# Feedback control of wall turbulence with wall deformation

Takahide Endo\*, Nobuhide Kasagi, Yuji Suzuki

Department of Mechanical Engineering, The University of Tokyo, Hongo 7-3-1, Bunkyo-ku, Tokyo 113-8656, Japan

## Abstract

Direct numerical simulation of turbulent channel flow was made in order to evaluate feedback control with deformable walls. When the local wall velocity is determined by an active cancellation control scheme similar to that of Choi et al. (Choi, H., Moin, P., Kim, J., 1994. J. Fluid Mech. 262, 75–110), the drag is decreased by about 12% with the wall deformation of the magnitude on the order of one viscous length. On the basis of the typical dimensions of the wall deformation thus obtained, a novel array of deformable actuators elongated in the streamwise direction is proposed. A new realizable control scheme by using wall information is developed based on physical arguments of the near-wall coherent structures. The location of quasi-streamwise vortices accompanied with streak meandering is successfully detected about 50 viscous lengths downstream from the sensing location, at which the spanwise gradients of wall shear stresses are measured. The wall velocity of each actuator is determined to counteract the wall-normal velocity induced by the streamwise vortices. By the present control scheme with the arrayed sensors and actuators, 10% drag reduction is achieved through selective manipulation of the streamwise vortices and streak meandering. It is also found that the energy input of the present control is one order of magnitude smaller than the pumping power saved. © 2000 Begell House Inc. Published by Elsevier Science Inc. Keywords: Turbulence control; DNS; Arrayed deformable actuators

#### 1. Introduction

Turbulence and concomitant phenomena such as heat transfer, diffusion, friction drag and noise play important roles in industrial and environmental problems. From the view point of saving power and protecting the environment, it is strongly desired to develop efficient turbulence control techniques for drag reduction and/or heat transfer augmentation. In the last three decades, various control strategies have been proposed (Bushnell and Hefner, 1990; Gad-el-Hak, 1994a). Among various methodologies, which are roughly classified into passive and active control, active feedback control attracts much attention because of its large control effect with small control input (Moin and Bewley, 1994; Gad-el-Hak, 1996; Kasagi, 1998).

Since the 1960s, a considerable degree of knowledge has been accumulated on the turbulent coherent structures and their underlying mechanism (Cantwell, 1981). Kline and Robinson (1989) grouped coherent motions observed in wall turbulence into eight classes. Among those coherent structures, quasi-streamwise vortices (QSV) are known to play a dominant role in the near-wall turbulent transport phenomena

(Robinson, 1991; Kasagi et al., 1995). Jeong et al. (1997) proposed a conceptual model of the near-wall coherent structures, which consists of a train of QSVs having alternative signs of the streamwise vorticity. They also showed that QSV tilted in the spanwise direction have close relation with the meandering of low-speed streaks, and have major contribution to the regeneration mechanism. Kravchenko et al. (1993) showed that the streamwise vorticity accompanied with QSV has strong correlation with the wall shear stress upstream of the QSV. Kasagi and Ohtsubo (1992) found that the production and destruction of the Reynolds shear stress as well as the turbulence heat flux are concentrated in the regions close to QSV.

These facts indicate that an effective control of friction drag and/or heat transfer in wall turbulence can be established through selective manipulation of QSV.

Choi et al. (1994) investigated turbulent channel flow with local blowing/suction on the wall, which is opposite to the wall-normal velocity in the buffer layer. They obtained 30% drag reduction in their DNS, and found that QSV are attenuated. Bewley et al. (1993) employed a suboptimal control theory (Choi et al., 1993) in order to determine the distribution of wall blowing/suction as the control input. They obtained 15% drag reduction and showed that the spatial distribution of blowing/suction determined by their suboptimal scheme is similar to that of Choi et al. (1994).

Lee et al. (1997) have developed a control algorithm based on neural networks. They determined the control input by using only wall variables, and found that the wall shear is

substantially decreased when the blowing/suction rate is roughly proportional to the spanwise gradient of the spanwise shear stress. Lee et al. (1998) proposed a suboptimal control scheme with the Fourier transformation, and showed that their control scheme by using elaborate cost function is very effective in reducing drag.

