OBITUARIES 2255

BOOK REVIEWS 2256

REVIEWS OF ACOUSTICAL PATENTS 2257

SELECTED RESEARCH ARTICLES [10]

The force between two parallel rigid plates due to the radiation pressure of broadband noise: An acoustic Casimir effect — Andrés Larraza, Christopher D. Holmes, Robert T. Susbilla, Bruce Denardo — 2267

The effect of compression ratio and release time on the categorical rating of sound quality — Arlene C. Neuman, Matthew H. Bakke, Carol Mackersie, Sharon Hellman, Harry Levitt — 2273

GENERAL LINEAR ACOUSTICS [20]

Lamb waves as thickness vibrations superimposed on a membrane carrier wave — J. D. Achenbach — 2283

Aperture synthesis of time-limited X waves and analysis of their propagation characteristics — Argyrios A. Chatzipetros, Amr M. Shaarawi, Ioannis M. Besieris, Mohamed A. Abdel-Rahman — 2287

Wave propagation in a wavy fiber–epoxy composite material: Theory and experiment — Kwang Yul Kim, Wei Zou, Wolfgang Sachse — 2296

Sound transmission through a periodic cascade with application to drill pipes — Niels J. C. Lous, Sjoerd W. Rienstra, Ivo J. B. F. Adan — 2302

NONLINEAR ACOUSTICS, MACROSONICS [25]

A finite element algorithm for the study of nonlinear standing waves — L. Elvira-Segura, E. Riera-Franco de Sarabia — 2312

The acoustic radiation force in lossless fluids in Eulerian and Lagrangian coordinates — K. Beissner — 2321

(Continued)

CONTENTS—*Continued from preceding page*

UNDERWATER SOUND [30]

Measurement and localization of interface wave reflections from a buried target	Eric Smith, Preston S. Wilson, Fred W. Bacon, Jason F. Manning, John A. Behrens, Thomas G. Muir	2333
Scattering of interface waves from pointlike obstacles	Eric Smith	2344
A fast integral equation approach to acoustic scattering from three-dimensional objects using a natural basis set	D. T. Moroney, P. J. Cullen	2354
Acoustical properties of end-initiated explosive line charges	William J. Marshall	2365
Nonlinear acoustic method for bubble density measurements in water	A. M. Sutin, S. W. Yoon, E. J. Kim, I. N. Didenkulov	2377

ULTRASONICS, QUANTUM ACOUSTICS, AND PHYSICAL EFFECTS OF SOUND [35]

Radiation impedance of resonant ultrasound spectroscopy modes in fused silica	Hong Zhang, R. S. Sorbello, Carsten Hucho, Joseph Herro, Jeffrey R. Feller, D. E. Beck, Moises Levy, D. Isaak, J. D. Carnes, O. Anderson	2385
A new approximation method for thermoacoustic calculations	Richard Raspet, James Brewster, Henry E. Bass	2395
Focusing and steering through absorbing and aberrating layers: Application to ultrasonic propagation through the skull	Mickaël Tanter, Jean-Louis Thomas, Mathias Fink	2403
Line-focusing of ultrasonic *SV* wave by electromagnetic acoustic transducer	Hirotsugu Ogi, Masahiko Hirao, Toshihiro Ohtani	2411
Lamb wave assessment of fatigue and thermal damage in composites	Michael D. Seale, Barry T. Smith, W. H. Prosser	2416

TRANSDUCTION [38]

A finite element analysis of an interferometric optical fiber hydrophone	Jong-in Im, Yong-rae Roh	2425
Ultrasonic three-dimensional probe modeling in anisotropic solids	A. Jonas Niklasson	2432

STRUCTURAL ACOUSTICS AND VIBRATION [40]

Modal excitation and control of membrane waves on cylindrical shells	Joseph E. Bondaryk	2443
Sound radiation by a simply supported unbaffled plate	B. Laulagnet	2451

ACOUSTICAL MEASUREMENTS AND INSTRUMENTATION [58]

Measurement of the reflection matrix of a discontinuity in a duct	Mohamed Akoum, Jean-Michel Ville	2463

ACOUSTIC SIGNAL PROCESSING [60]

Known source detection predictions for higher order correlators	Lisa A. Pflug, George E. Ioup, Juliette W. Ioup	2469
Reference-beam detection for scanning laser acoustic microscopy	Moisés Cywiak, Cristina Solano, Glen Wade, S. Isakson	2478
An adaptive noise reduction stethoscope for auscultation in high noise environments	Samir B. Patel, Thomas F. Callahan, Matthew G. Callahan, James T. Jones, George P. Graber, Kirk S. Foster, Kenneth Glifort, George R. Wodicka	2483
Projection data error estimation and correction for high-resolution tomographic acoustic microscopy	Richard Y. Chiao, Davis Kent, Hua Lee	2492

(Continued)

CONTENTS—*Continued from preceding page*

PHYSIOLOGICAL ACOUSTICS [64]

Spectral-ripple representation of steady-state vowels in primary auditory cortex — Huib Versnel, Shihab A. Shamma — 2502

PSYCHOLOGICAL ACOUSTICS [66]

Within-channel gap detection using dissimilar markers in cochlear implant listeners — Monita Chatterjee, Qian-Jie Fu, Robert V. Shannon — 2515

Analysis of the performance of a model-based optimal auditory signal processor — Lisa C. Gresham, Leslie M. Collins — 2520

Beneficial effects of notched noise on intensity discrimination in the region of the ''severe departure'' — Christopher J. Plack — 2530

Auditory filter nonlinearity at 2 kHz in normal hearing listeners — Stuart Rosen, Richard J. Baker, Angela Darling — 2539

Modeling interaural-delay sensitivity to frequency modulation at high frequencies — Kourosh Saberi — 2551

Forward masked excitation patterns in multielectrode electrical stimulation — Monita Chatterjee, Robert V. Shannon — 2565

The masking-level difference in low-noise noise — Joseph W. Hall III, John H. Grose, William Morris Hartmann — 2573

The influence of stimulus envelope and fine structure on the binaural masking level difference — David A. Eddins, Laura E. Barber — 2578

Masker fluctuation and the masking-level difference — John H. Grose, Joseph W. Hall III — 2590

Spontaneous classification of complex tones at high and ultrasonic frequencies in the bat, *Megaderma lyra* — Annemarie Preisler, Sabine Schmidt — 2595

The pitch of a mistuned harmonic: Evidence for a template model — Jian-Yu Lin, William M. Hartmann — 2608

Monaural phase discrimination by macaque monkeys: Use of multiple cues — David B. Moody, Colleen G. Le Prell, Andrew J. Niemiec — 2618

Lateralization and binaural discrimination of patients with pontine lesions — Vered Aharonson, Miriam Furst, Robert A. Levine, Michael Chaigrecht, Amos D. Korczyn — 2624

Spectro-temporal factors in two-dimensional human sound localization — Paul M. Hofman, A. John Van Opstal — 2634

SPEECH PRODUCTION [70]

Acoustic, aerodynamic, physiologic, and perceptual properties of modal and vocal fry registers — Michael Blomgren, Yang Chen, Manwa L. Ng, Harvey R. Gilbert — 2649

Automatic parametrization of differentiated glottal flow: Comparing methods by means of synthetic flow pulses — Helmer Strik — 2659

SPEECH PERCEPTION [71]

''How to milk a coat:'' The effects of semantic and acoustic information on phoneme categorization — Susan Borsky, Betty Tuller, Lewis P. Shapiro — 2670

Auditory-visual speech recognition by hearing-impaired subjects: Consonant recognition, sentence recognition, and auditory-visual integration — Ken W. Grant, Brian E. Walden, Philip F. Seitz — 2677

SPEECH PROCESSING AND COMMUNICATION SYSTEMS [72]

An analysis of the effect of basilar membrane nonlinearities on noise suppression — Jayadev Billa, Amro El-Jaroudi — 2691

MUSIC AND MUSICAL INSTRUMENTS [75]

Jet-wave amplification in organ pipes — Shigeru Yoshikawa — 2706

NOTES CONCERNING ARTICLE ABSTRACTS

1. The number following the abstract copyright notice is a Publisher Item Identifier (PII) code that provides a unique and concise identification of each individual published document. This PII number should be included in all document delivery requests for copies of the article.
2. PACS numbers are for subject classification and indexing. See June and December issues for detailed listing of acoustical classes and subclasses.
3. The initials in brackets following the PACS numbers are the initials of the JASA Associate Editor who accepted the paper for publication.

Document Delivery: Copies of journal articles can be ordered from the new Articles in Physics online document delivery service (URL: http://www.aip.org/articles.html).

SOUNDINGS

This front section of the *Journal* includes acoustical news, views, reviews, and general tutorial or selected research artcles chosen for wide acoustical interest and written for broad acoustical readership.

ACOUSTICAL NEWS—USA

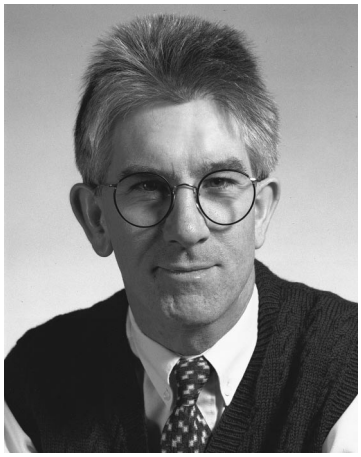
Elaine Moran
Acoustical Society of America, 500 Sunnyside Boulevard, Woodbury, New York 11797

Editor's Note: *Deadline dates for news items and notices are 2 months prior to publication.*

New Fellows of the Acoustical Society of America

Armand Dancer—For research on effects of intense sound on hearing.

John P. Seiler—For contributions to acoustical measurements and standards development.



Quentin Summerfield—For research in auditory grouping and speech perception.

Harvey Sussman—For contributions to the understanding of speech production.

The 134th meeting of the Acoustical Society of America held in San Diego, California

The 134th meeting of the Acoustical Society of America was held 1–5 December 1997 at the Town and Country Hotel in San Diego, California. This was the sixth time the Society has met in this city, the previous meetings being held in 1952, 1969, 1976, 1983, and 1990.

The meeting drew a total of 996 registrants. There were 175 nonmembers registered of whom over 33% joined the Society at the time of registration. Additionally, 189 students were in attendance.

Attesting to the international ties of our organization, 112 of the registrants (that is, about 11%) were from outside North America, the United States, Canada, and Mexico, which accounted for 854, 26, and 4, respectively. There were 31 registrants from Japan, 9 each from Sweden and France, 8 each from Germany and Russia, 7 from the United Kingdom, 6 from Denmark, 5 each from Brazil and Italy, 4 from the Netherlands, 3 each from Norway and Spain, and Australia, 2 each from Finland, Korea and Singapore, and 1 each from Austria, China, India, Israel, and Slovakia.

A total of 679 papers organized into 77 sessions covered the areas of interest of all 12 Technical Committees and 1 Technical Group. The meeting also included 21 different meetings dealing with standards, indicating a healthy level of activity in this area of our endeavors.

The local meeting committee arranged technical tours to the Hubbs Sea-World Research Institute and to FLIP, the 355-foot-long manned spar buoy developed and operated by the Marine Physical Laboratory of Scripps Institute of Oceanography.

The tutorial lecture series was continued at the San Diego meeting.

 0001-4966/98/103(5)/2241/4/$10.00

FIG. 1. President Lawrence Crum (l) and Executive Director Charles Schmid present the Distinguished Service Citation to Alice H. Suter.

FIG. 2. Robert. W. Young (c), new Honorary Fellow, receives congratulations from President Lawrence Crum and Vice President Ilene J. Busch-Vishniac (l), Evelyn Young and Robert S. Gales (r).

FIG. 3. Herman Medwin (c), recipient of the Silver Medal in Acoustical Oceanography, receives congratulations from President Lawrence Crum (l), Eileen Medwin and Clarence Clay (r).

FIG. 4. Robert E. Apfel (c), recipient of the Silver Medal in Physical Acoustics, is congratulated by Vice President Ilene Busch-Vishniac and President Lawrence Crum (l) and Nancy Apfel (r).

FIG. 5. Patricia K. Kuhl (c), recipient of the Silver Medal in Speech Communication, is congratulated by Vice President Ilene Busch-Vishniac, President Lawrence Crum (l) and Kenneth Stevens (r).

FIG. 6. Russell Johnson (c), recipient of the Wallace Clement Sabine Medal, with ASA President Lawrence Crum (l) and William Cavanaugh (r).

FIG. 7. President Lawrence Crum and Vice President Ilene Busch-Vishniac (r) present the Science Writing Award for Professionals in Acoustics to John R. Potter, Michael J. Buckingham, and Chad L. Epifanio (l–r).

FIG. 8. President Lawrence Crum (l) and Vice President Ilene Busch-Vishniac (r) present certificates to the newly elected Fellows of the Acoustical Society of America.

Whitlow W. L. Au of the Hawaii Institute of Marine Biology lectured on ''The Dolphin Echolocation System'' to an audience of about 100, attesting to the broad interest of the subject.

The plenary session included the presentation of awards, announcement of newly elected Fellows of the Society, and recognition of the meeting organizers. The President presented eight Society awards (see Figs. 1 through 7) and announced the election of 24 new Fellows. The Science Writing Award in Acoustics for Journalists was awarded to Richard Wolkomir for his article in the February 1996 issue of *Smithsonian* titled ''Decibel by Decibel, Reducing the Din to a Very Dull Roar.'' Mr. Wolkomir was unable to attend the meeting. The Science Writing Award for Professionals in Acoustics was presented to Michael J. Buckingham, John R. Potter, and Chad L. Epifanio for their article in the February 1996 issue of *Scientific American* titled ''Seeing Underwater with Background Noise.'' The Distinguished Service Citation was presented to Alice H. Suter of Alice H. Suter Associates, Ashland, Oregon, ''for increasing public awareness of acoustics and for dedicated service to the Society as editor of *Echoes*.'' Honorary Fellowship was conferred upon Robert W. Young, Consultant in Acoustics, San Diego, California, ''for contributions encompassing many areas of acoustics, to international standards and acoustical terminology, and for sustained and devoted service to the Society.'' The Silver Medal in Acoustical Oceanography was presented to Herman Medwin of Ocean Acoustics Associates, Pebble Beach, California, ''for contributions to the understanding of acoustical scattering, absorption and ambient noise, particularly in relation to the acoustics of bubbles in the sea.'' The Silver Medal in Physical Acoustics was presented to Robert E. Apfel of Yale University, New Haven, Connecticut, ''for contributions to the understanding of acoustic cavitation, acoustic radiation pressure, and the bioeffects of medical ultrasound.'' The Silver Medal in Speech Communication was presented to Patricia K. Kuhl of the University of Washington, Seattle, ''for contributions to the understanding of the innate and learned aspects of speech perception and production.'' The Wallace Clement Sabine Medal was presented to Russell Johnson of Artec Consultants, New York, New York ''for contributions to the understanding of the acoustics of performance spaces and the design of concert halls, theaters and opera houses throughout the world.'' Election of the following persons to Fellow grade was announced: Robert J. Bernhard, Nicholas P. Chotiros, Walter L. Clearwaters, Diana Deutsch, Gary W. Elko, Albert S. Feng, Shimshon Frankenthal, Andrew S. Harris, Yun-Fan Hwang, Akira Ishmaru, C. Scott Johnson, Gerald R. Kidd, Marjorie R. Leek, Brenda L. Lonsbury-Martin, Nicholas Makris, Matthew A. Nobile, Daniel R. Raichel, Richard J. Salvi, Klaus Scherer, Astrid Schmidt-Nielsen, Guido F. Smoorenburg, Arnold Tubis, Richard M. Warren, and George Winzer (see Fig. 8).

The President expressed the Society's thanks to the Local Committee for the excellent execution of the meeting, which clearly required meticulous planning. He introduced the Chair of the Meeting, Mauro Pierucci, who acknowledged the contributions of the members of his committee including: Michael J. Buckingham and Ann E. Bowles, Technical Program Cochairs; Grant B. Deane and Joel R. Bock, Audio-Visual; Paul A. Baxley, Socials and Receptions; Charles F. Greenlaw, Exhibits; Robert J. Vent, Facilities; Frederick H. Fisher, Public Relations; Mary Pierucci, Penny Buckingham, Janet Bock and Donna Baxley, Hospitality; D. Vance Holliday, Paper Copying Service; Jo Griffith and Gail Smith, Registration; Duncan E. McGhee, Signs; Francis X. Byrnes, Technical Tours, Linda Sax Crossland, Visitors' Program.

The President also extended thanks to the members of the Technical Program Organizing Committee: Michael J. Buckingham and Ann E. Bowles, Technical Program Cochairs; Darrell R. Jackson, Christian P. de Moustier, and Gerald R. D'Spain, Acoustical Oceanography; Ann E. Bowles and David A. Helweg, Animal Bioacoustics; David Lubman and Neil Shaw, Architectural Acoustics; Lawrence A. Crum, Bioresponse to Vibration/Biomedical Ultrasound; Scott D. Sommerfeldt, Education in Acoustics; Steven Baker, Engineering Acoustics; R. Dean Ayres, Musical Acoustics; Louis A. Sutherland, Noise; Andres Larraza and Thomas L. Hofler, Physical Acoustics; Robert V. Shannon, Psychological and Physiological Acoustics; David I. Havelock and Gary R. Wilson, Signal Processing in Acoustics; Terrance M. Nearey, Edward Auer, and Paul Iverson, Speech Communication; Courtney B. Burroughs and Scott D. Sommerfeldt, Structural Acoustics and Vibration; Newell O. Booth and Michael D. Collins, Underwater Acoustics; Gail Smith and Graziella Bruni, Coordinators.

LAWRENCE A. CRUM
President 1997–1998

USA Meetings Calendar

Listed below is a summary of meetings related to acoustics to be held in the U.S. in the near future. The month/year notation refers to the issue in which a complete meeting announcement appeared.

1998

13–15 May	28th Annual Symposium, Ultrasonic Industry Assn., King of Prussia, PA [Ultrasonic Industry Assn., Inc., P.O. Box 1420, Cherry Hill, NJ 08034-0054; Tel.: 609-424-8998; Fax: 609-424-9248].
4–7 June	7th Symposium on Cochlear Implants in Children, Iowa City, IA [Center for Conferences and Institutes, The University of Iowa, 249 Iowa Memorial Union, Iowa City, IA 52242-1317; Tel.: 800-551-9029; Fax: 319-335-3533].
20–26 June	135th meeting of the Acoustical Society of America/16th International Congress on Acoustics, Seattle, WA [ASA, 500 Sunnyside Blvd., Woodbury, NY 11797, Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org, WWW: http://asa.aip.org].
26 Jun.–1 Jul.	International Symposium on Musical Acoustics, ISMA 98, Leavenworth, WA [Maurits Hudig, Catgut Acoustical Society, 112 Essex Ave., Montclair, NJ 07042, Fax: 201-744-9197; E-mail: catgutas@msn.com, WWW: www.boystown.org/isma98].
7–12 July	Vienna and the Clarinet, Ohio State Univ., Columbus, OH [Keith Koons, Music Dept., Univ. of Central Florida, P.O. Box 161354, Orlando, FL 32816-1354, Tel.: 407-823-5116; E-mail: kkons@pegasus.cc.ucf.edu].

12–15 July Transportation Research Board A1F04 Summer Meeting on Transportation Related Noise and Vibration, Tallahassee, FL [Win Lindeman, Florida Department of Transportation, 605 Suwannee St., M.S. 37, Tallahassee, FL 32399-0450, Tel.: 850-488-2914; Fax: 850-922-7217; E-mail: win.lindeman@dot.state.fl.us].

9–14 Aug. International Acoustic Emission Conference, Hawaii [Karyn S. Downs, Lockheed Martin Astronautics, P.O. Box 179, M.S. DC3005, Denver, CO 80201; Tel.: 303-977-1769; Fax: 303-971-7698; E-mail: karyn.s.downs.@lmco.com].

13–17 Sept. American Academy of Otolaryngology—Head and Neck Surgery, San Francisco, CA [American Academy of Otolaryngology—Head and Neck Surgery, One Prince St., Alexandria, VA 22314; Tel.: 703-836-4444; Fax: 703-683-5100].

18–19 Sept. 6th Annual Conference on Management of the Tinnitus Patient, Iowa City, IA [Richard Tyler, Univ. of Iowa, Dept. of Otolaryngology—Head & Neck Surgery, 200 Hawkins Dr., C21GH, Iowa City, IA 52242; Tel.: 319-356-2471; Fax: 319-353-6739; E-mail: rich-tyler@uiowa.edu].

12–16 Oct. 136th meeting of the Acoustical Society of America, Norfolk, VA [ASA, 500 Sunnyside Blvd., Woodbury, NY 11797, Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org, WWW: http://asa.aip.org].

15–19 March Joint meeting: 137th meeting of the Acoustical Society of America/Forum Acusticum [Acoustical Society of America, 500 Sunnyside Blvd., Woodbury, NY 11797, Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: asa.aip.org].

27–30 June ASME Mechanics and Materials Conference, Blacksburg, VA [Mrs. Norma Guynn, Dept. of Engineering Science and Mechanics, Virginia Tech, Blacksburg, VA 24061-0219; Fax: 540-231-4574; E-mail: nguynn@vt.edu; WWW: http://www.esm.vt.edu/mmconf/]. Deadline for receipt of abstracts: 15 January 1999.

ACOUSTICAL STANDARDS NEWS

Avril Brenig, Standards Manager
Standards Secretariat, Acoustical Society of America, 120 Wall Street, 32nd Floor, New York, New York 10005-3993 [Tel.: (212) 248-0373; Fax: (212) 248-0146; e-mail: asastds@aip.org]

George S. K. Wong
Acoustical Standards, Institute for National Measurement Standards, National Research Council, Ottawa, Ontario K1A 0R6, Canada [Tel.: (613) 993-6159; Fax: (613) 990-8765; e-mail: george.wong@nrc.ca]

American National Standards (ANSI Standards) developed by Accredited Standards Committees S1, S2, S3, and S12 in the areas of acoustics, mechanical vibration and shock, bioacoustics, and noise, respectively, are published by the Acoustical Society of America (ASA) through the American Institute of Physics (AIP). In addition to these standards, a Catalog of Acoustical Standards—ASA Catalog 17-1997—is available. For a copy, contact Avril Brenig.

Comments are welcomed on all material in Acoustical Standards News.

Standards Meetings Calendar—National

The next meetings of the Accredited Standards Committees for national standards development, the review of International Standards, and planning of future meetings are scheduled to be held during the joint 135th ASA/16th ICA Meetings at the Westin Hotel and the Seattle Sheraton Hilton Hotel, Seattle, WA, 20–28 June 1998. Meetings of the Accredited Standards Committees are open to the public for participation. Organizations and individuals with expertise that may enhance the performance of the acoustical standards effort are encourage to participate.

• ***Monday, 22 June 1998, 7:00 p.m***.
ASACOS Steering Committee

• ***Tuesday, 23 June 1998, 7:30 a.m.***
ASA Committee on Standards (ASACOS). Meeting of the committee that directs the Acoustical Society Standards Program

• ***Wednesday, 24 June 1998, 9:00 a.m.***
Accredited Standards Committee S2 on Mechanical Vibration and Shock (also Technical Advisory Group for ISO/TC 108 Mechanical Vibration and Shock as well as ISO/TC 108/SC1, Balancing, Including Balancing Machines; ISO/TC 108/SC2 Measurement and Evaluation of Mechanical Vibration and Shock as applied to Machines, Vehicles and Structures; ISO/TC 108/SC 3 Use and Calibration of Vibration and Shock Measuring Instruments, ISO/TC 108/ SC5 Condition Monitoring and Diagnostics of Machines, and ISO/TC108/SC 6 Vibration and Shock Generating Equipment).

• ***Thursday, 25 June 1998, 8:00 a.m.***
Standards Committee Plenary Group
[To discuss national items relevant to all S Committees (S1, S2, S3, and S12), plus a review of the international standardization activities under ISO and IEC for which the S Committees form the respective U.S. Technical Advisory Groups (TAGS)]

• ***Thursday, 25 June 1998, 9:30 a.m.***
Accredited Standards Committee S12 on Noise (also Technical Advisory Group for ISO/TC 43/SC 1—Noise and ISO/TC 94/SC 12—Hearing Protection)

• ***Thursday, 25 June 1998, 2.00 p.m.***
Accredited Standards Committee S3 on Bioacoustics (also Technical Advisory Group for ISO/TC 43 Acoustics, IEC/TC 29—Electroacoustics, and ISO/TC 108/SC 4—Human Exposure to Mechanical Vibration and Shock)

• ***Thursday, 25 June 1998, 3.30 p.m.***
Accredited Standards Committee S1 on Acoustics (also Technical Advisory Group for ISO/TC 43—Acoustics and IEC/TC 29—Electroacoustics)

Standards News from the United States

(Partially derived from *ANSI Reporter*, and *ANSI Standards Action*, with appreciation)

Call for comment on proposed American National Standards and American National Standards proposed for Reaffirment or Withdrawal

This section lists proposed American National Standards that solicit public comments and review. The final dates for offering comments, listed in parentheses, are for information only. Copies of these documents are available from ANSI.

SHOCK AND VIBRATION (30 September 1997)

BSR S2.2-1959, Methods for the Calibration of Shock and Vibration Pickups (**reaffirmation of** ANSI S2.2-1959 (R1990))

Selects five methods as the standard methods for the calibration of acceleration, velocity, and displacement pickups. They are described in Section 4 of this standard. It is impracticable to calibrate all pickups by one standard method over the entire frequency and amplitude range of vibrations and shocks to be measured by the pickups. Several methods are accordingly described. Each method is limited to a range of frequency and amplitude, and to the weight of pickup that can be calibrated. The limitations may include, in addition, other variables such as volume of the pickup and temperature of operation.

BSR S2.4-1976, Method for Specifying the Characteristics of Auxiliary Analog Equipment for Shock and Vibration Measurements (**reaffirmation of** ANSI S2.4-1976 (R1990))

Applies to the auxiliary equipment used between a shock or vibration transducer and the final indicator, recorder, or signal processor. This document presents a standard format for indicating pertinent characteristics, but does not in any respect become a standard on the performance of the equipment. Since this standard was prepared to cover a wide variety of equipment in considerable detail, not all items will be pertinent to a specific piece of equipment. Also, it is not the intent of this standard to establish an ironclad rule as to which of the characteristics should be included, although in many cases important characteristics are emphasized.

BSR S2.5-1962, Recommendations for Specifying the Performance of Vibration Machines (**reaffirmation of** ANSI S2.5-1962 (R1990))

Examines three types of vibration machines that are used for exciting vibrations in equipment or structures, in order to provide assurance that such equipment or structures are able to withstand the conditions of vibration they may encounter in later service. Shakers, such as are used for sifting, mixing, or unloading operations, and machines designed specifically for fatigue testing are excluded. Three types of vibration machines are considered: the mechanical direct-drive: the mechanical reaction type, which includes the vibration exciter and vibration machine as separate items; and the electrodynamic. Other types, involving hydraulic excitation, resonant systems, piezoelectric application for instrument calibrations, and special vibration machines for testing packages come under the general scope of this standard: however, the exploratory nature of this work does not make a complete coverage of this field appear feasible at this time.

BSR S2.7-1982, Balancing Terminology (**reaffirmation of** ANSI S2.7-1982 (R1986))

Contains a collection of terms and definitions relating to balancing procedures and equipment. The terms are grouped into seven major categories covering the subject of (1) machines, (2) rotors, (3) unbalance, (4) balancing, (5) balancing machines and equipment, (6) flexible rotors, and (7) rotating rigid free-bodies (i.e., aerospace vehicles). An alphabetical index follows at the end.

BSR S2.8-1972, Resilient Mountings, Guide for Describing the Characteristics of Resilient Mountings (**reaffirmation of** ANSI S2.8-1972 (R1986))

Outlines, in standardized form, what data should be presented to enable the experienced designer to apply resilient mountings correctly. Also, the standard defines terminology, in a further effort to ease the problem of communication between user and manufacturer. It is beyond the scope of this standard to present characteristics of resilient mountings.

BSR S2.9-1976, Nomenclature for Specifying Damping Properties of Materials (**reaffirmation of** ANSI S2.9-1976 (R1990))

Presents the preferred nomenclature (parameters, symbols, and definitions) for specifying the damping properties of uniform materials and uniform specimens, where ''uniform'' implies homogeneity on a macroscopic scale. For reference purposes, certain nonstandard damping parameters are discussed (Appendix A). Also included is a classification of damping test parameters (Appendix B). The term ''damping'' as used in this standard is restricted to those properties of a material that are related to the process of cyclic energy dissipation during harmonic vibration. This definition specifying excludes: energy transfer devices such as dynamic absorbers; external damping processes such as air-damping or acoustic radiation; and energy dissipation during transient or random vibration.

BSR S2.10-1971, Methods for Analysis and Presentation of Shock and Vibration Data (**reaffirmation of** ANSI S2.10-1971 (R1990))

Covers vibration in the following idealized classes that are described in 2.2§ 1) Periodic vibration; (2) Aperiodic vibration; (3) Random vibration; (4) Transient vibration (including shock). It is assumed that the data are available as time-histories of a variable associated with shock and vibration, for example, acceleration, velocity, force, etc., and that any distortion resulting from the transducer, recording system, etc., has been eliminated. Also, assumed that the mean value of a random vibration is zero. It is recognized that in many instances the vibration does not conform to this classification of two or more classes. Suggestions are given for separating the classes as a necessary step in data analysis.

BSR S2.11-1969, Calibrations and Tests for Electrical Transducers Used for Measuring Shock and Vibration, Selection of (**reaffirmation of** ANSI S2.11-1969 (R1986))

Includes considerations relevant to commonly employed electromechanical shock and vibration measurement transducers, but not to those transducers primarily designed for measurement of acoustic or pressure phenomena. In general, the tests and calibrations listed are pertinent to the transducer portion of integrated measuring systems, but are not intended to be comprehensive in regard to associated circuitry or electronic accessory instruments.

BSR S2.14-1973, Methods for Specifying the Performance of Shock Machines (**reaffirmation of** ANSI S2.14-1973 (R1986))

Details the shock machines employed for diagnostic testing and for demonstration of evaluation of the effect of shock conditions representative of use environment. Several techniques for generating the desired shock motion are discussed. Two basic types of pulse shock machines are considered: those that provide the shock by a controlled reduction of the velocity of the test specimen (declaration or impact), and those that apply the shock

by a controlled increase in the specimen velocity (acceleration or impulse). A vibration machine employed to generate controlled transient vibratory shocks and some pulse shocks is also discussed.

BSR S2.15-1972, Specification for the Design, Construction, and Operation of Class HI (High Impact) Shock-Testing Machine for Lightweight Equipment (**reaffirmation of** ANSI S2.15-1972 (R1986))

Describes the design and construction of a class HI (High-Impact) shock-testing machine. By means of this standardized design, the ability of various types of equipment to withstand shock loadings may be compared. Also outlines recommended test procedures.

BSR S2.17-1980, Machinery Vibration Measurement (**reaffirmation of** ANSI S2.17-1980 (R1986))

Details vibration measurement quantities, equipment, and procedures involved in operating machinery. Calibration of vibration measurement and calibration equipment are discussed in the document. The standard has applications to preventive maintenance programs, equipment selection, and equipment quality.

BSR S2.19-1980, Mechanical Vibration—Balance Quality Requirements of Rigid Rotors—Part 1, Determination of Permissible Residual Unbalance (**reaffirmation of** ANSI S2.19-1989)

Contains recommended balance tolerances for various types of rotors and a detailed explanation of how they are to be understood for selected rotor planes. This document also deals with methods of allocating the recommended permissible residual unbalance to rotors with narrowly spaced, overhung, and/or unsymmetrically located correction planes. This standard is the U.S. counterpart of ISO 1940/1-1986, *Mechanical Vibration Balance Quality Requirements of Rigid Rotors—Part 1: Determination of Permissible Residual Unbalance*. It is a revised version of the prior standard ANSI S2.19-1975, American National Standard for Balance Quality of Rotating Rigid Bodies.

BSR S2.20-1983, Air Blast Characteristics for Single Point Explosions in Air, with a Guide to Evaluation of Atmospheric Propagation and Effects (**reaffirmation of** ANSI S2.20-1983 (R1989))

Provides consensus quantitive definitions of explosion characteristics for a single point explosion in air, along with methodologies for scaling these characteristics for a wide range of yield and ambient air conditions. Factors for use with common solid explosives are also included. Methods are provided for predictions of long range propagation under atmospheric refractive influences. Target damage estimation procedures are provided for use in explosion operational planning and evaluation.

BSR S2.31-1979, Methods for the Experimental Determination of Mechanical Mobility, Part I: Basic Definitions and Transducers (**reaffirmation of** ANSI S2.31-1979 (R1986))

Covers basic concepts and definitions and serves as a guide for the selection, calibration, and evaluation of the transducers and instruments used in mobility measurements. The material in Part I is common to most mobility measurement tasks. This standard is the first part of a series of five standards covering the experimental determination of mechanical mobility of structures by a variety of methods appropriate for different test situations. This document supersedes ANSI S2.6-1963 (R1976).

BSR S2.32-1982, Methods for the Experimental Determination of Mechanical Mobility, Part II: Measurements Using Single-Point Translation Excitation (**reaffirmation of** ANSI S2.32-1982 (R1990))

Comprises the second part of a set of five standards covering the experimental determination of mechanical mobility of structures by a variety of methods appropriate for different test situations. Part I of the set (American National Standard Methods for the Experimental Determination of Mechanical Mobility, Part I: Basic Definitions and Transducers, ANSI S2.31-1979) covers basic concepts and definitions as well as instruments used in mobility measurements. The material in Part I is common to most mobility measurement tasks. The present Part II of the set describes measurements in situations in which single-point translational excitation with an attached vibration exciter is appropriate.

BSR S2.34-1984, Guide to the Experimental Determination of Rotational Mobility Properties and the Complete Mobility Matrix (**reaffirmation of** ANSI S2.34-1984 (R1990))

Determines the mobility properties of structures derived from the complex amplitudes of translational and rotational responses and the complex amplitudes of excitation forces and moments within the audio frequency range.

BSR S2.38-1982, Field Balancing Equipment—Description and Evaluation (**reaffirmation of** ANSI S2.38-1982 (R1990))

Provides the description and evaluation of portable equipment used for field (in-place) balancing of rotating machinery. It tells the equipment manufacturer which performance parameters need to be specified and in what terms, so that the prospective user can assess the applicability of the equipment for his purpose. At the same time, a prospective user is given guidance on how to describe his requirements to the equipment manufacturer.

BSR S2.40-1984, Mechanical Vibration of Rotating and Reciprocating Machinery—Requirements for Instruments for Measuring Vibration Severity (**reaffirmation of** ANSI S2.40-1984 (R1990))

Establishes the requirements of instrumentation for accurately measuring the vibration severity of machinery. Limitations for frequency, sensitivity, amplitude range, calibration, and environmental factors are presented in this standard.

BSR S2.41-1985, Mechanical Vibration of Large Rotating Machines with Speed Range from 10 to 200 rev/s—Measurement and Evaluation of Mechanical Vibration Severity *in situ* (**reaffirmation of** ANSI S2.41-1985 (R1990))

Describes measurement and evaluation of vibration severity of large rotating machinery *in situ* and is the U.S. counterpart of ISO 3945-1977. This standard, which is in complete technical agreement with ISO 3945-1977, is not applicable to reciprocating machinery. The values of vibration severity recommended as limits in this standard are intended to serve as standard values for machines of similar type, when measured in accordance with the procedures described in this standard. The recommended vibration limits may be used for acceptance standards or for monitoring the satisfactory performance of the machine during service operations.

BSR S2.42-1982, Procedures for Balancing Flexible Rotors (**reaffirmation of** ANSI S2.42-1982 (R1990))

Classifies rotors into groups by their balancing requirements as influenced by the rotor's flexural stiffness and unbalance distribution. Certain classes of rotors may be balanced by normal or modified rigid rotor techniques. Other more flexible rotors may require high-speed balancing. The fundamentals of flexible rotor balancing are discussed as well as methods of assessment of final unbalance. Guidance is given in judging the final balance quality; however, this standard is not intended to serve as an acceptance specification for any rotor group. It is offered to provide direction on how to avoid gross deficiencies or unattainable requirements.

BSR S2.43-1984, Criteria for Evaluating Flexible Rotor Balance (**reaffirmation of** ANSI S2.43-1984 (R1990))

Specifies criteria for evaluating flexible rotors in a balancing facility in terms of (a) permissible vibration at specified measuring points (derived from ISO 2372-1974, Mechanical vibration of machines with operating speeds from 10 to 200 rev/s-Basis, for specifying evaluation standards, and ISO 3945-1977, Mechanical vibrations of large rotating machines with speed range from 10 to 200 rev/s—Measurement and evaluation of vibrations severity *in situ*; and (b) permissible residual unbalance in specified correction planes [derived from ASA STD 2-1975 (ANSI 2.19-1974), American National Standard for Mechanical Vibration—Balance Quality Requirements of Rigid Rotors—Part I, Determination of Permissible Residual Unbalance]. This standard is the U.S. counterpart of ISO 5343-1983 and is to be used in conjunction with American National Standard Procedures for Balancing Flexible Rotors, ANSI S2.42-1982 (ASA 46-1982)

BSR S2.45-1983, Electrodynamic Test Equipment for Generating Vibration—Method of Describing Equipment Characteristics (**reaffirmation of** ANSI S2.45-1983 (R1990))

Provides a method for specifying the characteristics of electrodynamic test equipment for generating vibration and serves as a guide to the selection of such equipment. It applies to electrodynamic vibration generators and power amplifiers, both individually and in combination. The standard provides means to assist a prospective user to calculate the performance of equipment provided by two or more manufacturers, even if the vibration generator and the power amplifier are from different manufacturers.

BSR S2.46-1989, Characteristics to be Specified for Seismic Transducers (**reaffirmation of** ANSI S2.46-1989 (R1991))

Specifies the characteristics of a seismic transducer (pickup) that can serve as an adequate description of the capabilities of the pickup to perform a shock or vibration measurement in various environments. It is intended as a guide to instruct in specifying, selecting, or preparing performance description by users. This standard is the national counterpart of ISO 8042-

1988, *Shock and Vibration Measurements—Characteristics to be Specified for Seismic Pick-Ups.*

BSR S2.47-1990, Vibration of Buildings—Guidelines for the Measurement of Vibrations and Evaluation of Their Effects on Buildings (**reaffirmation of** ANSI S2.47-1990)

Provides guidelines for the measurement of building vibrations and evaluation of their effects on buildings. It is intended to establish the basic principles for carrying out vibration measurement and processing data, with regard to evaluating vibration effects on buildings. The evaluation of the effects of building vibration is primarily directed at structural response, and includes appropriate analytical methods where the frequency, duration, and amplitude can be defined. It is the U.S. counterpart of the International Standard, ISO 4866-1990.

BSR S2.48-1993, Servo-Hydraulic Test Equipment for Generating Vibration—Methods of Describing Characteristics (**reaffirmation of** ANSI S2.48-1993)

Provides a method for specifying the characteristics of servo-hydraulic test equipment for generating vibration and serves as a guide to the selection of such equipment. It applies to servo-hydraulic vibration generators and power amplifiers, both individually and in combination. The standard provides means to assist a prospective user to calculate and compare the performance of equipment provided by two or more manufacturers, even if the vibration generator and the power amplifier are from different manufacturers.

BSR S2.58-1983, Auxiliary Tables for Vibration Generators—Methods of Describing Equipment Characteristics (**reaffirmation of** ANSI S2.58-1983 (R1990))

Provides a method for specifying the characteristics of eight types of auxiliary tables for vibration generators. It serves as a guide to the prospective user of auxiliary tables to assist in the objective comparison of the performance of auxiliary tables available from different manufacturers.

BSR S2.60-1987, Balancing Machines—Enclosures and Other Safety Measures (**reaffirmation of** ANSI S2.60-1987)

Describes a balancing machine's potential hazards to its operator and the surrounding workshop area, relates accident probabilities, and enumerators precautionary measures. The major portion of the standard deals with the danger from rotor particles or components separating during rotation, and specifies safety measures in five different protection classes. The effects of fragment mass, shape, material, and velocity are discussed and a standard projectile for penetration resistance testing is established. Finally, a table lists parameters for fragment enclosures for a representative series of general-purpose balancing machines.

BSR S2.61-1989, Guide to the Mechanical Mounting of Accelerometers (**reaffirmation of** ANSI S2.61-1989 (R1991))

Specifies methods for mounting contact accelerometer and delineates the limitations of the recommended methods, such as frequency range of interest, amplitude, and phase measurement accuracy. Characteristics of the mounting arrangements used by specific accelerometers, which should be specified by the manufacturer are established and guidance is provided to the user to optimize performance of a recommended mounting method.

BSR S3.34-1986, Human Exposure to Vibration Transmitted to the Hand, Guide for Measurement and Evaluation of (**reaffirmation of** ANSI S3.34-1986 (R1992))

Specifies the recommended method for the measurement, data analysis, and reporting of human exposure to hand-transmitted vibration. A standard format is established for measurement, data analysis, and reporting of hand-transmitted vibration, periodic or random, in up to three orthogonal axes, in the frequency range from 5.6 Hz to 1400 Hz. Three Appendices, which are not part of the standard, provide information for the assessment of exposure to hand-transmitted vibration, on the latent period for the development of symptoms due to hand-transmitted vibration, and on further publications on the subject.

ACCELEROMETERS

BSR/IEEE 836-1992 (R1997), Recommended Practice for Precision Centrifuge Testing of Linear Accelerometers (**reaffirmation of** ANSI/IEEE 836-1992) (11 Nov. 1997)

Describes the conduct and analysis of precision tests that are to be performed on linear accelerometers using centrifuge techniques.

Final actions on American National Standards

ANSI's Board of Standards Review has taken the final action indicated on the standards listed below. When the approved standards are published, an announcement will be carried in *Standards Action*, in ANSI's Supplements to the Catalog of American National Standards, and in trade publications.

ACOUSTICS

ANSI S1.4-1983 (R1997), Specification for Sound Level Meters (**reaffirmation of** ANSI S1.4-1983 (R1994)): 29 July 1997.

ANSI S1.6-1984 (R1997), Preferred Frequencies, Frequency Levels, and Band Numbers for Acoustical Measurements (**reaffirmation of** ANSI S1.6-1984 (R1994)): 29 July 1997.

ANSI S1.8-1989 (R1997), Reference Quantities for Acoustical Levels (**reaffirmation of** ANSI S1.8-1989): 29 July 1997.

ANSI S1.10-1966 (R1997), Method for the Calibration of Microphones (**reaffirmation of** ANSI S1.10-1966 (R1986)): 7 July 1997.

ANSI S1.12-1967 (R1997), Specifications for Laboratory Standard Microphones (**reaffirmation of** ANSI S1.12- 1967) (R1986)): 29 July 1997.

ANSI S1.22-1992 (R1997), Scales and Sizes for Frequency Characteristics and Polar Diagrams in Acoustics (**reaffirmation of** ANSI S1.22-1992): 29 July 1997.

ANSI S1.25-1991 (R1997), Specification for Personal Noise Dosimeters (**reaffirmation of** ANSI S1.25-1991): 29 July 1997.

ANSI S1.40-1984 (R1997), Specification for Acoustical Calibrators (**reaffirmation of** ANSI S1.40-1984): 29 July 1997.

ANSI S3.14-1997 (R1997), Rating Noise with Respect to Speech Interference (**reaffirmation of** ANSI S3.14-1997 (R1986)): 29 July 1997.

ANSI S12.5-1990 (R1997), Requirements for the Performance and Calibration of Reference Sources (**reaffirmation of** ANSI S12.5-1990): 29 July 1997.

ANSI S12.10-1985 (R1997), Methods for the Measurement and Designation of Noise Emitted by Computer and Business Equipment (**reaffirmation of** ANSI S12.10-1985 (R1990)): 29 July 1997.

ANSI S12.11-1987 (R1997), Method for the Measurement of Noise Emitted by Small Air-Moving Devices (**reaffirmation of** ANSI S12.11-1987 (R1993)): 29 July 1997.

ANSI S12.12-1992 (R1997), Engineering Method for the Determination of Sound Power Levels of Noise Sources Using Sound Intensity (**reaffirmation of** ANSI S12.12-1992): 29 July 1997.

ANSI S12.14-1992 (R1997), Methods for the Field Measurement of the Sound Output of Audible Public Warning Devices Installed at Fixed Locations Outdoors (**reaffirmation of** ANSI S12.14-1992): 29 July 1997.

ANSI S12.15-1992 (R1997), Acoustics—Portable Electric Power Tools, Stationary and Fixed Electric Power Tools, and Gardening Appliances—Measurement of Sound Emitted (**reaffirmation of** ANSI S12.15-1992): 29 July 1997.

ANSI S12.16-1992 (R1997), Guidelines for the Specification of Noise of New Machinery (**reaffirmation of** ANSI S12.16-1992): 29 July 1997.

