for the observed electronic transitions of V<sub>2</sub>, Cr<sub>2</sub>, Nb<sub>2</sub>, and Mo<sub>2</sub>, we find that the bond dissociation energies of the second-row diatomic molecules are consistently higher than those of their first-row congeners (Table II), analogous to the trend found for first- and second-row transition metal cluster compounds.24

 $SCF-X\alpha-SW$  calculations on  $Mo_2(O_2CH)_4$  are used to discuss the metal-metal and metal-ligand bonding in molybdenum(II) carboxylates and interactions between the two. Comparisons are made with similar calculations on  $HCO_2^-$ ,  $MO_2^{4+}$ , and  $Mo_2$ , and previous work on  $Mo_2Cl_8^4$  and  $Re_2Cl_8^2$ . The ordering of the metal-metal orbitals for the carboxylates appears to be the same as for the chloro anions, but the metal-ligand bonding is more covalent, the Mo-Mo bond is stronger, and interactions between the Mo-O  $\pi$  and Mo-Mo bonds are greater in the former. Possible structural implications of these interactions are explored. Mo<sub>2</sub> is found to have a sextuple metal-metal bond, due to the stabilization, relative to  $Mo_2^4$ and  $Mo_2(O_2CH)_4$ , of a 5s-orbital  $\sigma$ -bonding combination which becomes the HOMO. The possibility of such an orbital being occupied in very covalent  $D_{4h}$  complexes is discussed. The calculations are in excellent agreement with the UV photoelectron spectrum of Mo<sub>2</sub>(O<sub>2</sub>CH)<sub>4</sub>; the observed peaks at 7.7, 9.5, 11.6, and 12.7 eV are assigned mainly to ionization of Mo-Mo  $\delta$ , Mo-Mo  $\pi$ , Mo-O, and Mo-Mo  $\sigma$  orbitals, respectively. The 80-K electronic spectrum of Mo<sub>2</sub>(O<sub>2</sub>CH)<sub>4</sub> shows peaks at 22.9, 30.8, 33.5, and 4.44  $\mu$ m<sup>-1</sup>, with oscillator strengths of 0.0008, 0.03, 0.19, and 0.02, respectively. These are tentatively assigned to forbidden  $\delta \to \pi^*$ , allowed  $\delta \to \delta^*$ , allowed  $\delta \to C - O \pi^*$ , and allowed  $\pi \to \pi^*$  transitions, respectively.

Recently, the nature of the quadruple metal-metal bonds in Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup> and Re<sub>2</sub>Cl<sub>8</sub><sup>2-</sup> has been defined in detail using SCF-X $\alpha$ -SW calculations.<sup>3,4a</sup> A consistent assignment for the electronic spectra of these ions has also been achieved by combining the  $X\alpha$ -SW predictions with polarization data from spectra of single crystals.<sup>3-5</sup> For theoretical studies of strong metal-metal bonding, the chloro anions have the advantage of simple structure. However, they are known only for Mo, Re, and Tc.<sup>6</sup> By far the largest class of compounds of this general structural type  $(D_{4h}$  symmetry) is the dinuclear carboxylates,  $M_2(O_2CR)_4L_2$ , which are well characterized for M = V, Cr, Mo, Re, Ru, Co, Rh, and Cu and a variety of axial ligands L.<sup>7</sup> The occurrence of the same basic structure forso many metals makes these compounds ideal for a theoretical comparison of metal-metal bonding as a function of  $d^n$ configuration. We have begun such an investigation with

SCF-X $\alpha$ -SW calculations on molybdenum(II) formate,  $Mo_2(O_2CH)_4$ . This paper reports the results of these calculations and a proposed assignment for the electronic spectrum of the compound. A preliminary account of the calculations, done with sphere radii ca. 5% smaller than those used here, has appeared.<sup>8</sup> We also present some interesting theoretical results on the species  $Mo_2^{4+}$  and  $Mo_2$ .

### **Computational and Experimental Section**

Initial Parameters for  $Mo_2(O_2CH)_4$ . The SCF-X $\alpha$ -SW method has been thoroughly reviewed.<sup>9</sup> The bond parameters Mo-Mo = 2.09 Å, Mo-O = 2.11 Å, C-O = 1.29 Å, and angle Mo-Mo-O =  $92^{\circ}$ were taken from the x-ray structure of  $Mo_2(O_2CH)_4$ <sup>10</sup> the C-H distance used was 1.08 Å. Coordinates to the nearest 0.00001 bohr were derived from these parameters using the relation 1 bohr = 0.529 177 Å and the assumption of  $D_{4h}$  symmetry. The coordinate system is shown by

Schwarz's  $\alpha_{\rm HF}$  values<sup>11</sup> were used for the atomic exchange parameters, except for hydrogen, for which 0.77725 was used.<sup>12</sup> For the extramolecular and intersphere regions, a weighted average of the atomic  $\alpha$ 's was employed, the weights being the numbers of *valence* electrons in the neutral atoms (6 for each Mo, 6 for each O, 4 for each C, and 1 for each H). The outer sphere was centered at the inversion center of the molecule. Overlapping-sphere radii were obtained by our nonempirical procedure;<sup>13</sup> they are 2.505, 1.736, 1.623, 1.308, and 8.548 bohrs for the Mo, O, C, H, and outer regions, respectively. Although these are not fully optimized with respect to the virial theorem, we believe they are within 0.05 bohr of the optimum values.

