Received December 29, 1997

The formation and properties of a wide range of metal ion monohydrates,  $M^{n+}-OH_2$ , where  $n = 1$  and 2, have been studied by ab initio molecular orbital calculations at the MP2(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* and CCSD(T)(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* computational levels. The ions M are from groups 1A, 2A, 3A, and 4A in the second, third, and fourth periods of the periodic table and the first transition series. Structural parameters, vibrational frequencies, bonding enthalpies, orbital occupancies and energies, and atomic charge distributions are reported. Trends in these properties are correlated with the progressive occupancy of the *s*, *p*, and *d* orbitals. Except for  $K^+-OH_2$  and  $Ca^{2+}-OH_2$ , the O–H bond lengths and HOH angles are greater in the hydrates than in unbound water. The M–O bond lengths decrease proceeding from group 1A → 4A but become larger in proceeding from the second → fourth period. The bonding enthalpies,  $\Delta H_{298}^\circ$ , are found to be inversely linearly dependent on the M–O bond length  $M^{n+}$  according to equations of the form  $\Delta H_{298}^\circ = A + B(1/M-O)$  for  $n = 1$  and  $n = 2$ . Within each monohydrate the distribution of atomic charge reveals a small but definite transfer of charge from water to the metal ion. Compared to unbound water there is, in a metal-ion-bound water complex, an increase in the electronic (negative) charge on the oxygen atom, accompanied by a (significantly) larger decrease in the electronic charge on the hydrogen atoms. The bonding of the water molecule, although electrostatic in origin, is thus more complex than a simple interaction between a point charge on the metal ion, and the water dipole.

## Introduction

The interaction of metal cations with neutral ligands, such as water, occurs in a wide variety of physical, chemical, and biological phenomena.<sup>1</sup> For example, one-third of all proteins require a metal ion for their structure and/or function:<sup>2</sup> and many of these protein-bound metal ions are bonded to at least one water molecule.<sup>3</sup> Furthermore, metalloenzymes are often active only when the metal ion is a specific one. In several enzyme systems the catalytic activity involves deprotonation of a metal ion-bonded water molecule giving a hydroxyl group, which then acts as a nucleophile that can attack the substrate.<sup>4</sup> Knowledge of the fundamental nature of the metal ion–water bonding and the deprotonation process is therefore necessary for a full understanding of the mechanism of action of such enzymes.

Deprotonation has long been known as a characteristic property of water when bound to a metal ion. Metal ion hydrates are only stable in a moderately acidic solution. At higher pH values an “ion-pair” complex, such as the monohy-

droxide,  $M^{n+}[OH]^-$  is formed, and at still higher pH values the polyhydroxide  $M^{n+}[OH]_n^-$  is precipitated.<sup>5,6</sup>

The importance of the metal ion–water interaction has led to extensive computational molecular orbital studies by many investigators of hydrates of metal ions ranging over much of the periodic table.<sup>7–12</sup> Many have concentrated on the physical and/or chemical properties of metal ion hydrates with multiple water molecules, e.g., clusters such as  $Be[H_2O]_4^{2+}$ ,  $Ca[H_2O]_6^{2+}$ ,  $Mn[H_2O]_6^{2+}$ , and  $Zn[H_2O]_6^{2+}$ .<sup>13–17</sup> Other studies have explored the properties of the monohydrates in a specific

group, e.g., the alkali metals,<sup>11,12</sup> or in a particular row, e.g., the monovalent first row transition metals.<sup>8,9</sup> Still other studies have examined the energetic consequences of sequential hydration, where the results can be compared directly with experiment.<sup>18</sup>

To gain more insight into the factors involved in the deprotonation we have carried out ab initio molecular orbital calculations at the MP2(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* and CCSD(T)(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* levels on the metal ions,  $M^{n+}$ , the monohydrates,

$M[H_2O]^{n+}$ , and the monohydroxides,  $M[OH]^{(n-1)+}$ . In the present paper, we report structural parameters, bonding enthalpies, vibrational frequencies, orbital occupancy and atomic charges for a wide variety of monohydrates, where the metal ions,  $M^{n+}$ , are taken from the second, third and fourth rows of the periodic table, and the formal charge on the metal,  $n$ , is 1 or 2. Results for boron, carbon and silicon (although not metal ions) are also included so that trends in these various properties can be related to the progressive occupancy of the  $s$ ,  $p$ , and  $d$  shells. These results represent studies done consistently on all metal ions under the same conditions, and therefore are suitable for comparative analyses.

The deprotonation of metal hydrates can be expressed as

or as a proton-transfer reaction

Deprotonation would be favored by stronger bonding in the hydroxide in relation to the weaker bonding in the hydrate. The interplay between the factors which bring about the bonding of  $H_2O$ , and the bonding of  $OH^-$  to metal ions, are thus key elements in understanding the natural selection of one or the other particular metal ion for a specific enzyme system. The most likely ions to be involved in biochemical systems are those that are stable in water, namely the divalent cations  $Be^{2+}$ ,  $Mg^{2+}$ ,  $Ca^{2+}$ ,  $Mn^{2+}$ ,  $Fe^{2+}$ ,  $Co^{2+}$ ,  $Cu^{2+}$ ,  $Zn^{2+}$ , and the trivalent cations  $Al^{3+}$ ,  $Cr^{3+}$ ,  $Mn^{3+}$ , and  $Fe^{3+}$ , since, in principle at least, they could be readily accessible from an aqueous environment for bonding to the protein. It is well-established that  $Mg^{2+}$ ,  $Ca^{2+}$ , and  $Zn^{2+}$  play such a role.<sup>16,17,19</sup> The present study is the first stage in the investigations of such a process.