ANSI S12.30-1990 (R1997), Guidelines for the Use of Sound Power Standards and for the Preparation of Noise Test Codes (**reaffirmation of** ANSI S12.30-1990): 29 July 1997.

ANSI S12.33-1990 (R1997), Engineering Methods for the Determination of Sound Power Levels of Noise Sources in a Special Reverberation Test Room (**reaffirmation of** ANSI S12.33-1990): 29 July 1997.

ANSI S12.34-1988 (R1997), Engineering Methods for the Determination of Sound Power Levels of Noise Sources for Essentially Free-Field Conditions over a Reflecting Plane (**reaffirmation of** ANSI S12.34-1988 (R1993)): 29 July 1997.

ANSI S12.36-1990 (R1997), Survey Methods for the Determination of Sound Power Levels of Noise Sources (**reaffirmation of** ANSI S12.36-1990): 29 July 1997.

BIOACOUSTICS

ANSI S3.4-1990 (R1997), Procedure for the Computation of Loudness of Noise (**reaffirmation of** ANSI S3.4-1980 (R1992)): 29 July 1997.

ANSI S3.13-1987 (R1997), Mechanical Coupler for Measurement of Bone Vibrators (**reaffirmation of** ANSI S3.13-1987 (R1993)): 29 July 1997.

ANSI S3.21-1978 (R1997), Method for Manual Pure-Tone Threshold Audiometry (**reaffirmation of** ANSI S3.21-1978 (R1992)): 29 July 1997.

ANSI S3.35-1985 (R1997), Method of Measurement of Performance Characteristics of Hearing Aids under Simulated *in-situ* Working Conditions (**reaffirmation of** ANSI S3.35-1985 (R1990)): 29 July 1997.

ANSI S3.37-1987 (R1997), Preferred Earhook Nozzle Thread for Postauricular Hearing Aids (**reaffirmation of** ANSI S3.37-1987 (R1992)): 29 July 1997.

ANSI S3.42-1992 (R1997), Testing Hearing Aids with a Broad-Band Noise Signal (**reaffirmation of** ANSI S3.42-1992): 29 July 1997.

LOUDSPEAKERS

ANSI S4.56-1997, Recommended Practice for Professional Audio—Subjective Evaluation of Loudspeakers (new standard): 30 September 1997.

Standards News from Abroad

(Partially derived from ANSI Reporter and ANSI Standards Action, with appreciation)

Newly published ISO and IEC Standards and Technical Reports

This section lists new and revised standards and technical reports recently approved and promulgated by ISO and IEC. These documents together with catalog listing several thousand current ISO and IEC standards are available from ANSI.

ISO Standards

ACOUSTICS (TC 43)

ISO 10847: 1997, Acoustics—*In-situ* determination of insertion loss of outdoor noise barriers of all types.
ISO 10843: 1997, Acoustics—Methods for the description and physical measurement of single impulses or series of impulses.
ISO 11819-1: 1997, Acoustics—Measurement of the influence of road surfaces on traffic noise—Part 1: Statistical Pass-By method.

International documents submitted to the U. S. for vote and/or comment

Some of the documents processed recently by the ASA Standards Secretariat. Dates in parentheses are deadlines for submission of comments and recommendation for vote, and they are for information only.

U.S. TAG	ISO Documents
S3 & S12	**1st ISO/CD 12124**—''Procedures for the Measurement of real-ear Characteristics of hearing aids,'' 4 June 1997.
S12	**ISO/DIS 362**—Acoustics—Measurement of Noise Emitted by Accelerating Road Vehicles—Engineering Method (Affirmative w/Comments), 7 February 1997.
	ISO/DIS 14163—Acoustics—Guidelines for Noise Control for Silencers (Negative w/Comments), 31 January 1997.
	ISO/DIS 1680—Acoustics—Test Code for the Measurement of Airborne Noise Emitted by Rotating Electrical Machinery (Negative w/Comments), 7 February 1997.
	ISO 1996/2:1987 DAM 1—Acoustics—Description and Measurement of Environmental Noise—Part 2: Acquisition of Data Pertinent to Land Use, Amendment 1 (Affirmative w/Comments), 12 March 1997.
	ISO/DIS 3741—Acoustics—Determination of Sound Power Levels of Noise Sources Using Sound Pressure—Precision Methods for Reverberation Rooms (Negative w/Comments), 31 January 1997.
	ISO/DIS 10846-3—Acoustics and Vibration—Laboratory Measurements of Vibro-acoustic transfer Properties of Resilient Elements, Part 3: Dynamic Stiffness of Elastic Supports for Translatory Motion—Indirect Method (Affirmative w/o Comments), 19 June 1997.
	ISO/FDIS 10847—Acoustics—*In situ* determination of Insertion Loss of Outdoor Noise Barriers of All Types (Negative w/Comments), 30 April 1997.
	ISO/FDIS 10846-1—Acoustics and Vibration—Laboratory Measurements of Vibro-acoustic transfer Properties of Resilient Elements, Part 1: Principles and Guidelines, 18 June 1997.
	ISO/FDIS 10846-2—Acoustics and Vibration—Laboratory Measurements of Vibro-acoustic transfer Properties of Resilient Elements, Part 2: Dynamic Stiffness of Elastic Supports for Translatory Motion—Direct Method, 18 June 1997.

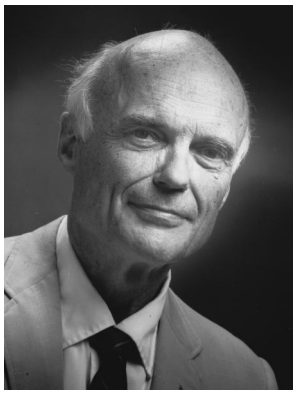
OBITUARIES

This section of the Journal publishes obituaries concerning the death of Fellows of the Society and other acousticians eminent in the world of acoustics. When notified, the Editor-in-Chief solicits a summary of the person's life and contributions from an ASA member thoroughly familiar with the details, if possible. If a promised obituary is never received, a brief obituary notice may be published later.

Ross E. Williams • 1922–1997



Ross E. Williams, a Fellow of the Acoustical Society of America and a valued contributor and leader in the underwater acoustics research community, died 8 November 1997 at the age of 75. Williams was noted for major contributions to the knowledge and applications of underwater sound. He had been an associate director of Hudson Laboratories of Columbia University, and a founder and President of Ocean and Atmospheric Sciences, Inc. (OAS) of Dobbs Ferry, New York.

Born in Carlinville, Illinois, Williams was raised in Scarsdale, New York where he graduated first in his high school class. He graduated in 1943, Summa Cum Laude, in physics and mathematics from Bowdoin College in Brunswick, Maine. He was elected to Phi Beta Kappa and Sigma Xi. He served as an officer in the US Navy aboard the USS YORKTOWN in WWII. He earned a master's degree in physics in 1947 at Columbia University, then worked for Sperry Products, Incorporated. He became a graduate assistant at Columbia in 1949, where he received a Ph.D. in physics in 1955 doing his research on Pi Meson scattering.

After 5 years as a consultant to the U.S. government and industry, Dr. Williams joined the Hudson Laboratories of Columbia University as a Senior Research Associate, and became Associate Director in 1966. In 1968 he was appointed Professor of Applied Science and Engineering at Columbia, and Director of the Ocean Engineering Program, a post he retained until 1974. During that time he published extensively in underwater signal processing and underwater propagation. He served as Technical Director of Project Artemis, a large active sonar research project sponsored by the Office of Naval Research.

In 1974 Williams joined Ocean and Atmospheric Sciences, Inc. where he served at different times as President, Chief Scientist, and Board Chairman, and where he also continued his career as a scientist, specializing in underwater sound research. In addition to more than 30 papers published in scientific journals, Williams authored more than 100 technical reports on sponsored research programs, and served numerous committees for the Navy and for professional societies such as IEEE and the American Society of Photogrammetry.

Throughout his life Williams loved the New Hampshire woods and wildlife, and bought tracts of land in New Hampshire to preserve them as national forest. He also collected and drove antique cars, and was an active lay leader and trustee of Asbury United Methodist Church in Scarsdale, New York. Ross Williams will be fondly remembered by his colleagues and his clients, reflecting his own personal warmth, his broad experience and deep technical understanding. He is survived by his wife, Madeline; his children, Katherine J. Williams and Ross Edward Williams; and his sister, Beverly Whitehead.

Mediacoustic—Teaching Acoustics by Computer

Héléne Gröll, Jean Paul Lefevre, *et al.*

01dB, Villeurbane, France.
CD-ROM. Price in the U.S. $699.

This CD-ROM teaching software package represents the collaborative efforts of acoustical experts from Ecole Polytechnique de Lausanne, Liverpool University, E.N.T.P.E., Acouphen, Estudi Acustica, Laboratoire informatique ARIA, and other European institutions. The disk is available in two languages: French and English (with British spelling). With the advent of multi-media in computers, the acoustics teacher is no longer relegated to providing pedagogical examples through lectures or ''chalk talks.'' The range of coverage and material depth permit use of this CD-ROM for introducing basic acoustics to high school students while incorporating sufficient sophistication to serve college level introductory courses. *Mediacoustic*, based on a central core, contains the fundamentals of acoustics plus a number of specialized modules. The central core consists of: 1. Introduction, 2. Basic Physics, 3. Noise & Man, 4. Room Acoustics, and 5. Noise Control. The program layout is fairly self-obvious, with hypertexts providing additional information but the user might get sidetracked occasionally that he or she might have to return to the main text by clicking onto the index. Each module contains sound clips, text, pictures, photographs, and animated cartoons featuring a rather amusing pair of caricatured ears named Audio and Acoussa (who slightly resemble the Potatoheads of television renown). Audio and Acoussa play musical instruments, sing, operate audio gear, and perform other chores in their joint capacity as virtual teaching aides.

An extremely brief historical overview is provided, starting with Vitruvius of the 1st century B.C. who made use of acoustic amphorae to modify the acoustical environment of amphitheaters. Bypassing the discoveries of Galileo, Leonardo, Mersenne, Sauveur, Grimaldi, and others, a sudden leap is made to the eighteenth century and beyond, with descriptions of acoustical contributions by d'Alembert, Helmholtz, Lord Rayleigh, and Sabine.

In the segment on basic physics, a ''slinky'' coil is shown to represent sound transmission; it would be more desirable to more accurately demonstrate the propagation effect by showing rarefactions and condensations in the format of dots representing fluid molecules in motion about their equilibrium points, with their distribution density representing rarefaction (less dense, fewer dots) and condensation (denser, more dots)—this was done in a different context where plane waves are shown being generated by a piston.

Among the commendable features of the disk are the superimposition of pure tones to demonstrate the harmonic content of a signal, the reduction of a signal by 3 dB or 6 dB to simulate the effect of doubling and quadrupling the distance from a source, the difference between pink and white noise, the modification of a signal passing through an octave or one-third octave filter, the effect of inserting noise barriers, simulation of different sound sources (jackhammer, musical instrument, singing voice, lowing cow, overhead jetcraft, etc.).

A high school student would benefit from the introduction to principles of propagation, the attributes of sound, definition of the decibel, and how the ear functions. Some of the more complex equations entailing calculus are discreetly hidden within hypertexts. On the collegiate level, both engineering and architectural students can hear, understand, and appreciate examples of reverberation effects. One particularly effective method of demonstrating pure tones and the concept of octaves and their harmonics, and at the same time, showing the effect of superpositioning, is the separate activation of mono-frequency signals defined by

$$p_1 = p_{\max} \sin(\omega t),$$

$$p_2 = p_{\max} \sin(2\omega t),$$

$$p_3 = p_{\max} \sin(3\omega t)$$

and the composite signal:

$$p = p_{\max}[\sin(\omega t) + \sin(2\omega t) + \sin(3\omega t)].$$

The listener can hear for him/herself the effect of combining the harmonics. The elements of the frequency analyzer are also described but some of the instrumentation shown do not appear to be state-of-the-art. The *2001* theme from Richard Strauss's *Also Sprach Zarathusa* provides a vivid example of the range from ppp (triple pianissimo) to fff (triple fortissimo). The module on hearing contains nearly all of the elements of interest to aspiring audiologists in dealing with frequency range of hearing, the concept of loudness and equal loudness contours, subjective judgement of loudness, differential loudness threshold, and loudness effects of short versus long sounds, and other aspects of psychoacoustics. Audiograms of people with normal hearing and partial deafness are shown and discussed, and there is even a musical excerpt to demonstrate how a person with normal hearing perceives differently from a person who has been sensorineurally affected by noisy environment at work. In the modules on architectural acoustics and noise control, emphasis is properly placed on the importance of the design stage to prevent acoustical debacles.

Other excellent examples of acoustic phenomena abound, which clarify the difference between longitudinal and transverse waves, illustrate the difference in propagation velocities in gases, liquids, and solids, the difference between the velocities of light waves and sound waves (thunder is heard a few seconds after the lightning clap), the effects of reflection, refraction, and diffraction, methods of cutting down on noise, the principle of the Helmholtz resonator, etc. The program material also would provide a suitable review course for practicing engineers and other professionals with appreciable mathematical backgrounds.

This disk may be deemed a meritorious teaching device, but its steep price of $699 will surely preclude its widespread dissemination. But if this program can be mounted on a server, then the cost takes on a more reasonable aspect.

REVIEWS OF ACOUSTICAL PATENTS

Daniel W. Martin
7349 Clough Pike, Cincinnati, Ohio 45244

The purpose of these acoustical patent reviews is to provide enough information for a Journal reader to decide whether to seek more information from the patent itself. Any opinions expressed here are those of reviewers as individuals and are not legal opinions. Printed copies of United States Patents may be ordered at $3.00 each from the Commissioner of Patents and Trademarks, Washington, DC 20231.

43.35.Zc METHOD FOR ULTRASONIC IMAGING AND DEVICE FOR PERFORMING THE METHOD

Eric I. Madaras, assignor to the United States of America
25 November 1997 (Class 73/644); originally filed 7 September 1993

This patent discloses a method for ultrasonic imaging of structures and flaws in a test specimen having an irregular contact surface. The ultrasonic transducer is coupled acoustically to the irregular surface through a number of ultrasonic waveguides that are thin and bendable so that they adapt to variations in the distance between the transducer and different parts of the contact surface. Since the waveguides are of equal length the delay times are also equal, and all parts of the irregular contact surface receive the sound waves in phase. The waveguides can be arranged in the form of an ultrasonic brush. By bevelling the bristle ends, shear mode waves can be produced.—DWM

5,668,865

43.38.Si ECHO CANCELER E-SIDE SPEECH DETECTOR

Donald Lars Duttweiler *et al.*, assignors to Lucent Technologies, Incorporated
16 September 1997 (Class 379/410); filed 26 February 1996

This telephone echo canceler performs speech detection on near-end, far-end, and outgoing signals. If the echo canceler output is greater than the echo signal, and a coarse far-end detector does not detect near-end speech, then a more accurate near-end detector is used to fine-tune the canceler output.—DLR

5,649,020

43.38.Si ELECTRONIC DRIVER FOR AN ELECTROMAGNETIC RESONANT TRANSDUCER

G. W. McClurg *et al.*, assignors to Motorola, Incorporated
15 July 1997 Class (381/151); filed 24 July 1994

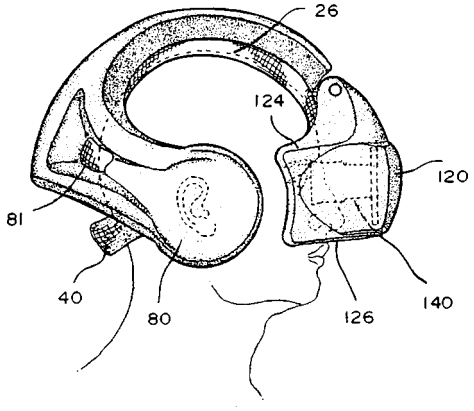
A vibrotactile alerting device is described which can be used to replace motor/offset weight alerting devices in applications such as cellular telephones. Methods of driving an electromagnetic resonant transducer utilizing resonant spring and nonlinear hardening spring resonant armature systems are disclosed. The device may be used for both vibrotactile alerting and voice communication.—JE

5,682,172

43.38.Si HEADSET FOR PRESENTING VIDEO AND AUDIO SIGNALS TO A WEARER

Paul J. Travers and Robert E. Taylor, assignors to Forte Technologies, Incorporated
28 October 1997 (Class 345/8); filed 30 December 1994

A headset is described for physically presenting a visual display and audio signals to the user. The headset has a beam extending over the vertex



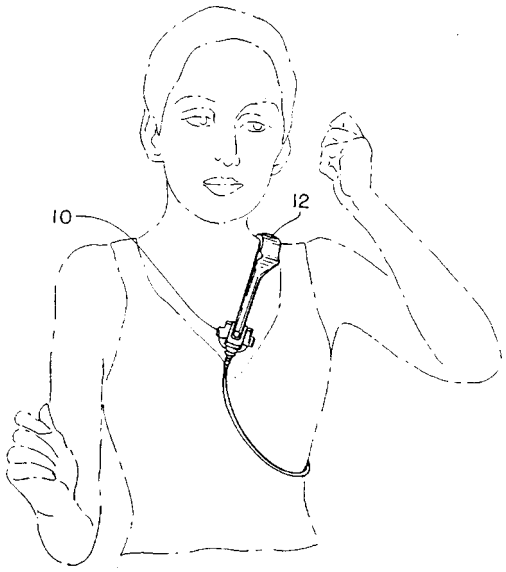
of the head that contacts the brow at one end and has a nape strap at the other end for adjusting the fit.—SFL

5,687,244

43.38.Si BONE CONDUCTION SPEAKER AND MOUNTING SYSTEM

Peter Untersander, assignor to Stanton Magnetics, Incorporated
11 November 1997 (Class 381/151); filed 28 March 1996

The patent shows a bone conduction receiver placed against the ster-



num to produce audible sounds, such as music, as vibrations. A mounting system is shown to hold the bone vibrator in place.—SFL

5,632,045

43.40.Ng ANTIVIBRATION GLOVE

D. D. Chase and D. A. Talonn, assignors to Chase Ergonomics, Incorporated
27 May 1997 (Class 2/161.6); filed 8 May 1995

This is an antivibration glove comprised of one to three layers of viscoelastic material. The damping layers may be of different thickness for different regions of the glove.—JE

5,673,437

43.40.Ng VIBRATION ATTENUATING MEMBER AND METHOD OF MAKING SAME

D. D. Chase and D. A. Talonn, assignors to Chase Ergonomics, Incorporated
7 October 1997 (Class 2/167); filed 6 May 1996

Use of one to three layers of resilient material to reduce hand-transmitted vibration is described. To assure registration of each layer with the others during manufacture, the patent describes a pin registration system.—JE

5,655,980

43.40.Tm VIBRATION DAMPING DEVICE FOR SPORTING IMPLEMENTS

Ahid D. Nashif and Gopichand Koganti, assignors to Roush Anatrol, Incorporated
12 August 1997 (Class 437/520); filed 2 November 1995

This patent pertains to dynamic vibration absorbers that may be attached to a tennis racquet or built into it for the purpose of reducing the shock and vibration transmitted to the user's hand. Two configurations are described: one consists of a mass that is attached to the strings near the racquet's throat; the other consists of a viscoelastically damped cantilever that is built into the handle near its end. The absorber is tuned to the racquet's natural frequency that it is intended to suppress, so that it vibrates essentially 180° out of phase with its attachment point.—EEU

5,669,594

43.40.Tm VIBRATION ISOLATING SYSTEM

David L. Platus and Donald A. Durran, assignors to Minus K Technology
23 September 1997 (Class 267/141); filed 3 May 1995

This patent is a continuation or extension of others relating to ''minus K'' systems. These systems make use of elastic structures that are loaded beyond their critical buckling limit, and that then exhibit a negative spring rate. In such a system a buckled structure is arranged in mechanical parallel with a conventional spring having a positive spring rate that is selected so that the net spring rate of the assembly is near zero. The present patent relates to an assembly that can provide near-zero spring rates for all six rigid-body degrees of freedom.—EEU

5,671,909

43.40.Tm OSCILLATING ROD MEMBER EQUIPPED WITH DYNAMIC DAMPER

Masaaki Hamada and Takashiro Aoi, assignors to Tokai Rubber Industries
30 September 1997 (Class 267/141); filed in Japan 13 May 1994

A rod or a shaft that may vibrate axially, laterally, and/or rotationally is provided with a vibration absorber (tuned damper) that in essence consists of a rubber sleeve with one or more massive rings imbedded in it. By placing the portion of the sleeve that contains a mass ring over a reduced diameter portion of the rod, or by configuring that portion of the sleeve to have an over-sized inside diameter, room is provided for excursions of the ring relative to the rod. The damper is tuned by appropriate selection of the ring masses and the cross-sectional geometry of the rubber sleeve.—EEU

5,676,352

43.40.Tm VIBRATION ABSORBER WITH MOUNT

Thomas Mayer *et al.*, assignors to Daimler-Benz Aerospace AG
14 October 1997 (Class 267/140.4); filed in Germany 1 December 1994

This vibration absorber assembly is intended to be fastened to the inside surface of the rim of a wheel like that used on rail vehicles. It consists of a number of short, flat metal strips with plastic material between them, together with a support element with its outer surface curved so as to fit the curvature of the inside surface of the wheel rim. Several such absorber assemblies are to be mounted around the circumference of the wheel.—EEU

5,678,840

43.40.Tm VIBRATION DAMPING DEVICES FOR SKIS AND OTHER APPLICATIONS

Stepan S. Simonian, Torrance, CA
21 October 1997 (Class 280/602); filed 20 March 1995

Two kinds of damping devices are described in this patent. One is called a ''cantilevered impact/friction damper (CIFD)'' and the other an ''improved constrained layer damper.'' A CIFD consists of a tubular cantilever spring that is filled with a particulate material and carries a mass at its tip, which mass can impact against adjustable limit stops if its excursion is great enough. The constrained layer dampers, which are meant to be attached to the upper surface of a ski, are special cases of spaced constrained viscoelastic layer configurations that have been discussed in the literature and have been employed in other applications.—EEU

5,620,303

43.50.Gf ROTOR SYSTEM HAVING ALTERNATING LENGTH ROTOR BLADES FOR REDUCING BLADE-VORTEX INTERACTION (BVI) NOISE

Robert C. Moffitt and Joseph A. Visintainer, assignors to Sikorsky Aircraft Corporation
15 April 1997 (Class 416/87); filed 11 December 1995

This patent applies to the control of blade–vortex interaction noise which is of particular concern during low forward-speed descending flight of rotorcraft. Blade–vortex interactions are most prevalent for descents during which the downward velocity of the rotor causes it to fly into its own wake. Tip vortices are shed from one rotor blade and interact with a following blade as it rotates through the vortex field. This interaction induces impulsive air loading which in turn creates an acoustic pressure wave that is the source of blade–vortex interaction noise. The use of different length rotor blades causes a spatial separation of shed vortices, a weakening of blade–vortex interactions, and a reduction in associated noise.—HHH

5,663,700

43.50.Gf SOUND DAMPENING SOLENOID

Glenn C. Spence and Dennis A. Maller, assignors to Trombetta Corporation
2 September 1997 (Class 335/257); filed 25 August 1995

This patent applies to push-type, pull-type, and rotary solenoids in order to minimize the noise created by the impact of the moving element against the stop or pole piece. Air pressure in the space between the pole piece and the moving element is regulated by vents to reduce the velocity of the moving element at the time of impact.—HHH

5,670,756

43.50.Gf SILENCER

Akihiko Ohtaka *et al.*, assignors to Honda Gilken Kogyo Kabushiki Kaisha
23 September 1997 (Class 181/256); filed 25 September 1995

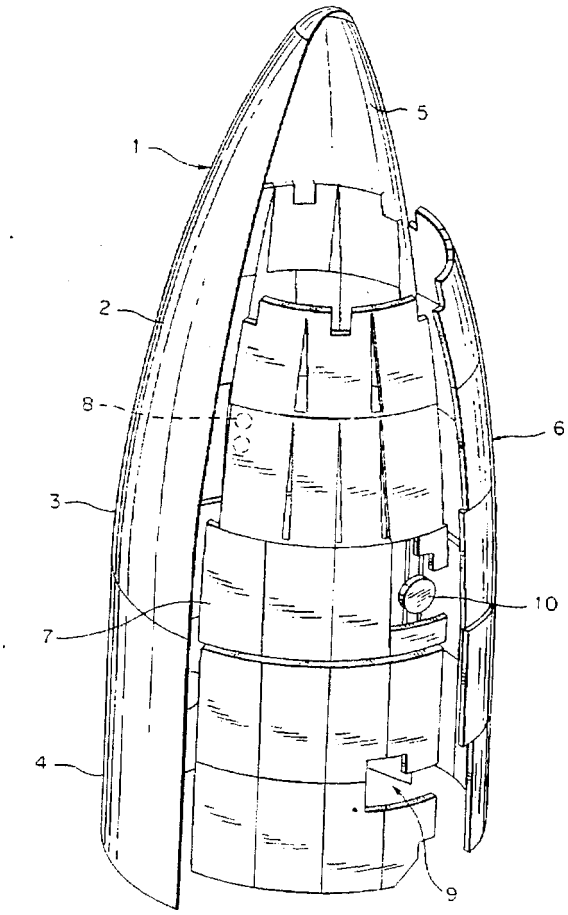
This patent relates to exhaust silencers which have an inner sleeve with pores and heat resistant fibers packed between the inner and outer sleeves, such as those on some automobiles. The fibers are configured with the addition of a heat resistant binder to enhance the press fitting of the fibrous liner.—HHH

5,670,758

43.50.Gf ACOUSTIC PROTECTION ON PAYLOAD FAIRINGS OF EXPENDABLE LAUNCH VEHICLES

Ingo U. Borchers *et al.*, assignors to Oerlikon-Contraves AG
23 September 1997 (Class 181/286); filed in Switzerland 20 April 1995

This patent relates to the reduction of environmental noise in the frequency range below 90 Hz which may cause damage or malfunction in



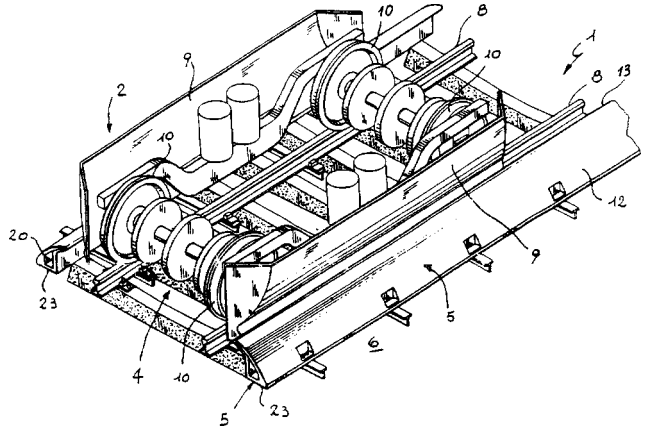
rocket vehicle payloads. Arrays of tuned acoustical absorbers, molded from low surface density foamed plastic, are bonded to the inside surfaces of the external vehicle fairings. Such arrays are noted to be effective during liftoff and the initial ascent phases of flight without large weight penalties.—HHH

5,671,685

43.50.Gf ACOUSTIC BARRIER, PARTICULARLY FOR RAILWAY SUPERSTRUCTURES

Stefano Ughi, Milano, Italy
30 September 1997 (Class 105/452); filed in Italy 28 February 1995

This patent is aimed at the attenuation of wheel-rail noise during the passage of trains. It consists of one member attached to the train in the



vicinity of the bogies, and another located near ground level and attached to the road bed. These two members together form a barrier to the sideways propagation of noise from the bogies.—HHH

5,678,676

43.50.Gf ROLLER SHAFT MOUNTING FOR SOUND AND MOTION CONTROL

Bruce A. Pierson, assignor to HK Systems, Inc.
21 October 1997 (Class 193/37); filed 20 January 1995

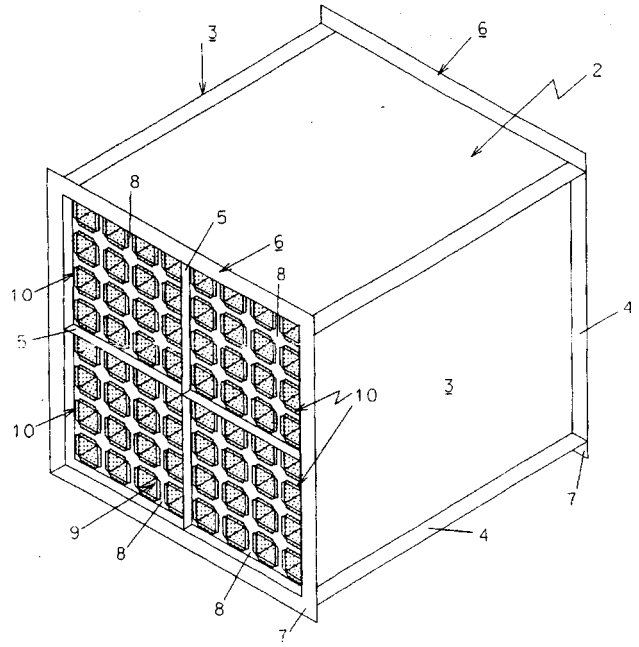
This patent relates to the control of noise and vibration of a roller conveyer by tightening the fit of each roller shaft in the conveyer frame. A tight fit is provided either by tapering each rotor shaft or by providing a tapered cap for each shaft.—HHH

5,679,931

43.50.Gf SOUND ATTENUATING APPARATUS AND METHOD OF FORMING THE SAME

John H. Furse and Robert A. Noreen, assignors to AAF-International
21 October 1997 (Class 181/224); filed 10 July 1995

This patent relates to the reduction of noise in an airflow along with a standardized method for adding passive acoustical treatment. Depending on



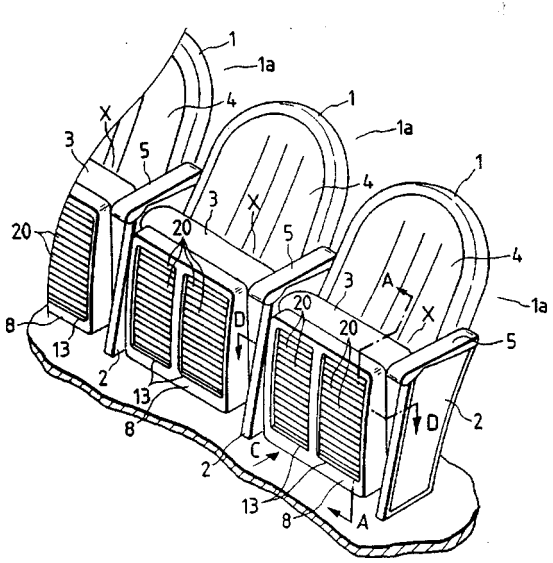
the amount of airflow, the size of duct, and the amount of noise reduction required, treatment can be added systematically.—HHH

5,700,052

43.55.Ev CHAIR FOR AN ACOUSTICALLY DESIGNED BUILDING

Ryokichi Yamazaki *et al.*, assignors to Yamaha Corporation
23 December 1997 (Class 297/217.3); filed in Japan 14 November 1994

The theater-type chair has absorptive material in the seat bottom, covered by slats **20** of a movable louver **13**. When the seat **3** is down (occupied), the louver is closed. When the seat is up (unoccupied), the louver is open, and the sound absorptive infill provides the means to absorb as much sound as the seat plus occupant, thus providing a more stable reverberation time for the hall.—CJR

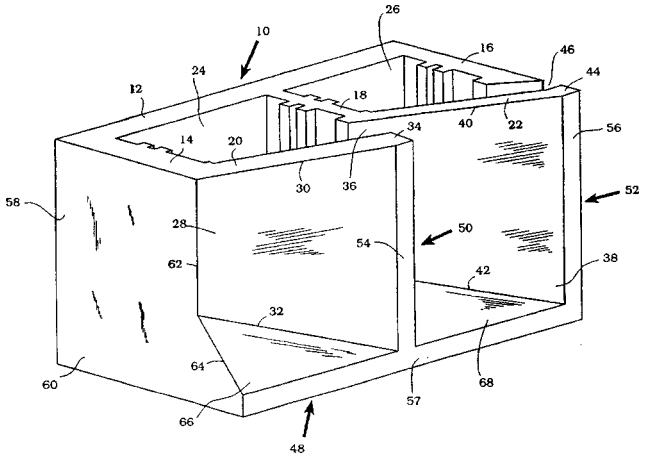


5,700,983

43.55.Ev SOUND ATTENUATING STRUCTURAL BLOCK

Kelly L. VonDross, assignor to Best Block Company
23 December 1997 (Class 181/285): filed 26 August 1996

This structural concrete masonry block has angled faces and open slits that allow sound energy to penetrate the block. With no infill, the block provides a resonant absorber with peak absorption around 200 Hz. With



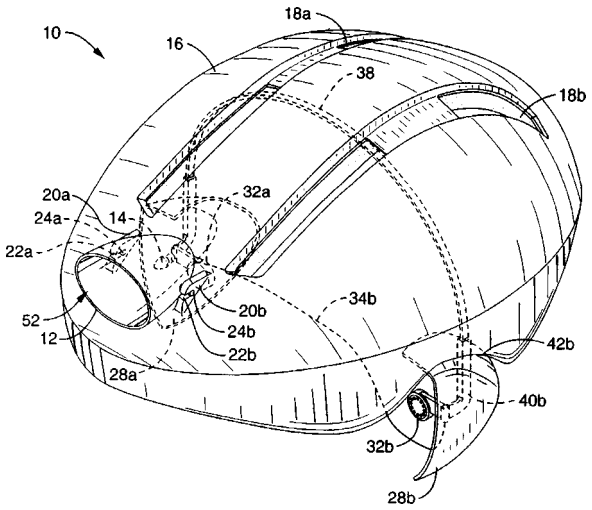
fibrous absorption in the cores, the absorption characteristics cover a broader frequency range, with coefficients of absorption around 0.4 at higher frequencies. The design of the block provides good structural support. Grooves on the sides of the core allow a separator to be slipped into place to divide the cavity so that the rear portion can be filled with concrete to carry additional structural weight.—CJR

5,691,514

43.66.Qp REARWARD SOUND ENHANCING APPARATUS

Timothy J. Landis, assignor to OP-D-OP, Incorporated
25 November 1997 (Class 181/129); filed 16 January 1996

This helmet for cyclists has a cup **12** mounted in a rearward facing direction, containing a microphone **14** for responding to noises behind the cyclist. The microphone signal is amplified and reproduced at the wearer's



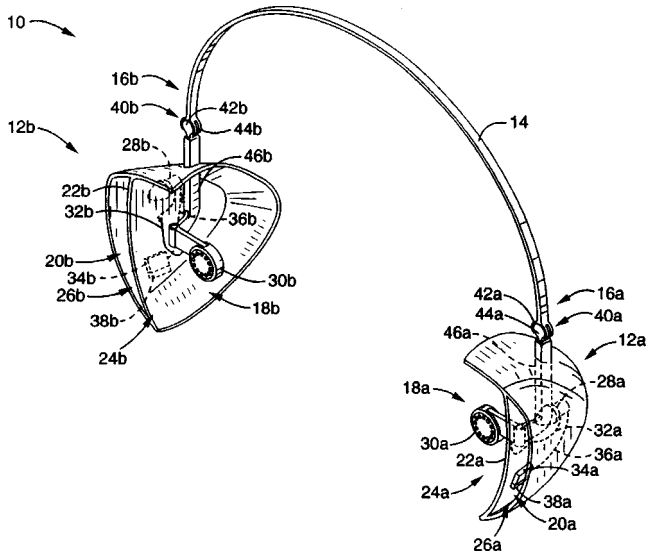
ears by earphones **32a** and **32b** to alert the cyclist aurally to vehicles that are following. Housings **28b** are shaped to reduce wind turbulence noise at the wearer's ears.—DWM

5,691,515

43.66.Qp REARWARD SOUND ENHANCING APPARATUS

Timothy J. Landis, assignor to OP-D-OP, Incorporated
25 November 1997 (Class 181/129); filed 28 June 1996

This patent discloses a headset to be worn by cyclists to alert them to the noise of vehicles that are following them. The patent is closely related to the same inventor's patent 5,691,514 (reviewed above). In this patent microphones **28a** and **28b** are mounted in an outer compartment of ear covers



12a and **12b**, respectively, in place of the helmet-mounted microphone cup in patent 5,691,514. Earphones **30a** and **30b** are in inner compartments. Shields **22a** and **22b** are intended to prevent acoustical feedback between the microphones and earphones.—DWM

5,696,356

43.66.Qp PASSIVE SOUND GATHERING APPARATUS

James P. Dudley *et al.*, assignors to OP-D-OP, Incorporated
9 December 1997 (Class 181/136); filed 7 March 1996

A cyclist helmet is shown in this patent that eliminates the electronic amplification provided in patents 5,691,514 and 5,691,515 (both reviewed above), and substitutes a pair of helmet-mounted sound gathering horns with rearward facing mouths. The throats of the horns deliver the acoustically amplified noise to shells covering the wearer's ears.—DWM

5,682,020

43.66.Ts SEALING OF HEARING AID TO EAR CANAL

Robert J. Oliveira, Maplewood, MN
28 October 1997 (Class 181/130); filed 17 January 1996

The patent shows a flexible sealing device that is particularly useful for in-the-canal hearing aids. It is held in place on the surface of the aid by an adhesive layer on one face. The opposite face, which makes contact with the skin of the ear canal is a layer of retarded recovery polymeric foam, provides an effective acoustic seal.—SFL

5,687,241

43.66.Ts CIRCUIT ARRANGEMENT FOR AUTOMATIC GAIN CONTROL OF HEARING AIDS

Carl Ludvigsen, assignor to Topholm & Watermann APS
11 November 1997 (Class 381/68.4); filed in Germany 1 December 1993

A circuit arrangement is shown for a programmable hearing aid in which the processing circuit contains means for continuous determination of percentile values of the input signal, whereby the gain and/or frequency response of the system are optimized. Block diagrams of the signal processing circuits are given.—SFL

5,687,242

43.66.Ts HEARING AID CONTROLS OPERABLE WITH BATTERY DOOR

Lester Iburg, assignor to Resistance Technology, Incorporated
11 November 1997 (Class 381/69.2); filed 11 August 1995

The patent shows a battery door for a hearing aid that also includes two switching functions. After the battery door is closed, two single-pole switches are available by rotating the battery holder either way using a small knob provided on the battery holder. The switches appear to make contact only when rotating pressure is applied.—SFL

5,573,015

43.66.Vt EXTRUDED EAR PLUG

Colin D. Williams, Charlotte, NC
12 November 1996 (Class 128/864); filed 28 March 1995

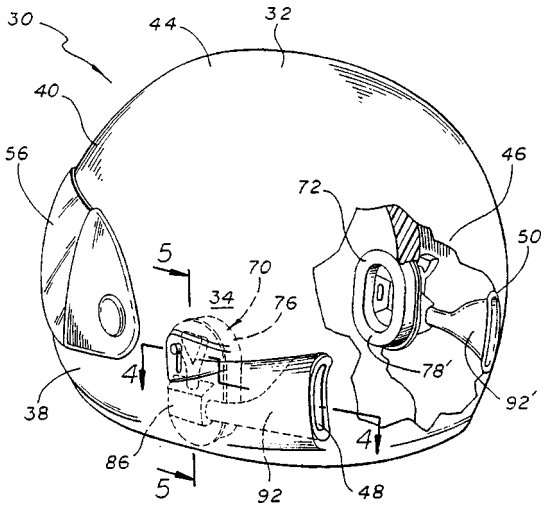
A method for producing an extruded, as opposed to molded, ear plug is described. The ear plug consists of a rigid core surrounded by a foam sheath.—JE

5,632,048

43.66.Vt PROTECTOR HEARING HELMET

D. Mortell *et al.*, assignors to Protector Development
27 May 1997 (Class 2/423); filed 20 September 1995

A helmet is described which incorporates a chamber enclosing each of the ears of a motorcycle or bicycle rider. The chambers include a rearward facing opening to the outside of the helmet and a ventilation loop which can



be opened or closed. No acoustical treatment of the openings is disclosed. The authors say that the helmet reduces wind noise. Nothing is said about protection from intense sounds, nor is the helmet likely to provide such.—JE

5,619,180

43.66.Wv APPARATUS FOR PROVIDING VIBROTACTILE SENSORY SUBSTITUTION OF FORCE FEEDBACK

M. J. Massimino, Houston, TX
8 April 1997 (Class 340/407.1); originally filed 3 November 1993

A vibrotactile stimulus is provided to the operator of a remote manipulator. The vibrotactile stimulus amplitude is proportional to the force applied by the remote manipulator. Sensor location on the manipulator may be replicated by the location of the feedback transducer on the operator or by the frequency of the vibrotactile stimulation.—JE

5,673,703

43.66.Wv APPARATUS FOR AUTOMATED DETERMINATION OF LOW FREQUENCY TACTILE THRESHOLDS

J. H. Fisher *et al.*, assignors to Ztech L.C.
7 October 1997 (Class 128/739); filed 17 February 1995

Several methods exist for the purpose of determining vibrotactile thresholds in humans. Many of these require an analog input signal to the transducer which has been produced by the computer and then converted to an analog signal in a D/A converter internal to the computer. This system uses a frequency-modulated signal from a standard PC to control a motor which drives a tactile stimulator. One stated goal is ''to provide a system and method to accurately and reproducibly determine a patient's threshold to vibrotactile stimuli...''. However, no method is provided for controlling the force of contact between the stimulator and the patient.—JE

43.72.Ar SYSTEM AND METHOD FOR PERFORMING PREDICTIVE SCALING IN COMPUTING LPC SPEECH CODING COEFFICIENTS

Mark A. Ireton, assignor to Advanced Micro Devices, Incorporated
30 September 1997 (Class 395/2.28); filed 13 November 1995

This speech analysis method is an improvement on a previously known method of linear prediction analysis. The FLAT analysis method involves iteratively removing contributions of successive reflection coefficients from the speech power as represented in coefficient matrices. As the matrix element magnitudes are reduced, a loss of resolution occurs in the digital values. This patent adjusts for that loss by scaling the matrix at each iteration.—DLR

5,668,925

43.72.Gy LOW DATA RATE SPEECH ENCODER WITH MIXED EXCITATION

Joseph Harvey Rothweiler *et al.*, assignors to Martin Marietta Corporation
16 September 1997 (Class 704/220); filed 1 June 1995

This vocoder uses line spectral frequencies (LSF) coding, performing simultaneous analyses using different numbers of blocks per frame and choosing the best fitting result. A variable distortion threshold is adjusted to maintain a roughly constant transmit data rate. The pitch coding is improved by a 1-bit jitter code, which controls the addition of random fundamental frequency jitter in the receiver.—DLR

5,671,327

43.72.Gy SPEECH ENCODING APPARATUS UTILIZING STORED CODE DATA

Masami Akamine *et al.*, assignors to Kabushiki Kaisha Toshiba
23 September 1997 (Class 395/2.28); filed in Japan 21 October 1991

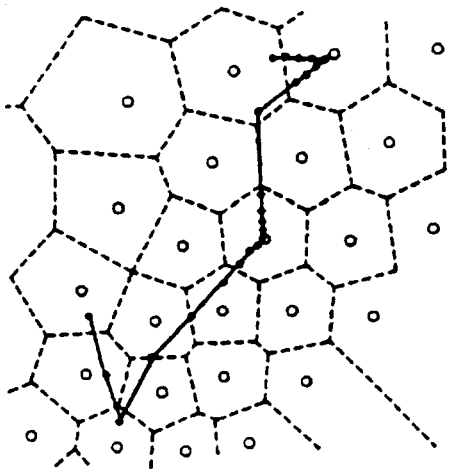
This patent describes a code-excited (CELP) vocoder which uses an adaptive codebook. Linear predictors are computed for frames of input speech and the residual is divided into four subframes for the codebook search. On finding the excitation which best reproduces the target speech subframe, the codebook is modified by merging the target excitation into the winning codebook entry.—DLR

5,675,701

43.72.Gy SPEECH CODING PARAMETER SMOOTHING METHOD

Willem Bastiaan Kleijn and Hans Petter Knagenhjelm, assignors to Lucent Technologies, Incorporated
7 October 1997 (Class 395/2.31); filed 28 April 1995

A vector quantizer speech vocoder uses some type of codebook for encoding one or more aspects of the speech signal. However, the code resulting from each search encodes not the specific target, but a region in a



space of many potential targets. This patent describes a method of processing (''dithering'') the code sequences before transmission so as to minimize the perceptual effect of abrupt transitions across regions of the code space.—DLR

5,675,702

43.72.Gy MULTI-SEGMENT VECTOR QUANTIZER FOR A SPEECH CODER SUITABLE FOR USE IN A RADIOTELEPHONE

Ira A. Gerson *et al.*, assignors to Motorola, Incorporated
7 October 1997 (Class 395/2.32); filed 26 March 1993