SCF Calculations for  $Mo_2(O_2CH)_4$ . The initial molecular potential was constructed by superposition of neutral-atom SCF-X $\alpha$  results. Spherical harmonics through l = 4, 2, 1, and 0 were used in the outer, Mo, O and C, and H regions, respectively, to expand the wave functions. Core energy levels were never frozen; in each iteration they were calculated explicitly using only the surrounding-atomic-sphere potential. Iterations were continued until all levels had converged to 0.0002 hartree or better.

Excited and Ionized States for Mo<sub>2</sub>(O<sub>2</sub>CH)<sub>4</sub>. The SCF ground-state potential was used to search for excited-state levels up to -0.025 hartree. The same potential was then used as the starting point for calculating electronic transitions and ionization energies using the transition-state procedure.<sup>9a</sup> Two different spin-unrestricted calculations were done for each electronic transition, with the upper half-occupied orbital first having the opposite and then the same spin as the lower orbital. These give predictions of the triplet energy and the simple average of the singlet and triplet energies, respectively. Combination of the two numbers allows calculation of the singlet (spin-allowed) energy explicitly (e.g., for  $2b_{2g} \rightarrow 2b_{1u}$ , the energy of the  ${}^{1}A_{1g} \rightarrow {}^{1}A_{2u}$ , rather than  ${}^{1}A_{1g} \rightarrow {}^{3}A_{2u}$ , process).<sup>14</sup>

 $Mo_2^{4+}$  and  $Mo_2$ . SCF calculations were carried out in a manner analogous to those for  $Mo_2(O_2CH)_4$ . For  $Mo_2^{4+}$  complete results were obtained with Mo-Mo = 3.5, 4.0, 5.0, and 6.0 bohrs; for  $Mo_2$ , with Mo-Mo = 4.0, 4.5, and 5.0 bohrs. Equilibrium bond distances were obtained by fitting a quadratic to the curve of total energy vs. bond distance. The usual procedure for choosing sphere radii<sup>13</sup> was modified to avoid biasing the equilibrium-distance calculation by forcing satisfaction of the virial theorem at some particular distance. Instead, Mo radii were uniformly taken to be 25% greater than those required for touching spheres at the distance in question.<sup>15</sup> Outer-sphere radii were chosen to touch the Mo spheres.

**Electronic Spectra for Mo**<sub>2</sub>(**O**<sub>2</sub>**CH**)<sub>4</sub>. The compound was prepared by a published procedure.<sup>10</sup> Electronic spectra were recorded on a Cary 17 instrument for oxygen-free methanol solutions at room temperature and for a 4:1 ethanol-methanol glass at 80 K. Oscillator strengths were obtained for each room-temperature band by recording the band in the absorbance range 0.4–0.8, replotting on an energy scale, and weight-integrating the Gaussian-resolved bands.

#### Results

The valence energy level diagram for  $Mo_2(O_2CH)_4$  may be divided into three basic regions. In the range -1.07 to -0.51hartrees are 20 essentially unperturbed  $HCO_2^-C-H$ ,  $C-O\sigma$ , and O 2s lone-pair orbitals. The 20 orbitals from -0.43 to -0.19 hartree have C-O  $\pi$ , Mo-O, or Mo-Mo bonding character or represent O 2p lone pairs. The ten unoccupied orbitals from -0.15 to -0.02 hartree are of Mo-Mo, Mo-O, or C-O antibonding type.

Ground-state energies, charge distributions, and ionization energies for levels in the second and third regions are given in Table I; the last are compared there with experimental values from UV photoelectron spectroscopy.<sup>16</sup> The highest six levels of the first region are also included, since ionization energies have been measured for them. In Figure 1 the second-

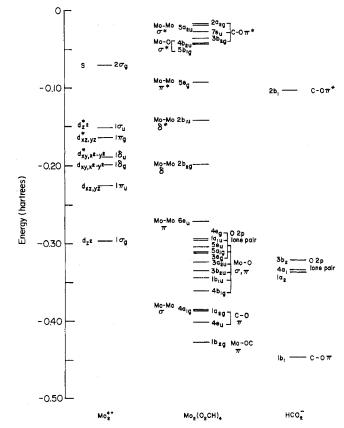

Figure 1. Calculated energy levels for  $Mo_2(O_2CH)_4$  above -0.5 hartree, compared with corresponding levels for  $Mo_2^{4+}$  (with Mo-Mo = 5.0bohrs) and  $HCO_2^-$ . The  $HCO_2^-$  calculation was stabilized by a Watson sphere; the  $Mo_2^{4+}$  levels have been shifted upward by 0.95 hartree to make the energy of the  $1\delta_g$  level equal to that of the  $2b_{2g}$  level in  $Mo_2(O_2CH)_4$ . The highest occupied levels are  $1\delta_g$ ,  $2b_{2g}$ , and  $3b_2$  for  $Mo_2^{4+}$ ,  $Mo_2(O_2CH)_4$ , and  $HCO_2^-$ , respectively. The first contains two of a possible four electrons, while the last two are fully occupied with two electrons each. The main character of the orbitals is indicated. For  $Mo_2^{4+}$ ,  $d_{xy_2x^2-y^2}$  refers to a degenerate bonding combination of  $d_{xy}$  or  $d_{x^2-y^2}$  orbitals,  $d_{x_2}$  to a nondegenerate antibonding combination of  $d_{z^2}$  orbitals, etc.