It is noted that in most previous DNS studies for controlling wall turbulence, an infinite number of sensors and actuators were assumed, and their volumes were neglected. Since this assumption is unrealistic, it is desired to develop a new control algorithm assuming arrayed sensors and actuators of finite spatial dimensions.

Devices for turbulence feedback control should have spatio-temporal scales comparable with those of the coherent structures (Gad-el-Hak, 1994b). Recent development of microelectromechanical systems (MEMS) technology enables us to fabricate prototypes of such micro devices (Ho and Tai, 1996). Among various kinds of actuators, wall deformation is considered to be one of the most promising candidates, because of its robustness against the hostile environment. Grosjean et al. (1998) fabricated pneumatic wall deformation actuators with MEMS techniques, and showed that these actuators survived transonic flight test with large temperature fluctuation.

Carlson and Lumley (1996) employed a Gaussian-shaped deformable bump as an actuator in their DNS of a minimal channel flow (Jiménez and Moin, 1991). They found that, when a bump having a maximum height of 12 viscous lengths and a maximum velocity of one friction velocity swells underneath the high-speed regions, the faster moving fluid is displaced away from the wall, and thus the friction drag is decreased as much as 7%. However, the effect of the wall motion on the near-wall coherent structures and the detailed friction drag reduction mechanism remain to be resolved.

Mito and Kasagi (1998) assumed sinusoidal wall oscillation uniform in the streamwise direction, of which amplitude and period is given by a predetermined way. They found in their DNS of a turbulent channel flow that the wall deformation induces long-term variation of wall friction, and makes lowspeed streaks more stable and less meandering in the spanwise direction during the time period when the friction drag is reduced. Their result indicates that the wall deformation should be effective in wall turbulence modification.

The objectives of the present study are to develop a new control algorithm based on the dynamics of near-wall coherent structure, which requires only wall variables, and to evaluate arrayed wall deformable actuators for drag reduction as a leading design of practical turbulent control devices. For this purpose, we employed DNSs of turbulent channel flow with two deformable walls.

#### 2. Numerical procedure

The flow geometry and the coordinate system are shown in Fig. 1. The governing equations are the incompressive Navier–Stokes equations and the continuity equation. Wall deformation is represented with a boundary-fitted coordinate system for moving boundary. Periodic boundary conditions are employed in the streamwise (x-) and spanwise (z-) directions, while non-slip boundary condition is imposed on the top and bottom deformable walls.

A modified Crank–Nicolson type fractional-step method (Choi and Moin, 1994) is used for the time advancement, while a second-order finite difference scheme is employed for the spatial discretization of both flow variables and metrics on a staggered mesh (Mito and Kasagi, 1998). The pressure Poisson equation is solved with the multi-grid method (Demuren and

Fig. 1. Flow geometry and coordinate system.

Ibraheem, 1998). Three levels of meshes are used to accelerate the convergence, in which a successive over relaxation (SOR) method is adopted in the finest and medium meshes, whilst an incomplete LU conjugate gradient squared (ILUCGS) method is used in the coarsest mesh.

The size of the computational volume is, respectively,  $2.5\pi\delta$ and  $0.75\pi\delta$  in the x- and z-directions, where  $\delta$  is the channel half width. The simulation is performed under the constant flow rate condition throughout the present study. The Reynolds number based on the bulk mean velocity  $U_b$  and the channel width  $2\delta$  is 4600 (about 150 based on the wall friction velocity  $u_{\tau}$  and  $\delta$ ). The computational domain is about 1180 and 360 viscous length scales in the x- and z-directions, respectively, which are about 2.5 and 3.6 times larger than the minimal flow unit (Jiménez and Moin, 1991). Hereafter, ()<sup>+</sup> represents a quantity non-dimensionalized by the friction velocity  $u_{\tau}$  in the plane channel flow without control and the kinematic viscosity v.

The number of grid points is 96, 97 and 96 in the x-, y- and z-directions, respectively. A non-uniform mesh with a hyperbolic tangent distribution is employed in the y-direction. The first mesh point away from the wall is given at  $y^+ = 0.25$ . The computational time step is chosen as  $0.33v/u_{\tau}^2$ . The initial condition is given from a fully developed velocity field of preceding channel flow DNS.