The patent describes the construction of a vector-sum-excited (VSELP) vocoder using a fixed point lattice (FLAT) method of computing the linear prediction filters. The FLAT technique allows efficient implementation on a fixed point processor. The method is applicable to either single or multi-segment codebook searches and performs additional scalar quantization to reduce codebook storage requirements.—DLR

5,673,362

43.72.Ja SPEECH SYNTHESIS SYSTEM IN WHICH A PLURALITY OF CLIENTS AND AT LEAST ONE VOICE SYNTHESIZING SERVER ARE CONNECTED TO A LOCAL AREA NETWORK

Tatsuro Matsumoto, assignor to Fujitsu Limited
30 September 1997 (Class 395/2.69); filed in Japan 12 November 1991

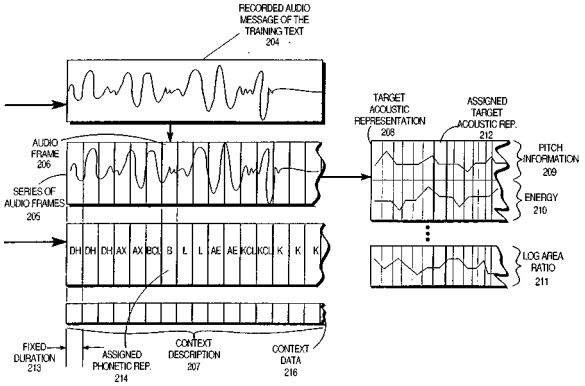
This patent describes the construction of a speech synthesis server suitable for providing text-to-speech audio services to a number of clients, similar to the type of data services provided by a typical local area network file server. Various functional units in the server perform text parsing, text-to-phoneme, phoneme-to-parameter, and parameter-to-waveform conversions, routing partially processed streams among these functions as required.—DLR

5,668,926

43.72.Ja METHOD AND APPARATUS FOR CONVERTING TEXT INTO AUDIBLE SIGNALS USING A NEURAL NETWORK

Orhan Karaali *et al.*, assignors to Motorola, Incorporated
16 September 1997 (Class 704/232); filed 28 April 1994

This method consists of a procedure for training a neural network to generate specific sounds such as speech sounds when a given input is applied to the network. In a training phase, sounds either in the form of



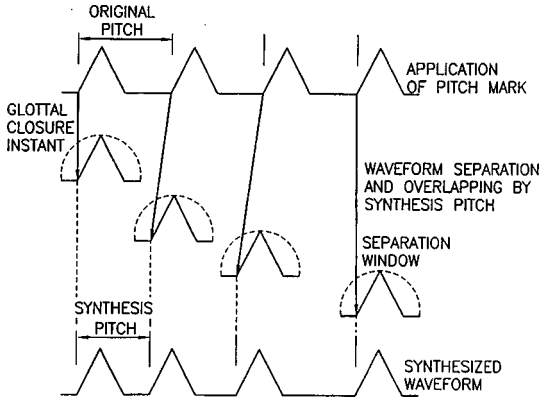
waveform frames or analysis vectors such as log area ratios are associated with phonetic symbols. A phonetic sequence is then sequentially applied to the network, reproducing the acoustic output by use of an appropriate playback or decoding method.—DLR

5,671,330

43.72.Ja SPEECH SYNTHESIS USING GLOTTAL CLOSURE INSTANTS DETERMINED FROM ADAPTIVELY-THRESHOLDED WAVELET TRANSFORMS

Masaharu Sakamoto *et al.*, assignors to International Business Machines Corporation
23 September 1997 (Class 395/2.77); filed in Japan 21 September 1994

This speech synthesis system is based on the addition of overlapped waveform segments representing short speech elements. The system achieves improved output quality by using the moment of glottal closure to align the waveform fragments in the overlapped interval. Accurate estimates



of the moments of glottal closure are possible by using dyadic wavelet conversion and local peak search.—DLR

5,675,703

43.72.Ja APPARATUS FOR DECODING COMPRESSED AND CODED SOUND SIGNAL

Hirofumi Sato, assignor to Nippon Steel Corporation
7 October 1997 (Class 395/2.39); filed in Japan 12 April 1994

This is an improved method for decoding the audio channels of a motion picture experts group (MPEG) coded signal. Typically, the MPEG decoding operations are described as a sequence of separate steps, such as coefficient scaling, band expansion, and waveform reconstruction. In this apparatus the steps are integrated into a single waveform reconstruction operation, using bit shifts wherever possible to improve implementation efficiency.—DLR

5,677,985

43.72.Kb SPEECH DECODER CAPABLE OF REPRODUCING WELL BACKGROUND NOISE

Kazunori Ozawa, assignor to NEC Corporation
14 October 1997 (Class 395/2.29); filed in Japan 10 December 1993

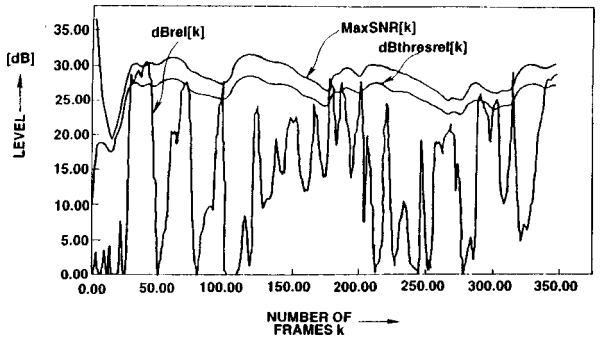
In speech communications systems, such as cellular telephones, the listener's overall perception can be improved by the introduction of a reasonable quality reproduction of the background noise during nonspeech intervals. This system does that with a very small bitrate increase by occasionally sending a code for the best choice from among a fixed set of random number generators which simulate various background noises.—DLR

5,668,927

43.72.Kb METHOD FOR REDUCING NOISE IN SPEECH SIGNALS BY ADAPTIVELY CONTROLLING A MAXIMUM LIKELIHOOD FILTER FOR CALCULATING SPEECH COMPONENTS

Joseph Chan and Masayuki Nishiguchi, assignors to Sony Corporation
16 September 1997 (Class 704/240); filed in Japan 13 May 1994

This patent describes a variety of noise reduction systems based on the concept of comparing a raw speech measure to a smoothed version of that measure. When the raw measure is smaller, the signal is judged to be background noise and is used to adapt a noise reduction filter. Measures discussed include rms energy, spectral band energies, and spectral probability estimates. A maximum likelihood noise filter adjusts band amplitudes based on band probabilities.—DLR



5,668,928

43.72.Ne SPEECH RECOGNITION SYSTEM AND METHOD WITH AUTOMATIC SYNTAX GENERATION

Gabriel F. Groner, assignor to Kor Team International, Incorporated
16 September 1997 (Class 704/243); filed 31 January 1995

This system is an automated syntax builder for use with a speech recognizer and voice-controlled application program. It accepts lists of possible words or phrases which could be used to activate each of the program's functions. The potential word sequences are then checked for redundancy and rated according to uniqueness of association with one of the functions. A grammar is then constructed suitable for use with a syntax-operated voice recognition system.—DLR

5,671,328

43.72.Ne METHOD AND APPARATUS FOR AUTOMATIC CREATION OF A VOICE RECOGNITION TEMPLATE ENTRY

Gregory P. Fitzpatrick *et al.*, assignors to International Business Machines Corporation
23 September 1997 (Class 395/2.55); filed 30 December 1992

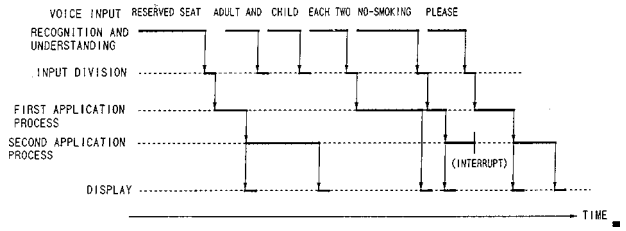
For use with a discrete utterance recognition system, this template builder constructs phrase templates by combining subtemplates representing individual words or short phrases. The template builder assigns a function command, such as a keystroke sequence, to each combined template and sets up training sessions to elicit the combined speech utterances.—DLR

5,671,329

43.72.Ne SPEECH DIALOGUE SYSTEM IN WHICH A RECOGNITION AND UNDERSTANDING PROCESS, APPLICATION PROCESS, AND VOICE INPUT RESPONSE ARE PERFORMED SIMULTANEOUSLY WITH VOICE INPUT

Kaichiro Hatazaki, assignor to NEC Corporation
23 September 1997 (Class 395/2.62); filed in Japan 9 March 1993

This automated reservations taking system uses a speech recognition system together with a decision stage for translating spoken input into system inputs, voice responses, or display controls. The recognizer is configured to provide partial outputs without waiting for the detected end of speech. The partial outputs are processed by a type of grammar driven parser, which then takes the appropriate system action.—DLR

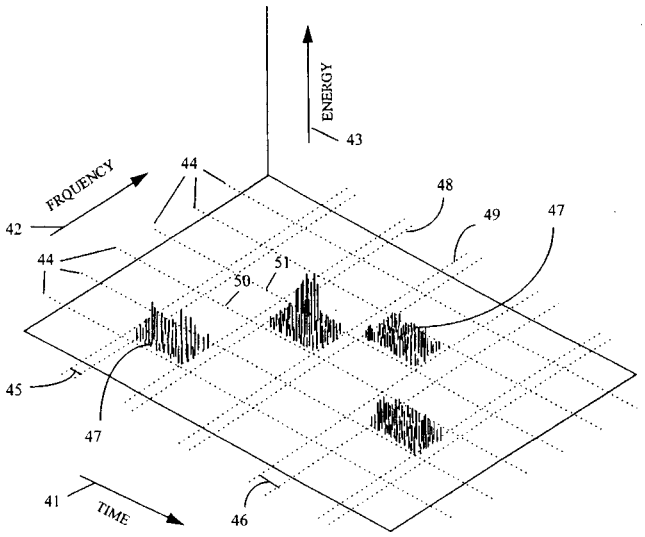


5,675,705

43.72.Ne SPECTROGRAM-FEATURE-BASED SPEECH SYLLABLE AND WORD RECOGNITION USING SYLLABIC LANGUAGE DICTIONARY

Tara Chand Singhal, Torrance, CA
7 October 1997 (Class 395/2.63); filed 27 September 1993

The field of large-vocabulary, continuous recognition has recently been dominated by the use of phoneme or segment level hidden Markov modeling. This recognizer uses a different approach based on the recognition of syllables from a set of roughly a thousand patterns. The syllables are



recognized by their known spectral peak structures, although formants are not explicitly extracted in the analysis. The patent text includes an interesting discussion of a hierarchy of elements of syllable structure.—DLR

5,675,706

43.72.Ne VOCABULARY INDEPENDENT DISCRIMINATIVE UTTERANCE VERIFICATION FOR NON-KEYWORD REJECTION IN SUBWORD BASED SPEECH RECOGNITION

Chin-Hui Lee and Rafid Antoon Sukkar, assignors to Lucent Technologies, Incorporated
7 October 1997 (Class 395/2.65); filed 31 March 1995

This extension to keyword spotting techniques uses a two-level verification strategy to improve accuracy. Keywords are recognized by subword portions, typically diphonelike in structure, adding a degree of vocabulary independence to the system. The verification methods include both HMM scoring and text string scoring.—DLR

5,675,704

43.72.Pf SPEAKER VERIFICATION WITH COHORT NORMALIZED SCORING

Biing-Hwang Juang *et al.*, assignors to Lucent Technologies, Incorporated
7 October 1997 (Class 395/2.55); filed 9 October 1992

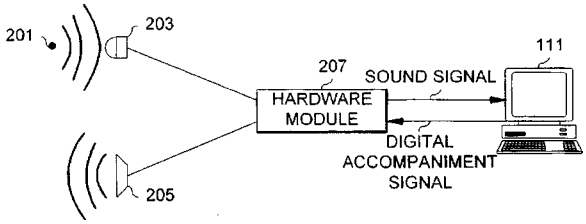
The patent describes a voice dialing system which allows both dialing and collect call charging by means of speaking either the party's name, a preassigned ''nickname,'' the actual dialed digits, or a speed dialing code. The system includes a ''cohort scoring'' method of speaker verification in which the input vectors are compared to both the purported speaker's reference and a reference for a small group of ''cohort'' speakers having similar voice characteristics. The cohort scores are used to normalize the speaker scores, providing for more robust speaker verification.—DLR

5,693,903

43.75.Rs APPARATUS AND METHOD FOR ANALYZING VOCAL AUDIO DATA TO PROVIDE ACCOMPANIMENT TO A VOCALIST

Allen J. Heidorn *et al.*, assignors to Coda Music Technology, Incorporated
2 December 1997 (Class 84/668); filed 4 April 1996

A computer **111** stores a digitized musical accompaniment for a specific published edition of a musical piece. It also stores parameters of a



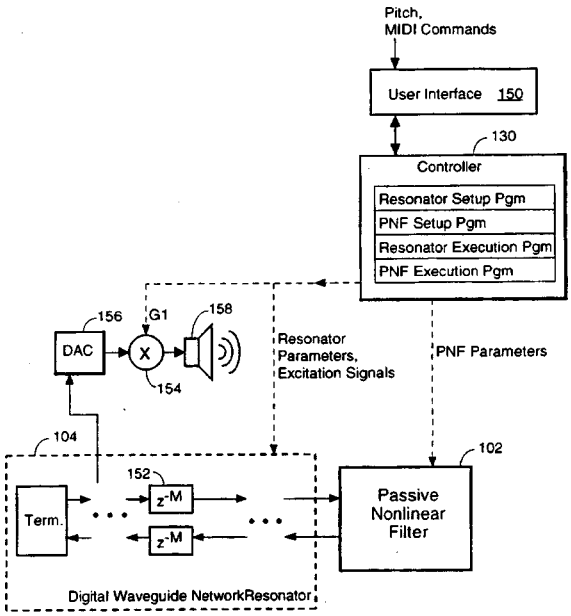
musical solo with which the accompaniment is to be synchronized. As a vocalist **201** sings the solo, microphone **203** transmits the sung tones to the computer for comparison to the stored solo tones, for triggering corresponding accompaniment signals to be mixed with the sung tones in hardware module **207** for reproduction by loudspeaker **205**.—DWM

5,703,313

43.75.Wx PASSIVE NONLINEAR FILTER FOR DIGITAL MUSICAL SOUND SYNTHESIZER AND METHOD

John R. Pierce and Scott A. Van Duyne, assignors to Leland Stanford Junior University
30 December 1997 (Class 84/622); filed 10 May 1994

This music synthesizer uses ''digital signal processing techniques which passively spread energy in a manner that mimics the frequency spreading in cymbals and Chinese gongs.'' It has a ''main resonator waveguide network (e.g., a loop or mesh) that is coupled to a digital passive



nonlinear filter. The passive nonlinear filter receives traveling wave signals propagating in the resonant network and passively modifies those received signals so as to generate modified traveling wave signals having a different frequency spectrum than the received traveling wave signals without chang-

ing the received traveling wave signals' energy content. The passive nonlinear filter then transmits the modified traveling wave signals back into the resonator.''—DWM

5,680,863

43.80.Vj FLEXIBLE ULTRASONIC TRANSDUCERS AND RELATED SYSTEMS

John A. Hossack *et al.*, assignors to Acuson Corporation
28 October 1997 (Class 128/662.03); filed 30 May 1996

Shape sensors such as strain gauges are used to produce signals that indicate the prevailing curvature of an ultrasonic transducer array. The curvature can be changed by a user-controlled actuator. The ultrasonic transducer can be positioned for different scan formats and the flexible part of the system may have a cross-sectional dimension of less than 10 mm to facilitate insertion into a tortuous vessel.—RCW

5,682,895

43.80.Vj THREE-DIMENSIONAL ULTRASOUND IMAGE-PROCESSING SYSTEM

Masaaki Ishiguro, assignor to Fuji Photo Optical Co.
4 November 1997 (Class 128/660.04); filed in Japan 12 October 1995

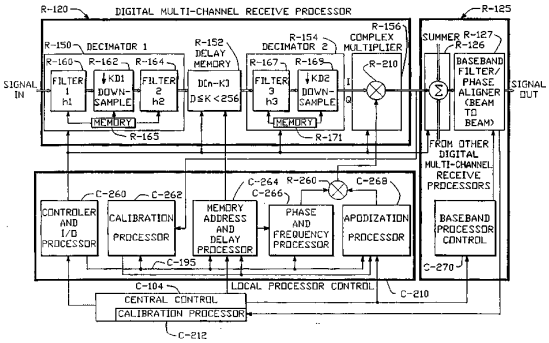
This system includes a cross-sectional ultrasonic image capture unit, a three-dimensional image generator to compile sequentially captured cross-sectional images, a processor to produce a three-dimensional image display on a screen, and another processor that produces a cut-away section of the original three-dimensional ultrasonic image.—RCW

5,685,308

43.80.Vj METHOD AND APPARATUS FOR RECEIVE BEAMFORMER SYSTEM

J. Nelson Wright *et al.*, assignors to Acuson Corporation
11 November 1997 (Class 128/660.07); filed 2 May 1994

This beamformer contains a number of programmable multichannel receivers, a local controller for each receiver processor, a unit that combines



signals from other receiver processors, and a central control unit. Each local controller receives focusing data from the central control unit and calculates dynamic focus delay, phase, apodization, and calibration values for each receiver signal. The unit that combines signals includes a baseband filter for post-beam-formation phase adjustments and signal shaping. The system can be used with different transducers and can implement various imaging modes.—RCW

The force between two parallel rigid plates due to the radiation pressure of broadband noise: An acoustic Casimir effect[a)]

Andrés Larraza, Christopher D. Holmes,[b),d)] and Robert T. Susbilla[c),d)]
Department of Physics—Code PH/La, Naval Postgraduate School, Monterey, California 93943

Bruce Denardo
Department of Physics and Astronomy, and National Center for Physical Acoustics, University of Mississippi, University, Mississippi 38677

(Received 21 July 1997; accepted for publication 26 November 1997)

Theoretical and experimental results are presented for the force law between two rigid, parallel plates due to the radiation pressure of broadband acoustic noise. The noise is in the band of 5–15 kHz and has an intensity of 133 dB ($re:\ 10^{-12}$ W/m^2). Excellent quantitative agreement is shown between theory and experiment. These results constitute an acoustic *analog* for the Casimir effect, which is the force experienced by two closely spaced uncharged conducting plates due to the quantum electromagnetic zero-point field. In contrast to this case, however, band-limited noise can cause the force to be *attractive* or *repulsive* as a function of separation between the plates. © *1998 Acoustical Society of America.* [S0001-4966(98)04003-X]

PACS numbers: 43.10.Ln, 43.25.Qp [MAB]

INTRODUCTION

In 1948, the Dutch physicist Hendrik Brugt Gerhard Casimir made the quantum electromagnetic prediction that two closely spaced uncharged parallel conducting plates would be mutually attractive.[1,2] Due to the presence of the plates, the mode structure of the quantum electromagnetic zero-point field (ZPF) changes relative to free space. The difference between the vacuum electromagnetic energy for infinite plate separation and a finite plate separation is the interaction energy between the plates, from which the force is calculated. If the plates are a distance d apart, the force per unit area is

$$f=\frac{\pi^2}{240}\frac{\hbar c}{d^4}, \tag{1}$$

where $\hbar$ is the reduced Planck's constant and c is the speed of light in vacuum. It can be easily shown by dimensional analysis that $\hbar c/d^4$ is the only possible combination in which $\hbar$, c, and d can be united to yield a force per unit area.

In spite of the large theoretical attention that this effect has received since Casimir's original article, it is only recently that a conclusive experimental confirmation has been made by Lamoreaux.[3] Previously, Sparnaay[4] attempted direct measurement of the Casimir force, achieving measurements of the correct shape, but with 100% uncertainty. Lamoreaux's results agree within 5% with the expression for the Casimir force.

Physically, the electromagnetic ZPF fluctuations induce local dipoles in both plates. As a result of the spatial correlations of the fluctuations, the interaction of these dipoles leads to a net attractive force. Based on this argument, there must also be a Casimir force between two parallel dielectric plates.[5]

The attraction between the two parallel plates can also be understood in terms of the radiation pressure exerted by the plane waves that comprise the homogeneous, isotropic ZPF spectrum. In the space between the conducting plates, the modes formed by reflections off the plates act to push the plates apart. The modes outside the cavity formed by the plates act to push the plates together. The total outward pressure and the total inward pressure are infinite, but it is only the difference that is physically meaningful. This difference leads to an attractive force. Because the energy per mode of the zero-point field has the same value $\frac{1}{2}\hbar\omega$ between and outside the plates, one may incorrectly be led to attribute the attractive character of the force as due to the fact that there are fewer modes between the plates. Surprisingly, as we will show in Secs. I and III, the force can be *repulsive* for band-limited noise.

The ZPF is homogeneous and isotropic. It is also Lorentz invariant (any two inertial observers do not see a difference). The ZPF can be said to be undetectable in any inertial frame because homogeneity, isotropy, and Lorentz invariance do not allow an observer to see any contrast between directions, times, and inertial frames. The Casimir effect is one of the several indirect manifestations of the ZPF. Other indirect manifestations include the van der Waals force between polarizable matter,[5] as well as spontaneous emission of radiation and the Lamb shift.[6]

A Lorentz transformation Doppler shifts the frequency and also alters the intensity of radiation. The only spectral shape that is the same for any inertial frame is proportional to ω^3.[7] This spectral shape implies an energy per mode proportional to the frequency, in agreement with the quantum zero-point energy $\frac{1}{2}\hbar\omega$ per mode of the electromagnetic vacuum.

---

b)LT, US Navy.
c)LCDR, US Navy.
d)Some of the experimental aspects of this article were submitted in partial fulfillment for the MS degree in Physics at the Naval Postgraduate School.

At finite temperatures, there must also be a force between the plates due to real photons. Thus the Casimir effect is the zero-temperature limit of the electromagnetic radiation pressure. However, thermal effects can be ignored when $\hbar\omega \gg k_B T$, where k_B is Boltzmann constant. The lowest frequency that contributes to the radiation pressure inside the plates is $\omega = \pi c/d$. Thus thermal effects can be ignored for separations $d < \pi\hbar c/k_B T$. At room temperature this corresponds to a distance of about 50 μm.

If the ZPF can be thought of as broadband noise of an infinite spectrum, it should be possible to use an acoustic broadband noise spectrum as an analog to some ZPF effects. An acoustic spectrum has several advantages. Because the speed of sound is six orders of magnitude less than the speed of light, the length and time scales are more manageable and measurable. Also, in an acoustic field, the shape of the spectrum as well as the field intensity can be controlled.

We refer to this new area of research as *Casimir acoustics*. By analogy to the Casimir effect, the measurement of the force between two plates in a homogeneous, isotropic, acoustic field is the acoustic Casimir effect.

An aspect of our analog is the extension of the Casimir effect due to zero-point phonons. Thus for a sufficiently large Debye temperature the force per unit area between two rigid plates due to zero-point phonons has the same form as Eq. (1), except that c should be replaced by the value of the speed of sound in the medium. As would be the case for liquid helium at low temperatures, there should also be a factor of $\frac{1}{2}$ because longitudinal phonons have no polarization. However, if the plates are also conducting, the Casimir force due to the electromagnetic zero-point field dominates the Casimir force due to zero-point phonons by at least six orders of magnitude. As shown in Sec. III, the band-limited acoustic noise due to commercial loudspeakers yields a force that is three orders of magnitude greater than the Casimir force due to the electromagnetic zero-point field, recently measured by Lamoreaux.[3]

I. THEORY

One of the key ideas in the derivation of the ZPF Casimir force is the fact that the energy per mode $\frac{1}{2}\hbar\omega$ is the same for modes both outside and between the plates, which can be understood with the adiabatic theorem.[8] To this purpose, imagine that the plates are initially far apart so that the spectral intensity (intensity per unit frequency interval) of the ZPF is that of free space: $I_\omega = \hbar\omega^3/2\pi^2 c^3$. If we now adiabatically move the walls toward each other, the modes comprising the ZPF will remain in their ground state; only their frequencies will be shifted in such a way that the ratio of the energy per mode E to the frequency ω remains constant, or $E/\omega = \hbar/2$. Thus the main effect of the boundaries is to redistribute ground state modes of which there is an infinite number. It should be noted that the energy per mode being a constant implies that the space between the plates cannot be considered as a resonant cavity unless the quality factor Q is unity.

In contrast to the ZPF Casimir effect, in the acoustic Casimir effect the adiabatic theorem does not apply both because of inherent losses in the system and because the spectrum can be arbitrary. Also, while external drivers can provide a steady state noise spectrum from which we can infer the energy per mode by dividing by the density of states $\omega^2/2\pi^2 c^3$, this energy may be different in the cavity formed by the plates as a result of Q amplification. However, for this open resonant cavity the quality factor is poor, so we may assume it to be equal to unity, which renders the energy per mode equal to its value in free space.

The shape of the acoustic spectrum is determined by the input to the drivers and their the frequency response. Good acoustic drivers have a flat response over a frequency band. With appropriate filters, one may shape the spectrum within the driver's frequency response and obtain, in principle, different force laws. We specialize the derivation of the force law below for a flat spectral shape over a finite frequency band.

In general, the radiation pressure of a wave incident at angle θ on a *rigid* plate is

$$P = \frac{2I}{c}\cos^2(\theta), \tag{2}$$

where I is the average intensity of the incident wave and c is the wave speed. The factor of 2 is due to perfect reflectivity assumed for the plate. Equation (2) follows from the time-averaged second-order acoustic pressure, which equals the time-averaged potential energy density minus the time-averaged kinetic energy density.[9] When the acoustic case is constrained to one dimension, mass conservation yields an explicit dependence of the radiation pressure on the elasticity of the medium characterized by γ, the ratio of specific heats, namely $P = (1+\gamma)I/c$.[10] However, for the three-dimensional open geometry in our case, the constraint due to mass conservation does not apply and the acoustic and electromagnetic expressions for the radiation pressure at a perfectly reflecting surface are identical.[11]

We consider broadband acoustic noise of constant spectral intensity I_ω in a band of frequencies from ω_1 to ω_2. The total intensity is then $I = (\omega_2 - \omega_1)I_\omega$. The spectral intensity in the wave vector space of traveling waves is

$$I_{\mathbf{k}} = \frac{cI_\omega}{4\pi k^2}, \tag{3}$$

where the wave vector is $\mathbf{k} = (k_x, k_y, k_z)$ whose magnitude is the wave number $k = \omega/c$. We choose the z axis to be normal to the plate, so that $k_z = k\cos(\theta)$. From Eq. (2), the total radiation pressure due to waves that strike the plate is then

$$\begin{aligned} P &= \frac{2}{c}\int dk_x\, dk_y\, dk_z\, I_{\mathbf{k}}\cos^2(\theta) \\ &= \frac{I_\omega}{2\pi}\int dk_x\, dk_y\, dk_z\, \frac{k_z^2}{k^4}, \end{aligned} \tag{4}$$

where the integration is over $\mathbf{k}$ values corresponding to waves that strike the plate. Converting Eq. (4) to polar coordinates, and performing the azimuthal integration, yields

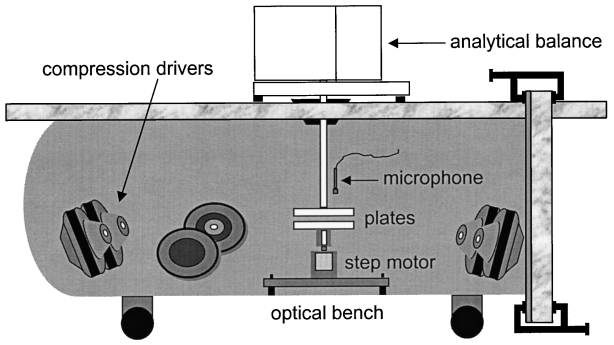

FIG. 1. Apparatus to measure the force between two rigid parallel plates due to the radiation pressure of broadband acoustic noise. The tank is made of 0.64-cm steel, and has length 1.5 m and diameter 0.5 m. One end is ellipsoidal while the other is flat with a steel faceplate to which is mounted a 5-cm-thick, 61.5-cm-square acrylic access cover secured by four C-clamps. A sliding 5-cm-thick acrylic bar allows the positioning of the balance at a desired location and also serves for spectral measurements of the noise along the tank. A microphone was positioned within 1 cm of the top plate to provide spectrum intensity measurements.

$$P = I_\omega \int_{\theta=0}^{\pi/2} d\theta \, \sin(\theta)\cos^2(\theta) \int_{k=k_1}^{k_2} dk = \frac{1}{3}(k_2 - k_1) I_\omega , \tag{5}$$

which can be expressed simply in terms of the total intensity as

$$P = \frac{I}{3c}. \tag{6}$$

Although Eq. (6) was derived for a constant spectral density I_ω, it can readily be shown to be valid for *any* isotropic spectral distribution. Equation (6) can be understood by a simplistic approach: If one-sixth of the intensity is considered to be propagating in each of six possible orthogonal directions, then the radiation pressure (2) becomes $2(I/6c)$, which is identical to Eq. (6).

Broadband noise outside two parallel rigid plates drives the discrete modes between the plates. For convenience, we continue to deal with the traveling wave (rather than standing wave) modes, which we label with wave vector components $k_x = n_x \pi / L_x$, $k_y = n_y \pi / L_y$, and $k_z = n_z \pi / L_z$, where n_x, n_y, and n_z are signed integers and L_x, L_y, and L_z are the dimensions between the plates. As in the previous analysis, the z axis is chosen to be normal to the plates. As a result of the quality factor of the modes being approximately unity, the intensity $I_{\text{in}}(\mathbf{k})$ of each mode between the plates is expected to be approximately the same as the outside broadband intensity in a bandwidth equal to the wave vector spacing of the inside modes: $I_{\text{in}}(\mathbf{k}) = I_{\mathbf{k}} \Delta k_x \Delta k_y \Delta k_z$, where $I_{\mathbf{k}}$ is given by Eq. (3) and where $\Delta k_i = \pi / L_i$. In the limit of large dimensions, this expression for the inside intensity yields the correct wave vector spectral intensity $I_{\mathbf{k}}$. From Eq. (2), the pressure on a plate due to the inside modes is

$$P_{\text{in}} = \frac{2}{c} \sum I_{\text{in}}(\mathbf{k}) \frac{k_z^2}{k^2}, \tag{7}$$

where the sum is over values of $\mathbf{k}$ corresponding to modes that strike the plate, which we can take to be those for which $n_z > 0$. We assume that the dimensions L_x and L_y of the plates are sufficiently large that the corresponding components of the wave vectors are essentially continuous. In comparison to Eq. (4), the total inside pressure (7) is therefore

$$P_{\text{in}} = \frac{I_\omega}{2\pi} \sum \Delta k_z \int dk_x \, dk_y \, \frac{k_z^2}{k^4}. \tag{8}$$

We now let $n = n_z$ and $d = L_z$, and define the fundamental transverse wave number (perpendicular to the plates) $k_0 = \pi / d$. As in Eq. (5), the range of k values in Eq. (8) is in a hemispherical shell of thickness $k_2 - k_1$. However, it is easier to calculate the radiation pressure (8) in this shell by performing an integration over a hemisphere of radius k_2 and subtracting the integration over a hemisphere of radius k_1. Employing polar coordinates for the parallel wave vector, and performing the azimuthal integration, yields

$$P_{\text{in}} = k_0^3 I_\omega \sum_{n=1}^{[k_2/k_0]} n^2 \int_0^{\sqrt{k_2^2 - k_0^2 n^2}} \frac{\kappa \, d\kappa}{(\kappa^2 + k_0^2 n^2)^2} - (k_2 \to k_1), \tag{9}$$

where $[k_2/k_0]$ is the greatest integer less than or equal to k_2/k_0. Transforming to the dimensionless variable $x = (\kappa/k_0)^2$ leads to

$$P_{\text{in}} = \frac{\pi I_\omega}{2d} \sum_{n=1}^{[k_2 d/\pi]} n^2 \int_0^{(k_2 d/\pi)^2 - n^2} \frac{dx}{(x+n^2)^2} - (k_2 \to k_1). \tag{10}$$

The difference $P_{\text{in}} - P_{\text{out}}$ between Eqs. (7) and (4) is the force f per unit area between the plates. Performing the integrals and sums in Eq. (10), and using Eq. (5), we obtain

$$f = \frac{\pi I_\omega}{2d} \left(N_2 - N_1 - \frac{N_2(N_2+1)(2N_2+1)}{6(k_2 d/\pi)^2} + \frac{N_1(N_1+1)(2N_1+1)}{6(k_1 d/\pi)^2} - \frac{2(k_2 - k_1)d}{3\pi} \right), \tag{11}$$

where $N_1 = [k_1 d/\pi]$ is the greatest integer equal to or less than $k_1 d/\pi$, and similarly for N_2. Equation (11) is continuous and piecewise differentiable, and can alternate between negative (attractive force) and positive (repulsive force) values. On the other hand, if the lower frequency in the band is zero, the force is always attractive. For the case when the spectrum extends over an infinite frequency interval $(0,\infty)$ the force (11) reduces to the value

$$f = -\frac{\pi I_\omega}{4d}, \tag{12}$$

corresponding to an attractive force. Equation (12) can be derived by noting that $k_1 = 0$ when the lower frequency is zero, so the second and fourth terms in Eq. (11) vanish, while in the limit of large values of k_2 the ratio $\pi N_2 / k_2 d$ equals unity.

Equations (1) and (12) are evidence of the direct relation that exists between the force law for two parallel plates and power law spectra. Thus while a flat spectrum yields an inverse distance force law (12), a spectrum proportional to the cube of the frequency yields force law (1) that is proportional to the inverse fourth power of the distance.

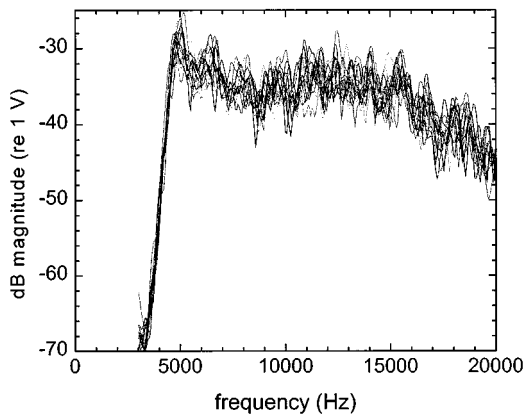

FIG. 2. Acoustic field intensity measurements for nine horizontal positions (left–center–right, 33–44–54 cm from the tank access) and three vertical positions (high–low–center), covering the internal location of the optical bench with step motor. The spectrum is essentially flat from 5 kHz to 15 kHz, and rolls off 20 dB from 15 to 20 kHz.

II. APPARATUS

In addition to the plates, the equipment for the acoustic Casimir effect experiment consists of three major components: an acoustic chamber, an optical bench with a step motor, and an analytical balance (Fig. 1). The acoustic chamber provides a nearly homogeneous, isotropic sound field. The internal optical bench with step motor provides precise plate separation, and the analytical balance provides the force measurement for the acoustic Casimir effect.

The acoustic chamber is a converted cylindrical air compressor tank mounted on wheels for mobility. The tank is made of 0.64-cm steel and has length 1.5 m and diameter 0.5 m, and is covered with 1.8-mm automotive sound deadening self-adhesive pads. The addition of the pads lowered the quality factor (Q) of flexural modes of the cylinder thereby minimizing external radiation. The drivers in the acoustic chamber are capable of providing an acoustic noise field of intensity as large as 135 dB (re: 20 μPa). One end of the cylinder is ellipsoidal while the other is flat with a steel faceplate that mounts a 5-cm-thick, 61.5-cm-square acrylic access cover plate secured by four C-clamps. There is a rubber gasket on the faceplate to improve the seal with the square acrylic plate. The ellipsoidal end is desirable because it improves isotropy of the noise.

Six J. B. Lansing (JBL) 2455J compression drivers provide the desired acoustic noise intensity within the acoustic chamber. The voltage source for the compression drivers is a General Radio Company 1390-B random noise generator, whose output is passed through three bandpass filters each followed by dual channel amplifiers. One filter is a 115-dB/octave bandpass filter [Stanford Research Systems (SRS) 650] set at a band of 5–15 kHz. The other two filters are 48-dB/octave bandpass filters (Krohn-Hite 3988) set at a band of 10–15 kHz. The separate bandpass filters allowed the flexibility of manipulating the spectral shape of the noise. The filter outputs are amplified by three dual channel Techron 5530 power amplifiers.

Acoustic field measurements were made within the tank using a sensing probe with a mounted Larson Davis $\frac{1}{4}$-in. microphone that has a flat response (± 1 dB to approximately 22 kHz). Measurements were taken at high, center, low, left and right positions along the length of the tank (14–94 cm), and showed that the six compression drivers were capable of providing a homogeneous isotropic field between 5 and 15 kHz.

Figure 2 is a plot of the acoustic field intensity measurements for nine horizontal positions (left–center–right, 33–44–54 cm from the tank access) and three vertical positions (high–low–center), covering the internal location of the optical bench with step motor. The spectrum is essentially flat from 5 kHz to 15 kHz, and rolls off 20 dB from 15 to 20 kHz.

The step motor was mounted on a small aluminum optical bench. The three-point leg adjustments of the bench compensated for the tank curvature allowing for leveling of the step motor and attached plate. The step motor is a Vexta PH266-02-A29, 2-phase, 1.8 degree/step, 12-V dc motor which provides accurate repeatable plate separation. The number of steps (1–255 steps) and direction (up or down) are varied with a microchip controller. Attached to a machined screw with 20 threads/in., the step motor mount yields a displacement ranging from 6.35 μm for one step (1.8 degrees) to 1.27 mm for 200 steps (360 degrees). The step motor displacement was verified through the range of the machined screw using a linear variable differential transformer.

Two 15.00-cm-diam plates were used for the acoustic Casimir force measurement. The bottom plate was 6.35-mm (1/4-in.)-thick aluminum, attached firmly to the top of the step motor mount. The top plate was 5.57-mm (7/32-in.) thick PVC which was vacuum aluminized and hung beneath the analytical balance by an aluminum bar screwed into the plate and attached to the balance by a hook (Fig. 1). Both plates were grounded to a common ground to eliminate electrostatic effects, thereby minimizing fluctuations in the force measurements.

For 20-cm by 20-cm plates separated less than 0.3 cm in a 120 dB (re: 20 μPa) noise field from 5- to 15-kHz frequency, the force acting on a plate due to acoustic radiation pressure is calculated from Eq. (6) to be approximately 0.1 mN, which corresponds to a weight of 10.2 mg. To meet such resolution weight measurements, we used a Mettler-Toledo AT261 Delta Range AT analytical balance with fully automatic self-calibration (FACT), ISO 9001 certification, and a resolution of 0.01 mg. The weight of a 15-cm-diam $\frac{1}{4}$ -in.-thick PVC plate is roughly 150 g, which is well within the 200-g weighing capability of the AT261.

III. MEASUREMENTS

In an experiment dealing with an acoustic analog to the Casimir effect, an important question is whether other nonzero time-averaged (dc) effects can play an important role. The only second order dc effects in acoustics are radiation pressure and streaming. Any other dc effect would be fourth order in the acoustic pressure, and at least 40 dB smaller in our case. Employing smoke in the apparatus described above, we detected no acoustic streaming when driving with broadband acoustic noise at the intensity levels used in the

experiment. Because the noise in our experiment can be thought of as collection of monochromatic waves over a band of frequencies with randomly varying phases, we would expect very little or no streaming when the characteristic time of phase variations is less that the diffusion time. Furthermore, because acoustic streaming is driven along the boundary from a pressure antinode to a pressure node, in the presence of broadband noise the pressure nodes and antinodes of the different noise components are densely distributed along the boundary, thus reducing or eliminating the streaming.

To measure the acoustic Casimir force, the optical bench with step motor was centered in the acoustic chamber 46 cm from the tank access. As indicated by a leveling bubble, the three height adjustment screws were used to level the step motor mount with the bottom plate attached. The top plate was hung from the Mettler-Toledo AT261 analytical balance and the bottom plate was raised beneath it. The plates were visually aligned to be parallel, and the initial plate spacing was determined with a spark plug gap gauge. The plate separation distance was verified to be uniform by measurements at different locations between the plates. A Larson Davis 2530 microphone was positioned within 1 cm of the top plate to provide spectrum intensity measurements. The acoustic chamber was sealed and the system allowed to stabilize. Once the oscillations of the top plate damped out and the balance reading locked in on the weight of this plate, which was 168.1653 g, the balance was tared to zero. All force measurements were made relative to this zero.

Force measurements were carried out sequentially as follows. The acoustic noise field was turned on for each step and the force measurement recorded once the balance readout first locked-in. Simultaneously, the internal microphone measured the sound field intensity which was averaged over 50 measurements with a HP 35670A dynamic signal analyzer. The sound field was then turned off and the reading of the balance was verified to return to zero. The plates were displaced an additional 1.27 mm (200 steps of the step motor), and the measurement procedure described above was repeated through the full 6.3-cm range of the step motor mount.

We first selected a uniform broadband noise spectrum between roughly 5 and 15 kHz. The lower limit was selected well above the lower modes of the tank in order to excite a noise distribution as homogeneous as possible. The upper limit was due to the JBL 2445J compression drivers rolling off 20 dB from 15 to 20 kHz. Figure 3(a) shows the measured noise spectrum which, except for 5-dB variations throughout, is nearly flat within the spectral range of 4.8–16 kHz. The total intensity is 133 dB (re: 10^{-12} W/m^2).

Using a spark plug gauge, we measured the initial plate separation to be 0.76 mm. As shown in Fig. 3(b), throughout a range of distances less than the smallest half-wavelength (no modes between the plates), the measured force is approximately independent of distance, and agrees with the expected value for an intensity level of 133 dB. When the half-wavelength of the highest frequency fits between the plates (10.63 mm for 16 kHz), the force begins to decrease nonmonotonically and becomes repulsive (i.e., negative) at

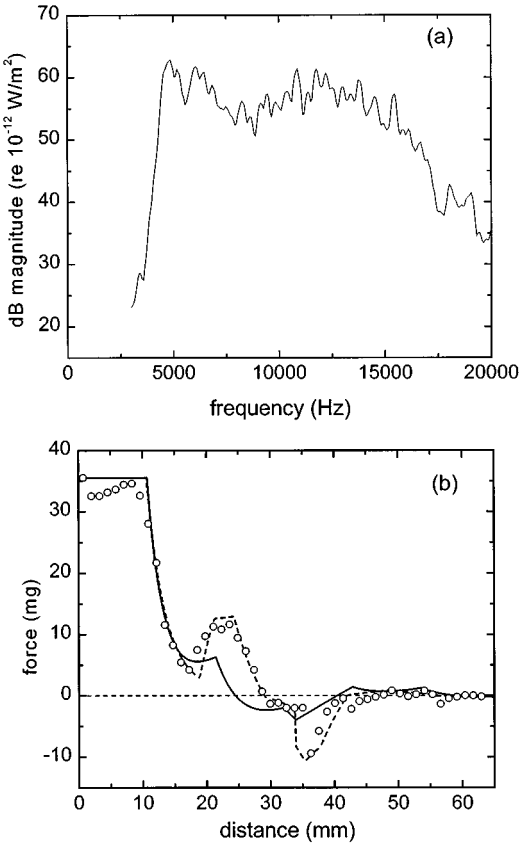

FIG. 3. (a) Experimental spectrum in a band of frequencies between 4.8 and 16 kHz. The spectrum is relatively flat and exhibits structure (dip) and an overall 5-dB roll off. The total intensity of the noise is 133 dB (re: 10^{-12} W/m^2). (b) Force between two parallel rigid plates as a function of the distance between them. The points are experimental data, the solid curve is from the theory (11) with no adjustable parameters, and the dashed curve is obtained from Eqs. (4) and (7) with a spectrum that approximates the experimental spectrum.

30–40 mm. Based on the experimental spectral range of 4.8–16 kHz for the theory, with a total intensity of 133 dB, the solid curve shows good quantitative agreement between experiment and theory [Eq. (11)] which has no adjustable parameters. The differences between experiment and theory could be a result of the lack of smoothness of the spectrum, the small roll off of 5 dB over the band, the lack of a sharp cutoff at the upper end of the band, and Q not necessarily being equal to unity. Based on Eqs. (4) and (7), calculations that incorporate power law variations from a uniform spectrum have been performed.[12] However, in contrast to the case of a flat spectrum [Eq. (11)], there is not a closed form expression for the force law. The dashed curve in Fig. 3(b) is the result of incorporating these modifications in the spectrum. The theory now fully accounts for the previous deviations, indicating that Q does not play a significant role, and that radiation pressure is the dominant mechanism.

