### 1. INTRODUCTION

Solidification models in which the liquid phase is moving toward the substrate have applications in several important engineering problems such as crystal growth, icing, casting, and others. It is also interesting from a fundamental point of view in metal spray deposition problems, because it allows one to understand the effect of the flow strain on the solidification behavior.

The classical Stefan solidification model considers the solidification of the liquid in a semi-infinite domain in contact with a fixed temperature substrate [1, 2]. The Neumann solution of the Stefan solidification problem has been widely used in the analytical and numerical studies of the droplet deposition process [3–6]. The stagnation-flow solidification model presented by Rangel and Bian [7–9] includes the effect of the fluid motion on the solidification process. In these studies, the substrate was represented as a fixed-temperature boundary condition of the solid phase. Another common procedure to include the effect of the substrate on the solidification process is to assume the substrate depth as semi-infinite and the temperature variation of the substrate is solved in this semi-infinite domain [10–12]. Early experimental and analytical studies of the solidification and melting of a stagnation flow can be found in the work of Savino and Siegel who reported experimental results and analytical studies of the phase change process during the stagnation flow of a warm liquid on a cold plate [13, 14]. In the present work, the effect of the substrate depth on the stagnation-flow solidification problem is studied by analytical and numerical methods. In addition, the effect of the substrate temperature and the liquid temperature and strain rate on the solidification process is investigated. It is shown that the solidification process approaches a quasi-steady behavior, and remelting of the substrate may take place for large substrate depth and higher liquid temperature.

### 2. MATHEMATICAL FORMULATION

In reference to Fig. 1, consider stagnation flow with an initial temperature  $T_i$  impinging on a solid substrate of thickness  $h$  and initial temperature  $T_0$ . Phase change takes place at the interface and the motion of the interface is controlled by the thermal and fluid dynamics of the problem. The governing equations for this problem are described in [7].

The heat conduction equation for the solid phase is:

$$\frac{\partial^2 T_s}{\partial y^2} = \frac{1}{\alpha_s} \frac{\partial T_s}{\partial t} \quad \text{in } -h < y < s(t), t > 0 \quad (1)$$

with the boundary condition:  $T_s(y, t) = T_0$  at  $y = -h, t > 0$ .

Assuming inviscid flow, the energy equation of the liquid phase is

$$\frac{\partial T_l}{\partial t} - 2A(y-s(t)) \frac{\partial T_l}{\partial y} = \alpha_l \frac{\partial^2 T_l}{\partial y^2} \quad \text{in } s(t) < y < \infty, t > 0 \quad (2)$$

with the boundary condition:  $T_l(y, t) \rightarrow T_i$  as  $y \rightarrow \infty$ .

The coupling conditions at the interface  $y = s(t)$  are:

$$T_s(y, t) = T_l(y, t) = T_m \quad (3)$$

$$k_s \frac{\partial T_s}{\partial y} - k_l \frac{\partial T_l}{\partial y} = \rho h_{st} \frac{ds(t)}{dt} \quad (4)$$

Remelting of the substrate plays an important role in enhancing the bonding characteristics of the deposit. The occurrence of remelting at  $t = 0$  may be predicted using the Schwarz solution reported in ref. [1]. The criterion for initial remelting when the liquid initial temperature is  $T_i$  and the substrate initial temperature is  $T_0$  is:

$$\frac{T_i - T_m}{T_m - T_0} \frac{\sqrt{a_s}}{a_k} > 0. \quad (5)$$

**3. QUASI-STEADY SOLUTION**

In analogy to the quasi-steady solution of the inviscid stagnation-flow solidification on a constant temperature cold substrate [7], a quasi-steady solution is used to study the long-time solidification behavior of the problem. In employing the quasi-steady approximation, we neglect the time derivative in the governing equations (1) and (2). The boundary and initial conditions remain unchanged.

The solid-phase equation has the solution

$$\theta_s = \frac{T_s - T_m}{T_m - T_0} = \frac{y - s}{h + s} \tag{6}$$

while the liquid-phase solution is

$$\theta_l = \frac{T_l - T_m}{T_l - T_m} = \frac{\int_s^y \exp\left[-\frac{2A}{\alpha_l}\left(\frac{y'^2}{2} - sy'\right)\right] dy'}{\int_s^\infty \exp\left[-\frac{2A}{\alpha_l}\left(\frac{y'^2}{2} - sy'\right)\right] dy'} \tag{7}$$

The energy balance [equation (4)] can be written as

$$\rho h_s \frac{ds}{dt} = \frac{k_s(T_m - T_0)}{h + s} - \frac{k_l(T_l - T_m) \exp\left(\frac{As^2}{\alpha_l}\right)}{\int_s^\infty \exp\left[-\frac{2A}{\alpha_l}\left(\frac{y'^2}{2} - sy'\right)\right] dy'} \tag{8}$$

Employing the error function, equation (8) can be simplified to:

$$\rho h_s \frac{ds}{dt} = \frac{k_s(T_m - T_0)}{h + s} - 2(T_m - T_0)\theta_l k_l \sqrt{\frac{A}{\pi\alpha_l}} \tag{9}$$

which in turn can be rewritten in a dimensionless form as

$$\frac{1}{St} \frac{d\bar{s}}{d\tau} = \frac{1}{\bar{h} + \bar{s}} - \frac{2a_k\theta_l}{\sqrt{a\pi}} \tag{10}$$

The asymptotic value of  $\bar{s}$  can now be obtained by using the fact that  $d\bar{s}/d\tau \rightarrow 0$  as  $\tau \rightarrow \infty$  [7]. Then equation (10) gives

$$\bar{s} \rightarrow -\bar{h} + \frac{\sqrt{a\pi}}{2a_k\theta_l} \text{ as } \tau \rightarrow \infty \tag{11}$$

which indicates that there exists an upper limit of the solid phase thickness as time goes to infinity. This solution also shows that if  $\bar{h} = \sqrt{a\pi}/(2a_k\theta_l)$ , the final interface location is equal to the initial one. Furthermore, the final solid thickness is independent of  $\bar{h}$ .