#### 3. Active cancellation by wall deformation

In the first stage of the present study, a simple feedback algorithm similar to the v-control scheme (Choi et al., 1994) is employed in order to evaluate the performance of wall deformation on drag reduction. The velocity of the wall deformation  $v_w$  is given to be out-of-phase of the wall-normal velocity in the buffer region;  $v_w$  at each grid on the deformable wall is determined as follows:

$$v_{\rm w}^+(t_{n+1}) = -(v_{\rm s}^+(t_n) - \langle \langle v_{\rm s}^+(t_n) \rangle \rangle) - 0.31 y_{\rm w}^+(t_n), \tag{1}$$

where  $t_n$  denotes time step *n*, while  $v_s$  is the wall-normal velocity at  $y/\delta = 0.1$  ( $y^+ \sim 15$ ). The second term is devised to keep the total volume of the flow domain constant, where the double bracket  $\langle \langle \chi \rangle \rangle$  denotes an ensemble average of quantity  $\chi$  in the *x*-*z* plane at each time step. The third term of the RHS of Eq. (1) is a damping term to suppress excessive wall deformation, where  $y_w$  is the displacement of the wall.

Time trace of the drag coefficient normalized with its value for the uncontrolled plane channel flow is shown in Fig. 2. Note that the form drag of the deformable walls are found to be negligible, so the friction and total drags are employed synonymously in the present study. The friction drag is decreased to as large as 12% at  $t^+ = 600$ , and the mean drag reduction rate during  $t^+ = 0-600$  is about 10%. Fig. 3 shows an instantaneous shape of wall deformation. It is evident that the deformation is much elongated in the streamwise direction. Two-dimensional (x-z) spectrum of the wall velocity  $v_w$  is shown in Fig. 4. Two marked peaks are observed at  $(\kappa_x, \kappa_z) = (3, 3)$  and (5, 5). Thus, the typical length scales estimated from these peaks are  $(m_x^+, m_z^+) = (200, 60)$  and (120, 36), where the spanwise scale is in between the mean diameter of QSV and the spacing of the near-wall streaky structures. As described later, dimensions of arrayed deform-

Fig. 4. Two-dimensional spectrum of the wall velocity.

able actuators are determined based on these characteristic lengths.

Fig. 2 also shows that the rms value of the wall displacement is fairly small and is about  $1.0\nu/u_{\tau}$ . Wall roughness within  $y^+ = 5$  is categorized as "hydraulically smooth" (Schlichting, 1960), and considered to have a minor effect on the turbulent flow field. It is also noted that Goldstein and Tuan (1998) found in their DNS that the drag is slightly increased for the V-shaped riblet surface having  $9\nu/u_{\tau}$  in height and  $62.8\nu/u_{\tau}$  in spacing, of which spacing is close to the characteristic spanwise scale of the wall deformation obtained in the present study.

On the other hand, the rms value of the wall velocity is  $0.15u_{\tau}$  and almost the same as that of the wall-normal velocity fluctuation at  $y^+ = 10$ . According to the v-control scheme by Choi et al. (1994), the optimal wall elevation of the sensor location is at  $y^+ = 10$ . Therefore, the drag reduction presently obtained should be due to the wall-normal velocity of the fluid induced by the wall deformation rather than the deformed shape of the wall.

#### 4. Detection of quasi-streamwise vortex based on wall variables

It is now evident that the wall deformation determined with appropriate control scheme is effective in drag reduction. In this section, a new algorithm to identify QSV based on the wall information is proposed from the argument on the dynamics of near-wall coherent structures.

It is well known that the near-wall streaky structures do not always flow straight in the streamwise direction, but often meander in the spanwise direction. Johansson et al. (1991) made a conditional average of a DNS database (Kim et al., 1987) and found that the turbulent production was very large near the streaky structures asymmetric in the spanwise direction. Hamilton et al. (1995) pointed out that QSV and the streaky structure have a close dynamical relationship with each other, and the meandering of streaks plays an important role in a quasi-cylic process of turbulence regeneration. Jeong et al. (1997) proposed a schematic model of QSV alternatively tilting in the x-z plane associated with the meandering of the nearwall low-speed streak. From the information mentioned above, it is expected that QSV can be identified from the wall information by detecting the streak meandering.