The repulsive force can be understood as follows. When the distance between the plates is comparable to the half-wavelength associated with the lower edge of the frequency band, the corresponding modes inside the plates have wave vectors that are nearly perpendicular to the plates. However, the modes outside the plates corresponding to the same fre-

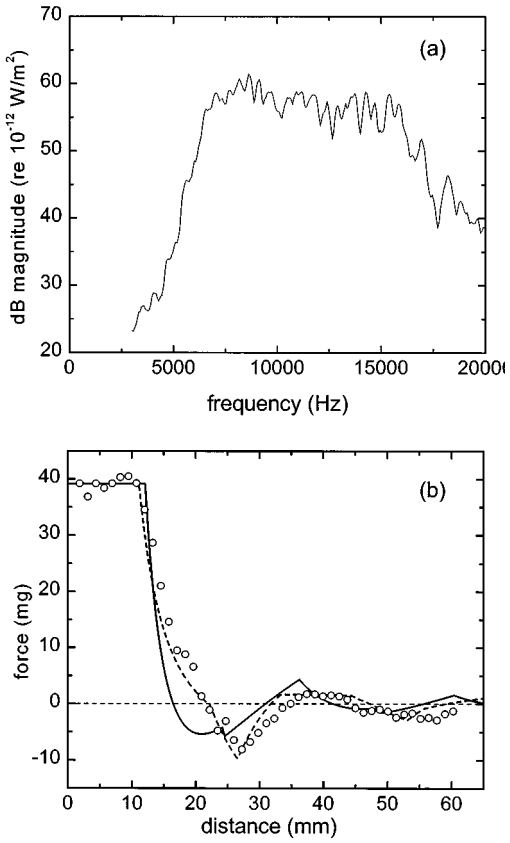

FIG. 4. (a) Experimental spectrum in a band of frequencies between 7.4 and 15.3 kHz. The spectrum shows less structure and a flatter spectral shape compared to Fig. 3(a). The total intensity of the noise is 133.5 dB (re: 10^{-12} W/m^2). (b) Force between two parallel rigid plates as a function of the distance between them. The points are experimental data, the solid curve is from the theory (11) with no adjustable parameters, and the dashed curve is obtained from Eqs. (4) and (7) with a spectrum that approximates the experimental spectrum.

quencies are spread over all possible angles of incidence. Thus for the same total intensity, the momentum transfer due to waves inside the plates is over a narrow cone while the momentum transfer due to waves outside the plates extends over all angles, leading to a repulsive force.

Next we selected an octave frequency band of roughly 7.5–15 kHz to investigate what effect a different spectrum would have on the acoustic Casimir force. Figure 4(a) shows the measured spectrum of the noise, which is nearly flat between 7.4 and 15.3 kHz. The total intensity is 133.5 dB.

With this spectrum, we set the initial plate separation to 0.96 mm. Figure 4(b) shows again that the force between the plates is independent of distance up to about 11.11 mm, corresponding to the half-wavelength of the highest frequency. Note that a repulsive force starts at a smaller distance (20 mm), covering a larger range (20–40 mm) than in the previous case, in agreement with theory. The solid curve corresponds to the theory (11) based on the experimental spectral range of 7.4–15.3 kHz, with a total intensity of 133.5 dB. The dashed curve is obtained from Eqs. (4) and (7) with a spectrum that approximates the experimental spectrum.

IV. CONCLUSIONS

In the presence of broadband acoustic noise, there is a force between two rigid parallel plates due to an imbalance in the radiation pressure between and outside the plates. The force can be attractive or repulsive as a function of the separation between the plates, and there is excellent quantitative agreement between theory and experiment. The theory reveals that the repulsive force is *not* due to possible Q-amplification of the modes between the plates, but rather to the noise being in band of frequencies with a nonzero lower cutoff. This successful experiment has opened up the field of Casimir acoustics as a viable means to investigate the probe by analogy some effects due to the zero point field.

Experimental evidence of attractive and repulsive forces within a finite acoustic bandwidth also suggest new means of acoustic levitation. The force between two objects can be manipulated by changing the distance between the objects and/or varying the spectrum. While the Casimir force is small compared to the force of the Earth's gravity, in a low gravity environment a method of material control through the manipulation of an acoustic noise spectrum or plate geometry may be possible.

The acoustic Casimir effect can also be a potential tool in noise transduction. Through direct measurement of the force between two plates, or any other cavity, it may be possible to determine background noise. The shape of the force over distance is an instantaneous time average over all frequencies and may provide an alternative to measurements of background noise.

ACKNOWLEDGMENTS

We are grateful to Metler-Toledo for the generous loan of their AT261 analytic balance for the duration of this experiment. This work was sponsored in part by the Naval Postgraduate School Merit Research Program, and by the Office of Naval Research.

The effect of compression ratio and release time on the categorical rating of sound quality[a)]

Arlene C. Neuman, Matthew H. Bakke,[b)] Carol Mackersie,[c)] Sharon Hellman, and Harry Levitt

Center for Research in Speech and Hearing Sciences, Graduate School, City University of New York, 33 West 42nd Street, New York, New York 10036

(Received 19 March 1996; accepted for publication 26 November 1997)

Two experiments were carried out to determine how manipulating the compression ratio and release time of a single-band wide dynamic range hearing aid affects sound quality. In experiment I, compression ratio was varied over the range from linear to 10:1 (low compression threshold, attack time=5 ms, release time=200 ms). In experiment II, compression ratios of 1.5, 2, and 3:1 were combined with release times of 60, 200, and 1000 ms (attack time=5 ms). Twenty listeners with sensorineural hearing loss rated the clarity, pleasantness, background noise, loudness, and the overall impression of speech-in-noise (Ventilation, Apartment, Cafeteria) processed through a compression hearing aid. Results revealed that increasing compression ratio caused decreases in ratings on all scales. Increasing release time caused ratings of pleasantness to increase, and ratings of background noise and loudness to decrease. At the 3:1 compression ratio, increasing the release time caused increases in ratings of clarity, pleasantness, and overall impression, and a decrease in background noise. Significant correlations were found between scales. Regression analysis revealed that the contributions of the scales of clarity, pleasantness, background noise, and loudness to the prediction of overall impression differed as a function of the competing noise condition. INTRODUCTION

In recent years, wide dynamic range compression has been incorporated into hearing aids with the purpose of achieving an increase in speech intelligibility and/or increased comfort for a wider range of input levels. At comfortable listening levels, a well-fit compression hearing aid and a well-fit linear hearing aid result in similar speech recognition performance (see meta-analysis of compression studies by Dillon, 1996). It is generally agreed that wide dynamic range compression amplification will result in better speech recognition performance than will linear amplification for low input levels, provided that the user does not adjust the gain of the linear hearing aid. The success of wide dynamic range compression in expanding the range of input signals that can be listened to comfortably without volume control adjustment is undisputed [see Dillon (1996) for an extensive review of the literature].

These two benefits of wide dynamic range compression can be achieved with either syllabic compression or with slow-acting compression. Release times <150 ms are considered to be syllabic, >150 ms are slow-acting (Johannson and Lindblad, 1971). Several researchers have argued the potential usefulness of slow-acting compression (Braida *et al.*, 1979; Walker and Dillon, 1982; Van Tasell, 1993). In the past, most compression hearing aids had fast attack and release times (syllabic compression). Hearing aids with longer release times were not commonly available. In the most recent generation of hearing aids, programmable and digital hearing aids allow control over many compression parameters. In some hearing aids, attack and release time may be controlled directly. When this option is available, release times may vary over a large range (e.g., 7–500 ms in one hearing aid currently in use). In some hearing aids, the option of using longer release times is now made more attractive by incorporating multiple attack and release times or adaptive attack and release times. This allows fast-acting gain control for high level transient sounds and slow-acting gain control for changes that are primarily due to long-term changes in input level. Multiple attack and release times alleviate the concern that the use of long release times will prevent the hearing of low level sounds that follow high level sounds.

Digitally programmable and digital wide dynamic range compression hearing aids may also allow control of compression ratio and compression threshold. Compression ratios most commonly can be varied over the range from 1:1 to 5:1 in either a single band or two bands. Compression thresholds may also be varied over a range (usually 45–65 dB SPL). Therefore wide dynamic range compression hearing aids may include either short or long time constants and a large range of compression ratios.

Since either slow-acting or syllabic compression can be used to increase user comfort and to expand the listener's dynamic range, knowledge of how compression parameters affect sound quality should be considered in the selection of compression parameters. However, the effect of compression amplification on speech quality has been largely overlooked.

[a)]''Selected research articles'' are ones chosen occasionally by the Editor-in-Chief that are judged (a) to have a subject of wide acoustical interest, and (b) to be written for understanding by broad acoustical readership.

A recent study of Neuman and colleagues (1994) showed that sound quality preferences of hearing-impaired listeners were significantly affected by compression ratio, the competing noise type and level, and the dynamic range of the listener. Paired-comparison judgments of sound quality were obtained for a slow-acting (5-ms attack time, 200-ms release time) single-band compression amplifier. Lower compression ratios were judged to have significantly better sound quality than compression ratios greater than 3:1. Background noise level was found to interact with compression ratio. On average, subjects selected a linear hearing aid or the lowest compression ratio (1.5:1) for the noise having the highest level, and slightly more compression (up to 2:1) for two other noises presented at lower levels.

An early study by Nabelek (1984) found that hearing-impaired listeners were relatively insensitive to the manipulation of attack and release time (discrimination paradigm). Similarly, Bentler and Nelson (1997) failed to find significant differences in the preferences of hearing-impaired listeners for release time in a two-channel AGC hearing aid. In contrast, Neuman and colleagues (1995b) found that sound quality judgments were differentially affected by release time as a function of the background noise and compression ratio (release time was varied from 60 ms to 1000 ms, in combination with compression ratios of 1.5, 2, and 3:1). Longer release times were selected with the higher level background noises.

In the studies of the effect of compression on speech quality by Neuman and colleagues (1994, 1995b), the criterion of quality was not defined for the subject. Because sound quality is a multidimensional attribute, the instructions to the subject were purposely general in order to allow the listener to use his/her own definition of sound quality. Therefore, it is unknown what criterion subjects were using or whether common criteria were used among subjects.

The purpose of the present study was to determine: (1) how manipulating compression ratio and release time affects the perception of specific aspects of sound quality; i.e., clarity, pleasantness, background noise, loudness, and overall impression of sound; (2) the relation among these different aspects of sound quality; and (3) the relation between the global rating of overall impression and the more specific quality ratings. In experiment I, compression ratio was manipulated in a single-band compression hearing aid with a 200-ms release time. In experiment II, both release time and compression ratio were manipulated.

I. METHOD

A. Subjects

Twenty listeners with sensorineural hearing loss (mean age of 59.8 years) served as subjects. These subjects had served in two earlier experiments in which paired-comparison judgments of quality were obtained through the same experimental compression amplification system (Neuman *et al.*, 1994, 1995b). A complete description of the personal and audiometric characteristics of these subjects may be found in Neuman *et al.* (1994). Briefly, half of the subjects had a small dynamic range for speech ($\leqslant$30 dB between the speech reception threshold and loudness discomfort level) and half of the subjects had a large dynamic range ($>$30 dB). The small dynamic range group of subjects had moderately severe or severe degree of hearing loss with sloping configuration. The large dynamic range group had moderate sloping sensorineural hearing loss. All subjects were experienced hearing aid users. Fifteen of the subjects wore linear hearing aids. The remaining five subjects wore linear hearing aids with compression limiting.

B. Instrumentation and stimuli

A digital test system consisting of a personal computer and an Ariel DSP 16 board was used to simulate a hearing aid with input compression [model and formulas were those of Kates (1993)]. In the compression simulation, compression occurs when the control voltage exceeds the specified compression threshold (peak detection circuit). Post-compression filtering (64 tap finite impulse response filter) was used to implement the NAL-R frequency response (Byrne and Dillon, 1986). In calculating the target frequency response, the real-ear constants specified by Byrne and Dillon were included in the formula, as were real-ear-to-headphone corrections (Cox, 1986). These corrections were used in order to make the signal at the listener's eardrum as similar as possible to that which would have been obtained had a conventional hearing aid been used.

A two-channel digital audio tape recorder was the source of the speech and noise stimuli. The speech and noise levels were adjusted at the outputs of the tape recorder using two programmable attenuators. The speech and noise signals were then mixed and passed through an anti-aliasing filter (7.5-kHz low pass filter). Signals were digitized (20-kHz sampling rate, 16-bit quantization), compressed, filtered, and amplified by the simulated hearing aid. The processed signal was converted back to an analog signal, passed through an anti-imaging filter (7.5 kHz), attenuated, amplified, and sent to a TDH-50P earphone (mounted in a MX-41/AR cushion) for monaural presentation to the listener.

Both the static and dynamic characteristics of the simulated compression hearing aids were defined and measured using the procedures specified in ANSI S3.22-1987 (ANSI, 1987). Calibration of input levels was verified during each experimental session by checking the electrical input. Output levels were verified acoustically in a 6-cc coupler.

C. Experimental protocol

Continuous discourse (female talker) was presented at a level 20 dB above the compression threshold. This level was used to guarantee that for all conditions the speech would be fully compressed. Three different competing noises were used. The noises varied in their temporal characteristics as well as in level. The ventilation noise was used to represent a quiet environment with a constant background noise (ventilation noise), the apartment noise was used to represent an environment with fluctuating noise, and the cafeteria noise was used to represent a somewhat more difficult listening environment with both a constant level and fluctuations superimposed. Ventilation noise was 15 dB below the com-

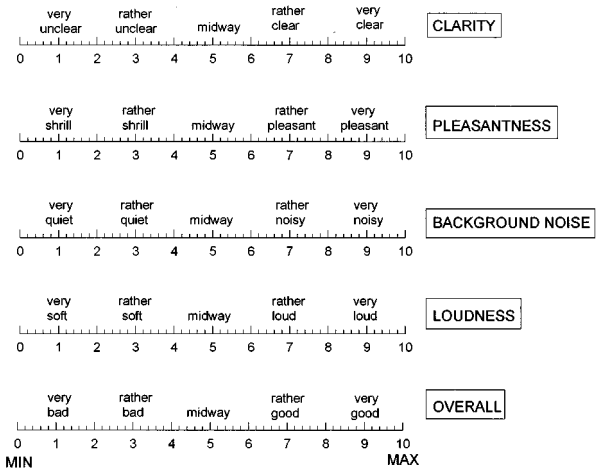

FIG. 1. A sample of the response form used for the rating procedure.

pression threshold, apartment noise was 5 dB below the compression threshold, and the cafeteria noise was 5 dB above the compression threshold. It is recognized that the signal-to-noise ratios used are better than would be found in most environments. The use of poorer signal-to-noise ratios would have degraded speech intelligibility. For the purposes of this experiment we wanted to maintain good speech intelligibility across conditions. Only then, can differences in sound quality be measured independently of changes in speech intelligibility (Preminger and Van Tasell, 1995).

D. Rating procedure

The method of categorical rating as developed and implemented by Gabrielsson and colleagues was used (Gabrielsson *et al.*, 1979b,c, 1988, 1990). Ratings are obtained on a scale ranging from 0 to 10. Five scales were used: clarity, pleasantness, background noise, loudness, and overall impression. The loudness scale was included as a check of the loudness matching procedure used in the experiment.

Subjects were instructed to listen to speech through the simulated hearing aid in a given background noise and to rate what they heard on each of the five rating scales that appeared on the response form. An example of the response form appears in Fig. 1. Subjects were given written instructions for the task (see the Appendix) and were given the opportunity to ask for clarification of the instructions.

Testing was preceded by a practice/training procedure designed to determine that subjects understood the task and would assign diverse ratings when the hearing aid parameters were changed. The training task included conditions that were expected to yield a range of scores on several rating scales. Conditions included a change in input level (linear hearing aid with the output at MCL, a hearing aid with the output 20 dB below MCL) and a large change in compression characteristics (linear hearing aid and a hearing aid with a 10:1 compression ratio). Speech presented in a background of cafeteria noise (15-dB signal-to-noise ratio) was the input signal for all practice conditions. The ratings of the subjects were examined to determine that the clarity, loudness, and background noise ratings decreased as the hearing aid output was lowered. Based on our previous study showing a decrease in the perceived quality of hearing aids with high compression ratios, we also expected that ratings on several of the scales would be poorer for the compression hearing aid than for the linear hearing aid. Subjects were allowed to ask questions during this practice/training phase. The collection of data was begun when the subject felt that he/she understood the task and when the experimenter had ascertained that the subject's ratings were consistent for a given listening condition.

TABLE I. Summary of the main effects from the analysis of variance done for each rating scale for experiment I. Significance levels are indicated as follows: $*p<0.05$, $**p<0.01$, $***p<0.001$.

		Clarity	Pleasant	Noise	Loud	Overall

II. EXPERIMENT I

Compression ratio (CR) was varied (CR=1, 1.5, 2, 3, 5, and 10:1). All other parameters of the compression system were held constant (compression threshold was 20 dB below the rms level of the speech, attack time=5 ms, and release time=200 ms). The gain of each hearing aid was specified to place the processed speech at the midpoint of the listener's most comfortable listening range (Dirks and Kamm, 1976). Since loudness varied with compression ratio, loudness matching was achieved by equating the 90th percentile of the cumulative distribution of the compressed speech to the same point on the cumulative distribution of uncompressed speech (Levitt and Neuman, 1991; Bakke *et al.*, 1991).

Ratings were obtained for each of the six compression ratios (1, 1.5, 2, 3, 5, and 10:1) in each of three different competing noises (ventilation, apartment, and cafeteria). Data were collected in blocks of 18 trials (six hearing aids ×three replications for a particular background noise). A trial consisted of rating a particular hearing aid on the five scales. The order of presentation of the hearing aids for the three replications was randomized within a block. The order of testing in different background noise conditions was also randomly assigned to subjects.

III. RESULTS

A. Analysis of variance

The procedures for statistical analysis outlined by Gabrielsson (1979a) were followed. A separate analysis of variance was carried out for each rating scale to determine the effect of compression ratio (CR), noise type (N), dynamic range group (DR), and their interactions. A general mixed model analysis of variance was used with subjects nested within a group factor.

A summary of the five analyses appears in Table I. Compression ratio and noise type were found to be significant for all of the scales except for that of loudness. Dynamic range group was found to be a significant factor only for the loudness scale. None of the interactions was significant.

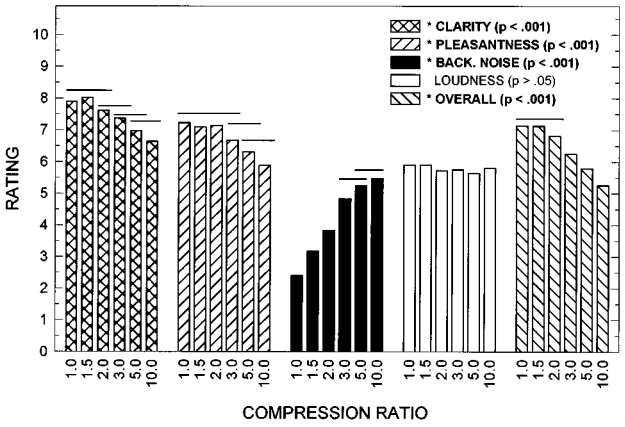

FIG. 2. Mean ratings on five quality scales as a function of compression ratio. Significance levels for each scale appear in parentheses.

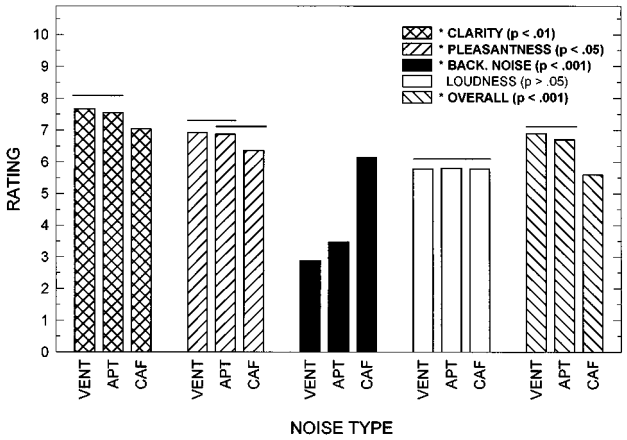

FIG. 3. Mean ratings on five quality scales as a function of noise type. Significance levels for each scale appear in parentheses. The horizontal lines above the graph indicate means that do not differ significantly ($p>0.05$).

The mean scores representing the main effect of compression ratio and the results of the tukey *post-hoc* analysis appear in Fig. 2. In general, increasing the compression ratio causes a decrease in the ratings of clarity, pleasantness, and overall impression. The rating of background noise increases with increasing compression ratio, i.e., the sound is perceived as being noisier and quality is degraded. For all four scales, ratings for compression ratios of 1, 1.5, and 2:1 were significantly better than for compression ratios of 5:1 or 10:1. The loudness ratings demonstrate that loudness has been matched successfully. Mean scores remain constant, approximately at the middle of the 11 point scale.

The main effect of noise type is illustrated in Fig. 3. Recall that the three different noises differ in level; the ventilation noise is lowest in level and the cafeteria noise is highest in level. The ratings of clarity, pleasantness, and overall impression decrease significantly in the cafeteria noise condition and there is a general trend for ratings to decrease with increasing noise level. The rating of background noise increases significantly as noise level increases. Loudness is the only scale whose ratings are unaffected by the noise type/level.

The factor of dynamic range group was found to be significant only for the loudness scale. The mean loudness rating for the small dynamic range group was 6.2 and for the large dynamic range group was 5.4. An examination of the means as a function of compression ratio reveals that the small dynamic range group consistently assigned higher loudness ratings than the large dynamic range group. This, despite the fact that for all subjects the output of the hearing aid was placed at the measured MCL (the midpoint of the MCL range). The finding is consistent with the results of a previous study on the same group of subjects that revealed that the preferred listening level of the small dynamic range group of subjects was slightly below the midpoint of the MCL range, while the preferred listening level of the large dynamic range group was slightly above the midpoint of the MCL range (Neuman *et al.*, 1995a).

B. Relationship among scales

A correlation analysis was done to determine the relationships among the different scales. The results of these analyses appear in Table II. For all three noise conditions, significant correlations were found between scales. Only the Loudness scale was not significantly correlated with the other scales. The pattern of correlations found for the apart-

ment and cafeteria noise conditions were similar to those for the ventilation noise condition, but correlations were weaker.

When subjects rate a hearing aid for overall impression, presumably they are using several different criteria simultaneously. Significant correlations were found between the overall impression scale and clarity, pleasantness, and background noise for all three noise conditions. A separate multiple linear regression analysis was carried out for each noise condition to determine which scales were predictive of the overall impression scale. Because of the significant correlation between clarity and pleasantness, a ridge regression analysis was done to control for the problem of multicollinearity. In the analysis, a lambda of 0.10 was used (CSS Statistica, 1991). Results of the analysis appear in Table III.

All of the ridge regression analyses were significant [ventilation noise: $F(4,115)=61.48$, $p<0.0001$, $R^2=0.68$; apartment noise: $F(4,115)=63.74$, $p<0.0001$, $R^2=0.69$; cafeteria noise: $F(4,115)=39.26$, $p<0.0001$, $R^2=0.58$). The beta values indicate that the predictive value of the independent variables varies with the competing noise condition. Clarity is most heavily weighted in the ventilation and apartment noise conditions. In the cafeteria noise, pleasantness is more heavily weighted.

IV. EXPERIMENT II

The same subjects, instrumentation, and rating scales were used as for experiment I. Compression ratio (CR=1.5, 2, or 3:1) and release time (60, 200, or 1000 ms) were varied. All other parameters of the compression system were held constant. The 90th percentile of the cumulative distribution of the uncompressed and compressed speech signals were matched for the three compression ratios for the 200-ms release time. This allowed for small variations in level within a compression ratio among release times. All gain values placed the output within ±2 dB of the midpoint of the MCL range.

Data were collected in blocks of 27 trials (nine hearing aids×three replications for a particular background noise). A trial consisted of rating a particular hearing aid on the five scales. The order of presentation of the hearing aids for the three replications was randomized within a block. The order of testing in different background noise conditions was also randomly assigned to subjects.

V. RESULTS

A. Analysis of variance

A separate analysis of variance was carried out for each rating scale to determine the effect of compression ratio (CR), release time (RT), noise type (N), dynamic range group (DR), and their interactions. A general mixed model analysis of variance was used with subjects nested within a group factor.

A summary of these analyses appears in Table IV. The factors of release time, compression ratio, and noise type were all found to be statistically significant on several of the scales. The factor of dynamic range was not found to be statistically significant. A number of interactions (CR×RT, RT×N, and DR×N) were also statistically significant on various scales.

The main effect of release time is illustrated in Fig. 4. The factor of release time was found to be significant on the pleasantness, background noise, and loudness scales. Clarity and overall impression ratings were unaffected by changes in release time. The results of the tukey *post hoc* analysis revealed that ratings of pleasantness were significantly higher for the 200- and 1000-ms release time than for the 60-ms release time. Background noise and loudness ratings decreased significantly with each increase of release time.

The main effect of compression ratio is illustrated in Fig. 5. Significant effects were found for all scales. The tukey *post hoc* analysis revealed that ratings of clarity and overall impression decreased significantly with each increase of compression ratio. Ratings of pleasantness and loudness

both decreased significantly at the 3:1 compression ratio. Background noise ratings increased significantly with each increase of compression ratio. Note that for the background noise scale, an increase in the rating indicates more noise and should be interpreted as a decrement in performance.

The main effect of noise type is illustrated in Fig. 6. *Post hoc* testing revealed that ratings on the scales of clarity, pleasantness, and overall impression were significantly lower with the cafeteria noise (highest noise level). Background noise ratings were significantly higher with cafeteria noise than with apartment noise, which in turn were significantly higher than with ventilation noise. Loudness did not differ significantly as a function of noise type.

The interactions of release time and compression ratio for the scales of clarity, pleasantness, background noise, and overall impression appear in Fig. 7. Mean scores within a compression ratio found to differ significantly on the tukey *post hoc* test ($p<0.05$) are indicated by filled symbols. This analysis reveals that the effect of release time is significant at the highest compression ratio utilized in this study. At the 3:1 compression ratio, the clarity rating for the 1000-ms release time is significantly higher than the rating for the 60-ms release time. Ratings change significantly with each change in release time on the pleasantness, background noise, and overall impression scales at the 3:1 compression ratio. On the background noise scale, the 1000-ms release time is rated significantly better (perceived as being less noisy) at all three compression ratios.

The interaction of release time and noise type was significant on the background noise scale. The interaction is illustrated in Fig. 8. Mean scores for a particular noise that differ significantly as a function of release time are indicated

FIG. 5. Mean ratings on five quality scales as a function of compression ratio. Significance levels for each scale appear in parentheses. The horizontal lines above the graphs indicate means that do not differ significantly ($p>0.05$).

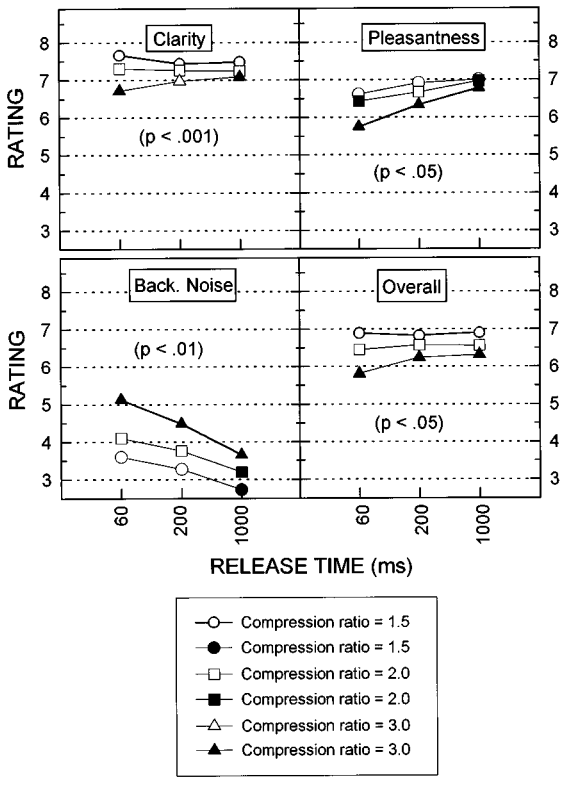

FIG. 7. Mean ratings of clarity, pleasantness, background noise, and overall impression as a function of compression ratio and release time. Significance levels for each scale appear in parentheses. FIG. 8. Mean ratings of background noise as a function of noise type and release time. Significance levels appear in parentheses. Mean scores for a particular noise that differ significantly as a function of release time ($p < 0.05$) are indicated by filled symbols.

by filled symbols (tukey *post hoc* test, $p<0.05$). For all three noises, the ratings of background noise decreased with increasing release time, meaning that shorter release times are perceived as being noisier than longer release times. However, there are different patterns as a function of noise type.

The interaction of dynamic range group and noise type was significant on the clarity, pleasantness, and overall impression scales. The mean ratings of the small dynamic range group were significantly lower (poorer) for the cafeteria noise condition than for the other noises on all three scales. The mean ratings of the large dynamic range group did not differ significantly as a function of the noise.

B. Relationship among scales

A correlation analysis was done to determine the relationships between the different scales (see Table II). Many significant correlations are evident between the scales. The pattern of correlations is similar for the three noises.

A ridge regression analysis was done using a lambda of 0.10. In the analysis, overall impression was the dependent variable and clarity, pleasantness, background noise, and loudness were the independent variables. The results of these analyses appear in Table III. All of the ridge regression analyses were significant [ventilation noise: $F(4,535)=204.78$, $p<0.001$, $R^2=0.60$; apartment noise: $F(4,535)=160.31$, $p<0.0001$, $R^2=0.55$; cafeteria noise: $F(4,535)=218.05$, $p<0.0001$, $R^2=0.62$]. R^2values indicate that the significant scales accounted for approximately 60% of the variance. The beta values indicate that the predictive value of the independent variables varies with the competing noise condition. Whereas clarity has the most predictive weight for the ventilation and apartment noise conditions, loudness is most heavily weighted in the cafeteria noise condition.

VI. DISCUSSION AND CONCLUSIONS

The results of these two experiments reveal that manipulating either the compression ratio or the release time of a compression amplifier systematically affects the sound quality ratings of hearing-impaired listeners. The rating data supplements and helps to clarify the findings obtained in our two previous studies of the perceived sound quality of compression amplification (Neuman *et al.*, 1994, 1995b). Of the two compression parameters studied, compression ratio clearly has the larger effect on perceived sound quality. Manipulation of compression ratio significantly affects sound quality ratings whether the compression ratios cover the range from linear to compression limiting (experiment I) or only mild ($\leqslant$3:1) compression ratios (experiment II). As compression ratio is increased, ratings of clarity, pleasantness, and overall impression decrease. Ratings of background noise increase.

In contrast, the manipulation of release time has a more subtle effect on perceived sound quality. The main effect of release time was significant for the scales of pleasantness, background noise, and loudness. Clarity and overall impression are also affected under certain conditions (release time $\times$compression ratio interaction, release time$\times$noise type interaction). The effect of release time was most obvious at the highest compression ratio tested (3:1) and under certain noise conditions where longer release times result in higher ratings of clarity, pleasantness, and overall impression. Background noise ratings and loudness ratings decrease with longer release times.

The pattern of results obtained with the rating procedure in experiment I is similar to that obtained using paired-comparison judgments of sound quality (Neuman *et al.*, 1994). Both methods of measurement reveal a degradation in perceived speech quality with increasing compression ratio. However, the results of the rating procedure yield specific information about various aspects of sound quality—clarity, pleasantness, and overall impression decrease, and background noise increases with increasing compression ratio. It is noteworthy that in both the paired-comparison and in the present study, there were significant degradations in quality for compression ratios greater than 3:1.

The results in experiment II are in general agreement with the results of our previous experiment using paired-comparison judgments of sound quality (Neuman *et al.*, 1995b). In that experiment, we failed to find a significant main effect for release time on judgments of sound quality (the same compression ratios and release times were used). In this present experiment, we found that ratings of overall impression are not affected by release time. However, we did find that increasing release time causes positive changes in the ratings of pleasantness and noisiness. Increasing the release time also causes a decrease in the rating of loudness.

The finding of a decrease in loudness with increasing release time is consistent with physical measures of the signal. The variations in speech level due to differences in release time within a given compression ratio were not large. The largest variation was at the 3:1 compression ratio ($\pm$2 dB from the 200-ms condition). Nevertheless, these differences in level did result in differences in perceived loudness.

The ridge regression analysis revealed that the variation in loudness figured importantly as a predictor of overall impression in the cafeteria noise condition.

In experiment II, several significant interactions were found. A significant interaction between release time and noise type was found on the background noise scale. The mean ratings of noisiness decreased significantly with each increase in release time and was most dramatic for the cafeteria noise (the highest noise level). When these same subjects made paired-comparison judgments of sound quality for these same test conditions (Neuman *et al.*, 1995b), a significant interaction was found between release time and noise type. Subject preference for the 200- and 1000-ms release time was significantly greater than for the 60-ms release time in the cafeteria noise condition (and the same trend was seen in the apartment noise condition). We suggested that changes in the background noise due to the use of short release times was the underlying cause of the preferences. The results of the present experiment appear to confirm this hypothesis.

The compression ratio×release time interaction demonstrates that release time affects ratings of clarity, pleasantness, noisiness, and overall impression at the highest compression ratio (3:1). The compression ratios of 1.5, 2, and 3:1 used in this experiment were selected based on our findings that these compression ratios did not significantly degrade sound quality in a compression amplifier with a 200-ms release time [Neuman *et al.* (1994) and experiment I reported here]. A significant main effect of compression ratio was demonstrated in experiment II, with significant decreases in ratings of clarity, pleasantness, and overall impression being found as compression ratio increased. Background noise ratings increased significantly with increasing compression ratio, i.e., as compression ratio increased there was a perception of higher background noise levels. This finding, in combination with the compression ratio×release time interaction, indicates that the selection of compression ratio and release time should not be made in isolation. While the effect of release time is minimal at compression ratios $\leqslant$2:1, release time has a significant effect for the 3:1 compression ratio. At the 3:1 compression ratio, the shortest release time (60 ms) resulted in lower ratings of clarity, pleasantness, and overall impression. Similar compression characteristics are often used in single-band compression hearing aids.

In both experiments, testing was done at a single input level and with a single compression threshold. The results are indicative of what happens to sound quality when the speech is fully compressed and the noise level/type is changing. A more complete picture would be obtained with signals at multiple input levels or with several compression thresholds. The present results demonstrate that in a single-band compression hearing aid, compression ratios $<$3:1 will preserve good sound quality. Experiment I reveals that in a single-band compression hearing aid with a low compression threshold and a release time of 200 ms, compression ratios greater than 3:1 will degrade the overall impression of quality. The specific dimensions of clarity and pleasantness will be degraded. The perception of background noise will increase. Significant degradations of sound quality were observed at the 3:1 compression ratio in experiment II.

Experiment II reveals that release time does not significantly affect sound quality in a single-band compression hearing aid with compression ratios $\leqslant$2:1. However, when the compression ratio was 3:1, the 60-ms release time (syllabic) did result in significantly poorer ratings on all quality scales than did the 200-ms or the 1000-ms release times. In this experiment, we did not include release times longer than 1000 ms because we felt that using longer times would be detrimental to the hearing of soft sounds immediately following louder sounds in a hearing aid with a single set of time constants. Even longer release times can be safely implemented in hearing aids with multiple attack/release times or adaptive attack/release times. Overall, our results would suggest that superior sound quality will be obtained if multiple or adaptive release times are used in single-band compression hearing aids with compression ratios $>$2:1.

The rating procedure used in these two experiments allows a quantification of the relationship among different conditions. When paired-comparison judgments of sound quality were obtained in our previous experiments, we were able to rank the hearing aids with regard to sound quality but we had no indication of the magnitude of differences among hearing aids. The rating procedure gives an indication of how much sound quality changes with the manipulation of compression parameters or competing noise. Furthermore, the descriptors attached to the endpoints and to various intermediate points of the scales may be helpful in interpreting the importance of changes in rating. For example, in experiment I the largest changes in rating as a function of compression ratio occurred on the scales of background noise and overall impression. On the background noise scale, the mean rating for the linear hearing aid was 2.4, indicating the background noise was in the ''rather quiet'' range. For the 10:1 compression ratio, the mean rating of 5.5 is indicative that the background noise is approximately midway between ''very quiet'' and ''very noisy.'' The mean rating for the linear condition for overall impression was 7.1, indicating a judgment of the quality being ''rather good.'' The rating for the 10:1 compression condition was 5.3, or just above midway between ''very good'' and ''very bad.''

The rating procedure used in these experiments was quite sensitive to differences among hearing aids. In particular, the differences among the hearing aids in experiment II were quite subtle. This type of procedure may be useful in selecting the compression characteristics for individual listeners. Further research would be required to determine which rating scales would be most useful for this purpose. The rating scales used were a subset of those previously developed for studying the manipulation of frequency response in sound systems. We found these scales to be significantly correlated, although they all made significant contributions to the prediction of overall impression. Other scales not included in this study might have provided additional information about the effects of varying compression parameters. The development of a set of descriptors specifically relevant to the use of compression may be useful for future research and for clinical use.

ACKNOWLEDGMENTS

This research was supported by PHS Grant No. 5P50DC00178 from the National Institute on Deafness and Other Communication Disorders. We would like to thank Karen Bromberg for assistance in collection of data of experiment II. Portions of this paper were presented in a poster session at the First Biennial Conference on Hearing Aid Research and Development, September, 1995, National Institutes of Health, Bethesda, MD.

APPENDIX: INSTRUCTIONS GIVEN SUBJECTS FOR THE RATING TASK

You will be listening to speech along with background noise through a number of different hearing aids. You will be asked to judge five aspects of sound quality for each hearing aid using a rating scale. These qualities are

CLARITY
PLEASANTNESS
BACKGROUND NOISE
LOUDNESS
OVERALL IMPRESSION

Please listen carefully to each hearing aid and then rate it on each of the scales you see on the response form. There will be a separate scale for each of the five hearing aid qualities that you rate.

Each scale goes from 0 (minimum) to 10 (maximum). You may mark any place on the scale (including in between numbers).

Please be as accurate as you think necessary, and do your rating on each scale without looking at the other scales.

Classical Lamb waves in an homogeneous, isotropic linearly elastic plate are reconsidered. The displacement components are obtained in terms of thickness motions superimposed on a membrane carrier wave which defines the propagation along the plate. The carrier wave can be any solution of the reduced wave equation for a membrane. The analysis of the thickness motions results in the usual Rayleigh–Lamb frequency equation. A number of special cases for the carrier wave are considered. © *1998 Acoustical Society of America.* [S0001-4966(98)04705-5]

INTRODUCTION

The usual way to construct solutions to the elastodynamic equations of motion for homogeneous, isotropic, linearly elastic solids is to express the components of the displacement vector as the sum of the gradient of a scalar potential and the curl of a vector potential, where the potentials must be solutions of classical wave equations whose propagation velocities are the velocities of longitudinal and transverse waves, respectively.

This approach has generally also been used to investigate the propagation of waves in an elastic layer; see, for example, Refs. 1 and 2. For plane-strain conditions, time-harmonic waves in an elastic layer were first investigated by Lamb.[3] It is well known[1,2] that there are an infinite number of modes which may be split into antisymmetric and symmetric modes, corresponding to thickness shear and thickness stretch motions relative to the mid-plane of the layer.

As discussed in this paper, the particular nature of these layer motions suggests an alternative formulation in terms of a membrane motion of the mid-plane of the layer, which acts as a carrier wave of superimposed thickness motions. The corresponding formulation presented in this paper shows that the carrier wave satisfies a reduced membrane wave equation. The functions representing the superimposed thickness motions are solutions of ordinary differential equations. The formulation has the advantage that the carrier wave can be determined separately in a fairly general form. The analysis of the thickness motions results in the usual Rayleigh–Lamb frequency equations relating the circular frequency, ω, and a wave number-like quantity, k. The nature of the selected solution of the membrane equation affects the interpretation of k, but not the general form of the thickness motions.

Section I proposes general forms for the displacement components in terms of a single potential, and shows that these forms satisfy the displacement equations of motion. The connection with symmetric and antisymmetric modes of wave propagation is discussed in Sec. II. A number of examples for the solution of the membrane equation which governs the propagation of the Lamb wave along the plate, and its variation along wavefronts, are discussed in Sec. III.

I. GOVERNING EQUATIONS

A layer of homogeneous, isotropic, linearly elastic material of thickness $2h$ is referred to a Cartesian coordinate system such that the x_1x_2 plane coincides with the mid-plane of the plate, as shown in Fig. 1. Greek indices exclusively refer to the x_1 and x_2 axes, while Latin indices refer to all three directions. We seek solutions for the displacement components in the forms

$$u_\alpha = \frac{1}{k} v(x_3) e^{i\omega t} \varphi_{,\alpha}(x_1, x_2), \tag{1}$$

$$u_3 = w(x_3) e^{i\omega t} \varphi(x_1, x_2). \tag{2}$$

Here k is a wave number-like quantity, i.e., its dimension is 1/length. The function $\varphi(x_1, x_2)$ is dimensionless. In what follows we will seek steady-state solutions, and we will omit $\exp(i\omega t)$.

Equations (1) and (2) yield for the divergence of the vector **u**

$$u_{k,k} = \frac{1}{k} v(x_3) \varphi_{,\beta\beta} + \frac{dw}{dx_3} \varphi. \tag{3}$$

Substitution of (1)–(3) into the equations of motion

$$(\lambda + \mu) u_{k,ki} + \mu u_{i,kk} = \rho \ddot{u}_i \tag{4}$$

yields for $i = \alpha = 1,2$:

$$(\lambda + \mu) \left[\frac{1}{k} v(x_3) \varphi_{,\beta\beta\alpha} + \frac{dw}{dx_3} \varphi_{,\alpha} \right] + \mu \left[\frac{1}{k} v(x_3) \varphi_{,\alpha\beta\beta} + \frac{1}{k} \frac{d^2 v}{dx_3^2} \varphi_{,\alpha} \right] = -\frac{\rho\omega^2}{k} v(x_3) \varphi_{,\alpha}, \tag{5}$$

and for $i = 3$:

$$(\lambda + \mu) \left[\frac{1}{k} \frac{dv}{dx_3} \varphi_{,\beta\beta} + \frac{d^2 w}{dx_3^2} \varphi \right] + \mu \left[w(x_3) \varphi_{,\beta\beta} + \frac{d^2 w}{dx_3^2} \varphi \right] = -\rho\omega^2 w(x_3) \varphi. \tag{6}$$

These equations can be rewritten as

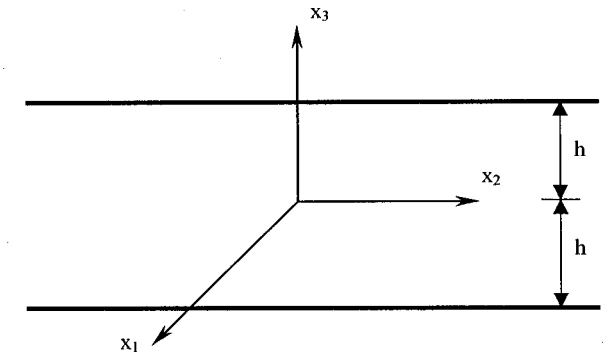

FIG. 1. Elastic plate.

$$\frac{\lambda+2\mu}{k}v(x_3)\varphi_{,\beta\beta\alpha}+\left[(\lambda+\mu)\frac{dw}{dx_3}+\frac{\mu}{k}\frac{d^2v}{dx_3^2}+\frac{\rho\omega^2}{k}v(x_3)\right]\varphi_{,\alpha}=0, \tag{7}$$

$$\left[\frac{\lambda+\mu}{k}\frac{dv}{dx_3}+\mu w(x_3)\right]\varphi_{,\beta\beta}+\left[(\lambda+2\mu)\frac{d^2w}{dx_3^2}+\rho\omega^2 w(x_3)\right]\varphi=0. \tag{8}$$

We now select equations for $v(x_3)$ and $w(x_3)$ such that both (7) and (8) are satisfied if $\varphi(x_1,x_2)$ is a solution of the reduced membrane wave equation

$$\varphi_{,\beta\beta}+k^2\varphi=0. \tag{9}$$

Clearly this can be achieved if

$$(\lambda+\mu)\frac{dw}{dx_3}+\frac{\mu}{k}\frac{d^2v}{dx_3^2}+\frac{\rho\omega^2}{k}v(x_3)=k^2\frac{\lambda+2\mu}{k}v(x_3), \tag{10}$$

$$(\lambda+2\mu)\frac{d^2w}{dx_3^2}+\rho\omega^2 w(x_3)=k^2\left[\frac{\lambda+\mu}{k}\frac{dv}{dx_3}+\mu w(x_3)\right]. \tag{11}$$

Equations (10) and (11) are a set of coupled ordinary differential equations for $v(x_3)$ and $w(x_3)$.

