# **S** Supporting Information

[AB](#page-5-0)STRACT: [The halopero](#page-5-0)xidase-catalyzed in vivo oxidation of thiocyanate ion  $(SCN^-)$  by  $H_2O_2$  is important for generation of the antimicrobial hypothiocyanite ion (OSCN<sup>−</sup>), which is also susceptible to oxidation by strong in vivo oxidizing agents (i.e.,  $H_2O_2$ , OCl<sup>−</sup>, OBr<sup>−</sup>). We report a detailed mechanistic investigation on the multistep oxidation of excess  $SCN^-$  with peroxomonosulfate ion  $(HSO_S^-$  in the form of Oxone) in the range from pH 6.5 to 13.5. OSCN<sup>−</sup> was detected to be the intermediate of this reaction under the above conditions, and a kinetic model is proposed. Furthermore, by kinetic separation of the consecutive reaction

steps, the rate constant of the direct oxidation of OSCN<sup>−</sup> by HSO<sub>5</sub><sup>−</sup> was determined:  $k_2 = (1.6 \pm 0.1) \times 10^2$  M<sup>−1</sup> s<sup>−1</sup> at pH 13.5 and  $k_2$ <sup>H</sup> = (3.3  $\pm$  0.1)  $\times$  10<sup>3</sup> M<sup>-1</sup> s<sup>-1</sup> at pH 6.89. A critical evaluation of the estimated activation parameters of the elementary steps revealed that the oxidations of SCN<sup>−</sup> as well as the consecutive OSCN<sup>−</sup> by HSO<sub>5</sub><sup>−</sup> are more likely to proceed via 2e<sup>−</sup>transfer steps rather than 1e<sup>−</sup> transfer.

# **■ INTRODUCTION**

The diverse, and often catalytic oxidation reactions of thiocyanate anion (SCN<sup>−</sup>) are intensively studied (vide infra) because the biological importance of this anion is connected to its vivid in vivo redox chemistry.<sup>1</sup> In addition, SCN<sup>−</sup> is an environmental pollutant, and its oxidative removal from industrial wastewater is essential. Furthermore, the in situ oxidation of SCN<sup>−</sup> is of fundamental importance during thiocyanation of various compounds in synthetic organic chemistry.

Thiocyanate ion is enzymatically oxidized by  $H_2O_2$  to the antimicrobial hypothiocyanite ion<sup>2</sup> (OSCN<sup>-</sup>) in vivo.<sup>3-5</sup> The rate of the direct  $SCN^- + H_2O_2$  reaction is slow,<sup>6</sup> but defensive peroxidase enzymes found in ne[ut](#page-5-0)rophils  $(m$ yeloper[ox](#page-5-0)i[d](#page-5-0)ase $^7)$ and eosinophil granulocites (eosinophil peroxi[da](#page-5-0)se<sup>8</sup>) catalyze this reaction effectively. Extracellular enzymes in m[ilk](#page-5-0) (lactoperoxidase<sup>9</sup>), in airways (lactoperoxidase<sup>10</sup>), a[nd](#page-5-0) in saliva (salivary peroxidase $^{11}$ ) are also efficient catalysts for the oxidation of SC[N](#page-5-0)<sup>−</sup> by  $H_2O_2$ . Furthermore, O[SC](#page-5-0)N<sup>−</sup> is a potent bactericide and plays [an](#page-5-0) important role in multiple stages of the nonimmune defense system $3,4$  at several physiological locations (e.g., in the mouth<sup>12</sup> and in airways<sup>13,14</sup>). Thus, the insufficiently low in vivo l[oca](#page-5-0)l concentration of its precursor SCN<sup>−</sup> is assumed to pl[ay](#page-5-0) an important role [in the](#page-5-0) development of several chronic diseases, like cystic fibrosis.1,15 SCN<sup>−</sup> can be oxidized to OSCN<sup>−</sup> in a noncatalytic way by hypochlorous acid  $(HOCl)<sup>16</sup>$  $(HOCl)<sup>16</sup>$  $(HOCl)<sup>16</sup>$  and by hypobromous acid  $(HOBr)<sup>17</sup>$  These reactions may be important in controlling the redox activities of those [d](#page-5-0)efensive peroxidase systems where SCN<sup>−</sup>[/O](#page-5-0)SCN<sup>−</sup>

and Cl<sup>−</sup>/OCl<sup>−</sup> or Br<sup>−</sup>/OBr<sup>−</sup> are simultaneously present. The understanding of the in vivo redox chemistry of SCN<sup>−</sup> is further complicated by the fact that the 2e<sup>−</sup> oxidation product of SCN<sup>-</sup>, OSCN<sup>-</sup>, can be subsequently oxidized by the same oxidizing agents as  $SCN^-$ , i.e.,  $H_2O_2$ , HOCl, or HOBr.<sup>3-5</sup> The reactions of OSCN<sup>−</sup> with these oxidizing agents are difficult to study because OSCN<sup>−</sup> cannot be synthesized in the ab[sen](#page-5-0)ce of excess SCN<sup>−</sup>. This problem is attributed to the "overoxidation" of OSCN<sup>−</sup>, which is assumed to be of a similar order of magnitude as its production from SCN<sup>−</sup>. 3,5,18 The half-life of the decomposition of OSCN<sup>−</sup> is on the order of several minutes at  $pH 7<sup>19</sup>$  further limiting the ap[plicab](#page-5-0)le experimental conditions.