Fig. 5 shows a schematic of a modelled streaky structure. When the velocity gradients in the two horizontal directions are taken into account, the edges of the streak can be grouped into four events as tabulated in Table 1, depending on the signs of  $\partial u'/\partial x$  and  $\partial u'/\partial z$ . Note that E1 and E4, and also E2 and E3 are, respectively, of mirror symmetry in the spanwise direction.

In order to examine flow characteristics associated with each event, a conditional average of a plane channel flow is made, given the condition of the signs of  $\partial u^+/\partial x^+$  and  $\partial u^+/\partial z^+$  at  $y^+ = 15$ . A threshold of 0.32 is employed for both gradients to extract strong events only.

Fig. 5. Schematic of a modelled streaky structure.

streaks.

Fig. 6 shows contours of the conditionally averaged streamwise velocity  $\langle u'^+ \rangle$  at  $y^+ = 15$  for Events E1 and E2. The contours of negative  $\langle u'^+ \rangle$ , which correspond to the low-speed streaks, are elongated in the streamwise direction and tilted in the spanwise direction for both events. As depicted in Fig. 5, the detection point in E1 corresponds to the downstream edge of the low-speed streak, while that in E2 to the upstream edge.

Fig. 7 shows contours of the conditionally averaged streamwise vorticity  $\langle \omega_{v}^{+} \rangle$  at  $y^{+} = 15$  for Events E1 and E2. In

E4	Positive	Negative

Fig. 6. Contours of conditional-averaged streamwise velocity at  $y^+ = 15$ . The detection point is at  $x^+ = 0$  and  $z^+ = 0$ . (a) Event E1, (b) Event E2.

Fig. 7. Contours of conditional-averaged streamwise vorticity at  $y^+ = 15$ . The detection point is at  $x^+ = 0$  and  $z^+ = 0$ . (a) Event E1, (b) Event E2.

The equation of the streamwise vorticity  $\omega_x^+$  is given as follows:

$$\frac{D\omega_x^+}{Dt^+} = \omega_x^+ \frac{\partial u^+}{\partial x^+} - \frac{\partial w^+}{\partial x^+} \frac{\partial u^+}{\partial y^+} + \frac{\partial v^+}{\partial x^+} \frac{\partial u^+}{\partial z^+} + \nabla^2 \omega_x^+, \tag{2}$$

where the first term of the RHS is the stretching term, while the second and third terms correspond to the tilting and twisting terms, respectively. Brooke and Hanratty (1993) showed that  $(\partial w/\partial x)(\partial u/\partial y)$  is the largest in Eq. (2) near the wall, and  $\omega_x$  is mainly produced by the tilting of  $\omega_y$  in its early stage. Once  $\omega_x$  is produced, however, the stretching term have substantial contribution (Sendstad and Moin, 1992). Since both  $\partial u^+/\partial x^+$  and  $\omega_x^+$  are positve at Event E1,  $\omega_x^+$  is further produced by the stretching term  $\omega_x (\partial u/\partial x)$ , which results in the peak of  $\omega_x^+$  shown in Fig. 7(a). On the other hand,  $\partial u^+/\partial x^+$  is negative for Event E2 while  $\omega_x^+$  is positive, so that the magnitude of  $\omega_x^+$  should be decreased. Thus, the streak meandering should contribute to the evolution of  $\omega_x$  and hence the regeneration mechanism of QSV.

It is now clear the QSV accompanied with the meandering streaks can be detected by using  $\partial u^+/\partial x^+$  and  $\partial u^+/\partial z^+$  at  $y^+ = 15$ . In order to identify the meandering based on wall variables, we examined spatial relation between the streaks and the wall shear stress fluctuations. As a result, it is found that the spanwise gradients of  $\tau_u^+ (\equiv \partial u'^+/\partial y^+|_w)$  and  $\tau_w^+ (\equiv \partial w'^+/\partial y^+|_w)$  instead of the velocity gradients in the buffer layer are good indicators for the meandering streaks. The signs of the shear stress gradients and the corresponding events are summarized in Table 2. A negative value of  $\partial \tau_w/\partial z$  is observed  $50v/u_r$  upstream of Events E1 and E4, while  $\partial \tau_w/\partial z > 0$  for E2 and E3. Note that Event E1 can be distinguised from E4 by the sign of  $\partial \tau_u/\partial z$  at the same location.

