it can not be excluded that post harvest treatment could influence IR in exceptional cases. But, as detailed information is lacking and it is assumed to play a minor role, it is not considered in this study.

Seasonal variations which can play an important role for δ^{2}H- and, to a minor degree, also δ^{13}C-values, e.g. in wine authentication (Christoph, Rossmann, & Voerkelius, 2003), can be neglected in this case as normally for orange juices and, especially for concentrates fruits are taken from several harvests or even several years.

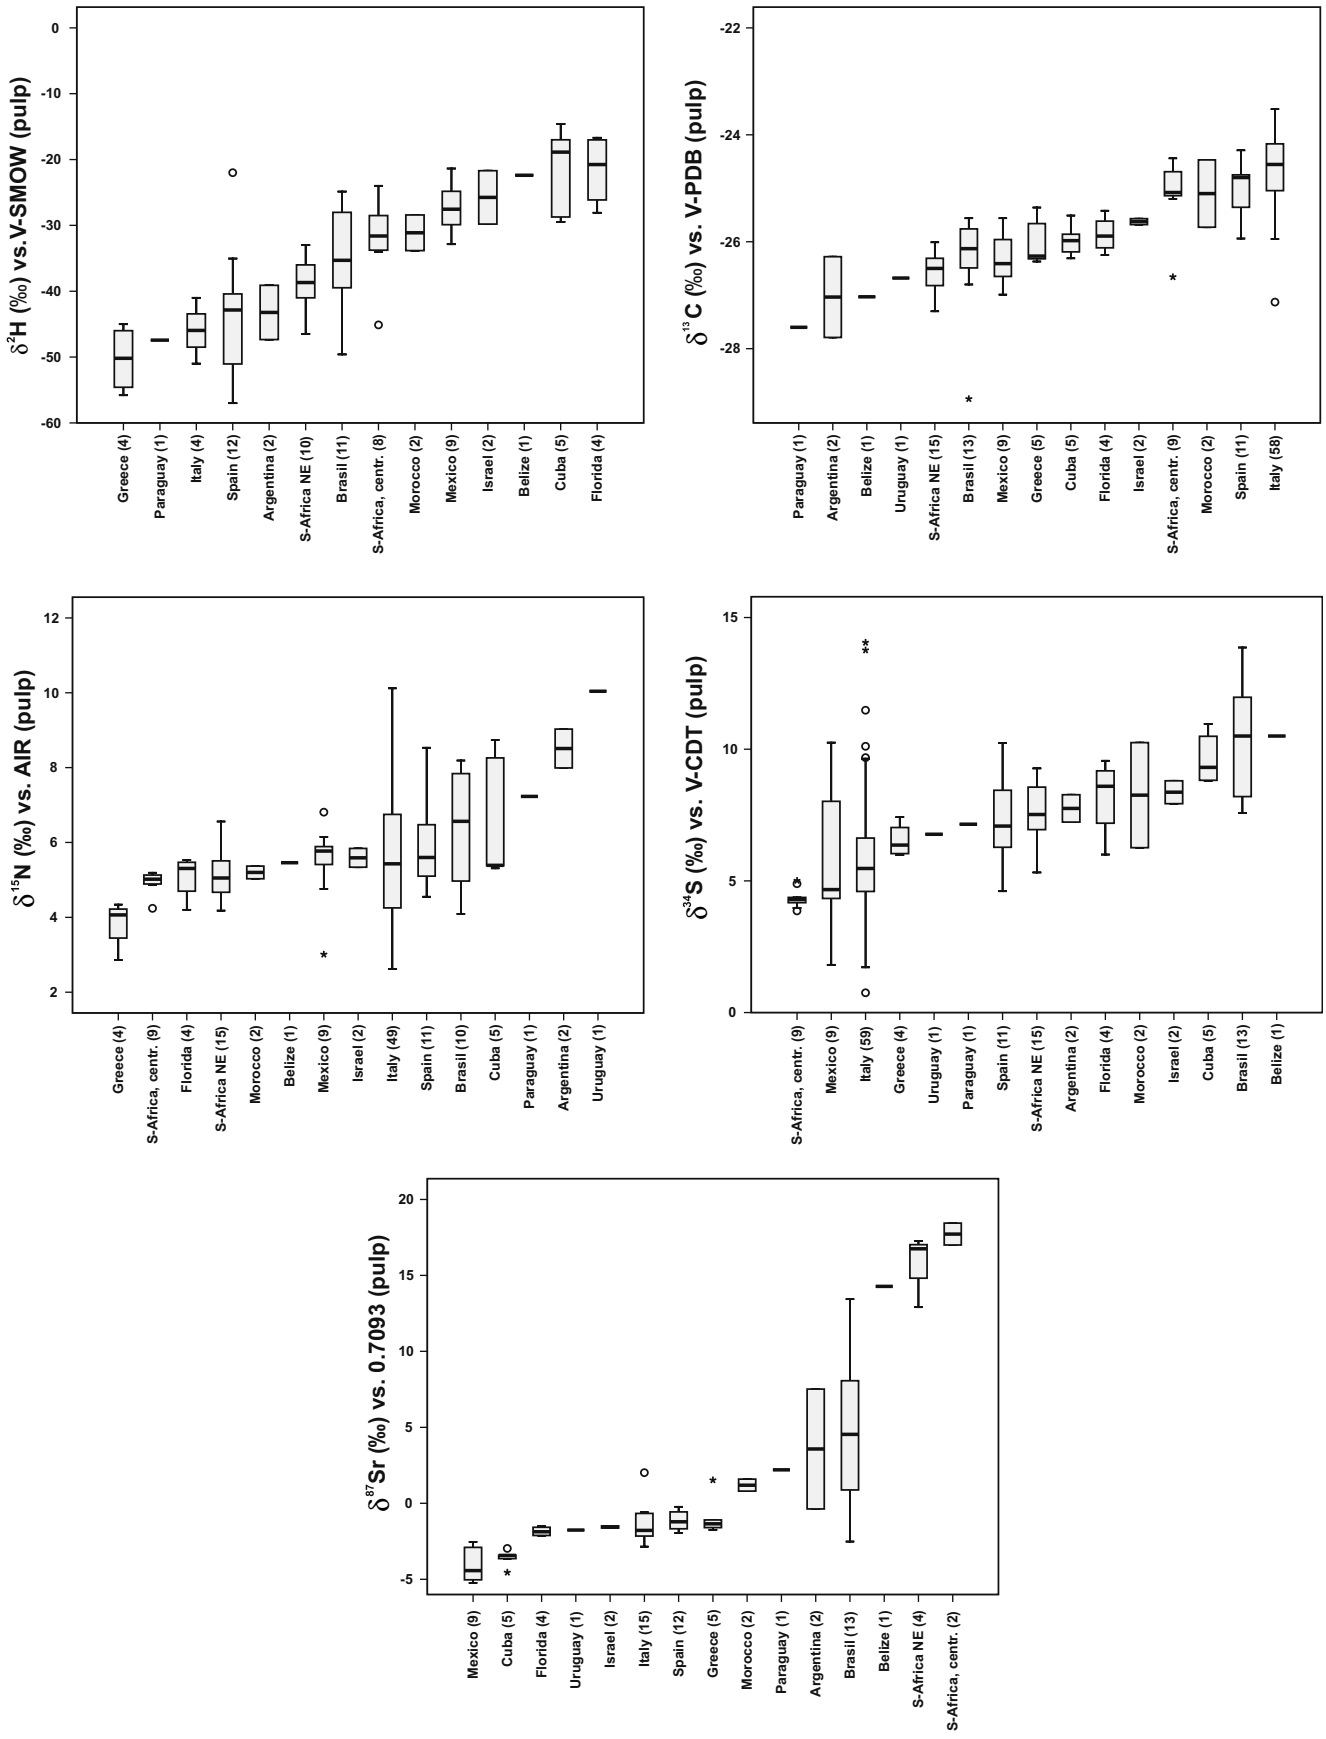

Fig. 2. All results displayed as boxplots. The boxes comprise the range between the first and the third quartile of the distribution. Box length is called interquartile range (IQR). The vertical lines (''whiskers") at the lower and upper end of the axis represent minimum and maximum values which are not considered as outliers or extreme-values. ○: outliers (data points between 1.5 and 3 times IQR lower than the first or higher than the third quartile). *: extreme-values (data points even lower or higher than outliers) The vertical line within the box is the median value of the distribution. Numbers in brackets are numbers of analysed samples.

Although all orange farms normally are located in warmer regions measured δ^2H-values of the pulps of our samples are not as similar as expected, but instead clear differences are observed. Like Heaton, Kelly, Hoogewerff, and Woolfe (2008), who analysed lipids in beef, we also find a correlation between δ^2H-values and latitude: δ^2H-values of the insoluble part of orange juices are getting more negative the further the sampling site is away from the equator. Consistently, highest values are found for samples from Cuba, Mexico and Florida, which are lying most closely to the equator. The next group are samples from Morocco showing slightly more negative values. The samples from Brazil show, expectedly, a very wide range of values as there are both samples from Northern and Southern regions included in this data set. Accordingly, samples from South-Africa show similar values as those from Brazil. Lowest δ^2H-values can be found in European samples from Italy, Spain and Greece.

In that oranges are C3-plants, δ^{13}C values of respective juices are low (−29‰ to −23‰). Nevertheless, the values show slight differences, possibly due to environmental conditions of the plants which shall not be discussed here. In any case, values can roughly be divided into three groups: the lowest values (−27.79‰ to −26.28‰) are found in the samples from Argentina, Belize and Paraguay; medium values (−28.94‰ to −25.36‰) in Brazilian-, Cuban-, Floridian-, Greek-, Mexican- and South-African (North-Eastern part) samples. Samples from South-Africa (central part) and Mediterranean countries show the highest values (−26.66‰ to −23.63‰).

Results of nitrogen isotope analysis show relatively wide overlaps between each single origin of the orange juices with values roughly between 5‰ and 8‰. While δ^{15}N values from Brazil, Cuba and Spain scatter widely and, therefore, are of limited use for origin assignments, samples from Florida, Mexico and Morocco group well within narrow ranges. Exceptions are samples from Argentina which show higher values (8–9‰) and Greek as well as Italian samples which display lower values (<4‰). The latter, after all knowledge, can be explained with application of synthetic nitrogen fertilizers. In contrast, rather high δ^{15}N values in juices from Argentina, Brazil or Cuba may be due to widespread use of organic manure.

The variation of sulphur IR in all samples of this study is covering a relatively small range (from ~0‰ to +14‰) compared to the δ^{34}S variation of vegetation worldwide (from −10‰ to +20‰) as shown by Krouse, Stewart, & Grinenko, 1991. In many cases, reasons for the observed variability can hardly be given because a combination of different sulphur sources may well lead to similar δ^{34}S values. Additionally, plants can take up sulphur from the

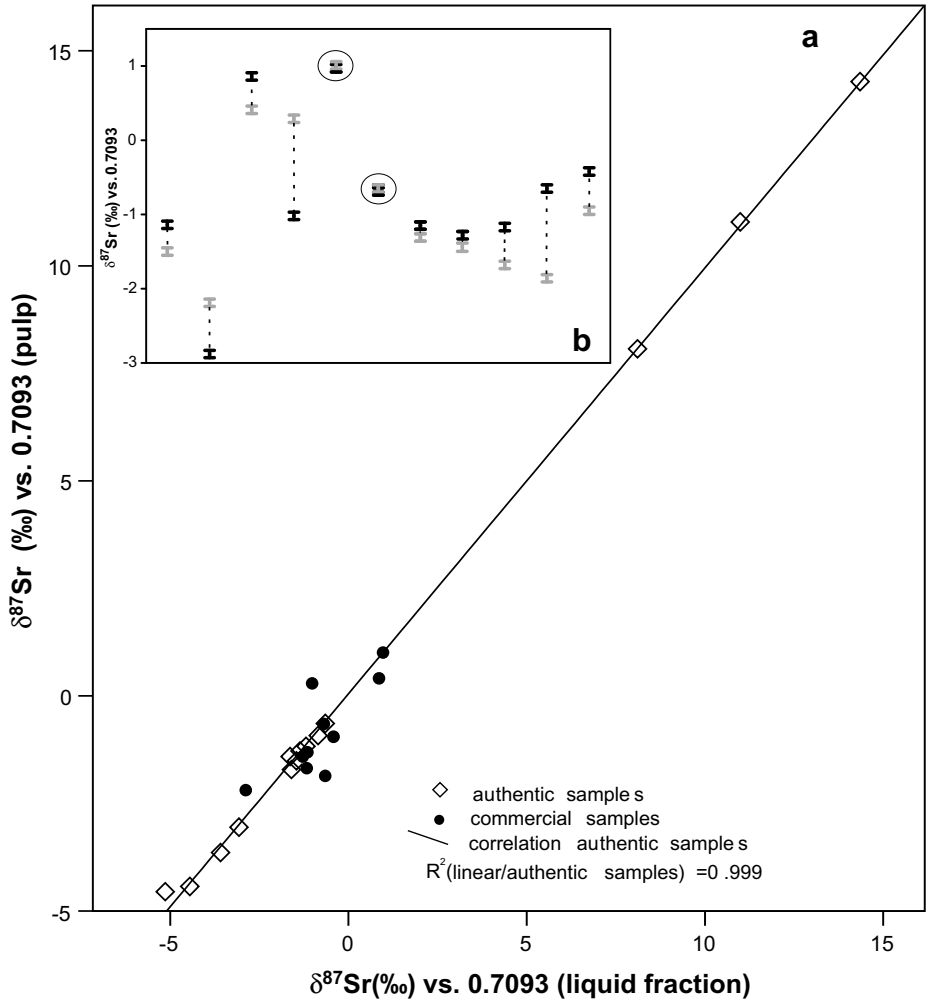

Fig. 3. (a) Comparison of δ^{87}Sr of the pulp and the liquid fraction of orange juices to detect illegal adding of foreign concentrate to single strength juices. Authentic single juice samples show identical values in both components (correlation coefficient R^2 = 0,999). Uncertainty ranges for δ^{87}Sr are much smaller than the symbol-size. (b) δ^{87}Sr values for commercial juice samples (black symbols: liquid, grey symbols: pulp) are displayed (dashed lines connect pulp-juice pairs of corresponding samples) to show the absolute differences between the fractions. The range of the symbols represents the measured value ± a combined uncertainty of 0.05‰. Samples with δ^{87}Sr-differences between pulp and liquid larger than the uncertainty are supposed to be adulterated, the two encircled samples are accepted as authentic.

atmosphere with their stomata. Hence, if there is a source of significant amounts of atmospheric sulphur, like for example, emissions of power plants, δ^{34}S-values in plants cannot be linked solely to the substrate but mixtures have to be considered.

Although results of δ^{34}S-analysis overlap to a certain degree, some sites of orange cultivation are defined very well. For example, Cuba and Mexico show overlapping values for IR of all other elements but can be discriminated by using sulphur isotopes. Obviously due to a seaspray-influence δ^{34}S-values in Cuban samples (8.8–10.96‰) are mostly higher than those from Mexico (1.81–10.25‰) where a volcanic influence is evident. Brazilian samples, mostly showing relatively higher values (7.6–13.7‰) can be well distinguished from those from Spain (4.6–10.2‰). In the case of Southern Africa it is even possible to discriminate within one country as the samples from the South-East display an average δ^{34}S-value of 7.6‰ whereas those from the central part are significantly lower with an average δ^{34}S-value of 4.3‰.

By referring to the prevailing geological conditions, Sr-isotopes often show a high potential for assigning the juice samples. The sampling sites of Cuba and Mexico show quite similar results with $^{87}Sr/^{86}Sr$ between 0.7056 and 0.7075. Sr-IR higher than 0.7065 are related to widespread Mesozoic (240–66 Ma) sediments, whereas $^{87}Sr/^{86}Sr$ below 0.7065 are due to basalts, gabbros or ultramafic rocks like serpentinites.

Both in Brazil ($^{87}Sr/^{86}Sr$: 0.7075–0.7188) and in South-Africa ($^{87}Sr/^{86}Sr$: 0.7185–0.7224) a Precambrian to Proterozoic basement (composed of 2500–600 Ma old granites and gneisses) is responsible for the mostly very high Sr-IR in the juice samples. The variation range of $^{87}Sr/^{86}Sr$ is due to heterogeneous compositions and varying grades of metamorphism of the lithology. Whereas in South-Africa large areas are exclusively dominated by Precambrian gneisses, the influence of Mesozoic sedimentary rocks and basalts is more important in Brazil – especially for the southern part in the Parana area – where also lower values (<0.7080) were found.

The $^{87}Sr/^{86}Sr$-values of the Spanish sampling sites are ranging from 0.70809 to 0.70913. This is explainable by the predominance of Mesozoic sediments in these regions.

Florida ($^{87}Sr/^{86}Sr$: 0.7078–0.7083) is completely covered with tertiary and quaternary sediments though the Sr-IR are quite similar to those we know from areas underlain by Mesozoic sediments like e.g. in Spain. An explanation for this is that the source area for the Floridian rocks, namely the youngest parts of the Appalachian Mountains is composed of Cretaceous sediments.

The Italian samples ($^{87}Sr/^{86}Sr$: 0.7073–0.7107) originate from Calabria and Sicily. In spite of this rather small area Sr-IR show – similar to the δ^{34}S values – a striking variation which is caused by very heterogeneous geological and lithological conditions in Southern Italy. There are both young basaltic rocks from the Etna volcanic complex leading to low IR, Mesozoic sediments resulting in intermediate values and crystalline rocks in Calabria with relatively high values. Large areas are covered with Cenozoic sediments consisting more or less of a mixture of these precursors. Therefore, this part of Italy is a striking example for a rather small region, where Sr IR (as well as δ^{34}S-values) can show significant variation over small distances.

A common procedure of adulteration in single strength orange juices is blending with rediluted concentrate in order to increase the production and/or to decrease the production costs. While this practice is allowed for juices made from concentrate it is illegal for single strength juices. Such kind of adulteration can be detected by analysis of both pulp and liquid fraction. Here, Sr-isotope analysis turned out to be most applicable. Authentic single strength juices do not show any significant difference in isotopic composition of Sr between soluble and insoluble components (Fig. 3a). From what is known about Sr-isotope analysis in plant material the fractions even should be identical whereas those of blended samples can show considerable differences of more than 1‰ (Fig. 3b). In routine work, samples where $^{87}Sr/^{86}Sr$ of liquid and pulp are equal within an uncertainty of ±0.05‰ are accepted as authentic but all samples with a larger inter-component-difference are judged as adulterated.

Although homogenisation between the liquids of the authentic juice and the added rediluted concentrate takes place to a certain degree, the strontium which is fixed in the pulp, (similar to cal-

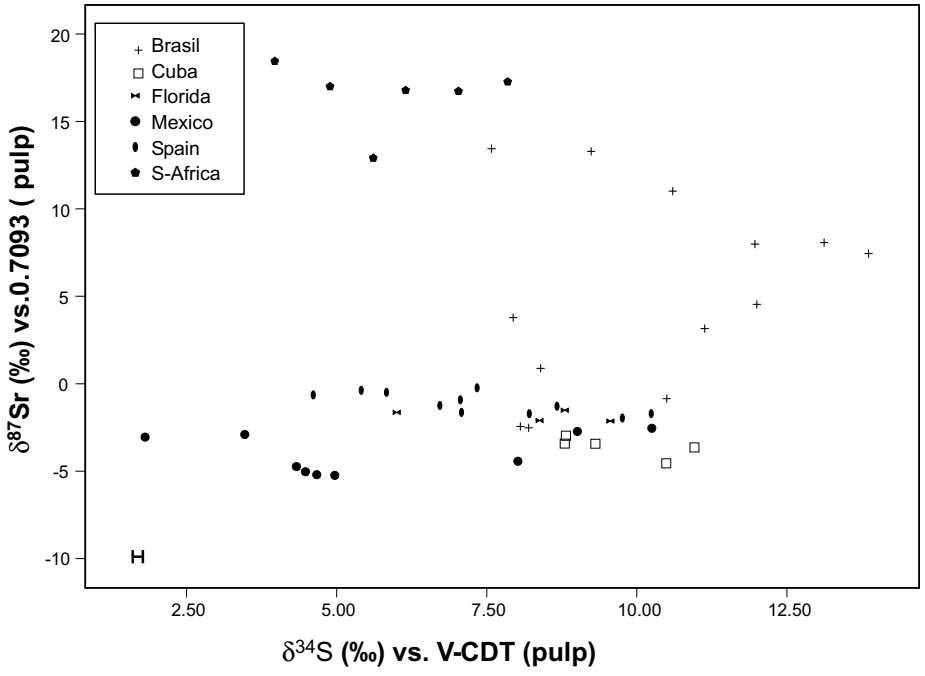

Fig. 4. δ^{87}Sr versus δ^{34}S in pulp of selected authentic orange juices. Vertical line indicates uncertainty range for δ^{34}S, uncertainty range for δ^{87}Sr is much smaller than the symbol-size.

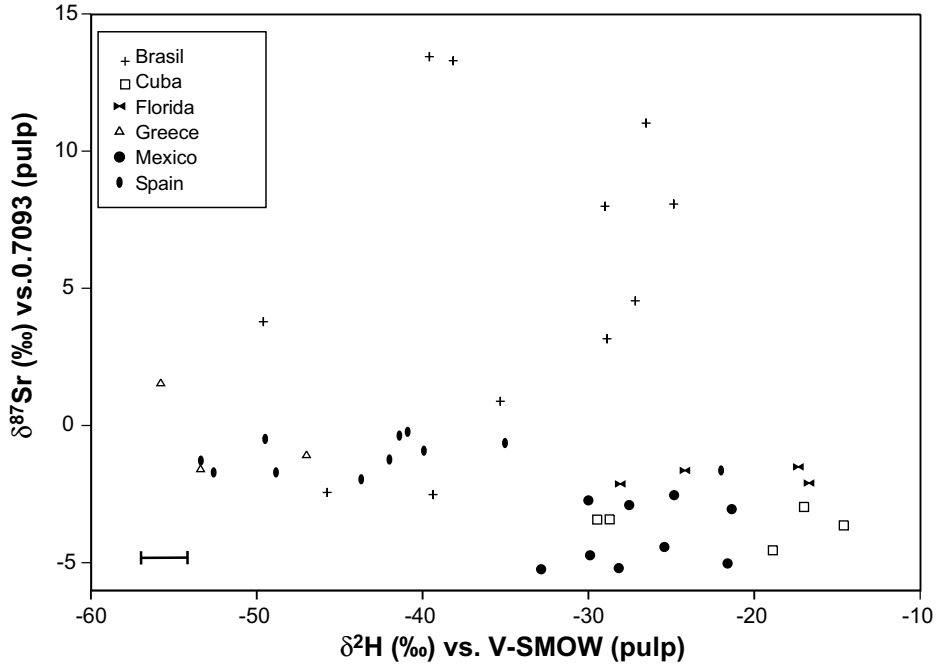

Fig. 5. $\delta^{87}Sr$ versus $\delta^{2}H$ in pulp of selected authentic orange juices. Vertical line indicates uncertainty range for $\delta^{2}H$, uncertainty range for $\delta^{87}Sr$ is much smaller than the symbol-size.

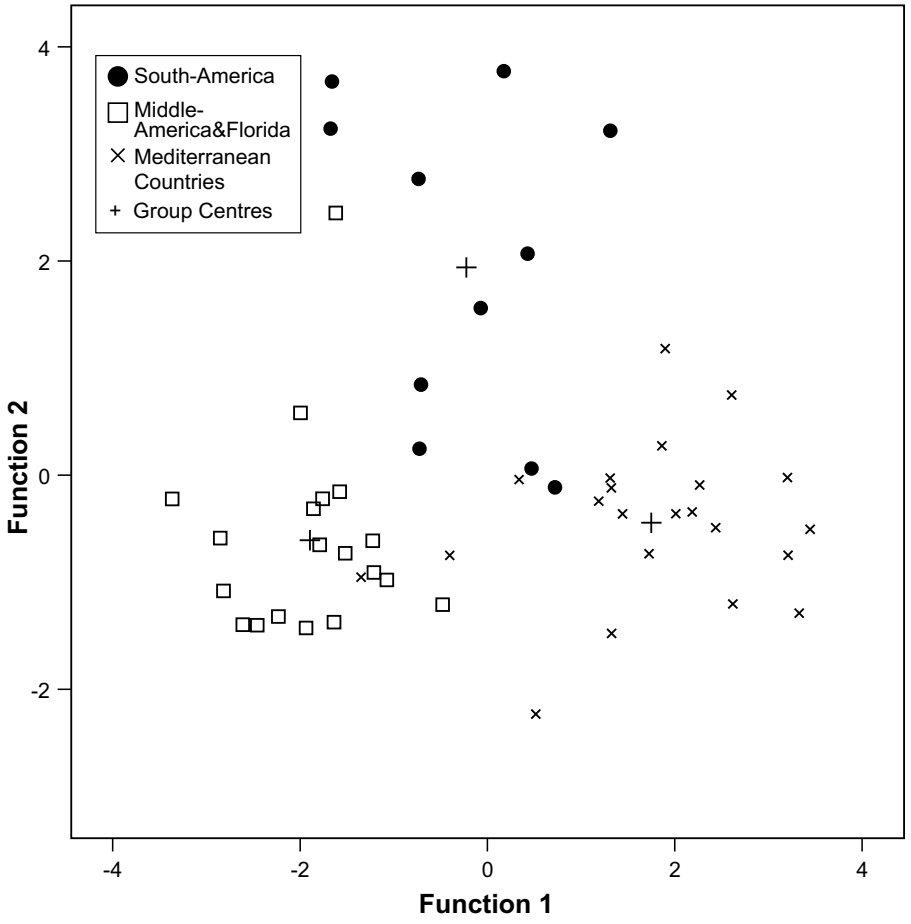

Fig. 6. Discriminant analysis for authentic orange juices samples worldwide. Employed variables are $\delta^{2}H$, $\delta^{13}C$, $\delta^{15}N$, $\delta^{34}S$, $\delta^{87}Sr$, all measured in pulp.

cium, e.g. as pectinate), remains unchanged. Therefore, it is still possible to detect such falsifications, basically using the pulp as "internal standard". However, it is only possible to quantify the amounts of added material when the concentrations of both components are known which is normally not the case. Statements about the different origins of the mixtures cannot definitely be made but sometimes be presumed if values of authentic samples are considered.

The potential of applying a multi-element approach is demonstrated in Figs. 4 and 5. Although it is sometimes possible to ascertain the geographic origin of a sample by considering only IR of one element, in most cases it is advisable or even necessary to take into account all mentioned isotopic parameters to come to an unambiguous conclusion. Additionally, it is relatively easy to falsify one parameter to pretend another origin but it is nearly impossible and – moreover – extremely costly to "adjust" several or all parameters isotopically.

For example, juices from Mexico and Cuba cannot be distinguished by means of Sr- but very well by considering S-isotopes (Fig. 4). Spanish samples can be clearly separated from Florida, Mexico and Cuba by combining $\delta^{87}Sr$ with $\delta^{2}H$ (Fig. 5) and Brazilian samples can be separated from Spanish samples – a common problem in routine – by applying a combination of $\delta^{87}Sr$, $\delta^{34}S$ and $\delta 2H$. Apart from South-African samples which can be separated from almost all others by only applying Sr-IR it can be clearly seen from the figures that an overlap between single origins exists to a certain degree. This limitation cannot be completely overcome but, however, this factor can be strongly minimised with increasing number of reference samples and by applying a multi-element-approach.

With increasing numbers of parameters evaluation and interpretation of data becomes more difficult. Therefore, we applied discriminant analysis where a classification of groups (=origins) is made which are defined by several variables (=IR). In a first step adequate parameters and discriminant functions have to be figured out which lead to a best possible separation within a data set of authentic samples. In a second step – which is not carried out here – unknown samples can be introduced in the model and are allocated to the most probable group (For further basics concerning multivariate statistics and discriminant analysis see Backhaus, Erichson, Plinke, & Weiber, 2006). Software used for statistical data evaluation here is SPSS 15.0 for windows.

A precondition for applying discriminant analysis is a homogeneous distribution of samples per group. As this is not given in our data set – on the one hand we have only one sample from Belize, on the other hand for some parameters we have over fifty samples from Italy – we split our data into three very broad groups: Mediterranean countries (Greece, Italy, Morocco, Spain), South-America (Argentina, Brazil, Paraguay, Uruguay) and Middle-America with Florida (Belize, Cuba, Mexico, Florida). Employed variables are $\delta^{2}H$, $\delta^{13}C$, $\delta^{15}N$ and $\delta^{87}Sr$, all of pulp. The result can be seen in Fig. 6. For function 1 $\delta^{2}H$ and for function 2 $\delta^{87}Sr$ proved to be the most discriminatory parameters. Function 1 accounts for 72.1%, function 2 for 27.9% of the variation. In the cross validation test, performed by the software for every sample (each sample is left out and treated as unknown), 88.5% are classified correctly.

This kind of evaluation can also be useful to distinguish between subgroups as it has been done within European regions (Fig. 7). In this case cross validation led to correct classification of 75% of the samples. Although we know that the number of sam-

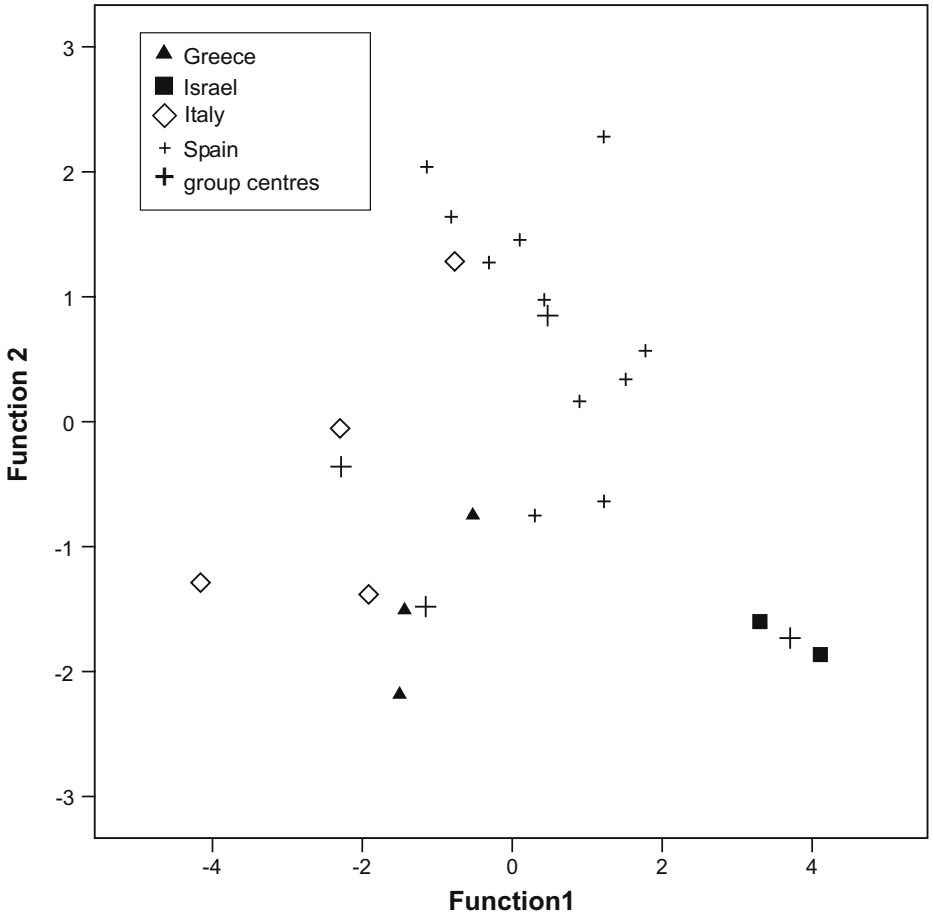

Fig. 7. Discriminant analysis for authentic Mediterranean orange juices samples. Employed variables are $\delta^{2}H$, $\delta^{13}C$, $\delta^{15}N$, $\delta^{34}S$, $\delta^{87}Sr$, all measured in pulp.

ples is much too low for an unambiguous classification, first results are looking very promising. A further improvement is expected with an increasing number of data.

However, discriminant analysis always has to be handled with care for these kind of investigations. No analytical uncertainties are taken into account and the addition of new authentic data might change the picture dramatically. Therefore, discriminant analysis provides a useful tool to get a rough idea about the provenance of a sample, but in order to avoid wrong conclusions it is essential to regard every sample individually e.g. in case of an expertise.

6. Conclusion

Within the presented project it could be clearly shown that both established and newly developed methods (i.e. sulphur- and strontium-isotope analysis as well as a combination of all investigated parameters) proved very useful for determination and verification of the geographical origin of orange juices. As in this study the regional distribution of the samples has been very patchy it is inevitable to extend the data set especially for regions which are very heterogeneous concerning climate and lithology or are relevant in practice, respectively (e.g. Brazil, Spain, Italy, etc.). Additionally, data of some important orange producers like e.g. India, China or Portugal are still missing. The collection and analysis of samples from these countries will be another future task to obtain a data set as complete as possible. It is also required to have a higher amount of authentic samples to improve further statistical evaluations.

Usually, it is not the task of the control institution to find out about the origin of the orange or the juice thereof – which would be much more difficult – but the laboratory has to confirm or to reject a declared origin. Often this problem can readily be solved by analysing the IR of the light elements. But in those cases where the results remain ambiguous strontium-isotope analysis should be performed additionally. Thus with the capability of combining several independent parameters a solid tool has been developed which allows a correct assignment of most samples.

Interpretation and evaluation of the data presented here base firstly on regional conditions influencing the isotopic parameter and secondly on results of authentic sample material. The next step would be the development of a model which allows predictions of isotope values for certain regions. This is currently done in another EU-project called TRACE. First results for different parameters have been achieved so far, e.g. for $^{87}Sr/^{86}Sr$ in mineral waters (Voerkelius et al., in preparation) or for stable IR in lamb meat (Camin et al., 2007). The planned extension to several further food commodities will be of great use also for problems concerning the origin of orange juices.

Acknowledgements

The authors would like to thank the European Union for funding and the Schutzgemeinschaft der Fruchtsaftindustrie (SGF), especially Dr. W. Rieth and Mr. K. Schulz for the coordination of the project "Pure Juice" (Projekt Nr. G6RD-CT-2002-00760). Additionally, we are grateful to two reviewers for very constructive remarks. S. Rummel would like to thank Stefan Gottschaller for careful proofreading.

Angerosa et al., 1999) found that both the $^{13}C/^{12}C$ and $^{18}O/^{16}O$ of olive oils from Italy, Greece, Spain, Tunisia, Morocco and Turkey change according to the latitude, suggesting as co-factors of variability the distance from the sea and environmental conditions during the growing of plants (water stress, atmospheric moisture and temperature). Finally, Aramendia et al. (2007) observed that the $^{18}O/^{16}O$ values of bulk olive oils were influenced by the variety of the olives and by their geographical origin, but not by the altitude, ripening degree and harvesting date of olives. To our knowledge, no papers are available in the literature regarding the isotopic ratio of deuterium/hydrogen (D/H) in olive oil.

With regard to the mineral content of olive oil, interest initially focused on the presence of toxic lead or cadmium elements and of copper and nickel as catalysts for oxidative reactions affecting the flavour and stability of oils (De Souza et al., 2005). In the last few years, studies have also been carried out to verify whether the mineral profile could be a useful marker of geographical origin, cultivar, harvesting period and adulteration with cheaper vegetable oils (Benincasa, Lewis, Perri, Sindona, & Tagarelli, 2007; Cindric, Zeiner, & Steffan, 2007; Dugo, La Pera, Giuffrida, Salvo, & Lo Turco, 2004). The high organic load and viscosity and very small mineral content of olive oils were a handicap to the development of a simple and effective preparation method and subsequent analysis. Several approaches were used, such as emulsion in water with the aid of some surfactant or solvent (Anthemidis, Arvanitidis, & Stratis, 2005; Castillo, Jimenez, & Ebdon, 1999; De Souza et al., 2005; Jimenez, Velarte, & Castillo, 2003), liquid–liquid extraction (Dugo et al., 2004), wet ashing (Lo Coco et al., 2003) and total microwave digestion (Benincasa et al., 2007; Cindric et al., 2007; Zeiner, Steffan, & Cindric, 2005). Of the analytical techniques, the following were more frequently applied: electrothermal and graphite furnace atomic absorption spectrophotometry (Cindric et al., 2007; Dugo et al., 2004), derivative potentiometric stripping (Dugo et al., 2004; Lo Coco et al., 2003) and, increasingly in the last few years, inductively coupled plasma–optical emission spectrometry (Anthemidis et al., 2005; Zeiner et al., 2005; Cindric et al., 2007) and plasma–mass spectrometry (ICP–MS) (Benincasa et al., 2007; Castillo et al., 1999; Jimenez et al., 2003).

The present work focuses on the $^{13}C/^{12}C$ in bulk oil and extracted glycerol and $^{18}O/^{16}O$ in glycerol of 539 authentic PDO and PGI extra-virgin olive oils produced from 2000 to 2005 throughout Italy, sampled by the Ministry of Agricultural, Food and Forestry Policy and analysed to establish an yearly databank of isotopic reference values. This was done to evaluate the geographic authenticity of commercial samples, as has been done since 1987 for wine (EEC Reg. No. 2729/2000). Moreover, the mineral composition, the $^{18}O/^{16}O$ and, for the first time, the D/H in bulk oil of around one hundred 2005 extra-virgin olive oils are shown and discussed for their variability.

2. Materials and methods

2.1. Sampling

Authentic and well settled extra-virgin olive oils ($N = 539$) were officially collected by the Ministry of Agricultural, Food and Forestry Policy from 2000 to 2005 in the production regions of the only one PGI and the 34 out of 37 PDOs recognised at the present in Italy, according to the EC Reg. No. 510/2006. Traditionally, each PDO defines multi-varietal oils (e.g. PDO Chianti can include up to 76 varieties). The sampling tried to cover all the harvest time, the variability of the multi-varietal blends and the production area. $^{13}C/^{12}C$ in bulk olive oil and the extracted glycerol, as well as $^{18}O/^{16}O$ in the glycerol, were measured in 2000 ($N = 82$), 2001 (102), 2002 (66), 2003 (95), 2004 (58) and 2005 (136) samples. In 2005, measurement of the $^{18}O/^{16}O$ and D/H of bulk olive oil also took place. Finally, the mineral content of a selection of 99 samples of 2005 was measured.

2.2. Chemicals

2.2.1. Isotopes

All the solutions were prepared with Milli-Q water (18M Ωcm resistivity; Millipore, Bedford, MA). Sodium hydroxide 2N (RP grade; Carlo Erba Reagents, Milan, Italy), hydrochloric acid at 37% (RP; Carlo Erba Reagents), diethyl ether (Normapur; VWR International, Leuven, Belgium), ethanol at 96% (Sigma–Aldrich GmbH, Steinheim, Germany), tin and silver capsules (Säntis analytical AG, Teufen, Switzerland), P_2O_5 at 97% (Sigma–Aldrich GmbH) and nitrogen gas at 99.999% (Linde Gas, Milan, Italy) were used.

The isotopic values (expressed in $\delta‰$, as described below) were calculated against working in-house standards (commercial olive oil and glycerol), calibrated against international reference materials: fuel oil NBS-22 (IAEA-International Atomic Energy Agency, Vienna, Austria) and sugar IAEA-CH-6 (IAEA) for $^{13}C/^{12}C$ measurement; IAEA-CH-6 (IAEA) for $^{18}O/^{16}O$ and NBS-22 for D/H. Whereas in the past the data regarding $^{18}O/^{16}O$ in glycerol were usually calibrated against glycerol used in the European project SMT4-CT98-2236 (Camin et al., 2004), in this work they were calibrated against the IAEA-CH6 value ($\delta^{18}O = +36.4‰$ vs. V-SMOW) assigned since 2005 (Boschetti & Iacumin, 2005) and accepted in the European TRACE project (contract No. FP6-2003-FOOD-2-A 006942).

The isotopic values of the aforementioned international reference materials and therefore also of the samples were expressed in $\delta‰$ vs. V-PDB (Vienna - Pee Dee Belemnitella) for $\delta^{13}C$ and V-SMOW (Vienna – standard mean ocean water) for $\delta^{18}O$ and δD, according to the following formula: $[(Rs-Rstd)/Rstd] \times 1000$, where Rs is the isotope ratio measured for the sample and Rstd is the isotope ratio of the international standard.

2.2.2. Elements

Nitric acid at 69.5% (Superpure; Merck, Darmastadt, Germany), hydrochloric acid at 37% (ACS; Riedel-deHaën, Seelze, Germany), ICP Multielement Standard Solution VI (Merck), Multielement Calibration Standard 1 (Agilent Technologies, Santa Clara, CA, USA), and Cesium 1000 ug/ml (Ultra Scientific, Bologna, Italy) were used. Standard solutions were diluted and stabilized with the addition of a 1% HNO_3 and 0.2% HCl solution. SRM 2387 'Peanut butter' (National Institute of Standard and Technologies, Gaithersburg, MD, USA) was used as standard reference material to check the accuracy of the method. Sc 0.1 mg/L, Rh 0.1 mg/L and Tb 0.1 mg/L were used as internal standards. All the glassware was rinsed with nitric acid (5% v/v) and twice with milli-Q water before use.

2.3. Apparatus

2.3.1. Isotopes

The analysis was performed using an isotopic ratio mass spectrometer (IRMS) (Finnigan DELTA XP, Thermo Scientific, Bremen, Germany) coupled with an Elemental Analyser (Flash EA^{TM}1112, Thermo Scientific,) for $^{13}C/^{12}C$ measurement and with a Pyrolyser (Finnigan^{TM}TC/EA, high temperature conversion elemental analyzer, Thermo Scientific,) for D/H and $^{18}O/^{16}O$ measurement. To separate the gases, the Elemental Analyser was supplied with a Porapack QS (3 m; 6 × 4 mm, OD/ID) GC column and the Pyrolyser with a Molecular Sieve 5A (0.6 m) GC column. The devices were equipped with an autosampler (Finnigan AS 200, Thermo Scientific)

and interfaced with the IRMS through a dilutor (Conflo III, Thermo Scientific) dosing the sample and reference gases.

2.3.2. Elements

The analysis was performed using an Agilent 7500ce ICP–MS (Agilent Technologies, Tokyo, Japan) equipped with an autosampler ASX-520 (Cetac Technologies Inc., Omaha, NE, USA). After extraction, the samples were introduced into a Scott spray chamber using a MicroMist nebulizer and then into a Fassel type torch. An octopole reaction system (ORS) using He and H_2 as collision and reaction gases, respectively, was used to remove polyatomic interferences.

2.4. Sample preparation and analysis

2.4.1. Isotopes

Glycerol was obtained through hydrolysis of 20 ml of oil in NaOH, acidification of the solution, extraction of fatty acids and purification by under vacuum distillation, according to the method described for fat from cheese in Camin et al. (2004).

Aliquots of 0.3 mg of sample were weighed in tin capsules for determination of $^{13}C/^{12}C$ and silver capsules for quantification of $^{18}O/^{16}O$ and $^{2}H/^{1}H$.

For $^{13}C/^{12}C$, the precision of measurement, expressed as standard deviation when measuring an oil sample 10 times, was 0.1‰.

For $^{18}O/^{16}O$ and D/H analysis, the samples were stored in a desiccator above P_2O_5 for at least 24 h, then weighed into silver capsules and put into the auto-sampler equipped with a suitable cover. During measurement, dryness was guaranteed by flushing nitrogen continuously over the samples. The pyrolyser temperature was 1450 °C. The D/H and $^{18}O/^{16}O$ ratios of bulk olive oils were measured simultaneously in one run. The IRMS measured first D/H and then, following the magnet jump, $^{18}O/^{16}O$, taking about 10 min for each sample. Before measuring D/H, the H3 factor, which allows correction of the contribution of [H3]+ to the m/z 3 signal (Sessions, Burgoyne, & Hayes, 2001), was verified to be lower than 9. The precision of measurement, expressed as standard deviation when measuring an oil sample 10 times, was 0.3‰ for $^{18}O/^{16}O$ and 2‰ for D/H.

2.4.2. Elements

About 15 g of sample were weighed into a 50 ml conical vial of polypropylene (PP) and 15 ml of 1% HNO_3/0.2% HCl water solution was added. The mixture was thoroughly shaken for 30 s using a vortex mixer and immediately placed in an ultrasonic bath (170 W × 5 min) to extract the trace elements from the oil to the acid solution. The mixture was centrifuged (4000 rpm × 5 min) to separate the two phases. The upper oil phase was accurately removed by aspiration and the lower aqueous phase transferred into a clean PP vial and subjected to ICP–MS analysis of Li, B, Na, Mg, K, Ca, Mn, Co, Cu, Ga, Se, Rb, Sr, Mo, Cd, Cs, Ba, La, Ce, Nd, Sm, Eu, Yb, Tl, Pb, and U. Isotopes and ORS gases are shown in Table 1. Extraction and analysis was carried out in duplicate. The accuracy of the extraction method was evaluated in a natural oil sample spiked with a defined aliquot of the reference material (0.6 g of 'semi-solid' peanut butter mixed into 15 g of oil until thoroughly combined). The oil and fortified mixture were both extracted and analysed 10 times. Recoveries were calculated on the difference of the mean content of the spiked and the un-spiked samples. The detection limit (DL) of each element was calculated as three times the standard deviation of the signal of the blank sample, extracted and analysed ten times, whereas the blank sample was prepared using Milli-Q water to substitute the oil sample in the extraction step. Precision (RSD%) was evaluated by preparing and analyzing an oil sample 10 times. DL and RSD% are shown in Table 1.

Different letters correspond to significantly different median values ($p < 0.001$) *N* = number of samples.

2.5. Statistical analysis

The data were statistically evaluated according to the procedures of the software Statistica 7.1 (StatSoft Italia srl, Padua, Italy). Non parametric tests (Kruskall–Wallis and multiple bilateral comparison) were applied because of the low and unequal numbers of samples per group and the not always normal distribution (Soliani, 2003).

3. Results and discussion

3.1. Stable isotope ratios

In Table 2 the median, minimum and maximum values of bulk and glycerol $\delta^{13}C$ and of glycerol $\delta^{18}O$ were summarised for 2000–2004 production and the different Italian regions listed according to the latitude. $\delta^{18}O$ was measured in the glycerol instead of in the bulk oil because the former was assumed to be more closely related to the isotopic characteristics of ground water (Schmidt, Werner, & Rossmann, 2001).

The $\delta^{13}C$ values measured in glycerol were always lower than in bulk olive oil, with a mean difference ± standard deviation of 1.87 ± 0.67, confirming previous results (Zhang, Buddrus, Trierweiler, & Martin, 1998). Moreover, $\delta^{13}C_{glycerol}$ and $\delta^{13}C_{bulk}$ of the 403 samples were significantly correlated ($\delta^{13}C_{glycerol} = 1.1114 \times \delta^{13}C_{bulk} + 1.4057$; $p < 0.001$). If we consider 2000, 2001, 2002 and 2004 individually, the intercepts ranged from −0.3075 to +6.3585 and the slopes from 1.0435 to 1.2841. The correlation for 2003, also significant, showed particular and extreme values, both as regards intercept (−7.0134) and slope (0.8162).

Significant differences ($p < 0.001$) were found among the years of harvest (Table 2). In particular 2003, well-known as one of the hottest years in the last few decades in Italy, was different ($p < 0.001$) for at least one isotopic parameter from all the other years, showing enrichment in the heavier isotopomeres.

All the isotopic parameters showed a trend for the values to increase from Trentino to Sicily in all years (Table 2), with this being less evident in 2003. This trend, already observed in wine (Rossmann et al., 1996; Rossmann et al., 1999), is probably positively related to vicinity to the sea and dryness of the climate and negatively to latitude, as suggested by some authors (Angerosa et al., 1999; Bréas et al., 1998). Indeed, the $\delta^{13}C$ values of plant compounds are influenced by the availability of water, relative humidity and temperature, which control stomatal aperture and the internal CO_2 concentration in the leaf (O'Leary, 1995). The $\delta^{18}O$ of carbohydrates and their immediate descendants, such as glycerol, is correlated to the $\delta^{18}O$ of leaf water (Schmidt et al., 2001), which reflects the isotopic composition of groundwater and average precipitation in the region – mainly related to latitude, distance from the sea and altitude (Clark & Fritz, 1997) – and the extent of evapotranspiration, mainly influenced by humidity and temperature (Rossmann et al., 1999).

For statistical evaluation, we grouped the regions into four clusters on the basis of their latitude and the similarity of their isotopic ratios: North (Trentino, Veneto, Lombardia, Emilia Romagna), Centre (Liguria, Tuscany, Umbria, Abruzzo, Lazio), South-1 (Campania, Apulia) and South-2 (Calabria, Sicily). Applying the non parametric test of Kruskall–Wallis (Fig. 1), olive oil from Northern Italy showed isotopic values for at least one parameter significantly lower ($p < 0.01$) than for the South-2, Centre and South-1 in 5, 3 and 2 years respectively, out of the 5 years. Central Italy was never separated from South-1, whereas it was different from South-2 in two out of 5 years. The two southern macro areas could be distinguished from one another in three out of 5 years.

Comparing the few PDOs with at least five samples within each region and each year, we observed some significant differences ($p < 0.01$). In Lazio, the two 'Canino' and 'Sabina' PDOs were significantly different in 2000, 2002 and 2003 for $\delta^{13}C$ and in 2001 for $\delta^{18}O$. This could be ascribed to the inland location of the production area of 'Sabina', nearer Rieti than the 'Canino' area, closer to the sea near Tuscany, as well as to the possible effect of the prevailing olive cultivar (Aramendia et al., 2007). In Abruzzo and Apulia the comparison was only possible for one year (2000 and 2001, respectively). Significant differences in the $\delta^{13}C$ values were observed between 'Aprutino Pescarese' and 'Colline Teatine' in Abruzzo and between 'Dauno' and 'Collina di Brindisi' in Apulia.