For the layer shown in Fig. 1 we seek solutions of (10) and (11) of the general forms

$$v(x_3)=Ve^{ipx_3} \tag{12a}$$

and

$$w(x_3)=We^{ipx_3}, \tag{12b}$$

where V and W are constants. Substitution of (12a) and (12b) into Eqs. (10) and (11) yields a set of homogeneous algebraic equations for the constants V and W. The condition that the determinant of the coefficients must vanish yields the following equation:

$$p^4+\left(2k^2-\frac{\omega^2}{c_L^2}-\frac{\omega^2}{c_T^2}\right)p^2+\left(\frac{\omega^2}{c_L^2}-k^2\right)\left(\frac{\omega^2}{c_T^2}-k^2\right)=0, \tag{13}$$

where c_L and c_T are the velocities of longitudinal and transverse waves, respectively,

$$c_L^2=\frac{\lambda+2\mu}{\rho} \tag{14a}$$

and

$$c_T^2=\frac{\mu}{\rho}. \tag{14b}$$

The two solutions of Eq. (13) are

$$p^2=\frac{\omega^2}{c_L^2}-k^2 \tag{15a}$$

and

$$q^2=\frac{\omega^2}{c_T^2}-k^2. \tag{15b}$$

The corresponding solutions of (10) and (11) may then be written as

$$v(x_3)=Ae^{ipx_3}+Be^{iqx_3}, \tag{16}$$

$$w(x_3)=\frac{ip}{k}Ae^{ipx_3}+\frac{k}{iq}Be^{iqx_3}. \tag{17}$$

In summary, it has been shown that Eqs. (1) and (2) are solutions of the elastodynamic equations (4), provided that $\varphi(x_1,x_2)$ is a solution of Eq. (9) and $v(x_3)$ and $w(x_3)$ are given by Eqs. (16) and (17).

In addition to a homogeneous layer, the formulation presented here also applies to homogeneous and layered full spaces, homogeneous and layered half-spaces and layered plates where the x_3 direction should be normal to the layering. It may also be applicable to certain simple cases of anisotropy. It will be of interest to investigate the applicability to cases of continuous inhomogeneity in the x_3 direction.

II. SYMMETRIC AND ANTISYMMETRIC MODES

Let us first consider displacements represented by the real parts of Eqs. (16) and (17), i.e.,

$$v(x_3)=A\cos(px_3)+B\cos(qx_3), \tag{18}$$

$$w(x_3)=-\frac{p}{k}A\sin(px_3)+\frac{k}{q}B\sin(qx_3). \tag{19}$$

These expressions represent motions that are symmetric relative to the mid-plane of the layer. They define the so called thickness-stretch modes of the layer. The displacement components given by Eqs. (1) and (2) with $v(x_3)$ and $w(x_3)$ defined by Eqs. (18) and (19) do not yet satisfy the conditions on the faces of the layer. These conditions are

$$\text{at } x_3=\pm h: \quad \tau_{3\beta}=0, \ \tau_{33}=0. \tag{20}$$

To obtain expressions for $\tau_{3\beta}$ and τ_{33} we use Hooke's law:

$$\tau_{ij}=\rho(c_L^2-2c_T^2)u_{k,k}\delta_{ij}+\rho c_T^2(u_{i,j}+u_{j,i}). \tag{21}$$

By using Eqs. (1) and (2) the relevant stress components may be expressed as

$$\tau_{3\beta}=\rho c_T^2\left[w(x_3)+\frac{1}{k}\frac{dv}{dx_3}\right]\varphi_{,\beta}, \tag{22}$$

$$\tau_{33}=\rho(c_L^2-2c_T^2)\left[\frac{1}{k}v(x_3)\varphi,_{\beta\beta}+\frac{dw}{dx_3}\varphi\right]+2\rho c_T^2\frac{dw}{dx_3}\varphi. \tag{23}$$

To satisfy the boundary conditions, Eq. (20), at $x_3=\pm h$, we must then have

$$w(h)+\frac{1}{k}\frac{dv}{dx_3}\bigg|_{x_3=h}=0, \tag{24}$$

$$-\rho k(c_L^2-2c_T^2)v(h)+\rho c_L^2\frac{dw}{dx_3}\bigg|_{x_3=h}=0, \tag{25}$$

where $\varphi,_{\beta\beta}$ has been eliminated by the use of Eq. (9). Substitution of $v(x_3)$ and $w(x_3)$ from Eqs. (18) and (19) yields a system of homogeneous algebraic equations for the constants A and B. The condition that the determinant of the coefficients must vanish yields after some manipulation

$$\frac{\tan(qh)}{\tan(ph)}=-\frac{4pqk^2}{(q^2-k^2)^2}. \tag{26}$$

Equation (26) is recognized as the well-known Rayleigh–Lamb frequency equation for symmetric layer modes, see, e.g., Ref. 2.

In a similar manner we can consider the imaginary parts of Eqs. (16) and (17), i.e.,

$$v(x_3)=A\ \sin(px_3)+B\ \sin(qx_3), \tag{27}$$

$$w(x_3)=\frac{p}{k}A\ \cos(px_3)-\frac{k}{q}B\ \cos(qx_3). \tag{28}$$

These expressions represent motions that are antisymmetric relative to the mid-plane of the layer. They are the so-called thickness-shear modes. Substitution of (27) and (28) into (24) and (25) yields the Rayleigh–Lamb frequency equation for anti-symmetric layer modes:

$$\frac{\tan(qh)}{\tan(ph)}=-\frac{(q^2-k^2)^2}{4pqk^2}. \tag{29}$$

The Rayleigh–Lamb frequency equations (26) and (29) relate the wave number, k, to the frequency, ω. To obtain detailed and precise numerical information the roots of (26) and (29) are obtained numerically by choosing a real-valued frequency ω and calculating the infinite number of corresponding values of k. Each value of k corresponds to a mode of wave propagation in the layer. The calculated values of k may be real, imaginary or complex. Real-valued wave numbers correspond to propagating wave modes. Imaginary and complex wave numbers correspond to standing waves with decaying amplitudes in the x_1x_2 plane. For small values of the frequency, as small as $\omega=0^+$, Eqs. (26) and (29) each have one real-valued solution for k. All the other solutions for k then are either imaginary or complex. The two real-valued k's correspond to the lowest symmetric and antisymmetric modes.

The interesting result of this section is that the thickness motions governed by Eqs. (26) and (29) which are well-known for the plane-strain case, apply to a general class of wave motions in the layer as long as $\varphi(x_1,x_2)$ is a solution of the reduced membrane wave equation (9).

III. EXAMPLES

The approach presented in this paper makes it possible to determine the carrier wave in a very simple manner as the solution of a reduced membrane wave equation. The corresponding thickness motion are independent of the choice of the carrier wave. In this section we present examples.

First we consider plane-strain waves in the layer. This case corresponds to a solution of the membrane equation of the form

$$\varphi(x_2)=e^{-ikx_2}. \tag{30}$$

Here k is the wave number, where $k=\omega/c$, c being the phase velocity. Equation (1) shows that the out-of-plane displacement, $u_1(x_2,x_3t)$, vanishes. The remainder of the analysis presented in Secs. I and II then reduces to the conventional Lamb-wave result as, for example, presented in Ref. 2.

As a generalization of Eq. (30) let us consider a wave standing in the x_1 direction but propagating in the x_2 direction, i.e.,

$$\varphi(x_1,x_2)=\sin(\xi x_1)e^{-i\eta x_2} \tag{31a}$$

$$=\frac{1}{2i}[e^{i(\xi x_1-\eta x_2)}-e^{i(-\xi x_1-\eta x_2)}]. \tag{31b}$$

Now we have

$$k^2=\xi^2+\eta^2. \tag{32}$$

For a specific frequency, the parameter k is still obtained from either (26) or (29), but now ξ and η must satisfy (32). Thus if a wave of a specific frequency and wave number η in the propagation direction is being considered, the variation with x_1 is fixed, and follows by obtaining ξ from (32).

Next let us consider axisymmetric motion. Equation (9) then becomes

$$\frac{\partial^2\varphi}{\partial r^2}+\frac{1}{r}\frac{\partial\varphi}{\partial r}+k^2\varphi=0. \tag{33}$$

The solution of (33) to form an outgoing wave compatible with $\exp(i\omega t)$ is

$$\varphi(r)=H_0^{(2)}(kr),\ \text{ where }\ r=(x_1^2+x_2^2)^{1/2}. \tag{34}$$

Equation (1) yields

$$u_1=v(x_3)e^{i\omega t}H_1^{(2)}(kr)\frac{x_1}{r}, \tag{35}$$

$$u_2=v(x_3)e^{i\omega t}H_1^{(2)}(kr)\frac{x_2}{r}. \tag{36}$$

Clearly the resulting displacement in the x_1x_2 plane is in the r direction

$$u_r=v(x_3)e^{i\omega t}H_1^{(2)}(kr). \tag{37}$$

Again the thickness vibrations follow from the analysis of Sec. II.

When the motion is not axially symmetric Eq. (9) becomes in polar coordinates

$$\frac{\partial^2\varphi}{\partial r^2}+\frac{1}{r}\frac{\partial\varphi}{\partial r}+\frac{1}{r^2}\frac{\partial^2\varphi}{\partial\theta^2}+k^2\varphi=0. \tag{38}$$

A solution of Eq. (38) is

$$\varphi(r,\theta)=H_n^{(2)}(kr)\sin(n\theta). \tag{39}$$

It may be checked that for this case we may define radial and circumferential displacements where

$$u_r=\frac{1}{k}v(x_3)e^{i\omega t}\frac{\partial\varphi}{\partial r}, \tag{40}$$

$$u_\theta=\frac{1}{k}v(x_3)e^{i\omega t}\frac{1}{r}\frac{\partial\varphi}{\partial\theta}, \tag{41}$$

while u_3 is given by

$$u_3=w(x_3)e^{i\omega t}\varphi(r,\theta). \tag{42}$$

The approach presented here also lends itself to investigate by an asymptotic approach the propagation of more general waves. As an example, we consider a wave which propagates out radially over a sector spanned by an angle $2\hat{\theta}$, such that the distribution along the wavefronts is represented by a Gaussian. For large value of kr we seek a solution of Eq. (38) of the form

$$\varphi(r,\theta)=A\frac{e^{-i(kr-\pi/4)}}{(kr)^{1/2}}e^{-\theta^2/2\hat{\theta}^2}\left[1+\frac{b_0+b_2\theta^2}{kr}+\frac{c_0+c_2\theta^2}{(kr)^2}+\cdots\right]. \tag{43}$$

This expression will satisfy Eq. (38) with greater accuracy, the more terms are included in the brackets. Substitution of Eq. (43) into (38) yields a sequence of terms of orders $r^{-(n+1)/2}$, where $n=0,1\ldots$. Here we will keep terms up to order $r^{-5/2}$. It can be verified that the terms of orders $r^{-1/2}$ and $r^{-3/2}$ vanish identically. The condition that the terms of order $r^{-5/2}$ should be equal to zero leads to the equation

$$\left(2ib_0+\frac{1}{4}-\frac{1}{\hat{\theta}^2}\right)+\theta^2\left(2ib_2+\frac{1}{\hat{\theta}^4}\right)=0. \tag{44}$$

The requirement that the two terms should vanish separately yields expressions for b_0 and b_2. It follows that $\varphi(r,\theta)$ may be written as

$$\varphi(r,\theta)=A\frac{e^{-i(kr-\pi/4)}}{(kr)^{1/2}}e^{-\theta^2/2\hat{\theta}^2}\left[1+\frac{i}{kr}\left(\frac{1}{8}-\frac{1}{2\hat{\theta}^2}+\frac{\theta^2}{2\hat{\theta}^4}\right)+O(kr)^{-2}\right]. \tag{45}$$

The actual displacements for this case then follow from Eqs. (40)–(42), with $\varphi(r,\theta)$ defined by Eq. (45).

It is of interest to note that for $\hat{\theta}\to\infty$, i.e., for a uniform distribution along the wavefront, Eq. (45) reduces to the first two terms of the asymptotic expansion of $H_0^{(2)}(kr)$, in accordance with Eq. (34).

IV. CONCLUSIONS

This paper has shown that time-harmonic wave motion in an elastic plate can be analyzed on the basis of a carrier wave and superimposed thickness motions. The carrier wave, which can be any solution of a reduced membrane wave equation, describes the propagation along the plate. The superimposed thickness motions have the same general form for any choice of the carrier wave. The relation between the frequency, ω, and a wave number-like quantity, k, is governed by the classical Rayleigh–Lamb frequency equations, but the interpretation of k depends on the choice of the carrier wave. The approach is attractive because it simplifies the consideration of a broad class of Lamb waves.

The feasibility of exciting a localized X-wave pulse from a finite aperture is addressed. Also, the possibility of using a finite-time excitation of a dynamic aperture to generate a finite-energy approximation to an X-wave pulse is explored. The analysis is carried out by using a Gaussian time window to time limit the infinite X-wave initial excitation. Huygens' construction is used to calculate the amplitude of the radiated wave field away from the finite-time source. The decay rate of the peak of the X wave is compared to that of a quasi-monochromatic signal. It is shown that the finite-time X-wave propagates to much farther distances without significant decay. Furthermore, the decay pattern of the radiated X-wave pulse is derived for a source consisting of an array of concentric annular sections. The decay behavior of the radiated pulse is similar to that of an X-wave launched from a finite-time aperture. This confirms the fact that time windowing the infinite energy X-wave excitation is a viable scheme for constructing finite apertures. A discussion of the diffraction limit of the X-wave pulse is also provided. © *1998 Acoustical Society of America.* [S0001-4966(98)00605-5]

INTRODUCTION

In this paper, we address the possibility of exciting localized X-wave pulses from finite apertures. A large class of localized wave (LW) solutions to the scalar wave and Maxwell equations have been studied extensively.[1–12] A number of these pulsed wave solutions are finite-energy variants of the focus wave mode (FWM).[13,14] They are usually derived either as superpositions of infinite-energy FWM pulses,[8–11,14] or by time limiting various FWM-like excitations to construct finite-energy aperture fields.[2–7] Alternatively, such LW pulses can be synthesized as superpositions over Bessel beams with appropriately chosen spectra.[15] Our approach is based mainly on the proven possibility of exciting Bessel beams from infinite apertures.[1–4] It has been shown that a Bessel beam defined initially on an infinite plane (e.g., $z=0$) propagates under the effect of Huygens' operator in the positive z direction.[1–4] Any possible contributions from acausal (negative z-directed) components sum up to zero.

In contradistinction to other solutions excited from infinite apertures, such as plane waves and Bessel beams, the excitation of the FWM pulse does not require infinite power. This is the case because as the generating aperture becomes infinitely large, the intensity of the field exciting it decreases to zero as $(ct)^{-2}$, while the area of the aperture increases as $(ct)^2$. These two effects balance each other and the power of the excitation wave field remains constant. The energy of the generated pulse becomes infinite because the aperture is illuminated for an infinitely long time. Time limiting the excitation wave field results in the generation of finite-energy LW pulses.

Other pulsed solutions exhibiting distinct similarities to FWM-like pulses are the X-wave pulses introduced by Lu and Greenleaf.[16–23] Similarly to the FWM-like pulses, the X-waves have extended ranges of localization and acquire large focus depths in the near field. These properties make these pulsed wave fields ideal for applications involving detection of objects buried at unknown depths, as well as in high-resolution imaging. The use of X-wave pulses in ultrasonic medical imaging has been investigated by Lu and Greenleaf.[16–23] They have shown that X-waves can be generated using ultrasonic transducers consisting of annular arrays of concentric piezoelectric rings excited by independent waveforms applied at different times (Refs. 16, 18; cf. also Ref. 24). Furthermore, Lu and Greenleaf have studied experimentally the improvement in pulse-echo imaging using X-waves.[21] Applying X-waves to tissue-equivalent phantoms and standard test objects, they have shown that resolution of pulse-echo images obtained using X-waves are superior to that obtained with focused Gaussian beams.[21,22] In addition to their large focus depths, X-waves and FWM-like pulses are both wideband wave fields. This property renders them suitable for applications involving parameter characterization using backscattered signals from objects of varying sizes. Along this direction, Donnelly and Power[25] have shown that an acoustical LW pulse backscattered from compressible spheres immersed in water can accurately provide information about the materials as well as the sizes of the spheres.

Similar results can be obtained using X-wave acoustical pulses. As a consequence, these pulsed wave fields can have applications in parameter characterization and nondestructive testing of materials.

The excitation wave field of an X-wave pulse has the form of an annulus whose radius varies with time. The speed of expansion v_{ap} of the aperture field is related to the speed of the pulse center v_p and can be greater than the wave speed c of the medium. The temporal and spatial frequency content of an X-wave pulse will be calculated in order to improve our understanding of the decay pattern of the radiated wavefield. Similarly to the FWM-like solutions, we shall explore the possibility of using a finite-time excitation of an X-wave by imposing a Gaussian time window on the infinite time initial X-wave field. The amplitude of the radiated pulse will be calculated in the near-to-far field range and its decay pattern will be compared to that of a quasi-monochromatic pulse characterized by a specific carrier frequency. It will be shown that the finite-time version of the X-wave propagates without significant decay much further than quasi-monochromatic signals.

I. THE X-WAVE APERTURE

The X-wave solution to the 3-D scalar wave equation may be expressed as

$$\Psi_{XW}(\rho,z,t)=\frac{z_0}{[(z_0\rho)^2+(a_1z_0+i(z-ct\ \coth\beta))^2]^{1/2}}, \tag{1}$$

where a_1 and β are free real parameters and $z_0=1/\sinh\beta$. Note that $c\ \coth\beta$ is the propagation speed of the pulse. To ensure that the field will propagate in the forward direction, we restrict β to be positive. The solution given in Eq. (1) is identical to that derived by Lu and Greenleaf[16,17] if the following substitutions are made: $a_1z_0\rightarrow a_0/\cos\eta$, $z_0\rho\rightarrow\rho\tan\eta$ and $c\ \coth\beta\rightarrow c/\cos\eta$. In the notation used by Lu and Greenleaf,[16] α_0 is a real parameter and η is the axicon angle.

The infinite energy solution given in Eq. (1) was used in Ref. 16 to excite an aperture of a finite size situated at $z=0$ and then to compute the radiated field. In this paper, we construct a finite aperture in a different manner. We use the fact that the X-wave excitation at $z=0$ acquires the form of an annulus whose radial position is time dependent. By time limiting the excitation wave field, we restrict the radius of the time-dependent annulus to be smaller than a finite maximum value. The advantage of such an approach is that the spatio-temporal spectral structure of the radiated pulse becomes very transparent. One can then have a better understanding of the depletion of the spectral content of such a pulse, as well as its behavior as it decays away from its source.[2,4–7] Subsequently, this information can be used to design other localized variants of X waves. First, we shall present some of the aspects of the X-wave excitation given in Eq. (1) without time-limiting it. In Sec. II, the finite-time X-wave will be studied in detail.

Consider the X-wave excitation of a planar aperture positioned at $z=0$, viz.,

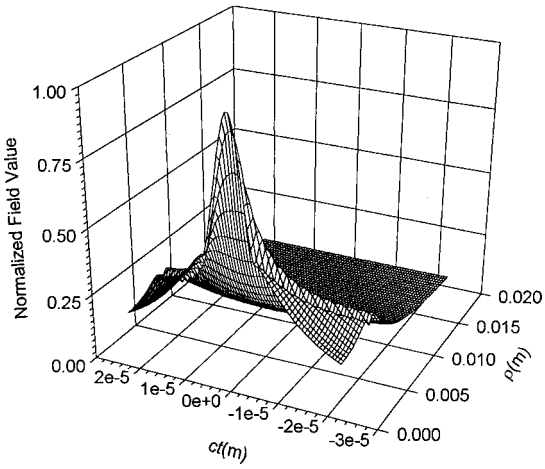

FIG. 1. Surface plot of the real part of the X-wave pulse on the aperture plane ($z=0$) for the parameters $a_1=0.004\ \mathrm{m}^{-1}$, $\beta=7.4$, and $c=1500$ m/s.

$$\Psi_{XW}(\rho,z=0,t)=\frac{1}{[\rho^2+(a_1-iy_0t)^2]^{1/2}}, \tag{2}$$

where $y_0=c\ \cosh\beta$. The surface plot of the real part of the aperture field given in (2) is shown in Fig. 1 for $a_1=0.004$ m and $\beta=7.4$. The wave velocity of the medium is chosen to be $c=1500$ m/s. The intensity of the infinite energy excitation of an X-wave aperture is given as

$$I(\rho,0,t)=\Psi(\rho,0,t)\Psi^*(\rho,0,t)=\frac{1}{[(\rho^2-(y_0t)^2)^2+a_1^4+2a_1^2\rho^2+2a_1^2(y_0t)^2]^{1/2}}. \tag{3}$$

After rearrangement, the denominator in (3) becomes

$$D=[\rho^4+(y_0t)^4-2\rho^2(y_0t)^2+a_1^4+2a_1^2\rho^2+2a_1^2(y_0t)^2]^{1/2}, \tag{4}$$

and for $\rho\gg a_1$

$$D\cong[\rho^4+(y_0t)^4-2\rho^2(y_0t)^2]^{1/2}=[\rho^2-(y_0t)^2]. \tag{5}$$

Expressions (3) and (5) show how the intensity of the illumination wave field varies with time at the various radial positions ρ on the aperture plane. At the centroid of the excitation field ($\rho=0$ and $t=0$) the intensity I is finite and is equal to $1/a_1^2$. For large values of ρ and t, the highest intensity occurs at $\rho=y_0t$. Thus, the illumination of the X-wave aperture acquires the form of an annulus whose radius changes linearly with time. The intensity at $\rho=y_0t$ varies as $1/a_1\sqrt{a_1^2+4\rho^2}$, as it can be deduced from Eq. (3). Since the area of an annulus is proportional to ρ, it follows that the power of the initial X-wave on the aperture (=intensity $\times$area) remains constant as $ct\rightarrow\infty$. The energy of the excitation wave field is infinite because the aperture is illuminated for an infinite time duration.

The time dependence of the radius of the X-wave aperture is found from the real part of Eq. (2). The amplitude of the real part is maximum on the aperture at $\rho=0$ and $t=0$. The highly focused central portion of the aperture has a ra-

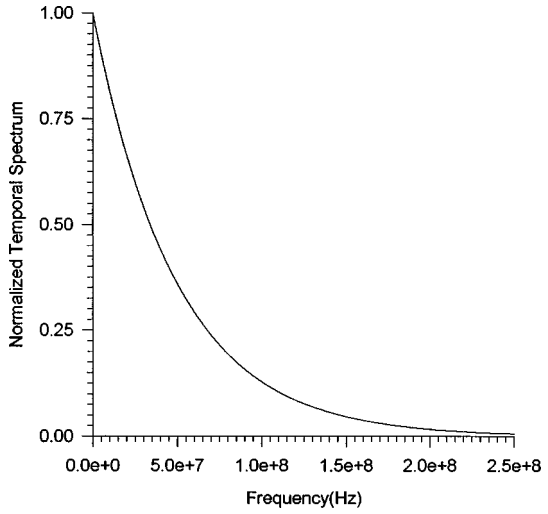

FIG. 2. Temporal frequency content, $\Phi_t(\rho,\omega)$, of the X-wave pulse at $\rho=0$ for the parameters $a_1=0.004\ \mathrm{m}^{-1}$, $\beta=7.4$, and $c=1500$ m/s.

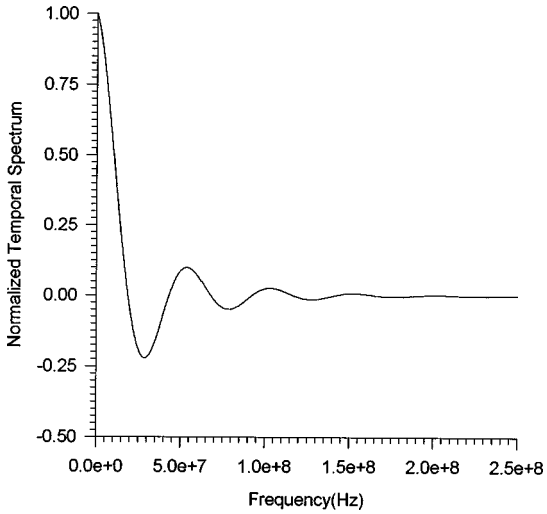

FIG. 3. Temporal frequency content, $\Phi_t(\rho,\omega)$, of the X-wave pulse at $\rho=2.5$ cm for the parameters $a_1=0.004\ \mathrm{m}^{-1}$, $\beta=7.4$, and $c=1500$ m/s.

dius $R_{\min}=R(t=0)=a_1$. As y_0t becomes larger than a_1, the annulus forms at $R(t)=y_0t$ with a width of order $a_1 \ll R(t)$. As a consequence, a good estimate of the radius of the excitation wave field as a function of time is given by

$$R(t)=y_0t+R(0). \tag{6}$$

For $y_0t \gg a_1$, the speed of the expansion of the aperture is given by $v_{\mathrm{ap}}=y_0=c\ \cosh\beta$. The speed of the centroid of the radiated pulse and that of the expansion of the aperture are always greater than c. However, the faster the centroid of the pulse travels, the slower the expansion of the aperture becomes.

II. FREQUENCY SPECTRA OF THE X-WAVE

In order to gain a better understanding of the spectral content of the X-wave pulse, we need to define the temporal and spatial frequency contents of the excitation wave field given in Eq. (2). Both spectra have to be studied because the X-wave illumination is a pulsed wave field exciting different parts of the generating aperture at different times. The spectrum of the initial excitation given in Eq. (2) is deduced from the Fourier inversion

$$\Phi(\chi,\omega)=\int_{-\infty}^{+\infty}dt\int_0^{+\infty}d\rho\ \rho J_0(\chi\rho) \times e^{-i\omega t}\frac{1}{[\rho^2+(a_1-iy_0t)^2]^{1/2}}. \tag{7}$$

The integration over ρ is carried out using (6.554.1) of Ref. 26; as a consequence, we obtain

$$\Phi(\chi,\omega)=\frac{1}{\chi}\int_{-\infty}^{+\infty}dt\ e^{-i\omega t}e^{-\chi(a_1-iy_0t)}. \tag{8}$$

The integration over t yields the following Fourier spectrum:

$$\Phi(\chi,\omega)=\frac{2\pi}{\chi}\,e^{-\chi a_1}\delta(\omega-\chi y_0). \tag{9}$$

One should note that the argument of the Dirac δ function couples the temporal frequency ω to the spatial wave number χ. This is a characteristic attribute of most LW pulses. A similar δ function appears in the Fourier spectrum of the infinite-time FWM excitation of a flat aperture studied in Refs. 1 and 2. For the FWM spectrum we have $\omega \propto \chi^2$, while the X-wave exhibits an $\omega \propto \chi$ coupling. The appearance of a Dirac δ function in the spectrum signifies that the initial wave field illuminates the aperture for an infinite time.

To identify the temporal frequency content of the excitation wave field at various positions on the aperture we define the temporal spectrum as follows:

$$\Phi_t(\rho,\omega)=\int_0^{\infty}d\chi\ \chi J_0(\chi\rho)\Phi(\chi,\omega) =2\pi\int_0^{\infty}d\chi\ \chi J_0(\chi\rho)\,\frac{e^{-\chi a_1}}{\chi}\,\delta(\omega-\chi y_0). \tag{10}$$

The above integration gives

$$\Phi_t(\rho,\omega)=\frac{2\pi}{y_0}\,J_0(\omega\rho/y_0)e^{-\omega a_1/y_0}\mathbf{H_s}(\omega), \tag{11}$$

where $\mathbf{H_s}(\omega)$ is the Heaviside unit-step function. The highest contribution to the temporal frequency content comes from values close to $\omega=0$ rad/s. The maximum frequency is determined from the exponential and is given explicitly as

$$\omega_{\max}=(4y_0/a_1)=(4c\ \cosh\beta/a_1). \tag{12}$$

For the parameters $a_1=0.004$ m, $\beta=7.4$, and $c=1500$ m/s, the maximum frequency becomes $\omega_{\max}=1.227\times10^9$ rad/s or $f_{\max}=195.3$ MHz. This implies that the minimum wavelength in this case is $\lambda_{\min}=1.54$ m. The temporal spectrum given in Eq. (11) is plotted in Fig. 2 for $\rho=0$. The same spectrum is shown in Fig. 3 at $\rho=0.025$ m. The oscillations appearing in the latter case indicate that an integration over ω should yield a smaller amplitude. This is consistent with the field given in Eq. (2), where the amplitude is maximum at $\rho=0$ and decreases as ρ becomes larger.

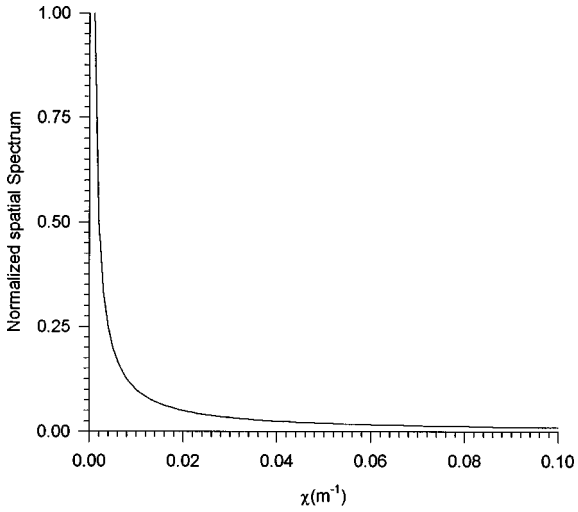

FIG. 4. Spatial frequency content, $\Phi_s(\chi,t)$, of the X-wave pulse at $t=0$ for the parameters $a_1=0.004$ m^{-1}, $\beta=7.4$, and $c=1500$ m/s.

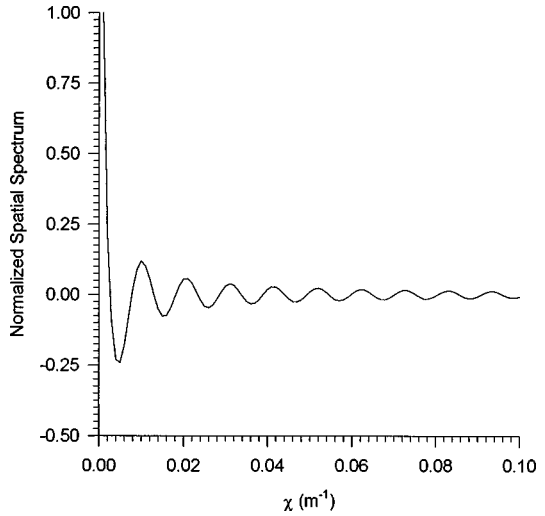

FIG. 5. Spatial frequency content, $\Phi_s(\chi,t)$, of the X-wave pulse at $t=5\times10^{-4}$ s for the parameters $a_1=0.004$ m^{-1}, $\beta=7.4$, and $c=1500$ m/s.

The spatial spectrum, on the other hand, describes the spatial distribution of the source elements on the aperture plane for various times. We define the spatial spectrum as

$$\Phi_s(\chi,t)=\frac{1}{2\pi}\int_0^\infty d\omega\; e^{i\omega t}\,\frac{2\pi}{\chi}\,e^{-\chi a_1}\delta(\omega-\chi y_0) \qquad (13)$$

or

$$\Phi_s(\chi,t)=\frac{1}{\chi}\,e^{-\chi a_1}e^{i\chi y_0 t}. \qquad (14)$$

The spectrum given in Eq. (14) is shown in Figs. 4 and 5 for $t=0$ and $t=5\times10^{-4}$ s, respectively. The oscillations appearing in the latter case indicate that the amplitude of the X wave decreases after the highly focused central portion of the pulse has been launched from the aperture.

III. FINITE TIME EXCITATION

We have shown in Sec. I that the power required to excite an X-wave aperture is always finite and that the excitation energy is infinite simply because the source is excited for an infinite duration of time. As a consequence, the excitation wave field, having the shape of an annulus, is allowed to expand to infinite dimensions. The illumination given in Eq. (2) thus requires an infinite aperture to be realized. Because of the time dependence of the radius of the significant annular contributions to the excitation wave field, we can construct a finite-energy source using one of the following two methods. First we can apply the X-wave excitation given in Eq. (2) to an aperture having a finite radius R and calculate the amplitude of the pulse radiated into the $z>0$ half-space. Lu and Greenleaf[16] used this method to construct a finite X-wave aperture. One should note that at some instant in time we will have $R(t)>R$; subsequently, the excitation wave field inside the finite radius of the aperture becomes very small and can be neglected for all practical purposes. One can then presume that the illumination wave field is turned off at that time instant. Alternatively, we can start by time limiting the infinite excitation given in Eq. (2). This allows the radius of the annular excitation to expand to a finite radius before the initial wave field is turned off. The same approach has been used extensively in defining finite FWM excitations.[2,3,5,6] The latter approach has the advantage of providing a deeper insight into the spectral structure of the radiated LW pulses. Within such a framework, we have been able to demonstrate that the spectral depletion of LW pulses is essentially different from that of the usual quasi-monochromatic pulses.[6] This spectral approach has also helped us in deriving a diffraction-limit formula capable of characterizing the decay behavior of ultra-wideband LW pulses.[7] Because of these advantages, we seek to use this approach to time limit the X-wave excitation (2), thus constructing a finite-energy X-wave aperture. The decay patterns of the radiated fields calculated using both approaches will be compared and the differences between the two methods will be discussed.

A convenient time window to use is the Gaussian $\exp(-t^2/4T^2)$. In this case, the Fourier spectrum of the initial excitation can be calculated as follows:

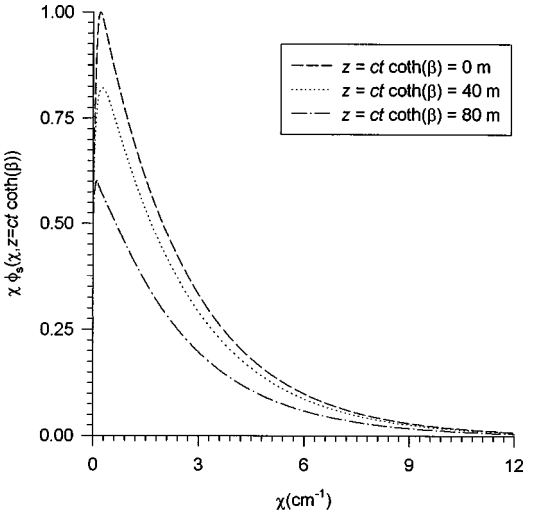

FIG. 6. Normalized spatial spectrum of the finite-time X wave at different distances $z=ct$ coth $\beta=0$, 40, and 80 m for $R_{\max}=0.15$ m.

$$\Phi(\chi,\omega)=\int_{-\infty}^{+\infty}dt\int_{0}^{+\infty}d\rho\ \rho J_0(\chi\rho)$$

$$\times e^{-i\omega t}\frac{e^{-t^2/4T^2}}{[\rho^2+(a_1-iy_0t)^2]^{1/2}}. \tag{15}$$

The integration over ρ is carried out using (6.554.1) of Ref. 26, yielding

$$\Phi(\chi,\omega)=\frac{e^{-\chi a_1}}{\chi}\int_{-\infty}^{+\infty}dt\ e^{-it(\omega-\chi y_0)}e^{-t^2/4T^2} \tag{16}$$

or

$$\Phi(\chi,\omega)=\frac{2\pi}{\chi}\,e^{-\chi a_1}\hat{\delta}(\omega-\chi y_0), \tag{17a}$$

where $\hat{\delta}(\omega-\chi y_0)$ is a Gaussian function given explicitly by

$$\hat{\delta}(\omega-\chi y_0)=\frac{T}{\sqrt{\pi}}\,e^{-T^2(\omega-\chi y_0)^2}. \tag{17b}$$

Note that the parameter T characterizes the cutoff time of the illumination of the aperture. As a consequence, it determines the maximum radius of the aperture, i.e., the maximum radius of the annular illumination before the field is cutoff. Even though for a Gaussian window we cannot define a precise cutoff time, it is convenient to use such a function because its Fourier transform is a smooth Gaussian. A rectangular time window provides a definite cutoff time, but its Fourier transform is highly oscillatory and more spread out than the Gaussian ω-window given in Eq. (17b). As a consequence, the Gaussian time window is easier to handle numerically, while its e^{-2} point provides a reasonable estimate of the cutoff time. The use of other time windows and their effect on the decay patterns of FWM-like pulses have been investigated.[5,7] We have shown that the decay of the centroid of LW pulses can be altered significantly in the near-to-far-field range by changing the time sequence of the initial excitation. We believe that similar results can be obtained for finite-time X-wave apertures. For large T values, the Gaussian ω window in (17b) reduces to a narrow distribution centered around $\omega\sim\chi y_0=\chi c\cosh\beta$. The spectral width of such a window is chosen to be smaller than $\omega_{\max}$. Therefore, the temporal spectrum can be viewed as a juxtaposition of these windows centered around all the significant χ components determined by the spatial spectrum given in Eq. (14).

Using Huygen's formula,[27] the field radiated into the $z>0$ half-space can be expressed as[1–3]

$$\Psi(\rho,z,t)=\int_{0}^{+\infty}d\chi\ \chi J_0(\chi\rho)$$

$$\times\int_{0}^{+\infty}d\omega\ \Phi(\chi,\omega)e^{i\omega t}e^{-i\sqrt{(\omega/c)^2-\chi^2}z}. \tag{18}$$

Substituting the spectrum given in Eq. (17a), the amplitude of the radiated field may be expressed as a superposition over the spatial spectral content of the X-wave pulse; specifically,

$$u(\rho,z,t)=\Re e\{\Psi(\rho,z,t)\}$$

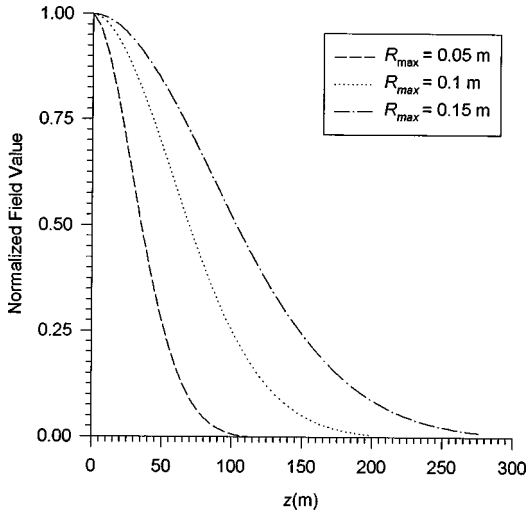

FIG. 7. Decay pattern of the centroid of the finite time X wave for different values of the maximum aperture radius.

$$=\int_{0}^{+\infty}d\chi\ \chi J_0(\chi\rho)\hat{\Phi}_s(\chi,z,t). \tag{19a}$$

Here, $\hat{\Phi}_s(\chi,z,t)$ is the spatial spectral content at a distance z and time t. It is given explicitly by

$$\hat{\Phi}_s(\chi,z,t)=\int_{0}^{+\infty}d\omega\ \frac{2\pi}{\chi}\,e^{-\chi a_1}\hat{\delta}(\omega-\chi y_0)$$

$$\times\cos(\sqrt{(\omega/c)^2-\chi^2}z-\omega t). \tag{19b}$$

For the field generated from an infinite aperture ($T\to\infty$), the Gaussian in Eq. (19) becomes a Dirac δ function forcing ω to equal χy_0. In this limit, the argument of the sinusoidal term becomes equal to $\chi\sinh\beta(z-ct\coth\beta)$, leading to the diffraction-free X wave moving with speed $v_p\equiv c\coth\beta$. For the finite-time excitation, the fine spectral balance that yields the exact $(z-ct\coth\beta)$ functional dependence is upset. Instead, as the pulse travels away from the source plane, the sinusoidal term progressively introduces oscillations into the Gaussian windows $\hat{\delta}(\omega-\chi y_0)$ centered around all the significant spectral χ components.[3,5–7] Since these oscillations increase with distance, the integration over ω yields smaller spectral contributions at the different χ frequencies. As a consequence, the integration over χ in Eq. (19a) gives a field amplitude that decreases with distance. The depletion of the spatial spectral components of the X wave is depicted in Fig. 6, where we have plotted the spatial spectrum given in Eq. (19b) for $cT=91.69$ μm and at $z=ct\coth\beta=0$, 40, and 80 m. This figure shows that the spatial spectral components acquire smaller amplitudes as the pulse travels away from the aperture. Consequently, the integration over χ in Eq. (19) yields the expected decay pattern of the centroid of the radiated pulse. The decay of the peak ($\rho=0$ and $z=ct\coth\beta$) of the X wave, normalized with respect to the peak amplitude at the aperture, is shown in Fig. 7. The curves are plotted for the cutoff times $cT=30.56$, 61.13, and 91.69 μm. Such cutoff times correspond to time-dependent apertures acquiring maximum radii $R_{\max}=R(2cT)=5$, 10, and 15 cm.

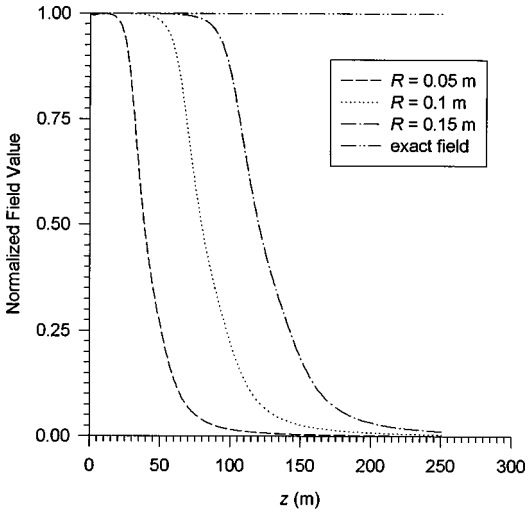

FIG. 8. Decay pattern of the centroid of the X-wave pulse generated by an array of concentric annular sections for different radii.

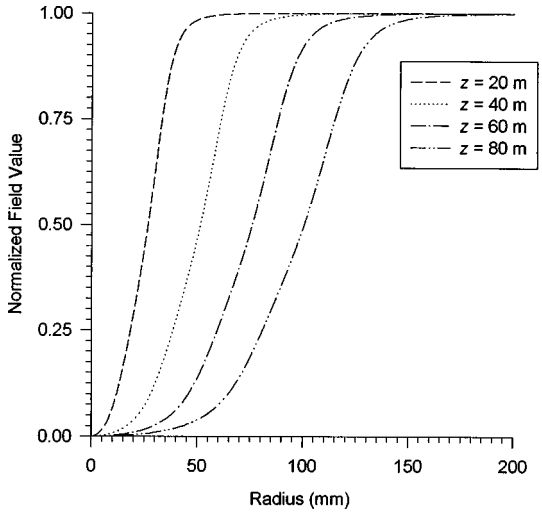

FIG. 9. Contribution of the different annular sections to the field amplitudes at various distances.

To verify the validity of the estimated maximum radii, we deduce the decay pattern of the peak of the X-wave using a finite-radius aperture. For such a construction the source is assumed to consist of a large number of concentric annular array elements. The amplitude of the initial excitation is specified on each distinct element and the radiated field along the axis of propagation ($\rho=0$) is evaluated using the following discrete version of Huygens' formula:

$$u_H(0,z,t)=-\sum_{n=1}^{N}\frac{A_n}{4\pi R_n}\left\{[\partial_{z'}u]-[\partial_{ct'}u]\frac{z-z_0}{R_n}-[u]\frac{z-z_0}{R_n^2}\right\}. \tag{20}$$

Here, A_n is the area of the annular section labeled n, N is the total number of annular sections, $\rho_n'=n\Delta\rho'$ specifies the radial position of the annular section labeled n, and z is the distance at which the field of the radiated pulse is reconstructed. The distance from the source point to the observation point is denoted by $R_n=\sqrt{(n\Delta\rho')^2+(z-z_0)^2}$ for $\rho=0$. The square brackets in Eq. (20) indicate that the enclosed quantities are evaluated at the retarded time $t'=t-(R_n/c)$. The main purpose of the numerical reconstruction procedure embodied in Eq. (20) is to focus on the possibility of using space–time sources on the aperture plane $z=0$ in order to generate LW pulses in the region $z\geqslant 0$. A second objective is to gain more physical insight into the propagation characteristics of the reconstructed pulses.

For annular elements of width $\Delta\rho'=1$ mm, we can construct apertures having radii $R=5$, 10, and 15 cm by using $N=50$, 100, and 150 sections, respectively. The decay patterns of the LW pulses radiated by these three apertures are plotted in Fig. 8 for the values of a_1 and β used earlier. A comparison between Figs. 7 and 8 shows that the ranges of the two decay patterns are similar. For the finite-time dynamic apertures, the centroids of the radiated X waves start decaying at close ranges and their rolloff is smoother than that of X waves generated from discrete circular arrays. The centroids of the X-wave pulses generated by discrete circular arrays exhibit a very slow decay in the near field. The decay in the far field, however, is more abrupt than that corresponding to the finite-time pulses. The smoother decay is attributed to the continuous turnoff of the initial finite-time excitation due to the application of the Gaussian time window. The excitation wave field, therefore, acquires smaller amplitudes at larger radial positions as the illumination of the aperture approaches its turn off point. We would like to emphasize, however, that the finite-time aperture performance is very close to that of a physically bounded source even though the former has no physical edge containing the illumination wave field. This is a crucial point allowing us to use finite-time dynamic sources in our analysis instead of physical apertures. The former lend themselves nicely to the advocated spectral depletion approach. In Fig. 9 we display a set of curves showing how the amplitude of the peak of the propagating X wave, at a specific distance, consists of contributions from the illumination of a finite domain of the aperture. This information can be used to determine the size of the aperture needed to radiate a decay-free pulse up to a specific distance z (cf. Ref. 20 for an experimental procedure along this path).