Fig. 8 shows the contours of the streamwise velocity fluctuation  $\langle u'^+ \rangle$  at  $y^+ = 15$ , conditionally averaged for S1

Table 2Four signals and corresponding events

e		e

S1	Positive	Negative	E1	Positive
S2	Positive	Positive	E2	
S3	Negative	Positive	E3	
S4	Negative	Negative	E4	Negative

Fig. 8. Contours of streamwise velocity at  $y^+ = 15$ , given the conditions of  $\partial \tau^+_{\mu}/\partial z^+ > 0.035$  and  $\partial \tau^+_{w}/\partial z^+ < -0.005$ .

Fig. 9. Contours of streamwise vorticity at  $y^+ = 15$ , given the conditions of  $\partial \tau_{u}^{+}/\partial z^+ > 0.035$  and  $\partial \tau_{w}^{+}/\partial z^+ < -0.005$ .

Fig. 10. Contours of wall-normal velocity at  $y^+ = 15$ , given the conditions of  $\partial \tau_u^+ / \partial z^+ > 0.035$  and  $\partial \tau_w^+ / \partial z^+ < -0.005$ .

 $(\partial \tau_u^+/\partial z^+ > 0.035 \text{ and } \partial \tau_w^+/\partial z^+ < -0.005)$ . Although the tilting angle of the streak is slightly smaller than that shown in Fig. 6, the meandering of the low-speed streak corresponding to E1 is well captured at  $50v/u_\tau$  downstream from the detection point. A large positive peak of  $\omega_x^+$  at  $y^+ = 15$  is also observed in the same region, where the streak meanders as shown in Fig. 9. Although it is not shown here, a large negative peak of  $\omega_x^+$  is associated with S4  $(\partial \tau_u^+/\partial z^+ < -0.035 \text{ and } \partial \tau_w^+/\partial z^+ < -0.005)$ , which corresponds to Event E4. Thus, QSV as well as its direction of rotation can be detected by the combination of the signs of  $\partial \tau_u^+/\partial z^+$  and  $\partial \tau_w^+/\partial z^+$ .

Fig. 10 shows contours of the conditionally averaged wallnormal velocity  $\langle v'^+ \rangle$  at  $y^+ = 15$  for S1. Positive and negative peaks are aligned side-by-side in the spanwise direction, and they, respectively, correspond to the ejection and sweep motions. The spanwise distance of the positive and negative peaks is above  $30v/u_{\tau}$ , which is almost the same as the mean diameter of QSV (Robinson, 1991).

It is noted that the present control scheme based on the dynamics of the near-wall coherent structure is similar to the algorithm by Lee et al. (1997, 1998) in the sense that it requires  $\partial \tau_w / \partial z$ , although they employ different schemes such as a suboptimal control scheme and an adaptive control method based on neural network.

#### 5. Feedback control with arrayed deformable actuators

In previous studies, sensors and actuators are assumed to be infinitely small, and placed at each computational grid point on the wall. In the present study, we assume control devices having finite dimensions, and design arrayed actuators and sensors based on the discussion described above.

Fig. 11(a) shows a schematic of deformable actuator assumed in the present computation. By taking into account the characteristic length of the wall deformation shown in Fig. 4, the streamwise and spanwise dimensions of the actuator is chosen as 172 and  $60\nu/u_{\tau}$ , respectively. Each actuator is assumed to be deformed only in the *y*-direction. The shape is determined with a sinusoid in the spanwise direction, in such a way that the distance between the peak and trough is about the mean diameter of QSV.

Fig. 11. Schematic of arrayed actuators and shear stress sensors. (a) Dimension of a single deformable actuator. (b) Arrangement of the actuators and the sensors.

Fig. 11(b) shows an arrangement of arrayed shear stress sensors and deformable actuators. A shear stress sensor is assumed to be centered at  $12.3v/u_{\tau}$  upstream from the upstream end of the deformable actuator. Hence, the streamwise distance between the sensor and the center of the actuator is  $50v/u_{\tau}$ , which corresponds to the displacement between the detection point of Events E1 and E4, and the peak of the streamwise vorticity shown in Fig. 9. In the present study, 36 actuators (6 × 6 in the streamwise and spanwise directions) are distributed with a regular pitch on both walls of the channel.