From environ[me](#page-5-0)ntal aspects, SCN<sup>−</sup> and cyanide ion (CN<sup>−</sup>) are considered to be the main inorganic anionic pollutants of wastewater and recycled water from metallurgical, mostly gold extraction plants. Although the toxicity of CN<sup>−</sup> is undoubtedly higher than that of SCN<sup>−</sup>, the latter can be found in larger quantities in metallurgical wastewater and is more toxic to fish. The removal of SCN<sup>−</sup> is important for the detoxification of industrial water because molecular oxygen can oxidize SCN<sup>−</sup> to sulfate  $(SO_4^2$ <sup>-</sup>) and  $CN^-$  on a longer time scale, especially under UV radiation. For this reason, the admissible limit of SCN<sup>−</sup> in metallurgical wastewater is usually as low as 0.05 mg/ L. Technologically feasible processes for SCN<sup>−</sup> removal almost exclusively utilize oxidative degradation approaches.<sup>20</sup> The

Received: November 20, 2012 Published: January 30, 2013

<span id="page-1-0"></span>fundamental reactions of these processes are catalytic, $21-23$ photocatalytic,  $2^{4,25}$  and also biological oxidations.  $2^{6,27}$  The universal goal is to convert SCN<sup>−</sup> quantitatively into en[viron](#page-5-0)mentally mor[e tole](#page-5-0)rable cyanate ion (OCN<sup>−</sup>) [or car[bona](#page-5-0)te ion  $(CO_3^2$ <sup>2–</sup>) and nitrogen  $(N_2)$ ] and  $SO_4^2$ <sup>–</sup>. The oxidizing agents of choice are usually hydrogen peroxide  $(H_2O_2)^{21}$  and ozone  $(O_3)^{23}$  in order to avoid the formation of any hazardous side products.

T[he](#page-5-0) oxidation of SCN<sup>−</sup> plays a crucial role in organic synthetic strategies aiming at the preparation of thiocyanated compounds. To create a reactive intermediate for thiocyanation of both aromatic<sup>28−30</sup> and aliphatic<sup>31−33</sup> compounds, a mixture of various oxidizing agents is used in situ with thiocyanate salts. Some of these s[ynthet](#page-5-0)ic methods [util](#page-5-0)i[ze](#page-6-0)  $\mathrm{HSO}_5^-$  in the form of Oxone as the oxidizing agent in order to achieve milder reaction conditions with higher yields.<sup>30,32,33</sup>

 $HSO_5^-$  is a peroxo compound and resembles  $H_2O_2$  in its redox behavior, although the reactions of  $HSO_5^ HSO_5^ HSO_5^-$  with inorganic reducing agents<sup>34,35</sup> are characteristically faster than those of  $H_2O_2$ . The oxygen-transfer reactions of  $HSO_5^-$  to halide ions (Cl<sup>−</sup>, Br<sup>−</sup>, and [I](#page-6-0)<sup>−</sup>[\)](#page-6-0) are described in detail.<sup>34</sup> Stoichiometric<sup>36</sup> and kinetic results<sup>37,38</sup> indicate that the oxidation of SCN<sup>−</sup> by  $\mathrm{HSO}_5^-$  is a complicated multistep pr[oce](#page-6-0)ss under aci[dic](#page-6-0) conditions, from [pH](#page-6-0) 2.2 to 6.3. The end products were identified as OCN<sup>-</sup>, CN<sup>-</sup>, and  $SO_4^{2-36}$  On the basis of calculations by the initial rate method and using numerical integration for simulating kinetic obse[rva](#page-6-0)tions, Smith and Wilson concluded that the key initial step in the overall reaction is the equilibrium (R0H) between  $\text{SCN}^-$  and  $\text{HSO}_5^{-37,38}$ where "HOSCN" is an uncharacterized intermediate.

$$
HSO_5^- + SCN^- \rightleftharpoons SO_4^{2-} + HOSCN
$$
 (R0H)

The formation of a second intermediate [thiocyanogen:  $(SCN)_2$  is proposed in the rapid comproportionation of SCN<sup>−</sup> and HOSCN, which inhibits accumulation of HOSCN under acidic conditions. This comproportionation is well characterized in the literature.<sup>19,39</sup> In our present study, the kinetics and mechanism of the oxidation of SCN<sup>−</sup> by  $\mathrm{HSO}_5^{-}$ are characterized in a wide [ra](#page-5-0)[ng](#page-6-0)e of pH values from the physiologically relevant neutral to the highly basic, where the comproportionation of  $SCN^-$  +  $OSCN^-$  to give  $(SCN)_2$  is negligible;<sup>19</sup> thus, OSCN<sup>−</sup> accumulates.

#### ■ EXP[ERI](#page-5-0)MENTAL SECTION

Reagents and Solutions. NaSCN (99.99+ %) and Oxone were purchased from Sigma-Aldrich and used without further purification. The KHSO $<sub>5</sub>$  content of Oxone was regularly checked by iodometric</sub> titration. All other chemicals were purchased in the highest available purity and used without further purification. Ultrafiltered (Milli-Q, Millipore) water was used for preparing solutions. The pH of the reaction mixture was maintained either by phosphate buffer (from pH 6.5 to 7.8), by borate buffer (from pH 8.0 to 10), or by NaOH (from pH 11 to 13). The pH was measured by a Metrohm 6.0234.110 combined glass electrode attached to a Metrohm 721 NET Titrino titrating unit. The electrode was calibrated by two buffers according to IUPAC recommendations.<sup>40</sup> The ionic strength was adjusted by NaClO<sub>4</sub>.