Prior to 1989, experimental values of the binding enthalpies for  $M[H_2O]^+$  were available only for the alkali metal ions  $Li^+$ ,  $Na^+$ ,  $K^+$ ,  $Rb^+$ , and  $Cs^+$ ,<sup>20</sup> dissociation energies of the transition metal ion complexes  $Cu[H_2O]_n^+$  ( $n = 3-5$ ) had also been reported.<sup>21-23</sup> In 1989, however, three papers appeared, all based on collision-induced dissociation (CID) experiments, that expanded the available binding enthalpies to include all the *monovalent* first-row transition metals.<sup>24-26</sup> In 1994, Dalleska et al.<sup>27</sup> reported revised values of the hydration enthalpies for these transition metals, based on CID experiments in a guided ion beam mass spectrometer, and the error bars on these values were significantly smaller than those from earlier results.<sup>24-26</sup> As first noted by Corongiu and Clementi,<sup>28</sup> *divalent* cations can behave differently than singly charged ions, when interacting with water. Specifically, the dissociation products of  $M[H_2O]^{2+}$

may be  $M^+ + H_2O^+$  instead of  $M^{2+} + H_2O$ , owing to the relative magnitudes of the ionization potentials for the metal ion and water. Curtiss et al.<sup>29</sup> calculated that for  $Fe[H_2O]^{2+}$  the crossover between the two dissociation pathways occurs only for an  $Fe-O$  distance greater than 6 Å. Unfortunately, very little direct experimental data is currently available concerning either pathway for most divalent metal ions.

## Computational Methods

*Ab initio* molecular orbital calculations were performed at the MP2(FULL)/6-311++G\*\*/MP2(FULL)/6-311++G\*\* level<sup>30,31a-e</sup> on the CRAY YMP computer at the National Cancer Institute and DEC alpha 3000/600 and SGI origin 2000 workstations using the GAUSSIAN 94 program<sup>32</sup> on the metal ions,  $M^{n+}$ , and the monohydrates,  $M[H_2O]^{n+}$ , with  $n = 1$  and 2. Since 6-311++G\*\* basis sets for potassium and calcium are not available in GAUSSIAN 94, calculations on  $K[H_2O]^+$  and  $Ca[H_2O]^{n+}$  ( $n = 1,2$ ) were carried out using Huzinaga <4,3,3,2,1/4,3> basis sets,<sup>33</sup> augmented by two  $p$ -type and two  $d$ -type polarization functions and one  $sp$ -type diffuse function on the potassium and calcium atoms. The 6-311++G\*\* basis set was still used for the oxygen and hydrogen atoms: six  $d$ -type functions were used only in these two cases. As noted by Kaupp and Schleyer,<sup>34</sup>  $d$  orbitals and core polarization are both important for cationic  $d^0$  metal complexes such as  $Ca[H_2O]^{2+}$ . Spin projected energies were used where appropriate, and spin conservation was assumed in all complex formation reactions. Complete optimizations were performed on all the monohydrates, and frequency analyses were carried out to confirm that the reported structures are local minima on the MP2(FULL)/6-311++G\*\* potential energy surface, and to evaluate the thermal energy contributions necessary for the calculations of enthalpy changes for the hydration reaction

at 298 K. Since calculations at the MP2(FULL)/6-311++G\*\* level do not always predict the correct electronic configuration for the ground state of some first-row transition metals,<sup>35</sup> single point CCSD(T)(FULL)/6-311++G\*\*/MP2(FULL)/6-311++G\*\* calculations were performed in selected cases to more accurately treat the effects of electron correlation in the calculation of the bonding enthalpies. Atomic charges were calculated from

<sup>a</sup> See Computational Methods for the basis set employed for the K<sup>n+</sup> and Ca<sup>n+</sup> calculations. The M–O and O–H bond lengths are in angstroms, the H–O–H bond angles are in degrees, and the bonding enthalpies, Δ*H*<sub>298</sub><sup>o</sup>, are in kcal/mol. Water [MP2(FULL)/6-311++G\*\*] OH = 0.959 Å, ∠HOH = 103.5°. Water [employed in K<sup>n+</sup> and Ca<sup>n+</sup> calculations, MP2(FULL)/6-311++G\*\*(6D)] OH = 0.960 Å, ∠HOH = 103.4°.

natural population analyses (NPA) using the MP2(FULL)/6-311++G\*\* density. For some of the hydrates, charges were also calculated using the Atoms in Molecules (AIM) method pioneered by Bader<sup>36</sup> and implemented in GAUSSIAN 94 by Ciołowski and co-workers.<sup>37a–c</sup> The effect of basis set superposition error, BSSE, has been discussed by Feller et al.<sup>12</sup> and found to be relatively small in these situations (e.g., ~0.5 kcal/mol for Li<sup>+</sup>–OH<sub>2</sub> at the MP2(FC)/aug-cc-pVDZ computational levels) and, therefore, has been ignored in this work.<sup>38</sup>