and third-region levels are compared with those of  $Mo_2^{4+}$  and  $HCO_2^{-}$  with which they most closely correlate. Wave function contour maps are shown in Figures 2 and 3 for the two important Mo-Mo  $\sigma$ -bonding orbitals and in Figures 4 and 5 for the two important Mo-Mo  $\pi$ -bonding levels. Table II gives the calculated electronic spectrum and an assignment of the experimentally observed peaks.

The equilibrium Mo–Mo distances calculated for  $Mo_2^{4+}$  and Mo<sub>2</sub> are 5.4 and 4.3 bohrs (2.9 and 2.3 Å), respectively. At present the X $\alpha$ -SW total energy is calculated in a much more approximate way than are the one-electron levels,<sup>15,17</sup> and bond lengths in diatomic molecules are always overestimated, apparently by ca. 0.3 bohr.<sup>15</sup> If this is true for  $Mo_2^{4+}$  and  $Mo_2$ , then the calculations done at 5.0 and 4.0 bohrs, respectively, should closely approximate results at the correct Mo-Mo distance. It is these energy levels which are diagrammed for  $Mo_2^{4+}$  in Figure 1 and for  $Mo_2$  in Figure 6 (along with the levels of atomic Mo). Figure 7 depicts the wave function for the highest occupied  $2\sigma_g$  level of Mo<sub>2</sub>. The ground-state configurations for the diatomics at the equilibrium distances were found to be those of minimum spin, i.e., with the degenerate  $1\delta_g$  level for  $M{o_2}^{4+}$  half-filled and the nondegenerate  $2\sigma_{\underline{g}}$  level for Mo<sub>2</sub> filled.

The calculated total energy for  $Mo_2(O_2CH)_4$  is -8706.860 hartrees, and the virial-theorem ratio -2T/V is 1.00024. The intersphere potential energy is -0.2131 hartree. The numbers

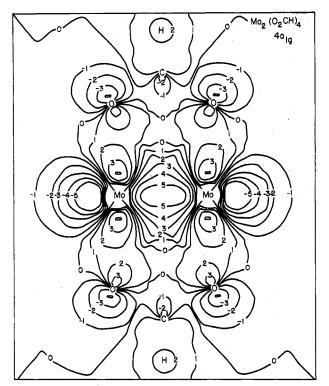

Figure 2. Contour map of the wave function for the  $4a_{1g}$  level of  $Mo_2(O_2CH)_4$ . This and all subsequent maps are in the xz plane; interior contours close to the atomic centers are always omitted for clarity. The contour values are  $0, \pm 1, \pm 2, \pm 3, \pm 4, \pm 5 = 0, \pm 0.02, \pm 0.05, \pm 0.09, \pm 0.13, \pm 0.17$ , respectively.

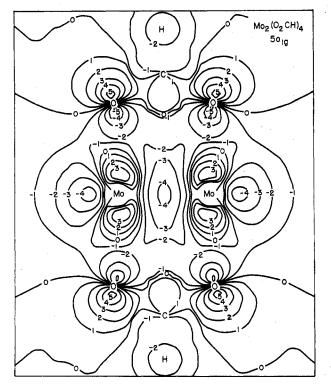

Figure 3. Contour map of the wave function for the  $5a_{1g}$  level of  $Mo_2(O_2CH)_4$ , with the same contour values as Figure 2.

of electrons within the Mo, O, C, H, intersphere, and outer regions are 41.03, 7.97, 5.20, 0.95, 5.43, and 0.14, respectively. **Discussion** 

**Bonding in Mo<sub>2</sub>(O<sub>2</sub>CH)**<sub>4</sub>. The basic features of the bonding are clear from Figure 1. Eight of the 16 C–O  $\pi$  and O 2p lone-pair orbitals of the four formate ions pick up 9–48% metal

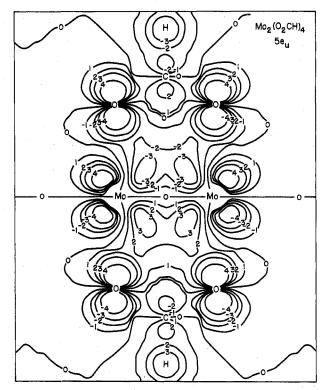

Figure 4. Contour map of the wave function for the  $5e_u$  level of  $Mo_2(O_2CH)_4$ . The contour values are  $0, \pm 1, \pm 2, \pm 3, \pm 4 = 0, \pm 0.04, \pm 0.07, \pm 0.092, \pm 0.135$ .