Finally, we provide in Figs. 10 and 11 a comparison between the shapes of the longitudinal envelopes of the propagating X waves at $z=100$. In Fig. 10 we display the time history of the X-wave pulse launched from a finite-time aperture and compare it to the initial pulse excitation at the aperture. On the other hand, in Fig. 11 we compare an X-wave pulse generated by a discrete circular array to the exact wave solution. The oscillations appearing in the front part of the radiated X wave are due to the discretization of the excitation wave field. Otherwise, the time histories of the pulses generated using the two suggested frameworks are almost identical to the exact wave solution.

IV. DIFFRACTION LENGTH ANALYSIS

For a quasi-monochromatic CW signal, the diffraction length is determined in terms of the Rayleigh distance $\pi R^2/\lambda_c$, where R is the radius of the source and λ_c is the

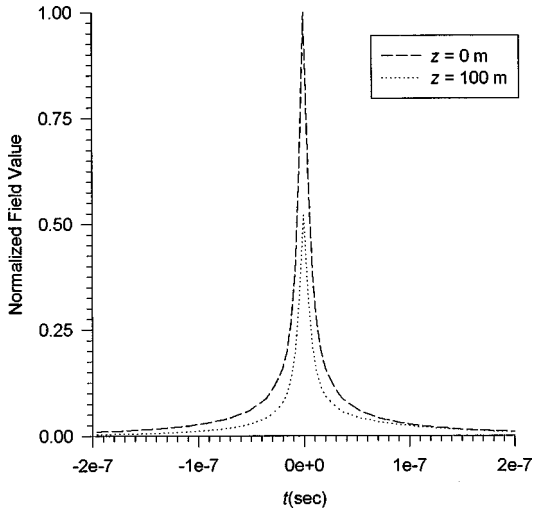

FIG. 10. The time history of the finite-time X-wave pulse at $z=0$, 100 m due to an aperture having radius $R_{\max}=0.15$ m.

wavelength of the carrier wave field. In contradistinction, any attempt to define the diffraction length of a LW pulse generated by a dynamic aperture antenna is more involved. The difficulty can be attributed to the ultra-wideband temporal bandwidth of the LW pulse, as well as the fact that the aperture is characterized by a time-varying radius. One of the earlier attempts to define a diffraction length for LW pulses generated by dynamic aperture antennas was undertaken by Hafizi and Sprangle.[28] Their diffraction length is given as $Z_{\mathrm{HS}}=(2\pi w_0 R_{\max})/\lambda_{\min}$, where w_0 is the beam waist, $R_{\max}$ is the maximum dimension of the aperture or antenna, and $\lambda_{\min}$ is the minimum wavelength. Specific applications of this formula to FWM-like LWs can be found in Ref. 7.

The Hafizi–Sprangle diffraction length gives a good *broad sense* estimate of the behavior of LW wave pulses as they propagate away from their generating aperture planes. However, it does not include special *local features* arising from different types of dynamic aperture excitations. In this section, the decay pattern of an X-wave pulse will be characterized using a diffraction length criterion that has been proposed recently.[7] Such a definition of the diffraction limit is based on the spatial depletion of LW pulses generated by ''finite-time'' dynamic apertures. One can argue that a pulse enters its far-field region when most of the initially significant spatial spectral components are depleted. These spectral components obviously characterize the spatial distribution of the source elements on the aperture. Hence, the loss of information through the depletion of these components signals the beginning of the far-field region. For ultra-wideband pulses one is faced with the ambiguity of determining what are the initially ''significant'' spatial spectral components. Should one use a 3-dB point as the highest ''significant'' frequency, or would a $(1/e^2)$ or $(1/e^4)$ point be a more suitable choice? This ambiguity reflects the fact that there is no sharp limit between the near- and far-field regions of ultra-wideband pulses. A definition of a diffraction limit can only be used to compare the relative performance of different LW pulses. The crucial issue here is to be consistent in our use of definitions of the radii and the bandwidths of the excitation wave fields. Since any of the above definitions can be used to specify the highest ''significant'' spatial spectral components, we shall use a generic cutoff frequency denoted by χ_d. In this case, we may refer to the following expression for the diffraction length of LW pulses [cf. Eq. (12) in Ref. 7]:

$$Z_d=\pi\left(\frac{4}{\eta(\omega/c)}\right)\left(\frac{\omega_0(\chi_d)}{\chi_d c}\right)^2 = \mu(\chi_d)R_{\max}R_{\min}(\omega_{\max}/c). \tag{21}$$

Here, $\eta(\omega/c)$ is the effective width of the spectral ω-window given in Eq. (17b) and $\omega_0(\chi_d)$ is the ω value of the center of $\hat{\delta}(\omega-\chi y_0)$ at $\chi=\chi_d$. The quantity $\mu(\chi_d)$ is a numerical factor of $O(1)$ that depends on the specific choice of χ_d, in general. The diffraction length in Eq. (21) is expressed in terms of spectral quantities depicting the excitation wave field,[7] or as a function of the dimensions of the utilized dynamic aperture and the bandwidth of its source elements.[2,3] The two expressions may be deduced from each other if one recalls that $R_{\max}=R(2T)$, $R_{\min}=a_1$, and $(\omega_{\max}/c)=(4\cosh\beta)/a_1$. Furthermore, one can choose the ''significant'' spatial components as those exhibiting amplitudes larger than $(1/e^4)$ of the maximum of the spatial spectrum. As a consequence, explicit expressions for the diffraction length given in Eq. (21) can be derived. For the X-wave pulse we define $\chi_d=4/a_1$, $\eta(\omega/c)=4/cT$, and $\omega_0(\chi_d)=c\chi_d\cosh\beta$. In this case, Eq. (21) reduces to

$$Z_d=\pi cT(\cosh\beta)^2, \tag{22}$$

which is independent of the choice of χ_d. This means that the source of the X-wave radiated field has the unique property of yielding a diffraction length that does not depend on the particular criterion chosen to define χ_d. In contrast, the diffraction length of the time-limited FWM pulse is proportional to χ_d^2.[7] Hence, X waves can serve to test the relative performance of other LW pulses of comparable source dimensions and temporal spectral bandwidths. For the parameter values used in Fig. 7, Eq. (22) gives $Z_d=64.25$, 128.5,

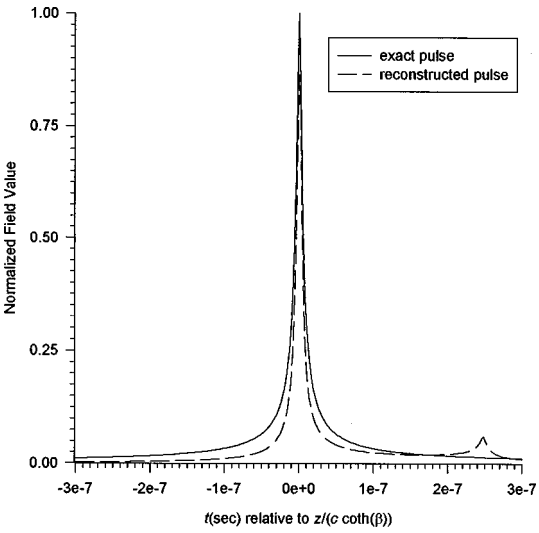

FIG. 11. The time history of the X-wave pulse reconstructed at $z=100$ m from a circular array and compared to the exact solution at the same distance.

and 192.75 m. Since the maximum dynamic radius is given by $R_{\max}=2cT\cosh\beta$, the diffraction limit given in Eq. (22) may be rewritten as

$$Z_d=(\pi/2)R_{\max}\cosh\beta=(\pi/4)D\cosh\beta, \tag{23}$$

where D is the diameter of the source. Apart from a small difference in the numerical constant multiplying the $D\cosh\beta$ dependence of the diffraction limit, our result is the same as the one derived by Lu and Greenleaf.[16–18] The difference in the numerical constant is due to the different criteria used to define the quantities involved in the two approaches.

The expression given in Eq. (21) illustrates the kind of performance enhancement that LW pulses exhibit when compared to quasi-monochromatic Gaussian wave fields. Consider, for example, the case of a quasi-monochromatic beam of waist $w_0=2R_{\min}$ equal to that of the highly focused central portion of the X wave. For a static aperture having $D\gg w_0$, the associated diffraction length is defined as $Z_w=\pi w_0^2/4\lambda_{\min}$. Using $(\omega_{\max}/c)=2\pi/\lambda_{\min}$, the enhancement in the diffraction range of the X wave over an equivalent quasi-monochromatic beam, of the same waist, is given by the ratio $(Z_d/Z_w)\propto(R_{\max}/R_{\min})$. For the parameters used in this paper, the enhancement in the depth of propagation of the X wave over a comparable quasi-monochromatic signal is of order $O(10)\rightarrow O(40)$. This demonstrates that LW pulses become advantageous when narrow pulsed wave fields are required to have extended focused ranges. A dynamic aperture illuminated by a wave field having a time-dependent radius provides an efficient scheme to generate narrow LW pulses from much larger sources. Finally, one should note that the diffraction limit given in Eq. (22) is independent of the parameter a_1. This indicates that the diffraction length can be kept constant for pulses having different temporal bandwidths. As such, an X-wave pulse can travel to the same diffraction-free range even if we use an excitation wave field having a smaller bandwidth. This is true; however, the radius of the highly focused central portion of the radiated field is equal to $R_{\min}=a_1$ and $\omega_{\max}\propto 1/a_1$. Hence, a smaller bandwidth corresponds to a larger focus radius $R_{\min}$ for which the enhancement ratio $(R_{\max}/R_{\min})$ acquires smaller values. Consequently, the use of smaller bandwidths reduces the enhancement achieved over quasi-monochromatic signals.

V. CONCLUDING REMARKS

In this paper, we have demonstrated that an X wave exhibits all the features characterizing other LW pulses. It has been shown that it is characterized by the spatio-temporal spectral coupling that distinguishes LW pulses from other pulsed wave fields.[6,7] A direct consequence of such a coupling is the unique depletion of the spectral components and, hence, the exhibited slow decay pattern of such LW pulses in the near-field range. The main difference between an X wave and other FWM-like wave fields is the functional dependence of the coupling between the temporal and spatial spectral components. Whereas the FWM displays an $\omega\propto\chi^2$ coupling, the X wave has an $\omega\propto\chi$ coupling. Once the similarity between an X wave and other LW pulses is recognized, we can bring together the apparently disparate results of the two research areas into a single framework.

It has also been shown that an X wave may be generated from finite-time dynamic apertures analogous to those proposed as sources for launching FWM-like pulses. One should note that such sources acquire finite sizes by turning on/off their illumination wave fields at finite times. They exhibit most of the essential features of physical apertures and at the same time are much easier to handle mathematically. The illumination of the dynamic source of an X wave acquires the shape of an annulus whose size varies with time. This should be contrasted with the excitation of the FWM aperture that has the shape of a disc having a time-dependent radius. A finite-time dynamic aperture does not have a physical edge bounding its illumination wave field. This might shed some doubt on the validity of the results deduced using such a construction. To examine the origin of any possible discrepancies, we have studied the decay properties of an X wave generated from a finite radius source consisting of discrete concentric annular sections. The resulting decay patterns of the X wave have been shown to compare nicely with those derived using a finite-time dynamic source.

Similarly to other LW pulses generated from dynamic apertures, the spectral depletion of an X wave differs from conventional quasi-monochromatic pulsed wave fields. The decay in the spectral components contributing to the amplitude of the centroid of the propagating pulse results from the increasing oscillations introduced into the spectral ω-windows with the distance z. One can, thus, utilize the knowledge gained from earlier investigations[2–7] to derive the diffraction limit characterizing an X wave. Our spectral depletion approach has established that an X wave has the attractive property that its diffraction length does not depend on the particular choice of χ_d. As a consequence, the decay behavior of any other LW pulses can be compared to that of an X wave.[29] Both fields should have equal aperture sizes, with illumination wave fields exhibiting comparable bandwidths. Furthermore, the two radiated fields should attain equal focused waists. Finally, it has been shown that the enhancement in the focused depth of an X-wave dynamic source, in comparison to a static aperture used to generate quasi-monochromatic signals of a comparable waist is proportional to the ratio $(R_{\max}/R_{\min})$.

Wave propagation in a wavy fiber–epoxy composite material: Theory and experiment

Kwang Yul Kim,[a] Wei Zou, and Wolfgang Sachse
Department of Theoretical and Applied Mechanics, Thurston Hall, Cornell University, Ithaca, New York 14853-1503

(Received 21 July 1997; accepted for publication 5 February 1998)

In this paper analytic formulas are developed for the ray path and travel time of a ray propagating in a wavy fiber–epoxy composite material and calculate them for rays initiating at various points with wave normals of differing directions. The arrival times observed by using various combinations of pointlike sources and pointlike detectors are found in good agreement with those predicted by the theory of geometrical acoustics. © *1998 Acoustical Society of America.* [S0001-4966(98)04805-X]

INTRODUCTION

Fiber-waviness is introduced in composite materials during manufacturing processes because of uneven curing and shrinkage of resin, and it has detrimental effects on mechanical properties, such as stiffness reduction and degradation of compressive strength.[1,2] Layer waviness also occurs in thick crossply or multidirectional laminates due to the lamination residual stresses built up during curing process. Therefore, it is important to detect and characterize fiber-waviness during and after fabrication of a fiber-reinforced composite, and nondestructive ultrasonic evaluation of the wavy composite remains a challenging problem.

There have been the investigations on the unidirectional wavy composite by means of ultrasonic waves. Wooh and Daniel[3] used a ray tracing method in an attempt to understand the waveforms detected by the piezoelectric transducers of finite size attached on one side of the flat surfaces. The waveforms were launched by the piezoelectric transducers of finite size on the same or opposite side of the flat surfaces. Using the finite difference method, McIntyre *et al.*[4] theoretically investigated the harmonic wave propagation with wave normal directed in the mean fiber-direction, and found the variation of amplitude in tune with the energy conservation principle implied by the transport equation.

In this paper we apply the results of geometrical acoustics to investigate ray paths and travel times along the various ray paths of ultrasonic waves propagating in a wavy graphite fiber–epoxy composite. Even though experimental verification of the theoretical ray paths is difficult to achieve because of the opaque composite specimen, it will be demonstrated that the observed travel times of the quasilongitudinal (QL) and shear horizontally (SH) polarized pure transverse (PT) modes propagating along the different ray paths are found in good agreement with those predicted by the theory of geometrical acoustics.

I. THEORY

A schematic diagram of a wavy composite specimen is drawn in Fig. 1, where the reinforcing fibers are running in a wavy pattern in the xy plane with their mean direction pointing along the x axis. We specify the waviness of the fiber-reinforced epoxy composite by the following sine wave function

$$y_f = A_f \sin(2\pi x/L_f), \tag{1}$$

where y_f is the fiber height in the y direction, A_f is the amplitude of fiber-waviness, and L_f is the periodical length of waviness. A local fiber-direction is specified by the angle β_f the x axis makes with the fiber. Here, $\tan\beta_f$ is given by

$$\tan\beta_f = \frac{dy_f}{dx} = \frac{2\pi A_f}{L_f}\cos\frac{2\pi x}{L_f}. \tag{2}$$

The imbedded wavy fibers notwithstanding, the fabricated wavy composite specimens are observed to have the uniform density ρ throughout the specimens, and we assume that the density of the wavy composite is constant. The wavy composite is also uniform along the z axis normal to the xy plane on which the waviness of the fibers is confined. The composite is also uniform along the y direction. As a result, both anisotropy and heterogeneity of the wavy composite is a function of one variable x only. Therefore, the wave normals, which are initially directed in the xy plane, are confined on the xy plane and refraction of the wave normals is governed by Snell's law during the propagation of rays in the xy plane. A composite material which has the fibers running straight in the x direction ideally has transversely isotropic symmetry about the x axis. However, because of a less-than-ideal fabrication procedure, it is better characterized as possessing weak orthorhombic symmetry with proximity to transverse isotropy. Let the x, y, and z directions be represented by indices 1, 2, and 3, respectively. Then, the composite specimen with straight fibers aligned in the x direction is characterized by nine elastic constants: C_{11}, C_{22}, C_{33}, C_{12}, C_{13}, C_{23}, C_{44}, C_{55}, and C_{66}.

Consider a small element of the wavy composite at a typical local point (x,y_0,z_0). The small local element is considered to have orthorhombic symmetry whose x and y symmetry axes are rotated about the third symmetry axis z_0z by the angle β_f from the x axis. Let's specify a wave normal **n** of the wave propagating in the xy plane by an angle θ mea-

[a]Electronic mail: kykim@msc.cornell.edu

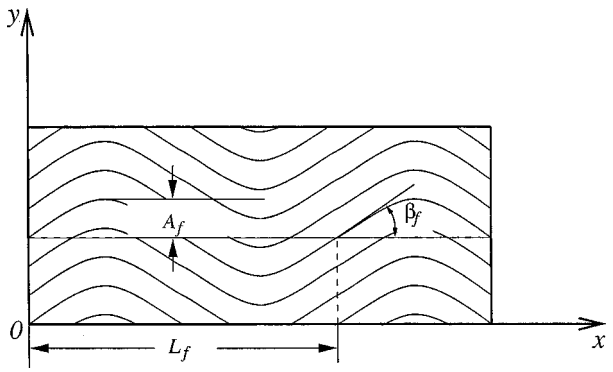

FIG. 1. Schematics of a wavy fiber composite specimen.

sured from the x axis. Then, the angle α which the wave normal **n** makes from the local fiber direction is

$$\alpha(x,\theta)=\theta-\beta_f=\theta-\tan^{-1}\left(\frac{2\pi A_f}{L_f}\cos\frac{2\pi x}{L_f}\right). \tag{3}$$

We invoke Snell's law and the formulas for the arrival time τ and ray path of a wave initiating from the point (x_0,y_0,z_0) and arriving at the point (x_1,y_1,z_0). Referring to the results established in the geometrical acoustics of inhomogeneous anisotropic media,[5,6] they can be written as

$$h=\frac{\sin\theta_0}{v_0}=\frac{\sin\theta}{v}=\text{constant}, \tag{4}$$

$$\tau=\int_{x_0}^{x_1}\frac{dx}{v\cos\theta-v'\sin\theta}, \tag{5}$$

$$y_1=y_0+\int_{x_0}^{x_1}\frac{v\sin\theta+v'\cos\theta}{v\cos\theta-v'\sin\theta}\,dx, \tag{6}$$

where $v(x,\theta)$ is the phase velocity and $v'=\partial v/\partial\theta$.

For the waves propagating in the xy plane, the eikonal and phase velocity equations are factored into three modes whose vibration directions are mutually perpendicular to each other: shear horizontally (SH) polarized pure transverse (PT) mode vibrating in the z direction, quasilongitudinal (QL) mode and quasitransverse (QT) mode. The QL and QT modes are both polarized in the xy plane. The SH polarized PT mode is uncoupled from the QL and QT modes. We first deal with the PT mode.

A. Pure transverse mode

The phase velocity v of the PT mode is given by[7]

$$\rho v^2=C_{44}\sin^2(\theta-\beta_f)+C_{55}\cos^2(\theta-\beta_f), \tag{7}$$

which we differentiate with respect to θ to obtain

$$\rho v v'=(C_{44}-C_{55})\sin(\theta-\beta_f)\cos(\theta-\beta_f). \tag{8}$$

Using Snell's law Eq. (4), Eq. (7) is expressed as

$$\begin{aligned}\rho\sin^2\theta&=h^2[C_{44}\sin^2(\theta-\beta_f)+C_{44}\cos^2(\theta-\beta_f)]\\&=h^2[(C_{44}-C_{55})\sin^2(\theta-\beta_f)+C_{55}],\end{aligned} \tag{9}$$

where $h=\sin\theta/v$ is the constant in Snell's law. Consider a case in which rays are initiating from a broadband source in virtually every direction inside the specimen. We choose an arbitrary ray whose wave normal at the source is directed at an angle θ_0 from the x direction. The fiber direction β_f at the source is obtained from Eq. (2). Then, we calculate the initial velocity v_0 corresponding to the wave normal θ_0 via Eq. (7) to determine the Snell's law constant h from Eq. (4). For a given x, the fiber angle β_f can be calculated via Eq. (2) and from Eq. (9), one obtains the solutions for θ, $\sin\theta$, and $\cos\theta$. Then the values of v and v' are obtained from Eqs. (7) and (8). Thus, one can calculate the values of $\sin\theta$, $\cos\theta$, and v and v' at many different values of x to determine the arrival time τ and ray path through Eqs. (5) and (6). One can repeat this procedure for rays with various initial wave normal directions.

For the special case of the initial wave normal **n** pointing in the x direction, $h=\sin\theta/v=0$, i.e., $\theta=0$ all along the ray path, and the arrival time and ray path integrals are simplified to

$$\tau=\rho\int_{x_0}^{x}\frac{dx}{[(C_{44}-C_{55})\sin^2\beta_f+C_{55}]^{1/2}}, \tag{10}$$

$$\begin{aligned}y-y_0&=\int_{x_0}^{x}\frac{(C_{55}-C_{44})\sin\beta_f\cos\beta_f}{C_{44}\sin^2\beta_f+C_{55}\cos^2\beta_f}dx\\&=\frac{C_{55}-C_{44}}{C_{44}}\frac{L_f^2}{4\pi^2A_f\,p}\\&\quad\times\tanh^{-1}\frac{p[\sin(2\pi x/L_f)-\sin(2\pi x_0/L_f)]}{p^2-\sin(2\pi x_0/L_f)\sin(2\pi x/L_f)},\end{aligned} \tag{11}$$

where

$$p=\sqrt{1+\frac{L_f^2C_{55}}{4\pi^2A_f^2C_{44}}}. \tag{12}$$

Equation (11) indicates that the ray with initial wave normal **n** directed along the x-axis follows a path with the same periodic length that the wavy fiber has.

B. Quasilongitudinal and quasitransverse modes

For simplicity of notation we introduce the following identities

$$C_{11\pm}=C_{11}\pm C_{66},\quad C_{22\pm}=C_{22}\pm C_{66},\quad C_{12\pm}=C_{12}\pm C_{66}. \tag{13}$$

The phase velocities of the QL and QT modes are given by[7]

$$2\rho\,v^2=C_{11+}\cos^2\alpha+C_{22+}\sin^2\alpha\pm\sqrt{D}, \tag{14}$$

where α is defined in Eq. (3), the upper and lower signs in $\pm$ in front of $\sqrt{D}$ correspond to the QL and QT modes, respectively, and

$$D=(C_{11-}\cos^2\alpha-C_{22-}\sin^2\alpha)^2+4C_{12+}^2\sin^2\alpha\cos^2\alpha. \tag{15}$$

Differentiating Eq. (14) with respect to θ, one obtains

$$\frac{v'}{v}=\frac{1}{4\rho v^2}\Bigg\{(C_{22+}-C_{11+})\sin 2\alpha\pm\frac{1}{\sqrt{D}}\times[(C_{22-}\sin^2\alpha-C_{11-}\cos^2\alpha)(C_{11-}+C_{22-})\times\sin 2\alpha+C_{12+}^2\sin 4\alpha]^{1/2}\Bigg\}. \tag{16}$$

Substitution of Snell's law Eq. (4) into Eq. (14) yields

$$2\rho\ \sin^2\ \theta=h^2[C_{11+}\cos^2(\theta-\beta_f)+C_{22+}\sin^2(\theta-\beta_f)\pm\sqrt{D}]. \tag{17}$$

Determination of the arrival time and ray path of a wave with initial wave normal θ_0 at the source can be carried out in a similar way to that described in the case of the PT mode. In the special case of $h=\sin\theta=0$, the evaluation of the integrals for the arrival time and ray path is also simplified as in the PT mode.

II. EXPERIMENTAL METHOD

Two kinds of specimens are fabricated using graphite-fiber prepregs: one is a unidirectional, straight graphite fiber–epoxy composite and the other is a wavy graphite fiber–epoxy specimen with sine wave period 40 mm and wavy amplitude 2 mm. Both specimens have the same density 1524 kg/m^3. The straight fiber direction in the unidirectional composite and the mean fiber direction in the wavy composite are taken as the x direction. The wavy fiber plane is denoted as the xy plane.

In order to fabricate the wavy composite, the top surface of an aluminum plate, which is 20 cm wide, 60 cm long, and 12.7 mm thick, is first machined in the desired sine wave pattern (2 mm amplitude and 40 mm period) on a numerically controlled machine. Then, the machined aluminum plate is split into two identical pieces, which are next aligned against each other with a gap, where many layers of graphite–fiber epoxy prepregs are sandwiched and cured.

The unidirectional composite, which is weakly orthorhombic, is prepared to determine its nine elastic constants from measurements of the travel times of ultrasonic waves propagating through the specimen. A cube of the unidirectional composite which has been cut perpendicular to the three symmetry axes is mechanically polished. The PT waves are launched from one side of the specimen and they are detected on the opposite side, while the PL (pure longitudinal) waves are generated and detected by the same transducer. Denoting the propagation and polarization directions of the phase velocity v of an ultrasonic wave by subscript indices i and j, respectively, the pure index elastic constants or the diagonal elements of C_{ij} matrix are expressed as

$$\rho[v_{ij}^2]=\begin{bmatrix}C_{11} & C_{66} & C_{55}\\ C_{66} & C_{22} & C_{44}\\ C_{55} & C_{44} & C_{33}\end{bmatrix}. \tag{18}$$

Thus, all six pure index elastic constants can be determined via Eq. (18) from the phase velocity measurements along the three symmetry directions. Given the values of the pure-index elastic constants, the mixed index elastic constant C_{ij} $(i\neq j)$ can be obtained from the wave speed measurements of the QL mode propagating in an oblique direction in the symmetry plane. For this purpose two opposite faces of three additional specimens cut from the large unidirectional composite are polished with one in 45° to the x axis and normal to the xy plane, another in 45° to the y axis and normal to the yz plane, and the other in 45° to the z axis and normal to the zx plane. From the measurement of the QL phase velocity propagating in 45° direction to the x axis in the xy plane, one uses Eq. (14) by setting $\beta_f=0$ and $\theta=45°$ to obtain the mixed index elastic constant C_{12}. One proceeds similarly for determination of C_{13} and C_{23}, using the other two obliquely cut specimens. The nine elastic constants of the orthorhombic unidirectional composite can also be determined from the group velocity measurements and this is described in detail elsewhere.[8,9]

One of the fabricated wavy composites has two opposite sides machined flat, which are normal to the wavy fiber plane and parallel to the x axis. It has next been polished with thickness 15.93 mm between the flat surfaces. Then another sample is prepared with two flat opposite faces normal to the x axis with thickness 30 mm between them. A schematic of a typical sample is shown in Fig. 1. First, a 28 μm thick, piezoelectric polyvinylidene fluoride (PVDF) film is laid on the top surface of the flat wavy composite and a glass capillary of size 0.10 mm inside diameter and 0.17 mm outside diameter is mounted on the PVDF film. Pointlike sources of the QL and QT modes are generated by breaking the glass capillary with a razor blade at various x positions on the top surface. The generated elastic waves propagate in virtually every direction inside the specimen and are detected at various x positions on the bottom surface by a pointlike piezoelectric detector of 0.75 mm diameter. The output of the PVDF film indicates a time of source generation and serves as a trigger for the output of the piezoelectric detector. From the arrival-time difference between the two signals, the travel time of the QL mode is determined. Identification of the QL ray arrival in a detected signal is easy, because the arrival is found at the point from which the signal first jumps from noise level. The QT mode in the detected signal is very difficult to identify and we did not attempt to measure its arrival time.

For measurements of the arrival times of the PT mode propagating on the xy wavy fiber plane, a line-type piezoelectric shear transducer, whose active area is 0.75 mm wide and 5 mm long, is mounted on the bottom face of the specimen at different x positions with its polarization aligned along the z direction. The polarization direction of the shear transducer is along the 5 mm lengthwise direction. It generates not only QL modes but also shear horizontally (SH) polarized pure transverse (PT) mode propagating along virtually every direction on the xy plane. The propagated PT modes are detected by a small piezoelectric shear transducer with active area of 0.75 mm diameter, which is attached on the various x positions of the top surface with its polarization aligned along the z direction. Identification of the PT mode arrival in the detected signals that travel through composite materials is not so easy, because its arrival trails that of the QL mode. How to identify the arrival time of the SH polar-

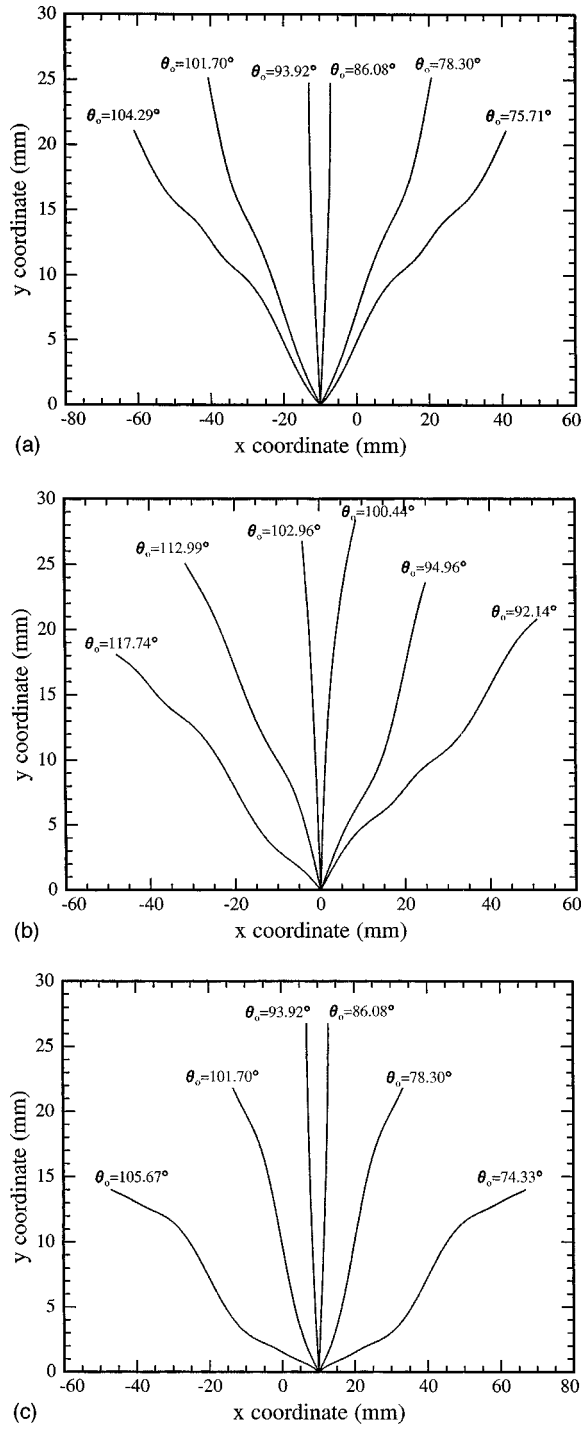

FIG. 2. Ray paths of the QL mode with sources at (a) $x=-10$ mm, (b) $x=0$ mm, and (c) $x=10$ mm.

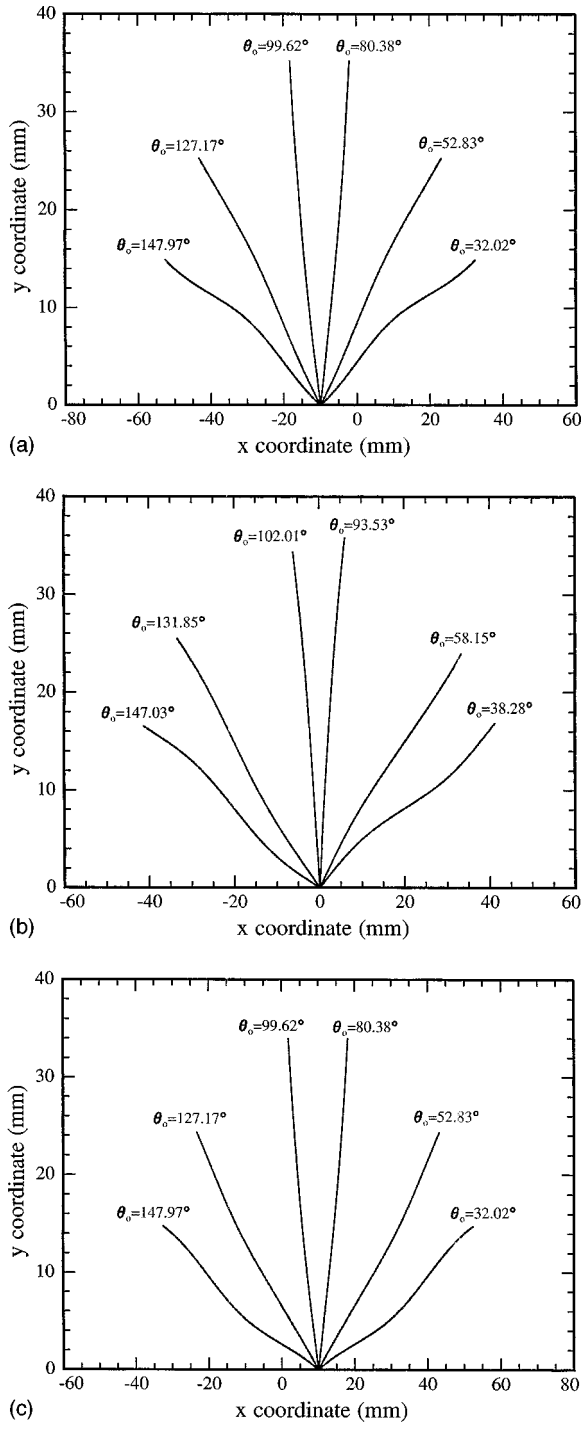

FIG. 3. Ray paths of the PT mode with sources at (a) $x=-10$ mm, (b) $x=0$ mm, and (c) $x=10$ mm.

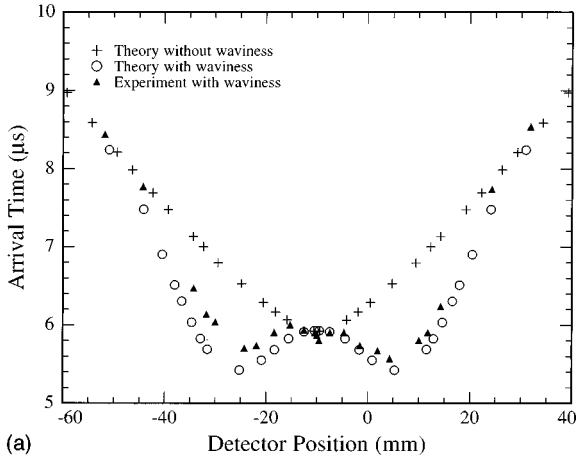
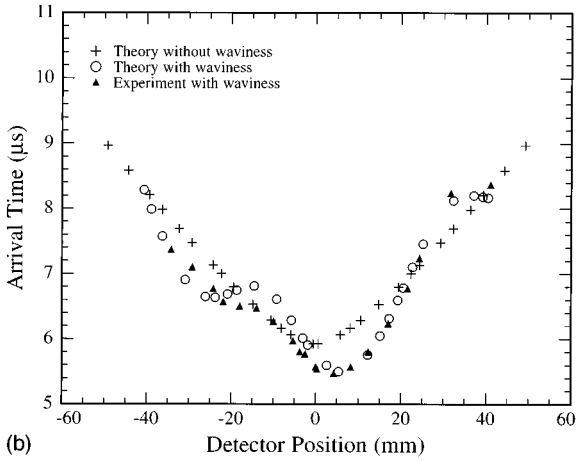
ized PT mode in the detected signal is described in Ref. 9.

It is noted that both the capillary fracture source and piezoelectric detector used for the QL mode have a frequency bandwidth extending well above 10 MHz, while both piezoelectric source and detector used for the PT mode have a broadband frequency spectrum which is centered around 5 MHz. These correspond to a wavelength of the QL mode less than 1 mm and that of the PT mode less than 0.2 mm. These wavelengths are much less than the wavy period of the composite, 40 mm and one expects that a high-frequency geometrical acoustics approximation would hold well in describing the propagation of wave fronts.

III. RESULTS

The obtained nine elastic constants of the unidirectional composite in units of GPa are: $C_{11}=130.3\pm1.5$, $C_{22}=11.00\pm0.28$, $C_{33}=12.46\pm0.44$, $C_{44}=2.95\pm0.08$, $C_{55}=5.47\pm0.22$, $C_{66}=4.96\pm0.08$, $C_{12}=6.01\pm0.36$, $C_{13}=1.04\pm0.09$,





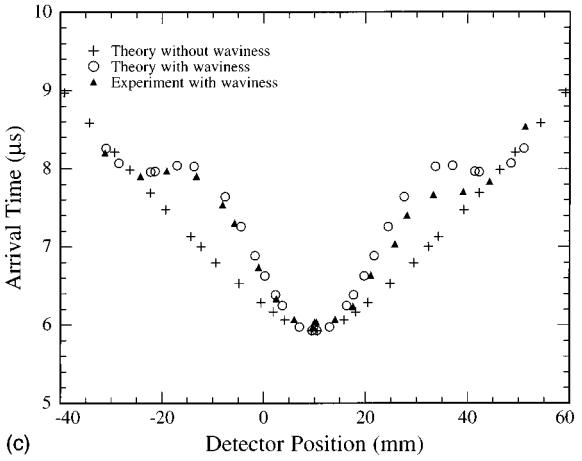


FIG. 4. Comparison of predicted arrival times of the QL ray with measured values. (a) Source at $x=-10$ mm, (b) source at $x=0$ mm, and (c) source at $x=10$ mm.

and $C_{23}=6.27\pm0.37$. We recall that the density and thickness of the wavy composite specimen are 1524 kg/m^3 and 15.93 mm, respectively.

Using these data, the ray paths of the QL mode with sources at $x=-10$, 0, and 10 mm on the bottom face are plotted in Fig. 2(a), (b), and (c), respectively. Those of the PT mode with sources at the same x positions are displayed in Fig. 3(a), (b), and (c), respectively. Although the capillary fracture QL sources are located on the top surface of the wavy composite, the ray paths are drawn as if they were

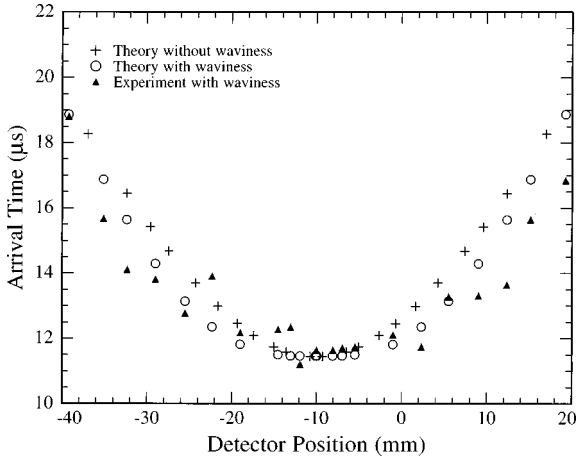

FIG. 5. Comparison between predicted arrival times of the PT ray with a source at $x=-10$ mm and measured values.

located on the bottom surface, which is given the coordinate of $y=0$. As expected, the ray paths of both QL and PT modes with the sources at $x=-10$ and 10 mm exhibit a symmetry pattern about the y axis passing through the source, while the symmetry is broken for the ray paths with a source at $x=0$ mm. θ_0 in these figures indicates the direction of the wave normal associated with a particular ray at the source point. Note that the rays are not only curved but also multiply curved for those substantially away from the vertical direction. QT ray paths are not plotted, because they can be refracted into QL modes anywhere on their path and the arrival of the QT rays are almost impossible to identify in the detected signals.

Comparison of theory with experiment on the ray arrival times of the QL mode is displayed in Fig. 4(a), (b), and (c) with sources at $x=-10$, 0, and 10 mm, respectively. Theoretical values of arrival times in a straight unidirectional fiber composite of the same thickness with similar source-to-detector configurations are also drawn with + (plus) symbols to elucidate the effect of fiber-waviness. It is seen that predicted values generally agree well with experimentally observed values. This signifies that the geometrical acoustics developed for a heterogeneous anisotropic medium provides a good approximation to the travel times of ultrasonic rays and it can be applied to the study of wave propagation in the wavy composite. It also indicates that geometrical acoustics, which is a high-frequency approximation, remains quite valid in the ultrasonic frequency range for description of wave front behavior in a wavy composite material. The deviations of predicted values from measured travel times at some detector positions are likely to be a result of rays passing through a local region where fiber arrangement deviates from the regular wavy pattern before the rays arrive at the detector. As expected, the QL ray arrival times with sources at $x=-10$ and 10 mm exhibit symmetry about their source positions. It is, however, interesting to see that the symmetry patterns are quite different in two cases.

Predicted arrival times of the PT mode are compared with measured values in Fig. 5. Theoretical arrival times in a corresponding straight fiber composite without waviness are also drawn with + (plus) symbols for comparison. The mea-

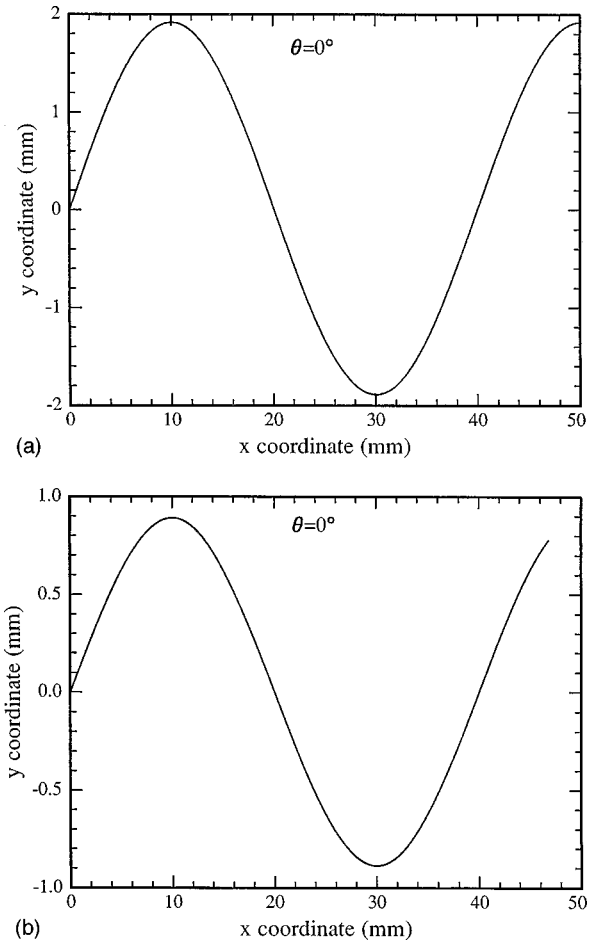

FIG. 6. The path of a ray initiating from origin with wave normal pointing in the x direction. (a) QL mode and (b) PT mode.

sured arrival times exhibit symmetry about the y axis that passes a source located at $x=-10$ mm, but they are more scattered than those of the observed QL mode. This is partly due to the difficulty of correctly identifying the PT mode arrival and as a result, the measured arrival times are considered approximate values with several % error.

Finally, the ray paths of the QL and PT modes initiating at origin ($x=0$ mm, $y=0$ mm) with initial wave normal pointing in the x direction are plotted in Fig. 6(a) and (b), respectively. In this case the direction of wave normal is constant, always in the x direction, all along the ray path, as Snell's law Eq. (4) implies. As can be seen from Fig. 6(a) and (b), both ray paths have the same periodic length as the wavy fiber has, but they have different amplitudes. In the case of the PT mode, this result is already predicted by Eq. (11). It is interesting to notice that the ray path of the QL mode with wave normal in the x direction closely follows a wavy fiber, while that of the PT mode deviates somewhat from the wavy fiber. One finds in Fig. 6(a) that the y coordinate of the QL ray at $x=30$ mm is -1.89 mm. We have prepared a specimen with two parallel sides terminating at $x=0$ mm and $x=30$ mm. The measured arrival time of the QL mode at the point ($x=30$ mm, $y=-1.89$ mm) with a source at origin is 3.33 μs, which agrees remarkably well with the predicted value 3.32 μs.

IV. CONCLUSIONS

We have established closed-form analytic solutions for the ray path and travel time of the QL, QT, and PT rays propagating in a wavy fiber composite. Predicted values of travel time of QL and PT modes are in good agreement with experimentally observed values. Geometrical acoustics developed for a heterogeneous anisotropic material can be useful for investigation of a wavy composite material. We have also shown that a high-frequency geometrical acoustics approximation holds well in the ultrasonic frequency range in describing the propagation of wave fronts in a wavy fiber composite. The method used in this paper may well be adapted to investigating wave propagation in various inhomogeneous anisotropic structures, such as devices with gradient of material properties (e.g., diffused concentration), depth-dependent media, and structures of inhomogeneous stress field, etc.