Kinetic Measurement[s.](#page-6-0) Fast kinetic experiments were carried out in an Applied Photophysics DX-17 MV stopped-flow instrument with either a photomultiplier tube or a photodiode array installed as the detector. Absorbance traces were collected using an optical cell of 10.0 mm path length. The dead time of the stopped-flow instrument was determined by the reaction of 2,6-dichlorophenol−indophenol with ascorbic acid (AA) under pseudo-first-order conditions with AA in excess.<sup>41</sup> The dead time of the instrument was measured to be 1.51  $\pm$  0.03 ms, allowing determination of the first-order rate constants  $(k_{obs})$ up to 500 s<sup>-1</sup>. The temperature was maintained within ±0.1 °C during all stopped-flow measurements with a Julabo F-12 refrigerated/heated circulator.

Electrospray Ionization Mass Spectrometry (ESI-MS). ESI-MS measurements were performed with a Bruker micr $\text{OTOF}_{\Omega}$  mass spectrometer equipped with a quadrupole and time-of-flight (Q-TOF) analyzer. The detailed description of the methodology is given in our recent study.<sup>19</sup> The aim of the MS experiments was to identify the intermediates and products of the  $\text{HSO}_5^-$  + SCN<sup>−</sup> reaction in a quick and sensitive[, b](#page-5-0)ut qualitative way.

**Software.** The raw data sets of the measurements were processed with instrument-controlling software. Typically, Micromath Scientist  $2.0^{42}$  was used for Levenberg–Marquard least-squares fitting procedures. Multiple sets of kinetic curves recorded under different ini[tial](#page-6-0) condititions were simultaneously evaluated with the program package  $ZiTa^{43}$  using the GEAR algorithm.<sup>44</sup>

#### ■ RESUL[TS](#page-6-0) AND DISCUSSION

Oxidation of SCN<sup>-</sup> with  $HSO<sub>5</sub><sup>-</sup>$  in the Range from pH 7 to 13. For the sake of simplicity, we studied the reaction of  $HSO_5^-$  with SCN<sup>-</sup> at pH 13.5 first, where  $HSO_5^-$  is fully deprotonated  $[pK_a(HSO_S^-)] = 8.35$  at  $I = 1.0 \text{ M}^{34}$ , and hypothiocyanite (OSCN<sup>−</sup>), the expected product of an oxygen transfer to SCN<sup>-</sup>, is stable for hours.<sup>45</sup> The reac[tio](#page-6-0)n was studied under high excess of SCN<sup>-</sup> ([SCN<sup>-</sup>]<sub>0</sub> = 50.0-500 [mM](#page-6-0)) over  $SO_5^2$ <sup>2=</sup> ([HSO<sub>5</sub><sup>-</sup>]<sub>0</sub> = 5.0 mM). The reaction is complete in a few seconds under the conditions applied, and additional kinetic effects were not observed on longer time scales. Kinetic traces were recorded at various wavelengths in the range of 350−500 nm (Figure 1) and analyzed by singular-

Figure 1. UV–vis spectral change recorded in the  $SO_5^{2-} + SCN^$ reaction system at pH 13.5. The absorbance maximum at 376 nm is characteristic of OSCN<sup>−</sup>. The first (blue) and last (red) spectra are highlighted. Inset: Kinetic curve recorded at 376 nm.  $[KHSO<sub>5</sub>]_{0} = 5.0$ mM;  $[NaSCN]_0 = 500$  mM; pH 13.5;  $I = 1.0$  M;  $T = 25.0$  °C.

value decomposition analysis (Table S1 in the Supporting Information) in order to determine the number of absorbing species in the system. $46,47$  It was found that the [increase in](#page-5-0) [absorbance](#page-5-0) during the reaction at around 375 nm can be attributed to the for[mation](#page-6-0) of a single species; no absorbing intermediates were detected. The observed product was unambiguously identified as OSCN<sup>−</sup> with an absorbance maximum at 376 nm.<sup>48</sup> OSCN<sup>−</sup> was also identified with an ESI-MS method (see the Supporting Information) described in our recent study.<sup>19</sup> I[n](#page-6-0) subsequent experiments, the kinetic curves were exclusively r[ecorded at 376 nm, whe](#page-5-0)re neither the reactants nor oth[er](#page-5-0) products contribute to the absorbance. All kinetic traces (Figure 2, right panel) could be fitted with a single-exponential function within the precision of the experimental data ( $R^2 > 0.98$  $R^2 > 0.98$  $R^2 > 0.98$ ) and show the following

<span id="page-2-0"></span>

Figure 2. Reaction of SCN<sup>−</sup> with SO<sub>5</sub><sup>2−</sup> at pH 13.5. Left panel: experimental pseudo-first-order kinetic curves; only 5% of the recorded points are shown for clarity. Right panel: pseudo-first-order rate constant as a function of the initial SCN<sup>−</sup> concentration. Inset: Final absorbance at 376 nm as a function of the initial SCN<sup>−</sup> concentration. The symbols are the same for the two panels. Circles: experimental points with SCN<sup>−</sup> in high excess. Triangles: comparable  $\text{[SCN]}_0$  and  $\text{[SO}_5{}^{2-}\text{]}_0$ . Lines: result of a global fit to the kinetic model of Scheme 1.  $\text{[KHSO}_5]_0 = 5.0 \text{ mM}; \text{[NaSCN]}_0 = 5.0-$ 500 mM; pH 13.5;  $I = 1.0$  M;  $T = 25.0$  °C.

characteristics: the final absorbance readings reach a limiting value by increasing  $[SCN^-]_0$ , and the experimental pseudo-firstorder rate constant  $(k_{obs})$  is linearly dependent on  $[SCN^-]_0$ with a nonzero intercept (Figure 2, left panel).