The most demanding calculations were those for the transition metal monohydrates as a consequence of the various possible

occupations of the d orbitals. It was not practicable to study all the possibilities for each monohydrate, although in most cases several electronic configurations were considered, see Table 1. For guidance as to the lower energy states of the monovalent monohydrates, M[H<sub>2</sub>O]<sup>+</sup>, extensive use was made of the work of Rosi and Bauschlicher.<sup>8</sup> These authors have pointed out that the overlap between the H<sub>2</sub>O and the five components of the 3d orbitals on the metals is expected to be ordered according to 3dδ(xy) ≈ 3dδ(x<sup>2</sup> – y<sup>2</sup>) < 3dπ(yz) < 3dπ(xz) < 3dσ(z<sup>2</sup>), where the symmetry axis is z and the molecule lies in the yz plane, see Figure 1. This ordering allows for the bending of the O–H bonds away from the metal ion, and as can be seen from Table 1, it is generally borne out at the MP2(FULL)/6-311++G\*\* computational level.<sup>8</sup> A few calculations on the divalent monohydrates have been reported in the literature,<sup>8,17,39,40</sup> and these results have also been used for guidance wherever possible.

(38) For comparison, at the MP2(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* computational level, BSSE lowers the calculated binding enthalpy of Al<sup>n+</sup>–OH<sub>2</sub> (*n* = 1, 2, 3) by 1.8, 1.9, and 0.5 kcal/mol, respectively.

<sup>a</sup> See footnotes to Table 1 for the geometrical parameters of isolated water. <sup>b</sup> At the MP2(FULL)/6-311++G\*\* level, the lowest energy of Fe<sup>+</sup>-OH<sub>2</sub> is for the <sup>4</sup>B<sub>2</sub> state. <sup>c</sup> At the CCSD(T)(FULL)/6-311++G\*\* level, the lowest energy of Fe<sup>+</sup>-OH<sub>2</sub> is for the <sup>6</sup>A<sub>1</sub> state. If the <sup>4</sup>B<sub>2</sub> state is used ΔH<sub>298</sub><sup>o</sup> is -35.8 kcal/mol. The MP2(FULL)/6-311++G\*\* geometrical parameters for the <sup>6</sup>A<sub>1</sub> state are Fe<sup>+</sup>-O, 2.117 Å; O—H, 0.967 Å; ∠HOH = 106.4°. <sup>d</sup> At the MP2(FULL)/6-311++G\*\* level, the lowest energy of Co<sup>+</sup>-OH<sub>2</sub> is for the <sup>3</sup>B<sub>1</sub> state. <sup>e</sup> At the CCSD(T)(FULL)/6-311++G\*\* level, the lowest energy of Co<sup>+</sup>-OH<sub>2</sub> is for the <sup>3</sup>A<sub>2</sub> state. The MP2(FULL)/6-311++G\*\* geometrical parameters for the <sup>3</sup>A<sub>2</sub> state are Co<sup>+</sup>-O, 2.003 Å; O—H, 0.964 Å; ∠HOH = 106.6°.

**Figure 1.** Coordinate system.

## Results

### A. Geometrical Parameters and Enthalpies of Hydration.

With the single exception of the <sup>3</sup>A'' excited state of Co<sup>+</sup>-OH<sub>2</sub>, see Table 1, the geometries of all the ground states and excited states of the main group and transition metal monohydrates we studied were found to be planar, see Figure 1.

The total molecular energies, thermal corrections, and entropies at the MP2(FULL)/6-311++G\*\* computational level of all the monohydrates and metal ions we studied are given in Table 1S of the Supporting Information; total molecular energies at the CCSD(T)(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* level are also given in Table 1S. An extensive comparison of our calculated geometrical parameters and bonding enthalpies of these metal ion monohydrates, with the calculated and experimental values of other authors, is given in Tables 2S and 3S of the Supporting Information. In those cases where a comparison can be made, there is generally good agreement between our calculated bonding enthalpies and experiment.

M—O and H—O bond distances, the HOH angles, and the bonding enthalpies for the main group metal ion monohydrates, M<sup>n+</sup>-OH<sub>2</sub> with n = 1 and 2, in groups 1A, 2A, 3A, and 4A of the first, second, and third periods are listed in Table 2, and the values for the transition metal ion monohydrates of the fourth period are given in Table 3. Data for Ca and Zn have been included in this table to provide baselines, Ca → Mn and Mn

### Chart 1

Sequence	M—O	O—H	∠HOH	ΔH <sub>298</sub> <sup>o</sup>
Group 1A → 2A → 3A → 4A	decr.	incr.	incr.	incr.
2nd Period → 3rd → 4th	incr.	decr.	decr.	decr.

→ Zn, from which the effect of adding the first five electrons and then an additional five electrons to the 3d orbital can be determined.

Comparison of the geometrical parameters for unbound water and for the bonded H<sub>2</sub>O in both the monovalent and divalent hydrates, see Tables 2 and 3, shows that the O—H bond length and the HOH angle are greater in all of the monohydrates except those of K<sup>+</sup>-OH<sub>2</sub> and Ca<sup>2+</sup>-OH<sub>2</sub>. As the s and p valence shells are filled progressively in going from main group 1A → 2A → 3A → 4A, there is a general tendency for both of these water parameters to increase; whereas, in going from second period → third → fourth, there is a tendency for them to decrease. For the corresponding changes in group and period, the M—O bond length tends to decrease and increase respectively, and, as might be expected, the longer the M—O bond length the smaller the enthalpy of hydration. These relationships are summarized in Chart 1.