For the 2005 samples, along with the aforementioned parameters, the $\delta^{18}O$ and δD in bulk oil were also measured (Table 3). δD was investigated as a possible additional parameter for the

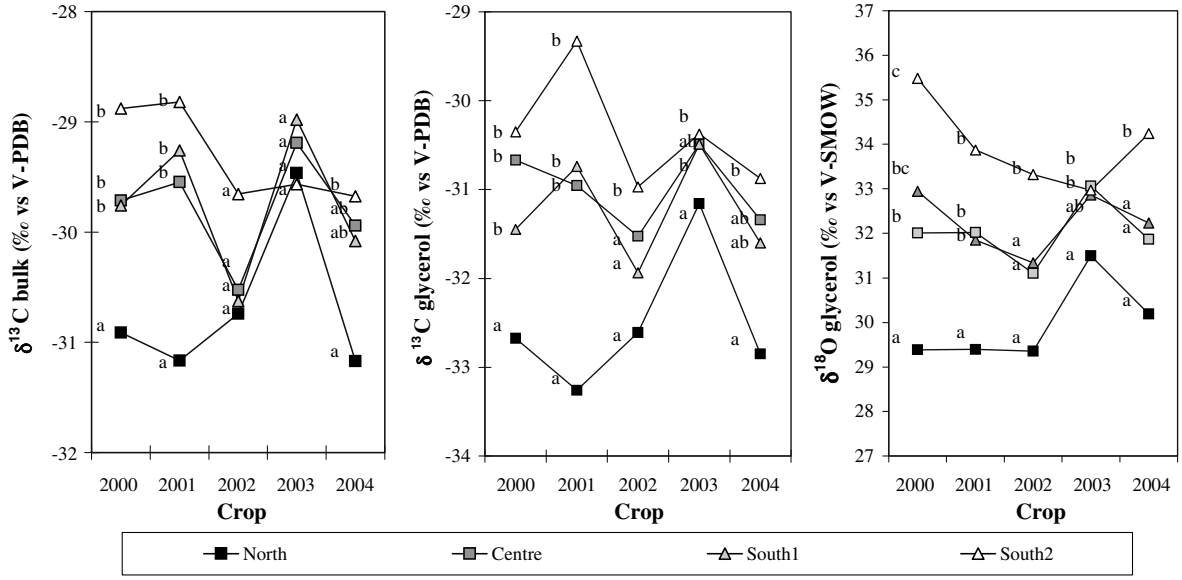

Fig. 1. Median values of the $\delta^{13}C$ (bulk olive oil and glycerol) and the $\delta^{18}O$ (glycerol) for North, Centre, South-1 and South-2 Italian olive oils (2000–2004) and results of the non-parametric statistical test (Kruskall–Wallis' test) among North, Centre, South-1 and South-2 Italian olive oils; different letters correspond to significantly different median values ($p < 0.01$).

Table 3
Median values of $\delta^{13}C$ (bulk olive oil and glycerol), $\delta^{18}O$ (bulk and glycerol) and 8D (bulk oil) for North, Centre, South-1 and South-2 Italian olive oils produced in 2005 and results of the non-parametric statistical test (KruskalWallis' test)

	N	$\delta^{13}C$ bulk (‰ vs. V-PDB)			$\delta^{13}C$ glycerol (‰ vs. V-PDB)			$\delta^{18}O$ glycerol (‰ vs. V-SMOW)			$\delta^{18}O$ bulk (‰ vs. V-SMOW)			$\delta^{2}H$ bulk (‰ vs. V-SMOW)		
		Median	Minimum	Maximum	Median	Minimum	Maximum	Median	Minimum	Maximum	Median	Minimum	Maximum	Median	Minimum	Maximum

Different letters correspond to significantly different median values $p < 0.01$.

characterisation of geographical origin, being influenced in plant products by the isotopic composition of the primary hydrogen source (source water through the leaf water) and by the geographical and climatic factors mentioned above for $\delta^{18}O$, together with their biosynthetic pathways (Schmidt, Werner, & Eisenreich, 2003).

As compared to previous years (Fig. 1), the median values of the isotopic parameters were lower, as a consequence of the rainy and cold climate characterising 2005.

The $\delta^{18}O$ values measured in bulk were significantly correlated with those in glycerol ($p < 0.001$): $\delta^{18}O_{bulk} = 0.837 * \delta^{18}O_{glycerol} - 3.2213$ ($R^2 = 0.8772$), the first always being lower, with a mean difference ± standard deviation of 8.15‰ ± 0.66.

The $\delta^{18}O$ and δD values in bulk olive oil were also correlated ($p < 0{,}001$), as happens in water (Clark & Fritz, 1997); the correlation equation is $\delta^{2}H_{bulk} = (-208{,}1 + 2{,}5091) \times \delta^{18}O_{bulk}$, but the R^2 value (0.4582) is low.

The $\delta^{18}O$ values of bulk olive oil showed the same capability as the $\delta^{18}O$ of glycerol in terms of distinguishing the four regional groups. The δD values showed similar capability to that of $\delta^{13}C$ and $\delta^{18}O$ to differentiate the four groups.

3.2. Mineral composition

The recoveries of the extraction method evaluated with the NIST sample were generally satisfactory for all the certified elements, being 82% for Zn, 84% for Mn, 90% for Ca, 92% for Mg, 95% for K, and 101 for Na. The precision of the analytical method ranged from 13% to 27% for the different elements (Table 1). Such values can be deemed satisfactory, considering the very low content of elements in olive oil.

Tables 1 and 4 show the concentration of the elements quantifiable over the DL in at least 10 samples. The content of Mo, Cd and Tl were below the respective DLs (0.18, 0.02 and 0.005 μg/kg respectively) in all the samples. Ga was found in quantifiable amounts (DL = 0.004 μg/kg) only in one Terra di Bari PDO oil (0.023 μg/kg). B was found in measurable amounts (DL = 1 μg/kg) only in five samples, with a maximum of 12.2 μg/kg for a Monte Etna PDO oil, in agreement with the results shown by Eschnauer for wines from grapes grown in volcanic areas (Eschnauer, 1982). Se was only detectable (DL = 0.014 μg/kg) in seven samples, with a maximum of 0.021 μg/kg, far below the content reported by Dugo et al. (2004), for 50 Sicilian oils analysed using cathodic stripping potentiometry and by Benincasa et al. (2007) for 36 oils from 4 Central–Southern Italian regions digested by microwave and analysed using ICP–MS. Nd was only quantifiable (DL = 0.023 μg/kg) in nine samples, with a maximum value of 0.932 μg/kg in a Terra di Bari PDO oil.

Tables 1 and 4 show the distribution of the mineral element content in the total sampling and for each PDO. As regards the content of Li, Rb, Cs, La, Ce and Yb shown in Table 1, we could not find other data for extra-virgin olive oils in the literature, while Mg, Ca, Mn, Sr, Sm, Eu and U were found in the concentration ranges reported in the literature. Na and K were measured in notably lower and higher amounts respectively, as compared to olive oils from Croatia analysed by Zeiner et al. (2005), and Cindric et al. (2007). The Co and Cu content were also in the ranges reported in literature, with the exclusion of the maximum values found for some of the aforementioned Croatian oils. The Ba content agreed with that found by Jimenez et al. (2003), and Anthemidis et al. (2005), but was far below the maximum content (700 μg/kg) measured by Castillo et al. (1999), using a semi-quantitative ICP–MS approach with direct emulsion nebulisation of the oil sample. The Pb content was low and always below the legal limits (0.1 mg/kg, EEC Reg. No. 466/2001), probably as a consequence of the increasingly widespread use of adequate equipment throughout the olive oil processing chain.

Table 4
Mineral content of well settled 2005 extra-virgin Italian olive oils displayed for region and for PDO or PGI

Comparison between the mineral content of the individual PDOs was not an aim of this first work carried out on Italian extra-virgin olive oils in agreement with the Italian Ministry of Agricultural, Food and Forestry Policy. At all events – taking into account only the 3 PDOs with at least 10 samples each, namely Garda, Umbria and Terra di Bari – a trend toward higher Mg, Ca, Mn and Sr content would seem to characterise the Garda oils, especially if compared to the Umbrian oils, possibly related to the soil of the region, mainly originating from dolomitic limestone rock.

4. Conclusions

This paper, shows the results of the largest investigation ever carried out on multi-element stable isotope ratio and mineral composition using IRMS and ICP–MS in authentic PDO and PGI Italian extra-virgin olive oils. The study was done in collaboration with the Ministry of Agricultural, Food and Forestry Policy to establish a national databank for olive oils.

The stable isotope ratios of carbon, oxygen and hydrogen in olive oil were shown to increase from Trentino to Sicily, making it possible to distinguish Northern Italy from Sicily and Calabria each year and confirming the trend observed for other commodities such as wine. Significant differences were found among the years of harvest and in some cases also between PDOs from the same region. The $\delta^{13}C$ and $\delta^{18}O$ values in bulk oil were significantly correlated with those in glycerol. The $\delta^{18}O$ in glycerol showed the same capability to differentiate the geographic origin as $\delta^{18}O$ in bulk, whereas in some years the $\delta^{13}C$ of glycerol showed a better capability to discriminate as compared to bulk. Because the discriminating capability achievable using $\delta^{13}C$ in glycerol is the same as that of $\delta^{18}O$ in bulk, it would seem preferable to directly measure the isotopic ratios in bulk, making savings in terms of time and costs. The δD values, measured in 2005 for the first time in oil, showed promising geographical discrimination capability.

The content of each mineral element in well settled olive oil, measured after ultrasound acid extraction, was basically low and similar to that seen in the literature. The capability to discriminate on the basis of minerals in PDOs could only be checked for few oils produced in specific areas with different geology and requires further research in order to be confirmed.

Fig. 1. Photographs of the minced meat samples and the meat chunk stored in a cold storage during the experiment. At intervals, one sample of minced meat and one slice from the chunk was taken, sealed and freeze-stored until the preparation for analysis.

stored next to the piece of meat in a cold storage (Fig. 1). At the same intervals as the chunk of pork was sub-sampled, one sample container with minced pork was removed from the tray, sealed and frozen. In this way we were able to get an estimate of maximum possible changes (as minced meat has more surfaces to evaporate water) and average changes of the isotope composition (taking slices from the chunk of meat) with storage time. The experiment started at 6.9.2005 and sampling took place approximately every hour per day over a period of almost 60 h.

Experiment 2: One big chunk of beef was taken from a fresh carcass from cattle from the Czech Republic. Half of it was minced, the second half remained intact. Sample preparations were performed in a similar manner to those described in Experiment 1 in a cold storage of the slaughterhouse. The experiment started at 27.9.2005 and lasted over an interval of approximately 26 h. This experiment was carried out in a different slaughterhouse to that used for Experiment 1 in order to test whether results varied between locations.

Experiment 3: One big chunk of pork was taken from a fresh carcass, also from a pig from Styria, and minced. The experiment started at 3.3.2006 and was carried out as described above. Once or twice a day over a period of 14 days, one sample container was removed, sealed and frozen to study the change of δ18O of meat juice over longer time periods.

Experiment 4: For the investigation of changes in δ18O of meat juice during the frying process, 1 cm of superficial meat was removed from one joint of meat from cattle from Lower Austria, after which it was cut into several slices of 1 cm thickness and similar size. The meat slices were put on a hot surface (~250 °C) and turned several times. At intervals of 1, 2, 3, 5, 7 and 9 min, one sample was removed from the hot surface, put into a sample bag and sealed.

Meat slice samples and sub-samples from the meat were cut into small pieces, put into a centrifuge container and centrifuged for 20 min at 6500 rpm.

Afterwards the extracted liquid was transferred to another sample container. If this procedure produced insufficient liquid it was repeated until the required sample amount had been extracted. The minced meat samples were put directly into centrifuge containers and centrifuged as described above. The extracted meat juice was pipetted into a glass flask for the oxygen isotope analysis and, when there was sufficient sample liquid, also for hydrogen isotope analysis.

δ^2H and $\delta^{18}O$ values of the water samples were measured using mass spectrometers Finnigan MAT 251 and Finnigan Delta + XL, each of which was coupled to an automatic equilibration device equipped with pneumatic valves (manufacturer: Finnigan and Parcom). For δ^2H, 5 ml of water was put into each vessel containing a platinum catalyst "Hokko Beads" (manufacturer: Shoko Ltd.) at a bath temperature of 20 °C. The whole system was evacuated and then filled with hydrogen up to a pressure of 300 mb. Isotope equilibrium was achieved within half an hour and the measuring process started. For $\delta^{18}O$ an aliquot of 3 ml was put into a glass vessel and attached to the equilibration device at a bath temperature of 20 °C. The system was evacuated automatically and filled with CO_2 up to a pressure of 300 mb. Each vessel was equipped with a magnetic stirrer to speed up the initial degassing of the water sample and to attain isotope equilibrium within 4 h. Evaluation of the raw data of ratios of mass 3–2 and 46–44, respectively, to δ^2H and $\delta^{18}O$ values was accomplished using two laboratory standards (Adriatic sea water and Vienna tap water), which were measured along with each batch of samples. These standards have been calibrated using the international standards VSMOW (Vienna Standard Mean Ocean Water) and SLAP (Standard Light Antarctic Precipitation) distributed by the IAEA (2001) (International Atomic Energy Agency).

All isotope results are reported using the conventional δ notation, defined as per mil (‰) deviation vs. VSMOW. Measurement uncertainty is 0.1‰ and 1‰ VSMOW for oxygen and hydrogen, respectively (1σ).

3. Results

Experiment 1: The initial $\delta^{18}O$ values in the minced pork and the chunk of pork were −4.9 and −5.6‰, respectively (Fig. 2). This difference in the initial values is explained by the minced pork and the pork chunk having been taken from different carcasses. Within the first 24 h there was a variation of ±0.4‰ of the values of the minced pork sample, without a trend but the initial value was the most depleted one. The pork chunk sample has a variation of up to 0.7‰ heavier and 0.1‰ lighter than the initial value. The following samples for the ground as well as for the chunk of pork remained within the limits found for the first 24 h, without a clear trend. The minced pork gained a daily average of about 0.1‰, a value that is within the uncertainty of measurement and less than the initial variation (first 24 h). Sub-samples from the pork chunk did not show a trend towards enriched values during the same time period.

The δ^2H values were only investigated for samples that had sufficient water extracted. The minced pork showed δ^2H values ranging from −21‰ to −18‰ (Fig. 3), with three outliers of significantly heavier isotope values up to −8‰. The isotopic trend was slightly positive, but if the outliers are disregarded, there was

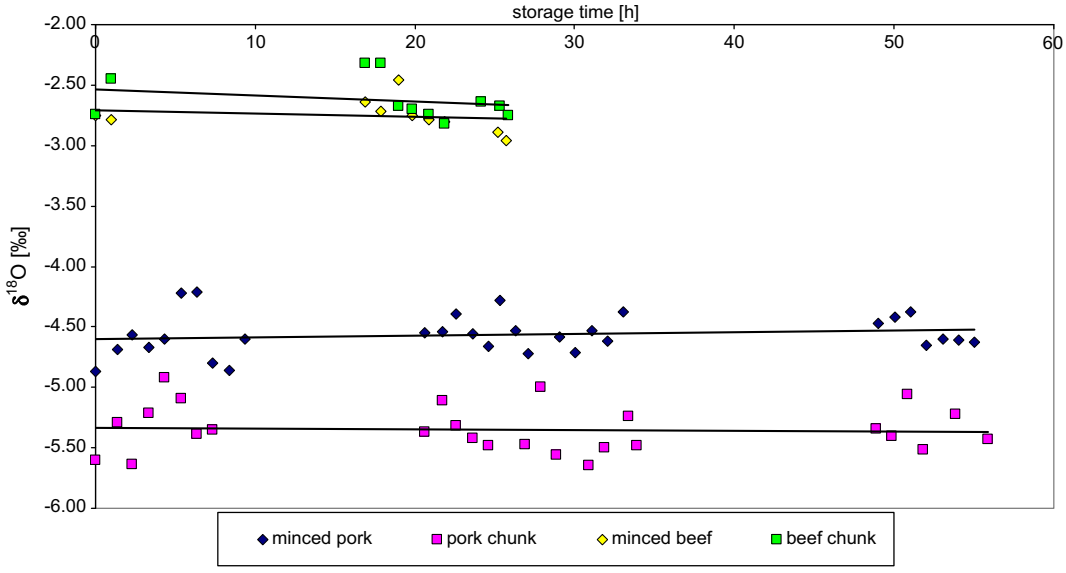

Fig. 2. Diagram with $\delta^{18}O$ V-SMOW values versus time (h) for Experiments 1 and 2 (pork and beef, respectively). Minced beef and chunk of beef come from the same carcass, minced and chunk of pork come from different animals.

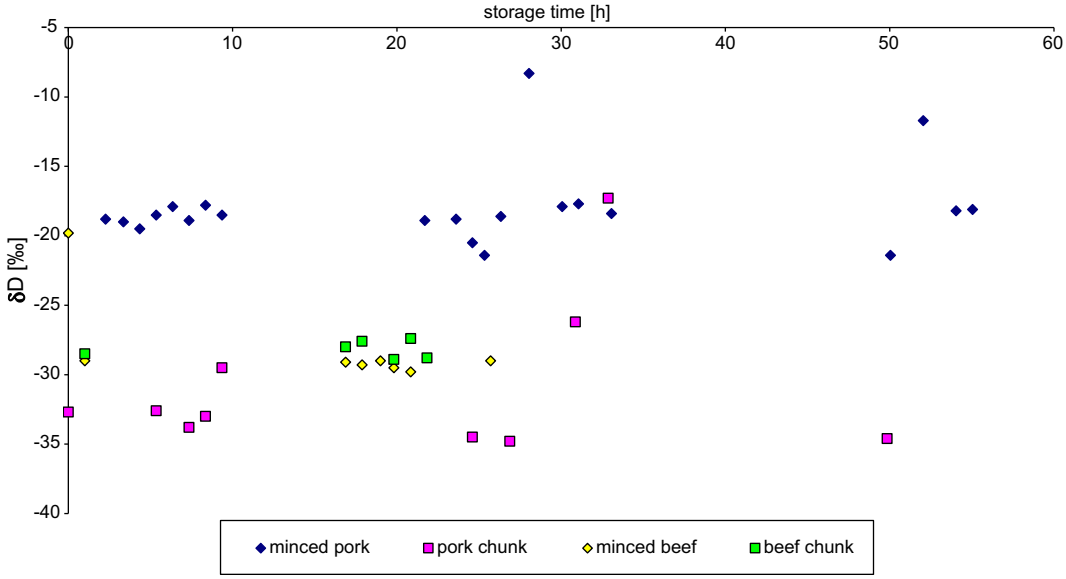

Fig. 3. Diagram with $\delta^{2}H$ V-SMOW values versus time (h) for Experiments 1 and 2 (pork and beef, respectively).

no significant change of the isotope range during the investigated period. Sub-samples from the meat chunk had $\delta^{2}H$ signatures ranging from −35‰ to −30‰, also with some outliers with heavier isotope values up to −17‰. As for the minced meat, the sub-samples taken from the meat chunk showed a small increase towards heavier values with time, but if we neglect the outliers, this trend was insignificant.

Experiment 2: The minced beef and the beef chunk were taken from the same carcass, and the initial $\delta^{18}O$ values were −2.8‰ and −2.7‰, respectively (Fig. 2). Within the experiment period the minced samples varied between −2.5‰ and −3.0‰ and the meat chunk between −2.3‰ and −2.8‰, the trends being slightly towards isotopically depleted values for both. For the $\delta^{2}H$ trends less data were available, as only the samples producing sufficient meat juice could be analysed for this parameter. However, the isotope values show almost no variations for either the minced meat or the meat chunk, ranging from −29‰ to −30‰ and −27‰ to −29‰, respectively (Fig. 3).

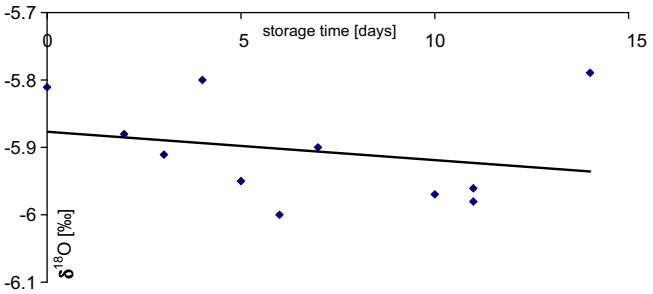

Fig. 4. Diagram showing $\delta^{18}O$ V-SMOW values versus time (14 days) for Experiment 3 (pork). No change in $\delta^{18}O$ can be detected, observed changes are within uncertainty of measurement.

Experiment 3: The pork for this experiment was not taken directly after slaughtering but from a carcass that has been slaughtered a few hours before. The initial $\delta^{18}O$ value was −5.8‰

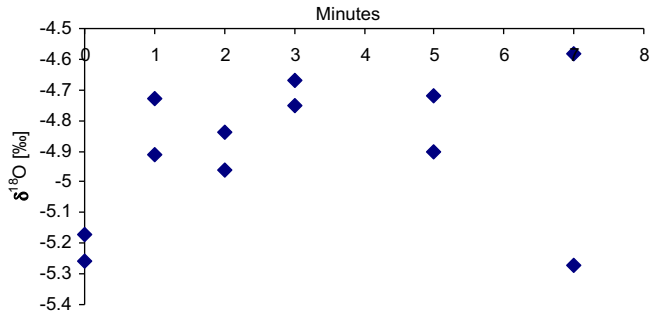

Fig. 5. Diagram showing $\delta^{18}O$ V-SMOW values versus time (min) for Experiment 4 with fried meat.

(Fig. 4). During the investigated period of 14 days, the minced samples had $\delta^{18}O$ values ranging from −5.8‰ to −6.0‰, the differences being only within experimental uncertainty and the $\delta^{18}O$ results without trend.

Experiment 4: The initial value of the raw chunk of beef was −5.2‰. The sample, that has been fried for 1 min on both sides, contained meat juice with an oxygen isotope value of −4.8‰, and there was little change with frying times up to 7 min; the 9 min sample did not contain sufficient meat juice to measure the $\delta^{18}O$ value (Fig. 5).

4. Discussion

Experiment 1, performed with pork, showed a maximum $\delta^{18}O$ variation of 0.8‰ for the chunk sub-samples and 0.7‰ of the minced samples. These variations occurred within the first 24 h and showed no significant trend. Throughout the entire experiment, the average values (per day) changed from around −4.6‰ to −4.5‰ and −5.3‰ to −5.4‰ for the minced meat and meat chunks, respectively, and thus remained within the uncertainty of measurement.

The $\delta^{2}H$ values showed a maximum variation from −21‰ to −8‰ and −35‰ to −17‰ for minced meat and the meat chunk, respectively. If we neglect the outliers the variations are reduced to −21‰ to −17‰ and −35‰ to −30‰ for minced meat and the slices from the meat chunk, respectively. If we take into account the outliers we get a slight trend towards increasing values with time, but if we disregard them there is no trend for either the minced meat or the meat chunk.

Experiment 2, performed with beef, showed a maximum $\delta^{18}O$ variation of 0.5‰ for minced beef and the slices from the meat chunk. For the investigated period of ca. 26 h, no trend towards heavier isotopes was found; on the contrary, there seemed to be a slight trend towards isotopically depleted values. The $\delta^{2}H$ ratios remain almost constant values between −28‰ and −29‰ and −27‰ and −29‰ for the minced meat and the meat chunk, respectively, almost within the uncertainty of measurement.

It is interesting to note, that the slices of meat taken from the meat chunk seem to show a slightly larger variation than the minced meat samples, although we expected to see a maximum isotope change with the minced meat samples. A possible explanation might be a slightly higher heterogeneity of the $\delta^{18}O$ in the meat chunk compared to the minced meat that would have been (at least partly) homogenised during the mincing process. The slightly negative trend for $\delta^{18}O$ in Experiment 2 raises speculation about the interaction of meat juice with air humidity. However, as no such a trend was visible in the $\delta^{2}H$ data, it can be discounted.

As previously reported by Boner and Förstel (2004), beef and pork showed different enrichments of hydrogen isotopes compared to their oxygen isotope compositions (Figs. 2 and 3). Thus the $\delta^{2}H$ values of the meat juice appear to be a potentially important tool for the control of origin and supplement the data obtained from oxygen isotope analyses. However, the presence of outliers in Experiment 1 shows that hydrogen isotopes might be less reliable at "non-ideal" storage conditions. Up to now we do not know what might have caused the outliers in $\delta^{2}H$. However, the equilibration technique with platinum catalyst used for $\delta^{2}H$ measurement sometimes experiences problems with juices, as this technique was developed for pure water samples, and it is known that contaminations of the water (e.g., sulphur) can influence the measurement. If this should be the source of error, measurement of the pure meat water can avoid this problem.

Experiment 3 was carried out to study long-time storage of meat in cold storages. The variation in $\delta^{18}O$ ranged within 0.2‰ and demonstrates that the isotope changes remained within the uncertainty of measurement.

These two experiments clearly demonstrate that the results of Thiem et al. (2004) do not apply to meat stored in industrial cold storages (Fig. 6).

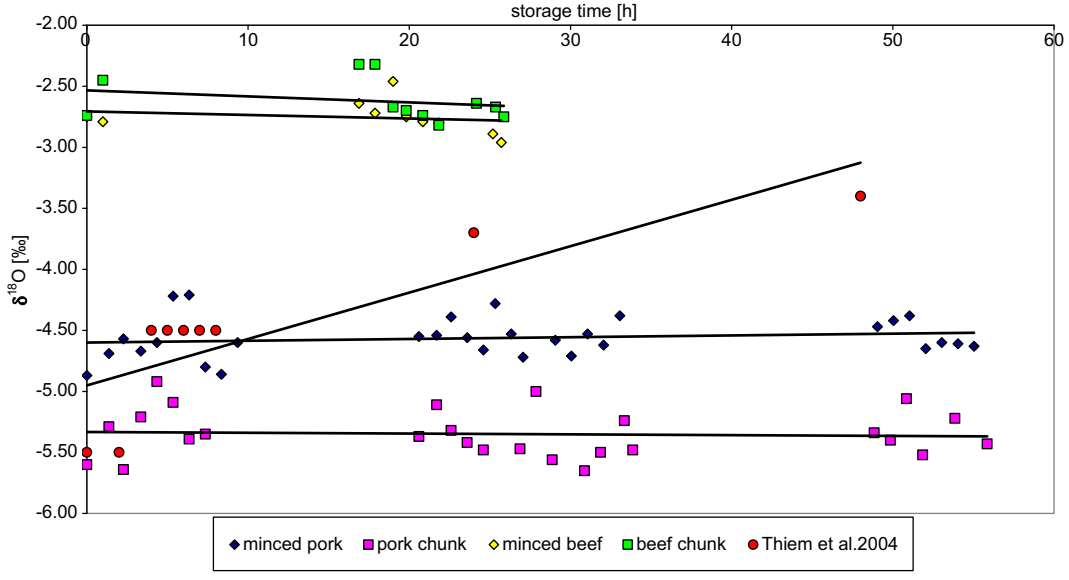

Fig. 6. Diagram with $\delta^{18}O$ V-SMOW values versus time (h) comparing the results of Experiments 1 and 2 with the results from Thiem et al. (2004) for meat stored at 0 °C.

A possible explanation for the differences in results between our findings and those of Thiem et al. (2004) is the influence of the type of cooling container used. Although not specified in their publication, we assume that Thiem et al. (2004) used a refrigerator to store the meat cube samples in their experiment. In a refrigerator there is a significant temperature gradient between the door and the cooling device, where water vapour condenses, and is permanently removed from the air in the refrigerator. Hence evaporation is increased and meat samples loose significant amounts of water. In modern industrial cold storages, air conditioning systems regulate both temperature and humidity. Almost no temperature gradients exist, keeping the air humid and preventing evaporation.

Therefore, we can conclude that meat (e.g., beef and pork) kept in industrial cold storages even for a longer period preserves its primary isotopic $\delta^{18}O$ meat juice value. However, for the processes after cool-storage of meat, such as portioning, packaging, transport to retailers and the storage of the meat at the retailer and consumer, the findings of Thiem et al. (2004) might be applicable and important.

5. Roasting

To test if it makes sense to apply $\delta^{18}O$ analyses to juice from prepared meat to authenticate its origin, we investigated changes of $\delta^{18}O$ in meat juice from fried meat. During the process of frying the meat juice experienced a maximum $\delta^{18}O$ change of 0.7‰ in our experiment. This can be explained by the small fractionation factor of water and water vapour at high temperatures (Friedman & O'Neil, 1977). As this is less than the maximum variation during storage, we regard the analysis of $\delta^{18}O$ of meat juice from roasted meat as a useful tool for estimating the $\delta^{18}O$ value of the raw meat. However, in practice "underdone" meat should be used for analysis to minimise the influence of frying, and it should be seal-packed directly after preparation, as evaporation at lower temperatures, e.g., on a plate, has a larger fractionation factor.

6. Conclusions

Our experiments clearly showed that there was no significant increase in $\delta^{18}O$ in meat juice during storage of meat in industrial cold storages. We found a maximum variation of 0.8‰ during storage, but without any trend with time. However, taking bigger samples and generously removing any meat surface in longer contact with the air should further decrease the isotopic variation. In an ideal case, as it seems to have occurred during our "long time experiment" over 14 days, the variation in meat juice $\delta^{18}O$ lies within 0.2‰. This shows that the results of Thiem et al. (2004) are not valid for meat stored in big industrial cold storages at temperatures below +5 °C. The processes after cool storing, such as portioning, packaging, transporting to supermarkets and storing in the freezers and fridges, were not investigated in the current work, and the findings of Thiem et al. (2004) suggest that such processes might have appreciable effects on the isotopic composition of meat juice.

Therefore, although it has been shown that the juice from fried meat reflects the $\delta^{18}O$ value of the raw meat, the measurement of meat juice from fried meat might not give the primary isotopic ratio, if it is not known which processes the raw meat may have undergone before it "ended in the pan".

Acknowledgments

We want to thank Schirnhofer GmbH and Marcher GmbH for allowing us to perform the experiments in their slaughterhouses and cold storages. We want to thank Mr. Höfer and especially Gerhard Rose for their support and enthusiasm and Ingrid Perz and Rudolf Tallian for reliably taking and freeze-storing the samples. Preparation of samples was done by Gerhard Spitzer and Erwin Tschank, and stable isotope measurements were carried out by Peter Kostecki. This study is part of the independent research program of the Austrian Research Centers GmbH – ARC.

analysis to determine the origin of meat products has been, up to now, not very common, and the existing studies have focused on distinguishing the provenance of samples from different European countries (Boner & Förstel, 2004; Camin et al., 2007; Heaton, Kelly, Hoogewerff, & Woolfe, 2008; Nakashitaa et al., 2008). Furthermore, isotopic traceability of animal products is more complex because livestock can consume foodstuffs of various origins and also be raised on several different farms during their lifetime. Most biological and physiological factors influencing the isotopic composition of animal tissues are still poorly understood (Heaton et al., 2008; Schmidt et al., 2005).

The aim of this work was to demonstrate the potential of carbon and nitrogen stable isotope analysis to trace the geographical origin of cattle in China, and to verify if a dual-isotopic approach can be an efficient tool for cattle origin characterisation.

2. Materials and methods

2.1. Sources of samples

A total of 59 castle raised at four distinct sites which differ in their geographical locations were used for the experiment and are shown on the map in Fig. 1. Twenty-one cattle samples were collected from Yushu city, Jilin province (44.47°N, 126.08°E) in June in 2005. Yushu is located in northeast China, its mean annual temperature is 4 °C, average altitude is 407 m, and the cattle feed is mainly maize. Sixteen cattle samples were collected from Anshun city, Guizhou province (26.23°N, 105.41°E) in November in 2005, which is located in southwest China. Anshun's mean annual temperature is 14–16 °C, the average altitude is 1378 m and the cattle feed is mainly C_3 and C_4 pasture. Ten cattle samples were collected from Tongxin county, Ningxia municipality (37.33°N, 106.29°E) in October in 2005, which is located in northwest China. Tongxin's mean annual temperature is 8.6 °C and the average altitude is 1715 m, the cattle feed is mainly a mixture of wheat and maize. Twelve cattle samples were collected from Zhangbei county, Hebei province (41.08°N, 114.43°E) in November in 2005. Its mean annual temperature is 2.6 °C, the average altitude is 1325 m and the cattle feed is mainly C_3 pasture.

Fig. 1. Regions of samples.

2.2. Preparation of samples

2.2.1. Muscle samples

The samples (500 g), taken from the rump, were removed from carcasses and stored at −20 °C until processing. Muscle was dried at 70 °C for 48 h and ground in a pulverizer. Lipids were extracted from the muscle powder with petroleum ether and the residue was sieved in a 0.08 mm sieve mesh (Boner & Förstel, 2004; Schmidt et al., 2005; Yi, Li, Zhang, Zhao, & Li, 2004). Finally, the lipids were recovered using a Rotary Evaporator.

2.2.2. Tail hair samples

The samples were collected from cattle kept and raised in local regions and fed an unchanging diet for at least three months. The hair length should be 45.9 mm in three months according to a minimum hair growth rate of 0.51 mm/d (Schwertl et al., 2005). For each cattle a 40 mm section of tail hair was cut with scissors from an area 1 cm^2 close to the skin.

The hair samples were first soaked and washed with distilled water and then dried at 60 °C before soaking in a 2:1 mixture of methanol/chloroform for 2 h. After which they were washed with distilled water, soaked for another 30 min, and rinsed in the methanol/chloroform mixture again. The dried hair was cut into 1–2 mm sections (De Smet, Balcaen, Claeys, Boeckx, & Van Cleemput, 2004; Schwertl, Auerswald, & Schnyder, 2003).

2.3. Sample analysis

Dry samples were weighed into tin capsules and introduced by means of an auto sampler into the elemental analyzer (Flash EA1112). The elements of carbon and nitrogen in the samples were combusted into CO_2 and NO_x gas at 1020 °C, and then the NO_x gas was reduced over copper wires at 650 °C to N_2. The flow rate of carrier gas helium was 90 ml/min, interfaced through a Conflo III to an isotope ratio mass spectrometer (Delta plus, Thermo Finnigan). The C and N stable isotope composition of each sample was measured in the same analysis. The values of the isotopic ratios are expressed in delta (δ) notation in parts per thousands (‰) relative to the accepted international standards; $\delta^{13}C$ (‰) relative to PDB and $\delta^{15}N$ (‰) relative to atmospheric AIR. The delta values were calculated as follows:

$$\delta_x = (R_{sample}/R_{standard} - 1) \times 1000$$

where δ_x is $\delta^{13}C$ or $\delta^{15}N$, and R is the respective $^{13}C/^{12}C$ or $^{15}N/^{14}N$ ratio.

The reference working gas CO_2 was calibrated with USGS 24 ($\delta^{13}C_{PDB} = -16.049‰$), and the reference working gas N_2 was calibrated with IAEA standard N1 ($\delta^{15}N_{air} = 0.4‰$). The analytical precision was 0.2‰ for both C and N.

2.4. Statistical analysis

The analysis of data including ANOVA, Duncan's LSD test, Correlation Analysis and Discriminant Analysis (DA) were performed using the SAS software package for windows, and the box-plot figures were drawn by SAS package (version 6.12).

DA was carried out to evaluate whether cattle from different origins could be distinguished by analytical parameters. The classification rules and mathematical model was developed using Euclidean distances discriminant analysis based on the full data set of 59 samples, and then using back substitution test to evaluate the prediction capability of the mode for each parameter. The

prediction capability is expressed as a percentage of correctly classified samples relative to the entire data set, and calculated as follows:

$$x\% = (\text{number of correctly classified individual} / \text{sample population}) \times 100.$$

A box-plot provides an excellent visual summary of a set of data. It is used to show the shape of the distribution, its median value, and variability. The picture produced consists of the most extreme values in the data set (maximum and minimum values), the lower and upper quartiles, and the median.

3. Results

3.1. Difference analysis

The results of ANOVA and Duncan's LSD test showed that there were highly significant differences according to region in the mean values of carbon and nitrogen isotope ratios in the cattle tissue. The order of the geographical origin was Jinlin > Guizhou > Ningxia > Hebei according to $\delta^{13}C$ values of cattle tissues (Figs. 2a–c). For $\delta^{15}N$ values, there were highly significant differences between samples coming from pasture (Guizhou and Hebei) and cultivated land (Jilin and Ningxia) (Figs. 2d and e). This indicated that stable isotope ratios of carbon and nitrogen in cattle tissues may be used to discriminate the geographical origin in China.

3.2. Correlation analysis

A significant correlation was found in carbon and nitrogen isotope ratios between de-fatted beef, crude fat and tail hair. The correlation coefficients of $\delta^{13}C$ values between de-fatted beef, crude fat and tail hair were 0.947, 0.961 and 0.955 ($P < 0.01$) respectively, the correlation coefficient of $\delta^{15}N$ values between de-fatted beef and tail hair was 0.874 ($P < 0.01$) (Figs. 3a–d). The results implied that the three tissues respond to diet in a similar pattern and, thus,

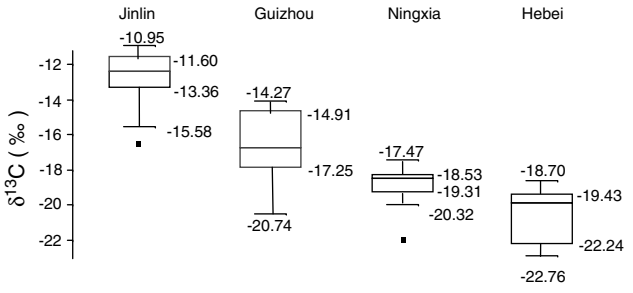

Fig. 2a. The $\delta^{13}C$ values of de-fatted beef from different regions.

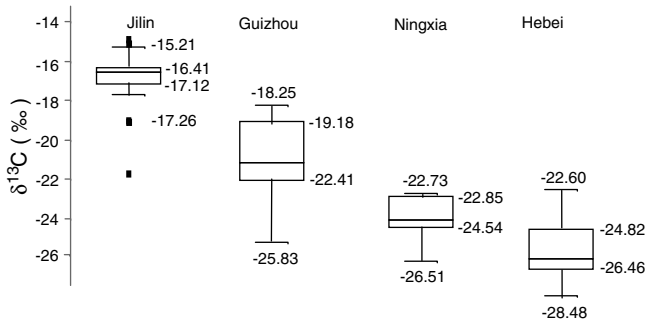

Fig. 2b. The $\delta^{13}C$ values of crude fat from different regions.

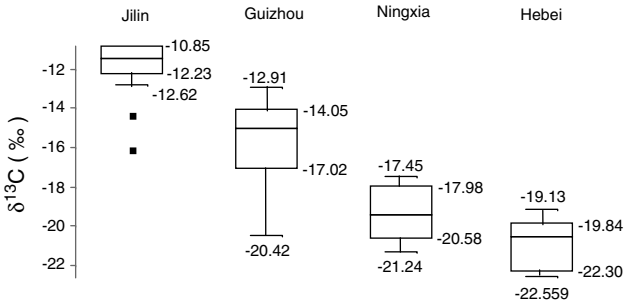

Fig. 2c. The $\delta^{13}C$ value of tail hair from different regions.

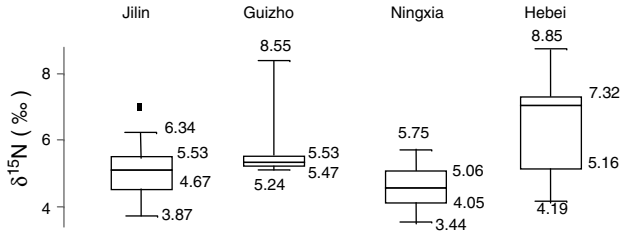

Fig. 2d. The $\delta^{15}N$ value of de-fatted beef from different regions.

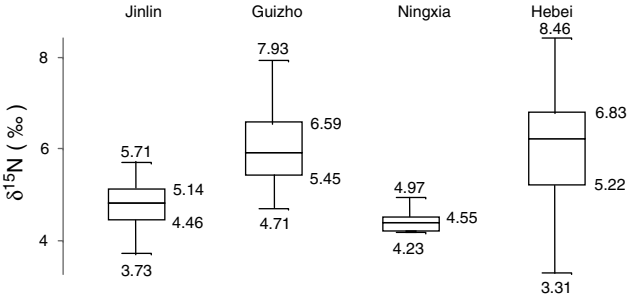

Fig. 2e. The $\delta^{15}N$ value of tail hair from different regions.

C and N isotope composition of either tissue, lipid or hair could yield useful information on dietary intake and geographical origin.

3.3. Discriminant analysis

From the comparison of discriminant analysis results based on a single indicator of $\delta^{13}C$ or $\delta^{15}N$, respectively (Table 1), it could be concluded that $\delta^{13}C$ was the better indicator to trace the origin of cattle than $\delta^{15}N$. Furthermore, correct classification could be improved by a combination of carbon and nitrogen isotope ratios, e.g., only 73% and 47% of samples were correctly classified by using the $\delta^{13}C$ and $\delta^{15}N$ in tail hair, respectively, but it could be improved to 85% by using the combination of $\delta^{13}C$ and $\delta^{15}N$ values in tail hair (Table 2).

4. Discussion

4.1. Isotopic ratios in cattle from different regions

There were significant differences based on carbon and nitrogen isotope ratios in cattle tissues from four regions in China. The $\delta^{13}C$ value of cattle was found to be highly dependent on diet composition, particularly with regard to the proportion of C_4 and C_3 plant material (De Smet et al., 2004; Schwertl et al., 2005). The main

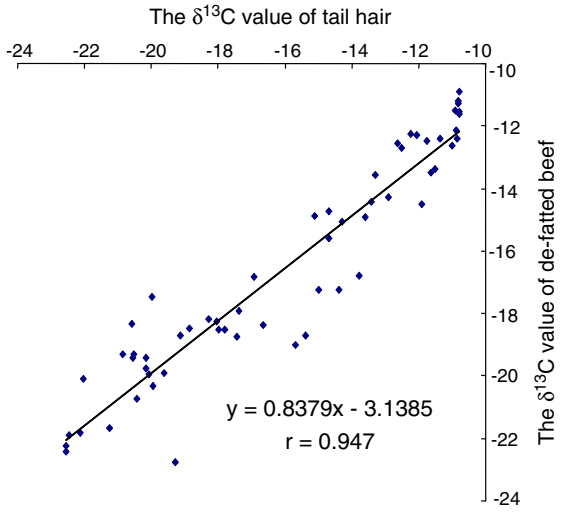

Fig. 3a. The correlation of $\delta^{13}C$ between tail hair and de-fatted beef.

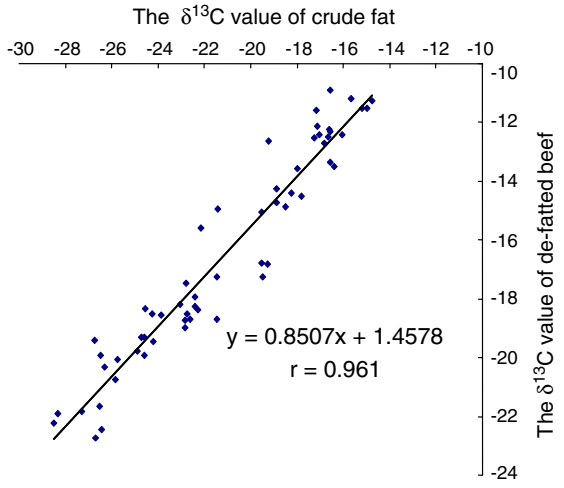

Fig. 3b. The correlation of $\delta^{13}C$ between crude fat and de-fatted beef.

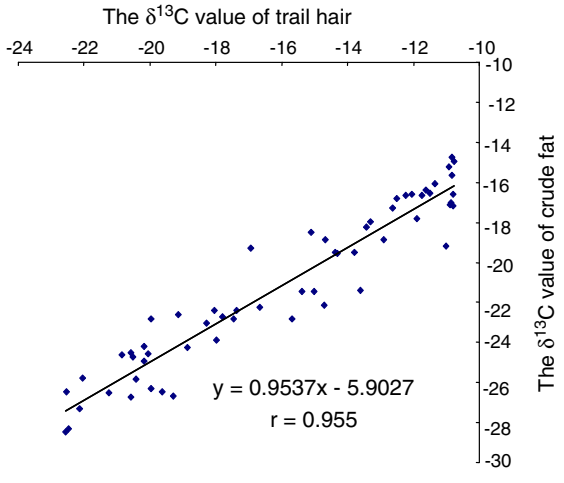

Fig. 3c. The correlation of $\delta^{13}C$ between tail hair and crude fat.

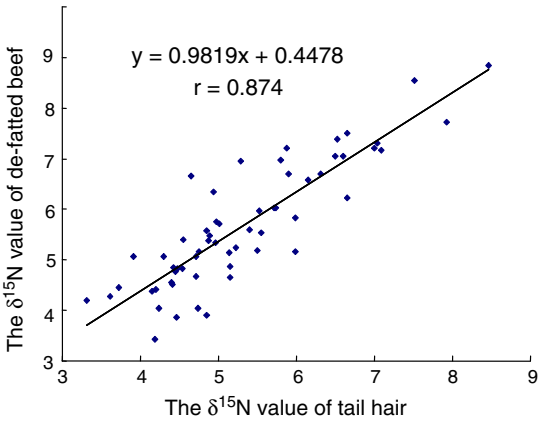

Fig. 3d. The correlation of $\delta^{15}N$ between tail hair and de-fatted beef.

feeds of cattle from four regions in China have shown significant differences, which are usually dependent upon the geographical location and climate factors. Jilin province is located in northeast China, where the mean annual temperature is relatively low (4 °C), and the maize is one of the primary crops. The cattle from Jilin were mainly fed on maize, but rice straw and soybean accounted for a small proportion of the feed. Maize is a C_4 plant; rice straw and soybean are C_3 plants, that is, cattle from Jilin were mainly fed on C_4 plants. Guizhou province is located in southwest China; cattle from here were mainly fed on C_3 and C_4 grass. Ningxia is located in northwest China, it is suitable for wheat and maize growing, and cattle from Ningxia were fed on the mixture of wheat and maize. Hebei province is adjacent to grassland; cattle reared here were mainly fed on C_3 pasture grass. These different diet compositions explain the reason why $\delta^{13}C$ values of cattle tissue from Yushu city, Jilin province were the highest among the four regions, and $\delta^{13}C$ values of samples from Zhangbei city, Hebei province were the lowest. The $\delta^{15}N$ values of animals depend on their diet and regions (Piasentier, Valusso, Camin, & Versini, 2003). Cattle from Jilin and Ningxia were mainly fed on cereal feed, while cattle from Guizhou and Hebei were mainly fed on pasture. The regions growing cereal crops usually depend on chemical fertilizer, while the regions producing pasture usually depend on organic fertilizer. Chemical fertilizer is depleted in ^{15}N relative to organic fertilizer (Cai, Zhang, & Zhang, 2002; Piasentier et al., 2003). That is the reason why the $\delta^{15}N$ value of cattle from pasture-feeding regions was significantly higher than those fed on cereal feeds. So we can draw the conclusion that $\delta^{15}N$ value may be used to differentiate the cattle from pasture-feeding regions and cereal feeding regions in the areas in China considered in this study.

4.2. Isotopic ratios in different cattle tissues

The $\delta^{13}C$ values varied significantly in different tissue. The order was tail hair > de-fatted muscle > crude fat. This result corresponds to the findings of others authors (De Smet et al., 2004; Kornexl, Werner, Roßmann, & Schmidt, 1997; Piasentier et al., 2003). De Smet et al. (2004) found that hair, muscle, blood and liver were enriched in ^{13}C compared with the $\delta^{13}C$ value of the diets, but the kidney fat was significantly depleted in ^{13}C. The $\delta^{15}N$ values in cattle tail hair were less positive than that of the de-fatted muscle, which probably may be due to the different amino acid composition between them. Though the significant differences of C and N isotopic ratios were observed between cattle tissues, high correlation coefficients were found between them. The results indicated that the three tissues respond to diet changes in a similar pattern and, thus, C and N isotope composition of either tissue could yield useful

Table 1
The percentage of observations correctly classified of cattle samples from four regions in China, on the basis of single indicator of carbon and nitrogen stable isotope ratios, respectively

Sample origin	$\delta^{13}C$ (‰)			$\delta^{15}N$ (‰)	
	De-fatted beef (%)	Crude fat (%)	Tail hair (%)	De-fatted beef (%)	Tail hair (%)
Yushu city, Jilin province	86	86	90	38	38
Anshun city, Guizhou province	50	75	69	25	6
Tongxin county, Ningxia municipality	60	50	50	70	80
Zhangbei county, Hebei province	75	67	67	75	92
% total	69	73	73	47	47

Table 2
The percentage of observations correctly classified of cattle samples from four regions in China, on the basis of combination indicators of carbon and nitrogen stable isotope ratios

Sample origin	$\delta^{13}C$ $\delta^{15}N$	$\delta^{13}C$ $\delta^{15}N$
	De-fatted beef (%)	Tail hair (%)
Yushu city, Jilin province	86	90
Anshun city, Guizhou province	69	81
Tongxin county, Ningxia municipality	80	60
Zhangbei county, Hebei province	75	100
% total	78	85

information of the dietary intake. However, the turnover rate of stable isotope showed significant difference between different tissues due to different metabolic activity (Bahar et al., 2005; De Smet et al., 2004; Harrison et al., 2007; Schwertl et al., 2003), and the correlations of isotopic ratios between different tissues depend on the sampling methods, sampling time and cattle feeding mode, which led to different results shown in previous research (Camin, Perini, Colombari, Bontempo, & Versini, 2008; De Smet et al., 2004; Piasentier et al., 2003; Renou et al., 2004). Cattle samples selected in our experiment were fed in the same regions with unchanged feeds for at least three months, and only the segment of tail hair which produced within this period was taken as samples. Therefore, most of isotopic composition in de-fatted muscle, crude fat and tail hair reached equilibrium with the feeds, and the $\delta^{13}C$ and $\delta^{15}N$ values in these three tissues could provide the regions and diets information where the cattle come from. Generally speaking, different tissues can reflect different periods of diet information, e.g., bone and bone collage provide long-term dietary information that may integrate decades of their lifetime, tissues like blood, fat, liver, muscle and brain reflect diet consumed within weeks to months (Schwertl et al., 2003). Every section of hair and hooves can be used to reconstruct an animal's dietary history (Harrison et al., 2007; Schwertl et al., 2003, 2005). Therefore, different modes should be built to predict the information of dietary change using different tissues, and the suitable tissues should be chosen according to the aims of the research undertaken.

4.3. Discriminant parameters for cattle geographical origin traceability

The $\delta^{13}C$ value was found to be a powerful parameter to determine the geographical origin of cattle followed by $\delta^{15}N$. In addition the single parameter of $\delta^{13}C$ and $\delta^{15}N$ was not sufficient to identify the cattle from different origins, due to overlap in the more extreme values, but the percentage of correctly classified observations can be significantly improved by the combination of these two parameters. That is the isotopic indicators of carbon and nitrogen could provide complementary information for tracing the geographical origin of cattle. This result is consistent with previous researchers. C-isotope ratios alone can distinguish dietary C_3/C_4 groups; N can provide additional information potentially useful for the authenticity investigation of beef (Bahar et al., 2005). In addition, the simultaneous consideration of $\delta^{13}C$, $\delta^{15}N$ and other isotope ratios such as $^{18}O/^{16}O$, $^{2}H/^{1}H$, $^{34}S/^{32}S$ and $^{87}Sr/^{86}Sr$ will improve the rate of correct classification greatly for Chinese cattle geographical origin traceability.