At high SCN<sup>−</sup> excess, OSCN<sup>−</sup> is produced following a 1:1  $OSCN^{-}$ -to- $SO_5^2$  stoichiometry. From the highest final absorbance,  $[OSCN^-]_{max} = 5.1$  mM was calculated using the literature value of the molar absorbance of OSCN<sup>−</sup> at 376 nm  $(26.5 \text{ M}^{-1} \text{ cm}^{-1})$ .<sup>48</sup> Phenomenologically, such observations can be explained by an equilibrium reaction between the reactants  $(R0)$ , which is [pse](#page-6-0)udo-first-order in both directions<sup>49</sup> (these conditions are fulfilled because  $SCN^-$  and  $SO_4^2^-$  are in large  $excess<sup>50</sup>$  over the limiting reagents):

$$
SO_5^{2-} + SCN^- \rightleftharpoons SO_4^{2-} + OSCN^-
$$
 (R0)

A similar equilibrium (R0H) was proposed previously in the kinetic model of the reaction of  $SCN^{-} + HSO<sub>5</sub>$  under acidic conditions.<sup>37,38</sup> Howe[ver,](#page-1-0) considering that the backward reaction of R0 is hardly feasible thermodynamically<sup>51</sup> and that the ki[netics](#page-6-0) of the  $SO_5^{2-}$  + SCN<sup>-</sup> reaction system proved to be [in](#page-6-0)different to the change in  $[SO_4^{2-}]_0$  (Figure S1 in the Supporting Information), the existence of equilibrium R0 was ruled out. An alternative kinetic model was constructed, [keeping in mind that](#page-5-0) the rate of oxidation of OSCN<sup>−</sup> by peroxo compounds is expected to be about the same order of magnitude as the rate of oxidation of SCN<sup>−</sup>. 3,5,18 In the kinetic model shown in Scheme 1, SCN<sup>−</sup> and its first-step oxidation product OSCN<sup>-</sup> are competing for the r[emain](#page-5-0)ing  $SO_5^2$ <sup>-</sup> in reactions R1 and R2, respectively. With an increasing excess of SCN<sup>−</sup>, the relative rate of the oxidation of OSCN<sup>−</sup> decreases; thus, the surviving amount of OSCN<sup>−</sup> increases. The stoichiometry of the production of OSCN<sup>−</sup> becomes 1:1 (OSCN<sup>--</sup>to-SO<sub>5</sub><sup>2-</sup>) at high [SCN<sup>--</sup>]<sub>0</sub>. The oxidation product of OSCN<sup>-</sup> (i.e.,  $O_2SCN^-$ ) is known to decompose in fast reactions (R3–R6, adopted from the literature $^{39,52}$ ) to yield the final mixture of stable anions:  $SO_4^{2-}$ ,  $SO_3^{2-}$ ,  $CN^-$ , and OCN<sup>-</sup>.<sup>19,39,52</sup> The production of  $SO_4^2^-$ , CN<sup>-</sup>, [an](#page-6-0)d OCN<sup>-</sup> is observed during the oxidation of  $SCN^-$  by  $HSO_5^-$  at acidic  $pH.<sup>36</sup>$  [T](#page-5-0)[he](#page-6-0) formation of  $SO_3^2$ <sup>-</sup> is detected during the decomposition of OSCN<sup>−</sup> at neutral pH.<sup>19</sup> The presence of CN<sup>[−](#page-6-0)</sup> and OCN<sup>−</sup> in the basic SCN<sup>−</sup> +  $SO_5^2$ <sup>−</sup> reaction mixture was verified by ESI-MS in this study ([se](#page-5-0)e the Supporting Information) with a method detailed earlier.<sup>19</sup> The experimental kinetic data set recorded at pH 13.5 was fit[ted globally](#page-5-0)

Scheme 1. Kinetic Model for the Oxidation of SCN<sup>−</sup> by  $SO_5^2$ <sup>-</sup> at around pH 13<sup>a</sup>

 $SO_5^{2-}$  + SCN  $\rightarrow SO_4^{2-}$  + OSCN  $k_{1}$  $(R1)$ 

$$
SO_5^{2-} + OSCN \rightarrow SO_4^{2-} + O_2SCN \qquad k_2 \qquad (R2)
$$

$$
2 O_2SCN \rightarrow O_3SCN + OSCN \tag{R3}
$$

$$
O_2SCN + OSCN \rightarrow O_3SCN + SCN \qquad (R4)
$$

$$
O_3SCN + 2 OH \rightarrow SO_4^{2-} + CN + H_2O \qquad (R5)
$$

$$
O_3SCN + 2 OH \rightarrow SO_3^{2-} + OCN + H_2O \qquad (R6)
$$

<sup>a</sup>Although  $k_1 \ll k_2$ , at high concentrations of SCN<sup>−</sup>, the first oxidation step (R1) can compete with the faster second step  $(R2)$ ; thus, OSCN<sup>-</sup> can accumulate. Reaction steps R3, R4, R5, and R6 in italics are<br>adopted from the literature<sup>52,39</sup> and assumed to be much faster than R1 and R2.

to the two-step kinetic model utilizing the ZiTa software package and assuming that both the R1 and R2 steps are firstorder for each species involved. The actual rates of reactions R3 and R4 were considered to be comparable and much faster than those of the rate-determining steps (R1 and R2) over the entire course of the reaction, thus not affecting the stoichiometry of the depletion of OSCN<sup>−</sup>. The fit was excellent even at comparable initial concentrations of SCN<sup>-</sup> and SO<sub>5</sub><sup>2-</sup> (Figure 2). The calculated rate constants are  $k_1 = 8.08 \pm 0.02 \text{ M}^{-1} \text{ s}^{-1}$ and  $k_2 = 164.8 \pm 0.5 \text{ M}^{-1} \text{ s}^{-1}$ .