**4. FINITE-DIFFERENCE SOLUTION**

For the numerical solution, it is convenient to recast the system of equations in a dimensionless form as:

$$\frac{\partial\theta_s}{\partial\tau} = \frac{\partial^2\theta_s}{\partial\bar{y}^2} \text{ for } -\bar{h} < \bar{y} < \bar{s}(\tau) \tag{12}$$

$$\frac{\partial\theta_l}{\partial\tau} - 2(\bar{y} - \bar{s}(\tau)) \frac{\partial\theta_l}{\partial\bar{y}} = a_x \frac{\partial^2\theta_l}{\partial\bar{y}^2} \text{ for } \bar{s}(\tau) < \bar{y} < \infty \tag{13}$$

$$\theta_l = \theta_s \text{ and } \frac{\partial\theta_s}{\partial\bar{y}} - a_k \frac{\partial\theta_l}{\partial\bar{y}} = \frac{1}{St} \frac{d\bar{s}}{d\tau} \text{ at } \bar{y} = \bar{s}(\tau). \tag{14}$$

Since the solution domain for the solid and liquid phases vary with time because of the moving interface position, the following transformations

$$\eta_s = \frac{4}{\pi} \tan^{-1} \left( \frac{\bar{y} - \bar{s}}{\bar{h} + \bar{s}} \right) \tag{15}$$

$$\eta_l = \frac{2}{\pi} \tan^{-1} (\bar{y} - \bar{s}) \tag{16}$$

are applied to transform the solution domain  $(-\bar{h}, \bar{s})$  into  $(-1, 0)$  and  $(\bar{s}, \infty)$  into  $(0, 1)$ . After the coordinate transformations, the Crank-Nicolson scheme is applied to obtain the finite-difference form of the system of equations. This system can then be solved to obtain the time-variation of the temperature distributions of the solid and liquid phases as well as the interface location. Similar transformations are employed in refs [8] and [12].

**5. RESULTS AND DISCUSSION**

Finite-difference solutions are obtained to study the stagnation-flow solidification process on a finite-thickness substrate of the same material. Aluminum properties are

employed. The effect of strain rate, Stefan number and other transport properties have been reported earlier for the limiting case of zero-thickness substrate at fixed temperature [7–9]. Figure 2 shows the effect of substrate thickness on the time evolution of the solid-front location. The most important feature is that the solid-front location approaches a fixed position predicted by the quasi-steady solution. If the initial solid substrate is thick enough,  $\tilde{h} = 10$  for example, it can be observed that the liquid will be solidified initially, but as time increases, the substrate will be remelted and the final position of the solid front will be lower than the initial interface. On the other hand, if the initial substrate thickness is sufficiently thin, the behavior of the solid-front location resembles the result obtained for the case of stagnation-flow solidification on a substrate with constant temperature [7, 8]. The case for  $\tilde{h} = 9.18$  corresponds to the situation where the final interface location is equal to its initial value.

The effect of the flow strain rate on the solidification behavior can be observed in Fig. 3. The strain rate is absorbed into the dimensionless time and position and, therefore, in order to see its effect, the solution must be plotted in dimensional units. For the case of aluminum with  $T_i = 1033$  K,

$T_0 = 300$  K,  $T_m = 933$  K, Fig. 3 shows that increasing the strain rate, increases the heat flux to the interface from the liquid side which has an adverse effect on the solidification process.

The dimensionless temperature distribution for two different substrate thicknesses at different times is shown in Fig. 4. It can be observed that in the final stages of solidification, the slope of the temperature distribution at the interface ( $\theta = 0$ ) on the solid side is very different from that in early times. The solid-state temperature gradient decreases, while the liquid-side temperature gradient remains constant due to the fact that the liquid temperature approaches a quasi-steady behavior more rapidly than the solid temperature does.

The effect of the initial liquid and substrate temperatures on the solidification process is shown in Fig. 5. It can be seen that increasing the initial temperature of the liquid to a high enough value will result in the remelting of the substrate. Increasing the initial temperature of the substrate will decrease the height of the final solid phase thickness. For a sufficiently thick substrate, the final solid front will be located below the original interface.

Fig. 2. Effect of substrate thickness ( $T_0 = 300$  K,  $T_i = 1033$  K,  $a_x = 0.43$ ,  $a_k = 0.40$ ,  $St = 1.67$ ).

Fig. 4. Effect of the substrate thickness on the temperature distribution ( $T_0 = 300$  K,  $T_i = 1033$  K).

Fig. 3. Solid-front time evolution for different strain rates ( $T_0 = 300$  K,  $T_i = 1033$  K,  $h = 0.1$  mm).

Fig. 5. Effect of initial liquid and substrate temperatures on the solid-front time evolution ( $\tilde{h} = 1$ ).