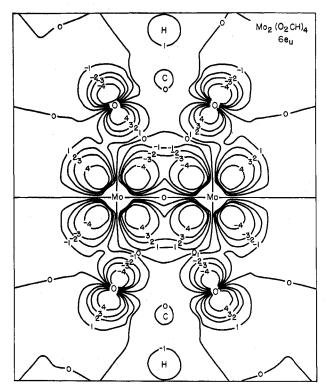

Figure 5. Contour map of the wave function for the  $6e_u$  level of  $Mo_2(O_2CH)_4$ , with the same contour values as Figure 4.

character and thus approximately represent the eight Mo–O bonds in the complex. Interaction with the formate ions greatly decreases the effective positive charge on the  $Mo_2^{4+}$  unit, thereby expanding its orbitals and increasing the effectiveness of metal-metal bonding. This is reflected in a marked decrease in Mo–Mo distance (2.09 Å for  $Mo_2(O_2CH)_4$ , 2.9 Å calculated for  $Mo_2^{4+}$ ) and a dramatically increased splitting of the

<sup>a</sup> All levels between -0.600 and -0.025 hartree except for diffuse Rydberg-state orbitals. These occur at -0.0855 ( $4a_{2u}$ ), -0.0744 ( $6a_{1g}$ ), and -0.0259 ( $7a_{1g}$ ). Only 3-18% of their charge is located within the atomic spheres. <sup>b</sup> Relative amounts of charge within the two molybdenum, eight oxygen, etc. spheres. The occupied and unoccupied levels have 74-100% and 37-93% of their charge within the atomic spheres, respectively. <sup>c</sup> Spherical harmonic basis functions contributing more than 10% of the molybdenum charge for the Mo-Mo and Mo-O levels, listed in order of decreasing importance. The largest non-d contribution is in the  $5a_{1g}$  level, which is 43% s within the Mo spheres. <sup>d</sup> Values in parentheses are estimates only, representing eigenvalues found in explicit transition-state calculations of other levels. Examination of shifts between the different explicit calculatons indicates that the estimates should be accurate to within 0.1 eV. <sup>e</sup> From ref 16. Shoulders on main peaks are indicated by sh; the ones at 10.1 and 12.0 eV, while evident in the published spectrum in ref 16, were not explicitly mentioned by the authors. The value 7.7 eV for the  $2b_{2g}$  level was given in their table as 7.5 eV, although the peak is clearly at 7.7 eV in the published spectrum. <sup>f</sup> The highest occupied level.

<sup>a</sup> Band positions were obtained from the calculated values using the relation 1 hartree = 21.947 46  $\mu m^{-1}$ . <sup>b</sup>  $\pi$ ,  $\pi^*$ ,  $\delta$ , and  $\delta^*$  denote the Mo-Mo character of mainly metal orbitals. O denotes an oxygen lone-pair orbital. <sup>c</sup> All spin- and dipole-allowed transitions below ca. 4.8  $\mu m^{-1}$  and the only spin-allowed, dipole-forbidden transition  $(2b_{2g} \rightarrow 5e_g)$  which should not be obscured by allowed bands. <sup>a</sup> Gaussian-resolved maxima at 80 K in a 4:1 ethanol-methanol glass, with oscillator strengths at room temperature given in parentheses. See text for basis of assignment to particular transitions. <sup>e</sup> Actually a prediction of the average transition energy to the four singlet states arising from the  $6e_u^{3}5e_g^{1}$  configuration. Only the transition to the  ${}^{1}A_{2u}$  state is dipole allowed and thus likely to be observed.

Mo-Mo bonding and antibonding orbitals. The interaction does not change the basic  $\sigma < \pi < \delta < \delta^* < \pi^* < \sigma^*$  ordering of these orbitals, except for a lifting of the degeneracy of the  $1\delta_g$  and  $1\delta_u$  pair; the  $d_{x^2-y^2} \pm d_{x^2-y^2}$  components, which point directly at the formate oxygen atoms, are greatly raised in energy, pick up 20-30% oxygen character, and are better considered as Mo-O  $\sigma^*$  than as a second pair of Mo-Mo  $\delta$ 

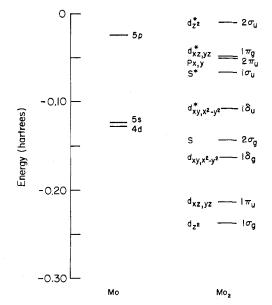

Figure 6. Valence energy levels for Mo and Mo<sub>2</sub> (with Mo-Mo = 4.0 bohrs). Mo has a  $4d^5 5s^1$  configuration, while Mo<sub>2</sub> is closed shell with  $2\sigma_g$  as the highest occupied orbital. The main character of the Mo<sub>2</sub> orbitals is indicated; see Figure 1 for explanation of symbols.