Each sensor measures the spanwise gradients of the instantaneous wall shear stresses,  $\partial \tau_u / \partial z$  and  $\partial \tau_w / \partial z$ . The wall velocity at the center of the peak/trough of the actuator  $v_m$  is determined by

$$v_m^+(t_{n+1}) = \begin{cases} \alpha \tanh\left(\frac{\partial \tau_u^+(t_n)}{\partial z^+}\frac{1}{\beta}\right) - \gamma y_m^+(t_n) & \text{if } \frac{\partial \tau_w(t_n)}{\partial z} < 0, \\ -\gamma y_m^+(t_n) & \text{otherwise,} \end{cases}$$
(3)

where  $y_m$  is the wall displacement at the peak/trough, and  $\alpha$ ,  $\beta$ , and  $\gamma$  are control parameters, respectively. The wall velocity of each grid point on the actuator is given by

$$v_{w}^{+}(t_{n+1}) = v_{m}^{+}(t_{n+1})f(x^{+}) \\ \times \exp\left[-\frac{(z^{+}-z_{c}^{+})^{2}}{\sigma_{z}^{+2}}\right] \sin\left[\frac{2\pi(z^{+}-z_{c}^{+})}{m_{z}^{+}}\right],$$
(4)

where the function  $f(x^+)$  is introduced to keep the shape of the actuator smooth in the streamwise direction. The function f is determined with a hyperbolic tangent as

Fig. 12. Time trace of the normalized mean pressure gradient.

$$\begin{split} f(x^{+}) \\ &= \begin{cases} \frac{1}{2} \left[ 1 + \tanh\left\{ \frac{(x^{+} - x_{c}^{+}) + 73.7}{\sigma_{x}^{+}} \right\} \right] & \text{if } -86 \leqslant x^{+} - x_{c}^{+} \leqslant -61.5, \\ 1 & \text{if } -61.5 \leqslant x^{+} - x_{c}^{+} \leqslant 61.5, \\ \frac{1}{2} \left[ 1 - \tanh\left\{ \frac{(x^{+} - x_{c}^{+}) - 73.7}{\sigma_{x}^{+}} \right\} \right] & \text{if } 61.5 \leqslant x^{+} - x_{c}^{+} \leqslant 86. \end{cases} \end{split}$$

In Eqs. (4) and (5),  $x_c$  and  $z_c$  denote the location of the center of the actuator. The parameters are somewhat tuned through preliminary computations, and chosen as  $\alpha = 2.3$ ,  $\beta = 0.077$ ,  $\gamma = 0.3$ ,  $\sigma_x^+ = 6.14$ , and  $\sigma_z^+ = 22.2$ , respectively.

Fig. 12 shows a time trace of the normalized pressure drop for the cases of local blowing/suction and the continuous wall deformation. It is seen that the drag is gradually decreased from the onset of the control. The present result, however, exhibits no control effect until  $t^+ = 200$ , and then the drag is decreased at  $t^+ > 200$ . A maximum drag reduction rate of 17% is obtained at  $t^+ = 800$ . Therefore, even with coarsely distributed sensors and actuators on the wall, the effect of the present control scheme appears to be efficient through selective manipulation of QSV.

The gain in pumping power G and the energy input to deform actuators  $W_{in}$  are calculated to evaluate the performance of the present control. After Mito and Kasagi (1998), (i) work of convecting of turbulent kinematic energy, (ii) pressure work, and (iii) stress work, are taken into account as energy input, although the work for stretching the wall material is neglected

$$G = \left[ \left( \overline{-\frac{\partial p}{\partial x}} \right)_{\text{No-control}} - \left( -\frac{\partial p}{\partial x} \right)_{\text{Control}} \right] Q, \tag{6}$$

$$W_{\rm in} = \int_{\Gamma_{\rm w}} \left[ \underbrace{p'_{\rm w} v_{\rm n}}_{\rm (i)} + \underbrace{k v_{\rm n}}_{\rm (ii)} + \underbrace{\left( -\frac{1}{Re} \frac{\partial k}{\partial n} \right)}_{\rm (iii)} \right] \mathrm{d}\Gamma_{\rm w},\tag{7}$$

where Q, k and  $p'_w$  denote the flow rate, turbulent kinetic energy, and wall pressure fluctuation, respectively. The subscript n denotes wall-normal direction, and Eq. (7) is the surface integration over the deformable wall.