In Figure 2, ΔH<sub>298</sub><sup>o</sup> is plotted versus 1/M—O for the main group monovalent hydrates, M<sup>+</sup>-OH<sub>2</sub>, in the second, third and fourth periods, using total molecular energies from the CCSD(T)(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* calculations and M—O distances and thermal corrections from the MP2(FULL)/6-311++G\*\* optimizations and frequency analyses. When the points for the group 3A hydrates are omitted there is a linear dependency of the form

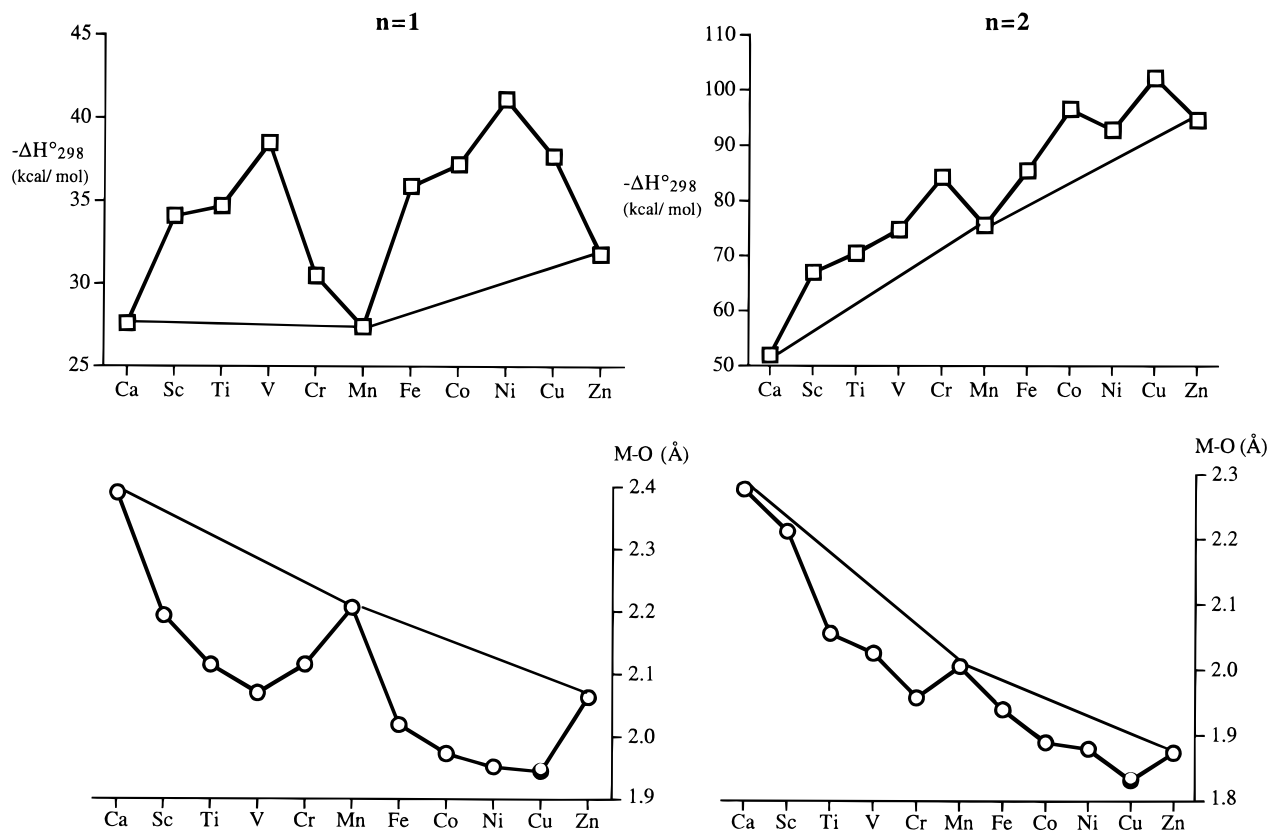

$$\Delta H_{298}^{\circ} = A + B(1/M-O) \quad (1)$$

Values for the parameters A and B and the correlation coefficients r are listed in Table 4A. The anomalous behavior of the group 3A hydrates (see Figure 2) is connected with the presence of a formally fully occupied s shell in conjunction with a totally unoccupied p shell. The anomaly is such that for the

**Figure 2.** Plots of  $-\Delta H_{298}^{\circ}$  versus  $1/M-O$  for the main group metal ion monohydrates,  $M^+-OH_2$  in groups 2A, 3A, and 4A in the second, the third, and the fourth periods, using energies from the CCSD(T)(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* single-point calculations; thermal corrections and M–O distances were calculated at the MP2(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* level. The anomalous behavior of the group 3A hydrates is connected with a formally fully occupied s shell in conjunction with a totally unoccupied p shell.

**Figure 3.** Variation of the enthalpy of hydration and the M–O bond distance for the monovalent ( $n = 1$ ) and divalent ( $n = 2$ ) transition metal ion monohydrates.

value of  $\Delta H_{298}^{\circ}$ , the M–O distance is smaller than expected, implying that for this particular electronic configuration the ion is more compact in relation to neighboring ions having valence shells with unpaired electrons.