and  $\delta^*$  orbitals. Essentially unperturbed C–O  $\pi^*$  levels appear at the top of the diagram. The highest occupied orbital is  $2b_{2g}$ , the Mo–Mo  $\delta$ -bonding component, giving a Mo–Mo bond order of 4 as expected.<sup>3,7</sup>

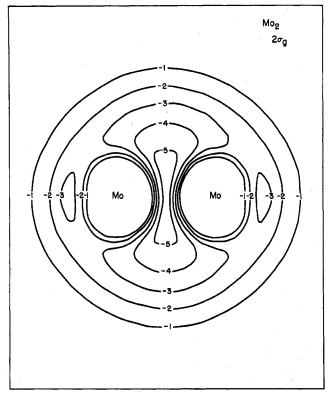

Figure 7. Contour map of the wave function for the  $2\sigma_g$  level of Mo<sub>2</sub>. The contour values are 0, -1, -2, -3, -4, -5 = 0, -0.02, -0.03, -0.04, -0.05, -0.06.

The energy level diagram for  $Mo_2(O_2CH)_4$  is completely analogous to that for  $Mo_2Cl_8^{4-}$  in the occupation and ordering of the metal-metal bonding and antibonding orbitals. The splitting between each bonding and antibonding pair is greater for  $Mo_2(O_2CH)_4$ , reflecting the stronger bond (2.09 Å in  $Mo_2(O_2CH)_4$ , 2.14 Å in  $Mo_2Cl_8^{4-}$ —a considerable difference in this range of bond order). The only other qualitative changes in level positions from the  $Mo_2Cl_8^{4-}$  diagram are a marked stabilization of the Mo-Mo  $\pi^*$  (5eg) orbital relative to the other metal-metal orbitals and appearance of four additional unoccupied orbitals of C-O  $\pi^*$  character. As discussed below, these two changes, though not important for ground-state bonding, have a significant effect on the electronic spectrum.

Examination of orbital character and wave function contour maps shows that the metal-ligand bonding is more covalent<sup>18</sup> and confirms that the Mo-Mo overlap is greater in  $Mo_2(O_2CH)_4$  than in  $Mo_2Cl_8^{4-}$ . The former is probably the main reason for the latter, since a smaller effective positive charge on the metal atoms means that their orbitals will be less contracted and hence overlap more effectively with each other. This is the most straightforward of a number of interesting interactions between the metal-metal and metalligand bonds revealed by the calculations; we discuss the others for the remainder of this section.

Although the  $4a_{1g}$  and  $6e_u$  orbitals are best classified as Mo-Mo bonding, and the  $5a_{1g}$  and  $5e_u$  orbitals, as Mo-O bonding, Figures 2-5 and Table I show that each has considerable character of both types. This complex situation is a result of strong interactions between the Mo-Mo bond and the Mo-O  $\pi$  bonds, much stronger than analogous interactions in Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup>. Mo-O  $\pi$  bonding may be classified as interior or exterior, i.e., on the same side of the Mo-O direction as the metal-metal bond or on the opposite side, respectively. The former will tend to "steer" charge into, and the latter out of, the metal-metal region, thus strengthening and weakening the metal-metal bond, respectively. In the  $e_u$  levels (Figures 4 and 5), the majority of the Mo-Mo  $\pi$  bonding is found in the upper level, as for Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup> (see Figure 3 of ref 3), but it is slightly weakened there by the presence of some exterior Mo-O  $\pi$  bonding and significantly enhanced in the lower  $e_u$  level by fairly strong interior bonding. Interior and exterior Mo-O  $\pi$  bonding of about equal strength occurs in the upper  $a_{1g}$  level (Figure 3); the overall effect is to delocalize the charge distribution to the extent that it becomes somewhat incompatible with the strongly localized character of the Mo-Mo  $\sigma$  bond, and most of this character escapes into the lower  $a_{1g}$ level (Figure 2), where the Mo-O bonding is  $\sigma$ . This contrasts with Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup>, where nearly all of the Mo-Mo  $\sigma$  bonding is in the upper  $a_{1g}$  level; what weak interactions with the Mo-Cl bond are present there are interior, thus reinforcing the Mo-Mo character (see Figure 2 of ref 3).

The contour maps, especially Figure 4, illustrate an important effect of the metal-metal bond on the ligand system which is entirely general for  $D_{4h}$  systems of this type, independent of which ligands or metals are present. Consider the electronic interaction between ligand donor atoms that face each other across the metal-metal axis. So long as a net metal-metal bond is present, there will be more orbitals in which this sort of interaction is attractive than orbitals in which it is repulsive. This comes about simply because any orbital whose symmetry is bonding rather than antibonding for metal-metal interaction will necessarily also be bonding for interactions between such ligands. All other things being equal, nonbridged  $D_{4h}$  dimers, such as Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup> and Cr<sub>2</sub>(CH<sub>3</sub>)<sub>8</sub><sup>4</sup> should therefore always have the eclipsed conformation. Of course, for  $d^4-d^4$  dimers, the eclipsed structure is more simply explained as due to  $\delta$  bonding, but in d<sup>5</sup>-d<sup>5</sup> dimers and those with more d electrons  $\delta$  bonding should be essentially (see following paragraph) absent due to occupation of the  $\delta^*$ orbital. The structures of such molecules should show whether the ligand-ligand interactions in question are attractive enough by themselves to force the eclipsed conformation. One such structure, that of  $\text{Re}_2\text{Cl}_4(\text{PEt}_3)_4$ , is known,<sup>19</sup> and it is eclipsed. Unfortunately, in this case the spatial requirements of the bulky phosphine ligands may dictate the stereochemistry. We hope for the synthesis of complexes that provide more clear-cut examples.