5. Conclusion

Carbon and nitrogen stable isotope analysis has proved a useful tool for tracing the diet and geographical origin of cattle in China. In addition, the $\delta^{13}C$ and $\delta^{15}N$ value either of de-fatted beef, crude fat and tail hair can provide similar information of the dietary intake and geographical origin.

Acknowledgements

The research is supported by Chinese National Sciences Fund (No. 30671484 and 30800862) and Eleventh Five-Year Plan for National Key Projects of Scientific and Technical Supporting Programs funded by Ministry of Science and Technology of China (No. 2006BAK02A16). We are grateful to the farmers for assistance in collecting beef samples, feeds samples and offering associated information.

brewed from the leaves of the *Camellia sinensis* plant. Traditionally picked by hand, the harvest involves plucking the top two leaves and bud from the end of the branches. These are all collected and processed within 24 h. Tea production is dominated by Asia and Africa. 'Today over 75% of tea is produced in India, China, Sri Lanka, Kenya, Turkey and Indonesia' (Traidcraft, 2004). The price of tea is determined by the quality, flavour and the reputation of the producing area.

One of the moist prestigious areas for growing tea is Darjeeling, which is located in the West Bengal state in India. Tea has been grown commercially in Darjeeling since being planted by the British in 1852. Today tea is grown in 85 gardens covering an area of 17,400 hc to produce approximately 11.5 million kg of tea per year. Darjeeling provides a unique growing location for tea due particularly to its altitude (1800–6300 feet) and climate. These conditions, combined with strict control of production processes, result in the production of a characteristic high quality tea, which has made the name Darjeeling famous throughout the world. This quality allows the producers to command a significantly higher price for their product.

Considerable research has already been carried out to establish the origin of food and plant products with trace element analysis being used to determine the origin of a range of commodities including pistachios (Anderson & Smith, 2005), wine (Almeida & Vasconcelos, 2003; Taylor, Longerich, & Greenough, 2003), garlic (Smith, 2005), thyme, honey (Terrab, Hernanz, & Heredia, 2004) and Welsh onions (Ariyama, Horita, & Yasui, 2004). Studies into the application of isotope analysis for origin and adulteration determination have also been carried out on a range of products including wine (Majcenovic, Schneider, Lepoutre, Lempereur, & Baumes, 2002; Roßmann, Schmidt, Hermann, & Ristow, 1998; Roßmann et al., 1996), olive oil (Angerosa, Camera, Cumitini, Gleixner, & Reniero, 1997; Angerosa et al., 1999; Spangenberg & Ogrinc, 2001; Woodbury, Evershed, Rossell, Griffith, & Farnell, 1995), cheese (Manca et al., 2001) and butter (Rossmann et al., 2000).

While several studies have been conducted on tea, these generally have only small sample sets or limited classifications. Valera, Pablos and Gonzalez (1996) combined chemical analysis with discriminant analysis to broadly classify tea samples as black or green. Liu et al. (1987) analysed tea samples for their content of cellulose, hemicellulose, lignin, polyphenols, caffeine and amino acids and then used principal component analysis to classify samples as green, black or oolong. Marcos et al. (1998) determined the trace element concentrations of tea samples using inductively coupled plasma atomic emission spectroscopy (ICP-AES) and inductively coupled plasma mass spectrometry (ICP-MS). They were able to distinguish between African and Asian teas and separate Chinese samples from other Asian samples. However, this was a small study with only 15 samples from 10 different countries and cannot be considered in any way definitive. Fernandez-Caceres, Martin, Pablos, and Gonzalez (2001) applied multivariate and chemometric techniques to concentration data of the major elements in tea obtained using ICP-AES for 46 samples. Their results suggest that discrimination according to geographical origin is possible using linear discriminant analysis, however only 24 samples from five regions were used in this classification. Moreda-Pineiro, Marcos, Fisher, and Hill (2001) investigated the effects of data pre-treatment techniques on the classification of tea samples as either African or Asian. Moreda-Pineiro, Fisher, and Hill (2003) used ICP-AES and ICP-MS and were able to separate Asian and African teas and classify Chinese, Indian and Sri Lankan teas. Studies to date have typically relied on discrimination based on either light stable isotopes or trace element data rather than investigating the potential of combining both techniques to provide a more robust and universally applicable provenance determination.

The current study investigates the potential of using a combination of stable isotope (C, N & H) and trace element data for 83 tea samples to establish the growing region. The effects of differences in tea type, harvest date and tea quality on this classification have also been studied. Linear discriminant analysis has been applied to obtain separation of growing regions and to identify the provenance of samples from different tea growing regions of Asia (China, India, Sri Lanka and Taiwan). The validity of the method for the determination of origin of unknown samples was then tested through the analysis of 20 commercial samples.

2. Materials and methods

2.1. Samples

Tea samples (see Table 1) were obtained through Australian tea importers. Details were recorded as to the growing region, plantation, harvest date, type and quality. An additional 20 samples were obtained through commercial outlets. These samples were treated as 'unknowns'.

2.2. Solution analysis using inductively coupled plasma mass spectrometry (ICP-MS)

Samples of tea (1 g) were accurately weighed into conical flasks in triplicate. Nitric acid (20 mL) (Ajax Finechem, NSW, Australia, AnalR, sub-boiling quartz still redistilled) was added to each sample. The flasks were covered with watch glasses and then placed on hotplates at 140 °C for eight hours. The temperature was reduced to 90 °C and samples left overnight. After this period, the watch glasses were removed and the nitric acid evaporated to leave a yellow residue. A further volume of nitric acid (10 mL) was added and the flasks, covered by watch glasses, were placed, on hotplates at 140 °C (2 h). After this time the watch glasses were removed and the nitric acid evaporated off. When dry, 4:1 nitric/perchloric acid mixture (15 mL) (Ajax Finechem, NSW, Australia, AnalR, sub-boiling quartz still redistilled) was added to each flask. The flasks were again covered by watch glasses and placed, on hotplates at 180 °C (3 h). After this time, the temperature was reduced to 100 °C and the samples left overnight to react. In the morning, the lids were removed and the nitric/perchloric acid mixture evaporated leaving a white residue. This was cooled to room temperature and then ta-

ken into solution with approx 20% nitric acid (7.5 mL) and gentle warming. The solution was transferred into pre-weighed and pre-cleaned (by soaking for 48 h in 10% nitric acid, washing with deionised water and air drying upside down) 70 mL plastic tubs. The flasks were rinsed several times with milliQ water with the washings being added to the tubs. The solutions were made up to 50 g using milliQ water.

Certified reference materials (CRMs), peach leaves and apple leaves (National Institute of Standards and Technology), were also included as samples during the digest. 0.5 g of each was weighed out in triplicate. These underwent the same acid dissolution procedure as the tea samples. Three acid blanks, which had also been taken through the entire dissolution procedure, were also included.

Prepared solution samples were analysed using solution ICP-MS (PQ3, Thermo-Elemental, Winsford, Cheshire UK) for ^{49}Ti, ^{51}V, ^{53}Cr, ^{59}Co, ^{60}Ni, ^{65}Cu, ^{66}Zn, ^{71}Ga, ^{73}Ge, ^{75}As, ^{82}Se, ^{85}Rb, ^{88}Sr, ^{89}Y, ^{90}Zr, ^{93}Nb, ^{98}Mo, ^{107}Ag, ^{111}Cd, ^{115}In, ^{120}Sn, ^{121}Sb, ^{126}Te, ^{133}Cs, ^{138}Ba, ^{139}La, ^{140}Ce, ^{141}Pr, ^{146}Nd, ^{152}Sm, ^{153}Eu, ^{158}Gd, ^{159}Tb, ^{162}Dy, ^{165}Ho, ^{166}Er, ^{169}Tm, ^{172}Yb, ^{175}Lu, ^{178}Hf, ^{181}Ta, ^{182}W, ^{203}Tl, ^{208}Pb, ^{209}Bi, ^{232}Th, and ^{238}U. A multi-element standard was run every 10 analyses to allow for drift correction. Correction and normalisation was carried out to the CRMs.

2.3. Elemental analysis isotope ratio mass spectrometry

Prior to analysing the samples for bulk isotope values, the dried tea leaves were ground to a fine powder (<500 μm) using an agate mortar and pestle. Analysis was performed using a Micromass IsoPrime isotope ratio mass spectrometer interfaced to a EuroVector EuroEA3000 elemental analyser.

2.4. $\delta^{13}C$ Analysis

Approximately 150–200 μg of the tea powder were weighed into a small tin capsule. This was then folded and compressed to contain the sample and minimise any air present. The prepared samples were introduced into the elemental analyser using an autosampler. The stable carbon isotopic composition is recorded in the delta notation relative to the Vienna Pee Dee Belemnite (VPDB) standard. CO_2 of known $\delta^{13}C$ content was introduced as a pulse of reference gas. Each sample is analysed a minimum of three times and the average and standard deviations calculated (values ranged between −29.1‰ and −23.2‰ ± 0.23 (SE)). An in-house sucrose standard and a beet sugar standard (IsoAnalytical IA-R005) of known $\delta^{13}C$ values (−10.5‰ and −26.03‰, respectively) were used for calibration purposes. Samples were analysed over a period of 18 months, with replicate samples analysed throughout the entire period to ensure reproducibility of results.

2.5. $\delta^{15}N$ Analysis

Tea powder (2–4 mg) was weighed and analysed in a similar manner to the samples used for carbon isotope analysis. Due to the increased amount of sample, the dilutor must be switched on just prior to the elution of the CO_2 peak and switched off immediately after to prevent the detector from being overloaded with CO_2. The $\delta^{15}N$ composition is reported relative to a reference gas pulse of known $\delta^{15}N$ composition. The isotopic compositions are recorded in delta notation relative to an air standard. Each sample is analysed a minimum of three times and the average and standard deviations calculated (values ranged between 0.2‰ and 7.1‰ ± 0.22 (SE)). A wheat flour standard (IsoAnalytical IA-R001) and Urea standard (EuroVector E11003) of known $\delta^{15}N$ values (2.55‰ and −0.5‰, respectively) were used for calibration purposes. Samples were analysed over a period of 18 months, with replicate samples analysed throughout the entire period to ensure reproducibility of results.

2.6. δD Analysis

The tea powder (550–650 μg) was weighed into a small silver capsule. This was folded and compressed to contain the sample and to remove any air. The prepared sample was introduced into the elemental analyser using an auto sampler. Hydrogen gas of known δD was inserted as pulses of reference gas. The gas is passed into the irMS and the isotope composition calculated using the delta notation relative to the Vienna Standard Mean Ocean Water (VSMOW) standard. Each sample is analysed a minimum of three times and the average and standard deviations calculated (values ranged between −93.4‰ and −11.5‰ ± 0.89 (SE)). Polyethylene (IAEA-CH7) and mineral oil (IA-R002) standards (δD = −100‰ and −111‰, respectively) were used for calibration purposes. Samples were analysed over a period of 18 months, with replicate samples analysed throughout the entire period to ensure reproducibility of results and that the results were not being affected by exchangeable hydrogen.

2.7. Statistical analysis

All data was transformed using a log transformation. Data analysis was performed using SPSS for Windows release 14.0.0. Discriminant analysis was undertaken to establish grouping of samples. The procedure generates a set of discriminant functions based on linear combinations of the predictor variables that provide the best discrimination between the groups. The functions are generated from a sample of cases for which group membership is known; the functions can then be applied to new cases that have measurements for the predictor variables but have unknown group membership (SPSS, 2005). Discriminant analysis was carried out using the stepwise method in which the model is built step by step. Variables are evaluated at each step; the variable that gives the best discrimination between groups is included in the analysis.

The database for discriminant analysis was formed using the data collected for the known tea samples. Samples were analysed in triplicate and each analysis was inserted into the database as an individual data point. The commercial tea samples were then inserted into the database as unlabelled cases and the discriminant analysis repeated as a test of the potential of the technique for determining the origin of unknown samples.

3. Results and discussion

3.1. Country classification

This study uses tea samples whose provenance is accurately known thereby enabling rigorous method validation and confirmation of the provenance identification potential of the methodologies used. Following the verification of the technique, test samples were analysed and subsequently classified against the database formed with the known samples. Study samples were labelled with their country of origin. In addition, Indian tea samples were subdivided into Assam, Darjeeling and Nilgiri, to allow a secondary classification following the initial country classification. These areas have distinct reputations which are carefully-protected and represent the three areas of Indian tea production which this paper is primarily concerned with uniquely identifying.

The scatter plot of the first 2 discriminant functions from the analysis of the known tea samples (Fig. 1a) confirms the capability for separation of samples into their growing region. While tea samples from Taiwan and China appear to be inseparable, inclusion of the third discriminant function (Fig. 1b) presents a clear separation of the two regions. Using these three discriminant functions 97.6% of the samples was correctly classified. The variables used to achieve this classification were δD, $\delta^{13}C$, ^{49}Ti, ^{53}Cr, ^{59}Co, ^{60}Ni,

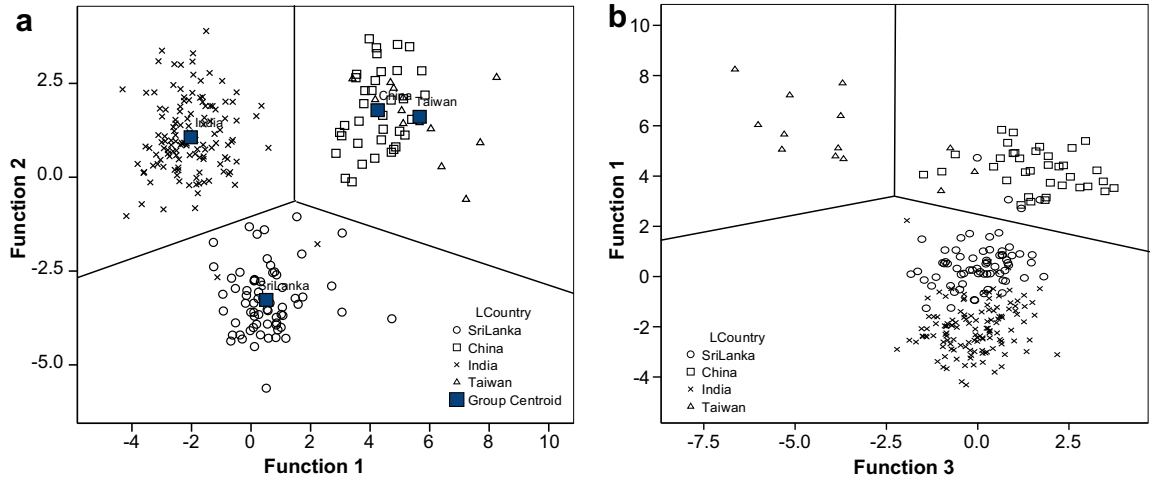

Fig. 1. (a) Scatter plot of the first 2 discriminant functions showing separation between Asian tea growing countries. (b) Scatter plot of discriminant functions 1 and 3 showing separation between China and Taiwan tea samples.

^{65}Cu, ^{71}Ga, ^{85}Rb, ^{88}Sr, ^{89}Y, ^{93}Nb, ^{111}Cd, ^{133}Cs, ^{138}Ba, ^{139}La, ^{140}Ce, ^{141}Pr, ^{153}Eu, ^{203}Tl, ^{208}Pb and ^{209}Bi.

After separation of the samples into their country region, it was investigated whether it was possible to separate the Indian tea samples into their individual growing regions. This was of particular interest due to the unique reputation of each of these regions. The discriminant analysis was repeated using a separate database consisting of the Indian samples, with classification according to region (Fig. 2).

For the method to be valid, it is important that when a sample from outside the database area is tested that it will not be incorrectly classified as coming from one of the test regions. To assess this, samples from other regions (including Africa and Australia) were inserted into the discriminant analysis as ungrouped cases. The discriminant analysis was run and the outcome assessed.

Fig. 3 presents the results from entering an African sample (labelled ungrouped cases) into the database. It can be seen that this sample forms a group completely separate from the Asian tea samples within the database, thus ensuring that misclassification would not occur.

3.2. Unknown samples

To test the validity of the method, a blind trial was conducted using 20 commercial tea samples. These samples were prepared and analysed and the data treated in the same manner as the database samples. The sample data was subsequently entered into the database as an ungrouped case and the discriminant analysis conducted to determine the likely growing region of the test samples. Following this the established origin was compared to the label. The majority of the samples could be matched with the listed growing region, while others were classified into an area different to that specified on the label.

Sample number 15, labelled Darjeeling, was inserted into the data set. Discriminant analysis grouped this sample with the Indian samples. As a further test, this sample was then inserted into the database of Indian teas to determine whether it would be possible to allocate it to a particular growing region within India. Discriminant analysis grouped this sample strongly (100%) with the Darjeeling group.

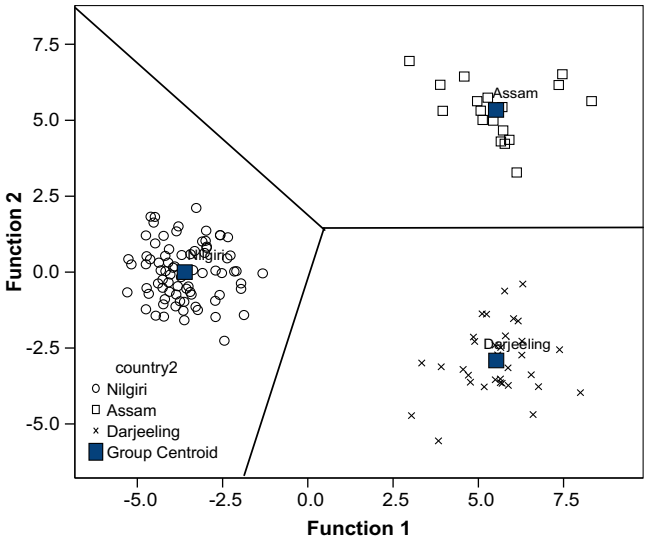

Fig. 2. Scatter plot of the first 2 discriminant functions showing separation of Indian teas according to growing region.

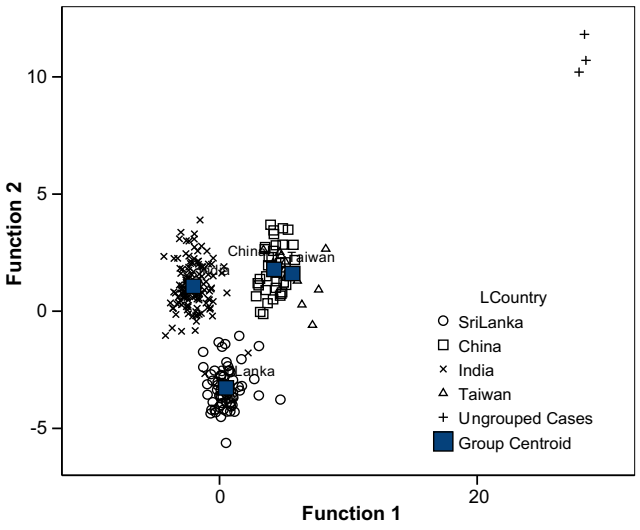

Fig. 3. Discriminant plot indicating the grouping of African tea sample (ungrouped cases) compared with the Asian tea database.

Table 2
Summary of established origin for commercial tea samples compared with the origin specified on the label

Sample #	Type	Established origin	Label
1	Jasmine	Taiwan	China
3	Black	Sri Lanka	Sri Lanka
4	Black	Sri Lanka	Sri Lanka
5	Black	2 China/1 Sri Lanka	India
6	Green	1 China/2 Sri Lanka	India
7	Black	Sri Lanka	Sri Lanka
8	Black	China	China
9	Earl Grey	China	Unlabelled
10	Black	China	China
11	Black	China	China
12	Black	India → Darjeeling	Darjeeling
15	Black	India → Darjeeling	Darjeeling
16	Black	Sri Lanka	Sri Lanka
17	Black	India → Assam	Assam
18	Black	Sri Lanka	Sri Lanka
19	Black	Sri Lanka	Sri Lanka
20	Black	Sri Lanka	Sri Lanka
21	Black	Sri Lanka	Sri Lanka
22	Black	Sri Lanka	Sri Lanka
23	Black	China	Blend

The analysis was repeated for each of the commercial tea samples. The established origin was then compared to the origin that was provided. The results are summarised in Table 2.

3.3. Intra-site variation

The tightness of the grouping of the samples gives an indication of the inter-site variation compared with the intra-site variation. The fact that the samples from one area group together, separate from the samples from other sites, indicates that the variation in chemical signatures between different sites is greater than the variation in signature between samples from the one site. This is particularly notable for the Nilgiri samples. These samples come from seven different plantations within Nilgiri. Samples also differed by grade, degree of processing, and harvest date (with a range of up to three years between harvests).

While it is obviously possible to distinguish between growing areas based on a chemical signature related to the local geology and climatology, it is also apparent from these data that the chemical signature of an individual area remains largely unchanged over a prolonged period of time. This is extremely important as it suggests that the investigator may be able to search a database of reference samples from previous harvests and determine a match. The ability to determine a match would be affected in the situation where there had been an extreme change in the climate or growing procedures of the crop, for example a change in fertilising practises. However, a benefit of the multi variable approach to the study is that it has been shown in previous studies (Gundersen, Bechmann, Behrens, & Sturup, 2000; Pilgrim, 2002) that not all minerals are significantly affected by the fertilising regime; it may therefore be possible to use the database to narrow down the regions from which further, current samples should be obtained to allow for a match. The data also suggests that there is a link between the metal content of the tea and the soil upon which it is grown. Further studies into this relationship may facilitate the development of generic databases, which will predict the chemical signature of teas on the basis of climatology, and geology, helping to identify the growing region of samples for which there is no data base entry.

Thirty-two tea samples were collected for analysis from the Nilgiri (Blue Mountains) region of Southern India. After initially establishing that the Nilgiri teas could be separated from teas the other growing regions, using discriminant analysis (Fig. 2), these samples were treated as a separate data set. The aim of this investigation was to establish whether samples could still be classified correctly despite seasonal and grade variations. In addition, the depth to which a sample could be distinguished from other samples grown in a similar area was also explored. Discriminant analysis was repeated exploring the separation that can be obtained comparing the signatures of the different plantations (Fig. 4a). 97.4% of cross-validated cases were correctly classified. The only samples that are not correctly classified are teas from the Havukal and Kairbetta gardens. The samples also appear to overlap. This is not surprising as the gardens are adjacent to each other. However, if the samples from the estates that clearly separate from each other are removed and the discriminant plot redrawn it is then possible to identify all Nilgiri teas and place samples correctly into the specific production garden (Fig. 4b). This gives an indication of the discriminatory power of the technique.

In conclusion, discriminant analysis of data obtained from trace element analysis in combination with stable isotope data, specifically δN and δD, can be used to determine the growing region of an unknown tea sample with a high degree of confidence. Results also indicate that these classifications are unaffected by the tea type (black, green or oolong), quality or harvest year. Preliminary

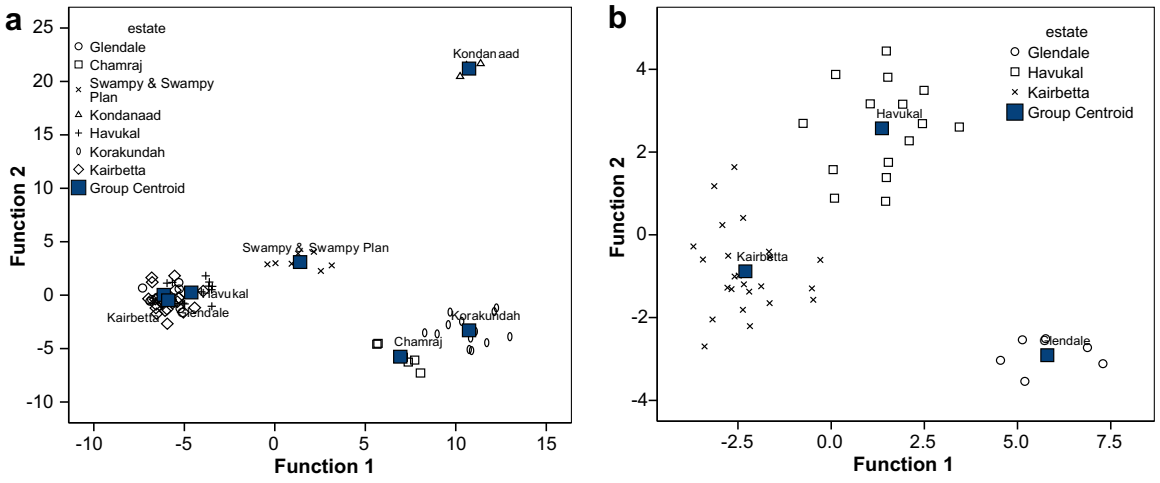

Fig. 4. (a) Scatter plot of first 2 discriminant functions showing separation between tea samples from different tea gardens within the Nilgiri region of India. (b) Scatter plot of the first 2 discriminant functions of the reduced Indian tea dataset showing separation between Havukal, Kairbetta and Glendale tea gardens.

results, based on samples from the Nilgiri region in India, indicate that once the country of origin is established, further data analysis would allow for determination of the garden on which the sample was grown.

Acknowledgements

The authors thank Sue Wang, Department of Chemistry at Curtin University of Technology, for assistance with irMS and Sven Fjastad and Allen Thomas, University of Western Australia, for assistance with ICPMS. The authors also thank Hillary and Nigel White from Elmstock Tea Company Pty. Ltd. Western Australia and David Thompson from Larsen and Thompson, Victoria for providing the tea samples and for their enthusiastic support of this research.

2. Materials and methods

2.1. Feeding trials

The controlled feeding trials were conducted at Harper Adams University College. Ross and Hubbard varieties of birds were used: the birds were reared as two groups according to the strain but with the males and females together. Initially, they were all fed a proprietary wheat/soya bean meal-based broiler feed that contained no maize or maize products. At 21 and 28 days of age, respectively, the Ross and Hubbard broilers were moved to the experimental feeding house to start on the controlled feeding trials. At 42 and 56 days, respectively, the Ross and Hubbard broilers were slaughtered and 5 males and 5 female birds from each treatment pen, with body weights within 2 SD from their group/gender means, were selected for analysis.

The selected birds were plucked, eviscerated and frozen before dispatch to the laboratory for analysis.

Three feeding trials were carried out. The first two were carried out on cohorts of 10 birds of each strain and the third carried out on a cohort of 10 Ross strain birds. Trials 1, 2 and 3 had 4, 5 and 7 treatments, respectively.

In the first trial, corn was added to the feed at concentrations of 0, 25, 50 and 75% (w/w) for the duration of the finishing period (21 days for Ross and 28 days for Hubbard).

In the second trial, the feeding of the 50% (w/w) corn diet was carried out for different periods of time: (A) for the duration of the finishing period, (days 21–42 for Ross and days 28–56 for Hubbard); (B) only for the first half of the finishing period, (days 21–31 for Ross and days 28–42 for Hubbard); (C) only for the second half of the finishing period (days 32–42 for Ross and days 42–56 for Hubbard); and (D) 75% (w/w) corn diet for the final 7 days only. A control feeding trial, containing no corn, was also incorporated into the study.

The third trial investigated the effect of possible confounding dietary factors on the Ross train of birds only: (A) No corn added but 'Prairie meal' (maize gluten meal, a valuable protein source derived from corn) added throughout the finishing period (21–42 days) at 10% (w/w); (B) No corn but the natural pigment Oroglo added to the feed throughout the finishing period; (C) 40% (w/w) corn plus 10% (w/w) Prairie meal added to the feed throughout the finishing period; (D) 40% (w/w) corn plus 10% (w/w) Prairie meal plus the synthetic pigment, Carophyll Red added to the feed throughout the finishing period; and (E) 50% (w/w) corn plus Oroglo added to the feed throughout the finishing period. One control feeding trial, with no corn fed throughout the finishing period, was also included in this study.

All the diets were nutritionally complete and had similar nutrient compositions (Tables 1 and 2).

The carotenoid content of corn is, on average, 6.4–11.3 mg kg^{-1} (Cruz et al., 2004). The marigold pigment used in this experiment, Oroglo, contains 20 g kg^{-1} of xanthophylls. By adding 1.5 g kg^{-1} of Oroglo, the aim was to add 30 g more xanthophylls per tonne of feed. A similar approach was taken with the Carophyll Red, which contains canthaxanthin. This contains 450 g kg^{-1} of xanthophylls, so 66 mg kg^{-1} of this was added. The maximum amount of canthaxanthin that is allowed in the diet, by EU regulation, is currently 25 mg kg^{-1} (EC Directive 2003/7/EC).

2.2. Sample preparation

Four samples of meat were taken from the breast of each bird. The samples were freeze-dried for three days then homogenised and combined to obtain a representative sample from each bird.

Blind samples were selected from the samples prepared from the first feeding trial.

Table 1
Ingredient composition (g/kg) and calculated nutrient concentrations (g/kg) in the experimental diets in feeding trials 1 and 2

Metabolisable energy (MJ/kg)	13.0	13.1	13.2	13.3

[a] Vitamin-trace mineral premix for broilers (Ian Hollows Feed Supplement, UK) added per kg of diet: 800 mg retinol, 150 mg cholecalciferol, 1.25 g tocopherol, 150 mg thiamin,500 mg riboflavin, 150 mg pyrodoxine, 750 mg cyanocobalamin, 3 g nicotinamide,0.5 g pantothenic acid, 75 mg folic acid, 6.25 g biotin, 12.5 g choline chloride, iron 1 g, 50 mg cobalt, 5 g manganese, 0.5 g copper, 4 g zinc, 50 mg iodine,10 mg selenium, and 25 mg molybdenum.

Dried meat (0.5 g) was weighed into a 4 mL vial and 2 mL of hexane was added (HPLC Grade, Sigma Aldrich) and placed in an ultrasonic bath for 20 min. The sample was then removed from the ultrasonic bath and the supernatant was removed. The liquid was filtered through a 0.45 μm PVDF (polyvinylidene fluoride) syringe filter into a 4 mL vial. The extraction procedure was repeated with a further 2 mL of hexane, and after filtering the extracts were combined. The hexane was evaporated under a stream of nitrogen to produce the lipid fraction. The remaining defatted meat (protein) fraction was air dried prior to analysis.

Chicken feed samples were analysed without prior lipid extraction.

2.4. $^{13}C/^{12}C$ Isotopic analysis

Lipid samples were diluted to a concentration of 0.2 mg mL^{-1} in hexane. Five microlitres of the resultant solutions were transferred to tin capsules (Exeter Analytical, solid, 5 × 2 mm) and the hexane was evaporated under a stream of nitrogen. One milligram aliquots of the protein fraction were weighed into tin capsules (Exeter Analytical, foil, 5 × 3.5 mm) for analysis.

The capsules containing lipid or protein fraction were placed in the autosampler of the elemental analyser (EA 1108, CE Instruments, Milan, Italy), and dropped into a vertical quartz tube maintained at a temperature of 1020 °C. The helium stream was then temporarily enriched with oxygen and the sample oxidised in a 'flash' combustion reaction. Quantitative combustion was achieved by passing the gas mixture over a catalyst layer of chromium oxide and a halogen scrubber layer of silvered cobaltous oxide. The combustion gases were then passed over elemental copper at a temperature of 650 °C, in a second quartz tube, to remove residual oxygen and convert nitrous oxides to nitrogen. Water was removed from the gas stream by a chemical trap containing anhydrous magne-

[a] Vitamin-trace mineral premix for broilers (Ian Hollows Feed Supplement, UK) added per kg of diet: 800 mg retinol, 150 mg cholecalciferol, 1.25 g tocopherol, 150 mg thiamin,500 mg riboflavin, 150 mg pyrodoxine, 750 mg cyanocobalamin, 3 g nicotinamide,0.5 g pantothenic acid, 75 mg folic acid, 6.25 g biotin, 12.5 g choline chloride, iron 1 g, 50 mg cobalt, 5 g manganese, 0.5 g copper, 4 g zinc, 50 mg iodine,10 mg selenium, and 25 mg molybdenum.

sium perchlorate. Following the water trap the components of the reaction gas mixture (N_2 and CO_2) were separated on a chromatographic column (Porapak PQS, PTFE, 2 m, 6 × 5 mm). A portion of the effluent from the elemental analyser (ca. 0.5 mL min^{-1}) was transferred into the Delta S isotope ratio mass spectrometer (Thermo Finnigan, Bremen, Germany), and the signal from ions at *m/z* 44, *m/z* 45 and *m/z* 46 was monitored.

The ^{13}C content was expressed as the ratio of $^{13}C/^{12}C$. Stable isotope ratios are routinely expressed as parts per thousand (‰) difference from the isotopic ratio of an international standard VPDB (Vienna Pee Dee Belemnite). Secondary calibration of the isotope ratios was carried out by reference to in-house reference materials including gases that were traceable back to VPDB.

3. Results

The results for the Hubbard and Ross birds fed with the varying proportions of corn (treatment 1) are summarised in Figs. 1 and 2, respectively. As expected, the $\delta^{13}C‰$ value of both the lipid and protein fraction in the corn-fed chickens became more positive with increasing corn content in their feed. The natural variation in $\delta^{13}C‰$ values for both the protein fraction and lipid fraction for the chickens in the same treatment was small, (standard deviations ⩽0.67‰ for lipid and ⩽0.26‰ for protein). The trend for the $\delta^{13}C‰$ values for protein fraction, from zero to 75% (w/w) corn, was less pronounced than for the $\delta^{13}C‰$ of the lipid and this was probably due to the adipose tissue carbon being influenced by the diet more rapidly than the muscle protein. As a result of this, the apparent gap between $\delta^{13}C‰$ values of the protein and lipid fractions decreased with increasing corn in the diet, a difference of 4.86‰ for no corn in the diet decreasing to 2.86‰ for 75% (w/w) in the diet.

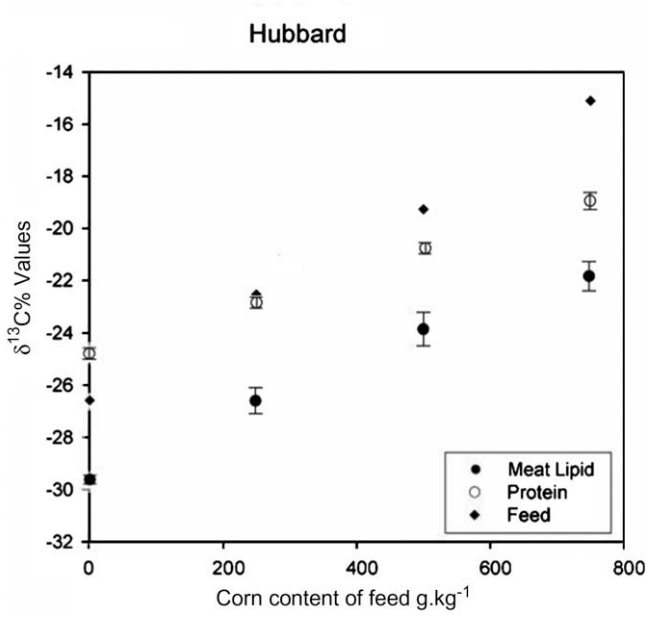

Fig. 1. The effect of corn content of diet on the $\delta^{13}C‰$ values of Hubbard birds. The error bars represent the standard deviation in the $\delta^{13}C‰$ values of 10 birds from the same treatment pen.

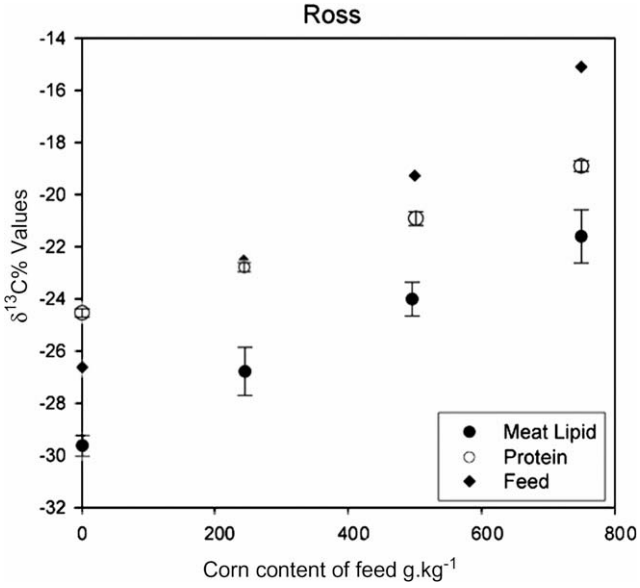

Fig. 2. The effect of corn content of diet on the $\delta^{13}C‰$ values of Ross broilers. The error bars represent the standard deviation in the $\delta^{13}C‰$ values of 10 birds from the same treatment pen.

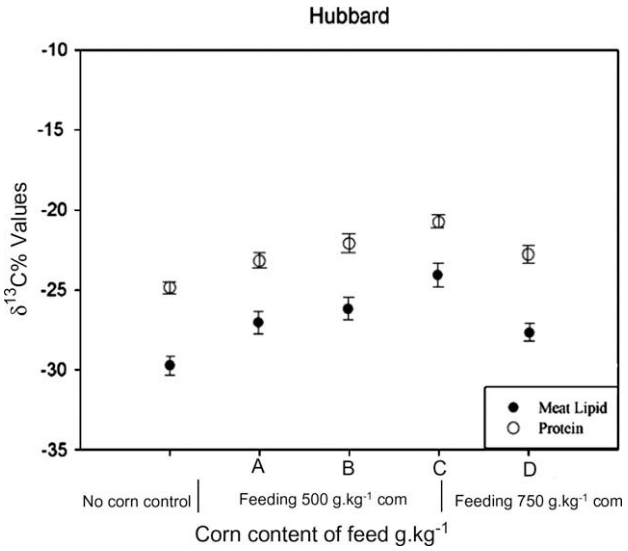

Fig. 3. $\delta^{13}C‰$ values of Hubbard birds fed with corn for varying amounts of time. A = 14 days feeding from 28 to 42 days, B = 14 days feeding from 42 to 56 days, C = 28 days feeding from 28 to 56 days and D = 7 days feeding from 49 to 56 days.

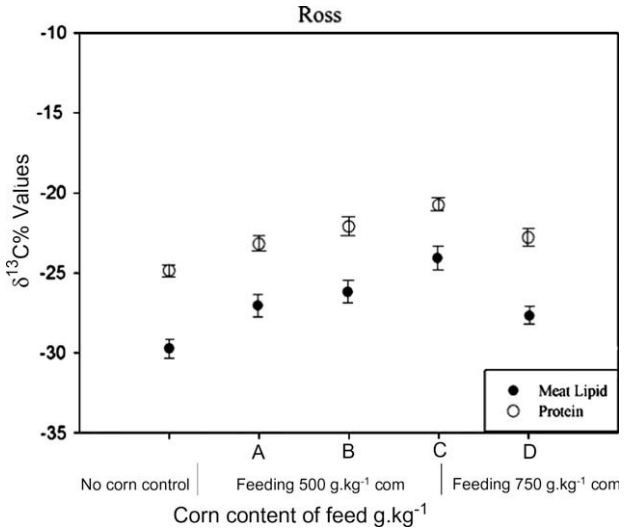

Fig. 4. $\delta^{13}C‰$ values of Ross broilers fed with corn for varying amounts of time. A = 10 days feeding from 21 to 31 days, B = 10 days feeding from 31 to 42 days, C = 21 days feeding from 21 to 42 days and D = 7 days feeding from 35 to 42 days.

Differences between the $\delta^{13}C‰$ values of both the lipid and protein fractions of the two varieties of birds were small but statistically significant ($P < 0.05$). Analysis of covariance showed that the breed had an effect on the intercept of the regression line amounting to a difference of only 0.1‰ for the protein fraction. This difference probably reflected the differences in the growth rates of the two varieties.

The carbon isotope ratio results for the chickens fed with the fixed levels of corn for varying amounts of time (treatment 2) are summarised in Figs. 3 and 4. The effect of varying the length of corn feeding was pronounced, with the 50% (w/w) corn-fed control samples, fed for all of their fattening period (half their life) having significantly more positive values than the samples where feeding was for only half the fattening period. The values for the samples from the birds fed with 50% (w/w) corn for the second half of their fattening period (42–56 days for Hubbard and 31–42 days for Ross) were more positive than the samples from the birds fed with 50% (w/w) corn in the first half of the fattening period but this was not statistically significant. The values for the samples where the feed contained 75% (w/w) corn for the last week were similar to those for 50% (w/w) corn for the second half of the fattening period for Ross broilers. However, the values for the Hubbard birds fed 75% (w/w) corn for the last week were less than those for the 50% (w/w) corn for the second half of the fattening period. Again, this probably was a reflection of the different growth rates of the two birds with the faster growing Ross strain incorporating more of the corn ^{13}C into both protein and lipid over the last quarter of the birds life.

The carbon isotope ratio results for the Ross Broilers fed with pigments and alternative feeds (treatment 3) are summarised in Fig. 5. The Prairie meal had a significant influence on the carbon values, leading to more positive $\delta^{13}C‰$ values. For the pigments, the effects on the carbon isotope ratios were less significant. There was no statistically significant difference in $\delta^{13}C‰$ values between the 50% (w/w) corn with 50% (w/w) corn plus Oroglo. This was also the case for the 40% (w/w) corn plus Prairie meal against the similar treatment with Carophyll Red added. The results also showed significant changes in the $\delta^{13}C‰$ of both the protein fraction and lipid values for the addition of Prairie meal, with the $\delta^{13}C‰$ protein fraction values increasing more than the $\delta^{13}C‰$ lipid values, contrary to what was observed with the addition of corn. (The difference between $\delta^{13}C‰$ protein and $\delta^{13}C‰$ lipid values for non corn-fed chickens was 4.97; for 50% (w/w) corn-fed chickens it was 3.05‰, and for Prairie meal-fed chicken was 5.96‰.)

Blind testing of samples from feeding trial one correctly identified all the samples that had not been fed corn and the samples that had been fed corn at 50% (w/w) in their diets for at least half of the fattening period – the generally recognised criteria for corn-fed chicken.

An evaluation of commercially grown corn-fed chickens and commercial corn chicken feed was carried out to assess whether the method was applicable to commercial conditions in the UK. Four samples of commercial chicken corn feed were analysed and had $\delta^{13}C‰$ values ranging from −19.25‰ to −21.7‰. A commercial non-corn chicken feed had a $\delta^{13}C‰$ value of −26.31‰.

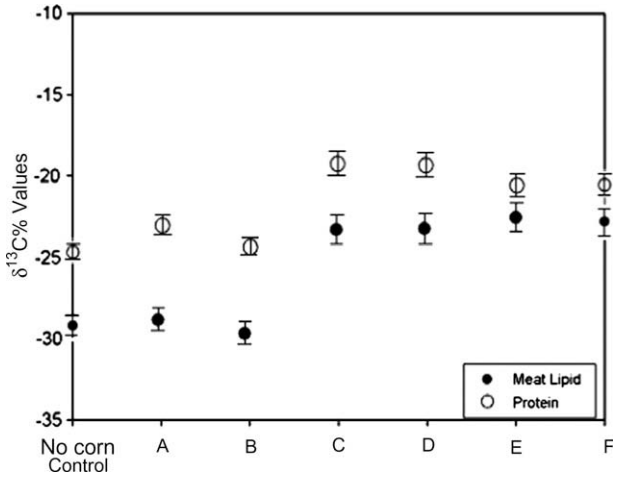

Fig. 5. The effect of feed type on the $\delta^{13}C‰$ values of Ross chickens. CR = Carophyll Red, A = Diet with Prairie meal, B = diet with Oroglo, C = 400 g kg^{-1} corn + Prairie meal, D = 400 g kg^{-1} corn + Prairie meal + Carophyll Red, E = 400 g kg^{-1} corn + Oroglo and F = 500 g kg^{-1} corn.

Analysis of the $\delta^{13}C‰$ values of protein from eight commercially grown corn-fed chickens (two producers) revealed a good correlation between $\delta^{13}C‰$ values and the corn-fed status of the birds, (mean $\delta^{13}C‰$ −20.75 st. dev. 0.37). In contrast, analysis of the chicken lipid was less conclusive, ($\delta^{13}C‰$ mean values −27.2 st. dev. 0.78) suggesting the chicken lipid was a less reliable indicator of dietary status. This reflected the observations made in the experimental samples where a larger variation was observed in the $\delta^{13}C‰$ values for lipid than for protein (standard deviations $\leqslant$0.67‰ for lipid and $\leqslant$0.26‰ for protein).

Analysis of three commercially reared chickens of different breeds to those in the experimental study (BAC 657, COB500 and Maron Gold line), grown on normal commercial diets, showed a mean $\delta^{13}C‰$ value of their protein to be −24.57 (st. dev. 0.31) and mean $\delta^{13}C‰$ value of their lipid to be −28.77 (st. dev. 0.60) indicating that the breed of chicken did not significantly influence the $\delta^{13}C‰$ value. (The Ross and Hubbard experimental samples fed on commercial diets had a mean lipid $\delta^{13}C‰$ values of 29.49 and a mean protein $\delta^{13}C‰$ value of −24.69.)

4. Discussion and conclusions

The data obtained in this study show that stable carbon isotopes can be used to differentiate between corn-fed and non corn-fed chicken. The linear trend in carbon isotope ratios with increasing amounts of corn in the diet was reflected in both the chicken lipid and protein. The amount of dietary fat that goes directly into the body fat depends on the dietary energy intake relative to the energy needs of the birds. The formulated diets were similar to commercial nutrient specifications and so were relatively energy dense, and so a high proportion of the dietary fat would have been deposited into the adipose tissue. Since all the diets contained the same amount of lipid the high corn diets would rapidly reflect the ^{13}C signature of corn lipid (Bavelaar and Beynen, 2003). This probably explains why more ^{13}C was observed in the body fat than in the protein.

The feeding time experiments indicated that it was possible to distinguish between chicken samples, where a corn diet was fed for a shorter period than recommended.

A comparison of the $\delta^{13}C‰$ data from the lipid and protein fractions from commercially produced corn-fed chicken, in order to evaluate the ability of the data to discriminate between the two rearing conditions, showed that the lipid values were less appropriate than the protein values.

The addition of Prairie meal to the diet was shown to increase the $\delta^{13}C‰$ values of both the protein and lipid in the chicken but to have a more marked effect on the protein value so that in the experimental samples it was possible to determine when Prairie meal had been used in the diet by examining the difference between the protein and lipid $\delta^{13}C‰$ values. In the light of the greater variability in the lipid $\delta^{13}C‰$ values of the commercially grown corn-fed chicken this would no longer be possible, so the addition of Prairie meal to the diet could probably not be distinguished from the addition of corn to the diet.

Analysis of the commercial feeds directly confirmed the hypothesis that the higher corn content of the feed was reflected in a more negative $\delta^{13}C‰$ value, and there were no other confounding factors in the commercial feeds.

Examining the protein $\delta^{13}C‰$ values from all of the experimental samples analysed showed that the non corn-fed chickens had a mean $\delta^{13}C‰$ value of −24.68 (st. dev. 0.17, $n = 40$), while the corn-fed chicken protein had a mean $\delta^{13}C‰$ value of −20.67 (st. dev. 0.34, $n = 50$). This compared very well with the commercial non corn-fed samples with a protein $\delta^{13}C‰$ value of −24.87; (st. dev. 0.35, $n = 14$) and the average $\delta^{13}C‰$ protein value the from commercial corn-fed samples of −20.75 (st. dev. 0.37, $n = 8$).

A calibration of $\delta^{13}C‰$ measurements against the proportion of corn in the diet produced a linear relation (Fig. 6). Four of the 140 results were judged to be outliers and were not used in the calibration. A critical value of −22.5 $\delta^{13}C‰$ was set because it was half way between the lower end of a 95% prediction interval of the calibration for 50%-corn-fed chicken and the upper end of a 95% prediction interval for 0%-corn-fed chicken. Measurement results below the critical value were used to identify chicken that had been fed less than the required 50% corn. The difference between the expected measurement results for chicken fed on 50% corn and the critical value was over eight times the standard error of prediction associated with the calibration at 50%. Hence, the false positive rate (proportion of samples from chicken fed on 50% corn identified as non corn-fed chicken) can be expected to be very low, effectively zero assuming measurement results are normally distributed (examination of the residuals showed that this assumption was reasonable). A threshold set at −22.5 $\delta^{13}C‰$ allows the method to reliably (>97.5%) assign chicken as non corn fed if the diet contains no more than 23.3% corn and by setting the threshold at −21.42 allows the method to reliably assign chicken fed on no more than 37% corn as non corn-fed.

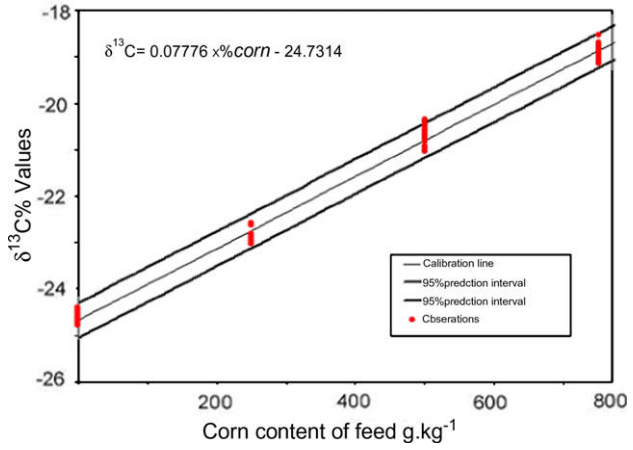

Fig. 6. Calibration curve of $\delta^{13}C‰$ values of chicken protein fraction and amount of corn in diet.

As part of the EU-funded TRACE project which aims to develop and apply analytical methods for the proof of geographical origin of food the usefulness of strontium isotope ratio investigations was evaluated.

Originally, the use of strontium isotope ratios was restricted to geosciences. However, since Chaudhuri (1978) published a study about the application of $^{87}Sr/^{86}Sr$ to investigate the origin of groundwater, the method has also been widely used in hydrology, although mostly for deep subsurface waters of higher temperature and/or salinity (Chaudhuri & Clauer, 1992; Hofmann & Baumann, 1986; Matter, Peters, & Ramseyer, 1987; Pampura, Plyusnin, & Sandimirova, 1980; Ufrecht & Hoelzl, 2006). Åberg (1995) presented the applicability of the method for several environmental studies.