A derivation on the basis of the system of simultaneous differential equations defined by Scheme 1 yields the following approximate expression for the concentration change of OSCN<sup>-</sup> as a function of time (see the Supporting Information):

$$
[OSCN^{-}] = \frac{k_{1}[SCN^{-}][SO_{S}^{2^{-}}]_{0}}{k_{1}[SCN^{-}] + k_{2}[SO_{S}^{2^{-}}]_{0}}
$$
  
× {1 - exp[-(k\_{1}[SCN^{-}] + k\_{2}[SO\_{S}^{2^{-}}]\_{0})t]} (1)

Although the derivation shows that Scheme 1 does not predict a simple first-order kinetic trace in a strict mathematical sense, eq 1 implies that the actual solution is close to an exponential curve with a pseudo-first-order rate constant  $k_{obs} = k_2 [\text{HSO}_5^-]_0$ +  $k_1$ [SCN<sup>-</sup>]<sub>0</sub>. This explains why the kinetic traces could be fitted to a simple first-order expression with reasonable

<span id="page-3-0"></span>accuracy. The  $k_{\rm obs}$  versus  $[\mathrm{SCN}^-]_0$  plot in Figure 2 (right panel) can be fitted to  $k_{obs} = m[\text{SCN}^-]_0 + a$  acceptably, yielding  $m = 8.351 \pm 0.001 \text{ M}^{-1} \text{ s}^{-1}$  $m = 8.351 \pm 0.001 \text{ M}^{-1} \text{ s}^{-1}$  $m = 8.351 \pm 0.001 \text{ M}^{-1} \text{ s}^{-1}$  and  $a = 0.601 \pm 0.001 \text{ s}^{-1}$  at constant  $[SO_5^{2-}]_0 = 5.0$  mM. A comparison with eq 1 gives  $k_1$  $= 8.35$  M<sup>-1</sup> s<sup>-1</sup> and  $k_2 = 120$  M<sup>-1</sup> s<sup>-1</sup>. These rate constants are in good agreement with those estimated by globally fitting the experimental data set to the kinetic model of Scheme [1](#page-2-0) without approximations. These results lend further support to the kinetic model proposed in Scheme 1.

The title reaction was also studied in detail at pH 6.[89](#page-2-0), where the protonated form of the oxida[nt,](#page-2-0)  $HSO_5^-$ , is predominant over  $SO_5^{2-}$ , but  $OSCN^-$  is still deprotonated  $[pK_a(HOSCN)] =$ 4.93 at  $I = 1.0 \text{ M}^{19}$ . In the first 100 ms after mixing the reactants, the kinetic behavior of the reaction is similar to that observed at pH 1[3.5](#page-5-0) (Figures 3 and S2 in the Supporting

Figure 3. Experimental kinetic curves recorded in the reaction of  $S\bar{C}N^-$  +  $HS\bar{O}_5^-$  at pH 6.89. Two kinetically separated phases are shown (a third slower step is not included in the figure). The faster process can be described with the kinetic model of Scheme 1. Open circles: experimental curves. Only 5% of the recorded points are shown for clarity. Lines: results of the global fit of the first part of the kinetic traces to the kinetic model of Scheme 1.  $[KHSO<sub>5</sub>]<sub>0</sub> = 5.0$  $[KHSO<sub>5</sub>]<sub>0</sub> = 5.0$  mM; [NaSCN]<sub>0</sub> = 25–500 mM; pH 6.89; I = 1.0 M; T = 25.0 °C.

Information). Thus, the findings can be interpreted using the kinetic model of Scheme 1 by replacing  $\text{SO}_5^{\,2-}$  with  $\text{HSO}_5^-$ :

$$
HSO_5^- + SCN^- \rightarrow SO_4^{2-} + OSCN^- + H^+ \qquad k_1^H
$$
\n
$$
(R1H)
$$

$$
HSO_5^- + OSCN^- \to SO_4^{2-} + O_2SCN^- + H^+ k_2^H
$$
\n
$$
(R2H)
$$

The values of the rate constants were estimated by globally fitting the first part of the kinetic curves with ZiTa:  $k_1$ <sup>H</sup> = 203  $\pm$ 1 M<sup>-1</sup> s<sup>-1</sup> and  $k_2$ <sup>H</sup> = (3.44 ± 0.03) × 10<sup>3</sup> M<sup>-1</sup> s<sup>-1</sup> (Figures 3 and S2 in the Supporting Information). On a longer time scale (>100 ms), two additional kinetically independent reaction steps were [observed. The second](#page-5-0) process (Figure 3) is characterized by a small decrease in the absorbance at 376 nm in a few seconds, and according to the matrix rank analysis of the multivawelength measurements, it does not involve the formation of any new absorbing species (Table S1 in the Supporting Information). A semiquantitative observation was made that the amplitude of the absorbance change during the [second process signi](#page-5-0)ficantly decreases with increasing  $[SCN^-]_0$ and even vanishes at high [SCN<sup>-</sup>]<sub>0</sub>. This phenomenon makes the quantitative description of this reaction step challenging but, on the other hand, leads to the assumption that the second process is probably attributed to the reaction of OSCN<sup>−</sup> with CN<sup>−</sup>:

$$
CN^{-} + OSCN^{-} \rightarrow OCN^{-} + SCN^{-}
$$
 (R7)