The corresponding data for the divalent ions of the main group hydrates,  $M^{2+}-OH_2$ , show a similar anomaly. In this case it would appear that the M–O values for the group 4A ion—which likewise have a formally fully occupied s shell and a totally

<sup>a</sup> Correlation coefficient. <sup>b</sup> Two-point data for groups 2A and 3A.

unoccupied p shell—are too small. Parameters for the linear equation based on the remaining points for the group 2A and 3A ions are also listed in Table 4A.

There is much less variation in the O–H bond length and HOH bond angle in the transition metal ion monohydrates as the 3d shell becomes filled in going from Sc<sup>n+</sup> to Zn<sup>n+</sup>, see Table 3, compared to values for main group metal ion hydrates. In the water moiety both bond lengths and angles are again greater in the hydrates than in unbound H<sub>2</sub>O. For the monovalent and divalent ion hydrates the O–H bond lengths are fairly constant, 0.965 ± 0.001 and 0.978 ± 0.002 angstroms, respectively, and the HOH bond angle is also fairly constant for the monovalent ion hydrates, 106.7 ± 0.6°. However, for the divalent ion hydrates there is a slight tendency for the bond angle to be less for the lower atomic number ions, 105.2 ± 0.8° for Sc<sup>2+</sup> to Mn<sup>2+</sup> compared to 107.6 ± 1.0° for Fe<sup>2+</sup> to Zn<sup>2+</sup>. In marked contrast, the M–O bond distance and the enthalpy of hydration are affected to a far greater extent as the 3d shell becomes filled. In common with many other properties of transition metal compounds the  $\Delta H_{298}^{\circ}$  values follow a typical “double-humped” curve with respect to baseline values for Ca<sup>n+</sup>, Mn<sup>n+</sup>, and Zn<sup>n+</sup> <sup>41a–f</sup> whereas the M–O bond distances lie on an inverted double-humped curve, see Figure 3. This double hump characteristic is due to the occupation of the 3d orbitals which project well out to the periphery of the

metal ions and are thus able to influence their environment significantly; hence many of the properties of these ions with a partly filled d shell are quite sensitive to the number and arrangement of the d electrons present.<sup>41g</sup>

Even though the M–O distance and hydration enthalpy of the transition metal monohydrates vary with atomic number in such a complex manner, they are nevertheless inter-related via eq 1 as are the values for the main group metal ion hydrates. Plots of  $\Delta H_{298}^{\circ}$  versus 1/(M–O) are set out in Figure 4, using total molecular energies from the CCSD(T)(FULL)/6-311++G\*\* calculations and M–O distances and thermal corrections from the MP2(FULL)/6-311++G\*\* calculations. If all the monovalent hydrates, Ca<sup>+</sup>–OH<sub>2</sub> through Zn<sup>+</sup>–OH<sub>2</sub> are taken together the correlation coefficient is rather poor, -0.70, see Table 4A. But if they are taken in two groups, Ca<sup>+</sup>–OH<sub>2</sub> through V<sup>+</sup>–OH<sub>2</sub> and Cr<sup>+</sup>–OH<sub>2</sub> through Zn<sup>+</sup>–OH<sub>2</sub> far better linear plots are obtained, Figure 4a<sub>1</sub> and 4a<sub>2</sub>, with correlation coefficients of -0.99 and -0.97, respectively. A distinguishing feature of the hydrates from Ca<sup>+</sup>–OH<sub>2</sub> to V<sup>+</sup>–OH<sub>2</sub> is that the lowest electronic states at both the MP2(FULL)/6-311++G\*\* and CCSD(T)(FULL)/6-311++G\*\* levels have one electron in the 4s orbital whereas, with the exception of Mn<sup>+</sup>–OH<sub>2</sub>, the lowest electronic states for Cr<sup>+</sup>–OH<sub>2</sub> and Fe<sup>+</sup>–OH<sub>2</sub> through Cu<sup>+</sup>–OH<sub>2</sub> have the 4s orbital formally unoccupied. No such division for the divalent monohydrates is necessary since the 4s orbital

**Figure 4.** Plots of  $-\Delta H_{298}^{\circ}$  versus  $1/M-O$  for the monovalent transition metal ion monohydrates, (a<sub>1</sub>)  $\text{Ca}^+$  to  $\text{V}^+$ , (a<sub>2</sub>)  $\text{Cr}^+$  to  $\text{Zn}^+$ , and for the divalent ion monohydrates, (b)  $\text{Ca}^{2+}$  to  $\text{Zn}^{2+}$ .

is formally unoccupied in all these cases. The plot in Figure 4b with all the points taken together,  $\text{Ca}^{2+}$  through  $\text{Zn}^{2+}$ , has a correlation coefficient of  $-0.99$ .

It should be noted that Rosi and Bauschlicher<sup>8</sup> found that the lowest electronic state of  $\text{Fe}^+-\text{OH}_2$  is a  ${}^6\text{A}_1$  state with one electron in the 4s orbital. At the MP2(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* level the lowest electronic state of  $\text{Fe}^+-\text{OH}_2$  is a  ${}^4\text{B}_2$  state and the  ${}^6\text{A}_1$  state is nearly 10 kcal/mol higher in energy. At the CCSD(T)(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* level, however, the  ${}^6\text{A}_1$  state is found to be lowest in energy, some 3.7 kcal/mol lower in energy than the  ${}^4\text{B}_2$  state, see Table 1. There is also a discrepancy as to the lowest electronic state of  $\text{Co}^+-\text{OH}_2$ , but the energy differences at both computational levels are quite small, see Table 1.