More recent investigations deal with the application of strontium isotope ratios for human migration studies in archaeology (Bentley, 2006; Hodell, Quinn, Brenner, & Kamenov, 2004; Hoogewerff et al., 2001; Montgomery, Evans, & Wildman, 2006; Price, Knipper, Grupe, & Smrcka, 2004; Åberg, Fosse, & Stray, 1998), for paleodietary studies (Lee-Thorp & Sponheimer, 2003) or for forensic purposes (Beard & Johnson, 2000; Rummel, Hoelzl, & Horn, 2007). In the field of food science the first investigations of origin determination were carried out for wine (Barbaste, Robinson, Guilfoyle, Medina, & Lobinski, 2002; Horn, Hoelzl, Todt, & Matthies, 1998; Horn, Schaaf, Holbach, Hoelzl, & Eschnauer, 1993), milk (Crittenden, Andrew, LeFournour, Young, & Middleton et al., 2007), butter (Rossmann, Haberhauer, Hoelzl, Horn, & Pichlmayer et al., 2000), British mineral waters (Montgomery et al., 2006), rice (Oda, Kawasaki, & Hirata, 2002), and fruit juices (Rummel, Hoelzl, Horn, Rossmann, & Schlicht, 2008).

In order to assign origin to a food sample on the basis of its strontium isotope composition, the isotope ratio of the sample must be compared to data of authentic samples from the region in question. However, because of the usually limited possibilities to compile an adequate database of authentic samples, it cannot be assured that these samples will represent the entire strontium isotope variability of the area. This aspect is especially relevant for products from remote areas where data for authentic reference samples are lacking or unobtainable.

In order to evaluate the results, a prediction should be carried out on the basis of thorough knowledge of the geological and pedological situation of the region in question (Horn et al., 1993).

The present large scale investigation of $^{87}Sr/^{86}Sr$ in natural mineral waters is used to test if it is possible to identify geologically derived key parameters predominantly responsible for the strontium isotopic signature in the water in order to predict data ranges for samples just by the knowledge of the geographical origin and the use of a common geological map.

First results of $^{87}Sr/^{86}Sr$ analyses in "surface" water samples, ammonium nitrate extracts from soil samples, and honey as well as wheat samples from specific sample regions within the TRACE project, will be used in this study to test the applicability and transferability of predicted data ranges for strontium isotope ratios, gained by the natural mineral water investigation, to other agricultural products and food commodities.

2. Fundamentals

$^{87}Sr/^{86}Sr$ is a parameter reflecting local geochronological and lithological settings by their natural spatial variation.

Strontium isotopic signatures in rocks have evolved over geological time. ^{88}Sr, ^{86}Sr and ^{84}Sr are stable and not radiogenic whereas the abundance of 87Sr increases with radioactive decay of ^{87}Rb (half life: 48.8 x 109 years). Thus, actual $^{87}Sr/^{86}Sr$ is a function of initial $^{87}Sr/^{86}Sr$, initial Rb/Sr and time.

For example, young and rubidium-poor rocks such as Quaternary basalts have low $^{87}Sr/^{86}Sr$ (from 0.702 to around 0.706), whereas older and/or rubidium-rich rocks such as Palaeozoic granites show considerably higher ratios (Faure, 1986).

Any groundwater – in this study bottled groundwater defined as natural mineral water – obtains its characteristic strontium and isotope content from the processes of dissolution and re-precipitation of strontium from minerals. As no significant isotope fractionation occurs the groundwater obtains its isotopic signature from the minerals of the soil and rock strata through which it percolates. Precipitation processes only change the strontium content but do not alter the isotopic signature.

The strontium isotopic composition of groundwater does not reflect the $^{87}Sr/^{86}Sr$ of the bulk soil or rock it comes into contact with, but that of the soluble minerals able to exchange chemically with the water (Horn, 2005; Horn et al., 1998; Åberg, Jacks, & Hamilton, 1989).

When water circulates through the underground ongoing dissolution and precipitation is controlled by the respective recalibrated hydrochemical and hydrophysical properties of the fluid by the surrounding conditions. In the region of Hegau-Schaffhausen at the Switzerland/Germany border detailed hydrogeological investigations, which include comprehensive strontium isotope ratio analyses, appear to indicate that in earth-alkaline waters a first hydrochemical equilibrium status is reached soon after infiltration. The implication is that the specific strontium content and isotopic signature is induced by soil and surface geology within only a couple of years.

If no significant change is enforced on the quasi hydrochemical equilibrium of an earth-alkaline water, the strontium isotopic signature will remain constant for long circulation periods even in more profound and geologically different layers (InterregIIIA-Projektbericht, 2008).

The isotopic composition of groundwater from aquifers in evaporites and marine limestones resembles the isotopic composition of the rocks due to the simple geochemical composition of these rocks and the solubility of the main minerals.

As the strontium concentration and isotope ratio is closely related to the carbonate system, isotope ratios measured in groundwaters from large limestone areas follow roughly the marine curve primarily published by Burke, Denison, Hetherington, Koepnick, & Nelson et al. (1982) and Veizer and Compston (1974), continuously revised e.g. by McArthur (1994) and McArthur, Howarth, and Bailey (2001).

The isotopic composition of groundwater filtered through clastic sediments, metamorphic or magmatic rocks resemble the composition of easily weathering minerals of the corresponding rocks.

3. Sampling

Between 2005 and 2006 participants of the TRACE project collected about 650 different natural mineral water brands predominantly of western Europe. For samples from Hungary, Slovakia, Switzerland, Scandinavian countries, Slovenia, Croatia and for half the samples of Poland private contacts were used. Sampling of bottled natural mineral water was mostly done by simply buying bottles in shops. Producers have voluntarily provided only small selections of waters. The geographical origin was determined by the indicated bottling locality (city) marked on the bottle and/or by the published lists of the EU (Official Journal C59, 09-03-2005; latest update 23-10-2006).

For mapping, all geographical coordinates have been determined by the same route planning software (ADAC TourPlaner Europe 2005/2006), which turned out to be the quickest and easiest way to find even the smallest towns. It is assumed that the locality

of the source is within a distance of about 15 km, which is acceptable in this context. It is known that often more than one water source is used for the bottling of one brand, or that the sources tap multiple rock types as there are often sources in complex tectonic fault zones and/or pumped from different geological units. But for our large scale survey these details play a minor role and have therefore been neglected.

The sampling was organised to get a widespread overview of the European market and to obtain a relatively complete geologic and geographic coverage. The availability of some brands was limited or sourcing was too expensive and intricate. As several European countries have quite different drinking cultures and natural mineral water markets, not every country provides the same spatial distribution of natural mineral waters. For example, Germany offers around 800 brands, while Ireland acknowledges only four brands.

Around 700 different (ground) waters – bottled and raw ones – were sampled. Over 90% of the samples were labelled as natural mineral waters. Furthermore, for better coverage of regions with lower amount of bottling plants we included waters labelled as spring – or medical waters, which are also bottled at source. In addition, to evaluate the effect of production processes and different bottling dates on strontium isotope ratios, about 40 raw water samples were measured. These analyses showed that influences from filtering and bottling processes and seasonal variations of strontium isotope ratios can be excluded (Voerkelius & Lorenz, 2009).

The analysed parameters include the analysis of the main ion content, trace element concentration, isotope ratios of S, O, H, Sr and the tritium content (Voerkelius & Lorenz, 2009). In the context of this paper only the tritium content, the total mineral content and the strontium isotope ratio is of relevance.

4. Measurement

The strontium isotope results discussed in this paper were produced in four different laboratories. Instruments used were one Thermal Ionisation Mass Spectrometer (TIMS) and three Multi Collector Inductively Coupled Plasma Mass Spectrometers (MC-ICP-MS). As the participating laboratories already had their established methods for sample preparation, and were equipped accordingly, each followed it's own sample preparation procedures, described below. To allow for comparison of measurement results, the laboratories worked according to the same standard operating procedure (SOP). The SOP included recommendations on Rb/Sr separations, corrections for procedural blanks, the prescription of the $n(^{86}Sr)/n(^{88}Sr)$ and $n(^{87}Rb)/n(^{85}Rb)$ reference values used for discrimination and interfering element corrections (0.1194 ± 0 and 0.38565 ± 0.00030, respectively), and requiring partial internal validation of methods by regularly measuring the NIST SRM® 987 (SOP, 2006).

Depending on the Sr content, from 1 to 50 mL of natural mineral water or soil extracts were evaporated. Honey and wheat (0.3–30 g) were digested by applying microwave digestion, high pressure microwave digestion, or ashing in a muffle furnace. Residues were dissolved in HNO_3 and subsequently Sr was separated from other elements such as Ca, Ba or Rb by ion chromatography on a Sr specific crown ether resin (Sr-spec®).

The TIMS was a MAT 261/262 Thermo Finnigan and measurements were carried out on tungsten single filaments. For quality control and to check for proper operation of the mass spectrometer an international Sr-standard (NIST SRM® 987) was analysed under the same conditions as the samples. One year standard measurements ($n = 100$) yield a precision of 60 ppm for 95% probability limits (0.71025 ± 0.00004). Duplicate analyses on ten samples showed a reproducibility of <40 ppm, and total blanks are mostly below 100 pg Sr, which is negligible compared to a total Sr content between 100 and 2000 ng in the samples.

The three MC-ICP-MS involved were a Nu Plasma (Nu Instruments), an Axiom (ex-VG Instruments), and an Isoprobe (ex-Micromass). Typically, the instrumentation was equipped with a minicyclonic jacketed cinnabar spay chamber or a porous membrane based desolvation unit, a 0.2 mL min^{-1} microcentric nebuliser and Ni or Pt sampler and skimmer cones.

All four laboratories were involved in five measurement comparisons on natural mineral water test materials. These tests showed for natural mineral water samples a degree of equivalence of about 150–200 ppm between the laboratories.

The results are given as isotope ratios and as δ notation in analogy to the isotopes of the light elements commonly used in the food chemistry sector (Rossmann et al., 2000, Rummel et al., 2008). The δ value is defined as

$$\delta^{87}Sr = (^{87}Sr/^{87}Sr_{analysed}/^{87}Sr/^{86}Sr_{Standard} - 1) \times 1000$$

with $^{87}Sr/^{86}Sr$ Standard = 0.7093 (approximation for baltic sea water) according to Rossmann et al. (2000).

For groundwater dating the analysis of the tritium content of the samples was carried out by Low Level Liquid Scintillation Counting (LSC) after electrolytic 3H enrichment (e.g. Clark & Fritz, 1997). The results are expressed in Tritium Units (TU) with 1 TU = 0.119 Bq/L.

5. Development of a prediction tool

Although the strontium isotopic signature of a natural mineral water is the result of an individual and often complicated genesis, it is believed that these individual influences will be evened out by the large sample number, so that the results of this large scale investigation can be used for the development of a simplified qualitative prediction tool for the isotopic signature of unknown samples.

As described above, comprehensive investigations in the region of Hegau-Schaffhausen indicate that groundwaters with relatively low mean residence time tend to reflect the strontium isotopic signature of the surface geology (InterregIIIA-Projektbericht, 2008). As a result of these investigations and additionally by knowledge about hydrochemical equilibrium in groundwaters (Hölting, 1989), we assumed that in young natural mineral waters the strontium isotopic signature is governed by that of the soil and surface geology.

In hydrology the analysis of tritium content is used to identify young groundwater. If the tritium content is above detection limit in the natural mineral waters, the groundwater or at least part of the groundwater has a mean residence time of 50 years or less (in the current investigation before 2005 to 2006) – and is classified as young water (Clark & Fritz, 1997). In approximately 85% of all analysed brands tritium exceeds the detection limit of 0.6 TU. Therefore it is justifiable to correlate the strontium isotopic signature of the water samples with surface geology.

In order to verify a correlation between surface geology and strontium isotopic signature of the natural mineral waters, a comparison was made to a geological map. The indicated geology at the production location, as well as information of the whole catchment region including possible geological transition zones, were considered in this comparison.

The European geological map used is GIS based and provided by Pawlewicz, Steinshouer, and Gautier (2003). The map differentiates between geochronology and lithology (intrusives, volcanic rocks, metamorphic rocks and sedimentary rocks).

For improved visualisation of the correlation of the geological units and the strontium isotope values of the natural mineral waters the map was simplified with the aid of geographic information system software (GIS: ESRI ArcMap 9.2) (Fig. 1): According to the prevailing $^{87}Sr/^{86}Sr$ range of the samples located on each geological unit, the natural mineral water samples were grouped correspondingly in six groups. Geological units with similar strontium isotope data ranges to those of the samples located on these units were aggregated in the map and allocated the same colour.

In cases where a limited number of samples were available to represent a geological unit, for example the Paleozoic intrusives, assumptions were made based on fundamental geological knowledge and experience.

In the map in Fig. 1 different geological units are assigned into six distinct groups, which are indicated in the legend in six different colours. The origin locations of the natural mineral water samples are also indicated as spots in Fig. 1. The colours of the individual natural mineral water samples represent the interval into which the measured strontium isotope value was classified. All strontium isotope values were divided into six groups, which correspond to typical values associated with the geological groups indicated on the map. Visual comparison of natural mineral water strontium isotope ratios to strontium isotope ratios of underlying surface geology is now possible. As visually indicated by a difference in the colour of some spots and the underlying geological unit, it is not in all cases possible to predict the strontium isotope value

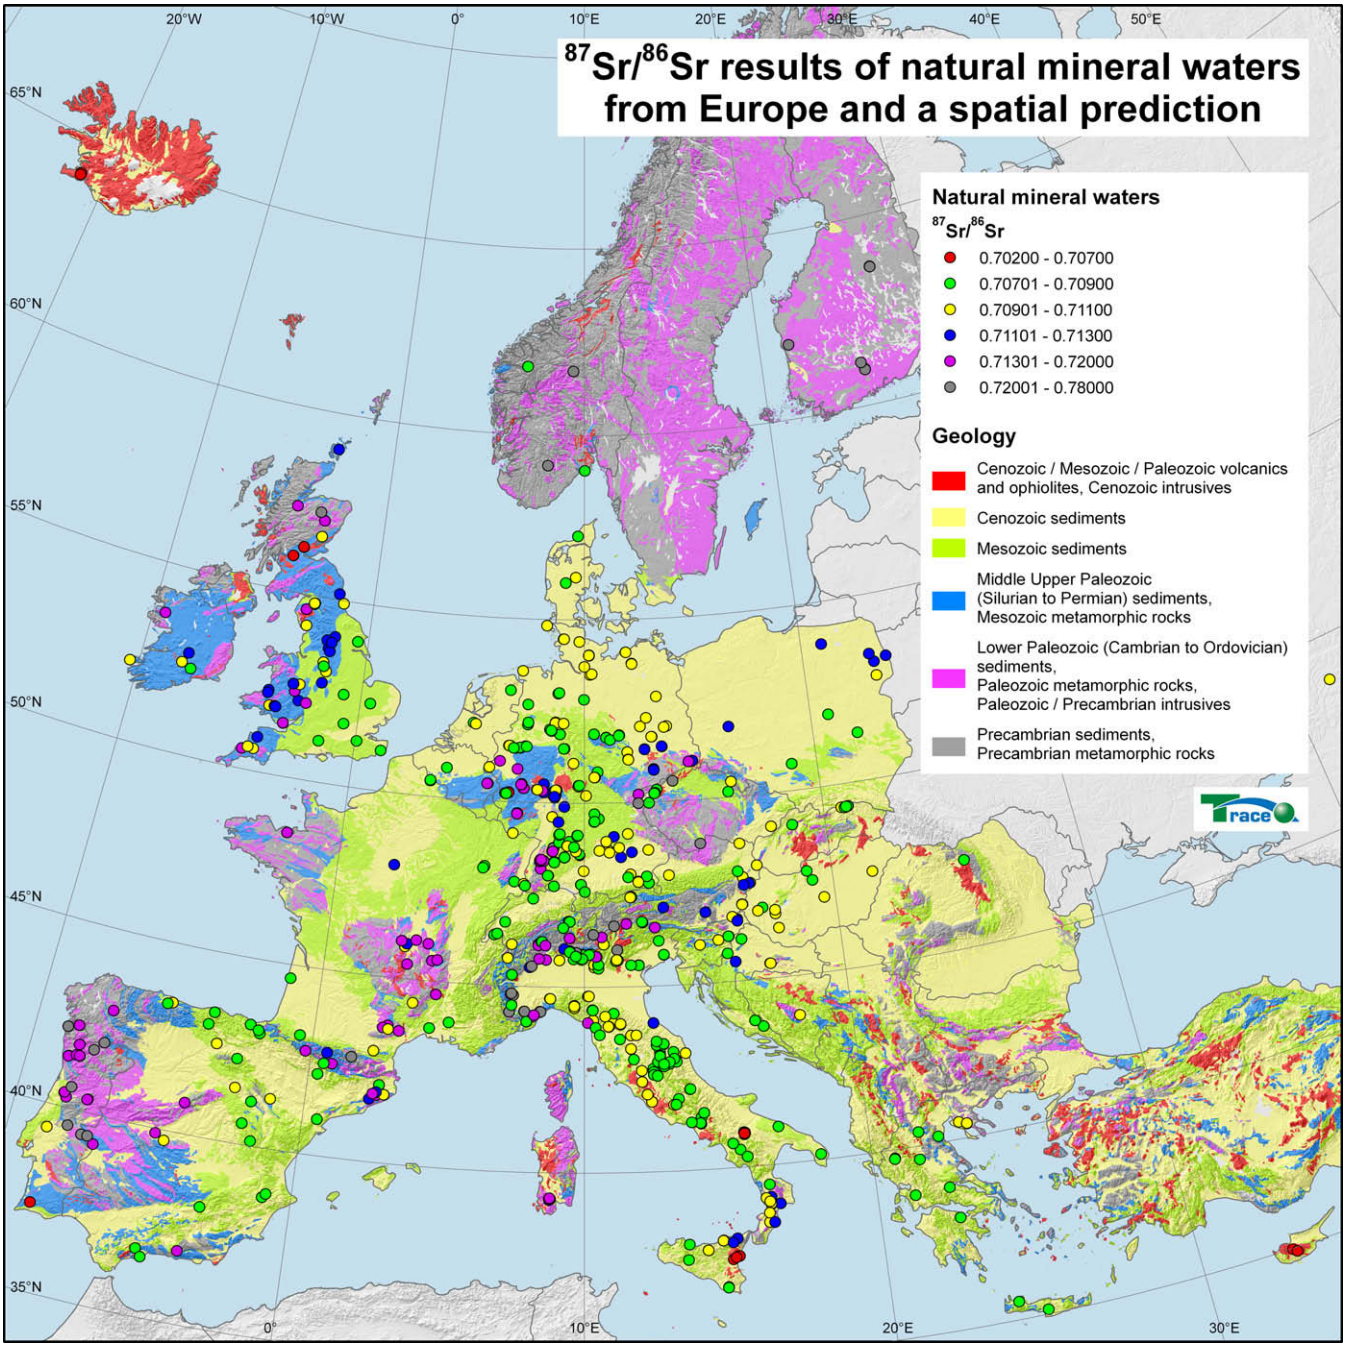

Fig. 1. Map with $^{87}Sr/^{86}Sr$ results of natural mineral waters from Europe and a spatial prediction (see Supplementary data). The map was drawn by simplifying a GIS based geological map from Pawlewicz et al. (2003).

of a sample based on the geological unit from which it was collected.

In a further iterative procedure, the data ranges were adjusted and allocated to the corresponding geological units. For this process especially natural mineral waters with their catchment area in transition zones of different geological units were checked.

6. Analytical results

656 bottled water samples were analysed and interpreted in this study. An overview of the results of the total mineral and strontium content as well as ranges for $^{87}Sr/^{86}Sr$ is given in Table 1 grouped according to the correlation ranges of surface geology of location and water samples. All results are plotted on the map of Fig. 1. The total mineral content varies from 11 to 12575 mg/L with a relatively low mean value of 797 mg/L. The strontium content ranges from <0.0002 to 22.8 mg/l (Voerkelius & Lorenz, 2009).

Results of $^{87}Sr/^{86}Sr$ of all 656 water samples show a wide range of 0.7035–0.7777 or given in δ notation from −10 ‰ to 96 ‰. This large data range of strontium isotope ratios in our water samples reflects the variation observed in young, mantle derived rocks to old continental crust.

7. Description of analytical results in correlation to the geographical origin and surface geology of production location

Low $^{87}Sr/^{86}Sr$ values of 0.7035 to 0.7070 (−8 to −3 ‰) are encountered in our natural mineral water samples from regions with basaltic volcanic rocks such as the Quaternary and Tertiary volcanic rocks of Europe (Iceland, Etna, Vulture, Alkali basalts of Latin, Eifel, Auvergne). Very low values are also observed in regions of basic Palaeozoic volcanic rocks e.g. in Scotland as also described by Montgomery et al. (2006).

The range from 0.7070 to 0.7090 (−3 to 0 ‰) is observed in water samples from regions with a surface geology of mostly Mesozoic marine sediments displayed in the map (Fig. 1) in green. Almost 40% of the analysed natural mineral waters belong to this group. It includes the natural mineral waters from large limestone areas providing natural mineral water resources of high quality compliable with modern taste.

Mudstones and more clastic sediments with lower carbonate contents but also from Mesozoic geological units, seem to produce waters with higher isotope ratios visible as blue and yellow spots on green ground. However, these rocks are underrepresented in our study and were therefore neglected for our approach.

Due to majority of clastic components in Tertiary and Quaternary sediments of the large plains and basin structures mostly derived from Palaeozoic and even Precambrian rocks, the range of analysed values of the water samples between 0.7090 and 0.7110 (0–2‰) is applied to origin regions of surface geology of these sedimentary units.

Natural mineral waters with $^{87}Sr/^{86}Sr$ values of the data range from 0.7090 to 0.7110, shown in yellow in Fig. 1, represent the second most abundant part of all analysed waters and account for about 30 %.

Surface geology of Palaeozoic low-metamorphic rock cover leads to $^{87}Sr/^{86}Sr$ from 0.7110 to 0.7130 (2–5‰) in the natural mineral waters (coloured blue in Fig. 1). The value range draws the line around Ordovician rocks. No clear differences were observed for samples of more clastic or carbonate rocks, respectively.

High ratios exceeding 0.7130 (>5‰) in natural mineral water samples are found exclusively (the only exceptions are Rhenish massif and Northern area of Black forest) in areas of Lower Palaeozoic and crystalline rocks of the old Variscian and Caledonian orogens. The clearest signal can be found in the Iberian Meseta of Portugal and Spain which also provided the highest $^{87}Sr/^{86}Sr$ of 0.7777 (96‰) analysed in one sample.

Ratios exceeding 0.7200 (>15 ‰) in water samples can even be distinguished from the lower ratios by differentiating between areas of surface geology of Palaeozoic sediments and low grade metamorphic rocks on the one hand, and areas of Precambrian and high-grade metamorphic rocks on the other hand. Although this differentiation could not be verified on every point of location, it was indicated by colouring in grey in contrast to lavender.

This study clearly shows an overall correlation between $^{87}Sr/^{86}Sr$ of the water samples with the surface geology (Fig. 1), which can easily be deduced from the compliance of the analysed values of the natural mineral waters with the postulated data ranges for the corresponding geological unit of the map. Exceptions to this correlation will now be considered:

Deviations are observed especially for samples originating in areas of Quaternary plains (coloured in yellow), which are mainly covered with glacial gravel. Samples from German plains show ratios between 0.7086 and 0.7109 (−1 and 2 ‰), whereas higher ratios even up to 0.7130 (5‰) were analysed in samples produced in Poland. The differences in value ranges can be accounted for by the detritus material which covers a wide range of rock ages and lithologies of metamorphic rocks, intrusives and volcanic rocks, and originates from Scandinavia (Henningsen & Katzung, 2006).

Other deviations were identified where Mesozoic sediments are dominated by mudstones instead of limestone as explained above.

Some of the natural mineral waters from areas with middle and upper Paleozoic surface geology in the UK and Ireland show lower ranges as indicated by the colouring of the geological unit of our map, and in contrast some samples from the Rhenish Massif in Germany show even higher ranges.

The groundwaters that are used for natural mineral waters in UK are often very young and pumped from shallow depths in comparison to other countries (Voerkelius and Lorenz; 2009). Therefore we suggest a significant unknown surface influence to account for the isotope deviation, but this point should be further addressed in future studies.

An example of deviations from the overall picture on a smaller scale is found in western Germany. The Eifel area is especially interesting because both Palaeozoic rocks and Quaternary volcanic rocks are exposed. The Volcanic area produces the CO_2 of the most traditional bottled natural mineral waters. "Natural mineral water" was originally established as a food commodity because of the popularity of natural sparkling waters (Green & Green, 1985). While sulphuric and thermal waters were used for medical applications, CO_2-rich waters of the Eifel became famous as table

Table 1
Strontium isotope ratios of 656 water samples in comparison to mineral – and strontium contents.

Number of samples	Number of samples (%)	Total mineral content (mg/L)	Sr (mg/L)	$^{87}Sr/^{86}Sr$	$\delta^{87}Sr$ (‰)
28	4	62–3523	<0.0002–3.69	<0.7070	<−3.24
245	37	29–1257	0.005–22.8	0.7070–0.7090	−3.24 to 0.42
179	27	28–8976	0.006–12.3	0.7090–0.7110	−0.42 to 2.40
66	10	36–3780	0.025–6.35	0.7110–0.7130	2.40–5.22
100	15	17–6631	<0.0005–3.45	0.7130–0.7200	5.22–15.09
38	6	11–7238	<0.0017–0.94	>0.7200	15.09–99.68

waters. Many Eifel natural sparkling waters are pumped from Devonian slate although the lower $^{87}Sr/^{86}Sr$ ratios still show the relation to the Quaternary volcanic rocks (around 0.7057– 0.7087 in contrast to >0.7136). Further detailed studies are required to determine if the observed isotope ratios refer to deep mantle fluids containing strontium or to soils and covers of the recharge, which contain easily accessible strontium from volcanic rocks and dust.

Though the highest ratios had been expected for samples coming from Scandinavia (see Fig. 1, also Henningsen & Katzung, 2006), two samples from Norway show surprisingly low values (<0.709). As carbonate sediments are rare in these regions an influence of seawater is discussed for these cases. Horn (2005) already suggested that in regions where the exposed rocks do not provide much strontium by weathering, the input of dust and precipitation will determine the strontium isotopic signature.

Although not many deviations were observed for similar geological units within the investigated Mediterranean and the northern areas of Europe, the transferability particularly for the great cratons (e.g. Africa) with thick weathering zones or arid zones remains to be proven through sampling and analysis.

8. Transferability of the prediction method to other food products

Beard and Johnson (2000) already tried to model the strontium isotope variation in the continental United States in order to use it as a general guide to expected isotopic variation in skeletal elements in a particular region. The model assumed that the $^{87}Sr/^{86}Sr$ varies only as a function of age of the surface geology. In contrast, our map (Fig. 1) is based on analysed natural mineral waters and can therefore be applied as a first estimation of strontium isotope ratios in young groundwater.

As water – and not rocks and sediments or soils – is completely bio-available to plants and animals, it is assumed that the value ranges observed and correlated with surface geology is an improvement over the use of a geological map for the prediction of strontium isotope variation in agricultural products.

The strontium isotopic signatures of water enter the food chain (i.e. plants and animals) and can be transferred to any organic material without significant fractionation (Horn et al., 1998). According to Horn (2005), in this application no significant influence by fertilizer is assumed.

Based on the map of Fig. 1 the $^{87}Sr/^{86}Sr$ value range for each of the sample regions within the TRACE project was predicted (Fig. 2). The sample regions range from 160 to 13500 sqm. The prediction considered not only the geological unit of the site but also that of the surroundings.

Comparison of the results of the mean values of the analysed "surface" water samples used for agriculture (mostly First order streams and springs) with the predicted value ranges show that around 90% of the mean values were within the predicted data range. Exceptions are the sample regions BAR and IRE: The sample region of BAR is geologically inhomogeneous with a special prediction of 0.707–0.720, sample region IRE is probably influenced by sea spray as the site is near to the Atlantic.

Comparison of first results of the samples of ammonium nitrate extracts from soil samples, as well as samples of the food commodities honey and wheat show a generally good correlation to the "surface" water samples. Noteworthy deviations from the value range of "surface" water is observed for honey and wheat samples

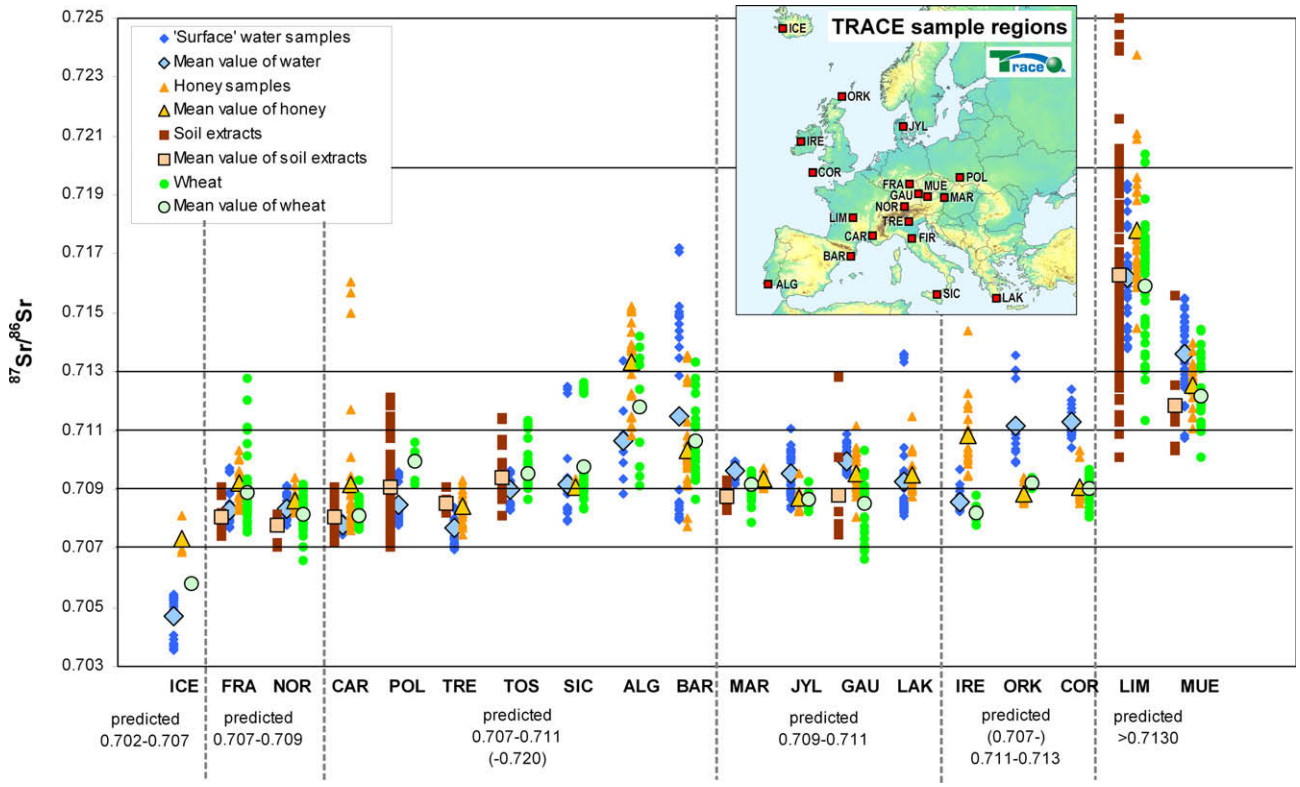

Fig. 2. $^{87}Sr/^{86}Sr$ results from water samples used for agriculture (mostly First order streams and springs), of water extracts from soil samples, of honey and wheat samples from several sample regions in Europe. The prediction of the $^{87}Sr/^{86}Sr$ value range for each of the sample region is based on the geological map of Fig. 1. The abbreviation for the sample regions are: ICE = Iceland, FRA = Germany (Franconia), NOR = Germany (Allgaeu), GAU = Germany (Gaeuboden), CAR = France (Carpentras), LIM = France (Limousin), POL = Poland, TRE = Italy (Trentino), TOS = Italy (Tuscany), SIC = Italy (Sicily), ALG = Portugal (Algarve), BAR = Spain (Barcelona), MAR = Austria (Marchfeld), MUE = Austria (Muehlviertel), JYL = Denmark (Jydland), LAK = Greece (Lakonia), IRE = Ireland, ORK = Orkney Islands and COR = England (Cornwall).

from the sample regions near the Atlantic ICE, COR, and ORK, indicating that here the influence due to sea spray is of higher significance for the $^{87}Sr/^{86}Sr$ values in the commodities than for the analysed "surface" water samples:

Honey samples from sample region ICE show higher strontium isotope values than the "surface" water samples, whereas honey and wheat samples from sample regions ORK and COR show lower values than the "surface" water samples. The food commodities from these regions seem to approach the $^{87}Sr/^{86}Sr$ value of seawater strontium of about 0.7092 (Capo & DePaolo, 1990).

Pourcelot, Stille, Aubert, Solovitch-Vella, and Gauthier-Lafaye (2008) suggest that dust and input from the atmosphere can have a significant influence on $^{87}Sr/^{86}Sr$ in the upper part of soil.

The overall correlation between the analysed and predicted value ranges (Fig. 2) confirms our assumption that our map can also be used for strontium isotope ratio prediction in other natural products.

9. Conclusion

In contrast to the numerous small scale investigations using strontium isotope ratios, this study presents results of a large scale investigation with a high amount of analysed water samples which clearly illustrate the potential of strontium isotope ratio analysis for authenticity control.

Though most of the natural mineral waters were not pumped from units of the surface geology but from deeper layers, a good or at least feasible correlation of the $^{87}Sr/^{86}Sr$ of the natural mineral water samples with the surface geology was observed.

Furthermore, the study presents an overview of the observed value ranges of this parameter. Combining the measured data with a GIS based geological map it is possible to predict qualitative spatial information of strontium isotope values. The information provided by this map can be used advantageously in authenticity control not only to estimate the isotopic signature of a natural mineral water, but also for other food products.

This is of relevance especially for the validation of the origin of products from remote areas where data for authentic reference samples are lacking or cannot be obtained. A prediction of the values from an area based on the geological map can also be used as a decisive tool to evaluate the potential of strontium isotope ratio analysis in a particular case of authenticity proof for any food product.

The applicability of the elaborated map for prediction of strontium isotope ratios for other agricultural products and food commodities was successfully tested by comparing first results of $^{87}Sr/^{86}Sr$ analyses in "surface" water samples, ammonium nitrate extracts from soil samples, as well as honey and wheat samples from specific sample regions within the TRACE project.

Based on this study it is proposed that strontium isotope ratios can contribute significantly to resolve questions of geographical origin. A prerequisite is, however, the knowledge of the spatial catchment area of an object.

An improvement of our system or provided map would be the construction of a "prediction" map with predicted value ranges for commodities produced at each geological unit. Based on complex statistical and graphical efforts the map may provide overlapping value ranges for the specific units and also consider big scale regional differences such as the observed deviations between the Quaternary plains of northern Germany and Poland (see above).

Acknowledgement

We kindly acknowledge the EU commission for funding the TRACE project. We remember gratefully ARCS, AUA, Eurofins Scientific Analyics, Fresenius, Geochem, Hydroisotop, IASMA, IFR, Insalus, NUID, UUFDG, colleagues, friends and relatives for sampling the natural mineral waters all over Europe. We thank the US Geological Survey and the United Nations for providing the georeferenced shape-file including legend of the geological map of Europe.

2. Counter-propagation artificial neural networks

To better deal with the complex statistical properties common to mineral water data, such as non-normality, strong colinearity and outlying values/populations, an advanced non-linear technique is applied known as counter-propagation artificial neural networks (CP-ANNs). Artificial neural networks belong to new evolving computer technologies in which a computer system has been designed to learn from data in a manner emulating the learning pattern in the brain. Basically, there are two main groups of artificial neural networks, which differ in architecture and in learning strategy; unsupervised and supervised self organising maps and supervised back-propagation artificial neural networks (Zupan & Gasteiger, 1999). The term "unsupervised or supervised" indicates if only input variables or descriptors plus output variables participate in the training, respectively.

Unsupervised self organising maps alias Kohonen neural networks represent a basic type of artificial neural networks. Its architecture is a two-dimensional grid of neurons (*x*–*y* in Fig. 1A), which are vectors of weights (*z* in Fig. 1A). The network is trained by taking the following steps until the weights are stabilised:

1. Prior to the learning step, the algorithm is initialised by assigning random numbers to all weights.
2. In the first learning step of learning an object from the learning set is presented to all neurons. The algorithm selects the neuron with its weights closest to the object ("winning neuron").
3. In the second step of learning the weights of the winning neuron are replaced by the object values and at the same time the neighbouring neurons are modified to become similar to them.

Counter-propagation artificial neural networks (CP-ANNs) are an extension of Kohonen neural networks. Their basic architecture is similar to the Kohonen networks, but the network and neurons now have two layers: an input layer (Kohonen layer) and an output layer (Fig. 1B). The learning in the input layer is the same as in Kohonen neural network, i.e. the similarity amongst input variables determines the arrangement of objects in the input layer map. After all object are arranged in the Kohonen layer, the positions of the objects are projected to the output where the weights are modified in a way that the weights on projected positions are equal to the values of corresponding objects. Both the weight levels and positions of the outputs can be visualised to further aid the interpretation of the results.

For this study we prepared a ANN Toolbox that performs the classification of multivariate data using the Kohonen mapping method, and predictive modelling using counter-propagation neural network (NIC_ANN_Programs). The toolbox runs under Matlab 7.

3. Experimental part

3.1. Description of the data set

For this study, 145 water samples were collected from Germany and a number of neighbouring European countries (see Fig. 2). The bulk of the samples concerns "natural mineral water" as defined in EU Directive 80/777/EEC, whereas the remaining bottled water samples are labelled as spring or table water ($N = 10$). In addition, 11 local tap water samples were included to cover areas where no mineral waters are produced.

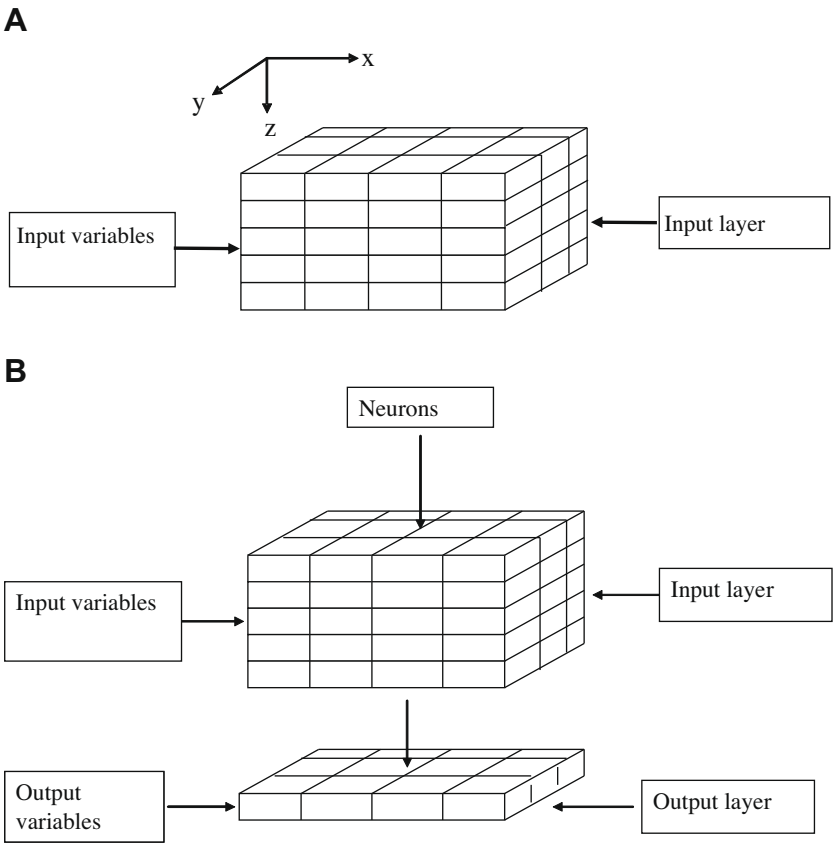

Fig. 1. Typical architecture of Kohonen neural networks (A) and counter-propagation artificial neural networks (B). Kohonen neural network architecture is two-dimensional grid of neurons, which are vectors of weights, *z* represents the number of input variables.

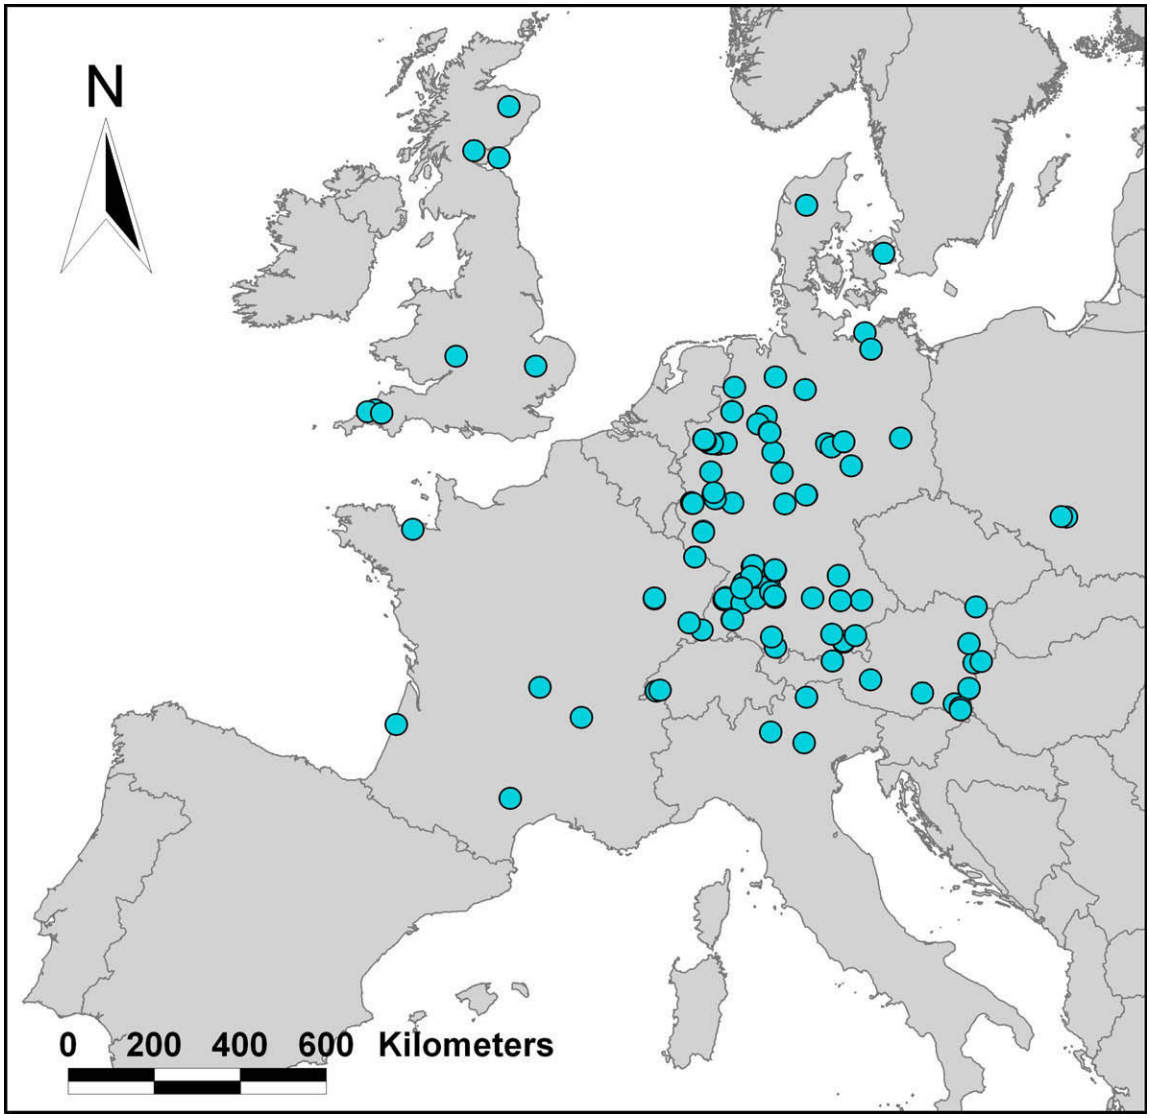

Fig. 2. Overview of mineral water sample locations (N_{tot} = 145).

For all water samples, the concentration of eight main ions (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, HCO_3^-, SO_4^{2-}, Cl^- and F^-) and pH was determined by an independent laboratory using different analytical techniques. The consistency of the analytical data was checked by determining the ionic charge balance of the samples. The reported precision on the analysis is within ±5% relative standard deviation over the range of concentrations.

3.2. Hydrochemical modelling

From the chemical composition of the samples, the saturation indices of a number of common mineral phases (calcite, dolomite, gypsum, anhydrite, halite and fluorite) as well as CO_2 (gas) are calculated. Although, the saturation indices just represent another linear combination of the same data, they might be better related to certain mineralogical characteristics of the lithology and thus improve the prediction power. This hypothesis is further tested in this study. The saturation indices were calculated using PREEQC (Parkhurst & Appelo, 1999) using T = 10 °C and assuming charge balance (pH).

3.3. Lithological classification of the samples

For each of the water samples, the geographical position of the aquifer was determined. Next, the geology of the aquifer was determined using different information sources: (A) the mineral water brand's website, (B) local geological maps or (C) regional geological maps. It should be noted that the position as well as geology of the aquifer is therefore often known only by approximation.

The original geological description of the source lithology of the mineral water samples consists of 12 lithological groups (Table 1). As can be seen, the majority of samples is found in unconsolidated sediments and carbonate areas, which provide large and often rather permeable aquifers. Mineral waters from magmatic and metamorphic areas – where the primary flow of water goes through fractures – are much less common.

Because of the limited number of samples in some groups, two alternative classification schemes have been developed to be used for further data analysis. Whereas the first scheme (lithology 1) in Table 1 is partly based on the presence of easily dissolved minerals (carbonates and gypsum), the second scheme (lithology 2) is more

Table 1
The lithological information of the water source and the two classification schemes tested in this study (N_{tot} = 145).

Original lithology	Lithology 1 – first scheme	Class (1–5)	Lithology 2 – second scheme	Class (1–4)	No. of samples
Granite	GGMGS	1	Magmatic rocks	1	11
Gneiss, mica shist	GGMGS	1	Metamorphic rocks	2	10
Limestone, dolomite, marble	LDMMUcarb	2	Biogenic-chemical sediments (carbonates)	4	19
Limestone, dolomite, marble (gypsum bearing)	LDMMUcarbgypsum	3	Biogenic-chemical sediments (carbonates)	4	26
Marl	LDMMUcarb	2	Biogenic-chemical sediments (carbonates)	4	5
Marl (gypsum bearing)	LDMMUcarbgypsum	3	Biogenic-chemical sediments (carbonates)	4	3
Graywacke, shale	GGMGS	1	Clastic sediments	3	14
Sandstone	S	4	Clastic sediments	3	13
Sandstone (gypsum bearing)	Sgypsum	5	Clastic sediments	3	8
Unsolidated rocks	S	4	Clastic sediments	3	5
Unsolidated rocks (carbonate)	LDMMUcarb	3	Clastic sediments	3	6
Unsolidated rocks (clastic)	S	4	Clastic sediments	3	25

based a classical geological approach. Both classification schemes are evaluated in this study.

3.4. Model construction and data pre-processing

The mineral water data set consists of 145 mineral water samples and 16 variables (descriptors), i.e. nine main elements and seven saturated indices. The dataset contained missing values that were marked −9999. This key (−9999) enables our adapted Kohonen and counter-propagation neural network software (Zupan, 1994) to handle the missing data (Grošelj et al., 2004; Zupan, Novič, & Ruisanchez, 1997).

Due to the fact that multivariate data analysis depends on the normalisation of variables autoscaling has been applied to all variables x_i, $i = 1 \ldots 9 \ldots 16$, in a continuous space

$$x_{ij}^{new} = \frac{x_{ij}^{old} - \bar{x}_i}{s_i} \quad (1)$$

where s_i is the standard deviation and x_i is the mean of variable i. The variables of the samples (descriptors) were represented as inde-

pendent variables (input data), whilst the classification groups as dependent variables (targets).

Four different data files were prepared. Datasets 1 and 2 were linked to the lithology classes: GGMGS, LGMMUcarb, LDMMUcarb-gypsum, S and Sgypsum (see Table 1). This is called lithology 1. Datasets 3 and 4 were linked to the lithology classes: magmatic rocks, metamorphic rocks, clastic sediments and biogenic-chemical sediments (lithology 2). Datasets 1 and 3 contain 16 descriptors, i.e. nine main elements and seven saturated indices, whereas Datasets 2 and 4 only include the nine main elements.

The four data files were trained with the artificial neural network algorithm using the ANN Toolbox (NIC_ANN_Programs; see Section 2). The network parameters were optimised by leave-one-out cross validation (Bos, Bos, & Van der Linden, 1993; Vračko, 2005) and were set as: the dimension of the network $N_x \times N_y$ = 12×12, the number of training epochs n = 1000, maximal correction factor η_{max} = 0.5 and minimal correction factor η_{min} = 0.01.

For each model, the Kohonen topmap, response surfaces and detailed position of the classes on the Kohonen topmap were obtained. The models were tested for the recall ability and validated by leave-one-out cross validation. The main difference between these two methods is that the recall ability gives the predictions of the entire training set, whereas the validation on leave-one-out classifies every object with a model built with the remaining objects.

4. Results and discussion

4.1. Recall ability

To analyse the results in more detail, the recall ability (RA) for each class was evaluated. The results are given in a classification matrix (Table 2). One can observe that the results obtained with the first and second models are more or less the same: about 50–60% of the samples are correctly classified, whereas the majority of remaining samples is classified as uncertain. Although, only few samples are incorrectly classified, the large number of uncertain answers makes the models unsuitable for prediction of the source lithology of mineral water samples on the basis of their chemical composition.

The third and fourth models in Table 2 show a much higher percentage of correctly classified samples vs. uncertain samples compared to the first and second models. For magmatic and metamorphic rocks the amount of samples classified as uncertain can still be considerable (>20%). This is most likely caused by the small number of samples contained in both classes. Nevertheless, these models appear more promising to infer the geology of the aquifer from the chemical composition of mineral water.