CN<sup>−</sup> is formed in reaction R5 (Scheme 1) after the oxidation of OSCN<sup>−</sup> by  $HSO_5^-$  (R2H). With increasing  $[SCN^-]_0$ , the produced amount of CN<sup>−</sup> decreases [a](#page-2-0)s the relative rate of oxidation of OSCN<sup>−</sup> (R2H) decreases. Similar observations were made previously regarding the role of CN<sup>−</sup> in the reaction system of  $SCN^-$  +  $HSO_5^-$  at highly acidic pH.<sup>36,37</sup> The  $CN^-$  + OSCN<sup>−</sup> reaction (R7) was already investigated in detail in a wide range of  $pH$  values by directly mixing th[e two](#page-6-0) reactants<sup>53</sup> and is known to be reasonably fast only at  $pH < 7$ , which explains the absence of this process in the  $SO_5^{2-} + SCN^ SO_5^{2-} + SCN^ SO_5^{2-} + SCN^$ reaction system at pH 13.5. The inclusion of R7 in the kinetic model of Scheme 1 is not necessary because the SCN<sup>−</sup> +  $HSO_5^-$  and  $OSCN^- + CN^-$  reactions are kinetically independent in the [a](#page-2-0)pplied pH range. The third and slowest process observed at pH 6.89 resulted in the complete depletion of OSCN<sup>−</sup> in minutes. This last and slowest process was identified as the hydrolytic decomposition of OSCN<sup>−</sup> to give simple inorganic anions such as  $\text{CN}^-$ ,  $\text{OCN}^-$ ,  $\text{SO}_4^2^-$ , and  $SO_3^{2-}$ , which were already described in our earlier work.<sup>19</sup>

The pH dependence of the  $(H)SO_5^- + SCN^-$  reaction was studied in the range from pH 6.9 to 13.5. The useful pH [ran](#page-5-0)ge was limited because HOSCN rapidly decomposes at 2 < pH < 6<sup>19</sup> and HOSCN and SCN<sup>−</sup> rapidly comproportionate to give  $(SCN)_2$  at pH < 2.<sup>39</sup> In order to determine the apparent rate c[on](#page-5-0)stants for the oxidation of both  $SCN^ (k_1^{\text{app}})$  and  $OSCN^ (k_2^{\text{app}})$  at a given [pH](#page-6-0), the kinetic experiments were run in duplicate at two different  $[SCN<sup>-</sup>]$ <sub>0</sub> values. The two rate constants were computed by simultaneously fitting these pairs of experimental kinetic curves to the kinetic model of Scheme 1. The values of both  $k_1^{\text{app}}$  and  $k_2^{\text{app}}$  decrease in a sigmoidal fashion with increasing pH, as seen in Figure 4. An excellent

Figure 4. pH dependence of the  $SCN^- + (H)SO_5^-$  reaction system. Closed circles (right y scale): apparent rate constants for the oxidation of SCN<sup>−</sup> with  $(H)SO_5$ <sup>−</sup>. Triangles (left y scale): apparent rate constants for the oxidation of OSCN<sup>-</sup> with  $(H)SO_5^-$ . Line: result of a simultaneous fit to eqs 2 and 3. The  $y$  scales are normalized to each other.  $[KHSO<sub>5</sub>]_{0} = 5.0$  mM;  $[NaSCN]_{0} = 50.0$  or 500 mM;  $I = 1.0$  M;  $T = 25.0 °C$ .

description of these pH profiles can be given by taking into account the reactivity difference between  $\text{HSO}_5^-$  and  $\text{SO}_5^{2-}$ :

$$
k_1^{\rm app} = k_1^{\rm H} \frac{\left[{\rm H}^+\right]}{K_{\rm a} + \left[{\rm H}^+\right]} + k_1 \frac{K_{\rm a}}{K_{\rm a} + \left[{\rm H}^+\right]} \tag{2}
$$

$$
k_2^{\rm app} = k_2^{\rm H} \frac{\left[{\rm H}^+\right]}{K_a + \left[{\rm H}^+\right]} + k_2 \frac{K_a}{K_a + \left[{\rm H}^+\right]}
$$
(3)

where  $K_a$  is the acid dissociation constant of  $HSO_5^-$  and rate constants  $k_1$ ,  $k_1^{\text{H}}$ ,  $k_2$ , and  $k_2^{\text{H}}$  are defined in previous paragraphs. In the final calculations, all kinetic traces recorded at various reactant concentrations and pH values were fitted simultaneously to the kinetic model of Scheme 1, taking into account the pH dependence of the system. These estimated values for  $k_1$ ,  $k_1^{\text{H}}$  $k_1^{\text{H}}$  $k_1^{\text{H}}$ ,  $k_2$ , and  $k_2^{\text{H}}$  are listed in Table 1. The excellent fit between