(Received 21 March 1997; revised 8 January 1998; accepted 16 January 1998)

Acoustical data transmission through the wall of drill pipes is considered. Drill pipes are known to behave like bandpass filters; the position of the pass bands can be determined analytically. This work extends the frequency domain drill pipe models presented by Barnes and Kirkwood [J. Acoust. Soc. Am. **51**, 1606–1608 (1972)], and more recently by Drumheller [J. Acoust. Soc. Am. **85**, 1048–1064 (1989)]. The approach discussed in this paper has the advantage that it yields explicit expressions for the fine structure of the drill pipe's frequency response in the pass bands. It furthermore allows the effect of energy dissipation and pipe segment length variations to be included in the model. The emphasis of the paper, however, lies on the time domain modeling of the drill pipe. The propagation of sound energy pulses through its wall, and the effect of multiple reflections and/or transmissions during this propagation, are described using a Markov chain. Explicit expressions result for the expected duration of an energy pulse's trip from one end of the drill pipe to the other, depending upon the number of drill pipe segments and the transmission coefficient at the tool-joints connecting them. The results are applicable to any situation where sound or energy transmission through a cascade of acoustic components occurs. © *1998 Acoustical Society of America.* [S0001-4966(98)00705-X]

INTRODUCTION

When performing soil drillings, one needs to know on the platform what happens at the drill bit. Adverse soil conditions and a too high temperature, among others, may invoke the necessity to stop drilling in order to avoid material damage. Relevant information may be gathered by equipment installed in the drill bit, but conveying the measured data to the platform is a problem as the severe circumstances in the bore hole do not allow wires to be installed.

The only communication method between drill bit and platform applied in practice is modulation of the mud stream inside the drill pipe. This stream is pumped downward through the pipe to cool or to drive the bit. At the lower pipe end, the drill pipe can be closed or opened by means of a flap. Closing the flap causes the pressure in the mud stream to increase, which can be measured at the upper drill pipe end. One information bit thus can be conveyed by respectively closing and opening the flap during one time unit. This method allows only a few bits to be transmitted each second.

In the present study, an alternative is considered where acoustical data are transmitted through the drill pipe wall (see also Barnes and Kirkwood, 1972; Drumheller, 1989). The drill pipe, consisting of steel, hollow, cylindrical segments, each about 10 m long, is excited at the lower end by a piezoelectrical transducer or by a hammer. The resulting sound signals travel through the wall of these segments, but are partly reflected at the tool-joints connecting them. Depending upon the reflection and transmission properties of the tool-joints, where the wall is thicker and includes a screw thread, sound signals of given frequencies do or do not reach the upper drill pipe end, with or without distortion and delay.

We first briefly discuss our drill pipe model in the frequency domain, which is similar to the one in Drumheller (1989), but allows a further-going analytical description of the data transmission process. We list the main modeling assumptions, give a short description of the behavior of tool-joints and pipe segments, and come to equations representing the transmission properties of the whole drill pipe. We then apply our model to consider energy dissipation and pipe segment length variations.

In the time domain, we introduce a few more modeling assumptions, and describe the configuration in terms of a Markov chain. This yields expressions for the time energy (or sound) pulses need to travel through the pipe.

We refer to Fig. 1 for names of drill pipe parts.

Both the frequency domain analysis and the time domain expressions are applicable to any situation where sound or energy transmission through a cascade of acoustic components occurs. In speech production models, for instance, the vocal tract shape is usually approximated by a series of small cylindrical tubes, not unlike a drill pipe. One of the main contributions of this paper is that we derive explicit expressions for the transmission behavior of a cascade of (regular) acoustic components. The emphasis, however, lies on the Markov chain analogue to the drill pipe, which extends the frequency domain results (Drumheller, 1989; Barnes and Kirkwood, 1972) to the time domain.

I. MODELING ASSUMPTIONS AND THEIR MOTIVATION

In this section, we introduce and motivate a number of modeling assumptions to obtain a mathematical description of the drill pipe.

We assume the whole configuration to be ''ideal'' in the sense that all pipe segments and tool-joints are exactly cylin-

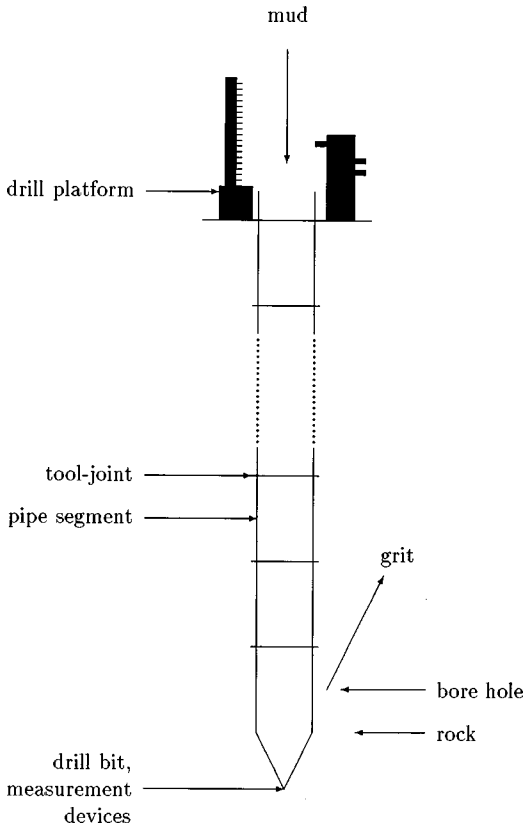

FIG. 1. Drill pipe.

drical, with a homogeneous wall of constant thickness, and that the screw thread of one tool-joint fits precisely into that of the next.

When the drill pipe is excited at its lower end, longitudinal, transversal, and spiraling sound waves result. The latter two cause wall displacements perpendicular to the pipe axis, and thus interact with the environment. As a consequence, they lose part of their energy by radiation. Furthermore, for the low frequencies considered (see below), any spiraling modes are cut off and will eventually vanish. Longitudinal waves, corresponding to wall displacements parallel to the pipe axis, are therefore likely to prevail in long drill pipes. In the sequel, we restrict ourselves to longitudinal sound waves. The cylindrical symmetry of the configuration implies that a one-dimensional mathematical description suffices.

We choose the co-ordinate system such that the z axis corresponds to the drill pipe axis (see Fig. 2). In drill pipe

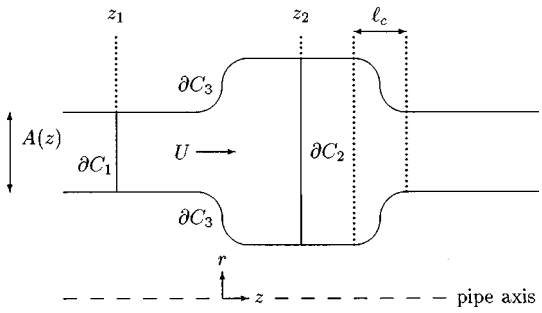

FIG. 2. Drill pipe wall of variable surface.

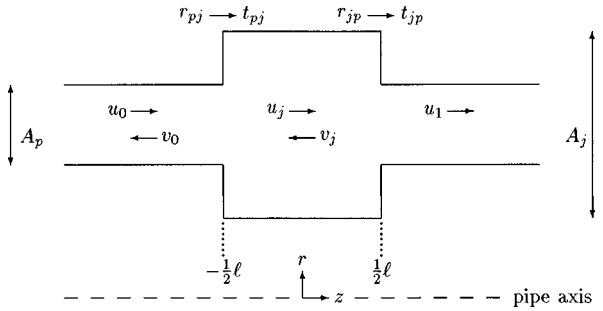

FIG. 3. Tool-joint modeled for large wave lengths.

parts where the configuration wall surface is constant, a combination of Newton's and Hooke's laws (Timoshenko *et al.*, 1974) yields an ordinary one-dimensional wave equation for the longitudinal displacement $U(z,t)$,

$$\frac{\partial^2 U}{\partial t^2} - c^2 \frac{\partial^2 U}{\partial z^2} = 0. \tag{1}$$

Its harmonic solutions are combinations of sound waves traveling to the left and to the right,

$$U(z,t) = \{u e^{i\kappa z} + v e^{-i\kappa z}\} e^{-i\omega t}, \tag{2}$$

in which $\kappa = \omega/c$ is the ratio of angular frequency and speed of sound in steel.

To simplify the model, we neglect the (cutoff) higher-order modes, and assume the plane waves (2) to be stepwise discontinuously connected at the joints. This assumption is reasonable for frequencies at which the wavelength λ is sufficiently larger than the drill pipe wall thicknesses h_p in the pipe segments, and h_j in the tool-joints. The length ℓ_c of the curved tool-joint part should typically not be much larger than h_p or h_j. Furthermore, to avoid tunneling effects, both the pipe segment length L and the tool-joint length ℓ should exceed the geometrical parameters h_p, h_j, and ℓ_c at the curved tool-joint parts. For the considered drill pipe, $h_p = 1$ cm, $h_j = 3.5$ cm, $\ell_c = 5$ cm, $L = 9.1$ m, and $\ell = 0.5$ m. The model is therefore restricted to frequencies satisfying $f \ll c/\ell_c \approx 100$ kHz for $c = 5100$ m/s in steel. Results are presented for frequencies up to 10 kHz.

We thus have reduced the real configuration to a series of straight segments and tool-joints in which only longitudinal, harmonic sound waves propagate. The drill pipe is driven at the lower end by a transducer; the upper end is assumed to reflect all sound waves completely, which follows from the observation that the normal force at that end equals zero, and Hooke's law.

We proceed by capturing tool-joints, transducer, and pipe segments in mathematical expressions. Their combination will yield the mathematical model.

II. FREQUENCY DOMAIN MODELING

In the sequel, we consider a drill pipe configuration consisting of $N+1$ pipe segments, numbered $n = 0,...,N$, and N tool-joints, numbered $n = 1,...,N$ (see Fig. 4). The outer ends may be counted as ''tool-joints'' 0 and $N+1$. The length of the nth pipe segments is L_n.

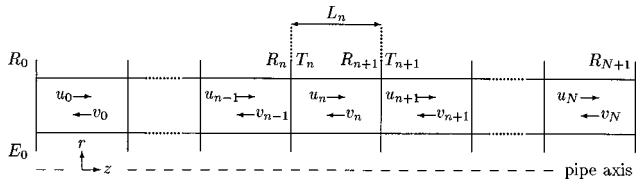

FIG. 4. Drill pipe modeled using reflection and transmission coefficients.

A. A tool-joint, transducer, and pipe segment model

We first describe a tool-joint in terms of reflection and transmission coefficients $R=v_0/u_0$ and $T=u_1/u_0$ (see Fig. 3) (Dowling and Ffowcs Williams, 1983, pp. 66–67).

We choose the origin of the coordinate system to correspond with the middle of a tool-joint with length ℓ. Continuity of displacement and normal force implies that at $z=-\frac{1}{2}\ell$, $U_0=U_j$, and $A_p\partial U_0/\partial z=A_j\partial U_j/\partial z$; A_p and A_j denote the wall surface of pipe segment and tool-joint, respectively. Similar equations result at $z=\frac{1}{2}\ell$. Substitution of (2)—with the correct wave amplitudes—into these expressions yields

$$R=2i\,\frac{r_{pj}\,\sin(\kappa\ell)}{1-r_{jp}^2\vartheta^4} \quad \text{and} \quad T=\frac{t_{pj}t_{jp}}{1-r_{jp}^2\vartheta^4}, \tag{3}$$

where $\vartheta=e^{i\kappa\ell/2}$. The coefficients $r_{jp}=(A_j-A_p)/(A_j+A_p)$, $t_{jp}=1-r_{jp}$, $r_{pj}=-r_{jp}$, and $t_{pj}=1-r_{pj}$ describe sound reflection at each of the wall area discontinuities[1] (Dowling and Ffowcs Williams, 1983, p. 64; Fletcher and Rossing, 1991, pp. 147–148).

Denoting the displacement amplitude in the pipe segment to which the transducer is connected by U_0, and assuming U_0 to satisfy (2), a mathematical model of a transducer (van de Ven, 1975) yields

$$u_0=\phi_0E_0+\phi_0^2R_0v_0, \tag{4}$$

where R_0 and E_0 are two transducer-dependent constants, and $\phi_0=e^{i\kappa L_0/2}$ is a phase change. The factor R_0 is similar to a reflection coefficient, but the transducer also keeps feeding energy into the drill pipe, which is described by the factor E_0.

If we substitute $z+\Delta z$ for z in Eq. (2), it appears that for sound waves that travel a distance Δz, only the phase changes by a factor $e^{i\kappa\Delta z}$. As a consequence, the pipe segments can be modeled as phase shifts.[2] We introduce the factor $\phi_n=e^{i\kappa L_n/2}$, describing the phase change of a sound wave traveling through half of the pipe segment n, i.e., over a distance $\frac{1}{2}L_n$.

B. A segmented drill pipe model

We denote the amplitude of the sound wave traveling to the right in the middle of pipe segment n by u_n; the wave moving to the left at that location has amplitude v_n. The reflection and transmission coefficients at tool-joint n are denoted R_n and T_n. We choose $z=0$ in the middle of the pipe segment connected to the transducer. We find

$$u_n=\phi_{n-1}T_n\phi_nu_{n-1}+\phi_nR_n\phi_nv_n, \quad n=1,...,N,$$

$$v_n=\phi_{n+1}T_{n+1}\phi_nv_{n+1}+\phi_nR_{n+1}\phi_nu_n, \quad n=0,...,N-1,$$

or, after rewriting in terms of matrices and applying induction,

$$\begin{pmatrix}u_N\\v_N\end{pmatrix}=\left(\prod_{n=1}^{N}(\Phi_nM_n\Phi_{n-1})\right)\begin{pmatrix}u_0\\v_0\end{pmatrix}=:\mathcal{T}\begin{pmatrix}u_0\\v_0\end{pmatrix}, \tag{5}$$

with

$$\Phi_n=\begin{pmatrix}\phi_n & 0\\ 0 & \phi_n^{-1}\end{pmatrix} \quad \text{for } n=0,...,N, \tag{6}$$

and

$$M_n=\begin{pmatrix}(T_n^2-R_n^2)/T_n & R_n/T_n\\ -R_n/T_n & 1/T_n\end{pmatrix} \quad \text{for } n=1,...,N. \tag{7}$$

The phase-shift matrices Φ_n and Φ_{n-1} describe the propagation of sound waves through (half) pipe segments; M_n models sound reflection and transmission at the joint between segments $n-1$ and n. $\mathcal{T}$ describes the behavior of sound waves traveling from segment 0 to segment N, and $\mathcal{T}^{-1}$ how sound waves propagate in the opposite direction. Symmetry thus implies that $\det(\mathcal{T})=\det(\mathcal{T}^{-1})$, and therefore $\det(\mathcal{T})=1$.

Assuming all pipe segments to have the same length L, and all tool-joints to have identical properties ℓ, ϕ, R, T, and M, we have $\mathcal{T}=(\Phi M\Phi)^N=:\mathcal{M}^N$. The powers of $\mathcal{M}$ can be determined explicitly, allowing explicit analytical results for the case $N\to\infty$.

The Cayley–Hamilton theorem (Tropper, 1969, pp. 72–73) states that each square matrix satisfies its characteristic equation, so that $\mathcal{M}^2-2\tau\mathcal{M}+\mathcal{I}=0$, where

$$\tau=\tfrac{1}{2}\,\mathrm{tr}(\mathcal{M})=\tfrac{1}{2}(\mathcal{M}_{11}+\mathcal{M}_{22}),$$

and we used the fact that the determinant of $\mathcal{M}$ is given by $\det\mathcal{M})=\mathcal{M}_{11}\mathcal{M}_{22}-\mathcal{M}_{12}\mathcal{M}_{21}=\det(\Phi)\det(M)\det(\Phi)=1\cdot1\cdot1=1$. The characteristic equation implies that $\mathcal{M}^n$ must be a linear combination of $\mathcal{M}$ and the unity matrix $\mathcal{I}$, i.e., $\mathcal{M}^n=a_n\mathcal{M}+b_n\mathcal{I}$. Similarly, the eigenvalues $\lambda_{1,2}$ of $\mathcal{M}$ satisfy its characteristic equation, and therefore $\lambda_{1,2}^n=a_n\lambda_{1,2}+b_n$. Some straightforward computations give

$$\lambda_{1,2}=\tau\pm\sqrt{\tau^2-1}, \quad \text{while } \lambda_1\lambda_2=1.$$

Combination of the latter two expressions yields two equations for a_n and b_n, from which both coefficients can be determined (assuming $\tau^2\neq1$, so that $\lambda_1\neq\lambda_2$). This yields the following expressions for the coefficients of $\mathcal{M}^N$:

$$\mathcal{M}_{11}^N=\frac{1}{\lambda_1-\lambda_2}\{(\mathcal{M}_{11}-\lambda_2)\lambda_1^N-(\mathcal{M}_{11}-\lambda_1)\lambda_2^N\}, \tag{8}$$

$$\mathcal{M}_{12}^N=\frac{1}{\lambda_1-\lambda_2}\{\mathcal{M}_{12}\lambda_1^N-\mathcal{M}_{12}\lambda_2^N\}=-\mathcal{M}_{21}^N, \tag{9}$$

$$\mathcal{M}_{22}^N=\frac{1}{\lambda_1-\lambda_2}\{(\mathcal{M}_{22}-\lambda_2)\lambda_1^N-(\mathcal{M}_{22}-\lambda_1)\lambda_2^N\}. \tag{10}$$

If $\tau^2=1$, similar expressions for the components of $\mathcal{M}^N$ can be found by taking limits for τ tending to ±1 in the latter equations.

At the platform end of the drill pipe, we have

$$v_N = \phi_N^2 R_{N+1} u_N . \tag{11}$$

Since all pipe segments are assumed to have the same length, $\phi_N = \phi$. Furthermore, in all numerical calculations performed in the sequel, we set $R_{N+1} = 1$, which corresponds to total reflection at the platform end of the configuration.

We thus have derived the four linear equations (4), (5), and (11) for the unknown amplitudes u_0, v_0, u_N, and v_N. Some calculations yield the total amplitude $U_N = u_N + v_N$ of the sound wave in the middle of pipe segment N:

$$U_N = \frac{\phi E_0 (1+\phi^2 R_{N+1}) \mathcal{M}_{11}^N}{1-(\phi^2 R_0 \mathcal{M}_{11}^N + \mathcal{M}_{12}^N)(\phi^2 R_{N+1} \mathcal{M}_{11}^N + \mathcal{M}_{12}^N)} . \tag{12}$$

A similar expression[3] can be derived for segment $n=0$; note that the coefficients $\mathcal{M}_{11}^N$ and $\mathcal{M}_{12}^N$ are known explicitly.

To study the behavior of (12) for $N \to \infty$, we distinguish two cases.

If τ has nonzero imaginary part, or if τ is real with $|\tau| > 1$, one of the eigenvalues λ_1, λ_2 of $\mathcal{M}$ has norm exceeding one. The Nth powers of both eigenvalues occur in (8)–(10), and so $\mathcal{M}_{11}^N$ tends to infinity if N does. Division of the denominator and the numerator of (12) by $(\mathcal{M}_{11}^N)^2$ thus implies $\lim_{N\to\infty} U_N = 0$.

If τ is real, and $|\tau| \leqslant 1$, both λ_1 and λ_2 (and their powers) have modulus 1, and are located on the boundary of the complex unit circle. In this case, (12) shows that U_N does not tend to zero for $N \to \infty$. Combining Eq. (3) for the tool-joint reflection and transmission coefficients with (5), and using the definition of τ, the following resonance condition results:[4] only sound waves with frequencies for which

$$\mathrm{Im}(\tau) = 0$$

and

$$|\tau| = \left| \cos \kappa \ell \cos \kappa (L-\ell) - \frac{1}{2}\left(\frac{A_j}{A_p} + \frac{A_p}{A_j}\right) \times \sin \kappa \ell \sin \kappa (L-\ell) \right| \leqslant 1 \tag{13}$$

are able to travel through long drill pipes, all segments and joints of which are identical.

This resonance condition (13), which is also reported in Barnes and Kirkwood (1972) and Drumheller (1989), explains the bandpass filter behavior of the drill pipe visualized in Fig. 5. However, it does not by itself give any information about the fine structure of the frequency response of the pipe's pass bands, which have only been considered numerically by Drumheller (1989) and Barnes and Kirkwood (1972). This fine structure is more apparent in Fig. 6, in which only one pass band is displayed.

Equation (12) gives an analytical expression for this spectrum structure, and allows energy dissipation and pipe segment length variations to be included in the model.

C. Energy dissipation

We model energy dissipation in the drill pipe wall by introducing a linear, dissipative term in the ordinary wave equation:

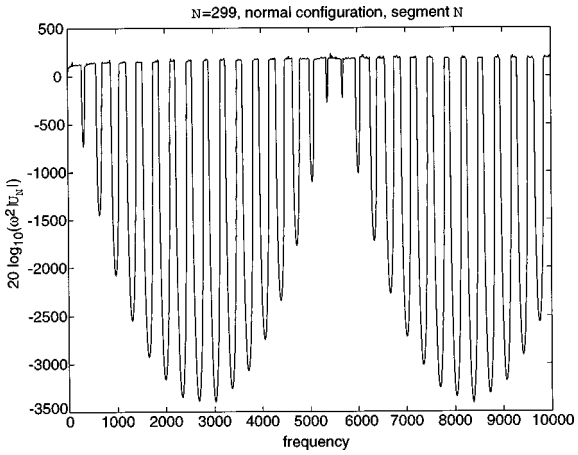

FIG. 5. $20 \log_{10} (\omega^2 |U_N|)$ in the middle of the last segment of a 300-segment drill pipe ($N=299$).

$$\frac{\partial^2 U}{\partial t^2} - c^2 \frac{\partial^2 U}{\partial z^2} = -\beta \frac{\partial U}{\partial t} .$$

Restriction to harmonic solutions as in (2) then gives[5] $(-\omega^2 + c^2 \kappa_e^2 - i\beta\omega) = 0$, or $\kappa_e^2 = \kappa^2 (1 + i\beta/\omega)$. For small dissipative terms β, we may write $\kappa_e = \pm(\kappa + i\alpha)$, with

$$\alpha = \frac{\beta/c}{1+\sqrt{1+i\beta/\omega}} \approx \frac{\beta}{2c} .$$

Equation (2) can be rewritten as

$$U(z,t) = (u e^{-\alpha z} e^{i\kappa z} + v e^{\alpha z} e^{-i\kappa z}) e^{-i\omega t},$$

i.e., the sound wave amplitude of sound waves traveling to the left or to the right decreases exponentially with the distance traveled.

Figure 7 shows the consequences of energy dissipation for sound transmission through the drill pipe: the resonance peaks vanish. We have chosen an amplitude attenuation of 10 dB/km, corresponding with $\alpha = 10^{-3}/\log_{10} e$. The configuration consists of 20 pipe segments, connected by $N=19$ tool-joints. Comparing with Fig. 6, we see that in a configu-

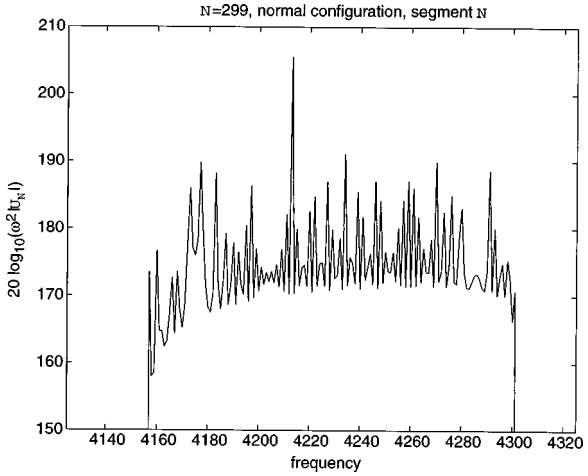

FIG. 6. $20 \log_{10} (\omega^2 |U_N|)$ in the middle of the last segment of a 300-segment drill pipe ($N=299$).

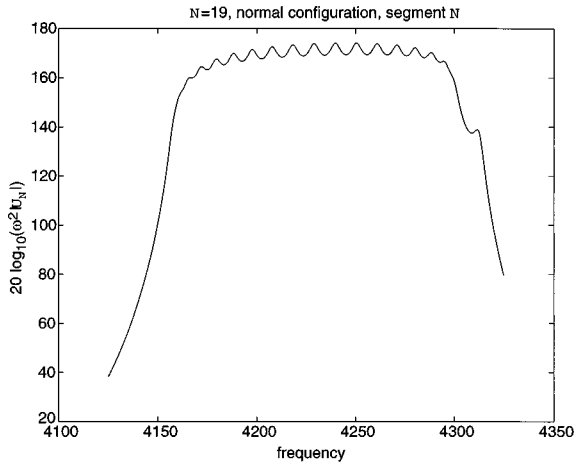

FIG. 7. $20 \log_{10} (\omega^2 |U_N|)$ in the middle of the last segment of a 20-segment drill pipe ($N=19$), with energy dissipation (10 dB/km).

ration with only 19 tool-joints the diffusion has removed the sharp peaks almost completely. This effect becomes even more pronounced for larger values of N.

An alternative way to model the effect of energy losses in the drill pipe is to assume them to occur at the tool-joints only. Instead of introducing a complex wave number κ_e, it then suffices to slightly change the tool-joint reflection and transmission coefficients R and T, such that the determinant Δ of $\mathcal{M}$ becomes smaller than one. Expression (12) remains valid if the second term in its numerator is divided by Δ^N. Furthermore, the eigenvalues λ_1 and λ_2 have to be changed to $\lambda_{1,2}=\tau \pm \sqrt{\tau^2-\Delta}$ and the conditions $\tau^2=1$ and $\tau^2 \neq 1$ have to be modified to $\tau^2=\Delta$ and $\tau^2 \neq \Delta$ (similarly for inequalities).

D. Pipe segment length variations

To roughly estimate the effect of small pipe segment length variations on the amplitude U_N in the rightmost drill pipe segment, the pipe segment lengths L_n occurring in the phase-shift matrices Φ_n [see (5)] have been disturbed with a normally distributed error l_n with mean zero and standard deviation σ_p.

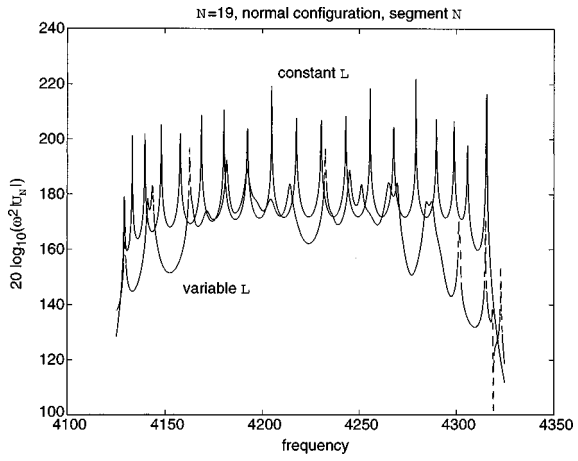

FIG. 8. $20 \log_{10} (\omega^2 |U_N|)$ in the middle of the last segment of a 20-segment drill pipe ($N=19$), with variable pipe segment length ($\sigma_p=0.05$).

The results for a drill pipe with 20 pipe segments and $N=19$ tool-joints are shown in Fig. 8; we have chosen $\sigma_p=0.05$. The peaks within the pass bands are less sharp compared to those in Fig. 6 (notice that the vertical scales differ in both figures). The stop bands appear to be less pronounced. In fact, the conditions for resonance are never fulfilled exactly if L varies, and neither are the conditions that make different parts of the drill pipe move in exact counterphase.

Small pipe segment length variations appear to affect mainly the drill pipe's sound transmission properties at higher frequencies. The location of the resonance peaks is slightly affected as well.

III. TIME DOMAIN MODELING

A. Additional simplifications and their motivation

As we want to study sound transmission through the drill pipe in the time domain, we must switch from a stationary situation with harmonic sound waves to a dynamical one, where sound signals are used of which the time duration is limited. We assume them to be so short that they do not interact, i.e., their duration is short compared to the time sound needs to propagate through a pipe segment.[6] In the sequel, we refer to such short time-duration signals as ''pulses'' $\hat{u}(t)$.

In order to make sure that the reflection and transmission of a pulse remains pulse shaped, we have to make restrictions on the reflection coefficient $R(\omega)$ at the tool-joints. Assume that an incident signal $u(\omega)$ yields a reflection $v(\omega)=R(\omega)u(\omega)$. After inverse Fourier transformation, this gives the time-domain expression

$$\hat{v}(t)=\int_{-\infty}^{\infty} R(\omega)u(\omega)e^{-i\omega t}\,d\omega$$

$$=\frac{1}{2\pi}\int_{-\infty}^{t} \hat{R}(t-t')\hat{u}(t')dt',$$

in which we used causality of $\hat{R}(t)$, the inverse Fourier transform of $R(\omega)$ (Rienstra, 1988). If $\hat{u}(t)=\delta(t)$, this reduces to $\hat{v}(t)=(1/2\pi)\hat{R}(t)$, which is in general not pulselike because $R(\omega)$ is in general not a constant or of the form $\sim e^{i\omega s}$. In fact, substitution of Eq. (3) for $R(\omega)$ yields

$$\hat{R}(t)=-2\pi r_{jp}\delta\left(t+\frac{l}{c}\right)+2\pi(1-r_{jp}^2)$$

$$\times\sum_{n=1}^{\infty} r_{jp}^{2n-1}\delta\left(t-(2n-1)\frac{l}{c}\right),$$

i.e., the reflection of a pulse is a pulse train. This calls for further modeling assumptions.

$\hat{R}(t)$ would be pulselike if $(1-r_{jp}^2)r_{jp} \ll r_{jp}$, or $r_{jp} \approx 1$, an uninteresting trivial case. Alternatively, $\hat{R}(t)$ can be considered pulselike if its energy is concentrated in the first N_0 pulses of the pulse train, such that $(1-r_{jp}^2)r_{jp}^{2N_0-2}$ is small enough, and the effective duration $N_0 \ell/c$ of $\hat{R}(t)$ and the corresponding length of the reflected signal $N_0 \ell$ are short enough.

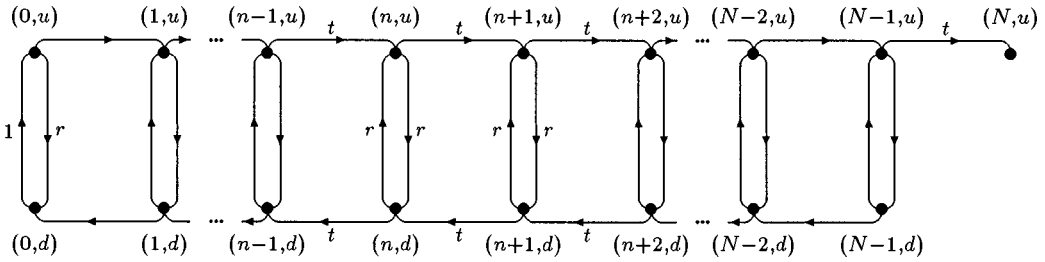

FIG. 9. Drill pipe modeled as a Markov chain.

Implementing these considerations, we assume $R(\omega)$ to be constant in the sequel, and neglect the tool-joint length.

The bandwidth of the sound signals used for data transmission will not exceed the width of the drill pipe's pass bands. According to Eq. (3), the values of R and T generally vary only slightly in such limited spectral intervals. Within the signal's frequency band, it therefore seems realistic indeed to approximate R by a constant.

Furthermore, since $u(\omega)=0$ outside this band, the reflected signal $R(\omega)u(\omega)$ does not change if we assume R to have the same constant value for all ω. By choosing a real value for the reflection coefficient, we neglect phase jumps at reflection.

A similar argument holds for the transmission coefficient T and, at the transducer end, for R_0. For the sake of demonstration we set $R_0=1$.

Clearly, with respect to the original equation (1), the results presented in the sequel will have to be interpreted as approximations.

B. A Markov model for the drill pipe

Consider an energy pulse of amplitude 1 traveling toward a tool-joint of which the constant reflection and transmission coefficients with respect to energy[7] are denoted by r and t. At the tool-joint, part of the pulse reflects and part of it is transmitted. Conservation of energy implies

$$1=r+t.$$

This observation leads to a statistical analogue for (sound) energy pulse propagation through the drill pipe.

We model energy pulses as marbles, rolling from left to right or vice versa within the pipe segments. At each tool-joint, they change direction with probability r. With probability t, they keep rolling in the same direction.

The drill pipe can now be modeled as a Markov chain, introducing two states for each pipe segment.[8] A ''marble'' is said to be in state (n,u) if it rolls upward in segment n. If it rolls downward, it is in state (n,d). The Markov chain is shown in Fig. 9.

Consider one ''marble'' which starts to roll upward in the first pipe segment at clock unit $k=0$. Let $\pi_k(n,j)$ be the probability that at clock unit k it moves in direction $j\in\{u,d\}$ in pipe segment n. Hence, $\pi_0(0,u)=1$ and for $k=1,2,...$ the probabilities $\pi_k(n,j)$ satisfy (see Fig. 9)

$$\pi_k(0,u)=\pi_{k-1}(0,d), \tag{14}$$

$$\pi_k(n,u)=t\,\pi_{k-1}(n-1,u)+r\,\pi_{k-1}(n,d), \quad n=1,...,N, \tag{15}$$

$$\pi_k(n,d)=t\,\pi_{k-1}(n+1,d)+r\,\pi_{k-1}(n,u), \quad n=0,...,N-1, \tag{16}$$

where $\pi_k(N,d)=0$ by definition. From these equations we can easily compute for consecutive values of k the probability distribution $\{\pi_k(n,j)\}$. Figure 10 displays this distribution for some values of k in a configuration with $N=15$ tool-joints (and 16 pipe segments), with $r=0.1$ and $t=0.9$. The value of $\pi_k(N,u)$ for consecutive values of k is shown in Fig. 11; it shows how much energy reaches the upper drill pipe end at each clock unit. We have chosen the same reflection and transmission coefficients, but $N=63$.

In terms of the physical problem, two effects influence the energy pulse propagation. The first will be called **direct transmission**: part of the pulse travels through the drill pipe without reflecting anywhere. This explains the rightmost peak in Fig. 10, for $k=4$ and $k=12$, and the small peak in Fig. 11 at time unit $k=63$. The second effect is similar to **diffusion**. Energy that reflects at a number of tool-joints appears to be distributed more or less regularly throughout the configuration, and diffuses to the upper end of the configuration. This is visible in Fig. 10, for $k=20$ and $k=28$, and explains the ''hump'' in Fig. 11 following the first peak at $k=63$.

The effect of decreasing t is similar to that of increasing N, and vice versa. For $t=1$, the ''hump'' disappears: all energy travels through the drill pipe at once. For small values of t, the diffusion effect is large compared to the direct trans-

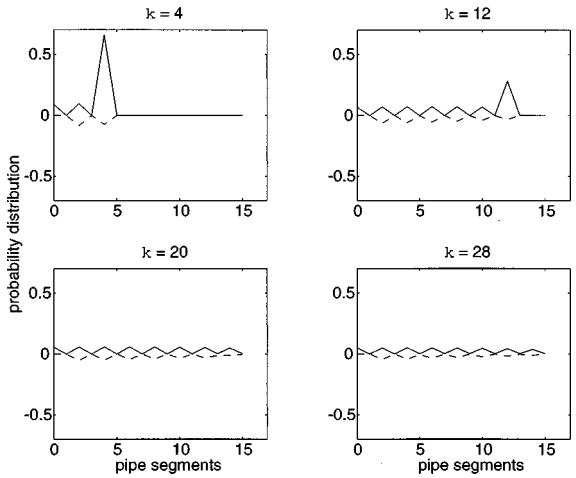

FIG. 10. Probability distribution of the energy pulse (''marble'') position after k time units; $N=15$, $r=0.1$, $t=0.9$ (downward probabilities with minus sign).

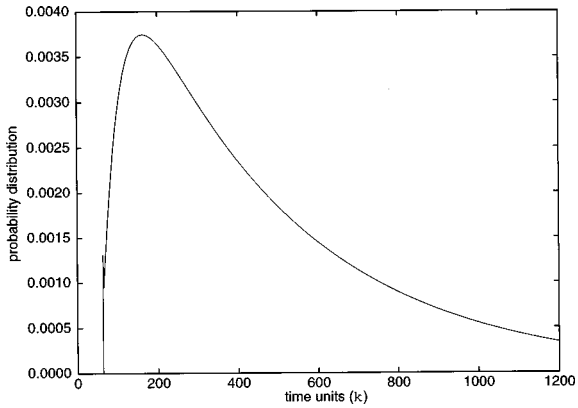

FIG. 11. Probability distribution of the energy pulse (''marble'') arrival after k time units; $N=63$, $r=0.1$, $t=0.9$.

mission, and only the ''hump'' reaches the upper drill pipe end.

In the following paragraphs, we show that the ''hump'' is a mixture of N geometric functions. This observation will allow exact determination of the expected traveling time of the energy pulse through an $N+1$-segment drill pipe. It will also yield an expression for the variance of this traveling time, i.e., an estimate for the width of the ''hump.'' We will finally show that two geometric functions suffice to closely approximate the shape of the ''hump.''

C. The ''hump'' as a mixture of geometric functions

We introduce the (probability) generating functions

$$F(n,j;z)=\sum_{k=0}^{\infty}\pi_k(n,j)z^k; \tag{17}$$

$F(N,u;z)$ is the generating function of the ''hump.'' We now show how to determine $F(N,u;z)$ explicitly. This will lead to a mathematical description of the ''hump'' in terms of geometric functions.

Equations (14)–(16) combined with the initial condition $\pi_0(0,u)=1$ yield

$$F(0,u;z)=zF(0,d;z)+1, \tag{18}$$

$$F(n,u;z)=tzF(n-1,u;z)+rzF(n,d;z), \quad n=1,...,N, \tag{19}$$

$$F(n,d;z)=tzF(n+1,d;z)+rzF(n,u;z), \quad n=0,...,N-1. \tag{20}$$

We rewrite expressions (19) and (20) to

$$\begin{pmatrix}F(n,u;z)\\F(n,d;z)\end{pmatrix}=\mathcal{W}(z)\begin{pmatrix}F(n-1,u;z)\\F(n-1,d;z)\end{pmatrix}, \quad n=1,...,N, \tag{21}$$

where

$$\mathcal{W}(z)=\begin{pmatrix}(t^2-r^2)z/t & r/t\\ -r/t & 1/tz\end{pmatrix}. \tag{22}$$

Applying induction to (21), we obtain

$$\begin{pmatrix}F(N,u;z)\\F(N,d;z)\end{pmatrix}=\mathcal{W}^N(z)\begin{pmatrix}F(1,u;z)\\F(1,d;z)\end{pmatrix}.$$

We combine this result with (18), and substitute $F(N,d;z)=0$. This leads to

$$F(N,u;z)=\frac{\det(\mathcal{W}^N(z))}{\mathcal{W}_{22}^N(z)+z\mathcal{W}_{21}^N(z)}=\frac{\det(\mathcal{W}(z))^N}{\mathcal{W}_{22}^N(z)+z\mathcal{W}_{21}^N(z)},$$

in which $\mathcal{W}_{ij}^N(z)$ denotes the ij-component of $\mathcal{W}^N(z)$ for $i,j=1,2$. Since $\det(\mathcal{W}(z))=1$ we eventually find

$$F(N,u;z)=\frac{1}{\mathcal{W}_{22}^N(z)+z\mathcal{W}_{21}^N(z)}=:\frac{1}{f(z)}. \tag{23}$$

As the components of $\mathcal{W}(z)$ are either constants, or multiples of z or $1/z$, it is readily verified that the function $f(z)$ may be written as

$$f(z)=\sum_{k=-N}^{N}f_kz^k,$$

hence $z^Nf(z)$ is a polynomial of degree $2N$.

With Eqs. (17) and (23) we have two different expressions for $F(N,u;z)$, one in terms of the probabilities $\pi_k(N,u)$, the other as the reciprocal of $f(z)$. We now express the probabilities $\pi_k(N,u)$ in terms of the zeros of $z^Nf(z)$. These expressions give rise to the mathematical description of the ''hump'' in Fig. 11 as a mixture of N geometric functions.

To compare (17) and (23), we first exploit some properties of $F(N,u;z)$. Note that it takes at least N clock units for a ''marble'' to reach pipe segment N and each segment passed in the downward direction must be passed again in the upward direction to ever reach the end of the drill pipe. This implies that $\pi_k(N,u)=0$ for $k<N$ and $\pi_{N+1+2k}(N,u)=0$ for $k\geqslant 0$. Hence

$$F(N,u;z)=z^N\sum_{k=0}^{\infty}\pi_{N+2k}(N,u)z^{2k},$$

from which we can conclude that $F(N,u;z)/z^N$ is even, and convergent for $|z|\leqslant 1$; it has no poles within the closed unit disk. Thus also $z^Nf(z)$ is even. So each zero of $z^Nf(z)$ has a companion zero with opposite sign. Furthermore, all zeros of $z^Nf(z)$ must be situated outside the closed unit disk. Denote the zeros of $z^Nf(z)$ by $z_1,-z_1,...,z_N,-z_N$, which we assume to be distinct. We may then write

$$z^Nf(z)=f_{-N}(1-(z/z_1)^2)\cdots(1-(z/z_N)^2).$$

Partial fraction decomposition of $F(N,u;z)$ now yields

$$F(N,u;z)=\frac{z^N}{z^Nf(z)}=\frac{z^N}{f_{-N}}\sum_{i=1}^{N}\frac{a_i}{1-(z/z_i)^2}=z^N\sum_{k=0}^{\infty}z^{2k}\sum_{i=1}^{N}\frac{a_i}{f_{-N}}\left(\frac{1}{z_i}\right)^{2k}, \tag{24}$$

with $a_i=1/\Pi_{j=1,j\neq i}^{N}(1-z_i/z_j)$. From (17) and (24) we finally get

$$\pi_{N+2k}(N,u)=\sum_{i=1}^{N}b_i(1-p_i)p_i^k, \quad k=0,1,2,... . \tag{25}$$

To ease the interpretation of (25), we introduced

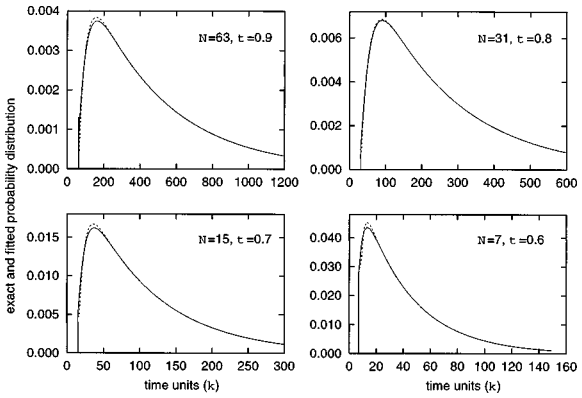

FIG. 12. Expected duration of the energy pulse (''marble's'') trip through the drill pipe, and its standard deviation as a function of N for various values of t.

$$p_i = 1/z_i^2, \quad b_i = \frac{a_i}{f_{-N}(1-p_i)}, \quad i = 1,...,N.$$

It follows that the probabilities $\pi_k(N,u)$ are mixtures of N geometric distributions for $k=N,\ N+2,...$; the ''hump'' in Fig. 11 is a mixture of N geometric functions.

D. Expectation and variance of an energy pulse's traveling time

Expression (25) is not useful for practical purposes, since it requires the determination of all zeros of the polynomial $z^N f(z)$. An approximation that appears to be remarkably accurate is obtained by constructing a suitable distribution that fits the mean μ_t and variance σ_t^2 of the time it takes the ''marble'' to reach the right end of the drill pipe. The distribution that will be used is a discrete version of the continuous K_2-distribution (Tijms, 1986). Such an approximation, of course, only makes sense if μ_t and σ_t^2 can be easily determined. This is indeed the case. Below we will derive explicit expressions for μ_t and σ_t^2, by utilizing again the generating function $F(N,u;z)$.