As shown in Fig. 13, the energy input for deforming actuators are much smaller than the pumping power saved. The mean efficiency  $\eta \ (\equiv G/W_{\rm in})$  is on the order of 10, and this fact demonstrates that the efficiency of the present control scheme with arrayed deformable actuators can be markedly large.

Fig. 14 shows the top views of instantaneous flow fields at  $t^+ = 0$  and 604. Vortical structures are identified with their

Fig. 13. The gain in pumping work and the energy input.

Fig. 14. Top view of the instantaneous flow field. Flow: left to right. White:  $II'^+ = -0.03$ , dark gray:  $u'^+ = -3.5$ , light gray:  $u'^+ = 3.5$ . (a)  $t^+ = 0$ , (b)  $t^+ = 604$ .

negative value of the second invariant of the deformation tensor  $(II' = u'_{i,j}u'_{j,i})$  (Chong et al., 1990; Kasagi et al., 1995). Under the present control with deformable actuators, QSV becomes less populated near the wall and the meandering of low-speed streak is supressed.

The quadrant analysis (Lu and Willmarth, 1973) is employed to examine a conditionally averaged flow field. The detection point is chosen at  $y^+ = 15$ , and the condition is given as

$$|u'v'| \ge Hu'_{\rm rms}v'_{\rm rms},\tag{8}$$

where the threshold H is set to be unity.

Fig. 15 shows the conditionally averaged streamwise velocity at  $y^+ = 15$  associated with the ejection event. For all cases examined, a low-speed streak is clearly observed near the ejection event. Although each realization of the low-speed streak is elongated over a few thousand viscous lengths in the streamwise direction (Kline and Robinson, 1989), the conditionally averaged field exhibits much shorter structure because of the meandering in the spanwise direction. As shown in Fig. 15(b), the low-speed streak with the local blowing/suction becomes much shorter than that in the uncontrolled plane channel. On the other hand, under the present control with arrayed deformable actuators, it becomes longer in the streamwise direction. This fact indicates that the meandering of the streak is suppressed and the low-speed streak itself is much stabilized. Although it is not shown here, the two-point

Fig. 15. Conditional averaged streamwise velocity near the Q2 event. (a) No control, (b) local blowing/suction, (c) present results with arrayed deformable actuators.

correlation of the streamwise velocity fluctuation persists longer in the streamwise direction as is often observed in drag reducing turbulent wall flows with polymer additives (Fortuna and Hanratty, 1972). Conditionally averaged displacement of the actuators near the ejection event shows that the actuators are deformed as a groove beneath the low-speed streaks. The groove follows the low-speed streak as it is convected downstream with keeping a depth of about  $1v/u_{\tau}$ .

This stabilization phenomenon of the low-speed streak is also shown in DNS of turbulent channel flow with sinusoidal wall oscillation uniform in the streamwise direction (Mito and Kasagi, 1998). Therefore, a possible drag reduction mechanism in the present control is that the breakdown process proposed by Hamilton et al. (1995) is surpressed, and the regeneration cycle of the near-wall turbulence vortex is hampered.

#### 6. Conclusions

Direct numerical simulation of turbulent channel flow was made in order to evaluate feedback control with deformable walls. The following conclusions can be obtained:

- Deformable wall can be an efficient actuator for wall turbulence with characteristic dimensions of 200 and 60 viscous lengths in the streamwise and spanwise directions, respectively. On the basis of this knowledge, a novel array of deformable actuators elongated in the streamwise direction is proposed.
- 2. A new simple control scheme is developed based on physical arguments of the near-wall coherent structures. The location of quasi-streamwise vortices accompanied with streak meandering is successfully predicted. It is about 50 viscous lengths downstream from the sensing location, where gradients of wall shear stresses,  $\partial \tau_u / \partial z$  and  $\partial \tau_w / \partial z$ , are measured.
- 3. About 10% drag reduction is achieved with arrayed sensors and actuators. The streamwise vortices and streak meander-

ing are selectively attenuated by the present control scheme. The energy input of the present control is one order of magnitude smaller than the pumping power saved.