**B. Vibrational Frequencies.** The vibrational modes for the monohydrates are depicted in Chart 2.<sup>12</sup> Vibrational frequencies for the main group metal ion monohydrates,  $\text{M}^+-\text{OH}_2$  and  $\text{M}^{2+}-\text{OH}_2$ , calculated using the MP2(FULL)/6-311++G\*\* computational level are listed in Supplementary Table 4S, and values for the transition metal ion monohydrates in Table 5S. For  $\text{Li}^+-\text{OH}_2$ , our calculated frequencies attributed to the water molecule within the complex of 1691, 3840, and 3924  $\text{cm}^{-1}$  are in good agreement with those obtained experimentally; 1648, 3832, and 3943  $\text{cm}^{-1}$ .<sup>11</sup>

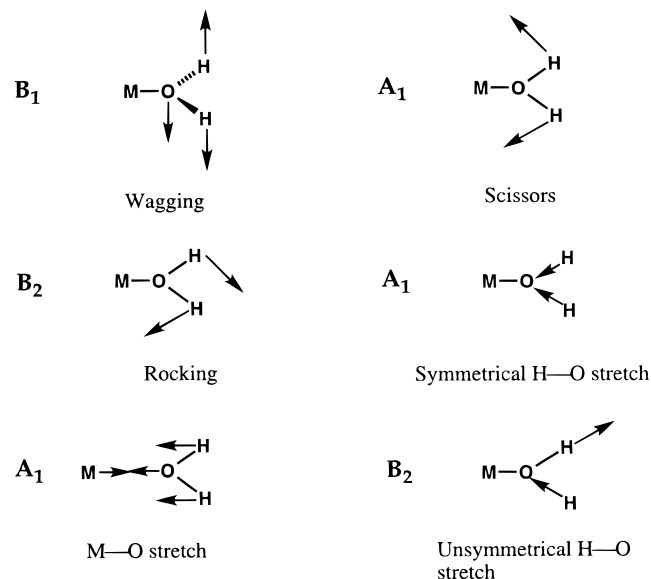

The scissors mode,  $\text{A}_1$ , and the symmetrical and unsymmetrical H—O stretching modes,  $\text{A}_1$  and  $\text{B}_2$ , are common to both bonded and free  $\text{H}_2\text{O}$ . Both of these stretching frequencies are smaller throughout groups 1A  $\rightarrow$  4A in the second, third and the fourth periods. Within these series, however, there is a difference. The  $\text{A}_1$  and  $\text{B}_2$  frequencies get progressively smaller in going from group 1A(2A) to group 4A; whereas both frequencies tend to increase in going from the second to the third, to the fourth period. The corresponding values for the transition metal ion mono- and divalent hydrates are also consistently smaller than those for free  $\text{H}_2\text{O}$ , but there seems to be no systematic variation with atomic number.

The wagging mode,  $\text{B}_1$ , the rocking mode,  $\text{B}_2$  (and the M—O stretching mode,  $\text{A}_1$ ) originate in the binding of the metal ion

**Figure 5.** Plots of the M—O stretching frequency,  $\text{A}_1$ , versus  $1/(M-O)$  for the monovalent transition metal ion monohydrates, (a<sub>1</sub>)  $\text{Ca}^+$  to  $\text{V}^+$ , (a<sub>2</sub>)  $\text{Cr}^+$  to  $\text{Zn}^+$ , and for the divalent metal ion monohydrates, (b)  $\text{Ca}^{2+}$  to  $\text{Zn}^{2+}$ .

**Chart 2.** Vibrational Modes<sup>12</sup>

to the water. There are no apparent trends in the  $\text{B}_1$  and  $\text{B}_2$  frequencies for the main group monohydrates. With the transition metal monohydrates  $\text{B}_1$  tends to decrease with increasing atomic number, but in an irregular manner. Nevertheless the values for the monovalent and the divalent ions of V and Cr, and likewise those for Ni and Cu, lie appreciably below the baselines defined by the values for Ca and Mn, and Mn and Zn, suggesting that there is an underlying *inverted* double-humped curve. The transition metal  $\text{B}_2$  frequencies, on the other hand, follow the more common double-humped curve, see Figure 1S. Overall, these frequencies increase as the M—O distance decreases, like the bonding enthalpies shown in Figure 3 and are found to obey the corresponding inverse relationship,

$$\nu = A + B(1/M-O) \quad (2)$$

(See Figure 2S and Table 6S of the deposited materials.)