Finally, if one considers the 16 occupied mainly ligand orbitals in Figure 1 (i.e., all but the Mo-Mo  $\sigma$ ,  $\pi$ , and  $\delta$ orbitals) as a group, one finds seven bonding, seven antibonding, and two  $(1a_{2g} and 1a_{1u})$  nonbonding with respect to Mo-Mo interaction. However, the bonding group averages 23% Mo in character, while the antibonding group averages only 7% Mo. There is thus a net positive contribution to Mo-Mo bonding from this set of orbitals, over and above the strong bonding found in the  $4a_{1g}$ ,  $6e_u$ , and  $2b_{2g}$  levels. The considerable Mo-Mo  $\sigma$  and  $\pi$  components of the 5a<sub>1g</sub> and 5e<sub>u</sub> orbitals, respectively, are the best example. This phenomenon has no particular importance for Mo<sub>2</sub>(O<sub>2</sub>CH)<sub>4</sub> itself, but it has possible structural implications for  $D_{4h}$  systems with more d electrons. When, e.g., the  $\delta^*$  orbital is filled, assuming it is the perfect complement of the  $\delta$  orbital, the  $\delta$  bonding present in the latter will be canceled. Some net  $\delta$  bonding may remain, however, in the lower orbitals. This may partially explain why the Re-Re bond in  $Re_2Cl_4(PEt_3)_4$  is only slightly, if at all, longer than in  $\text{Re}_2\text{Cl}_6(\text{PEt}_3)_2$ , although the  $\delta^*$  orbital should be fully occupied in the former and empty in the latter<sup>19</sup> (for another possible explanation, see the discussion of Mo<sub>2</sub> below). The point in general is that, as the  $\delta^*$ ,  $\pi^*$ , etc. orbitals are filled, the metal-metal bond will not necessarily lengthen as fast as might be expected from the simplest considerations. Our preliminary  $X\alpha$ -SW results for  $Rh_2(O_2CH)_4(H_2O)_2$ suggest that this is one reason that the Rh-Rh distance in the acetate analogue is shorter than expected for a single bond,<sup>20,21</sup> although this is all which is obtained from the occupation scheme for the *mainly Rh 4d* orbitals.<sup>22,23</sup>

 $Mo_2^{4+}$  and  $Mo_2$ . One of the most basic facts about the electronic structure of transition metals is that, as the positive charge on the metal atom increases, the d valence orbitals become more stable relative to the s valence orbitals. This is why, e.g., the 4s orbitals are filled before the 3d in the periodic table, but the 4s electrons are lost before the 3d in forming first-row transition metal ions.<sup>24</sup> The energy level diagrams for Mo2<sup>4+</sup> and Mo2 (Figures 1 and 6) provide a striking example of this principle; in Mo24+, all of the bonding and antibonding 4d-orbital combinations lie below the bonding 5s combination, while in Mo<sub>2</sub> the bonding s combination is stabilized to the point where it becomes the HOMO. The  $d^{10}s^2$ configuration of Mo<sub>2</sub> is in fact just a doubling of the  $d^{5}s^{1}$ configuration of atomic Mo. The interesting consequence is that the Mo-Mo bond order actually increases from quadruple in  $Mo_2^{4+}$  to sextuple in  $Mo_2$ ! The wave function for the  $Mo_2$ bonding s combination, the sixth component of the sextuple bond, is shown in Figure 7. Note that the contours required to achieve good resolution are much smaller than in Figures 2-5; the orbital is much more diffuse and the bonding interaction much weaker than in any of the  $Mo_2(O_2CH)_4$  levels. However, there is clearly some similarity in form with the  $5a_{1e}$ level of the formate (Figure 3), where the Mo contribution is 43% s in character.

Although Mo<sub>2</sub> is hypothetical at present, its eventual synthesis and characterization appear possible in view of the recent matrix isolation of  $Sc_2$  and  $Ti_2$ , including measurement of their electronic spectra.<sup>25</sup> The  $Mo_2^{4+}$  and  $Mo_2$  results also have a general implication for the electronic structure of the  $D_{4h}$  complexes: namely, as the metal atoms become more nearly neutral, the possibility of mainly s or p orbital combinations figuring prominently in the bonding increases.  $Re_2Cl_4(PEt_3)_4$  and  $Re_2Cl_6(PEt_3)_2$  (see last paragraph of preceding section) are certainly more covalent than  $\text{Re}_2\text{Cl}_8^{2-}$ , and the reason that the Re-Re bond in the first is not appreciably longer than in the second could be that the extra electrons do not enter the  $\delta^*$  orbital at all, but rather a mainly Re 6s or 6p orbital which is not strongly antibonding and perhaps is even weakly bonding with respect to Re-Re interaction.<sup>19</sup> Such orbitals would resemble the " $\sigma_n$ " set originally proposed by Cotton for all the dimers on qualitative grounds.<sup>7</sup> An explicit calculation on, e.g.,  $Re_2Cl_4(PH_3)_4$ , is called for to resolve this question.