These results in general show that using the proper lithological classification scheme is of much more importance than including the saturation indices. The fact that the second lithological classification scheme is in general much more successful than the first scheme mostly shows that the distinction between gypsum and non-gypsum bearing aquifers (first scheme) is insufficiently reflected by the chemistry to be picked up by the CP-ANN approach. Because gypsum and anhydrite are very soluble minerals, and the saturation indices of gypsum and anhydrite were included (first model), the results are quite unexpected. The lack of a sulphate signal could be the result an SO_4^{2-} overprint from oxidising sulphides during pre-processing of mineral water derived from non-gypsum/anhydrite bearing aquifers, but such waters are expected to be rather uncommon. As we do not have any information about the uncertainty associated with the original lithological classification, it can not be excluded that the information concerning the presence or absence of gypsum is much less precise than information about other lithological properties (e.g. carbonate vs. non-carbonate).

4.2. Leave-one-out cross validation

In Table 3 the results obtained for the recall ability are compared with the leave-one-out cross validation results. The cross validation results support the previous observations showing that the best responses are obtained for the third and fourth model. The difference between the fourth and the third model is marginal, implying that inclusion of the saturation indices (not included in the fourth model) has a rather negligible effect on the predictive power of the models. This can be understood recalling the fact that the saturation indices are only a different linear (re-)combination of the concentration of the major ions. As such, they do not add additional information to the model. In case of the first model (saturation indices included), inclusion of the saturation indices even has a slightly negative effect on the predictive power of the model.

4.3. Visualisation of the model

To make the analysis of the model more evident and understandable the third model is explained by using the MATLAB visualisation tools (NIC_ANN_Programs). On the final topmap of our selected model (Fig. 3A) the classes, which predominantly occupy the individual neuron, are given. It is seen that the classes 1 and 2 (magmatic and metamorphic rocks) are grouped in the left upper corner (class 1) and in the centre of the final topmap (class 2), whilst the classes 3 and 4 (biogenic-chemical and clastic sediments) predominantly occupy right upper corner and left lower corner of the final topmap, respectively.

The same is observed for the four response surfaces (Fig. 3B), where each output level shows the grouping of the individual class. Thus, on the first, second, third and fourth output level the grouping of classes 1–4 is shown, respectively.

Comparison of the final topmap and the response surfaces in Fig. 3 shows that samples of classes 1 and 2 (magmatic and metamorphic rocks) are clearly grouped and separated from each other. The confined responses might be related to the relatively small amount of samples in each class. Contrary to classes 1 and 2, the separation of class 3 (biogenic-chemical sediment) and especially class 4 (clastic sediments) is much less evident. This is not only caused by the larger amount of samples in both classes, but also due to the fact that both classes are rather divers in terms of their mineralogical composition, which will be reflected by the hydrochemistry. Furthermore, clastic sediments commonly contain small amounts of

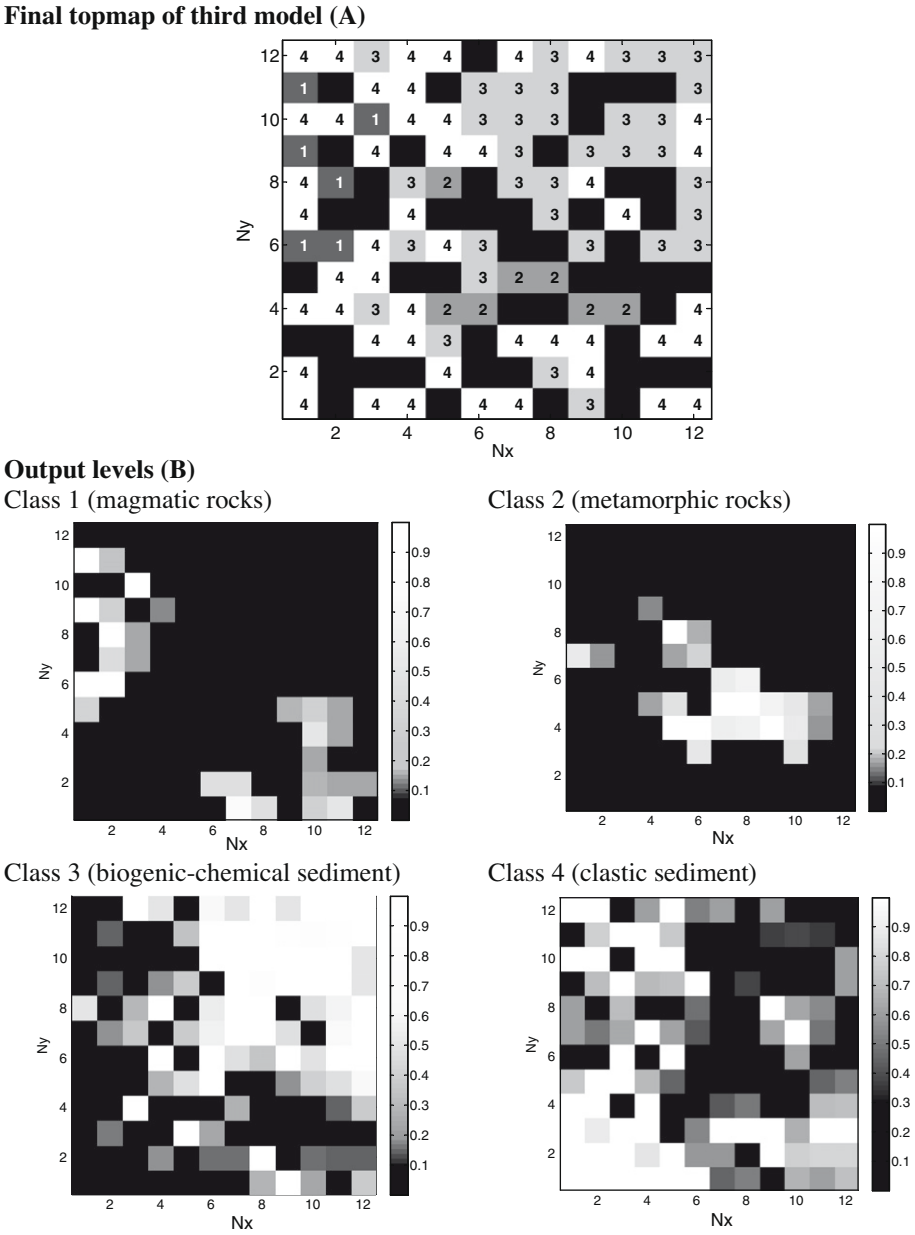

Fig. 3. Final topmap of third model. Map A shows the distribution of all four classes on the topmap. One neuron is represented on the map as a square. The colours and numbers represent the grouping and distribution of the classes: magmatic rocks (dark grey regions marked with 1), metamorphic rocks (grey region marked with 2), biogenic-chemical sediment (light grey regions marked with 3), clastic sediments (white regions marked with 4) and empty spaces (black regions). Four output levels (B) – four response surfaces (classes 1–4) – distribution of the individual class on one output level is shown.

carbonates. Because most carbonates have a high solubility, even small amounts of carbonatic material in an clastic aquifer could result in a hydrochemical signal which is more or less comparable to that from biochemic-chemical sediments such as limestones.

The observed partial overlap between classes 3 and 4 can further be explained by the fact that water from deeper aquifers could previously have been in contact with an overlying or nearby lithology of a different class, resulting in a mixed water type. This highlights the need for more detailed information about the aquifer lithology to further optimise the lithological classification scheme used for prediction.

5. Summary and conclusions

In this study we determined up to what extent the mineral water composition – in terms of the concentration of major ions (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, HCO_3^-, SO_4^{2-}, Cl^-, F^-) and pH – can be used to verify the geological origin of mineral water. For this purpose, we analysed a dataset of 145 European mineral water samples using counter-propagation artificial neural networks.

From the mineral water dataset, four different models were built using two different geological classification schemes and a different selection of variables (with or without the calculated saturation indices). These models were tested for recall ability (RA) and validated by leave-one-out cross validation (CV-LOO).

Results show that using the CP-ANN approach, the source geology of the mineral water samples can be reasonably well predicted using a lithological classification based on four classes: magmatic rocks, metamorphic rocks, biogenic-chemical sediments and clastic sediments. Although these are preliminary results, this technique could offer opportunities to test for the geological origin of commercially sold mineral waters within Europe.

Comparison of the different models shows that the geological classification scheme used to classify the samples is of most importance for a successful prediction of the geology. Although this seems trivial, the optimal classification scheme is not always a priori evident. This implies that when using such a supervised clustering technique, multiple (re-)classification schemes should be tested and evaluated. This requires detailed knowledge of the lithological composition of the aquifer and overlying formations.

In contrast to the lithological scheme used, the effect of including the saturation indices as additional variables has negligible effect on the predictive power of the models. The fact that inclusion of the saturation indices of different mineral phases has no effect on the results shows that they do not add information in multivariate setting.

from plants contain 5–10 different FAs. Simple seed oils composed of e.g. 5 different FAs may give 125 individual TAG molecules. Vegetable oils consist generally of fewer FAs than animal carcass fats, milk fats or fish oils. They seldom contain odd-numbered, branched-chain, or unsaturated FAs with fewer than 16 carbon atoms. Animal fats may be much more complex consisting of 10–40 different FAs.

In milk fat more than 400 different FAs have been identified. Most of those FAs arise from ruminal microbial metabolism and thus are unique to ruminant fats (Buchgraber et al., 2004).

Traditional analytical strategies to uncover adulteration and guarantee quality have relied on wet chemistry to determine the amount of a marker compound or compounds in a suspect material and a subsequent comparison of the value(s) obtained with those established for equivalent material (Karoui & De Baerdemaker, 2007). As the macro- and micro-components of oils are semi-volatile, both HPLC and GC techniques can be employed for their measurement. In the literature TAG and FA have received most attention. A relatively new concept is classification of oils or fats by their volatile profiles. The sensory properties of fats and oils differ considerably, which is mainly due to their volatile flavours. Therefore, volatile profiles may be useful for discrimination of fats and oils. Gas Chromatography (combined with olfactometry/flame ionization detection or mass spectrometry) (Högnadóttir & Rouseff, 2003; Luna, Morales, & Aparicio, 2006), electronic nose systems (Cosio, Ballabio, Benedetti, & Gigliotti, 2006; Hai & Wang, 2006) and proton transfer reaction-mass spectrometry (PTR-MS; Araghipour et al., 2007) are techniques for analysis of volatiles and are employed to generate classification data. As the more advanced evaluation methods used for authenticity tests of oils include a high number of variables (e.g. composition of TAGs), multivariate statistical methods are required for evaluation of the results (Cserháti et al., 2005).

In the present study the identities of seven types of fat (milk fat, cow fat, pig fat, poultry fat, coconut oil, palm oil, and palm kernel oil samples) were predicted applying partial least square discriminant analysis (PLS-DA) to (a) their multivariate FA profiles, (b) their TAG profiles, (c) their FA and TAG profiles combined, and (d) their profiles of volatile organic compounds (VOCs) measured by PTR-MS. FA and TAG profiling are rather conventional methods, but the non-targeted, non-biased chemometric approach (the PLS-DA) is an interesting new aspect, as well as the combination of multivariate datasets. PTR-MS analyses was explored because of its rapid data generation properties (full spectrum <30s). The success rates of the four approaches (FA, TAG, FA+TAG and PTR-MS) were compared.

2. Materials and methods

2.1. Materials

Eight regular and fourteen fractionated butter oil samples (8 soft and 6 hard fractions) were kindly provided by VIV Vreeland (Zelhem, the Netherlands) and Friesland Foods (Noordwijk, the Netherlands). Eight coconut oil, eight palm oil, and eight palm kernel oil samples were supplied by Unilever (Vlaardingen, The Netherlands). Samples originated from different batches. The animal fat samples from the Dutch industry consisted of eight cow fat samples, eight pig fat samples, and eight poultry fat samples. Three of them were commercial mixed samples from Smilde (Heerenveen, the Netherlands) and the others were samples from individual animals. The samples were selected taking into account as much as possible both natural and technology-induced variation. Sample material was stored at −20 °C in absence of light until analysis was carried out.

2.2. Methods

2.2.1. FA methyl ester (FAME) analysis

The fats were methylated and the fatty acid methyl esters analysed according to the international standard ISO 15885:2002. Nonanoic acid (C9:0) was added as internal standard (Sigma–Aldrich Chemie, Zwijndrecht, the Netherlands). As reference material a home-made standard FAME mixture composed of C4:0, methyl butyrate (Fluka, 19358, Sigma–Aldrich Chemie, Zwijndrecht, The Netherlands); C6:0, methyl capraote (Fluka, 21599); C8:0, methyl caprylate (Fluka, 21719); C10:0, methyl decanoate (Fluka, 21479); C12:0, methyl laurate (Fluka, 61689); C14:0, methyl myristate (Fluka, 70129); C16:0, methyl palmitate (Fluka, 76159); C18:0, methyl stearate (Fluka, 85769); C18:1, methyl oleate (Fluka, 75160); C9:0, methyl nonanoate (Sigma, 245895) was used to calculate calibration factors of the various FAMEs. Absolute concentrations (g fatty acid/100 g fat) as well as relative concentrations (the total FAME measured was normalized to 100%) were calculated. All fats and oils were analysed in triplicate.

2.2.2. TAG analysis

The TAG analysis was carried out according to the Draft International Standard ISO/DIS 17678|IDF 202 (Milk fat – Detection of foreign fats by gas chromatographic analysis of triglycerides). Tricaprion (C18) was added to each sample as internal standard. The reference material CRM 519 (IRMM, Geel, Belgium) was used for determining the calibration factor of each triglyceride. Both absolute concentrations of each TAG (g triacylglycerol/100 g fat) and relative concentrations (the total TAG measured was normalized to 100%) were measured. All fats and oils were analysed in triplicate.

2.2.3. PTR-MS analysis

For headspace analysis, 5 g of fat or oil was placed in a glass flask (100 ml) at 30 °C for 30 min to allow equilibration. Preliminary experiments showed that 30 min was sufficient for equilibration. Two replicates of each sample were analysed. The volatile organic compounds (VOCs) in the headspace of the samples were analysed at 30 °C by PTR-MS according to the method described by Lindinger, Hirber, and Paretzke (1993). A constant drift voltage of 600 V and a pressure of 2.09 ± 0.01 mbar were maintained in the reaction chamber. The headspace was drawn from the sample flask at a rate of 15 ml/min which was led through a heated transfer line into the high sensitivity PTR-MS for on-line analysis. Data were collected for the mass range m/z 20–149 using a dwell time of 0.2 s mass^{-1}. The instrument was operated at a standard E/N (ratio of electric field strength across the drift tube, E, to buffer gas density, N) of 138 Td (1Td = 10^{-17} cm^2 V molecule^{-1}). Inlet and drift chamber temperatures were 60°C. Each sample was analysed for at least 5 full mass scans. The headspace concentrations of the compounds during the cycles #2, #3 and #4 were calculated as described by Hansel et al. (1995) and background and mass discrimination corrections were applied. Headspace concentrations were subsequently averaged over the three mass scans for further statistical analysis. In preliminary experiments some of the samples were analysed for seven cycles: the results did not show consistent changes in headspace concentrations (especially no decrease) after the first cycle. Therefore, cycles #2, #3 and #4 were selected for calculations. Milk fat, coconut oil, palm oil and palm kernel oil samples were analysed in duplicate. Most animal fat samples were samples from individual animals, lack of sample material did not allow a sufficient number of PTR-MS analysis on the same samples to carry out PLS-DA analyses. Therefore, for the PTR-MS analysis, only milk fat and the vegetable oils were considered for statistical analysis.

2.2.4. Statistical analysis

PLS-DA models (Barker & Rayens, 2003) were estimated to predict the identity of the samples using either the FAME, TAG or VOC data. The analyses were carried out in Matlab using the PLS toolbox (Wise et al., 2006). PLS-DA performs a dimension reduction on the predictor variables. The dimensions (components) extracted are composed such that they exhibit maximal correlation with Y (class membership, e.g. milk fat, poultry fat, palm oil, etc.). After estimation of the classification model, its performance was evaluated by means of 10-fold cross-validation: 10% of the samples were randomly removed from the data set, and a model built with the remaining samples was used to classify these left out samples. The procedure was repeated ten times to obtain predictions for all samples. The number of components that is extracted is an important parameter in a PLS-DA model. Therefore, models with 1–8 components were investigated to select the most appropriate (optimal) number of components. Various standardization methods (on variables and on units) were investigated to improve prediction rates, i.e. mean-centering, auto-scaling, and log transformation.

After selecting the model, the 10-fold cross validation (which is a random process) was repeated 100 times to get insight into the repeatability of the classification results. The output of the 100 replications is summarized as follows. PLS-DA outputs, for each sample i, a posterior probability p_i (p_{i1}, p_{i2},. . ..p_{ik}) for membership in each of the k classes. The sample is assigned to the class with the highest posterior probability. Let p_{im} be the probability for this class, and let p_{im2} be the probability for the class with the second-largest posterior probability. Then

$$C_i = \frac{p_{it}}{p_{im} + P_{im2}}$$

(where $p_{it} = p_{im}$ when the classification is correct, and $p_{it} = p_{im2}$ when the classification is incorrect) has a value between 0 and 0.5 when sample i is incorrectly classified, and between 0.5 and 1 when it is correctly classified. The larger the difference between p_m and p_{m2}, the closer the value of C will be to either 1 or 0. If the difference between p_{im} and p_{im2} is small, C will be near 0.5. Therefore, values near 0 or 1 indicate high confidence, whereas values around 0.5 indicate lower confidence in prediction results. The box plots of C_i (one box plot for each sample) were composed as a summary of the results of the 100 repeated cross validations.

3. Results and discussion

3.1. FAME

The FAME compositions of the fats and oils characterized by 18 FAs are presented in Table 1. The FAME compositions of the cow fat (CV = 44%), pig fat (CV = 43%) and poultry fat samples (CV=34%) varied most across samples (CV based on variance between sample means, not between replicates). This is not surprising as these samples originated from different single animals.

The FAME data were subsequently subjected to PLS-DA. The best prediction rates appeared to be obtained with auto-scaling of the variables and no scaling of the units. The prediction success rates in single cross-validation runs varied from 74% (1 component) to 100% (100%: 4 and 8 components). It was therefore decided to run the 100 repeated cross-validations for 4 components to gain insight into the stability of the results. On average 1.4% of the fats were misclassified per replication. Fig. 1 shows box plots of the distribution of the 100 C_i-values obtained for each sample (for the definition of C, see the paragraph on 'Statistical Analysis'). The figure reveals that some samples are occasionally misclassified. Cow fat 8 is misclassified most often (column 38 in

[a] 69 out of 70 Samples were correctly classified (98.6%).
[b] Variables standardized by means of auto-scaling, no standardization on units applied.

the plot): 22 times out of 100 this sample is incorrectly classified as milk fat. However, in most cases the confidence in the incorrect classification is not very high (C_i closer to 0.5 than to 0). Four of the pig fat samples are occasionally misclassified as cow fats[1] (columns 55–62). Four more cow fat samples (columns 31–35) are sometimes incorrectly classified as pig fat. However, for these samples, the probabilities for the correct and incorrect class are almost equal, resulting in C_i -values of near 0.5. Therefore, these misclassifications are hardly visible in the box plot. Finally, one coconut fat sample (column 30) is occasionally misclassified with higher confidence, either as cow or pig fat.

More detailed results are now given for one particular cross validation run. For this run, the numbers of samples predicted into the various product groups are listed in Table 2. A scores plot of the first three dimensions of the model is shown in Fig. 2. In this run, only one cow fat sample was misclassified as poultry fat. But the posterior probability for this classification is not very high (0.13). As the second largest posterior probability is 0.05, this incorrect classification would result in a C_i-value of 0.05/0.18 = 0.28. The scores plot (Fig. 2) shows that the misclassified cow fat is positioned more or less halfway between the cow fat and the poultry fat samples.

A similar approach was adopted for the relative FAME data. With 4 components extracted, on average 1% of the classifications was incorrect.

3.2. TAG

The TAG compositions of the fats and oils were determined; they were characterized by 17 triglycerides (Table 3). The animal fats (CV = 21–40%) showed a more varied TAG composition than the vegetable oils (CV = 3–10%; CV considering variance between sample means only). TAG composition of the cow fat was generally within the ranges specified by Precht (1992), who developed a method for detection of foreign fat in milk fat. The compositions

[1] The box plot shows whether a sample is misclassified or not, it does not show into which incorrect class a misclassified sample is placed. This information is available, but due to space considerations, it is impossible to present it in a table. It was therefore decided to mention it in the text, where appropriate.

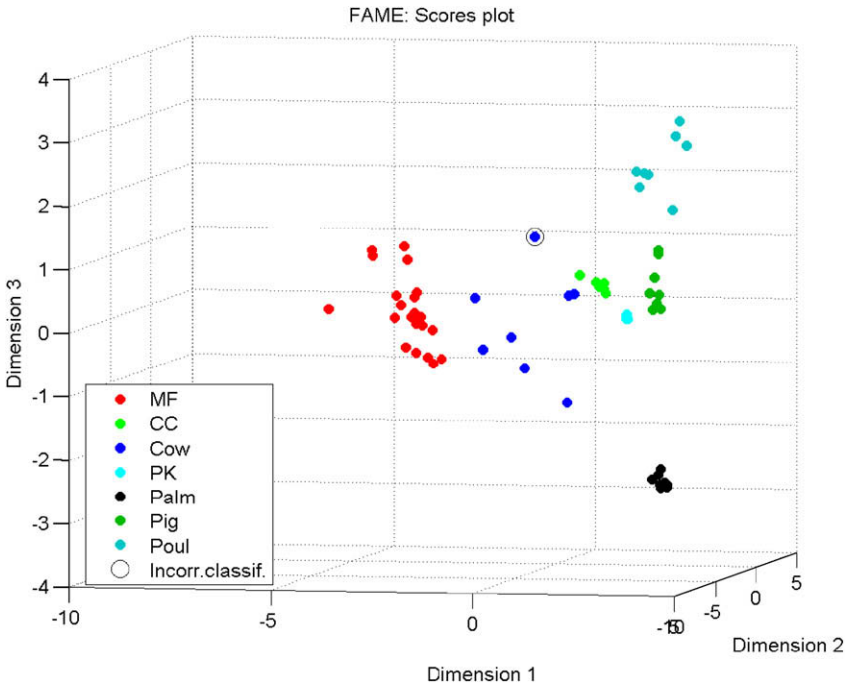

Fig. 2. Scores plot of the first three dimensions of PLS-DA on the absolute fatty acid composition data of seven oils and fats.

[c] Mean value of eight samples

of coconut oil and pig fat in the present study showed generally higher concentrations of the longer chain TAGs than those reported by Precht (1992).

For the TAG data too, auto-scaling of the variables and no scaling of the units appeared to give the best results. The optimal number of components was larger here than it was for the FAME data before. The cross-validation procedure was repeated 100 times for a solution with 6 components, giving a confidence box plot (Fig. 3). It appeared that all cow fat samples (columns 31–38) are occasionally classified as poultry fat samples, and all poultry fat samples (columns 63–70) sometimes as cow fat samples (see Footnote 1). Apparently, separating these two types of fat by their triglyceride compositions is a challenging task.

A similar approach was adopted for the relative TAG data. Here, with 6 components, on average 10 % of the samples was incorrectly classified. Without exception these were poultry and cow fats being confounded.

3.3. Combined FAME and TAG analysis

The FAME and TAG datasets were combined for further improvement of the identity prediction of the fats and oils. Optimal results regarding identity prediction were obtained with a six component PLS-DA model with auto-scaling of the variables and no scaling of the units. The confidence plot of this combined six component model is presented in Fig. 4. The box plot shows that all confidence levels are between 0.5 and 1.0 which indicates that the combined model classified 100% of the samples correctly. Combination of the two datasets resulted further in higher confidence in the predictions in general than for the single data sets: most values are close to 1.

A similar approach was adopted for the combined relative data. They resulted on average in a correct classification of 99 % of the samples.

3.4. VOC

Proton transfer reaction-mass spectrometry (PTR-MS) is a promising technique for analysis of volatile compounds and has been used to investigate different issues in food science. For instance the effect of technological conditions on the VOC profiles of orange juices has been studied (Biasioli et al., 2003). Pollien and co-workers used PTR-MS for on-line monitoring of acrylamide (Pollien, Lindinger, Yeretzian, & Blank, 2003). Correlation with sensory data (Biasioli et al., 2006) and real-time in-nose analysis (Fransnelli, van Ruth, Kriukova, & Hummel, 2005) are other

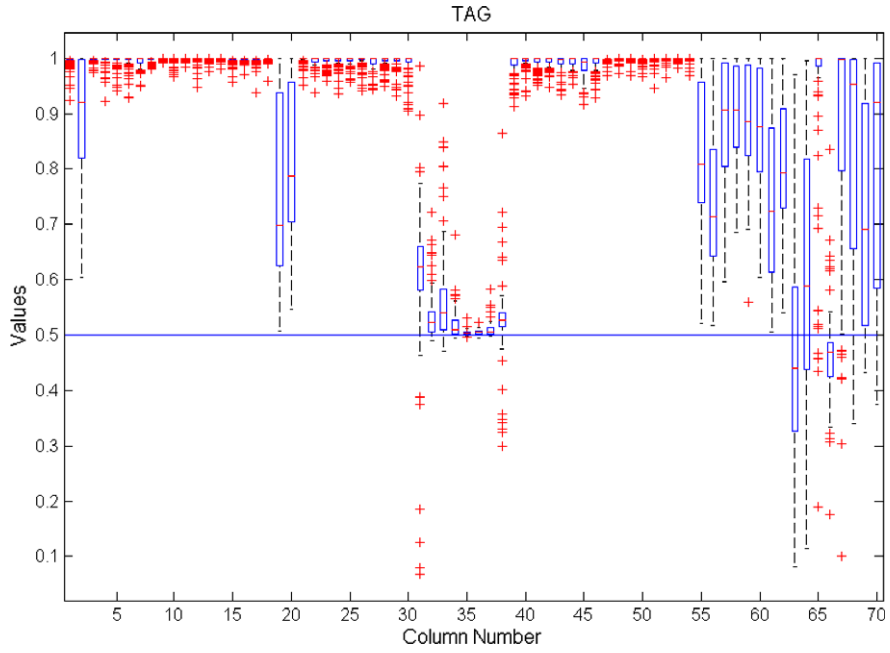

Fig. 3. Results for 100 replications of the random cross validation of the predicted classification of fat and oil samples by their absolute triacylglycerol compositions into identity classes (e.g. cow fat, palm oil, etc.) using PLS-DA models. For each of the samples, a box shows the location of the .25 and .75 quartiles of the quantity C (see text), the dotted lines (whiskers) are the whiskers; they have length 1.5 * the inter-quartile range (or shorter, if there are no more observations), and the crosses are outliers, lying outside the whiskers. The data have been sorted so that the 22 milk fat samples are displayed first (column 1–22), followed by 8 coconut oil (column 23–30), 8 cow fat (columns 31–38), 8 palm kernel oil (column 39–46), 8 palm oil (columns 47–54), 8 pig fat (columns 55–62), and 8 poultry fat samples (columns 63–70).

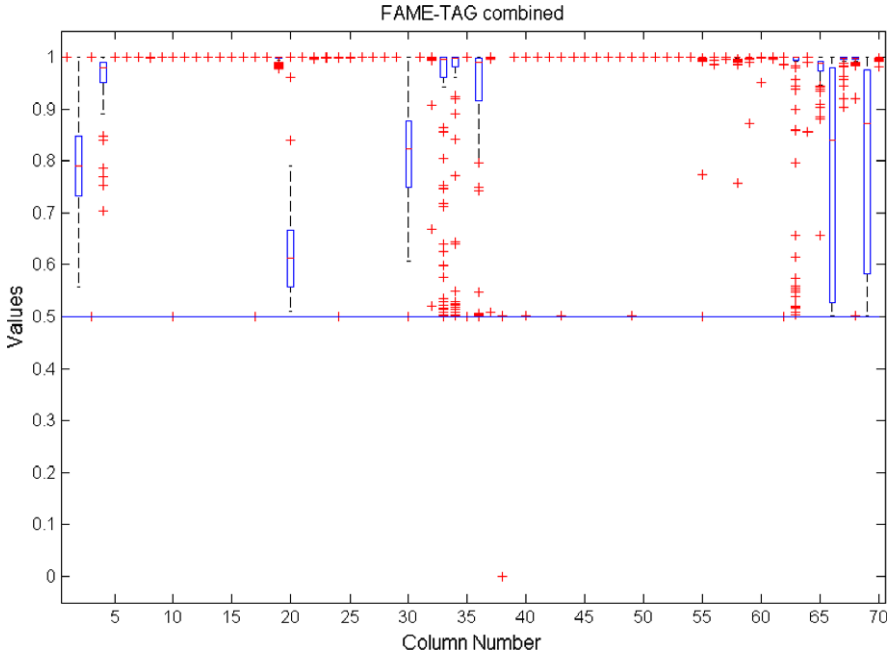

Fig. 4. Results for 100 replications of the random cross validation of the predicted classification of fat and oil samples by their combined absolute fatty acid and triacylglycerol compositions into identity classes (e.g. cow fat, palm oil, etc.) using PLS-DA models. For each of the samples, a box shows the location of the .25 and .75 quartiles of the quantity C (see text), the dotted lines (whiskers) are the whiskers; they have length 1.5 * the inter-quartile range (or shorter, if there are no more observations), and the crosses are outliers, lying outside the whiskers. The data have been sorted so that the 22 milk fat samples are displayed first (column 1–22), followed by 8 coconut oil (column 23–30), 8 cow fat (columns 31–38), 8 palm kernel oil (column 39–46), 8 palm oil (columns 47–54), 8 pig fat (columns 55–62), and 8 poultry fat samples (columns 63–70).

important applications. Proton transfer reactions are used to induce chemical ionisation of the vapours to be analysed. The sample gas is continuously introduced into a drift tube, where it is mixed with H_3O^+ ions formed in a hollow cathode ion source. Volatile compounds that have proton affinities higher than water (>166.58 kcal/mol) are ionised by proton transfer from H_3O^+, mass analysed in a quadrupole mass spectrometer and eventually detected as ion counts/s (cps) by a secondary electron multiplier. The outcome is a mass resolved fingerprint of the total volatile profile of a sample. PTR-MS is interesting for this fingerprinting

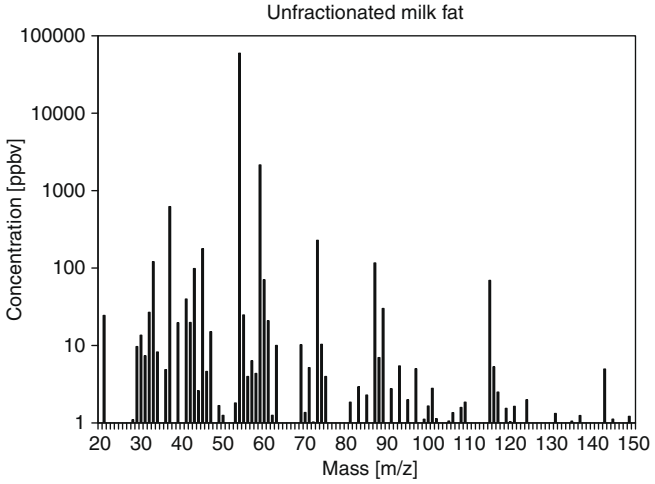

Fig. 5. Mean fingerprint mass spectrum of the volatile organic compounds in the headspace of regular milk fat obtained by proton transfer reaction mass spectrometry.

Table 4
Number and (percentages) of predicted classification of oils and fats into product classes by their volatile organic compound compositions using a three component PLS-DA model. The correctly classified samples in bold [a,b].

Sample	PLS-DA classification				Total correctly classified (%)
	Milk fat	Coconut oil	Palm oil	Palm kernel oil	
Milk fat	**22 (100%)**	0 (0%)	0 (0%)	0 (0%)	**100**
Coconut oil	0 (0%)	**7 (87.5%)**	0 (0%)	1 (12.5%)	**87.5**
Palm oil	0 (0%)	0 (0%)	**8 (100%)**	0 (0%)	**100**
Palm kernel Oil	1 (12.5%)	2 (25%)	1 (12.5%)	**4 (50%)**	**50**

[a] 41 out of 46 Samples were correctly classified (89.1%).
[b] Variables standardized by means of auto-scaling, no standardization on units applied.

approach as (i) it requires no pre-treatment of the sample, (ii) it allows rapid measurements (typically <1 min for a complete mass spectrum), and (iii) the technique is extremely sensitive (ppt level).

The PTR-MS data of the VOCs covered a range of 129 masses (data not shown). An example of the mean fingerprint mass spectrum of the regular milk fats is presented in Fig. 5. Results for one cross-validation run while applying a three component PLS-DA model with auto-scaling of the variables and no scaling of the units are presented in Table 4. The milk fats, coconut oils and palm oils were correctly classified except for one coconut oil. Palm kernel oils showed poor classification results, with only 50% of the samples being correctly classified. Misclassified palm kernel samples were placed into all product groups, therefore, it seems that the palm kernel oils were not characterized by specific VOCs, but showed great overlap with the VOCs of the other product groups. Overall, 89% of the samples were classified correctly using PTR-MS data. Therefore, classification was reasonably successful, but rates were not as high as for the FAME and TAG analysis. However, PTR-MS analysis has the advantage of being very rapid compared with the other analysis techniques, which would make it a potential technique for screening of particular fats and oils.

Table 5
Overview of correct classifications of fats and oils by their fatty acid, triacylglycerol or volatile organic compound composition using PLS-DA.

Techniques	Number of components in PLS-DA	Correct classifications (%)
Fatty acid composition, absolute data	4	99
Fatty acid composition, absolute date	6	97
Fatty acid composition, relative data	4	99
Triacylglycerol composition, absolute data	6	96
Triacylglycerol composition, relative data	6	90
Combined Fatty acid and triacylglycerol composition, absolute data	5	99
Combined fatty acid and triacylglycerol composition, relative data	6	100
Volatile organic compound composition measured by proton transfer reaction mass spectrometry	3	89

4. Conclusions

For identity prediction all techniques used were reasonably successful in classifying the various animal fats and vegetable oils (89–100%, Table 5). The identity of the samples was most successfully predicted using the combined absolute FAME and TAG data set (i.e. for the present dataset 100%). The combined FAME-TAG dataset has the additional advantage that a more robust prediction is obtained as the confidence in the predictions is generally higher than for the other datasets. Alternatively, if a certain prediction rate (e.g. 95%) is required, fewer PLS components are sufficient to obtain this success rate. PTR-MS analysis which results in a volatile fingerprint was least successful but still resulted in 89% correct classifications with the additional advantage of the speed of the technique. The technique gave promising results, but further studies are required to confirm its use as a good alternative for FA and TAG analyses.

chemical and sensorial, combined with statistical analysis, has greatly facilitated the fight against fraud in this sector. Moreover, the contribution of databases and mathematical algorithms is necessary in order to provide the classification required to fully guarantee both the geographical origin and authenticity of VOO (Aparicio & Aparicio-Ruiz, 2000).

Olive oil is mainly made up of triglycerides (more than 98%), whereas the unsaponifiable fraction of virgin olive oil (VOO) represents 1–2% of the oil. This fraction is made up of minor constituents, which may vary both qualitatively and quantitatively depending on vegetal species, climatic conditions, extraction and refining procedures, and storage conditions (Cañabate-Diaz et al., 2007; Harwood & Aparicio, 2000). These also greatly influence the organoleptic quality and stability of the oil. VOO may contain up to 0.7% hydrocarbons, which is mainly constituted by squalene, a precursor of other sterols and triterpenic alcohols (Bortolomeazzi, Berno, Pizzale, & Conte, 2001; Lercker & Rodriguez-Estrada, 2000). Besides squalene, the hydrocarbon fraction of olive oil comprises of low quantities of epoxy-squalene isomers and alkanes (C16–C35) (Grob, Lanfranchi, & Mariani, 1990; Mariani & Fedeli, 1986). Plant sterols or phytosterols make up the main part of the unsaponifiable fraction of olive oil. The most abundant olive oil sterol is β-sitosterol, followed by Δ5-avenasterol. Campesterol and stigmasterol are present in lower concentrations (Harwood & Aparicio, 2000). Regarding the tracking of commercial fraud, the sterol fraction has many applications, especially where the contamination of some vegetable oils with other cheaper ones is concerned. Positional isomers of the double bond in the sterol ring have been detected and can be used as fraud tracers in VOO (Aparicio & Aparicio-Ruiz, 2000; Biedermann, Grob, Mariani, & Schmidt, 1996; Lercker & Rodriguez-Estrada, 2000; Mariani, Venturin, & Grob, 1995). Of the tocopherols, α-tocopherol comprises about 90% of the total tocopherol fraction. The stability of VOO is mainly due to their relatively low fatty acid unsaturation and to the antioxidant activity of some of the unsaponifiable components: the activity of α-tocopherol and the effect it has on the oxidative susceptibility of an olive oil was researched by Deiana et al. (2002). Moreover, α-tocopherol showed a synergistic effect in association with some phenolic compounds with significant activity. The major phenolic compounds identified and quantified in olive oil belong to three different classes: simple phenols (hydroxytyrosol, tyrosol), secoiridoids, and the lignans. The cultivar, the system of extraction, and the conditions of processing and storage are critical factors for the polyphenol content of an olive oil (Aparicio & Luna, 2002). Other constituents of the unsaponifiable matter are the pigments which impart the characteristic colour to an olive oil. They are made up of carotenoids, most importantly β-carotene, which gives a yellow colour; chlorophylls, responsible for the green shades; and pheophytins (Minguez-Mosquera, Gandul-Rojas, Garrido-Fernandez, & Gallardo-Guerrero, 1990). Other components include aliphatic alcohols made up of docosanol, tetracosanol, hexacosanol and octacosanol; and at trace levels, tricosanol, pentacosanol, and heptacosanol. In smaller quantities the following triterpenic alcohols are present: cycloartenol, 24-methylen-cycloartenol, and α- and β-amirines; diterpenic alcohols: fitol and geranilgeraniol; and triterpenic dialcohols: erythrodiol and uvaol. These numerous compounds, present in tiny percentages in olive oil, hold great biological importance and are characteristic of each type of oil (Harwood & Aparicio, 2000). In fact, the composition of the unsaponifiable fraction of VOO is affected by several factors (Harwood & Aparicio, 2000) such as olive cultivar (Aparicio, Morales, & Alonso, 1997; Esti, Cinquante, & La Notte, 1998; Pinelli et al., 2003), altitude (Mousa, Gerasopoulos, Metzidakis, & Kiritsakis, 1996), climatology (Aparicio, Ferreiro, & Alonso, 1994), agronomic factors (Gutierrez, Albi, Palma, Rios, & Olias, 1989), time of harvest (Aparicio & Morales, 1998), olive storage after harvest (Mariani, Fedeli, Grob, & Artho, 1991), and oil extraction system (Angerosa & Di Giovacchino, 1996; Ranalli & Angerosa, 1996). The diversity and interrelation amongst all these factors is reflected in the chemical composition of VOO, and it is highly unlikely that this influence would be the same in different regions. So, the geographical characterisation of VOO regards all these agronomic, pedoclimatic and botanical aspects that characterise the oil of each origin (Aparicio, Alonso, & Morales, 1994; Esti et al., 1996). Therefore, it can be expected that the unsaponifiable fraction of VOOs may contain information for the geographical characterisation of olive oils.

The more commonly used methods for minor constituent determination in olive oil usually require isolation and several procedures of separation, identification and quantification. The conventional method for quantifying sterols and triterpenic alcohols involves capillary GC–FID of the fraction isolated by TLC [Commission Regulation (EEC) No. 2568/91]. Regarding the quantification of minor components in the unsaponifiable matter of olive oil, chromatographic methods have proven to be particularly suitable (Lercker & Rodriguez-Estrada, 2000). Thus, alkanols, squalene, α-tocopherol, and sterols were determined by GC (Giacometti, 2001); sterols were quantified by GC–FID for the classification and authentication of monovarietal and PDO olive oils (Alves, Cunha, Amaral, Pereira, & Oliveira, 2005); phytosterols were analysed by GC–MS in order to compare their content with that of sunflower oil and butter (Zhang et al., 2005); SPE and GC–MS were used to characterise free and esterified sterols (Cunha, Fernandes, & Oliveira, 2006); tocopherols, and phytosterols, quantified by reversed phase HPLC, discriminate between very similar oils (Lopez Ortiz, Prats Moya, & Berenguer Navarro, 2006); and seven phytosterols analysed by LC–MS distinguished different qualities of olive oils (Cañabate-Diaz et al., 2007). FT-Raman and FT-NIR spectroscopy has also been applied to characterise olive oil. Moreover, the spectra of the unsaponifiable matter of olive oil obtained by these techniques together with univariate and multivariate statistical models enabled the detection of hazelnut oil in olive oil at a level as low as 8% (Baeten et al., 2005). FT-Raman bands due to the major unsaponifiable series of compounds, i.e. squalene, sterolic, and terpenic fractions, analysed by unsupervised multivariate techniques allow us to differentiate between olive oils and other seed oils as well as and amongst varietal VOO (Baeten, Dardenne, & Aparicio, 2001). ^{1}H, ^{13}C and/or ^{31}P NMR analysis of the bulk oil, in combination with multivariate techniques, have been used to distinguish VOOs according to their geographical origin (Rezzi et al., 2005), as well as to detect adulteration of the oil (Fragaki, Spyros, Siragakis, Salivaras, & Dais, 2005; Garcia-Gonzalez, Mannina, D'Imperio, Segre & Aparicio, 2004). IRMS methods have also been used for the authentication of olive oil by analysing the bulk oil (Angerosa, Camera, Cumitini, Gleixner, & Reniero, 1997; Bianchi, Angerosa, Camera, Reniero, & Anglani, 1993; Breas, Guillou, Reniero, Sada, & Angerosa, 1998). Isotopic measurements of alcohol and sterol fractions of olive oil also proved to be useful for its geographical characterisation (Angerosa et al., 1999). ^{1}H NMR and the more recently developed hyphenated LC–SPE–NMR technique have been applied to study phenolic compounds in the polar fraction of olive oil for authentication purposes (Christophoridou, Dais, Tseng, & Spraul, 2005; Sacco et al., 2000).

In the present work, a new approach based on ^{1}H NMR fingerprinting of the unsaponifiable fraction of VOO is presented. VOO from six countries, namely Spain, Italy, Greece, Tunisia, Turkey, and Syria, were analysed. The spectral data was subjected to pattern recognition techniques, which can be used to classify a VOO according to its geographical origin. Moreover, ^{1}H NMR spectra of the bulk oil, and its corresponding unsaponifiable fraction, as well as the subfractions of the unsaponifiable fraction (alcohol, sterol, hydrocarbon, and tocopherol fractions) were studied in the search

for the markers that multivariate techniques revealed to be related to the geographical origin of olive oils.

2. Materials and methods

2.1. Samples and chemicals

Commercial virgin olive oils (99 samples) from six countries of the Mediterranean basin, namely Italy (19 VOOs), Spain (36 VOOs), Greece (12 VOOs), Tunisia (15 VOOs), Turkey (8 VOOs), and Syria (9 VOOs), were provided by the SSOG (Stazione Sperimentale per le Industrie degli Oli e dei Grassi, Milan, Italy), which was able to assure the true type (virgin) and origin of the olive oils at least at the national level. Virgin olive oils (23 samples) from different Italian (5 VOOs), Spanish (4 VOOs), and Greek (5 VOOs) PDOs as well as samples from Tunisia (5 VOOs) and Turkey (4 VOOs) were collected directly in the country of origin by the SSOG.

Deuterated chloroform for NMR analysis (99.8 at % D), chloroform (p.a.), 1-eicosanol, α-tocopherol, β-sitosterol, stigmasterol, campesterol, and silica gel on TLC plates diethyl ether were provided by Sigma–Aldrich Chemie (Steinheim, Germany); potassium hydroxide (p.a.), anhydrous sodium sulphate (p.a.), hexane (p.a.), and 2′,7′-dichlorofluorescein (TLC grade) by Merck (Darmstadt, Germany); diethyl ether (HPLC grade) by Fluka Chemie (Buchs, Switzerland); methanol (HPLC grade) by Carlo Erba (Rodano, Italy); and erythrodiol by Extrasynthèse (Genay France). Cycloartenol standard was prepared by extracting the unsaponifiable fraction from flax oil and performing a further purification of the extract by thin layer chromatography (TLC) (see Sections 2.2 and 2.3).

2.2. Preparation of the unsaponifiable fraction of olive oil

The unsaponifiable fraction was prepared using a modification of the method described in the regulation EEC-2568/91 (annex V, Section 5.1). The sample of olive oil is dried under a nitrogen flow and filtered. Then, 50 ml of methanolic potassium hydroxide 2 N is added to an aliquot of 5 g of the dried and filtered olive oil, and heated to a gentle boil in a water bath with continuous vigorous stirring under reflux for 1 h. Then the content is transferred quantitatively into a 500 ml funnel using several rinses of distilled water (about 100 ml), and three successive extractions with ethyl ether (80 ml) are performed. The ether phase is washed with distilled water until the wash water reaches a neutral pH. Once the water is removed, the extract is dried with anhydrous sodium sulphate for 30 min, filtered and the solvent removed using a rotavapor at 40 °C to dryness. The repeatability of the method was evaluated by extracting separately four aliquots of eight different samples of VOOs of four different geographical origins.

2.3. Preparation of the alcohol, sterol, hydrocarbon, and tocopherol fractions

The unsaponifiable fraction of the oil is dissolved in chloroform (5% w/v) and fractionated by TLC using hexane-diethyl ether (50:50, v/v) as the eluent. Once the plate is developed, it is dried by leaving it for a short time under a fume hood. Then, it is sprayed with an ethanolic solution of 2,7-dichlorofluorescein (0.2%, w/v), in order to make the bands of the different fractions and components visible under ultraviolet light: the hydrocarbon fraction (HF); tocopherol fraction (TF); alcohol fraction (AF), containing cycloartenol; and the sterol fraction (SF) and erythrodiol. Then, each single band is scraped off and extracted with diethyl ether (10 ml), filtered under vacuum, washed several times with diethyl ether, and evaporated to dryness by mild heating in a gentle flow of nitrogen. An aliquot of each fraction was analysed by GC–FID (regulation EEC-2568/91, annex V, Sections 5.3 and 5.4.2.1.) in order to control the performance of the fractionation procedure.

2.4. NMR analysis

Each unsaponifiable fraction of VOO or 40 μl of the bulk oil was dissolved in 200 μl of deuterated chloroform, shaken in a vortex, and placed in a 2 mm NMR capillary. The ^{1}H NMR experiments were performed at 300 K on a Bruker (Rheinstetten, Germany) Avance 500 (nominal frequency 500.13 MHz) equipped with a 2.5 mm broadband inverse probe. The spectra were recorded using a 7.5 μs pulse (90°), an acquisition time of 3.0 s (32*k* data points) and a total recycling time of 4.0 s, a spectral width of 5500 Hz (11 ppm), 64 scans (+4 dummy scans), with no sample rotation. Prior to Fourier transformation, the free induction decays (FIDs) were zero-filled to 64*k* and a 0.3 Hz line-broadening factor was applied. The chemical shifts are expressed in δ scale (ppm), referenced to the residual signal of chloroform (7.26 ppm) (Hoffman, 2006). The interesting regions of the NMR spectra for the analysis of the unsaponifiable fraction are from 0 to 5.44 ppm, and for the bulk oil, from 0 to 7 ppm. The spectra were phase- and baseline-corrected manually, and normalised to total intensity over the region 0–5.44 ppm for the unsaponifiable fraction and over the region 4.08–4.28 ppm for the bulk oil. The region of interest of the NMR spectra was binned with 0.04 ppm-wide buckets. TopSpin 1.3 (2005) and Amix-Viewer 3.7.7 (2006) from Bruker BioSpin GMBH (Rheinstetten, Germany) were used to perform the processing of the spectra. The data table generated with the spectra of all samples was then used for pattern recognition. One bucket in the region 3.96–4.00 ppm (artifact) in the unsaponifiable fraction analysis and five buckets in the region 4.08–4.28 ppm (reference region) in the bulk oil analysis were excluded in the multivariate data analysis.

2.5. Multivariate data analysis

The data set consisted of a 99 × 135 matrix, in which rows represented the samples (99 unsaponifiable fractions of VOO analysed), and columns the 135 buckets of the ^{1}H NMR spectrum. Each VOO was represented in the 135-dimensional space by a data vector made of the 135 variables. Data vectors belonging to the same category (geographical origin: Italy, Spain, Greece, Tunisia, Turkey, or Syria) were firstly analysed by univariate procedures (ANOVA, Fisher index and Box–Whisker plots), and afterwards, by the following multivariate techniques, already described in bibliography (Berrueta, Alonso-Salces, & Héberger, 2007): unsupervised as principal component analysis (PCA); and supervised as linear discriminant analysis (LDA), partial least squares discriminant analysis (PLS-DA), classification and regression trees (CART) and soft independent modelling of class analogy (SIMCA). Statistic and chemometric data analysis were performed by means of the statistical software packages Statistica 6.1 (StatSoft Inc., Tulsa, OK, USA, 1984–2004) and The Unscrambler 9.1 (Camo Process AS, Oslo, Norway, 1986–2004). Similarly, data sets made up of the ^{1}H NMR spectral data of the bulk oil and/or the unsaponifiable fraction of 23 VOO from Italy, Spain, Greece, Tunisia, and Turkey, were analysed by PLS-DA.

In LDA, the variable selection strategy was the following. Firstly, a modified best subset selection was used, which is a variable selection procedure that performs a search for the best subsets of a small number of variables that fulfil the criterion for choosing the best one (Wilks' lambda, rate of misclassification, etc.). This can be computed relatively quickly and in several steps: first, best subset selection applied to the complete data matrix to obtain the first best (small) subset of variables; then, in a second step, using best subset selection on a data set omitting the variables selected

in the first step, a second best subset is achieved, and so on. Finally, a refined selection of the variables selected successively in the previous steps was performed using forward stepwise selection (Berrueta et al., 2007).

The supervised techniques were applied to the autoscaled (or standardised) data matrix of the profiles of the unsaponifiable fractions of VOOs (in LDA, PLS-DA, and SIMCA) or to the PCA score matrix (principal components with eigenvalue higher than 1) (in CART). The models achieved were validated by threefold cross-validation or leave-one-out cross-validation (LOO) (Berrueta et al., 2007). The reliability of the classification models achieved was studied in terms of recognition ability (percentage of the members of the training set correctly classified) and prediction ability (percentage of the members of the test set correctly classified by using the rules developed in the training step). The model achieved by SIMCA for each category was also evaluated in terms of sensitivity (percentage of objects belonging to the category which are correctly identified by the mathematical model) and specificity (the percentage of objects foreign to the category which are classified as foreign).