t[he ex](#page-3-0)perimental results and the calculated data is illustrated in Figure 4. The estimate for  $pK_a(HSO_5^-) = 8.43 \pm 0.05$  (I = 1.0) M) is in good agreement with previously published values.<sup>34</sup> The a[pp](#page-3-0)arent rate constants  $k_1^{\text{app}}$  and  $k_2^{\text{app}}$  were found to decrease linearly with decreasing [H<sup>+</sup>] in the range from [pH](#page-6-0) 12.3 to 13.5 (Figure S3 in the Supporting Information), where  $[H^+] \ll K_a(HSO_5^-)$  and both eqs 2 and 3 are simplified to linear correlations. This obser[vation, together with the](#page-5-0) results of the full-scale pH-dependence s[tu](#page-3-0)dy, [is](#page-3-0) strong evidence against the presence of any acid/base-catalyzed processes in the  $(H)$ SO<sub>5</sub><sup>-</sup> + SCN<sup>-</sup> reaction system.

The temperature dependence of the  $HSO_5^-$  +  $SCN^$ reaction was studied in phosphate buffer at pH 6.54 (measured at 25.0  $^{\circ}$ C), where the rates of the reactions R1 and R2 are negligible compared to those of R1H and R2H, respectively. The pH was chosen to be far (at least 1.5 units away) from the  $pK_a$  values of both  $HSO_5^-$  and  $HOSCN$  [at 2](#page-3-0)5.0 °C, and phosphate buffer was chosen because its pH shows less than a −0.05 unit/+10 K dependence on the temperature.<sup>54</sup> Thus, all complications arising from the possible temperature-dependent shifting of the protolytic equilibria in the reaction [sys](#page-6-0)tem were averted by carefully choosing the experimental conditions. In order to obtain information on the temperature dependence of the rate of reactions R1H  $(k_1^H)$  and R2H  $(k_2^H)$ , the same approach as that in the pH-dependence study was used: two duplicate kinetic exp[erime](#page-3-0)nts were [run a](#page-3-0)t two different [SCN<sup>-</sup>]<sub>0</sub> values at a given temperature. The calculated rate constants  $k_1^{\text{H}}$  and  $k_2^{\text{H}}$  are shown in Figure 5 in the temperature range from 5.0 to 45.0 °C. Because both R1H and R2H are elementary reactions, the Eyring equation was used to calculate the activation parameters by utilizing a no[nlinea](#page-3-0)r leas[t-squ](#page-3-0)ares fitting algorithm:<sup>55</sup>

$$
k = \frac{k_{\rm b}T}{h} \exp\left(\frac{\Delta S^{\ddagger}}{R}\right) \exp\left(-\frac{\Delta H^{\ddagger}}{RT}\right) \tag{4}
$$

where  $k<sub>b</sub>$  is the Boltzmann constant, h is the Planck constant, R is the universal gas constant, and  $\Delta S^{\ddagger}$  and  $\Delta H^{\ddagger}$  are the activation entropy and enthalpy. The resulting activation parameters are listed in Table 1. The temperature dependence of the oxidation of SCN<sup>−</sup> with  $SO_5^2$ <sup>−</sup> (R1) was also studied at pH 13.5. The excess of SCN<sup>−</sup> used in these kinetic experiments  $([SO_5^{2-}]_0 = 5.0$  mM and  $[SCN^-]_0 = 750$  mM) was chosen to be high to avoid the oxidation of OSCN<sup>-</sup> by  $SO_5^{2-}$  (R2). In other words, the rate of reaction R2 was negligible compared to R1 under the applied experimental conditions, and  $k_1$  could be

Figure 5. Temperature dependence of the reaction between SCN<sup>−</sup> and  $HSO_5^-$  at pH 6.54. Circles (right y scale): rate constant of the oxidation of SCN<sup>-</sup> with  $HSO_5^-$  (R1H). Triangles (left y scale): rate constant of the oxidation of  $OSCN^-$  with  $HSO_5^-$  (R2H). Lines: results of nonlinear fits to the Eyring equation.  $[KHSO_{5}]_{0} = 5.0$  mM;  $[NaSCN]_0 = 50.0$  or 500 mM;  $I = 1.0$  M; pH 6.54 (me[asure](#page-3-0)d at 25.0  $\mathrm{^{\circ}C}$ ).