The M—O stretching frequencies,  $\text{A}_1$ , for the mono- and the divalent transition metal ion monohydrates also follow double-humped curves, see Figures 3S and 4S, respectively. The values increase as the M—O distance decreases, and likewise obey an inverse relationship, see Figure 5 and Table 6S. In the case of the monovalent hydrates the values fall into two groups,  $\text{Ca}^+$

**Figure 6.** Plots of the M–O stretching frequency,  $A_1$ , versus  $1/(M-O)$  for the monovalent main group metal ion monohydrates in group A of the second, third, and fourth periods.

to  $V^+$ , and  $Cr^+$  to  $Zn^+$ , like the  $\Delta H_{298}^\circ$  values in Figure 4. Since  $\Delta H_{298}^\circ$  and the M–O stretching frequency both show an inverse dependence on the M–O distance, it follows that there should be a linear relationship between the two. Good linear plots are obtained in accord with the equations

$$H_{298}^\circ = A' + B' \nu_{M-O} \quad (3)$$

and

$$\nu_{M-O} = A'' + B'' \Delta H_{298}^\circ \quad (4)$$

values for the parameters  $A'$ ,  $B'$ ,  $A''$ ,  $B''$  and the correlation coefficients are listed in Table 4B.

The M–O stretching frequencies for the main group metal ion monohydrates show similar behavior, although the values for the monovalent ions in group 3A and those for the divalent ions in group 4A, in which the outer valence shell is  $ns^2$ , appear to be abnormally low. See Figure 6 for the plots of  $\nu_{M-O}$  versus  $1/M-O$  for the monovalent ions, and Table 6S for the parameters and correlation coefficients in eq 2.

**C. Orbital Occupancy.** The metal orbital occupancy in the monohydrates of the main group and transition metal ions, calculated using natural population analysis (NPA) with the MP2(FULL)/6-311++G\*\* densities are listed in Tables 7S and 8S respectively in the Supporting Information.

A common feature of the NPA analysis of the main group monohydrates is a small (typically less than 0.1) electron deficit in the valence orbital,  $ns$ , of the metal ion along with a definite electron presence in the (formally unoccupied) Rydberg orbitals. For example, in the case of  $Al^+-OH_2$  we find  $3s^{1.92} 3p^{0.10} 3d^{0.10} 4p^{0.01}$ , for  $Al^{2+}-OH_2$  we find  $3s^{0.99} 3p^{0.12} 3d^{0.01} 4p^{0.01}$  and for  $Si^{2+}-OH_2$  we find  $3s^{1.91} 3p^{0.22} 3d^{0.02} 4s^{0.01} 4p^{0.01}$ .

The valence orbital occupancy in the transition metal ion monohydrates—3d, together with 4s in the case of many of the monovalent hydrates—falls into three categories. In the first group, similar to the main group hydrates, the valence occupancy is less than the formal integral value. These include  $Cr^+-OH_2$  to  $Zn^+-OH_2$ , and  $Co^{2+}-OH_2$  to  $Zn^{2+}-OH_2$ . For example, we find  $Co^+-OH_2$ ,  $3d^{7.80} 4s^{0.11} 4p^{0.03} 4d^{0.10} 4f^{0.02}$ , instead of the formally expected  $3d^8 4s^0$  values. In the second group the occupancy is greater than the formal integral value, and this

group includes  $Sc^+-OH_2$ ,  $Ti^+-OH_2$ ,  $V^+-OH_2$  as well as  $Sc^{2+}-OH_2$ ,  $Ti^{2+}-OH_2$ , and  $Cr^+-OH_2$ . Examples of this second group are  $Ti^+-OH_2$  where the calculated orbital occupancy is  $3d^{2.20} 4s^{0.87} 4p^{0.02} 4d^{0.02} 4f^{0.01}$  instead of the formal  $3d^2 4s^1 4p^0$ , and  $Cr^{2+}-OH_2$  with an orbital occupancy of  $3d^{4.08} 4s^{0.02} 4p^{0.02} 4d^{0.02} 4f^{0.01}$  instead of the formal  $3d^4 4s^0$ . In the third group, the values are the same, i.e.,  $Mn^{2+}-OH_2$ ,  $3d^{5.0}$ , and  $Fe^{2+}-OH_2$ ,  $3d^{6.0}$ .

The occupancy in the oxygen and hydrogen orbitals in the hydrates provides an explanation for the trends in O–H bond lengths and HOH bond angles noted in section A, Table 2. The formation of the O–H bond is attributable to the overlap of the  $2p_y$  and  $2p_z$  atomic orbitals of the O-atom with the  $1s$  orbital of the H atom, see Figure 1. Now the total occupancy in these orbitals (counting both H atoms) is found to decrease in going from  $Li^+$  to  $C^+$ , i.e., 4.202, 4.168, 4.087, and 3.978, and from  $Na^+$  to  $Si^+$ , i.e., 4.205, 4.185, 4.180, and 4.145, in accord with the observed lengthening of the O–H bond. The values for the divalent hydrates,  $Be^{2+}$  to  $C^{2+}$  and  $Mg^{2+}$  to  $Si^{2+}$ , show a similar decrease, namely 4.143, 3.976, 3.803 and 4.177, 4.120, and 4.098, respectively. On the other hand, the total occupancy in these orbitals is found to increase in going from the second to the third Period, in accord with the observed shortening of the O–H bond.

The monotonic increase in occupancy in the  $2p_y$  orbital in conjunction with the decrease in occupancy in the  $2p_z$  orbital accounts for the observed increased in the HOH bond angle in going from group 1A to 4A.