3. Results and discussion

3.1. ^{1}H NMR spectra of the bulk and unsaponifiable fraction and subfractions of VOOs

^{1}H NMR spectra of the 23 VOOs from five different countries (Italy, Spain, Greece, Tunisia, and Turkey) and their corresponding unsaponifiable fractions were recorded. Moreover, subfractions of the unsaponifiable fraction of two VOOs from different origins (Italy and Turkey) were also analysed by ^{1}H NMR: (i) alcohol fraction (AF), (ii) sterol fraction (SF), (iii) hydrocarbon fraction (HF), and (iv) tocopherol fraction (TF). The spectral region studied for the unsaponifiable fraction has been limited to 0–5.44 ppm, because very few signals appear at higher chemical shifts and a large hump is observable in many samples (possibly due to incomplete water removal or to the presence of microparticles). The authors are aware that in this study some information contained at fields lower than 5.44 ppm is lost, as for example characteristic ^{1}H signals of aldehydes and phenolic compounds are located at high chemical shifts in the spectral region discarded (Guillen & Ruiz, 2001; Sacchi et al., 1996). It is well known that the determination of the unsaponifiable matter is one of the most problematic methods used for oil and fat analysis (Harwood & Aparicio, 2000). However, the nature of these impurities is being studied in order to enable the use of all the information contained in the whole spectra, and further research on unsaponifiable fractions for the geographical characterisation of VOOs is being carried out.

Olive oil is mainly made up of triglycerides, differing in their substitution patterns in terms of length, degree, and kind of unsaturation of the acyl groups, and by minor components such as mono- and di-glycerides, sterols, tocopherols, aliphatic alcohols, hydrocarbons, fatty acids, pigments, and phenolic compounds (Harwood & Aparicio, 2000). The chemical shifts of the ^{1}H signals of the triglycerides are well known (Mannina & Segre, 2002; Sacco et al., 2000). Minor oil components are only observed by ^{1}H NMR when their signals do not overlap with those of the main components and their concentrations are high enough to be detected. Table 1 shows the common ^{1}H NMR signals of major and some minor compounds together with their chemical shifts and their assignments to protons of the different functional groups. Some signals of minor compounds were found in ^{1}H NMR of VOO since they were not overlapping with those of the triglyceryl protons: cycloartenol at 0.318 and 0.543 ppm, β-sitosterol at 0.669 ppm, stigmasterol at 0.687 ppm, squalene at 1.662 ppm, *sn*-1,2-diglyceryl group protons at 3.71 and 5.10 ppm, and three unknown terpenes at 4.571, 4.648, and 4.699 ppm, as already observed by other authors (Guillen & Ruiz, 2001; Sacchi et al., 1996), (D'Imperio et al., 2007; Mannina, Sobolev, & Segre, 2003).

The unsaponifiable fraction of VOOs has not been studied by NMR previously. Indeed, the ^{1}H NMR analysis of the unsaponifiable fraction provides useful data on minor compounds that are masked by the triglyceride signals in the ^{1}H NMR spectra of the bulk oil, and that can be interesting for the authentication of VOOs, as explained above. The ^{1}H NMR signals of the unsaponifiable fraction are listed in Table 2 with their chemical shifts. The ^{1}H NMR analysis of the subfractions of the unsaponifiable fraction and the standards available allow us to make assignments for the ^{1}H NMR signals by comparing their spectra, and/or using bibliographic references (D'Imperio et al., 2007; Guillen & Ruiz, 2001; Pouchert & Behnke, 1993). The signals in the spectra of the unsaponifiable fraction were slightly shifted with respect to the signals in the spectra of the bulk oil (0.013–0.015 ppm to higher chemical shifts). Some signals were due to a particular subfraction and/or could also be assigned to individual compounds: cycloartenol at 0.333, 0.558, and 0.974 ppm; β-sitosterol at 0.826, 0.834, 0.848, 0.921, and 0.934 ppm; stigmasterol at 0.702 ppm; and squalene at 1.431 ppm. The NMR spectra of the bulk oil and the unsaponifiable fraction and its subfractions provided information about the most influent NMR signals or regions for their classification of VOOs according to the geographical origin.

3.2. Repeatability of the analysis of the unsaponifiable fraction of VOOs

Four aliquots of eight VOOs of different origin were submitted to the saponification procedure and the ^{1}H NMR profiles of these unsaponifiable fractions were evaluated by PCA. Fig. 1 shows that the variability between replicates is smaller than between samples. So, the repeatability of the analytical method used for profiling unsaponifiable fractions of VOO is appropriate for the aim of this work.

3.3. Geographical characterisation of VOOs

The univariate analysis (ANOVA, Fisher test, Box and Whiskers plots) of the data set, made up of 135 variables (NMR buckets) and 99 unsaponifiable fractions of VOOs (no replicates included), revealed that none of the variables were able to discriminate between VOOs of different geographical origin by itself. Hence, it was necessary to move on to multivariate data analysis in order to achieve the desired distinction at the national level.

The presence of outliers in the dataset was analysed by PCA, and five extreme samples (three from Spain, one from Turkey and one from Tunisia) were removed after having noticed the presence of some irregularities in their NMR spectra. The tridimensional plots of the sample scores in the space defined by the three first principal components (accounting for 60% of total system variability) showed that samples were grouped according to their origin, but each cluster was partially overlapped by others. This indicates that the direction of maximum variability in the dataset did not correspond exactly to the direction of maximum discrimination amongst the classes, which suggests the presence of other sources of variability. Indeed, the influence of the saponification batch was observed in the score plots of the samples. From this observation, and taking into account the aforementioned presence of interferences due to the saponification procedure, special attention should be paid to this step of the analytical method and further research is being performed in order to reduce this effect to a minimum.

With the aim being the extraction of all the useful information contained in the dataset for the geographical classification of VOOs, several supervised pattern recognition techniques were used. The

Table 1

26	5.05–5.15	m	>CHOCOR (glyceryl group)	*sn* 1,2-diglycerides
27	5.22–5.28	m	>CHOCOR (glyceryl group)	Triglycerides
28	5.28–5.38	m	–CH=CH– (acyl group)	

[a] Signal multiplicity: s, singlet; d, doublet; t, triplet; m, multiplet.

results are shown in Table 3. The variable selection used for LDA afforded eight NMR buckets centred at the following chemical shifts: 4.86, 4.70, 3.62, 2.78, 1.46, 0.98, 0.66, and 0.54 ppm. These buckets correspond to signals of the alcoholic fraction (0.54, 0.98, 3.62, and 4.70 ppm), sterolic fraction (0.66, 1.46, and 2.78 ppm), hydrocarbon fraction (4.70 ppm), and tocopherol fraction (4.86 ppm). Hence, the four subfractions of the unsaponifiable fraction of VOOs contain information related to the geographical origin of the oils. Some of these signals could be assigned to particular compounds: cycloartenol (0.98 and 3.62 ppm), aliphatic alcohols (3.62 ppm), β-sitosterol and campesterol (0.66 and 1.46 ppm), and stigmasterol (1.46 ppm). Further studies on the identification of the individual compounds (markers) responsible of the origin differences are in progress.

The threefold cross-validated LDA model correctly classified all the Tunisian VOOs, and recognised almost all the Spanish samples (98%) and predicted 91% properly. For the Italian VOOs, the recognition and prediction abilities of the model were 87% and 84%, respectively. The model did not perform so well for the other classes, so, even though the recognition abilities were acceptable, being 93% for the Turkish VOO, 89% for the Syrian and 87% for the Greek VOOs, the prediction abilities were considerably worse, not reaching 80% of correct hits. For these three countries, the recognition and prediction abilities are substantially different, meaning that the decision rules depend too much on the actual samples in the training set, and therefore, cannot be generalised.

PLS-DA was performed on the dataset using also threefold cross-validation as in LDA, however this technique did not perform properly with this kind of validation, yielding, forepart from the Tunisian and Spanish VOOs, very low percentages of correct classification, and recognition abilities lower than the prediction abilities (data not shown). These facts indicated that these PLS models were not stable and therefore, not reliable. However, when LOO cross-validation was used to validate the PLS model, better

results were obtained. Indeed, LOO is recommended for small database sizes which present the problem of the inability to divide the data set into fairly-sized subsets for training and test sets (Basheer & Hajmeer, 2000; Berrueta et al., 2007).

In order to obtain classification models by PLS-DA using LOO, two approaches were carried out: PLS-1 and PLS-2. In the former approach, a model is computed for each class separately so that it distinguishes its samples from all the others; whereas in PLS-2, all the classes are modelled simultaneously (Esbensen, Guyot, Westad, & Houmøller, 2002). Almost the same recognition abilities were achieved by both approaches, except for the Syrian VOOs (Table 3). However, the prediction abilities of PLS-1 models were more successful. From accumulated experience in chemometrics, it can be seen that better prediction models are obtained by using a series of PLS-1 models (Esbensen et al., 2002). Indeed, all the Tunisian and Turkish VOOs were correctly classified by PLS-1 models. The Spanish and Syrian models recognised all their VOOs and satisfactorily predicted 88% and 78% of them, respectively. Regarding the Italian and Greek models, the recognition and prediction abilities were 95% and 79%, and 83% and 75%, respectively.

Table 4 shows the weighted regression coefficients (Esbensen et al., 2002) of the PLS models in the PLS-1 approach that indicate the importance of the NMR variables on the model: the larger the regression coefficient, the higher the influence of the variable on the PLS model. Thus, the most important variables for the distinction of the Italian VOO belong to the alcohol and hydrocarbon fractions, the cycloartenol content being characteristic for this class. The Spanish and Greek models are mainly influenced by signals that appear in the alcohol, hydrocarbon and sterol fractions. Some of these signals are due to β-sitosterol, campesterol, sigmasterol, and cycloartenol; particularly for the Greek class, also to aliphatic alcohols (3.62 ppm). The Tunisian VOOs present a characteristic sterol composition. What differentiated the Syrian VOOs were the signals from the tocopherol, sterol, and hydrocarbon fractions. Signals related to the four subfractions studied influence the model of the Turkish VOOs, as well as the squalene signal at 1.678 ppm. Most of LDA selected variables are also important in the PLS models, so consistent results are obtained by both pattern recognition

techniques. Moreover, these results provide information about the most important features for the characterisation of VOO according to their geographical origin, which can be useful for the identification of possible markers in further studies.

Other supervised pattern recognition techniques were also tested in the search for the best models for classification. The LOO validated models afforded by SIMCA present good sensitivities (94–100%) but in general low specificities to the other five classes (Italy: 0–57%; Spain: 0–100%; Greece: 0–14%; Tunisia: 43–89%; Turkey: 83–100%; Syria: 74–100%). These results can be explained

Table 5
Classification results obtained by supervised pattern recognition techniques for the geographical characterisation of VOO using ^{1}H NMR spectral data of the bulk oil and/or the unsaponifiable fraction

Data	Origin	*N*	a priori probability	PLS-DA					
				PLS-2			PLS-1

	Turkey	4	17	2	100	75	1	100	75

considering the fundamentals of SIMCA: this technique performs PCA on each class, which affords the directions of maximum variability in each class. As explained above, a source of variability due to the saponification batch was present in the data. This variability affected all classes in the same way and thus the PCA for each class. Therefore, the hyper-ellipsoids modelled by SIMCA for each class were oriented in similar directions and overlapping, which results in low specificities. Similarly, despite its great potential, CART applied on the sample scores of the principal components with eigenvalues higher than one (15 PCs), did not afford acceptable classification trees by threefold cross-validation.

Comparing the classification results obtained by the different supervised techniques used, PLS-DA (PLS-1 approach) performs better than or similar to LDA. The fact that performing LDA and CART with LOO validation was not feasible with the software available could be considered a limitation for these techniques to achieve better results, due to the relatively low number of samples available for some classes.

The results obtained by discriminant techniques (PLS-DA and LDA) are similar, so the data contains enough information to afford a model for the target classification (Berrueta et al., 2007). However, these classification results have to be considered as preliminary ones because this study has certain limitations, some of which have already been mentioned above and others are now explained. The aim of the work, i.e. the geographical characterisation of VOOs, is quite ambitious since six classes are considered, and the number of samples in each class is not balanced and for some classes relatively low. Indeed, it is known that the supervised techniques used perform worse with an increasing numbers of categories (Berrueta et al., 2007). Moreover, LDA, PLS-DA, and SIMCA are very sensitive to large imbalances in the number of samples in each class. So, if the number of objects in each class of the training set is not approximately equal, the class membership decision will be biased towards the class with the most representatives (Berrueta et al., 2007). Therefore, better results are expected in a future study for which an equal number of samples in each class is ensured by designed experiments. Furthermore, more data, i.e. a wider region of the NMR spectra will be included since the baseline distortion will be eliminated, and the source of variability due to the saponification procedure, carried out in batches, will be reduced as much as possible.

Additionally, other different analytical approaches for the geographical characterisation of VOOs were evaluated: the bulk oil and the corresponding unsaponifiable fractions of 23 different VOOs from five countries (Italy, Spain, Greece, Tunisia, and Turkey) were analysed by ^{1}H NMR. The NMR spectra of the VOOs (0–7 ppm, excluding 4.08–4.28 ppm) and the unsaponifiable fractions (0–5.44 ppm, excluding 3.96–4.00 ppm) were analysed by multivariate techniques both separately and together: (i) bulk VOO (23 samples $\times$ 170 buckets), (ii) unsaponifiable fraction of VOO (23 samples $\times$ 135 buckets), and (iii) bulk VOO and unsaponifiable fraction (23 samples $\times$ 305 buckets). In all three approaches, PCA score plots show that natural clustering occurred according to the geographical origin, but the groups were partially overlapped in the space defined by the first three principal components (accounting for 60–77% of total system variability). Since the number of variables exceeds the number of samples, LDA (without variable selection) could not be carried out, so PLS-DA was used in both versions of PLS (PLS-1 and PLS-2). Definitely, PLS-1 achieved considerably better classifications for the three analytical approaches (Table 5). These preliminary results suggest that the analysis of the bulk olive oil and its corresponding unsaponifiable fraction contain complementary information for the required classification. These approaches are being further studied with a considerably larger sample set.

4. Conclusion

Pattern recognition techniques applied to the ^{1}H NMR data of the unsaponifiable fractions of VOOs from Spain, Italy, Greece, Tunisia, Turkey, and Syria showed that these spectral data contained useful information for the geographical characterisation of VOOs. Moreover, a preliminary study of the ^{1}H NMR spectra of some oils from five different countries and their corresponding unsaponifiable fractions, suggested that they contain complementary information which would enhance the classification of VOOs according to their geographical origin. Furthermore, from the study of the subfractions of the unsaponifiable fraction (alcohol, sterol, hydrocarbon, and tocopherol fractions), some trends related to the geographical origin of the olive oils are observed. This new approach based on the NMR profile of the unsaponifiable fraction of olive oil is currently being explored and further research is being carried out. The availability of a larger data set of VOOs would further facilitate the classification at the national level and also provide a means to guarantee PDO/PGI classification CE.

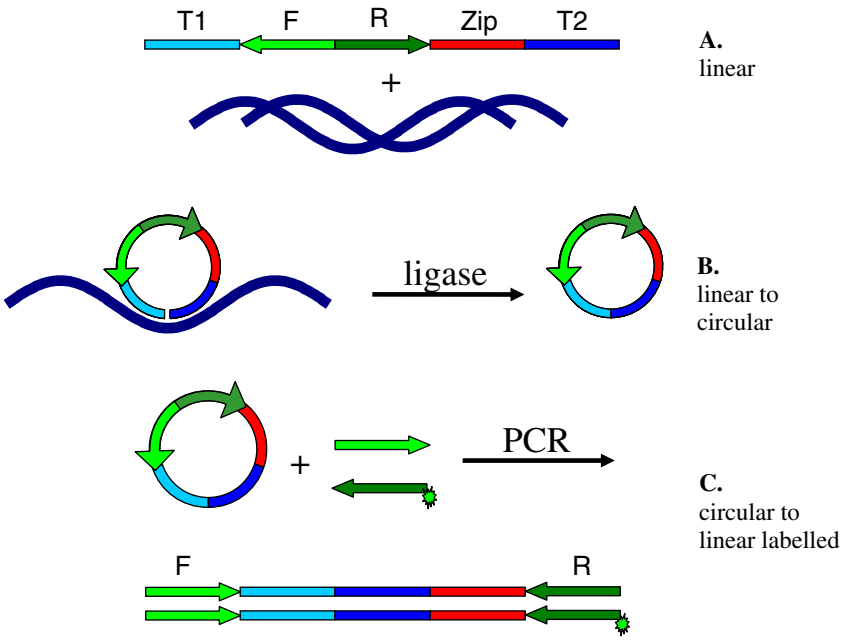

Fig. 1. Scheme of the padlock ligation procedure. A. Linear padlock with telomeric target (T) sequences can hybridise to their genomic counterpart. B. Upon hybridisation, the juxtaposed ends are ligated to form a circular molecule. C. The circular molecule are amplified by asymmetrical PCR with a forward (F) and reverse (R)-Cy3 primer to generate large amounts of linear ssDNA with a Cy3-labelled (✹) cZIP code.

a tetraploid crop with a BBA^{u}A^u genome, allowing discrimination on the absence (Golovnina et al., 2007) or presence (Bryan, Dixon, Gale, & Wiseman, 1998; Pasqualone, Montemurro, Grinn-Gofron, Sonnante, & Blanco, 2007; Terzi et al., 2005) of the D-genome. The alternative approach, positive identification of Farro della Garfagnana, is still difficult since the *Triticum* BB, A^{u}A^u and DD genome arose from a common ancestor Golovnina et al., 2007.

In this article a method for establishing the purity of Farro della Garfagnana batches is proposed that is based on the padlock ligation technology (Nilsson et al., 1994) in combination with microarrays.

Vora, Meador, Stenger, and Andreadis (2004) published the padlock probe approach to separately detect micro-organisms on a microarray. Since then, numerous related strategies were developed to fine-tune this method to tailor-made applications (Inoue, Shigemori, & Mikawa, 2006; Jarvius et al., 2006; Pang, Qureshi, Shanahan, & Harris, 2007; Szemes et al., 2005; Tian, He, & Mao, 2006). Padlock probes are based on the principle of ligation detection probes. A single stranded DNA molecule containing from left-to-right a 5′ target sequence, a reverse primer recognition site, a forward primer recognition site, a cZIP-code and a 3′ target site is hybridised with a DNA sample of interest. Upon recognition of the 5′ and 3′ target sites within the targeted DNA, the juxtaposed target sequence-ends can be ligated to form a circular molecule. Once formed, the molecule can be amplified on the basis of the primer recognition site combination on the circular probe. Since the reverse primer is Cy3-labelled, the resulting PCR products including the unique cZIP-codes also become labelled. In this way, the specific target sequence is coupled to a labelled cZIP-code. For a visual impression, the reader is referred to Fig. 1. Upon hybridisation on a microarray containing ZIP-codes, the presence of specific DNA molecules is revealed by illumination of the corresponding ZIP-code spot. Since this method is based on the amplification with two universal primers to generate unique cZIP-codes, the system is suitable for multidetection.

In this article the proof of principle is described for a robust assay to detect different cereal species and varieties in a complex cereal mixture. This assay can form the basis for effective maintenance of EU regulations with relation to EU-registered speciality products.

2. Materials and methods

2.1. Plant material and cloned sequences

Table 1 gives a listing of the plant material used in the experiments.

Cloned fragments containing the padlock probe target sequence:

The real-time PCR System for the specific detection of barley (*Hordeum vulgare*) was based on a unidentified barley sequence with accession number AY268139. The assay was developed with Primer Express 2.0 (Applied Biosystems, Foster City, USA). The forward primer: 5′ GCCAGGTCGTGAGGCAATAC 3′; reverse primer: 5′ GCCCGGGTAGAAGGATCCT 3′ and probe: 5′ FAM-CCGAGGTGCCATCCA-MGB 3′ were used in the real-time PCR, generating a fragment of 68 bp. The specificity of the system was tested with eight different cereals and proved to be specific.

The real-time PCR system for the specific detection of the D-genome was derived from the patent by Bryan and Gale (1998). Following sequences were used: forward primer: 5′ AAGGAGCTCGCCAACGG 3′; reverse primer: 5′ AACCGAGGGTCCAGAAGAGAC 3′ and probe: 5′ FAM- GCTAGATGGCTGGCTTCTATTTCATGATCCA-DQ 3′. This system proved specific for the D-genome of wheat (*T. aestivum*) and spelt wheat (*T. spelta*) generating a PCR fragment of 115 bp. In DNA of cereals lacking the D-genome no amplification was observed with this assay.

The real-time PCR was performed in a 20 μl reaction volume. It contained qPCR MasterMix (RT-QP2X-03) from Eurogentec (Seraing, Belgium); 800 nM of each primer, 400 nM of the probe and 50 ng of genomic DNA template. Amplification was performed in the ABI Prism® 7700 (Applied Biosystems, Foster City, USA) as follows: after one cycle at 50 °C for 2 min and one cycle at 95 °C for 10 min, the reaction was subjected for 50 cycles at 95 °C for 15 s and 60 °C for 60 s.

Table 1
Plant species used in the padlock experiments.

Genus and species	Name	Ploidy	1C[a] (pg)	Remarks
Avena sativa L.	Oat	2*n* = 42	13.23

Triticum aestivum L. ssp. *aestivum*	Wheat	2*n* = 42	17.33	Common bread wheat, hexaploid BBA^{u}A^{u}DD
Zea mays	Maize	2*n* = 20	2.73	

[a] 1C (Haploid genome weight: Bennett and Leitch (2003)).

A PCR fragment of 217 bp, specific for the chloroplast tRNA-Leu (*trnL*) gene, was amplified from genomic DNA extracted from *Avena sativa* (oat), using primers CER1F (5′-AATCCTGAGC-CAAATCCGTG-3′) and CER2R (5′-CATGTAGAATGGGACTCTCT-CTTTG-3′). Primers CER1F and CER2R have been designed by sequence homology research (alignment) of the *trnL* genes present in different plant species. These primers can amplify the *trnL* gene sequences in other species such as barley, rye and wheat, but the respective amplicon sizes differ from oat and can easily be distinguished by gel electrophoresis on a 1.6% agarose gel. On the basis of the sequence alignment, the 3′-terminal nucleotide of both primers were designed to mismatch with other species such as soybean, maize, walnut, pecan nut, almond, peanut, chestnut or rice. For this reason, those species should not be detected.

The fragments obtained by conventional PCR for oat and wheat (D-genome) and the real-time PCR fragment for barley (hordein gene) were purified using the QIAquick® PCR Purification Kit (Qiagen, Hilden, DE). The oat and wheat fragments were subsequently cloned in the pCR®2.1 vector using the Original TA Cloning® Kit (Invitrogen, Carlsbad, CA, USA). The barley sequence was cloned in the pCR®2.1-TOPO® vector using the TOPO-TA Cloning® Kit (Invitrogen, Carlsbad, CA). Subsequently, the *Eco*RI fragments containing the insert were cloned in the vector pUC18 using the Rapid DNA Ligation Kit (Roche, Mannheim, DE). Quality control was done by restriction analysis and PCR. Sequencing of the inserts was performed on a ABI Prism®3130 Genetic Analyzer using the BigDye® Terminator v3.1 Ready Reaction Cycle Sequencing kit and the universal M13 forward and reverse primers (Applied Biosystems, Foster City, CA, USA).

Based on the sequencing results for each plasmid, the clone containing the desired insert was used to make a 20 ml overnight culture. Plasmid DNA was extracted using the QIAprep® Spin Miniprep Kit (Qiagen, Hilden, DE). In the following step, two aliquots of 50 μl DNA were restricted with *Sca*I to linearise the plasmids and gel electrophoresis was performed to check if the digest was complete. The digested DNA was purified using the QIAquick® PCR Purification Kit. Elution was done in 2 steps (50 μl followed by 30 μl). The elutes were kept separately and quantified by fluorimetry (PicoGreen dsDNA assay kit, Molecular Probes Europe, Leiden, NL).

Recombinant Plasmid pIRMM-0040 contains the oat fragment, pIRMM-0044 contains the D-genome specific fragment and pIRMM-0046 contains the barley fragment.

Single stranded plant DNA-derived target sequences were derived from the combined 5′ and 3′ target sequence of the padlock probe. Target sequences were ordered (Biolegio, NL) in the reverse complement sequence to allow hybridisation and subsequent ligation of the padlock probes on the juxtaposed 5′ and 3′ target.

2.2. DNA extraction

Plant material (dry seeds and grains) was powdered under liquid nitrogen and 50 mg was used per DNA isolation. 150 μl MQ and 350 μl CTAB buffer (20 g/l CTAB; 1.4 M NaCl; 0.1 M Tris–HCl; 20 mM EDTA) was added together with 10 μl 20 mg/ml Proteinase K and incubated overnight at 42 °C. After a short centrifugation step (5 min at 14.000 rpm) the supernatant was incubated with 5 μl RNaseA (Qiagen, 100 mg/ml) and incubated at 65 °C for 15 min. Two hundred and sixty microliter of buffer AP2 (Qiagen DNeasy Plant Minikit) was added and this was incubated on ice for 5′. Further steps continued from step 10 of the Qiagen DNeasy Plant Minikit as described by the manufacturer's protocol (Qiagen: DNeasy plant handbook 07/2006) without modifications. DNA concentrations were measured with the NanoDrop spectrophotometer (NanoDrop ND-1000, software version 3.3.0).

2.3. Ligation detection probes

Padlock probes were designed by hand and checked with software available on the internet to calculate melting temperature and secondary structures. HYTHER™ (version 1.0, Nicolas Peyret and John SantaLucia, Wayne State University; Peyret, Seneviratne, Allawi, & SantaLucia, 1999; SantaLucia, 1998) was used to calculate the T_m of the 5′ and 3′ targets and of the whole linear molecule. Mfold (Zuker, 2003) was used to predict possible secondary structures. The choice of complementary ZIP-codes (Affymetrix) that were incorporated in the probes depended on cross-reactivity, availability and the likelihood of causing secondary structures. The concentration of the padlock probes (Biolegio, NL; Eurogentec Nederland bv, NL) was measured with the NanoDrop spectrophotometer and the stock contained either single probes or a mixture of probes in a concentration of 250 pM. The padlock probes all contain a 5′ phosphate group to allow ligation. See Table 2 for used sequences and cZIP-codes.

The target sequence within the plant genome and the total padlock probe sequence were checked for absence of restriction sites of endonucleases *Bam*HI, *Hin*dIII and *Eco*RI that are used to digest the genomic DNA. The padlock probes were checked with respect to the requirements to have a ~30 nt 5′ target with a T_m of 68–70 °C and a ~15 nt 3′ target with a T_m of 40 °C. The T_m calculations were performed using HYTHER™. Mfold was used to optimise the design to eliminate significant secondary structures in the

Table 2
Padlock probes: 5′ and 3′ target sequences, primer sites and coupled cZIP-codes. The sequences are in 5′-3′ direction.

[a] D-genome specific (Bryan and Gale, 1998).

molecule. The length of the designed padlock probes varies slightly since the target sequences have to meet the requirements. The cZIP-codes were selected within the high intensity Bin (Affymetrix) containing the qualitatively superior oligonucleotides and compatibility of the sequence with requirements regarding T_m and secondary structures was tested.

BLAST analysis (Altschul et al., 1997: blastn for short molecules; http://www.ncbi.nlm.nih.gov/blast/Blast.cgi) was performed with the gDNA target sequence to get an estimation of the potential crops/cultivars that enable the padlock probe to circularise. It should be noted that not all genome sequences are in the database and only verification by experimentation can validate the padlock probe as crop/cultivar specific.

Prior to the initial experiments the single stranded padlock probe integrity was checked on PAGE with subsequent silver staining (GE Healthcare/Amersham, ExcelGel, PlusOne DNA Silver-staining).

2.4. Digestion and ligation

DNA (1500 ng) was digested for 1 h at 37 °C (in 1× NEB2 buffer [New England biolabs] and 0.1 μg/μl BSA with 0.33 U/μl *Bam*HI, *Eco*RI and *Hind*III resp. in a final vol. of 30 μl) and heat-inactivated at 95 °C for 10 min.

Four microliter digest (200 ng of either single DNA or mixed DNA sample) was used in a ligation assay (1× *Pfu* ligation buffer (Stratagene); 12% PEG6000; 0.1 U/μl *Pfu* ligase (Stratagene), 25 pM of each padlock probe in a final volume of 10 μl) to allow circularisation (94 °C for 5 min; 95 °C 30 s, 65 °C 5 min for 30 cycles) in the BioRad iCycler 3.021. In case of a 20% DNA sample, the amount of DNA was replenished to 200 ng with herring sperm DNA (Promega, Madison, WI, USA).

2.5. Real-time PCR

Real-Time PCR was performed using SYBR Green (1× SYBR Green Supermix containing the iTaq DNA polymerase (BioRad); 0.5 μM forward primer and 0.5 μM reverse primer; 3 μl ligation mixture) in the BioRad MyiQ single-colour Real-time Detection System (95 °C for 3 min; 95 °C 10 s, 60 °C 45 s for 40 cycles; 95 °C 1 min). The melting curve was observed from 55 to 95 °C in 80 steps of 0.5 °C per 10 s. The data were studied using the optical system software program iQ5 version 2.0 (BioRad). See Table 2 for the sequence of the forward and reverse primer.

2.6. Padlock probe specificity testing

For specificity testing 25 pM of the padlock probe was examined with 200 ng digested genomic DNA and with a mixture of the five plant DNAs. A 40 ng genomic DNA sample (made up to 200 ng DNA with 160 ng herring sperm DNA) representing 20% (w/w) of the grand total was included to allow comparison of the C_t value of the 200 ng (100%), 40 ng (20%) target DNA in herring sperm background and the 40 ng target DNA (20%) in the mixture.

DNA (200 ng) contains a limited amount of copy numbers of a certain target. With the haploid genome weight (RBG Kew Plant DNA *C*-values database: Bennett & Leitch, 2003), the *C*-value reflects the weight of a haploid genome in pg. Thus, the calculated number of targets within a haploid genome is: barley = 36,036; maize = 73,260; oat = 15,117; soya = 176,991 and wheat = 3847 (Target is D-genome-specific and therefore present only 1/3 × 11,540 = 3847 times).

2.7. Microarray visualisation

Microarrays were prepared using the MicroGrid (Apogent Discovery) and contain 50 spotted ZIP-codes (20-mer oligonucleotides from Affymetrix) with a 10-mer A-tail (and C6 to linker) in quadruplicate. The ZIP-codes are demarcated by ZIP-PS01 spots (Table 2) for positioning purposes.

The microarrays were pre-hybridised overnight at 42 °C in previously boiled and rapidly cooled pre-hybridisation mix (5× SSC; 0.1% SDS; 0.1 mg/ml herring sperm DNA). After a repeated wash with 0.1× SSC for 5′ at RT on a rotary tablet, the slides were rinsed with MQ and dried by centrifugation (2' at 1000 rpm).

For probe amplification, 3 μl ligation mixture with potentially circularised padlock probes was amplified using the forward and reverse primer (see Table 2) sites on the padlock probe (1× ThermoPol PCR buffer (New England Biolabs, containing 2 mM $MgCl_2$); 2.5 mM $MgCl_2$; 200 μM dNTPs; 2 U Vent® exo$^-$ DNA polymerase (NEB); 500 nM Cy3-labelled reverse primer; 50 nM forward primer in a total volume of 25 μl). For detection purposes, the reverse primer was labelled with Cy3. After asymmetrical PCR amplification (95 °C for 15 min; 95 °C 15 s, 51 °C 2 s, 72 °C 5 s for 80 cycles), 1 μl was applied to 64 μl hybridisation mixture (5x SSC; 0.1% SDS; 0.1 mg/ml herring sperm DNA; 192 pM 5′Cy3-labelled cZIPPS01) to hybridise to the microarray in a confined area (Gene Frame frames and cover slips 1.5 × 1.6 cm for 65 μl, ABgene, UK) for 2 h at 65 °C in a moist atmosphere.

After removing the chambers the microarrays were washed twice in 1× SSC; 0.1% SDS for 5 min, twice in 0.1× SSC; 0.1% SDS for 5′, twice in 0.1× SSC for 1 min and once with 0.01× SSC for 30 s. The slides were dried by centrifugation (2 min at 1000 rpm) and stored in the dark.

The ScanArray Express HT microarray scanner (Perkin Elmer) was used to scan the signal of the individual spots at 543 nm. Here, a PhotoMultiplier Tube (PMT) gain was used between 70 and 90 at a laser power of 90%. The individual signals were quantified using

the optical system software program ArrayVision version 8.0 (Imaging Research Inc.) and processed in Excel (Microsoft).

3. Results

3.1. Validation of padlock probes

All padlock probes were able to recognise and subsequently circularise on the target sequence. As positive controls cloned target fragments were obtained in a linearised form. In addition, for maize and oat the target sequences were ordered as single stranded oligonucleotides to perform as positive controls. Remarkably, C_t values (the threshold cycle C_t represents the PCR cycle at which the software first detects a noticeable increase in SYBR green fluorescence above a baseline signal and is a measure for significance) of reactions with 200 ng digested gDNA of oat or maize as template were lower compared to the molecular equivalent in linearised double-stranded plasmid containing the target, or the single stranded target (not shown). Plasmid and ssDNA have been complemented with herring sperm DNA to obtain a final DNA concentration of 200 ng. Although the total amount of DNA and the molar amount of target was thus comparable, more efficient ligation and subsequent amplification of padlock probe-targets was observed in genomic DNA compared to cloned and linearised plasmid or even ssDNA. The discrepancy between an artificial target and the amplification of molar equivalents in genomic DNA samples, will require further attention when quantification is required.

3.2. Specificity of padlock probes

Once padlock probes were proven to be functional on the genomic DNA for which they were designed, the padlock probes were tested with a number of cereals and other seeds for cross-reactivity. These were maize, oat, wheat, barley and soya. In Table 3, the results of the specificity of the padlock probes are depicted. The padlock probe was tested with digested genomic target DNA and with a mixture of the five plant DNAs. A genomic DNA sample representing 20% (w/w) of the grand total was included to allow comparison of the C_t value of the 100%, 20% target DNA in herring sperm background and the 20% target DNA in the mixture.

In general the padlock probes showed good performance with their target DNA (white upper area of Table 3) and hardly or not at all with the other non-target gDNA samples (grey lower area). Non-target DNAs show C_t values similar to those of the MilliQ treated water control and are therefore considered to be negative. This shows the padlock probes to be very specific for the detection of their target DNA.

As expected, the ΔC_t values (the difference between the C_t of a sample assay and the C_t of the water control: $\Delta C_t = C_{t(\text{target})} - C_{t(\text{MQ})}$ are slightly lower for the 20% sample compared to 100% target DNA. For the maize and oat padlock probe, the 20% pure DNA sample has a slightly lower C_t value than the 20% sample in the mixture. For barley and soya padlock probes the C_t value for the 20% pure sample was slightly higher while the C_t value for the wheat padlock probe was similar for the 20% pure and 20% mixture samples.

3.3. Identification of authenticity of Farro della Garfagnana

The absence of the D-genome is a criterion that molecularly distinguishes Farro della Garfagnana from spelt wheat and common bread wheat. A padlock probe for D-genome detection was developed that recognizes common bread wheat genomic DNA, but not other cereals tested (see Section 3.2.). The next step was to investigate if the padlock probe is D-genome specific, or if it does show

Table 3
ΔC_t values (ΔC_t is calculated as C_t Exp – C_t MQ) for padlock probes with target DNA (bold upper area) and presumed non-target DNA (italic lower area). 20% DNA samples and DNA mix each contain 40 ng of the target DNA compared to the 100% sample (=200 ng). ΔC_t values are calculated from at least two in duplo experiments. Outliers were omitted from the analysis. PLP = padlock probe.

[b] Average of one *in duplo* experiment for all Rye samples.

some cross-reactivity with the B and A^u-genome within other members of the *Triticum* genus.

For this experiment closely related hulled cereals like einkorn (*T. monococcum*), spelt (*T. spelta* cv. Oberkulmer Rotkorn and Ostro) and two domesticated emmer lines (*T. dicoccum* line 'Züblin' and line 'Kleiner gelber Kahler') were used. In addition, durum wheat (*T. durum* cv. Combo) was included as a close relative.

As can be seen in Table 3, the wheat padlock probe strongly reacts with hexaploid *Triticum* species containing the D-genome like bread wheat, "Ostro" and "Oberkulmer Rotkorn" spelt. Of the alleged non-target species, rye and emmer lines 'Züblin' and 'Kleiner gelber Kahler' had low delta C_t values, while others do not show a reaction (maize, soya, barley, oat and einkorn). Farro della Garfagnana, which has no D-genome as such but could harbour partial D-genome copies/elements in the B or A^u-genome, showed only minor reactivity suggesting that Farro della Garfagnana is indeed not a spelt wheat but more likely an emmer.

The ΔC_t values of rye and emmer lines 'Züblin' and 'Kleiner gelber Kahler' (and Farro della Garfagnana for that matter) could be due to the fact that slight contamination with common bread wheat may be expected since no certified reference material was available. Rye and the emmer lines show the same peak in the melting curves (not shown), indicating that homoeology to the wheat target sequence might be present in their genomes. Some *Triticum* species without the D-genome show the same peak as wheat in the melting curve, but at a later C_t value. Nevertheless, the observed ΔC_t value in Farro della Garfagnana does allow discrimination between a pure sample and a mixture. Overall, the delta C_t values of non-target species (grey) are significantly lower than the target species (white).

Specificity and sensitivity of the D-genome-specific padlock probe was further tested by diluting DNA from common wheat into DNA from Farro della Garfagnana (see Figs. 2 and 3). In the previous experiment, the D-genome of common wheat was already detected in a background of 80% other genomic DNA. A dilution series was made up to 2.5% common wheat in a mixture with 97.5% Farro della Garfagnana. DNA amplification for DNA mixtures of Farro della Garfagnana and common wheat with percentages of common wheat of 20, 15, 10, 5, 2.5 and 0%, yield the standard curve in Fig. 3. At 2.5% common wheat, a ΔC_t value of 2.16 ± 0.61 was still discriminative from the background signal containing 100% Farro della Garfagnana 0.28 ± 0.02 (*t*-test: $p = 0.024$), allowing detection of contaminating D-genome sequences down to 2.5%.

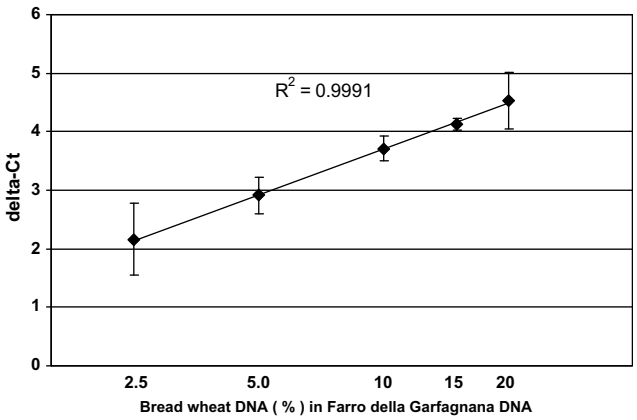

Fig. 3. ΔC_t values ($C_{t\ Exp} - C_{t\ MQ}$) of dilution series of bread wheat DNA in Farro della Garfagnana DNA using the wheat-specific padlock probe. The *x*-axis represents the log% of bread wheat DNA. Bread wheat (0%) has a delta C_t of 0.28 ± 0.02 (not shown in graph).

3.4. Microarray approach for visualisation of amplified padlock probes

A microarray approach for the detection of ligated padlock probes has the advantage that it can be rapidly extended (large numbers of) new ZIP-codes (coding for species or variety-specific padlock probes).

For this pilot experiment a microarray containing 50 spotted ZIP-codes was designed, flanked by positioning spots. This specific microarray could facilitate 50 different padlock probes to hybridise, but the microarray can easily be extended to accommodate a much larger number of target ZIP-codes. The microarray was

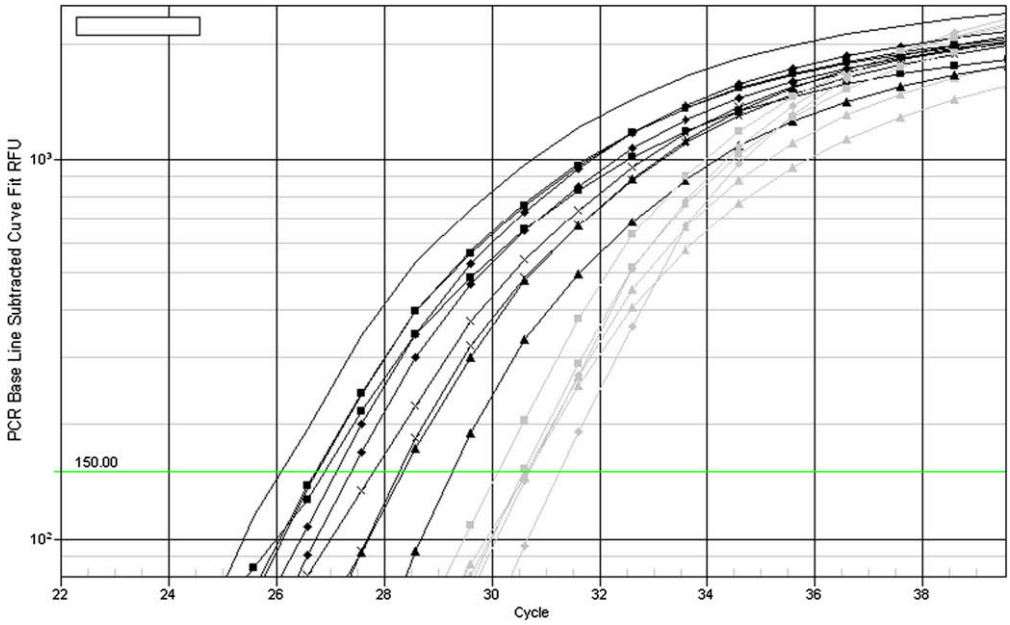

Fig. 2. Amplification plots (PCR cycles vs. relative fluorescence units) obtained from real-time PCR analysis of a dilution range (0–20% common bread wheat DNA in Farro della Garfagnana DNA) using the wheat-specific padlock probe. Black no symbol: 20% wheat; square: 15% wheat; diamond: 10% wheat; cross: 5% wheat; triangle: 2.5% wheat. Grey triangle: 0% wheat; diamond: MQ control; square: Non Target Control. The line at 150 RFU represents the threshold.

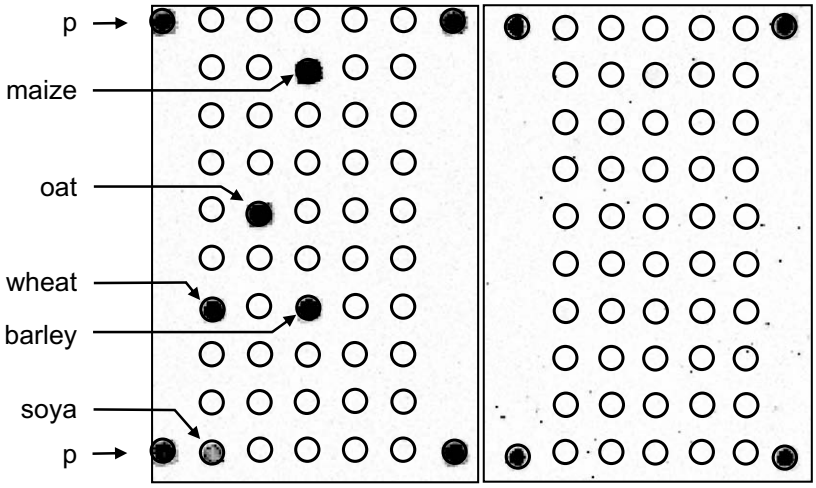

Fig. 4. Microarray hybridization shows specific and strong signals for 5-plex plant identification. Padlock probe ligation with the five corresponding probes was performed on 20% of each maize, oat, barley, wheat and soya. PCR labelling (Cy3) was followed by microarray hybridisation. Left: Microarray with the ZIP code signals corresponding to plant DNA, flanked by four positioning spots in the corners. Right: MilliQ treated water control sample.

exposed to a mixture of padlock probes (wheat, soya, maize, barley and oat), all previously allowed to circularise and amplify on a mixture of wheat:soya:maize:barley:oat at equal amounts of genomic DNA. In Fig. 4 the exposure of the five Cy3-labelled amplicons is visualised. Here, the dots representing wheat, soya, maize, barley and oat are intensely illuminated by Cy3, the resulting pattern being as anticipated. This indicates the combination of padlock probe ligation with universal PCR and microarray detection to be a truly multiplex system.

4. Discussion

For the maintenance of EU regulations related to speciality products such as PDO, PGIs and TSGs, it is necessary to develop specific and sensitive methods for the identification and establishment of authenticity of the different (agricultural) products. These methods should preferably be performed in a multiplex setting to not only allow the identification of the product itself, but also to establish the absence of any undesired admixtures in the product that will affect the quality or the economical advantage of the product.

In this paper a DNA-based method is presented that can specifically and sensitively detect a number of different cereal species in samples of speciality varieties. For the speciality product under investigation, the PGI wheat variety Farro della Garfagnana, it proved not feasible to develop product-specific markers that can be used to establish the identity of the basic product directly. But even if such markers were available, it would still be important to determine the purity of the product by eliminating the possibility that the speciality product had been mixed with other cereals with a lower economical profile. At this point only contamination by wheat varieties that do contain the D-genome as well as a limited number of other cereals can be ruled out: undesired admixture with other tetraploid emmer or durum wheat and diploid einkorn varieties will be difficult to exclude. The procedure as presented here, combining multiplex padlock ligation and microarray detection allows a rapid expansion of the approach to include more markers for individual cereal species or varieties that are either known to be speciality products or undesired admixtures. This will also further help to establish the purity of Farro della Garfagnana produce.

An additional advantage of the padlock-microarray system is that it is based on a target sequence spanning only approximately 45 nucleotides (~30 nt in the 5′ target and ~15 nt in the 3′ target of the padlock probe), compared to usually >100 nucleotides in an average PCR setting. This will improve the detection of the target in (more) processed products where some degree of DNA degradation has occurred compared to the traditional PCR approach.

For a detection system to be effective, it should be sufficiently sensitive. The padlock-microarray system described here is shown to be able to detect at least 20% of the different cereals in complex mixtures of plant genomic DNA. In a real-time PCR setting, a contamination of 2.5% common bread wheat DNA can be detected in a mixture with 97.5% Farro della Garfagnana DNA using a bread wheat specific padlock probe. This could be sufficient since Terzi, Malnati, Barbanera, Stanca, and Faccioli (2003) state that the Italian government currently prohibits the manufacture of pasta for sale in Italy containing more then 3% bread wheat. It remains to be seen what sensitivity is required to establish the authenticity of speciality products and whether this sensitivity can be achieved for all padlock probes using the system described here. The results so far are promising and make it plausible that increased sensitivity, should this be required, can indeed be achieved.

For the set-up and validation of effective detection and identification methods to underpin and maintain EU regulations on speciality products, it is of crucial importance that the basic quality of the products is well described. For the analytical characterisation of the products, reference materials for the individual products will become available. Reference materials can either confirm the purity of the authenticated product, or establish the band width of variation of the product that is still considered to be within the limits of the definition of the EU speciality product.

In this study, the GMO content of RoundUp Ready™ soya samples, constructed by mixing two differing GMO-containing samples, in different proportions, were measured using QUIZ and commercially tested by rt-PCR. RoundUp Ready™ soya is a convenient event to test the applicability of QUIZ because: the transgene has been characterised (Windels, Taverniers, Depicker, Van Bockstaele, & De Loose, 2001), providing sequence data for event-specific primer design; CRMs are available for the event in the form of ground soya meal (Fluka Biochemika); and there is a documented single copy lectin gene in soya (Germini et al., 2004) that can be used as a reference marker.

2. Materials and methods

The overview of QUIZ is shown in Fig. 1 and the technique can be divided into a number of steps.

2.1. Preparation of DNA

Soya Roundup Ready™ GMO reference material was purchased from Fluka Biochemika. Five samples, containing different GMO content, were constructed by mixing varying proportions of 0% and 5% CRMs (Table 1). DNA was extracted from each using a DNeasy kit (QIAGEN) following the manufacturer's instructions. An aliquot of each (2 μl) was run out on an agarose gel to determine quality, and quantified by comparison with known amounts of lambda DNA (New England Biolabs) (data not shown) and estimated to be ~20 ηg μL^{-1}.

2.2. Dilution of template

The haploid genome size of soya is ~1 pg (Plant DNA *C*-values Database, Royal Botanic Gardens, Kew, UK http://www.rbgkew.org.uk/cva1/database1.html), so 20 ηg μL^{-1} equates to 20,000 genomes in 1 μL. A dilution of 10^{-3} would therefore yield 20 copies of a single copy gene per μL. For the lectin marker, 5 μL of this dilution was added to each tube containing 1 mL of reaction mix for all samples apart from the 0% GMO sample. Corresponding dilutions were made to each sample to generate an equal number of GM markers. For the 0% sample, 10^{-4} dilution was made of the template for lectin gene detection. For amplification of the GM target 25 μL of the DNA sample was added to each mL of reagents to try and equalise the numbers of each marker (Table 1).

2.3. PCR conditions and fragment analyses

Primers (Sigma–Genosys) were designed from the sequences for the transgene junction for RoundUp Ready™ soya (EMBL Accession No. AJ308515) and for the lectin gene target (EMBL Accession No. K00821) as the taxon-specific reference (Table 2A).

Reactions containing DNA were made up in amber 1.5 mL microcentrifuge tubes (Star Lab – catalogue No. I 1415 1007). These were silanised by submerging in 'Silanization Solution II' (2% dimethylchlorosilane in 1, 1, 1-trichloroethane; Fluka Biochemika) for 10 min. The tubes were rinsed 10 times with water purified by reverse osmosis using a PRO/RO unit (Labconco Corporation) and air dried before use.

The silanised tubes were used for preparing the reaction mixes, containing 1× PCR buffer (as supplied), 2.5 mM $MgCl_2$, 0.25 μM each primer, 200 μM each dNTPs, 0.05 U μL^{-1} Fastart Taq (Roche), λ DNA to 1 ηg μL^{-1} with appropriate amounts of template added prior to dispensing into 384-well microtitre plates. One millilitre of reaction mix was made for each 96-well plate. Ten microlitre of reaction mix were dispensed into each well using an epMotion 5070 workstation (Eppendorf).

Cycling parameters – 5 min 94 °C initial denaturation was followed by 50 cycles of 92 °C 30 s, 55 °C 30 s, 72 °C 30 s; with final extension of 10 min 72 °C.