measured directly. With this approach, we lost the possibility of determining the activation parameters of R2 but excluded the possibility of any systematic error arising from the complicated simultaneous evaluation of two sets of kinetic data. The Eyring equation was used again to evaluate the activation parameters from the temperature-dependent study (Figure S4 in the Supporting Information), and the results are listed in Table 1. The entropies of activation of reactions R1H, R1, and also R2H [are large negative value](#page-5-0)s close to  $-100$  J mol<sup>-1</sup> K<sup>-1</sup>. Similar entropies of activation were measur[ed in](#page-3-0) the reactio[ns of](#page-3-0)  $HSO_5^-$  with halide ions (Cl<sup>−</sup>, Br<sup>−</sup>, and I<sup>−</sup>).<sup>34</sup> The analogy between the oxidation of halides and SCN<sup>−</sup> is not surprising, taking into account the well-established classifi[ca](#page-6-0)tion of SCN<sup>−</sup> as a pseudohalide ion. With the methodology presented in ref 34, one can conclude that the rate-determining step in the  $\text{HSO}_5^-$  + SCN<sup>−</sup> (R1H) elementary reaction cannot be a 1e<sup>−</sup>[tra](#page-6-0)nsfer step. At pH 7, the formal potential of the  $HSO_5^-/$ SO4<sup>•−</sup> couple is  $(1.19 + 0.0591 \times \log 10^{-7}) = 0.78 \text{ V}^{34}$ whereas the standard reduction potential of the SCN°/SCN<sup>-</sup> coupl[e](#page-6-0) is 1.63 V.<sup>56</sup> Thus, the free energy of the possible 1e<sup>−</sup>  $\text{HSO}_5^-$  + SCN<sup>-</sup> (R1H) elementary step would be [(1.63 –  $(0.78) \times 96.485$ ] [= 8](#page-6-0)2 kJ mol<sup>-1</sup>, which is much higher than the measured free en[ergy o](#page-3-0)f activation at 298 K: (26 + 298 ×  $(0.112) = 59$  kJ mol<sup>-1</sup>. Therefore, similarly to the reactions of halides, the  $\text{HSO}_5^-$  + SCN<sup>-</sup> (R1H) elementary step is more likely to proceed through an initial 2e<sup>−</sup> oxidation, probably involving concerted heterolytic O−O bond cleavage and S−O bond formation. This mechani[sm](#page-3-0) [is](#page-3-0) expected to involve much more geometric reorganization and characterized by higher activation entropy than a 1e<sup>−</sup>-transfer rate-determining step, which does not include atom transfer before the transition state. In accordance with the concluding thoughts of ref 34, a generalization is risky without a sufficiently high number of reliably measured activation parameters in the literature f[or t](#page-6-0)he reactions of HSO<sub>5</sub><sup>–</sup> and SO<sub>5</sub><sup>2–</sup>. Still the –80 to –110 J mol<sup>-1</sup>  $K^{-1}$  activation entropies of R1H, R1, and R2H seem to suggest that all of these processes proceed through 2e<sup>−</sup>-transfer ratedetermining steps rather t[han 1e](#page-3-0)<sup>−</sup>-transf[er step](#page-3-0)s.

# ■ **CONCLUSIONS**

We showed that peroxomonosulfate ion  $(HSO_5^-)$  oxidizes thiocyanate ion (SCN<sup>−</sup>) to hypothiocyanite ion (OSCN<sup>−</sup>) in the range from pH 6.9 to 13.5 ( $k_1^H = 2.0 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$  at pH

<span id="page-5-0"></span>6.89). The oxidation of OSCN<sup>-</sup> by  $HSO_5^-$  ( $k_2^H = 3.3 \times 10^3 \text{ M}^{-1}$  $s^{-1}$  at pH 6.89) also takes place in the reaction system of  $HSO_5^-$  + SCN<sup>-</sup>. On the basis of the estimated activation parameters, we concluded that the rate-determining steps in the above oxidation processes are more likely to be 2e<sup>−</sup>- than 1e<sup>−</sup> transfer steps. Because the rate constant of the oxidation of OSCN<sup>−</sup> is an order of magnitude higher than that of SCN<sup>−</sup>, these two compounds compete for the oxidant  $HSO_5^-$ , and the quantitative conversion of SCN<sup>−</sup> to OSCN<sup>−</sup> is possible only by minimizing the relative rate of the "overoxidation" reaction, using at least a 100-fold excess of  $SCN^-$  over  $HSO_5^-$ . We derived a simple kinetic model valid under neutral and basic conditions in the  $SCN^-$  +  $HSO_5^-$  reaction system and showed that the inclusion of the equilibrium step between SCN<sup>−</sup> +  $HSO_5^-$  and  $OSCN^- + SO_4^{2-}$  presented in the Smith and Wilson model<sup>36–38</sup> is not necessary under these conditions. This paper presents quantitative information on the kinetics of the oxidation [of](#page-6-0) a[nt](#page-6-0)imicrobial OSCN<sup>−</sup> by a peroxo compound, which seems to have no precedent in the literature. If the relative reactivities of SCN<sup>−</sup> and OSCN<sup>−</sup> are expected to be similar toward  $\mathrm{HSO}_5^-$  and  $\mathrm{H}_2\mathrm{O}_2$ , it is reasonable to assume that the in vivo accumulation of OSCN<sup>−</sup> during the defensive peroxidase-catalyzed  $SCN^-$  + H<sub>2</sub>O<sub>2</sub> reaction is limited by the presence of  $H_2O_2$  itself.

The high rate of the  $HSO_5^- + SCN^-$  reaction might make Oxone an attractive choice for technologies aiming at the oxidative removal of SCN<sup>−</sup> from metallurgical wastewater, keeping in mind that method optimization is required to completely avoid the formation of toxic CN<sup>−</sup> as a product.

We assume that, during the oxidative thiocyanation of aromatic and aliphatic compounds, the in situ formation of protonated HOSCN (hypothiocyanous acid) takes place in the fast reaction of  $\text{HSO}_5^- + \text{SCN}^-$ . In this case, the SCN moiety may act as an S-electrophile reagent because the high electronegativity of the oxygen atom significantly lowers the electron density of the soft sulfur atom. By the protonation of HOSCN to  $H_2OSCN^+$ , even the formation of  $^+SCN$  is predictable after water elimination. The formation of an electrophile during the in situ oxidation of SCN<sup>−</sup> can account for the success of this polarity inversion (umpolung) thiocyanation strategy among activated aromatic and  $\alpha$ -acidic oxo compounds.