Photoelectron Spectrum of Mo<sub>2</sub>(O<sub>2</sub>CH)<sub>4</sub>. As shown in Table I, the agreement between the calculated and experimental<sup>16</sup> spectrum is in general excellent. All calculated ionization energies are within 4% of their apparent experimental values, except for the  $1b_{2g}$  level, where the deviation is 8%. The  $1b_{2g}$ experimental position may in fact be somewhat in error, since the peak is asymmetric and the maximum poorly defined. On the basis of the calculated values and the general idea that mainly metal levels should have greater photoelectron intensity than mainly ligand levels,<sup>26</sup> it seems clear that the first two experimental peaks (7.7 and 9.5 eV) are mainly due to Mo-Mo  $\delta$  and  $\pi$  orbitals, respectively, the third (11.6 eV) to Mo-O orbitals, the fourth (12.7 eV) to the Mo-Mo  $\sigma$  orbital, and the last three (14.9, 16.1, and 16.7 eV) to formate-localized levels. It is of course difficult to unambiguously assign a few calculated ionizations in the 10-12-eV region to particular peaks or shoulders, since both experimental and theoretical levels are so closely spaced in this region.

The experimental spectrum up to 14 eV, i.e., through the first four peaks, has been determined independently with essentially the same results.<sup>10</sup> The actual spectral curves for  $Mo_2(O_2CR)_4$ , R = H, CH<sub>3</sub>, and CF<sub>3</sub>, were also compared

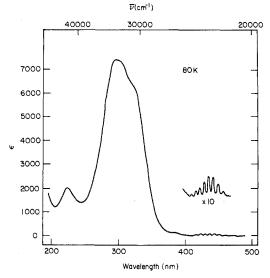

Figure 8. Electronic spectrum of  $Mo_2(O_2CH)_4$  at 80 K in a 4:1 ethanol-methanol glass. The spectrum was scanned at a bandwidth  $\leq 0.2$  nm.

directly. The only qualitative change among the three spectra, aside from a uniform energy shift consistent with the relative electronegativities of H,  $CH_3$ , and  $CF_3$ , is a different structure for the third peak in each. This is consistent with our assignment of that peak mainly to Mo–O bonding levels, whose position should be more sensitive to the R group than should the Mo–Mo levels mainly responsible for the other three peaks.

Electronic Spectrum of  $Mo_2(O_2CH)_4$ . The 80-K spectrum of  $Mo_2(O_2CH)_4$  in a 4:1 ethanol-methanol glass is shown in Figure 8; the Gaussian-resolved peak maxima are listed in Table II. Careful examination down to 80 cm<sup>-1</sup> shows no further electronic absorption bands. The spectra of Mo<sub>2</sub>- $(O_2CR)_4$ , R = CH<sub>3</sub>, CF<sub>3</sub>, C<sub>3</sub>F<sub>7</sub>, and CH<sub>2</sub>CH<sub>3</sub><sup>+</sup>, are virtually the same,<sup>27-29</sup> although band III, at 3.35  $\mu$ m<sup>-1</sup> in the formate, appears somewhat more sensitive to the R group than the other three bands. The small oscillator strength of band I, at 2.29  $\mu m^{-1}$ , strongly suggests a dipole-forbidden transition, and careful polarization measurements of this band for single crystals containing  $Mo_2(O_2CCH_2NH_3)_4^{4+}$ ,  $Mo_2(O_2CH)_4$ , and  $Mo_2(O_2CCH_3)_4$  leave no doubt that this is the case.<sup>29,30,32</sup> The oscillator strengths of bands II and IV, at 3.08 and 4.44  $\mu$ m<sup>-1</sup>, respectively, are similar to the value of 0.02 for the  $\delta \rightarrow \delta^*$  transitions in Re<sub>2</sub>Cl<sub>8</sub><sup>2-31</sup> and Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup>; <sup>32</sup> this and their lack of sensitivity to the R group suggest allowed transitions between metal-localized orbitals. The much larger oscillator strength of band III and its greater sensitivity to R suggest an allowed charge-transfer transition.