After cycling, each lectin amplification reaction was mixed with a reaction for the GMO target. One microlitre of the mix was added to 10 μL of Hi-Di (Applied Biosystems) with Rox-labelled size standards (81, 106, 173, 275, 358, and 408 nucleotides) and loaded onto a 3100 Genetic Analyzer (Applied Biosystems) with an injection time of 30 s. Size standards were made by amplification of pUC19 plasmid (Yanisch-Perron, Vieira, & Messing, 1985) using a Rox-labelled primer with different non-labelled primers to give the fragment sizes required (Table 2B).

The alignment of the tracks using the size standards was performed using Genemapper 3.7 software (Applied Biosystems) though each track was manually checked to ensure correct alignment. The presence, or absence of the two markers (see Fig. 2) were recorded and their numbers used to calculate the percentage GMO

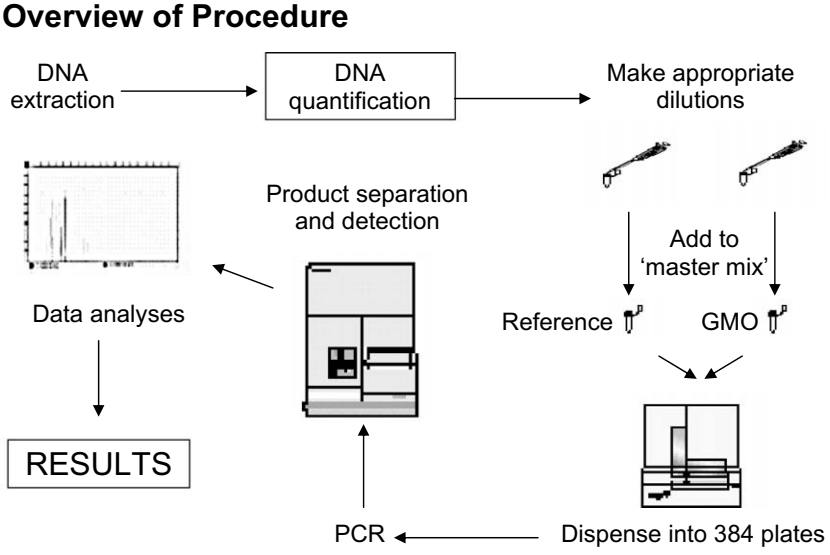

Fig. 1. Outline of the QUIZ procedure used in this study.

Table 1
Sample composition and measured GMO content

Sample	% (weight) 5% CRM	Nominal GMO content (%)	Number of lectin amplicons (total)[a]	Number of GM amplicons (total)[a]	Dilution factor	QUIZ determined GMO content (%)	% GMO content determined by rt-PCR (average)[b]
A	0	0	12	13	5×10^4	0.0022 ± 0.0009	0.009, 0.012 (0.01)
B	9.1	0.45	213 (384)	134 (368)	200	0.28 ± 0.03	0.149, 0.112 (0.130)
C	16.7	0.83	171 (384)	84 (384)	100	0.42 ± 0.06	1.253, 0.938 (1.095)
D	64.7	3.24	130 (384)	121 (368)	33.3	2.89 ± 0.37	3.078, 3.100 (3.089)
E	100	5	242 (383)	246 (382)	20	5.17 ± 0.49	4.275, 4.928 (4.601)

[a] Though 384 reactions were performed for each marker/dilution, some reactions were lost to evaporation.
[b] Samples were tested in duplicate and the results of both tests are given.

content in each sample. In cases (~20%) where the peaks were not oversized (fluorescence peak heights of >8000), peak heights greater than 500 were accepted as positives and everything else considered negatives.

2.4. Estimation of GMO content

The average number of molecules in each sample was calculated as:

$$\mu = -\log(\text{proportion of zeros}) \times \text{dilution factor}$$

The GMO content was determined as: $\mu_{gm}/\mu_{lectin} \times 100\%$.
Variance of percentage was calculated from:

$$\text{Var}_{(\text{ratio})} \approx \left(\left(\frac{p_l q_l}{N_1}\right) \cdot \left(\frac{1}{p_l}\right)^2 \cdot \left(\frac{\mu_g}{\mu_l}\right)^2 + \left(\frac{p_g q_g}{N_2}\right) \cdot \left(\frac{1}{p_g}\right)^2 \right) \cdot \left(\frac{1}{\mu_l}\right)^2$$

where p is the proportion of zeros, i.e. the proportion of negative amplifications, q is the frequency of positive $(1-p)$ amplifications for the lectin (l) and GMO (g) markers; N_1 and N_2 represent the total numbers of lectin and GMO reactions, respectively, μ_g and μ_l are the estimated numbers of molecules.

The formula for the variance of the ratio of (number of GM molecules)/(number of lectin molecules) was derived using the delta method, taking the distribution of p as binomial.

2.5. Quantification using real-time PCR

A set of samples containing 40 μL of each of the five admixtures was sent to IDna Genetics Ltd. (Norwich) to be tested for their RoundUp Ready™ content. Each sample was tested in duplicate and the results are summarised in Table 1.

3. Results and discussion

The outline of the QUIZ testing procedure is shown in Fig. 1. In this exercise we have exploited the nominal GMO contents to dilute the samples such that the expected numbers of reference and GMO targets are approximately equal. Though the number of reference targets can always be manipulated from the DNA concentrations this is not possible for samples where the GMO content is unknown. However, required dilutions can be determined empirically by testing a dilution series of the template. In fact methods of estimation can easily be extended to combine information from different dilutions and replicates of dilution series of template could be sufficient to determine whether a sample is below a given threshold without the need for further testing. Theory, verified by simulation (data not shown), demonstrates that the probabilities of no DNA template within the range 0.1–0.6 give the lowest errors in estimates of DNA concentration. This represents approximately an average of 0.5–2 target molecules per reaction giving a fourfold range of DNA concentration where the error is minimal.

The numbers of positive reactions for both lectin and GMO targets using extended numbers of PCR cycles (50 cycles) and FAM-labelled primers, for detection in automated genotypers, show successful amplification and detection from single molecules: given the DNA concentrations of the samples, it was statistically unlikely for all the reactions to contain more than one target amplicon. In fact, most peaks observed in the ABI3100 (Applied Biosystems) were oversized, even though only 0.5 μL of the reactions were used.

The amplification of near single copy template means that there are only small amounts of DNA in each reaction. Two steps were included in the procedure to reduce the loss of template DNA

Table 2A
GMO quantification: primer sequences and product length

which would impair the measurements: the silanization of the tubes to reduce DNA binding and the addition of bacteriophage λ DNA (to 1 ηg μL^{-1}) in the reaction mixes, as competitor to DNA binding sites on the tubes and pipette tips.

In addition to the 157 bp lectin amplicon, an additional fragment of 143 bp was also detected in many of the reactions (see Fig. 2). Sequence analysis of this second product show that it is amplified from a second lectin gene (EMBL Accession No. AY342212). The spatial distance of 143 bp between the primer sequences within this gene further supports this assertion. Both primers, which have been designed to amplify the 157 bp target, contain mismatches to this copy of the lectin gene (1 for the forward and 2 for the reverse primers) yet, the amplification of the 143 bp fragment was as effective as for the larger targeted amplicon, as judged from the numbers and intensity of the two products, even when co-amplified. Where the correct amplicon was detected most of the reactions (~80%) gave oversized bands when 0.5 μL of the reactions were loaded. For the remaining samples we applied a threshold of 500. We observed that the numbers of amplicons tailed off with both GM and lectin markers and, since the experiment was designed to amplify the two markers at similar numbers, any threshold level would give similar results. This may not be true if the numbers of GM and lectin targets were considerably different.

The co-amplification of the lectin genes highlights one of the differences between rt-PCR and QUIZ for quantification. With reference to standards, rt-PCR will measure the number of genes whereas QUIZ measures the number of molecules and, if two sequences are linked, they will not behave independently. The use of genomic controls as CRMs in rt-PCR compensates for multiple genes since the assays normalises the behaviour of the reference gene(s) on a 'per genome basis'. This would not be true if plasmid standards are used (Kuribara et al., 2002; Taverniers et al., 2005).

Quantitation results obtained using QUIZ compare favourably with those of the rt-PCR assay: the correlation between the measured and nominal values are 0.9901 and 0.9878, respectively (Fig. 3). Though the number of PCR reactions performed for QUIZ greatly exceeded those for rt-PCR, the amount of DNA required is substantially less, except for the 0% sample. For determining the number of lectin genes, only 400 pg of DNA was required for each sample. Detection and quantification using small amounts of DNA make it possible to quantify from samples where DNA levels will be low, e.g. processed foods, and potential inhibitors will be diluted with the DNA.

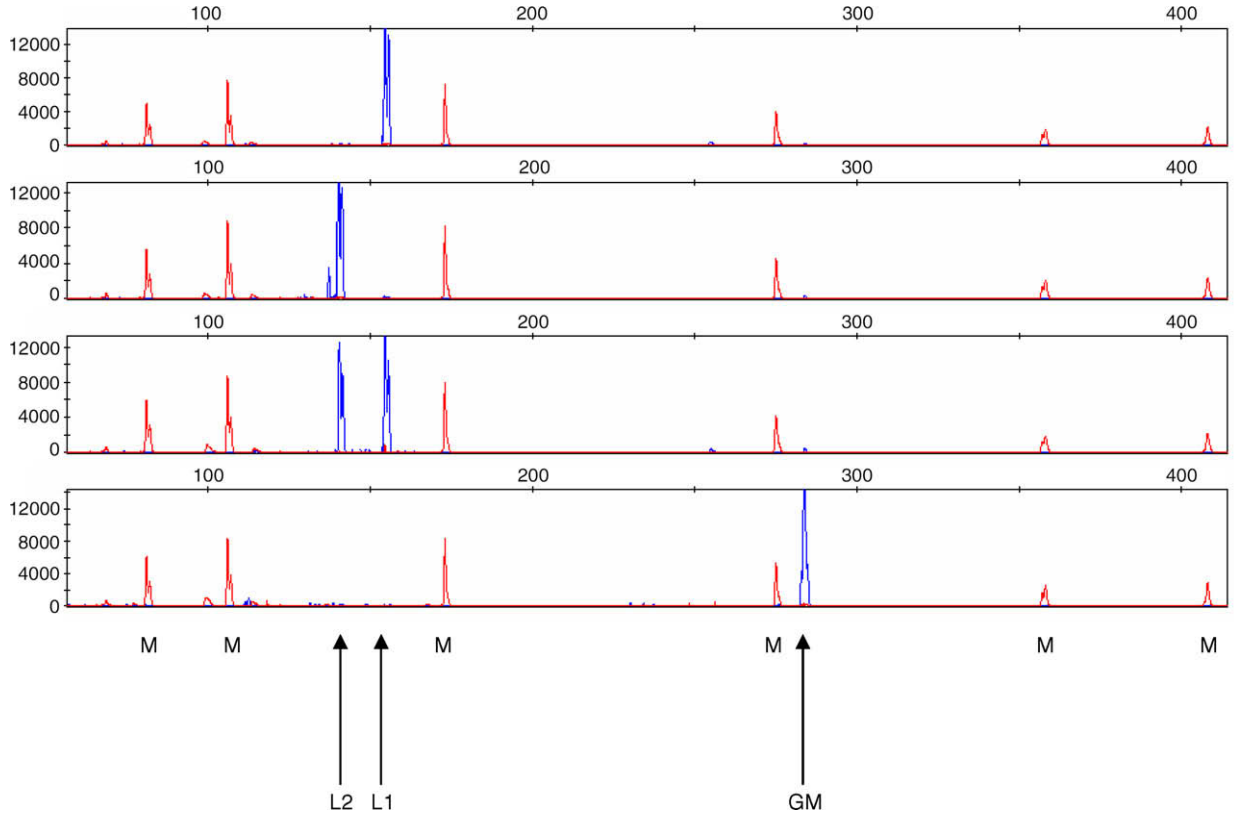

Fig. 2. Chromatograms showing the amplification of the fragments from lec 1 and lec 2 genes (L1 and L2, respectively) and event-specific amplicon (GM) in post-PCR mixes. The letter m denotes the internal Rox-labelled standards (see Table 2B) used to align tracks and numbers above the tracks represent sizes in nucleotides.

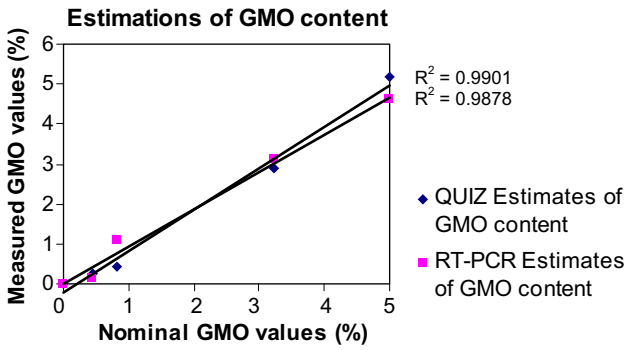

Fig. 3. The estimated GMO contents of the five samples, as determined using QUIZ and rt-PCR (iDNA Genetics Ltd.) are plotted against the nominal GMO content. The best fitting line is drawn for each method and the correlation of fit R^2 for each curve is shown.

QUIZ provides relative quantitation by comparing the abundance of each sequence which can be applicable in other systems, for example disease monitoring and gene expression. In the context of GMO testing, using GMO-specific and reference gene sequences, if the reference gene sequence is single copy, then the results from such tests can be expressed as % GMO per haploid genome, as favoured by the European Commission (EC Recommendation 2004/787). As such it does address some, but not all, of the problems of GMO labelling highlighted by Weighardt (2006). QUIZ offers a feasible alternative to quantify GMO contents of any sample, so long as suitable markers are available. The threshold for detection and quantification using QUIZ are down to single molecules: most probable number statistics are already applied to GMO detection in seed and grain (Macarthur et al., 2007; Remund, Dixon, Wright, & Holden, 2001) and the non-dependence on CRMs, which are not available for most approved events make this a potentially important GMO-testing procedure, especially for highly processed foods.

Acknowledgements

Huw Jones and Richard Horsnell are thanked for their help and patience demonstrating the ABI 3100. Jon White is thanked for helpful discussions and suggestions. This study has been carried out with financial support from the Food Standards Agency (FSA project G03025) and MLM is the recipient of a Ministero dell' Universita' e della Ricerca award from University of Naples Federico II.

plants used by bees as forage during the production of "Miel de Corse". Additionally, detection systems using real-time PCR for other plant species commonly identified in honey (acacia, linden, citrus, clover, heather, olive, rape, sunflower and rosemary) were also developed and validated. These real-time PCR systems were then used to distinguish Corsican honey from samples of honey from other geographic regions.

2. Materials and methods

DNA from acacia (*Acacia decora*, *Acacia longifolia*), almond (*Prunus dulcis*), blackberry (*Rubus fruticosus*), broom (*Cytisus scoparius*), chestnut (*Aesculus hippocastanum*), citrus (*Citrus grandis*, *Citrus limon*, *Citrus sinensis*), clover (*Trifolium alpestre*, *Trifolium medium*, *Trifolium montanum*, *Trifolium rubens*), heather (*Erica carnea*), eucalyptus (*Eucalyptus erythrocorys*), hazelnut (*Corylus avellana*), lavender (*Lavandula angustifolia*, *Lavandula lanata*, *Lavandula latifolia*, *Lavandula stoechas*), linden (*Tilia platyphyllos*), maize (*Zea mays*), melissa (*Melissa officinalis*), oak (*Quercus palustris*, *Quercus pubescens*, *Quercus robur*, *Quercus rubra*, *Quercus suber*), olive (*Olea europaea*), papaya (*Carica papaya*), rape (*Brassica napus*), rockrose (*Cistus ladanifer*, *Cistus monspeliensis*), rosemary (*Rosmarinus officinalis*), sage (*Salvia fruticosa*, *Salvia lavandulifolia*), sunflower (*Helianthus annuus*), sweet chestnut (*Castanea sativa*), thyme (*Thymus vulgaris*) and wheat (*Triticum aestivum*) was extracted from plant material (leaves, flowers or pulp) purchased from the Botanical Garden in Berlin, Germany or from commercially available plants. The plant material was ground in liquid nitrogen using the A11 Basic Analytical Mill (IKA, Germany) and stored at −80 °C. The DNA was extracted using a cetyltrimethylammonium bromide (CTAB) method based on the procedure published by Tinker, Fortin, and Mather (1993). DNA extracted from cattle (*Bos taurus*) and chicken (*Gallus gallus*) were used as negative controls.

Twelve to 15 different honeys were collected from each of four regions; Corsica, Spain (Galicia), Germany and the UK (Table 1). Only four regions were considered due to the wide variety found within each. These products were obtained in the appropriate countries from commercial sources or directly from the beekeeper. It was assumed that these honeys had not be adulterated or extended with material from other sources.

The extraction of DNA from honey described below was optimised and validated in a small-scale comparison with four independent laboratories. Honey (10 g) was diluted with water to 45 ml, incubated at 65 °C in a water bath and shaken for 30 min. Following centrifugation for 30 min at 2400*g*, the pellet was resuspended in 200 μl water and ground using a 3 mm Tungsten Carbide bead in a TissueLyser (QIAGEN GmbH) for 2 min at 30 Hz. Using the DNeasy Blood and Tissue Kit (QIAGEN GmbH) the sample was digested for 30 min at 56 °C in 50 μl of buffer Al with 25 μl of proteinase K. The remainder of the DNA extraction was carried out exactly according to the manufacturer's instructions (DNeasy Blood and Tissue Kit Handbook July 2006). The DNA concentrations of samples were determined by spectrophotometry (DynaQuant 200, Hoefer, Amersham Bioscience).

Candidate genes for TaqMan™ PCR were identified and sequence data obtained from the GenBank database (Benson, Karsch-Mizrachi, Lipman, Ostell, & Wheeler, 2005) (Section 3) or where no sequence entry was available (*actin*, *tRNA-Leu* (trnL), *HMG*2 and *adh*1) by DNA sequence analysis using consensus primers. With the exception of the primer pair used to amplify the *tRNA-Leu* (trnL) gene fragment (Taberlet, Gielly, Pautou, & Bouvet, 1991), all of the primers used were developed within this project (Table 2).

Conventional PCRs were performed in a total volume of 25 μl. The reaction mixture contained 0.2 mM of each deoxynucleotide triphosphate (dNTP), 0.2 μM of each primer (listed in Table 2), 1 × PCR buffer (GeneAmp® PCR buffer, PE Applied Biosystems), 2 mM $MgCl_2$, 1.5 units Taq polymerase (AmpliTaq Gold™ DNA Polymerase, PE Applied Biosystems), and 2 μl (10–50 ng) of template DNA solution. Amplification was performed in the Thermal Cycler GeneAmp PCR System 9700 (Applied Biosystems) with the following thermal cycling protocol: 95 °C for 10 min followed by 35 cycles of 95 °C for 30 s, an annealing step for 30 s, 72 °C for 30 s and a final single step of 72 °C for 6 min. The annealing temperature used for the respective systems was determined empirically to be 60 °C, with the exception of sweet chestnut (58 °C), sunflower (56 °C), rape (57 °C), linden (58 °C), clover (58 °C) and the general actin-system for plants (57 °C).

TaqMan™ PCRs were performed in a total volume of 10 μl. The reaction mixture contained 1 × TaqMan™ Buffer A, 1.5 units AmpliTaq Gold® Polymerase, and magnesium chloride buffer (all from the Applied Biosystems TaqMan™ PCR Core Reagent Kit), 0.2 mM of each dNTP, forward and reverse primers, dual labelled fluorescent probe, and 2 μl (5–25 ng) of template DNA solution. The final concentration of the primers, probe and magnesium chloride in the respective systems was optimised empirically (Table 3). The primers and probes were purchased from TIB MOLBIOL (Germany) or Sigma (UK) and are listed in Table 2. The high magnesium chloride values determined after optimisation, might be due to the comparatively low melting temperatures of some primers and the need for probe stabilisation in TaqMan™ assays (Applied Biosystems 7700

SDS Workshop). Amplification was performed on the Applied Biosystems 7900 HT Real-Time PCR FAST System, with the following thermal cycling protocol: 95 °C for 10 min followed by 45 cycles of 95 °C for 15 s and 60 °C for 1 min.

3. Results and discussion

The aim of this study was to develop a set of assays which, when used together on honey samples from Corsica, would provide a profile of the plant varieties visited by foraging bees, during honey production. These profiles would be indicative of the habitat on Corsica and could then be used as a reference against which honey samples could be authenticated.

The set of assays was composed of two elements: (a) a generic plant assay as proof of the presence of plants and (b) species specific assays for the detection of plants commonly found on Corsica and the EU mainland.

3.1. Development of plant specific TaqMan™ PCR systems

To develop a generic plant PCR system, which would detect a diverse range of plant pollen varieties in honey, several candidate genes were examined. It was found that the *rubisco activase*, *hydroxymethylglutaryl coenzyme A reductase*, *profilin* and *alcohol dehydrogenase* genes did not show sufficient interspecies sequence similarity to be suitable for the design of a generic plant PCR system (data not shown). However, in contrast, the *tRNA-Leu* (trnL) gene was found to be sufficiently similar between plant species and was, therefore used for the design of a generic plant PCR system (Table 2; plant nes-2), following in-house sequence analysis for a range of plant species, using primers previously shown to amplify a diverse range of plant species (Taberlet et al., 1991) (Table 2; plant 1-f, plant 1-r). This multicopy gene was particularly suitable for this application since there are very small amounts of pollen, and therefore DNA in honey and the use of a gene with more than one copy per cell increases the sensitivity of detection for TaqMan™ based assays. Fig. 1a shows the amplification plots of the generic primer and probe set using template DNA isolated from a variety of plant species.

Real-time PCR systems based on single copy gene sequences are central to the development of quantitative methods. To examine the possibility of applying a quantitative aspect to the characterisation of the plant content of honey, a PCR system (Table 2; act) based on a 103 bp region of the single copy gene *actin* was designed. When a range of plant species were tested using 5 ng DNA in a TaqMan™ PCR (Fig. 1b) the C_T values produced varied widely indicating that the assay could not be easily used to provide accurate quantitation. Factors contributing to the observed variation may include the presence of inhibitors, differing genome sizes, primer and probe sequence mismatches, and the degree of ploidy in differing species. To further complicate matters, it should be noted that the pollen profile of honeys can be season dependent, and that pollen from some plants can be strongly over or under-represented in various honeys. For example, levels of lavender pollen in honey derived from lavender plant nectar are typically very low. These factors contribute to make the characterisation of honey by the determination of the exact amount of a plant species in relation to the total plant content using real-time PCR problematical. Hence the approach in this study to characterise the origin of honeys based upon the determination of qualitative plant species markers specific for geographic regions.

3.2. Species specific detection

The design of species specific primer and probe sets used a variety of strategies, dependant upon whether sequence information was available on the NCBI database or if *de novo* sequence analysis was required. Sequence information was available for clover, eucalyptus, linden, oak, olive, rape, rockrose, sunflower and sweet chestnut. The design of most of these assays was therefore, relatively straight forward (gene, accession number and primer and probe sequences given in Table 2). There was little or no DNA sequence information available for the design of acacia, broom, citrus, heather, lavender or rosemary specific primer and probe sets. *De novo* sequence was generated for each of these species which was then used to design species specific primer and probe sets. The *alcohol dehydrogenase 1* (*adh*1) gene was amplified using consensus primers (Table 2; adh1-f, adh1-r2) designed using DNA se-

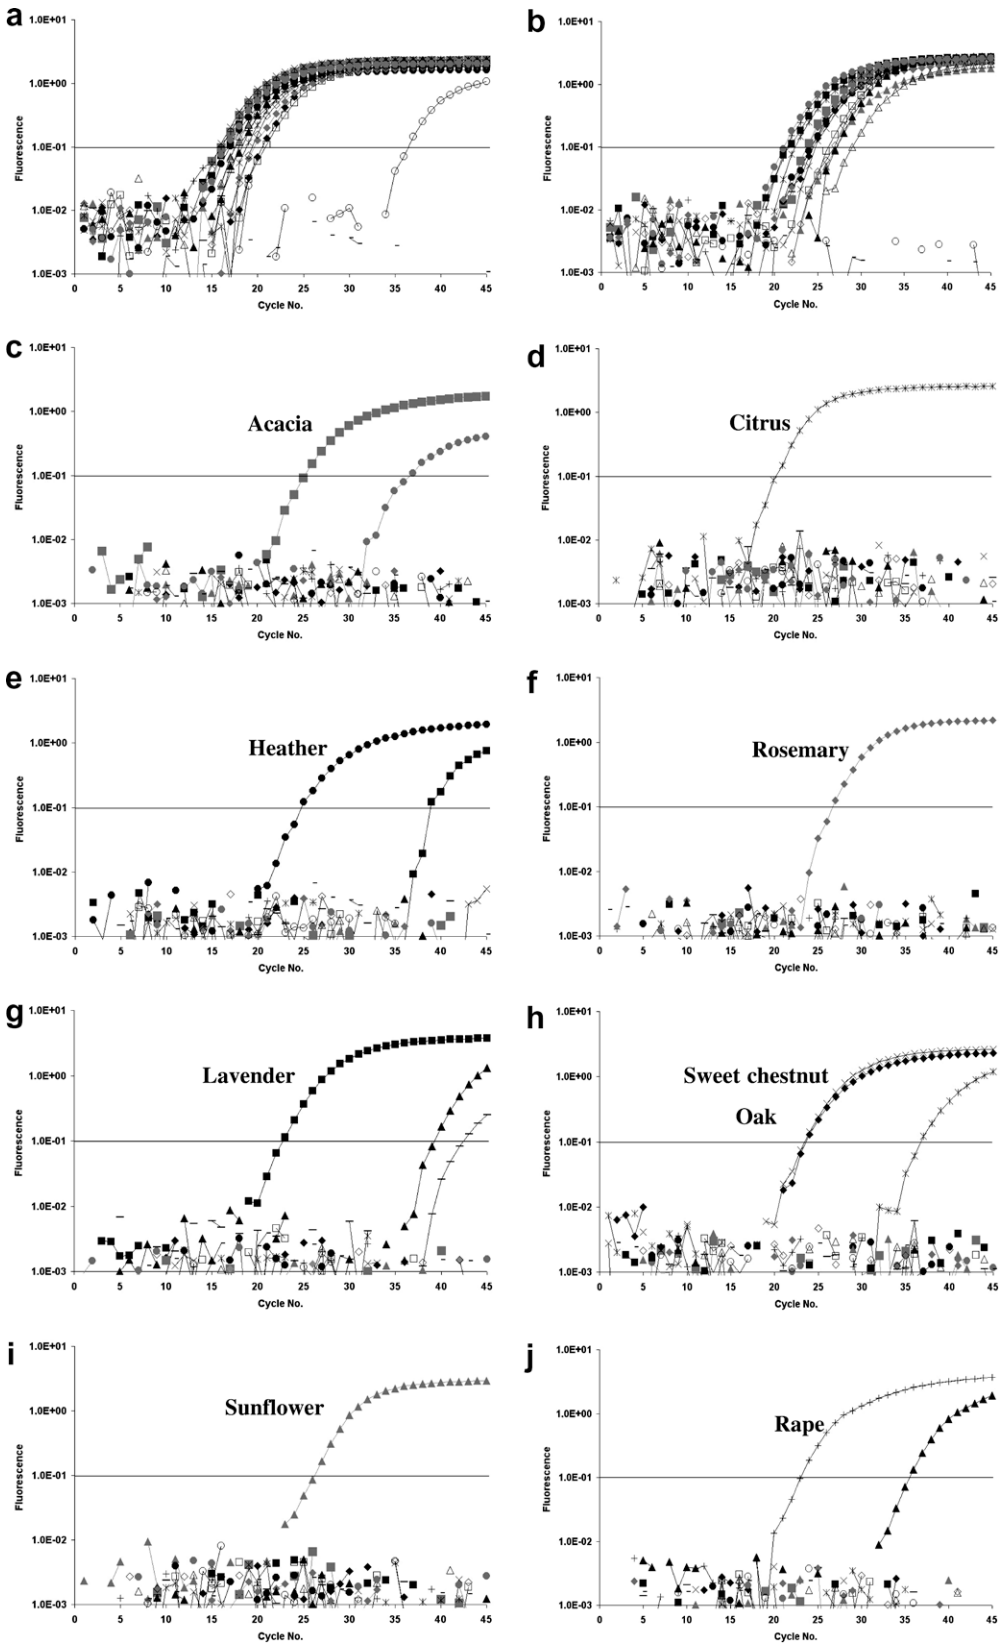

Fig. 1. *Specificity test*: fluorescence curves for samples of acacia (—■—), citrus (—✕—), heather (—●—), rosemary (—◆—), lavender (—■—), sweet chestnut (—◆—), sunflower (—▲—), rape (—┼—), linden (—⊟—), eucalyptus (—▬—), clover (—▲—), broom (—●—), rockrose (—△—), oak (—✕—), and olive (—◇—) including cattle (—⊖—) and water (—▬—) using the (a) plant nes-2, (b) act, (c) Aca_adh1, (d) Cit_adh1, (e) Eri_adh1, (f) Ros_CSL, (g) Lav_HMG2, (h) Cas-all-nes, (i) Heli-all-nes, (j) Bras_lip, (k) Til_nr, (l) Euc_LFY, (m) Tri_act, (n) Cyt_act, (o) Cis_DXR, (p) Querc_PAL and (q) olea_ole10 primer and probe system.

quence information from vine, sorghum, rice and barley. After DNA sequence analysis, specific primers and probes were successfully designed for the detection of acacia, citrus, heather and rosemary (Table 2, Fig. 1c–f, respectively). However, the primers and probe

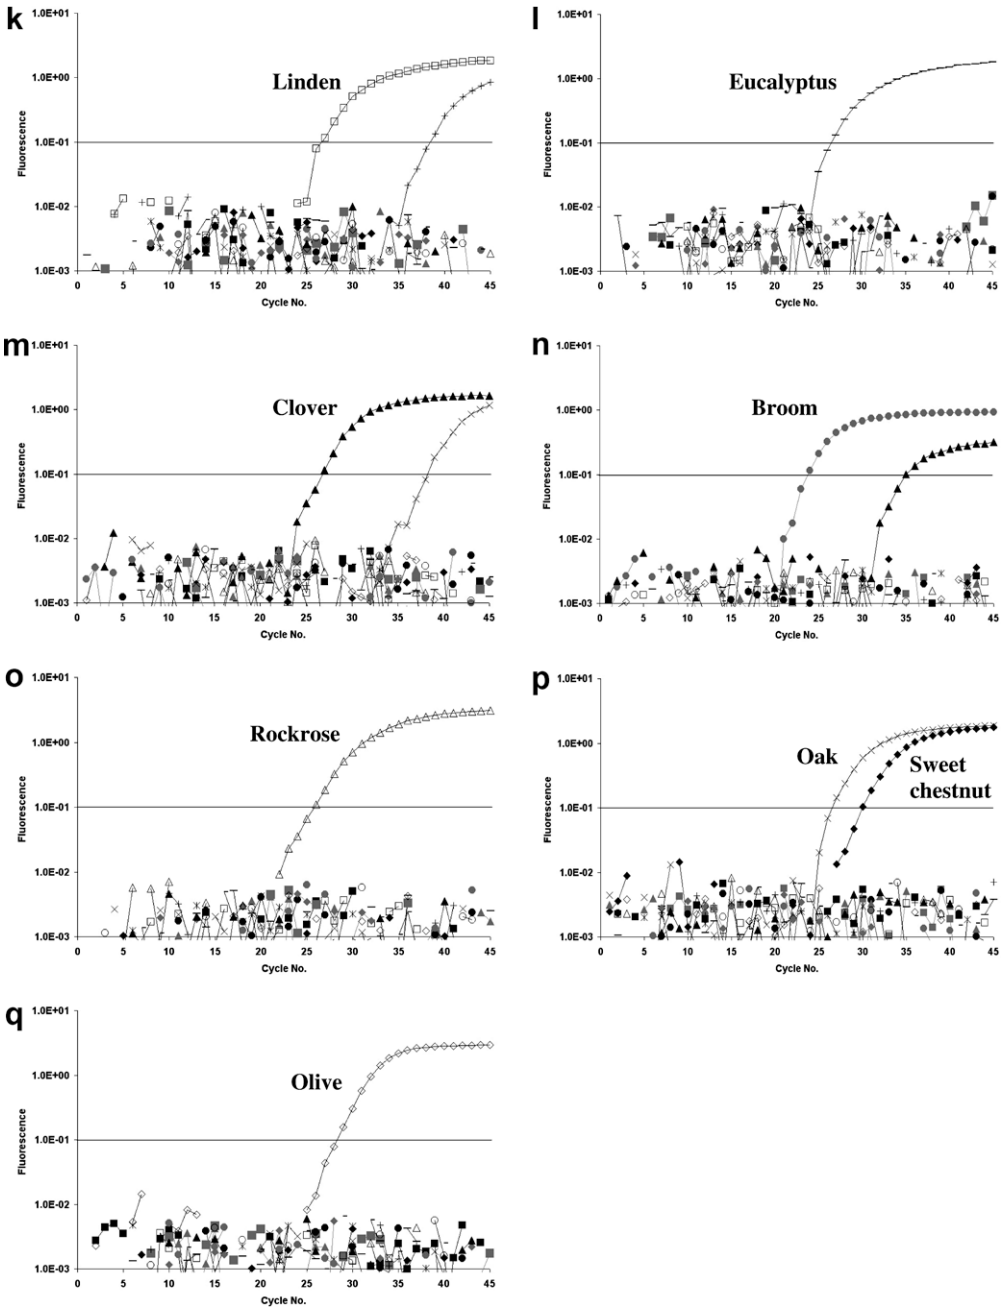

Fig. 1 *(continued)*

for the detection of *Lavandula stoechas* also amplified *Lavandula lanata* and *Lavandula latifolia*, although with significantly lower sensitivity (data not shown). An alternative PCR system was therefore developed, which would detect all lavender species with the same sensitivity. It was based on the *hydroxymethylglutaryl coenzyme A reductase* (*hmg*) gene for which sequence information for cotton, capsicum, tomato, potato and tobacco were available. After amplification and sequence analysis using consensus primers (Table 2; HMG2-border-f-w, HMG2-border-r-w) a specific primer and probe set was successfully designed which detected all lavender species with similar sensitivity (Table 2 and Fig. 1g). The detection system for sunflower was based on the *profilin* gene, however the NCBI database entry was for the mRNA and the amplicon size, for primers which had been designed to amplify a region 105 bp long, was found to be approximately 200 bp by gel electrophoresis. Sequence analysis of the amplicon (Table 2 for primers used: Heli-all-nes-f, Heli-all r1) revealed an intron/exon structure and therefore a new primer was designed which would amplify a DNA region of 106 bp. Sequence information of primers and probe is given in Table 2 and Fig. 1h shows the amplification plot for a selection of samples. The detection system for rape is based on the *lipase 1* gene. The NCBI database entry was also for the mRNA and after sequence analysis (see Table 2 for primers used: Bras_lip-f, Bras_lip-r) primers were designed to amplify a DNA region 122 bp long.

3.3. Specificity of species specific TaqMan™ PCR systems

The specificity of these primer and probe systems in TaqMan™ PCR was assessed using template DNA isolated from 25 plant species and two animal species as listed in Section 2. There was no significant cross amplification detected for the primer and probe

systems specific for acacia, broom, citrus, clover, heather, eucalyptus, lavender, linden, olive, rape, rockrose, rosemary and sunflower. Exemplary amplification curves are shown in Fig. 1. However, it was found that the sweet chestnut and oak primer and probe systems (Cas-all-nes and Querc_PAL) each cross amplified the other's DNA. Sweet chestnut (*C. sativa*) and oak (*Quercus* sp.) are closely related: in the same subfamily *Quercoideae* and on analysis of the DNA sequence it was found that there was a high degree of sequence similarity between these plant species. Therefore to distinguish sweet chestnut from oak, two alternative forward primers were designed which recognised two base differences within the PAL fragment (Cas_PAL-f and Querc_PAL2-f, Table 2). These alterations resulted in a delta C_T value of approximately 13 between oak and sweet chestnut and about six between sweet chestnut and oak using the new alternative oak and sweet chestnut primers, respectively. These differentials equate to a reduced sensitivity of approximately 100- and 10,000-fold on the alternate template DNA, for the new oak and sweet chestnut assays, respectively, and indicate a non-relevant quantity of a plant species in honey since the total DNA yield from honey is very low as described in the next section. Fig. 2 shows the fluorescence curves for a selection of samples.

3.4. Sensitivity and efficiency of the TaqMan™ PCR systems

The limit of detection (LOD), efficiency and linearity of the systems were assessed to determine the suitability and capacity of each. Tenfold dilution series of template DNA were tested in 10 replicates for each system (data not shown). It was found that for all systems the LOD was at least 25 pg, where the probability of obtaining a C_T value lower than 45 was 95%. On average a C_T value of 37 was measured. The efficiency of the systems was calculated to be between 88% and 117 % according to (Vaerman, Saussoy, & Ingargiola, 2004)

$$E = 10^{-\frac{1}{s}} - 1$$

where *E is the efficiency and s is the* slope of the regression line for the log DNA concentration plotted against C_T value. This range of efficiencies was acceptable since although logically a reaction efficiency cannot be greater than 100%, the measurement uncertainty could result in a calculated efficiency greater than 100%.

The dynamic range of the systems, where there was a linear relationship between the template concentration and the C_T values returned, were shown to be in the order of at least 3 $\log_{10}$ dilutions, confirmed by the strong linear relationship between C_T values and the $\log_{10}$ of the starting quantity up to 2.5×10^5 pg ($r^2 > 0.99$) (data not shown). The repeatability for each system was determined by measuring duplicates of three dilutions of template DNA, on three different days. The results showed a relative standard deviation of up to 33 % (data not shown).

3.5. Application of the real-time PCR systems to honey

The real-time PCR systems were used for the detection of plant species in honey. DNA was extracted and purified from honey samples from four target countries: Corsica, Spain (Galicia), Germany and England. The countries were chosen to have different flora thereby providing unique plant profiles for the honeys from each country.

Initially the DNA extracts of all the honey samples were analysed using the generic plant system and it was found that plant DNA could be unambiguously identified in all honey samples investigated. However, plant DNA was only present in low amounts, and thus at or close to the LOD of the PCR systems. In detail, using the general actin-system for plants which detects a single copy sequence an average C_T value of 34 was measured, whereas the general plant system that detects a multicopy sequence produced an average C_T value of 29. Using the plant species specific primer and probe systems an average C_T value of 36 was measured.

Analysing the DNA extracts of all the honey samples using the species specific real-time PCR systems (Table 4) it was found that there were geographical differences in the range of plant species found in honeys from Corsica, Galicia, Germany and England. In particular it was found that:

- rape was not detected in Corsican and Galician honeys, but in almost all German and English honeys analysed to date;
- sweet chestnut was detected in almost all honeys from Corsica and Galicia, but only in a few German and English honeys;
- rockrose and olive were only detected in some Corsican honeys.

These results indicated that a combination of plant species specific real-time PCR systems could be used to determine the geographical origin of honey samples from Corsica, when compared to honey samples from Galicia, Germany and England. The systems which were most informative were sweet chestnut, rockrose, rape and olive. The chi-square test was used to analyse each of the 15 detection systems to determine whether frequencies of positive results differed with geographical origin. The Fisher's exact test was used where sample sizes were too small for the chi-squared test to be accurate (expected frequency less than 5). The results are shown in Table 4 where the significance is given in terms of the *p*-value: the bigger the difference the smaller the *p*-value and where a *p*-value less than 0.05 refers to a significant difference. The results listed in Table 4 confirm that there is no statistical

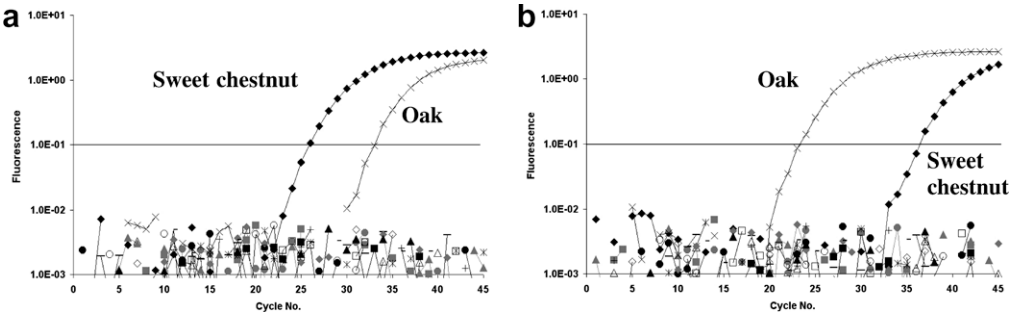

Fig. 2. Fluorescence curves for samples of acacia (—■—), citrus (—✕—), heather (—●—), rosemary (—◆—), lavender (—■—), sweet chestnut (—◆—), sunflower (—▲—), rape (—|—), linden (—□—), eucalyptus (—▬—), clover (—▲—), broom (—●—), rockrose (—△—), oak (—✕—), and olive (—◇—) including cattle (—○—) and water (—▬—) using the (a) Cas_PAL and (b) Querc_PAL2 primer and probe system.

Table 4
Statistical description for frequencies of positive results (%) using chi-square test or Fisher's exact test

Real-time PCR system specific for	Number of samples	Geographical origin of honey, percentage of positive results		*p*-Value
		Germany, UK, Galicia	Corsica	
Acacia	44	0	8	Not significant
Broom	58	5	0	Not significant
Citrus	37	0	30	0.015
Clover	47	29	0	0.019
Heather	58	17	44	0.043
Eucalyptus	58	2	0	Not significant
Lavender	53	0	13	Not significant
Linden	37	22	0	Not significant
Oak	58	7	25	Not significant
Olive	58	0	25	0.004
Rape	58	52	0	<0.001
Rockrose	58	0	63	<0.001
Rosemary	37	0	20	Not significant
Sunflower	53	5	0	Not significant
Sweet chestnut	58	57	60	Not significant

difference for Corsican honey versus German, English and Galician honeys for the frequency of the presence of DNA from acacia, broom, eucalyptus, lavender, linden, oak, rosemary, sunflower and sweet chestnut. In contrast Corsican honey samples contained DNA from citrus, heather, olive and rockrose more frequently than German, English and Galician honeys, although DNA from clover and rape could not been detected in Corsican honey. The lowest *p*-values were calculated for the olive, rape and rockrose systems. Sweet chestnut is an additional significant marker for Corsican and Galician honey compared to honey samples from Germany and England (data not shown). It was concluded therefore, that, as a proof of principle, four systems could be used to determine the geographical origin of Corsican honey. It should be noted that only 12–15 different honeys from only four countries were analysed and statistically evaluated. For more precise statements further samples, also from additional countries, should be analysed. It is very likely that honeys produced in other regions, with similar climate, would show a similar flora and therefore pollen profile. The identification of a particular plant that is only found on Corsica and the establishment of an appropriate real-time PCR detection system would have been the most promising strategy to confirm geographical origin, however, such a marker could not be identified for Corsica. Another possibility, also based on DNA methodology, would be the development of a system specific for the Corsican honey bee. Corsican honey is produced by the bee species *Apis mellifera corsica* and no other bee species have been imported onto Corsica since 1982, when a law prohibiting the importation of honeybees other than *A. mellifera corsica* came into force. Indeed, during this project, it was shown that additional DNA, other than that derived from plants, was detected in samples of honey (data not shown), where DNA from bees, aphids and bacteria were all found to be present. The identification of the Corsican honey via the identification of the species of honeybee, using genotyping, would be dependant upon the genetic drift of the Corsican honey bee since 1982, initial work on the identification of honeybee species looked promising although outside the main scope of this project.

4. Conclusions

Fifteen species specific TaqMan™ assays were developed for the detection of acacia, broom, citrus, clover, heather, eucalyptus, lavender, linden, oak, olive, rape, rockrose, rosemary, sunflower and sweet chestnut which showed no significant cross amplification when assessed on a further 10 plant species and two animal species. For the parallel detection of plants and to identify false-negative results (external amplification controls) a TaqMan™ system was developed based on a *tRNA-Leu* (trnL) sequence of approximately 90 bp. This multicopy chloroplast sequence was suitable for the detection of very low levels of plant DNA and was, therefore, applicable for the detection of plant DNA in honey. The development of a single copy *actin* sequence based system was less sensitive but may be of use for further applications, e.g. in the field of GMO or allergen analysis.

In this study, it was shown that a combination of species specific systems, selected from the pool of real-time PCR systems developed during this project, was able to produce a plant species profile unique to Corsican honey when compared to honey from Galicia, Germany and England, although the number of samples analysed was comparatively small and the locations relatively geographically remote from each other. With the detection of a particular plant in the sample that is only found in a specific location using the DNA based approach it should be possible to specifically confirm a honey's geographical origin.

of honey including improved oral health (Molan, 2001), antimicrobial properties (Ceyhan & Ugur, 2001) and wound healing effects (Mphande, Killowe, Phalira, Jones, & Harrison, 2007). Conversely, the ingestion of grayanotoxins in 'mad honey' (Koca & Koca, 2007) can lead to mortality.

A previous study utilised NMR spectroscopy for the characterisation of Corsican honey (Donarski, Jones, & Charlton, 2008). Multivariate statistical methods were used to identify spectral regions that are characteristic of the geographical origin of Corsican honey. A wide range of European honeys were used to establish the validity of the multivariate models. The approach taken resulted in the identification of a small number of peaks in the NMR spectrum, the intensities of which were used to identify Corsican honey with an overall accuracy of 96.2%. The compounds giving rise to these peaks were only partially characterised and their source was unknown. In this manuscript we investigate the peaks identified in the NMR spectrum that are characteristic of Corsican honey and correlate these with specific honey types. Data generated from the NMR spectroscopic analysis of a second harvest of Corsican honey is included here for the first time and demonstrates the validity of the biomarkers identified.

2. Materials and methods

2.1. Materials

Honey collected during Year 1: Honey (182 samples) was collected from five countries: Austria (18), France (129), Germany (18), Ireland (2) and Italy (15).

Honey collected during Year 2: Honey (192 samples) was collected from four countries: Austria (23), France (136), Germany (18) and Italy (15).

Commercial chestnut honey: Two chestnut honeys were purchased from commercial outlets. The honeys were from the French region of Périgord and the Italian region of Piemonte.

All non-commercial honeys were received in glass jars diluted using distilled water to 70°BRIX, containing 50 g of diluted honey. A Corsican honey from the region of Châtaigneraie was used to confirm the identity of kynurenic acid. Typical °BRIX values of undiluted honey range between 75 and 85, although the original °BRIX values of the honeys analysed in this project were not provided. Therefore, where calculations were performed to determine the concentrations of biomarkers, the concentration of the biomarker in a 70°BRIX solution was calculated. It is noted that these concentrations will under represent the biomarker concentration by 6.7–17.6%. Samples were stored at room temperature in the dark. All samples were analysed within 4 months of sample receipt.

In total, 220 Corsican honeys were analysed and the distribution of the different types of Corsican honey is presented in Table 1.

Table 1
Specific types and sample numbers of Corsican honey analysed.

Corsican honey type	Number of samples analysed
Arbousier	3

Spring Clémentinier	8

2.2. Chemicals

All chemicals used were of a purity of ⩾97%. Deuterium oxide (^2H_2O) was supplied by Goss Scientific Instruments Ltd. (UK). 3-Trimethylsilyl[2,2,3,3-D_4] propionic acid (TSP) and α-isophorone were supplied by Avocado Research Chemicals Ltd. (UK). Sodium azide, 2,5-dihydroxyphenylacetic acid, 4-oxoisopherone and kynurenic acid were supplied by Sigma–Aldrich Co. (UK). Di-potassium hydrogen phosphate and di-hydrogen potassium phosphate were supplied by BDH Chemicals Ltd., UK. Purine and hexakis (1H, 1H, 3H-tetrafluoropropoxy)phosphazine were supplied by Agilent Technologies (USA). Ultrapure water was obtained from an Elga Option 2 water purifier.

2.3. Sample preparation

A single 50 g jar of honey was homogenised using a Turrax mixer (11000 RPM) over five 20-s periods separated by 5 min to limit sample heating. The sample was placed onto a roller mixer at 35 RPM for 16 h until the honey was homogeneous, monitored by the distribution of a ultra-violet absorbing dye (data not shown).

2.3.1. Honey NMR spectroscopic analysis

Honey was diluted with ultrapure water to 15 ± 0.5°BRIX. All diluted samples were centrifuged to remove any remaining suspended material prior to filtration through a 0.2 μm PTFE syringe filter. The samples were prepared for NMR spectroscopic analysis by adding 480 μL of the filtered honey solution to 60 μL of sodium azide solution (10 mM dissolved in ^2H_2O, added to prevent microbial growth) and 60 μL of phosphate buffer solution (250 mM, pH 7.2 containing 10 mM TSP dissolved in ^2H_2O). The samples were thoroughly mixed using a vortex mixer prior to ^1H NMR spectroscopic analysis.

2.3.2. LC-TOF-MS analysis

A Corsican Châtaigneraie honey was diluted to 1.1 °BRIX using deionised water. The sample was centrifuged and filtered through a 0.2 μm PTFE syringe filter prior to analysis.

2.3.3. Kynurenic acid for NMR spectroscopic analysis

Kynurenic acid was prepared as a saturated solution at approximately 6 mM in ^2H_2O containing 1 mM TSP.

2.3.4. Kynurenic acid for LC-TOF-MS analysis

Kynurenic acid was prepared at a concentration of 10 μg mL^{-1} in deionised water.

2.4. NMR spectral acquisition parameters

All experiments were carried out using a Bruker Avance 500 MHz NMR spectrometer equipped with a TCI cryoprobe.

^1H NMR spectra, from all honeys, were acquired at a central frequency of 500.1323546 MHz using on-resonance pre-saturation to suppress the intensity of the water signal. A 60° observation pulse length of 5.1 μs and a delay between transients of 14 s were used. Complex data points (32768) were acquired with a spectral width of 14 ppm, giving an acquisition time of 4.6794 s. A recycle time of 18.7 s was determined experimentally to produce quantitative data with optimised sensitivity. Eight unrecorded (dummy) transients and 256 acquisition transients were used giving a total experiment time of approximately 1 h 20 min. One-dimensional (1D) ^1H NMR spectroscopic data were processed using FELIX software (Accelrys, San Diego, CA). A sine bell-shaped window function phase shifted by 90° was applied over all data points before Fourier transformation, phase and baseline correction. The chemi-

cal shift of all data was referenced to the TSP resonance at 0 ppm. The area of this resonance was set to unity for all spectra acquired.

The limit of detection of this experimental setup was determined from the signal to noise ratio of the internal standard. Representative ^{1}H NMR data from a single honey sample were used to determine a limit of detection for a resolved singlet resonance to be 6.3 μM. This is based on a minimum signal to noise ratio of 3.