**D. Atomic Charge Distribution.** The NPA atomic charges from the MP2(FULL)/6-311++G\*\* density on the metal, the oxygen, and the hydrogens— $q_M$ ,  $q_O$ , and  $q_H$ —in the mono- and divalent main group metal ions and the transition metal ions are listed in Tables 5 and 6; the values of  $q_O$  and  $q_H$  for unbound  $H_2O$  are  $-0.898$  and  $+0.449$ , respectively. The corresponding AIM charges for a variety of main group monohydrates are given in Table 9S of the Supporting Information. These charges tend to show less charge transfer to the metal than those of the NPA charges.

Comparison of the values for the hydrate with those for unbound water shows that hydrate formation is consistently accompanied by an increase in the electronic charge on the

oxygen and a (significantly larger) decrease in the electronic charge on the hydrogens. There is thus charge transfer from the water to the metal ion, see Tables 5 and 6. This transfer increases for both the mono- and divalent ions of the main group metal monohydrates in going from group 1 → 2 → 3 → 4, and decreases in going from second to the third and to the fourth period.

The charge on the metal,  $q_M$ , for both the mono- and divalent transition metal ion monohydrates follows an inverted double-humped dependency in going from Ca to Zn, see Figure 5S. This is reflected in the charge transfer which goes through two maxima in a corresponding double-humped curve, see Table 6.

## Discussion

Two aspects of the present results call for further comment. First, the magnitude of the ligand field stabilization energies for the monohydrates of the divalent transition metal ions (calculated using the bonding enthalpies for Ca<sup>2+</sup>-OH<sub>2</sub> and Mn<sup>2+</sup>-OH<sub>2</sub>, and Mn<sup>2+</sup>-OH<sub>2</sub> and Zn<sup>2+</sup>-OH<sub>2</sub> as baseline values) may be compared with the stabilization energies for multi-ligand species such as the aquo-ions [M<sup>2+</sup>(H<sub>2</sub>O)<sub>6</sub>]aq and halide and oxide crystal lattices. Taking the values for Fe<sup>2+</sup>, Co<sup>2+</sup>, Ni<sup>2+</sup>, and Cu<sup>2+</sup>, for example, we have calculated the ligand field stabilization energies for these monohydrates to be 6, 13, 6, and 11 kcal/mol, respectively (from Figure 4) compared to the experimental values for the aquo-ions 17, 24, 34, and 25 kcal/mol;<sup>41b</sup> for the fluoride crystal lattice 26, 28, 38, and 29 kcal/mol;<sup>41b</sup> for the chloride crystal lattice 16, 25, 30, and 28 kcal/mol;<sup>41c</sup> and for the oxide crystal lattice 18, 23, 36, and 32 kcal/mol.<sup>41d</sup> The bonding of just one water molecule thus accounts for a substantial fraction of the stabilization energy of the hexacoordinated aquo-ion, and it is perhaps surprising that

the values are as large as they are in relation to those for the charged species F<sup>-</sup>, Cl<sup>-</sup>, and O<sup>2-</sup>.

Second, the bonding enthalpies and the vibrational frequencies for the M-O bond in the monohydrates are very similar to the bond energies (Laidler parameters) and vibrational frequencies for covalent bonds such as C-S, C-Cl, and C-Br, i.e., 70 kcal/mol and 600–700 cm<sup>-1</sup>, 84 kcal/mol and 600–800 cm<sup>-1</sup>, and 71 kcal/mol and 500–600 cm<sup>-1</sup>, respectively.<sup>42,43</sup>

## Concluding Remarks

Our main findings are described in the following points.

(i) With the single exception of the 3A'' excited state of Co<sup>+</sup>-OH<sub>2</sub>, all the hydrates studied are planar at the MP2(FULL)/6-311++G\*\* level.

(ii) In general, the trends in the various properties can be correlated with the progressive occupancy of the s, p, and d orbitals.

(iii) In particular, attributing the formation of the O–H bond to the overlap of the  $2p_y$  and  $2p_z$  atomic orbitals of the O atom with the  $1s$  orbital of the H-atom, the trends in O–H bond length and  $\angle\text{HOH}$  for the main group hydrates can be accounted for by the progressive changes in the total electron occupancy in these orbitals.

(iv) In going from Ca to Mn to Zn the properties of the transition metal ion monohydrates follow typical “double-humped” curves.

(v) Both the enthalpies of formation and the M–O stretching frequencies are inversely proportional to the M–O distance: thus the stronger the bonding in the hydrate the larger the stretching frequency for the M–O bond.

(vi) Comparison of the distribution of atomic charge on the unbound water molecule with the distribution in the hydrates shows that hydrate formation is consistently accompanied by a small but definite increase in the electronic charge on the oxygen and a (significantly larger) decrease in electronic charge on the hydrogens, so that there is a net transfer of charge from the water to the metal ion.

(vii) With the exception of  $\text{Fe}^+-\text{OH}_2$  and  $\text{Co}^+-\text{OH}_2$ , the MP2(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* and CCSD(T)(FULL)/6-311++G\*\*//MP2(FULL)/6-311++G\*\* calculations find the same electronic configurations for the ground states of the first-row mono- and divalent transition metal monohydrates. Furthermore, the calculated binding enthalpies of *corresponding* states of these monohydrates are generally in good agreement at both computational levels, with the largest

difference, 4.8 kcal/mol, involving  $\text{Ni}^+-\text{OH}_2$  where the d shell is nearly complete.