The carboxylates thus differ from Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup>, Re<sub>2</sub>Cl<sub>8</sub><sup>2-</sup>, and Mo<sub>2</sub>(SO<sub>4</sub>)<sub>4</sub><sup>4-</sup>, for which single-crystal polarized spectra and X $\alpha$ -SW calculations agree in assigning the lowest spectral band to the  $\delta \rightarrow \delta^*$  transition.<sup>4,5,30</sup> Here, the polarized spectra completely rule out such an assignment for the 2.29  $\mu$ m<sup>-1</sup> band;<sup>29,30</sup> the  $\delta \rightarrow \delta^*$  excitation must occur at higher energy. Our predicted  $\delta \rightarrow \delta^*$  energy, 1.47  $\mu$ m<sup>-1</sup>, thus appears to be far too low. This was also the case for Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup>, where the comparable theoretical number is ca. 0.9  $\mu$ m<sup>-1</sup>, and the experimental  $\delta \rightarrow \delta^*$  energy is 1.88  $\mu$ m<sup>-1.3</sup> If our calculated  $\delta \rightarrow \delta^*$  energy as in Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup>, then the experimental band should lie at ca. 3.0  $\mu$ m<sup>-1</sup>. As pointed out above, the band at 3.08  $\mu$ m<sup>-1</sup> is in fact a most reasonable candidate for assignment to this transition.

What forbidden transition, then, is responsible for band I in Mo<sub>2</sub>(O<sub>2</sub>CH)<sub>4</sub>? The calculation predicts that the lowest such excitation,  $\delta \rightarrow \pi^*$ , should occur at 2.56  $\mu$ m<sup>-1</sup>, only slightly above the observed energy of 2.29  $\mu m^{-1}$  for band I. Moreover, one would expect the predicted energy to be somewhat high, as the resulting excited state is one of two  ${}^{1}E_{g}$  states rather close in energy, the other being from the  $6e_u \rightarrow 2b_{1u} \ (\pi \rightarrow \delta^*)$ transition. Since these two states are of the same symmetry, close in energy, and similar in character, they should interact significantly, one going lower and the other higher in energy than predicted by a purely one-electron calculation.<sup>33</sup> The  $\delta$  $\rightarrow \pi^*$  assignment is also supported to some extent by the results of analyses of the vibrational structure of band I, which suggest the involvement of a metal-localized transition.<sup>29,32</sup> Two independent discussions of the vibrational structure, however, disagree as far as the exact nature of the excited state is concerned. Specifically, one suggests a nondegenerate<sup>29</sup> and the other a degenerate<sup>32</sup> excited state. Only the second, of course, would be consistent with a  $\delta \rightarrow \pi^*$  assignment. All of the metal-localized forbidden transitions to excited states suggested by the first analysis  $({}^{1}A_{1u}, {}^{1}B_{1g}, \text{ and } {}^{1}B_{2g})^{29}$  are predicted to lie above 3.5  $\mu m^{-1}$ , and thus we consider them unlikely assignments for band I.

If the  $\delta \rightarrow \pi^*$  and  $\delta \rightarrow \delta^*$  assignments for bands I and II are correct, the error in the calculated energy for the latter is apparently chiefly in the energy of the  $\delta^*$  level. This is consistent with the good agreement between the calculated and experimental photoelectron spectrum. The calculated energies of 3.71 and 4.09  $\mu m^{-1}$  for the O  $\rightarrow \delta^*$  transitions (see Table II) may thus also be several tenths of a  $\mu m^{-1}$  too low, leaving  $\delta \rightarrow C \rightarrow O \pi^*$  as the reasonable assignment for band III. Band IV is then assigned to the  $\pi \rightarrow \pi^*$  excitation, as in the case of the analogous band in  $Mo_2Cl_8^{4-.34}$  Both suggestions are consistent with the observed oscillator strengths and R group dependence; moreover, in  $Mo_2(O_2CPh)_4$ , where the C–O and aromatic  $\pi^*$  systems should interact, band III appears to shift dramatically (to 2.37  $\mu$ m<sup>-1</sup>).<sup>27</sup>

The careful reader will have noted that we quoted 0.9  $\mu m^{-1}$ above as the predicted  $\delta \rightarrow \delta^*$  transition energy in Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup>, when in fact the number in Table IV of ref 3 is 1.37  $\mu$ m<sup>-</sup> There are two methods for explicitly calculating the singlet (spin-allowed) component of a particular orbital transition in the  $X\alpha$ -SW formalism. The method we did not use for Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup> originally now appears somewhat preferable on theoretical grounds,<sup>14</sup> and so we have employed it here for Mo<sub>2</sub>(O<sub>2</sub>CH)<sub>4</sub>; comparison of the Experimental Sections of the two papers will explain the difference between the two methods. For all transitions except  $\delta \rightarrow \delta^*$  in both Mo<sub>2</sub>Cl<sub>8</sub><sup>4-</sup> and  $Mo_2(O_2CH)_4$ , the two methods give the same answer within about 0.1  $\mu m^{-1}$ , and certainly no assignments are changed according to which is used. This ambiguity serves, however, to illustrate the difficulty of calculating electronic spectra with a basically one-electron method; many-electron effects are necessarily more important than in a calculation of, e.g., dipole moments or ionization energies. Even a perfect calculation of one-electron orbitals and charge distribution is no guarantee of accuracy in predicting the spectrum. Although the X $\alpha$ -SW method has been very successful in this regard for many transition metal complexes,<sup>35-39</sup> it provides only a tentative assignment here.