^{1}H–^{1}H TOCSY NMR spectra were acquired from representative samples containing the highest concentration of each biomarker. ^{1}H–^{1}H TOCSY spectra were acquired using the standard spectrometer library pulse sequence (Bax & Davis, 1985) with 56 transients, 384 increments, a spectral width of 13.33 ppm in both dimensions and a spin-lock mixing time of 100 ms. In the F2 dimension, 4096 datapoints were collected and the F1 dimension was zero filled to give 2048 datapoints. 90° pulse lengths were calibrated for individual experiments and on-resonance pre-saturation was used to suppress the intensity of the water signal. ^{1}H–^{1}H TOCSY NMR spectra were processed using Topspin version 1.3 software (Bruker BioSpin, Germany).

2.5. Liquid chromatography and mass spectrometry parameters

Samples were analysed by LC-TOF-MS using an Agilent LC/MSD TOF (Agilent, Santa Clara, CA, USA) consisting of a 1200 Series LC and a G1620 time-of-flight mass spectrometer. Separation was facilitated using an Agilent ZORBAX Eclipse XDB-C18 100 × 2.1 mm, 3.5 μm column. The mobile phase consisted of 0.1% aqueous acetic acid (channel A) and acetonitrile (channel B). At time t minutes the percentage A was as follows t = 0 (65%), t = 5 (50%), t = 10 (50%), t = 20 (0%) and t = 25 (0%). The flow rate was 0.4 mL min^{-1} with an injection volume of 5 μL.

TOF-MS analysis was carried out in positive mode electrospray with nebuliser pressure 60 psi, capillary 4000 V, gas temperature 350 °C, drying gas flow at 12 L min^{-1}, skimmer 60 V, fragmentor 150 V and octopole RF voltage 250 V. The mass range measured was 100–1100 m/z. An additional isocratic pump was used for delivery of the reference mass solution and reference mass correction was carried out using ions at 121.05873 (purine, CAS No. 120-73-0) and 992.009798 (hexakis(1H, 1H, 3H-tetrafluoropropoxy)phosphazine, CAS No. 58943-98-9).

2.6. Statistical analyses

Statistical analysis was completed using a custom written graphical user interface (GUI) for Matlab (The Mathworks, Natick, MA; Version 7.4.0.287 [R2007a]) known as Metabolab. Statistical analyses were completed using the full NMR spectrum excluding data from the residual water resonance (4.70–4.90 ppm) and from the methyl ^{1}H atoms of ethanol (1.16–1.21 ppm).

To generate robust statistical models the data was split into a training set and a test set. All models were generated using only the training set. The data were split into training and test sets using random sequences generated using the online resource www.random.org. Each sample was randomly assigned a number in the sequence 1–374. After the samples had been assigned a number, 100 unique random numbers were generated between 1 and 374 and these samples were chosen as the test set (corresponding to 26.7% of the data). This gave a training set of 274 samples (157 Corsican samples, 117 non-Corsican samples) and an unseen test set of 100 samples (63 Corsican samples and 37 non-Corsican samples). The data were sorted by increasing value of their random number to ensure no bias was introduced into the data.

Feature selection from the NMR data was performed using two-stage GP (Davis et al., 2006) as described in Donarski et al. (2008). Briefly, each round of the GP was completed using an island population of 300, five island populations, 10 generations between island migration, an island migration rate of 10%, a maximum GP tree size of eight, and a tree mutation rate of 50%. At each generation, trees were ordered by the value of their fitness function, which in this case was the classification rate. The top 10% of GP trees were kept, and the bottom 10% were removed. The stopping conditions enforced were either classification of 100% of the data or evolution for 200 generations. The first stage of GP used all variables. The variables used in the second stage were constrained to those that were used in the generation of the final GP trees of the first stage, with a tolerance on variable position of 10 U. Venetian blind cross-validation was used omitting 10% of the data from each calculation for subsequent validation.

Classification rates are presented according to sensitivity (Corsican samples correctly classified as Corsican samples), selectivity (non-Corsican samples correctly classified as non-Corsican samples) and overall correct classification (all samples correctly classified by the model).

3. Results and discussion

It was previously reported that biomarkers of geographical origin were detected in Corsican honey analysed by ^{1}H NMR spectroscopy (Donarski et al., 2008). The results were obtained from the statistical analysis of honey samples collected during Year 1 and demonstrated the utility of GP in the determination of biomarkers within complex NMR spectroscopic data. Results obtained from the statistical analysis of honey samples collected over both years are presented herein.

3.1. Statistical results

The final classification results obtained during model generation by two-stage GP were 94.9%, 94.0% and 94.5% for the sensitivity, selectivity and overall rate, respectively. To visualise the variables that were utilised in the generation of the GP trees, a histogram showing the frequency of occurrence of the variables used in the 10 GP trees, created during cross-validation, is shown in Fig. 1A. The 10 GP trees generated were used to classify the test data and the tree that gave the highest overall classification rate was chosen and is shown in Fig. 1B. The classification results obtained from the model validation of the GP tree shown in Fig. 1B were 92.1%, 91.9% and 92.0% for the sensitivity, selectivity and overall rate, respectively.

The variables most frequently used by the two-stage GP model were converted to their corresponding 1D ^{1}H NMR chemical shifts and these resonances were examined in the acquired NMR spectra. The data showed that biomarkers were present within the Corsican honey and that these biomarkers corresponded to specific types of Corsican honey. Evaluation of the Corsican honey data determined the presence of four distinct biomarkers (referred to in this manuscript at A, B, C and D). The following section describes each of the four identified biomarkers.

3.2. Biomarker A

Biomarker A, when analysed by a combination of 1D ^{1}H and 2D ^{1}H–^{1}H TOCSY NMR spectroscopy, was shown to contain five non-exchangeable, non-equivalent ^{1}H atoms that gave rise to four resonance peaks at chemical shifts of 8.221 (1H, d, 8.3 Hz), 7.868 (2H, m and s overlapping), 7.571 (1H, m) and 6.952 (1H, s) ppm (symbols used d, doublet; m, multiplet; s, singlet). Structural elucidation using chemical shift tables and J-couplings determined that the biomarker was a fused aromatic ring system and that kynurenic acid would produce NMR resonances that matched those of the biomarker. This was confirmed by spiking kynurenic acid into a

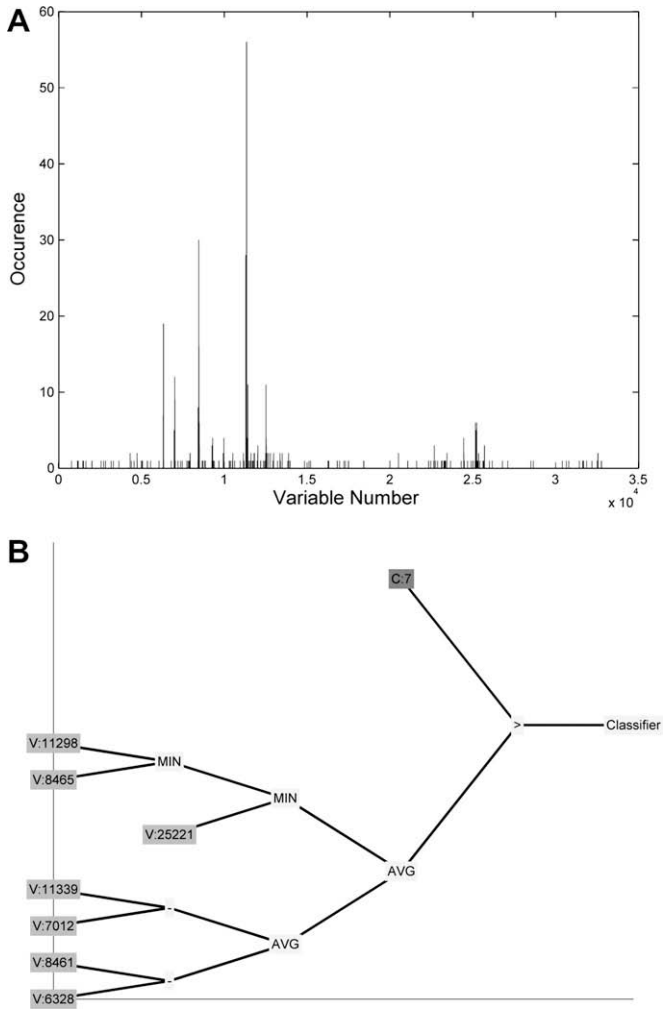

Fig. 1. (A) Variable use frequency in the final Corsican honey classification models generated by two-stage GP and (B) most successful GP tree. V, variable; C, constant; MIN, minimum; –, subtraction and AVG, average.

honey sample that contained biomarker A (Fig. 2A and B). Further confirmation of the presence of kynurenic acid was obtained using LC-TOF-MS (Fig. 2C–F). LC-TOF-MS analysis was performed using a standard solution of kynurenic acid, a Corsican honey containing biomarker A and a deionised water blank. The mass spectrum shown in Fig. 2F contains a peak not present in the kynurenic acid standard, with an accurate mass of 203.0526 Da. It was determined that this peak was from the protonated form of glucose that co-elutes with kynurenic acid using the LC conditions specified.

The relative intensity of the ^{1}H NMR spectroscopic resonance of kynurenic acid at 7.571 ppm in all of the Corsican honey analysed, is shown in Fig. 3A. Kynurenic acid was predominant in honey collected from the Châtaigneraie region of Corsica. The translation of Châtaigneraie from French to English is chestnut grove and it was hypothesised that kynurenic acid was a marker of sweet chestnut honey. It was noted that kynurenic acid was present in three non-Corsican honeys, collected from Italy, therefore this marker was not unique to Corsican honey. Two commercial non-Corsican chestnut honeys were analysed and both were shown to contain kynurenic acid, it was therefore concluded that kynurenic acid is a putative biomarker of chestnut honey.

The maximum concentration of kynurenic acid, observed by NMR spectroscopy, in the non-commercial samples was present in a Corsican honey from the region of Châtaigneraie. The concentration of kynurenic acid in this honey was determined by comparison of the peak intensities of kynurenic acid with the internal standard, TSP. The 15°BRIX solution of Châtaigneraie honey contained 0.91 mM kynurenic acid. The honeys were not supplied with their original °BRIX values so it was not possible to determine the concentration of kynurenic acid in undiluted honey. The honey was received at 70°BRIX therefore it was concluded that the concentration of kynurenic acid in the undiluted honey was $\geqslant$4.22 mM.

Kynurenic acid is a metabolite of L-tryptophan produced *via* the kynurenine pathway (Ruddick et al., 2006). It has been shown to occur naturally in human saliva (Kuc et al., 2006), urine (Furlanetto, Tognini, Carpenedo, La Porta, & Pinzauti, 1998) and cerebrospinal fluid (Stone, 1993). Kynurenic acid was previously identified by Beretta et al. in Italian honey from arboreal origin (Beretta, Caneva, & Facino, 2007) and in further work (Beretta, Caneva, Regazzoni, Bakhtyari, & Facino, 2008) they hypothesised that kynurenic acid is a biomarker of chestnut honey. Kynurenic acid was also identified in Linden, Buckwheat and multifloral honey (Kuc, Zgrajka, Parada-Turska, Urbanik-Sypniewska, & Turski, 2008) although the levels reported by Kuc et al. were approximately 150 times lower than those reported in this manuscript and that of Beretta et al. This could be due to a minor contribution from chestnut tree pollen/nectar to the composition of the honeys studied by Kuc et al. Potential neuroprotective properties of kynurenic acid have been hypothesised (Stone, 1993). Based on this hypothesis, the disruption of the kynurenine pathway is implicated in several disorders including schizophrenia (Nilsson et al., 2005), HIV related dementia (Guillemin, Kerr, & Brew, 2005) and Parkinson's disease (Németh, Toldi, & Vécsei, 2006). This has led to the development of novel drugs either based on kynurenic acid or designed to interact with the kynurenine pathway (Stone, 2000). The presence of kynurenic acid in food is not expected to affect the neurochemistry of consumers as the transport of kynurenic acid across the blood brain barrier is extremely low (Fukui, Schwarcz, Rapoport, Takada, & Smith, 1991). Kynurenic acid has also been hypothesised to contribute to the control of oral microflora (Kuc et al., 2006) and was reported to be present in human saliva at an average concentration of 3.4 nM, although patients with odontogenic abscesses showed kynurenic acid concentrations up to three times higher. It was hypothesised that this increase in kynurenic acid was produced in response to the abscesses. The consumption of kynurenic acid may therefore be beneficial to oral health.

3.3. Biomarker B

Biomarker B, when analysed by a combination of 1D ^{1}H and 2D ^{1}H–^{1}H TOCSY NMR spectroscopy, was shown to contain two non-exchangeable, non-equivalent ^{1}H chemical environments giving rise to two resonance peaks at chemical shifts of 7.350 (1H, d, 8.7 Hz) and 6.997 (1H, d, 8.7 Hz) ppm. It was concluded, based on their chemical shifts and *J*-couplings that these peaks were from a 6-membered aromatic ring system containing two non-exchangeable ^{1}H chemical environments. Analysis of the peak shapes determined that the aromatic ring system was either substituted at the 1,4 or 1,2,3,4 positions. The identity of biomarker B was not determined, aromatic compounds matching this description that have been demonstrated to be present in honey include; *p*-hydroxybenzoic acid and *p*-coumaric acid (Gheldof, Wang, & Engeseth, 2002). Acquisition of data from standard compounds determined that neither of these compounds were biomarker B. The highest concentration of biomarker B observed in a 15°BRIX solution of honey was in a spring Maquis honey and was calculated to be either 0.70 mM or 1.40 mM depending on whether biomarker B is 1,4 or 1,2,3,4 substituted, respectively. The highest concentration of biomarker B in undiluted honey was therefore calculated to be $\geqslant$ either 3.27 or 6.53 mM depending on the degree of substitution of the aromatic ring.

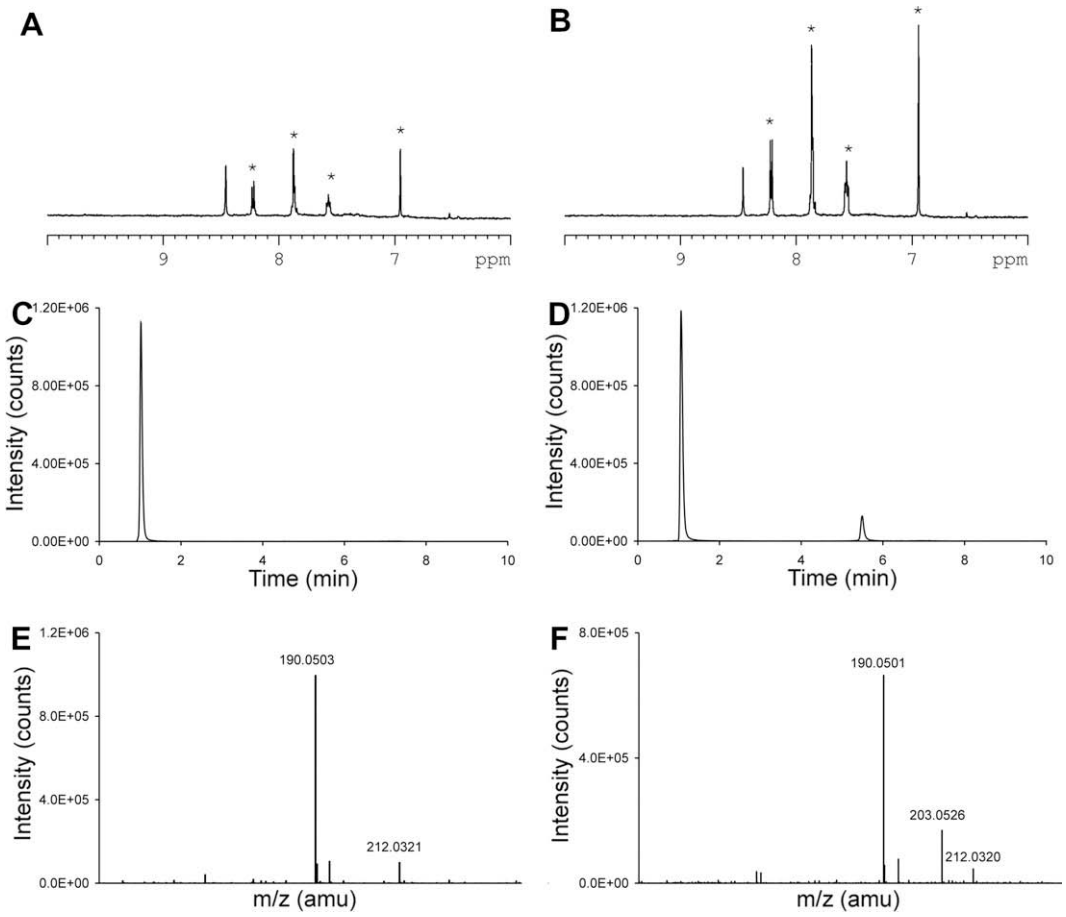

Fig. 2. Representation of the analytical data used to confirm the identity of kynurenic acid in honey. ^{1}H NMR spectrum of the region 6–10 ppm of (A) Corsican honey and (B) Corsican honey that was spiked with kynurenic acid. Peaks observed from kynurenic acid are labelled (∗). Extracted ion chromatogram of the mass range 189.8–190.3 Da corresponding to the protonated ion form of kynurenic acid in (C) kynurenic acid standard and (D) Corsican honey. Background subtracted mass spectrum observed at maximum intensity of the extracted ion chromatograms shown in (C) and (D) in the samples (E) kynurenic acid standard and (F) Corsican honey.

The relative intensity of the ^{1}H NMR spectroscopic peak of biomarker B at 6.997 ppm in all of the Corsican honey analysed is shown in Fig. 3B. Biomarker B was predominant in Corsican honey collected during the season of Spring. Spring Maquis honey contained the highest concentrations of biomarker B. Biomarker B was also detected in; Autumn Maquis, Summer Maquis and Châtaigneraie Corsican honey. Biomarker B was not detected in any non-Corsican honey. The Corsican Maquis is a shrubland consisting of different evergreen shrubs. Biomarker B was largely derived from spring flowering plants found uniquely in the Corsican Maquis, although further analysis would be required to confirm the source of this compound.

3.4. Biomarkers C and D

Biomarker C, when analysed by a combination of 1D ^{1}H and 2D ^{1}H–^{1}H TOCSY NMR spectroscopy, was shown to contain six non-exchangeable, non-equivalent ^{1}H chemical environments giving rise to six resonance peaks at chemical shifts of 6.188 (1H, bt, ~1.1 Hz), 2.752 (1H, d, 17.6 Hz), 2.503 (1H, dd, 17.6 Hz, 1.3 Hz), 1.863 (3H, d, 1.3 Hz), 1.180 (3H, bs) and 1.061 (3H, bs) ppm. (Symbols used bt, broad triplet; dd, double doublet; bs, broad singlet). All peaks associated with biomarker C were correlated by the ^{1}H–^{1}H TOCSY NMR experiment. The relative intensity and chemical shifts of each peak suggests that the biomarker contains the following chemical environments; a single alkene or aromatic environment (δ = 6.188), a methyl resonance attached to an alkene or aromatic environment (δ = 1.863), a methylene environment (δ = 2.752 and 2.503) and two methyl environments. The resonances observed for the methylene environment are at two different chemical shifts and this indicates that the molecule contains a chiral centre.

The highest concentration of biomarker C that was observed in a 15°BRIX solution of honey was in an autumn Maquis honey and was calculated to be 2.15 mM. The highest concentration of biomarker C in undiluted honey was therefore calculated to be $\geqslant$10.0 mM.

Biomarker D, when analysed by a combination of 1D ^{1}H and 2D ^{1}H–^{1}H TOCSY NMR spectroscopy, was shown to contain four non-exchangeable, non-equivalent ^{1}H chemical environments giving rise to four resonance peaks at chemical shifts of 6.811 (1H, m), 6.710 (2H, two m overlapping) and 3.482 (2H, bs) ppm. Analysis of these peaks using multidimensional NMR techniques determined that the molecule contained a six membered aromatic ring system substituted at the 1,2 and 5 positions and an alkyl chemical environment. The phenolic acid 2,5-dihydroxyphenylacetic acid, which has been reported by Cabras et al. to be a marker of Strawberry-tree honey (Cabras et al., 1999), contains these chemical environments. The ^{1}H NMR spectrum of 2,5-dihydroxyphenylacetic acid was acquired from a standard solution and confirmed biomarker D to be 2,5-dihydroxyphenylacetic acid.

The highest concentration of 2,5-dihydroxyphenylacetic acid that was observed in a 15°BRIX solution of honey was in the same autumn Maquis honey that contained the highest concentration of

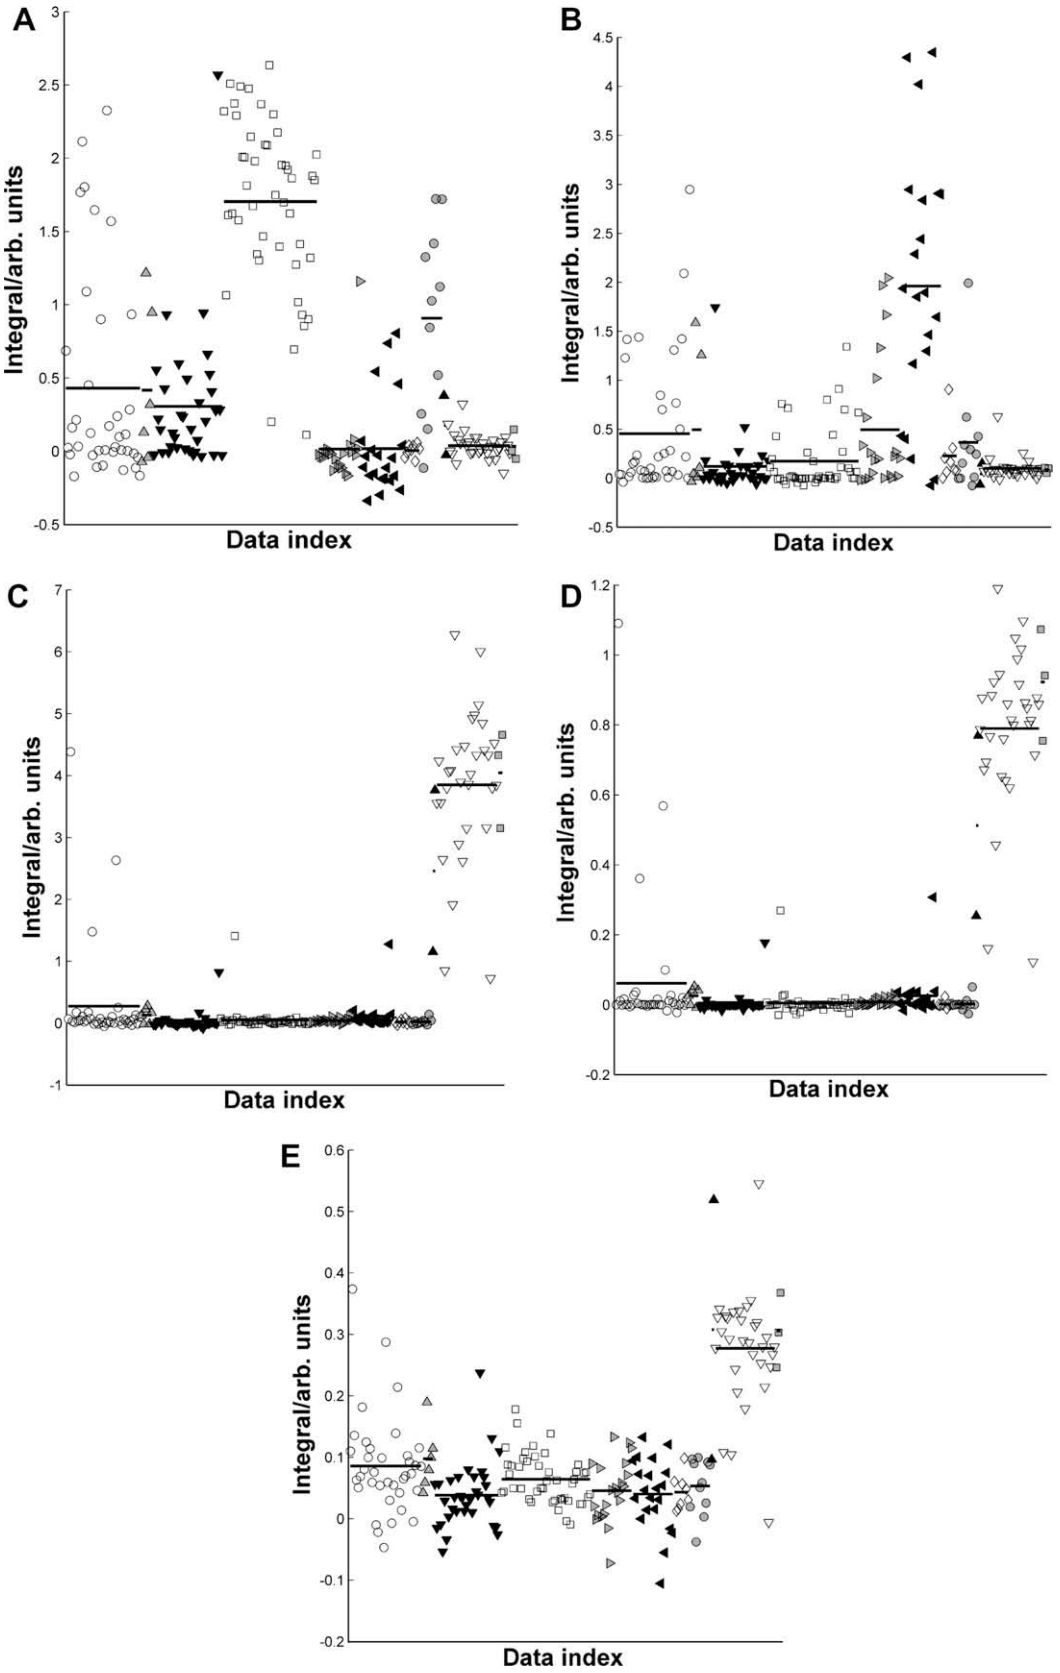

Fig. 3. Plot of the intensity of the resonances of: (A) kynurenic acid (δ = 7.571 ppm); (B) biomarker B (δ = 6.997 ppm); (C) biomarker C (δ = 6.188 ppm); (D) 2, 5-dihydroxyphenylacetic acid (δ = 6.811 ppm) and (E) α-isophorone (δ = 5.906 ppm), in all acquired Corsican ^{1}H NMR spectra. The data is labelled by Corsican honey type, ○ non-specific, ▲ non-specific Maquis, ▼ honeydew Maquis, □ Châtaigneraie, ▶ non-specific spring, ◀ spring Maquis, ◇ spring Clémentinier, ● summer Maquis, ▲ non-specific autumn, ▼ Autumn Maquis and ■ Arbousier. The mean value of each Corsican honey type is represented by a black bar passing through the range of data points from which the mean was calculated.

biomarker C and was calculated to be 0.72 mM. The highest concentration of 2,5-dihydroxyphenylacetic acid in undiluted honey was therefore calculated to be $\geqslant$3.4 mM.

The relative intensity of the ^{1}H NMR spectroscopic resonances of biomarker C and 2,5-dihydroxyphenylacetic acid at 6.188 ppm and 6.811 ppm in all of the Corsican honey analysed is shown in Fig. 3C and D, respectively. Biomarker C and 2,5-dihydroxyphenylacetic acid were predominant in Corsican honey collected during the season of Autumn. Autumn Maquis honeys contained the highest concentrations of biomarker C. Both biomarkers were also detected in; one Spring Maquis, one honeydew Maquis and in one Châtaigneraie Corsican honey. The biomarkers were also present in all three Corsican Arbousier honeys analysed. The French to English translation of Arbousier is Strawberry-tree and this is an autumn flowering tree found in the Corsican Maquis. As previously stated the phenolic acid 2,5-dihydroxyphenylacetic acid has been reported to be a biomarker of strawberry-tree honey. Other compounds reported to be markers of Strawberry-tree honey are the norisoprenoids α-isophorone, β-isophorone and 4-oxoisophorone (Bianchi et al., 2005). ^{1}H NMR spectra were therefore acquired from standards of α-isophorone and 4-oxoisophorone to determine whether these compounds were present. Data were not acquired from β-isophorone due to unavailability of the standard compound. α-Isophorone was detected in the majority of the Corsican autumn Maquis honey, but its spectral intensity was at the limit of detection of the NMR experiment. It was therefore not possible to accurately determine which non-autumn honeys, if any, contained α-isophorone or the concentration of α-isophorone present in honeys that did contain it. The relative intensity of the ^{1}H NMR spectroscopic peak of isophorone at 5.906 ppm in all of the Corsican honey is shown in Fig. 2E. 4-Oxoisophorone was not detected in any honey. It had previously been demonstrated (Bianchi et al., 2005) that the ratio of α-isophorone to β-isophorone varied between 4 and 8:1, it was therefore concluded that β-isophorone, if present, would be at a concentration too low to be observed with the ^{1}H NMR acquisition parameters used in this study.

It was noted that the ratio of biomarker C to 2,5-dihydroxyphenylacetic acid was constant in all the honey analysed. It was therefore hypothesised that biomarker C was also a biomarker of strawberry-tree honey.

4. Conclusion

^{1}H NMR spectroscopy has been shown to be a powerful analytical technique to screen for the presence of biomarkers of botanical origin in honey. The chemical properties inherent in pharmacoactive (either toxic or beneficial) organic compounds is such that when analysed by ^{1}H NMR spectroscopy they will resonate at chemical shifts usually not observed naturally in food matrices and are therefore often resolved. This is demonstrated well by the unique chemical shifts of kynurenic acid observed in honey.

Sample preparation is minimal, highly reproducible and using the acquisition parameters specified, able to detect compounds with an approximate limit of detection of 6.3 μM. Kynurenic acid is proposed as a putative biomarker of chestnut honey and the detection of 2,5-dihydroxyphenylacetic acid and α-isophorone, which corresponds with previous findings from other research groups, are also presented. Two characterised, but unidentified biomarker compounds, B and C, have been detected and it is concluded that these are marker compounds of Corsican spring Maquis and strawberry-tree honey, respectively.

Examining the prevalence of different biomarkers observed in spring, summer and autumn Maquis honey highlighted seasonal variations in honey composition. These honeys, although collected from geographically similar areas, contain different biomarkers that relate to botanical species. The determination of the geographical origin of honey using ^{1}H NMR spectroscopy is heavily dependant on variation in unrelated factors (e.g. botanical origin), which effect the product composition.

Acknowledgments

The authors thank the EU TRACE project and the UK Food Standards Agency for funding this work.

The honeys utilised in this research were collected as part of the TRACE (www.trace.eu.org) project by the Czech Bee Research Institute (Year 1) and Olivier Bidet (Year 2). The honeys were subsampled and distributed by The Irish Agriculture and Food Development Authority (Year 1) and the Institute of Chemical Technology, Prague (Year 2).

However, when specimens are small in size and once the shell is removed (as in canned products), they are generally unidentifiable. Hence, replacement with the cheaper razor clam species or mislabelling can occur, and consequently the development of a procedure for species authentication should be of the highest priority.

Genetic approaches based on DNA techniques are widely used nowadays to overcome this problem. Advantages of the use of DNA in these methodologies are: this molecule is very stable, contains more information than proteins and it is present in all tissues of all organisms. Thanks to the development of polymerase chain reaction (PCR) the molecular methods have been simplified being more easily applicable and less time-consuming. PCR amplification of species-specific fragments has been useful in fish traceability (Carrera et al., 2000; Céspedes et al., 1999) and in species identification (Asensio et al., 2001; Cross, Rebordinos, & Díaz, 2006; Rego et al., 2002).

The aim of this work was to develop an appropriate and reliable methodology for identification of five razor clams species, by means of a multiplex PCR methodology of ITS-1 region. The protocol, involving a one-step procedure, is rapid, accurate, and sensitive, enabling its use to identify razor clams in fresh and canned samples in an accurate and prompt manner.

2. Materials and methods

2.1. Materials

Samples of *E. arcuatus* and *E. siliqua* were collected by local fishermen in Rodas (Pontevedra, Spain) and Finisterre (A Coruña, Spain), respectively. Samples of *E. directus* (Denmark) were purchased from local fish suppliers and *E. macha* individuals (Chile) were supplied by Dr. Irene Lepez. All specimens were morphologically identified. A piece of foot was dissected and immediately stored in 95% ethanol until DNA extraction (less than five days). Canned and frozen products were purchased at local supermarkets.

2.2. DNA isolation and PCR amplification of ITS-1 region

Total genomic DNA was isolated from 25 mg of raw or processed foot sections using the protocol described by Fernández-Tajes and Méndez (2007).

Amplification of ITS-1 sequences were carried out using primer forward 5′-GTTTCCGTAGGTGAACCTG-3′ designed by Heath, Rawson, and Hilbish (1995) and reverse 5′-TGTGCGTTCAAGATGTCG-3′, designed in this work based on 5.8S rRNA gene sequences of several bivalve species. Amplification reactions were performed in 25 μl of reaction volume; the reaction mixture contained 15 ng of genomic DNA, 0.24 μM of each dNTP, 2 mM of $MgCl_2$, 1 μM of each primer, 0.625 U of Taq polymerase (Roche Applied Science, Barcelona, Spain) and the buffer recommended by polymerase suppliers. The thermal cycler profile consisted of an initial denaturation step of 5 min at 95 °C, 35 cycles at 94 °C for 20 s, 56 °C for 20 s and 72 °C for 1 min, and a final extension step at 72 °C for 5 min. PCR products were visualised by electrophoresis on a 2% w/v agarose gel.

2.3. Purification, cloning and sequencing of PCR products

The ITS PCR product was ligated into the plasmid pCR®2.1-TOPO®, using the TOPO-TA Cloning kit (Invitrogen), and transformed into TOP10F' cells. Plasmid DNA purification was carried out using QIAprep Miniprep Kit (Qiagen, Barcelona, Spain), which employs the modified alkaline method of Birnboim and Doly (1979). Sequencing of both strands of the insert of 4–6 clones/individual was performed with an automatic capillary DNA sequencer (CEQ™8000 Genetic Analysis System). The nucleotide sequences have been deposited in the EMBL database under accession numbers J966667-97 and AM933615-31.

2.4. Analysis of sequences and design of species-specific primers

Nucleotide sequences were aligned using ClustalX software (Thompson, Gibson, Plewniak, Jeanmougin, & Higgins, 1997), and alignments were edited with GeneDoc software (Nicholas, Nicholas, & Deerfield, 1997). Interspecific differences found at ITS-1 region of razor clams were employed for designing reverse species-specific primers using Primer3 software (Rozen & Skaletsky, 2000). Selection was done in such a way that each species-specific primer with a universal primer identical to the four species (in this case the forward described above) would produce a PCR amplification product of species-specific size. The PCR mix and thermal conditions are the previously described.

2.5. Multiplex PCR

Once all primers were tested, multiplex PCR was performed in order to simplify the species identification. Multiplex PCR was carried out using 0.24 μM of each primer, and with identical conditions as described above.

2.6. Market study

In order to evaluate the usefulness of our methodology in commercial samples 12 commercial cans were acquired in shops and stores from Galicia and Spain to check the correct labelling of the analysed products.

3. Results and discussion

The aim of this work was to develop a reliable and efficient method for genetic differentiation between European and non-European razor clam species. This identification was achieved by a multiplex PCR-based method based on ITS-1 region. The ITS spacers show more variability than their flanking coding regions, and they can be easily amplified with universal primers (Presa, Pardo, Martínez, & Bernatchez, 2002). Fresh, frozen and canned products were analysed using this methodology.

With this aim, amplification and sequencing of ITS-1 spacer of *E. arcuatus*, *E. siliqua*, *E. directus* and *E. macha* was done. Thus, PCR products of three individuals from all species were cloned and sequenced; the complete ITS-1 sequences obtained were determined to be 566 bp in *E. arcuatus* and *E. siliqua*, 535 bp in *E. directus*, and 560 bp in *E. macha*. Although there are some small differences in the length of obtained amplicons among species, they could not be detected by agarose electrophoresis.

The alignment of the sequences obtained with those from databases showed 314 variable sites, 248 nucleotide substitutions and 66 indels in a total of 585 bp, all of them in the spacer sequence. The number of species-specific sites was 11 for *E. arcuatus*, 12 for *E. siliqua*, 89 for *E. directus* and 74 for *E. macha*. The presence of this several species-specific sites allowed us to design reverse species-specific primers for razor clams characterisation. In order to make an unequivocally identification of the species, species-specific PCR can be developed because a specific sequence can be detected very sensitively in a pool of sequences of different organisms (Rodríguez et al., 2003). Table 1 shows the designed primers. No specific primers for *E. arcuatus* and *E. siliqua* were obtained, probably due to the small number of species-specific sites in both species.

Using each specific primer together with a common forward primer (ITS-F from Heath et al., 1995), a 296 bp band was obtained

Table 1
Sequence of species-specific primers designed.

Species amplified	Primer	Sequence
Forward primer	Heath et al. (1995)	5′- GTTTCCGTAGGTGAACCTG-3′
E. arcuatus/E. siliqua	ITSArSil-R	5′-CTTCGCGTCGGCAATA-3′
E. directus	ITSDir-R	5′- GACGGAGTGCATAGTGTATAAC-3′
E. macha	ITSMa-R	5′- CGTTGTTTGTGGTAATAAGGC-3′

for *E. arcuatus*/*E. siliqua*, a 223 bp PCR fragment was amplified from *E. directus* individuals, and a 386 bp band was yielded from *E. macha* samples. Amplification of 10 individuals for each razor clam species corroborated the expected product lengths.

Since our aim was to find a simple and straightforward method we carried out a multiplex PCR amplification using the three species-specific oligonucleotides (ITSArSil-R, ITSDir-R, and ITSMa-R) in the same reaction together with the ITS1N-F. The amplification of 26 individuals of *E. arcuatus/E. siliqua*, 27 individuals of *E. directus* and 20 of *E. macha* showed that no disturbance occurred among the primers during the amplification reaction and that the specific primers to each DNA species annealed on their target sequences. Fig. 1 shows the typical amplification pattern obtained with those species-specific primers. Although in this assay *E. arcuatus* and *E. siliqua* could not be identified, this problem could be solved by means of the method described by Freire, Fernández-Tajes, and Méndez (2008). Consequently, a combined protocol that implies the multiplex PCR described here and the PCR–RFLP method of ITS-1 previously developed would allow the identification of the four razor clam species.

The results shown above were obtained from raw (fresh and frozen) samples, and from processed material (canned samples). In fresh products individuals ranging in size from 10 to 15 cm, and in manufactured products 12 commercial cans were purchased at local supermarkets from Galicia and Spain. One of the main problems to apply molecular methodologies to processed products such as canned seafood is that the sterilization procedure could induce DNA fragmentation. Specifically, the sterilization process in razor clams is performed at 112.5 °C for 75 min, what produces DNA fragments about 200–700 bp. For this reason molecular methods used to identify commercial material of razor clams should employ fragments around this size. This criterion is fulfilled for the fragments generated with our specific primers. The methodology developed in this study allowed us to verify the species included in the analysed commercial products and their correct labelling.

ITS-1 and ITS-2 spacers are useful to distinguish between related species (e.g. Fernández et al., 2001; Pérez, Vieites, & Presa, 2005). In bivalves, RFLPs of this region were used for the identification of several *Mytilus* mussels (Heath et al., 1995; Toro, 1998), Veneridae clams (Fernández et al., 2001) and four scallop species (López-Piñón, Insua, & Méndez, 2002); length amplification was used to differentiate several freshwater mussels (White, McPheron, & Stauffer, 1994) and *M. edulis* from two *Modiolus* species (Dixon, Sole-Cava, Pascoe, & Holland, 1995).

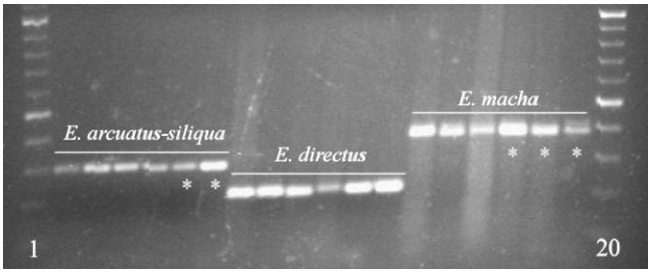

Fig. 1. ITS-1 products generated by multiplex PCR of fresh and canned (*) products with species-specific primers for *E. arcuatus/siliqua*, *E. directus* and *E. macha*. Lanes 1 and 20, 100 bp DNA ladder. Note: DNA was extracted from foot tissue sections both in canned and fresh samples.

A genetic method for the differentiation of these razor clam species, based on PCR–RFLPs of the 5S rDNA gene, was previously described (Fernández-Tajes & Méndez, 2007). Nevertheless, the organisation of ribosomal genes in multiple tandem arrays could be considered as a one of the major drawbacks in the use of these regions as genetic markers due to the intraspecific variation that could exist in the different repeats at individual level, giving rise to possible mutations and, consequently, to the loss or gain of restriction recognition sequences. However, concerted evolution tends to homogenise the repetition units present inside and among individuals of the species (Dover, Coen, & Strachan, 1982). Moreover, availability of more than one genetic marker is convenient as a technical support in the case of a legal requirement to demonstrate fraudulent substitution of species.

The results obtained in this work suggest that multiplex PCR amplification of selected ITS rDNA fragments using species-specific primers ITSArSil-R, ITSDir-R, and ITSMa-R together with ITS-F, is a powerful technique for the identification of razor clam species. Compared to alternative techniques such as direct sequencing of PCR products, PCR–RFLP or PCR–SSCP, multiplex PCR system is less consuming than these other molecular techniques, being easily performed in food inspection laboratories, especially when large numbers of samples are required to be analysed. Thus, the protocol described in this work offers an alternative tool for fraudulent species detention and for food authenticity in the market of razor clam products, as in raw as in manufactured samples.

Acknowledgements

This work was funded by a PFSHARE-90 (Sustainable HARvesing of Ensis (SHARE)) and by a TIMES (Towards a Integrated Management of Ensis stocks) grants from the European Community Initiative Programme INTERREG-IIIB "Atlantic Area" and partially funded by I3 Program 2007–08 "Programa de promoción da intensificación da actividade investigadora no sistema universitario de Galicia" financed by Xunta de Galicia. We are grateful to Mr. Jose García Gil for his technical assistance. We would also like to thank Dr. Irene Lepez for providing *E. macha* samples.

Fax: +44 (0) 1865 843960; E-mail: w.hurp@elsevier.com

FOOD CHEMISTRY

Aims and Scope

Food Chemistry publishes original research papers dealing with the chemistry and biochemistry of foods and raw materials covering the entire food chain from *'farm to fork.'* Topics include:

- Chemistry relating to major and minor components of food, their nutritional, physiological, sensory, flavour and microbiological aspects;
- Bioactive constituents of foods, including antioxidants, phytochemicals, and botanicals. Data must accompany sufficient discussion to demonstrate their relevance to food and/or food chemistry;
- Chemical and biochemical composition and structure changes in molecules induced by processing, distribution and domestic conditions;
- Effects of processing on the composition, quality and safety of foods, other bio-based materials, by-products, and processing wastes;
- Chemistry of food additives, contaminants, and other agro-chemicals, together with their metabolism, toxicology and food fate.

Analytical Section

Analytical papers related to the microbiological, sensory, nutritional, physiological, authenticity and origin aspects of food. Papers should be primarily concerned with new or novel methods (especially instrumental or rapid) provided adequate validation is described including sufficient data from real samples to demonstrate robustness. Papers dealing with significant improvements to existing methods, or data from application of existing methods to new foods, or commodities produced in unreported geographical areas, will also be considered.

- Methods for the determination of both major and minor components of food especially nutrients and non-nutrient bioactive compounds (with putative health benefits) will be considered.
- Results of method inter-comparison studies and development of food reference materials for use in the assay of food components;
- Methods concerned with the chemical forms in food, nutrient bioavailability and nutritional status;
- General authentication and origin [e.g. Country of Origin Labelling (COOL), Protected Designation of Origin (PDO), Protected Geographical Indication (PGI), Certificate of Specific Character (CSC)] determination of foods (both geographical and production including commodity substitution, and verification of *organic, biological* and *ecological* labelling) providing sufficient data from authentic samples should be included to ensure that interpretations are meaningful.

International Society for Nutraceuticals & Functional Foods

2009 Annual Conference

Nutraceutical, Functional Foods, and Dietary Supplements: Science, Methodologies and Applications

November 1-4, 2009
Holiday Inn-Golden Gateway Hotel
1500 Van Ness Avenue
San Francisco, CA, USA 94109

International Advisory Board
Mr. Anthony Almada (USA)
Dr. Debasis Bagchi (USA)
Dr. Colin Barrow (Australia)
Dr. Joseph Betz (USA)
Dr. Zhen-Yu Chen (Hong Kong)
Ms. Audra Davies (USA)
Dr. Colin Dennis (UK)
Dr. Xiao-Qin (Charles) Han (China)
Dr. Chi-Tang Ho (USA)
Dr. Kazuki Kanazawa (Japan)
Dr. Se-Kwon Kim (Korea)
Dr. Hannu J. Korhonen (Finland)
Dr. Hyong Joo Lee (Korea)
Dr. Kazuo Miyashita (Japan)
Dr. Bhimu Patil (USA)
Dr. Ronald B. Pegg (USA)
Dr. Peter Roupas (Australia)
Dr. Augustin Scalbert (France)
Dr. Fereidoon Shahidi (Canada)
Dr. Young-Joon Surh (Korea)
Dr. Gary Williamson (UK)
Dr. Rickey Yada (Canada)
Dr. Jerzy Zawistowski (Canada)

Conference Co-Organizers
Dr. Fereidoon Shahidi (Canada)
Dr. Chi-Tang Ho (USA)
Dr. Debasis Bagchi (USA)
Dr. C-K. Wang (Taiwan)

Conference Symposia
- Anti-aging nutraceuticals
- Nutraceuticals for arthritis and inflammatory diseases
- Nutraceuticals and brain health
- Nutraceuticals for type-2 diabetes
- Nutraceuticals for cardiovascular disease and cancer
- Nutraceuticals for obesity and weight control
- Omega-3 and other nutraceutical oils
- Marine nutraceuticals
- Nutraceutical and functional beverages
- Pre-, pro- and synbiotics
- Protein hydrolysates and biopeptides
- Phytochemicals: polyphenols, carotenoids, etc.
- Delivery systems for nutraceuticals and functional food ingredients, including nano-technology
- Absorption, metabolism and action mechanism of nutraceuticals and functional food ingredients
- Nutrigenomics, proteomics and metabolomics
- Nutraceuticals and functional food ingredients from co-products and by-products
- Global Regulations for nutraceuticals, dietary supplements and functional foods
- Analytical methodologies
- Quality assurance for nutraceuticals, dietary supplements and functional food ingredients
- Import-export issues for nutraceuticals and functional foods
- Inventor-investor and business to business
- Bioactive and minor components
- Traditional foods and health promotion
- Nuts and dried fruits: products, health and well-being
- Processing of nutraceuticals and functional food ingredients
- Voluntary papers (oral and poster)

Exhibition: 10 AM – 5 PM, November 2 & 3, 2009

Preconference:

Track A – Antioxidant Forum/Short Course-Methodologies, Assessments, Applications and Health (Oct. 31 & Nov. 1, 2009)

Track B – Omega-3 and Beyond: Fundamentals, Applications and Health (Oct. 31 & Nov. 1, 2009)

For further information, visit: ***isnff.org***

Disclaimer : Program details and speakers may change due to circumstances

International Society for Nutraceuticals and Functional Foods (ISNFF)

ANNOUNCEMENTS

The **Annual Conference and Exhibition of the International Society for Nutraceuticals and Functional Foods (ISNFF)** will be held 1-4 November 2009 in San Francisco, CA, USA. For further information and registration, please visit the website of ISNFF (www.isnff.org). For further information, please contact Peggy Ann Parsons (Tel: +1 (709) 737 8239; Fax: +1 (709) 737 4000, or E-mail: pparsons@mun.ca).

The **International Antioxidant Forum / Short Course – Methodologies, Assessments, Applications and Health** of the International Society for Nutraceuticals and Functional Foods (ISNFF) will be held in the Golden Gateway Holiday Inn in San Francisco, CA, USA on 31 October and 1 November 2009. For details visit the ISNFF website at (**www.isnff.org**). For further information, please contact Peggy Ann Parsons (Tel: +1 (709) 737 8239; Fax: +1 (709) 737 4000, or E-mail: pparsons@mun.ca).

The **Omega-3 and Beyond - Fundamentals, Applications and Health Short Course** of the International Society for Nutraceuticals and Functional Foods (ISNFF) will be held in the Golden Gateway Holiday Inn in San Francisco, CA, USA on 31 October and 1 November 2009. For details visit the ISNFF website at (**www.isnff.org**). For further information, please contact Peggy Ann Parsons (Tel: +1 (709) 737 8239; Fax: +1 (709) 737 4000, or E-mail: pparsons@mun.ca).

Fereidoon Shahidi Fellowship Award

The **International Society for Nutraceuticals and Functional Foods (ISNFF)** has announced the establishment of the above award for graduate students. The award carries a US$1500 check and a recognition plaque. For further information about nominations and applications, please visit the ISNFF website www.isnff.org or contact Peggy Ann Parsons (Tel: +1 (709) 737 8239; Fax: +1 (709) 737 4000, or E-mail: pparsons@mun.ca).

5th International Conference on Polyphenols Applications

Call for Abstracts
Network Session

Malta Polyphenols 2009

Bridging Bio-efficacy to Innovation & Applications

&

Satellite Symposium

Pomegranate Extracts: Clinical & Nutraceutical Applications

October 29 & 30, 2009

At

Radisson SAS Hotel, Bay Point Resort

St. Julian's, Malta

The aims of **Malta Polyphenols 2009** are to **provide answers** to give a **future vision** of how polyphenols can enhance human nutrition and help in the prevention and treatment of many chronic diseases. **Malta Polyphenols 2009** will target researchers and academic professors, R&D departments, clinical, pharmaceutical companies, food supplements companies, cosmetics companies, veterinary medicine companies, marketing departments, investors, start ups and all other stakeholders in the polyphenols industry.

CALL FOR ABSTRACTS

Abstracts can be sent as a word file to the following address: isanh-conferences@isanh.fr
Please indicate if you wish to submit your abstract for the Conference or Symposium and for **Oral or Poster presentation.**
All abstracts for oral or poster presentation will be submitted to the Scientific Committee.

IMPORTANT DATES

Early registration deadline: 7 September 2009
Abstract submission deadline: 1 October 2009

For further instructions on abstract submission and for details of the conference topics and sessions, visit **www.malta-polyphenols.com**