The mean and variance of the traveling time can be found by differentiating the generating function $F(N,u;z)$, yielding[9]

$$\mu_t = \sum_{k=1}^{\infty} k\pi_k(N,u) = F'(N,u;1) = -\frac{f'(1)}{f^2(1)} = -f'(1),$$

where the prime denotes the derivative with respect to z. For the variance of the traveling time, a similar derivation yields

$$\sigma_t^2 = f'(1)^2 - f''(1) - f'(1).$$

To determine $f'(1)$ and $f''(1)$ note that the format of $\mathcal{W}(z)$ in (22) is extremely similar to that of $\mathcal{M}$ in the frequency domain analysis. The components of $\mathcal{W}^N(z)$ are given by (8)–(10) after proper substitution of the components of $\mathcal{W}(z)$ for the ones of $\mathcal{M}$. So $f(z)$, and thus also $f'(1)$ and $f''(1)$, can be determined explicitly! After some algebra we find

$$\mu_t = \frac{1}{t} N(1+rN),$$

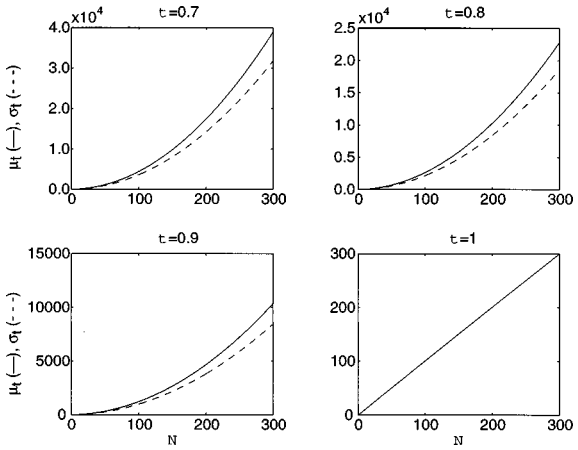

FIG. 13. Fitting of the probability distribution of the energy pulse (''marble'') arrival after k time units for various values of N and t; exact: —, fitted: ---.

$$\sigma_t^2 = \frac{2r}{3t^2} N(N+1)(1+(1+t)N+rN^2).$$

As could be expected for a diffusionlike process, the time energy pulses need to travel through the drill pipe increases quadratically with N, and so does its standard deviation. Figure 12 displays the results for different transmission coefficients t.

E. Approximation of the ''hump'' using two geometric functions only

We saw that the ''hump,'' following the ''direct-transmission-peak'' at $k=N$, is a mixture of N geometric functions. We now show that, by appropriate parameter choice, only two geometric functions suffice to approximate its shape.

In analogy to Eq. (25), we write

$$\pi_{N+2k}(N,u) = c_1(1-q_1)q_1^k + c_2(1-q_2)q_2^k, \quad k=1,2,... \tag{26}$$

thus replacing the N known geometric distributions by two distributions, the parameters of which have to be fitted to the mean and variance of the traveling time of a pulse. Note that the ''direct-transmission-peak'' is given by

$$\pi_N(N,u) = t^N. \tag{27}$$

The probabilities q_1 and q_2 and the coefficients c_1 and c_2 in (26) are chosen to satisfy

$$q_1 = \frac{a-(1+1/\hat{\mu})+\sqrt{2a-1}/\hat{\mu}}{a-1/\hat{\mu}^2-(1+1/\hat{\mu})^2},$$

$$q_2 = \frac{\hat{\mu}-q_1/(1-q_1)}{1+\hat{\mu}-q_1/(1-q_1)},$$

$$q_1 c_1 = (1-t^N) - q_2 c_2 = (1-t^N)\frac{q_1/(1-q_1)}{q_1/(1-q_1)-q_2/(1-q_2)},$$

where[10]

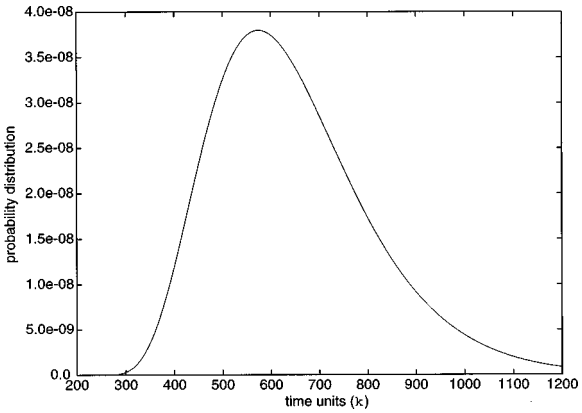

FIG. 14. Probability distribution of the energy pulse (''marble'') arrival after k time units, with energy losses at tool-joints; $N=255$, $r=0.1$, $t=0.9$, $d=0.01$.

$$a=\frac{\hat{\sigma}^2}{\hat{\mu}^2}-\frac{1}{\hat{\mu}},\quad \hat{\mu}=\frac{1}{2}\left(\frac{\mu_t-Nt^N}{1-t^N}-(N+2)\right),$$

$$\hat{\sigma}^2=\frac{1}{4}\left(\frac{\sigma_t^2}{1-t^N}-\frac{t^N}{(1-t^N)^2}(\mu_t-N)^2\right).$$

The resulting distribution, a discrete version of the continuous K_2-distribution (see Tijms, 1986, pp. 399–400), fits the mean and variance of the traveling time of a pulse, provided $\frac{1}{2}<a<1$. The fitting result is shown in Fig. 13. Apparently, only two geometrical distributions suffice to provide an excellent description of the ''hump.''

The mentioned condition on a holds when N is sufficiently large.[11] In case it does not hold, we refer to the recipe described by Adan *et al.* (1995) to find an appropriate discrete distribution to fit the ''hump.''

F. Energy dissipation

Energy dissipation in the drill pipe wall can be easily included in the model. Note that $\pi_k(N,u)$ indicates how much energy reaches the upper drill pipe end after k clock units in case there is no energy dissipation. If we assume a fraction d of the energy to dissipate in each clock cycle, the amount of energy reaching the drill pipe end after k clock units is $(1-d)^k\pi_k(N,u)$. This observation is used to obtain the results shown in Fig. 14. Only part of the signal energy reaches the upper drill pipe end. The ''hump'' therefore becomes less high, but sharper.

IV. CONCLUSIONS

In addition to the results found by Barnes and Kirkwood (1972) and Drumheller (1989), the frequency domain drill pipe model yields explicit expressions for the fine structure of the frequency response within the pass bands, of which the position along the frequency axis is found from a resonance condition as in the work of Barnes and Kirkwood (1972) and Drumheller (1989). After including energy dissipation in the model, the resonance peaks in the pass-bands become less pronounced. Small variations in pipe segment length have the same effect, but also slightly affect the position of these peaks on the frequency axis. The effect of length variations increases with frequency.

In the time domain, the drill pipe can be modeled as a Markov chain, from which expressions result for the expected time a sound signal needs to travel from one side to the other, and its standard deviation. Both increase quadratically with the number of pipe segments. Sound (pulse) propagation through drill pipe and tool-joints is comparable to a diffusion process. Energy pulses input at one end of the drill pipe are received at the other as energy ''humps'' that become flatter for decreasing transmission coefficient or for increasing drill pipe length. The ''humps'' appear to be mixtures of geometric functions. For practical purposes, their shape can be approximated well by two geometric functions only, i.e., by a discrete version of the K_2 distribution. Energy dissipation results in less flat, but smaller, output ''humps.''

ACKNOWLEDGMENTS

The research leading to this paper was done for, and partly funded by, Hollandse Signaalapparaten (HSA), Hengelo, The Netherlands, under supervision of Emiel Stolp, HSA. The derivation of the wave equation in the drill pipe wall, and the transducer model, are due to Fons van de Ven, TUE.

[1]For $|r_{jp}^2\phi^4|<1$, T can be written as $t_{pj}t_{jp}\{1+r_{jp}^2\phi^4+r_{jp}^4\phi^8+\cdots\}$. All sound waves that travel through the tool-joint are attenuated at both discontinuities, and therefore by $t_{pj}t_{jp}$. Waves that make a detour inside the tool-joint, and travel hence and forth once, have a resulting amplitude which is a factor r_{jp}^2 smaller, while their phase has changed by a factor ϕ^2. The remaining terms in the power expansion of T have a similar interpretation.

[2]The factors ϕ introduced to describe the tool-joints have a similar interpretation; we refer to footnote 1.

[3]The expression for U_N is similar to the one for T in (3). The numerators of both equations represent the effect on a sound wave of traveling through the whole configuration at once. The denominators represent the influence of sound waves that travel up and down the configurations a number of times before leaving them at the rightmost end.

[4]We assume $A_j/A_p+A_p/A_j$ to be smaller than 2. If it equals its upper bound 2, which is the case if $A_j=A_p$, then $|\tau|=|\cos\kappa L|\leqslant 1$ for all frequencies.

[5]Index e for energy.

[6]Given the pass-band width of some 250 Hz, and the pipe segment length of about 10 m, this assumption is not completely realistic. The Uncertainty Principle (Papoulis, 1984, p. 273) states that the time duration of sound signals with a bandwidth of 250 Hz is lower bounded by $\frac{1}{500}=0.002$ s; this is just equal to the time L/c sound needs to travel through a pipe segment.

[7]These are different from the amplitude reflection and transmission coefficients!

[8]We assumed complete reflection at the transducer end, and complete absorption at the upper end of the drill pipe.

[9]Note that $f(1)=\mathcal{W}_{22}^N(1)+\mathcal{W}_{21}^N(1)=1$. In terms of energy pulses, $f(1)=1$ corresponds to conservation of energy.

[10]$\hat{\mu}$ and $\hat{\sigma}^2$ are the mean and variance of the random variable $\frac{1}{2}(X-(N+2))$, where X is the traveling time a pulse needs to reach the upper end of the drill pipe, *given* that the traveling time is greater than or equal to $N+2$.

[11]Using the formulas for μ_t and σ_t^2 it is readily verified that $a\to\frac{2}{3}$ as $N\to\infty$. In most cases the condition $\frac{1}{2}<a<1$ appears to hold for small values of N already.

A finite element algorithm for the study of nonlinear standing waves

L. Elvira-Segura and E. Riera-Franco de Sarabia
Instituto de Acústica, C.S.I.C. Serrano 144, Madrid 28006, Spain

(Received 9 December 1996; accepted for publication 7 February 1998)

A finite element method (FEM) is presented for the study of nonlinear acoustic standing waves inside a chamber. The method is developed using the Galerkin–Bubnov weighted residual formulation and applied to solve the Lagrangian second-order wave equation, including thermal and viscous dissipation terms. A one-dimensional problem is studied in the frequency domain. Numerical data are compared with analytical results obtained by using a perturbation scheme for the cases of resonance and antiresonance in a rigid-walled tube with one-sided rigid or pressure release boundary condition. The FEM algorithm is shown to be well suited for the study of high-frequency standing wave fields in which the effect of absorption cannot be described by simple analytical expressions. © *1998 Acoustical Society of America.* [S0001-4966(98)05105-4]

ω_i	$i\omega$

INTRODUCTION

A numerical algorithm based on the finite element method is proposed for the study of standing wave fields. This procedure avoids some of the inherent difficulties in calculating a solution for the nonlinear acoustic wave equation. The method is specially suited to solving confined wave problems.

The normal modes theory is the main analytical tool employed for the study of a standing wave field when the wavelength and the size of the chamber are of the same order. However, if the wavelength is small in comparison with the chamber dimensions, the ray theory or statistical approaches are generally used. Nevertheless, there are intermediate cases in which none of these methods is applicable, and analytical solutions are difficult to find. If the shape of the boundaries is not regular or the geometry of the chamber is not simple, analytical solutions are also difficult to find, although modal or ray theories could be applied. In these situations, numerical methods are becoming the best way to proceed, as it is impossible to find an explicit solution for the wave equation. Finite element methods (FEM) and boundary element methods (BEM) are probably the most important of the numerical methods, for solving partial differential equations with boundary conditions. Nowadays, commercial programs based on these two methods are being developed and used for acoustic applications.

However, when the acoustic wave intensity increases, nonlinear effects become important and a change in the shape of the excitation wave is noticed. This change is related to the increase of higher harmonic amplitudes. So, linear equations are no longer valid for describing the acoustic field. An accurate general solution for the nonlinear wave equation has not yet been found and different approaches are used depending on the particular problem to be solved. The

numerical procedures are also made more complicated by nonlinearities.

Different numerical algorithms have been proposed to solve the nonlinear wave equation using Fourier series. Van Buren[1] used iterative wave superposition to compute the standing wave field inside a tube. Tjøtta and Aanonsen,[2,3] developed a numerical algorithm based on a finite difference scheme to solve the nonlinear wave equation for progressive waves. Tsuchiya and Kagawa[4] developed a finite element method to solve the nonlinear Kuznetsov equation. This method has proved to be an excellent tool for the computation of nonlinear focusing fields, improving the solutions provided by analytical methods.

In this paper, a finite element method is proposed to solve the second-order nonlinear equation in Lagrangian coordinates with thermal and viscous dissipation effects taken into account.[5] The Lagrangian coordinates are suitable for furnishing the boundary conditions, and it is precisely for this reason that these coordinates are commonly chosen for nonlinear acoustics problems in the description of standing waves. A one-dimensional problem is solved and the results are compared with the analytical results. These analytical solutions are obtained by means of a perturbation scheme for the cases of resonance and antiresonance in a rigid-walled tube with rigid or pressure release boundary conditions at one end. A piston vibrating sinusoidally is assumed at the other end.

I. THEORY

The nonlinear equation for the acoustic field inside a tube can be derived from a set of five equations with five unknowns:

The continuity equation

$$\rho_0=\rho\left(1+\frac{\partial\xi}{\partial a}\right). \tag{1}$$

The force equation

$$\rho_0\ddot{\xi}=-p'-p'_\nu. \tag{2}$$

The state equation for an ideal gas

$$P=P_0\left(\frac{\rho}{\rho_0}\right)^\gamma e^{(s-s_0/c_V)}. \tag{3}$$

The viscous dissipation equation on the walls of the tube

$$p_\nu=\frac{P_t}{S_t}\sqrt{\frac{\eta}{2\omega\rho_0}}\left(\frac{1}{\omega}\frac{\partial p}{\partial t}-p\right). \tag{4}$$

The thermal dissipation equation on the walls of the tube

$$\begin{aligned}p_t&=c_0^2\frac{\rho_0}{\gamma c_V}(s-s_0)\\&=\frac{P_t}{S_t}\sqrt{\frac{\kappa}{2\omega\rho_0 c_P}}(\gamma-1)\left(\frac{1}{\omega}\frac{\partial p}{\partial t}-p\right).\end{aligned} \tag{5}$$

It is assumed in Eqs. (4) and (5) that dissipative processes are weak. These equations, derived by Weston,[6] are based on Kirchhoff–Rayleigh's theory for wall absorption in a tube.

For second-order pressure changes, the following expansion can be substituted for Eq. (3):

$$\begin{aligned}p=P-P_0\approx c_0^2(\rho-\rho_0)&\\+c_0^2\frac{\gamma-1}{2\rho_0}(\rho-\rho_0)^2+c_0^2\frac{\rho_0}{\gamma c_V}(s-s_0).&\end{aligned} \tag{6}$$

The combination of Eqs. (1)–(6) yields to the wave equation in terms of displacement ξ,

$$(1-\sigma)\xi''-\frac{1}{c_0^2}\ddot{\xi}+\frac{\sigma}{\omega}\dot{\xi}''-2\beta\xi'\xi''=0, \tag{7}$$

where σ is the dissipation coefficient including both viscous and thermal absorption effects. This coefficient has the form

$$\sigma(\omega)=\frac{P_t}{S_t}\left(\sqrt{\frac{\eta}{2\omega\rho_0}}+(\gamma-1)\sqrt{\frac{\kappa}{2\omega\rho_0 c_P}}\right). \tag{8}$$

Equation (7) is similar to the wave equation obtained by Coppens and Sanders[7] for velocity. This nonlinear equation is simplified if there is a harmonic solution. In this case, the displacement can be expressed in terms of a Fourier expansion and Eq. (7) becomes a set of equations,

$$(1-\sigma_k)g_k''+\frac{\omega_k^2}{c_0^2}g_k+\sigma_k h_k''=fc_k, \tag{9a}$$

$$(1-\sigma_k)h_k''+\frac{\omega_k^2}{c_0^2}h_k-\sigma_k g_k''=fs_k,\quad k=0,1,2,..., \tag{9b}$$

where g_k and h_k are the Fourier coefficients of the expansion

$$\xi(a,t)=g_0(a)+\sum_{i=1}^{\infty}g_i(a)\cos(i\omega t)+h_i(a)\sin(i\omega t), \tag{10}$$

and the nonlinear terms fc_k and fs_k take the form

$$fc_0=\beta\left(2g_0'g_0''+\sum_{j=1}^{\infty}g_j'g_j''+h_j'h_j''\right), \tag{11a}$$

$$\begin{aligned}fc_k=\beta\Bigg(&\frac{1}{2}\sum_{j=0}^{k}(g_j'g''_{k-j}+g_j''g'_{k-j}-h_j'h''_{k-j}-h_j''h'_{k-j})\\&+\sum_{j=k}^{\infty}(g_j'g''_{j-k}+g_j''g'_{j-k}+h_j'h''_{j-k}+h_j''h'_{j-k})\Bigg),\end{aligned} \tag{11b}$$

$$\begin{aligned}fs_k=\beta\Bigg(&\frac{1}{2}\sum_{j=0}^{k}(h_j'g''_{k-j}+h_j''g'_{k-j}+g_j'h''_{k-j}+g_j''h'_{k-j})\\&+\sum_{j=k}^{\infty}(h_j'g''_{j-k}+h_j''g'_{j-k}-g_j'h''_{j-k}-g_j''h'_{j-k})\Bigg),\\&k=1,2,...\,.\end{aligned} \tag{11c}$$

If monochromatic excitation is assumed, higher harmonics tend to vanish. In fact, harmonics of third and larger order may be disregarded in a second-order approach. In this case, the infinite set of Eqs. (9) is reduced to a set of five equations

$$(1-\sigma_1)g_1''+\frac{\omega^2}{c_0^2}\,g_1+\sigma_1 h_1''=0, \tag{12a}$$

$$(1-\sigma_1)h_1''+\frac{\omega^2}{c_0^2}\,h_1-\sigma_1 g_1''=0, \tag{12b}$$

$$(1-\sigma_2)g_2''+\frac{(2\omega)^2}{c_0^2}\,g_2+\sigma_2 h_2''=\beta(g_1'g_1''-h_1'h_1''), \tag{12c}$$

$$(1-\sigma_2)h_2''+\frac{(2\omega)^2}{c_0^2}\,h_2-\sigma_2 g_2''=\beta(h_1'g_1''+g_1'h_1''), \tag{12d}$$

$$g_0''=\beta(g_1'g_1''+h_1'h_1''). \tag{12e}$$

In the following, a solution for this set of equations is proposed using a finite element algorithm.

II. FINITE ELEMENT EQUATIONS

To overcome the difficulty in finding a general solution for these differential equations, finite element methods propose a discretization of the continuum problem. In addition, it is possible to approach the true continuum solution as closely as desired as the number of discrete variables increases.

Two different procedures are available to integrate the discrete approximation proposed: the methods of weighted residuals and the determination of variational functionals.[8] The former was chosen in the present work as it is quite general and easy to apply. There are various types of weighted residual methods. Of these, the Bubnov–Galerkin method is widespread as it frequently leads to symmetric matrices, which increases the speed of the numerical algorithm computation. This is therefore the method used in our work.

Once our problem is discretized into a finite number of elements; the unknown functions g_k and h_k in each element of the domain are approximated by the expansions:

$$g_k=dg_{ki}\;\varphi^i(a), \tag{13a}$$

$$h_k=dh_{ki}\;\varphi^i(a), \tag{13b}$$

where the Einstein summation criterion is used. Functions φ^i are the interpolating polynomials. In these expansions, the number of terms is the same as the number of nodes in each element.

Using Eqs. (13) and integrating, the differential equations (9) are replaced by a set of integral equations

$$\int (1-\sigma_k)dg_{ki}\;\varphi''^i\varphi^j\,da+\int \frac{\omega^2}{c_0^2}\,k^2\,dg_{ki}\;\varphi^i\varphi^j\,da + \int \sigma_k\,dh_{ki}\;\varphi''^i\varphi^j\,da-\int fc_k\varphi^j\,da=0, \tag{14a}$$

$$\int (1-\sigma_k)dh_{ki}\;\varphi''^i\varphi^j\,da+\int \frac{\omega^2}{c_0^2}\,k^2\,dh_{ki}\;\varphi^i\varphi^j\,da - \int \sigma_k\,dg_{ki}\;\varphi''^i\varphi^j\,da-\int fs_k\varphi^j\,da=0, \tag{14b}$$

where constant terms can be taken out of the integrals.

Using a matrix formulation, Eqs. (14) can be rewritten as

$$(\mathbf{M_k}+\mathbf{K_k})\mathbf{dg_k}+\mathbf{C_k}\mathbf{dh_k}=\mathbf{FCc_k}+\mathbf{FNc_k}, \tag{15a}$$

$$(\mathbf{M_k}+\mathbf{K_k})\mathbf{dh_k}-\mathbf{C_k}\mathbf{dg_k}=\mathbf{FCs_k}+\mathbf{FNs_k}, \tag{15b}$$

where

$$\mathbf{K_k}=(1-\sigma_k)\int [\varphi'^i][\varphi'^j]da, \tag{16a}$$

$$\mathbf{M_k}=-\frac{\omega^2}{c_0^2}\,k^2\int [\varphi^i][\varphi^j]da, \tag{16b}$$

$$\mathbf{C_k}=\sigma_k\int [\varphi'^i][\varphi'^j]da, \tag{16c}$$

$$\mathbf{FCc_k}=(1-\sigma_k)[dg_{ki}\;\varphi'^i\varphi^j|_{a_{ini}}^{a_{fin}}]+\sigma_k[dh_{ki}\;\varphi'^i\varphi^j|_{a_{ini}}^{a_{fin}}], \tag{16d}$$

$$\mathbf{FCs_k}=(1-\sigma_k)[dh_{ki}\;\varphi'^i\varphi^j|_{a_{ini}}^{a_{fin}}]-\sigma_k[dg_{ki}\;\varphi'^i\varphi^j|_{a_{ini}}^{a_{fin}}], \tag{16e}$$

$$\mathbf{FNc_k}=-\int [fc_k][\varphi^j]da, \tag{16f}$$

$$\mathbf{FNs_k}=-\int [fs_k][\varphi^j]da. \tag{16g}$$

In these relations the subscript k refers to the harmonic, **M** is the mass matrix, **K** is the stiffness matrix, **C** is the absorption matrix, **FCc** and **FCs** include information about the boundary conditions and, finally, **FNc** and **FNs** are the nonlinear terms.

To find the solution for the system, Eqs. (15) must be first solved for $k=1$. In this case, the nonlinear terms are zero. The results obtained for g_1 and h_1 are then used to compute **FNc** and **FNs**, making it possible to find the solutions for $k=0$ and $k=2$.

III. ANALYTICAL SOLUTIONS

Analytical results may be used to validate the numerical algorithm developed. The case of a closed rigid-walled tube excited at one end is studied. At the other end two different boundary conditions (a rigid end and a pressure-release end) are investigated; the case of. The differential equations relating to the fundamental components are linear [see Eqs. (12)]. This implies that an exact solution for these terms can be found. The boundary conditions applied for the rigid termination are

$$\xi(0,t)=\Xi_0\,\cos(\omega t), \tag{17a}$$

$$\xi(l,t)=0, \tag{17b}$$

and the solutions for the components relating to the fundamental frequency are:

$$g_1=\frac{\Xi_0}{\sinh^2(\alpha_1 l)\cos^2(k_1 l)-\cosh^2(\alpha_1 l)\sin^2(k_1 l)} \times[\sinh(\alpha_1(l-a))\sinh(\alpha_1 l)\cos(k_1(l-a))\cos(k_1 l) -\cosh(\alpha_1(l-a))\cosh(\alpha_1 l)\sin(k_1(l-a))\sin(k_1 l)], \tag{18a}$$

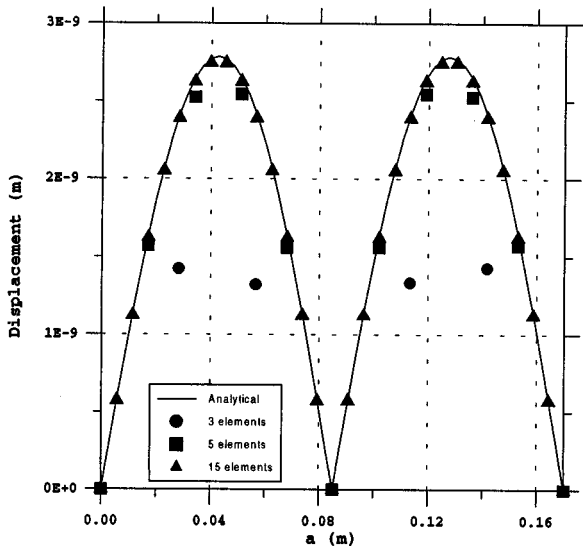

FIG. 1. Tube with rigid boundary condition at the end. Displacement for $k=0$. Resonance.

$$h_1=\frac{\Xi_0}{\sinh^2(\alpha_1 l)\cos^2(k_1 l)-\cosh^2(\alpha_1 l)\sin^2(k_1 l)}\times[\sinh(\alpha_1(l-a))\cosh(\alpha_1 l)\cos(k_1(l-a))\sin(k_1 l)-\cosh(\alpha_1(l-a))\sinh(\alpha_1 l)\sin(k_1(l-a))\cos(k_1 l)], \tag{18b}$$

where

$$k_1=\frac{\omega}{c_0}\left(1+\frac{\sigma_1}{2}\right), \tag{19a}$$

$$\alpha_1=\frac{\omega\sigma_1}{2c_0}. \tag{19b}$$

The nonlinear terms are calculated for resonance and antiresonance, giving the following expressions for the rigid-end case:

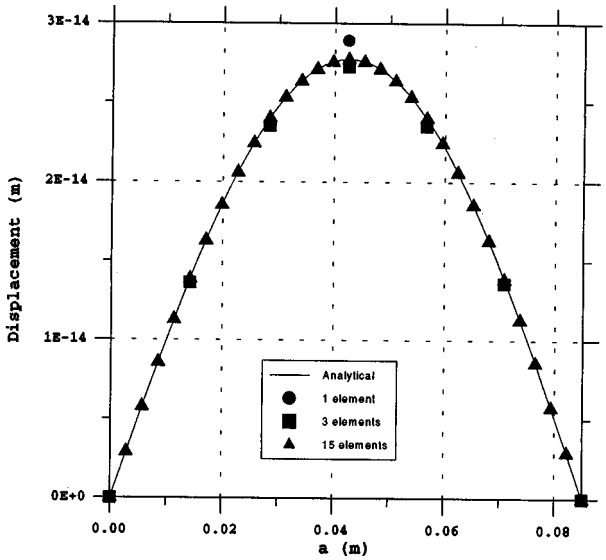

FIG. 2. Tube with rigid boundary condition at the end. Displacement for $k=0$. Antiresonance.

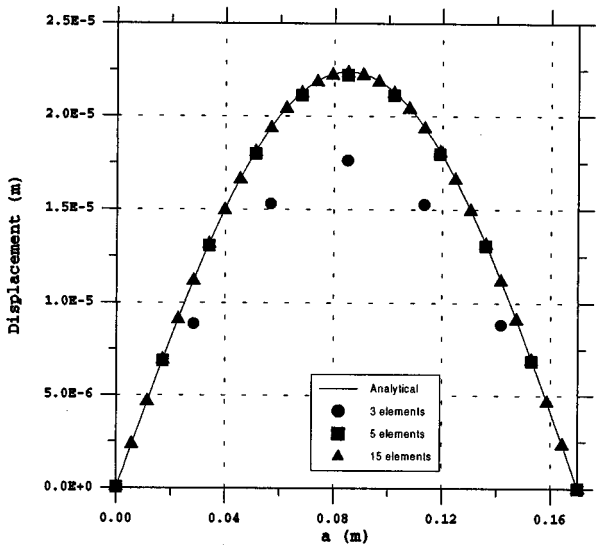

FIG. 3. Tube with rigid boundary condition at the end. Displacement for $k=1$. Resonance.

$$\text{Resonance}\quad k_1 l=n\pi, \tag{20a}$$

$$\text{Antiresonance}\quad k_1 l=(2n-1)(\pi/2)\quad n=1,2,\ldots. \tag{20b}$$

In both cases, Eqs. (18) are reduced to a simpler form. Retaining only terms of first and second order, the solutions found are:

Resonance

$$g_1=\frac{\Xi_0(-1)^n(l-a)}{l}\cos(k_1(l-a)), \tag{21a}$$

$$h_1=-\frac{\Xi_0(-1)^n}{\alpha_1 l}\sin(k_1(l-a)), \tag{21b}$$

$$g_2=\frac{\beta}{16}\left(\frac{\Xi_0}{\alpha_1 l}\right)^2\frac{k_1}{\sigma_1}\sin(2k_1(l-a)), \tag{21c}$$

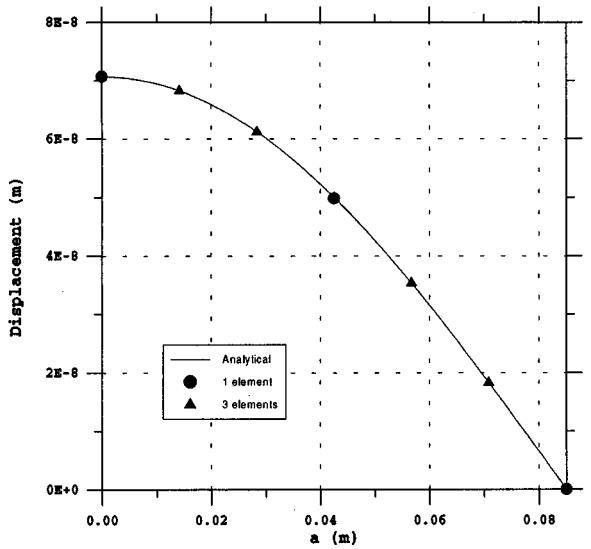

FIG. 4. Tube with rigid boundary condition at the end. Displacement for $k=1$. Antiresonance.

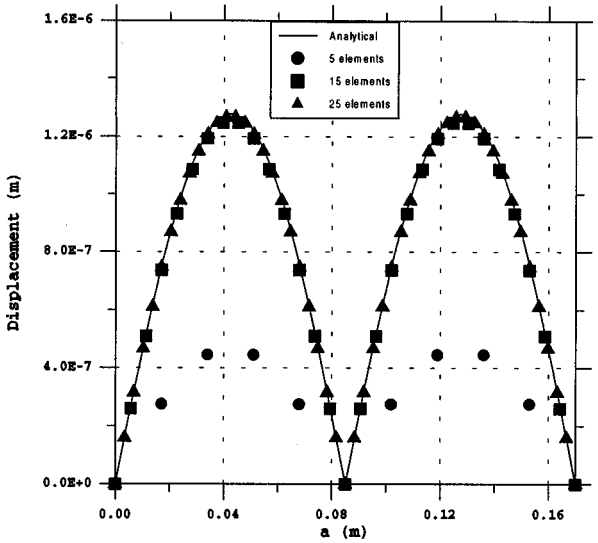

FIG. 5. Tube with rigid boundary condition at the end. Displacement for $k=2$. Resonance.

$$h_2=\frac{\beta}{16}\left(\frac{\Xi_0}{\alpha_1 l}\right)^2\frac{k_1}{\sigma_1}(\sqrt{2}+1)\sin(2k_1(l-a)), \tag{21d}$$

$$g_0=-\frac{\beta}{8}\left(\frac{\Xi_0}{\alpha_1 l}\right)^2 k_1\ \sin(2k_1(l-a)). \tag{21e}$$

These solutions are consistent with the results obtained by Coppens and Sanders,[7]

Antiresonance

$$g_1=-\Xi_0(-1)^n\ \sin(k_1(l-a)), \tag{22a}$$

$$h_1=-\Xi_0(-1)^n\alpha_1(l-a)\cos(k_1(l-a)), \tag{22b}$$

$$g_2=-\frac{\beta}{16}\Xi_0^2\frac{k_1}{\sigma_1}\sin(2k_1(l-a)), \tag{22c}$$

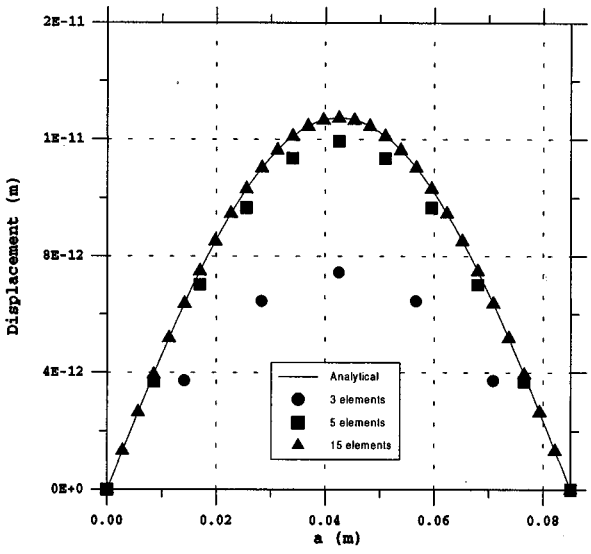

FIG. 6. Tube with rigid boundary condition at the end. Displacement for $k=2$. Antiresonance.

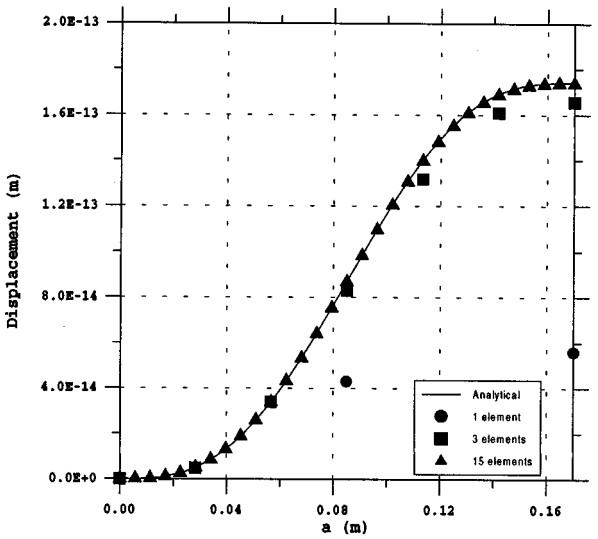

FIG. 7. Tube with pressure release boundary condition at the end. Displacement for $k=0$. Antiresonance.

$$h_2=-\frac{\beta}{16}\Xi_0^2\frac{k_1}{\sigma_1}(\sqrt{2}+1)\sin(2k_1(l-a)), \tag{22d}$$

$$g_0=-\frac{\beta}{8}\Xi_0^2 k_1\ \sin(2k_1(l-a)). \tag{22e}$$

The pressure-release boundary condition was also studied for the end of the tube. The boundary conditions applied in this case were:

$$\xi(0,t)=\Xi_0\ \cos(\omega t), \tag{23a}$$

$$\left.\frac{\partial\xi(a,t)}{\partial a}\right|_{a=l}=0. \tag{23b}$$

However, the conditions for resonance and antiresonance are now reversed:

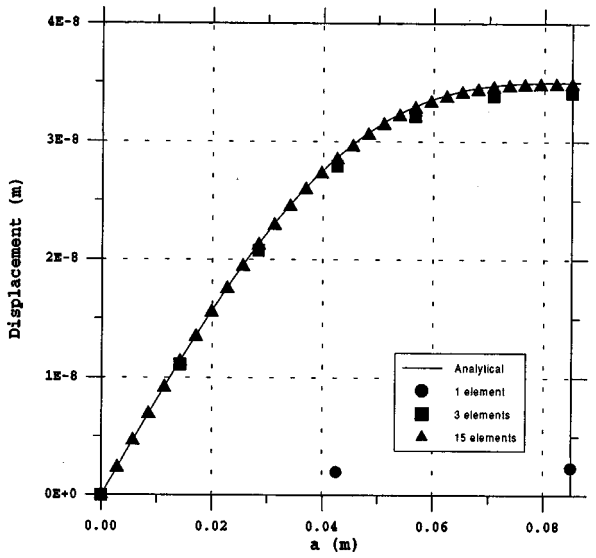

FIG. 8. Tube with pressure release boundary condition at the end. Displacement for $k=0$. Resonance.

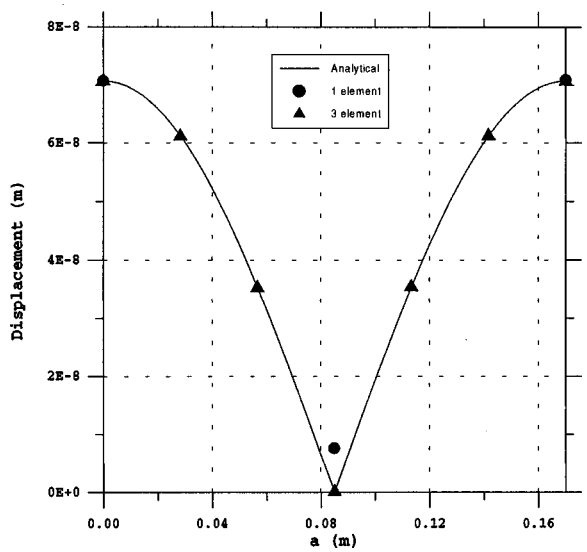

FIG. 9. Tube with pressure release boundary condition at the end. Displacement for $k=1$. Antiresonance.

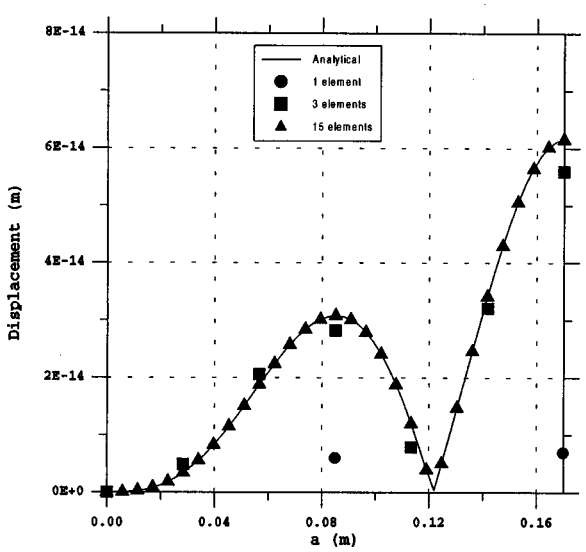

FIG. 11. Tube with pressure release boundary condition at the end. Displacement for $k=2$. Antiresonance.

$$\text{Resonance} \quad k_1 l=(2n-1)(\pi/2), \tag{24a}$$

$$\text{Antiresonance} \quad k_1 l=n\pi \quad n=1,2,\ldots . \tag{24b}$$

The analytical results are:

Resonance

$$g_1=-\frac{\Xi_0(-1)^n(l-a)}{l}\sin(k_1(l-a)), \tag{25a}$$

$$h_1=-\frac{\Xi_0(-1)^n}{\alpha_1 l}\cos(k_1(l-a)), \tag{25b}$$

$$g_2=\frac{\beta}{16}\left(\frac{\Xi_0}{\alpha_1 l}\right)^2 k_1[\sin(2k_1(l-a))+2k_1 a \times\cos(2k_1(l-a))], \tag{25c}$$

$$h_2=0, \tag{25d}$$

$$g_0=\frac{\beta}{8}\left(\frac{\Xi_0}{\alpha_1 l}\right)^2 k_1[2k_1 a+\sin(2k_1(l-a))]. \tag{25e}$$

Antiresonance

$$g_1=\Xi_0(-1)^n\cos(k_1(l-a)), \tag{26a}$$

$$h_1=-\Xi_0(-1)^n\alpha_1(l-a)\sin(k_1(l-a)), \tag{26b}$$

$$g_2=-\frac{\beta}{16}\Xi_0^2 k_1[\sin(2k_1(l-a))+2k_1 a \times\cos(2k_1(l-a))], \tag{26c}$$

$$h_2=0, \tag{26d}$$

$$g_0=\frac{\beta}{8}\Xi_0^2 k_1[2k_1 a+\sin(2k_1(l-a))]. \tag{26e}$$

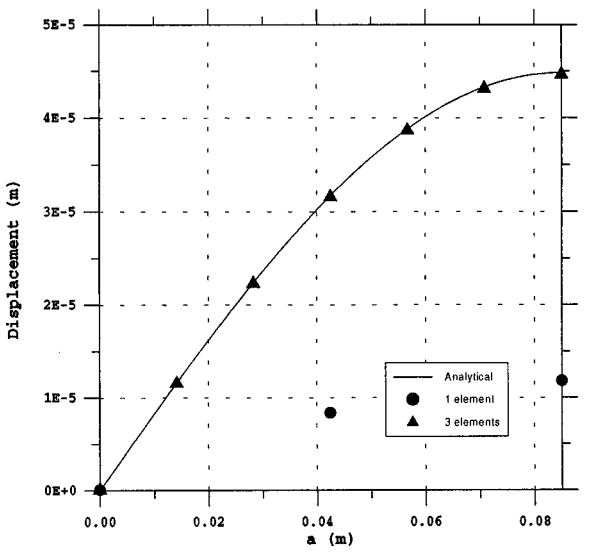

FIG. 10. Tube with pressure release boundary condition at the end. Displacement for $k=1$. Resonance.

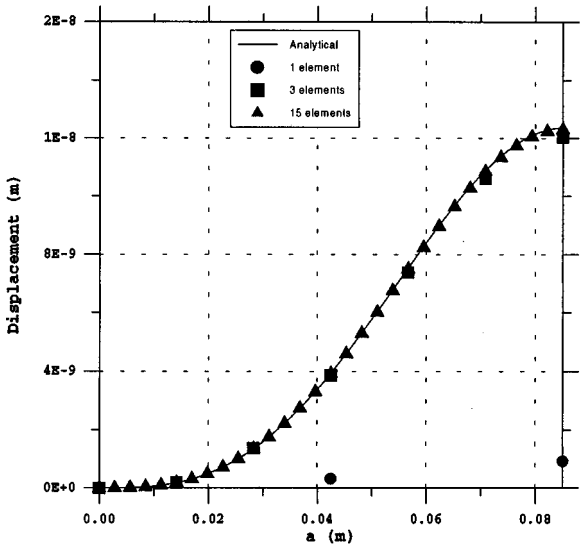

FIG. 12. Tube with pressure release boundary condition at the end. Displacement for $k=2$. Resonance.

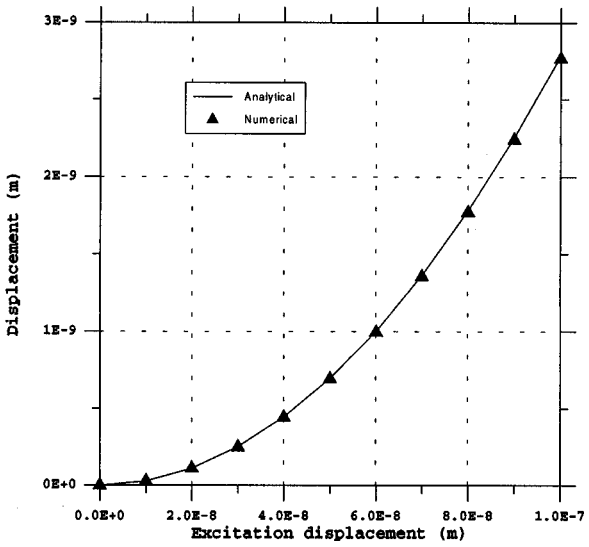

FIG. 13. Displacement of the $k=0$ component versus excitation level.

Further interesting acoustical magnitudes can be obtained from these results. Velocity can be found, for example, by derivating displacement with respect to time. Other magnitudes such as pressure or density can be calculated using Eqs. (1)–(5).

IV. NUMERICAL RESULTS

The same four cases were studied numerically, using the new finite element algorithm. Different meshes or discretizations were tested. It should be noted that the derivatives which relate to the nonlinear terms within the integrals are of second order. Accordingly, interpolating polynomials φ^i of second or higher order must be used.

A. Displacement distribution

The displacement distribution inside the chamber was studied for the cases mentioned above. The results presented

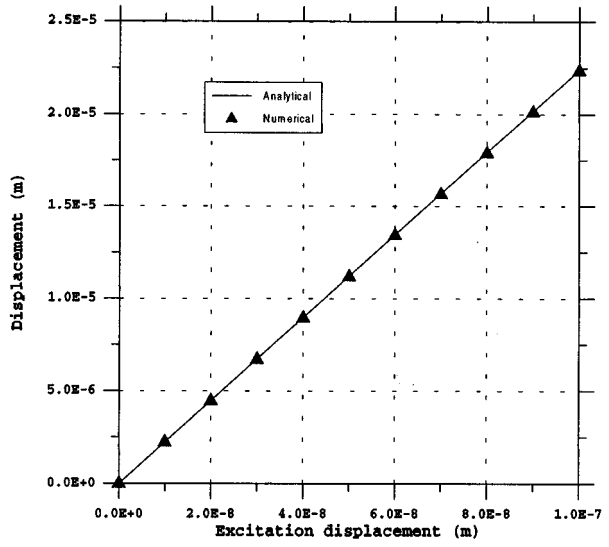

FIG. 14. Displacement of the $k=1$ component versus excitation level.

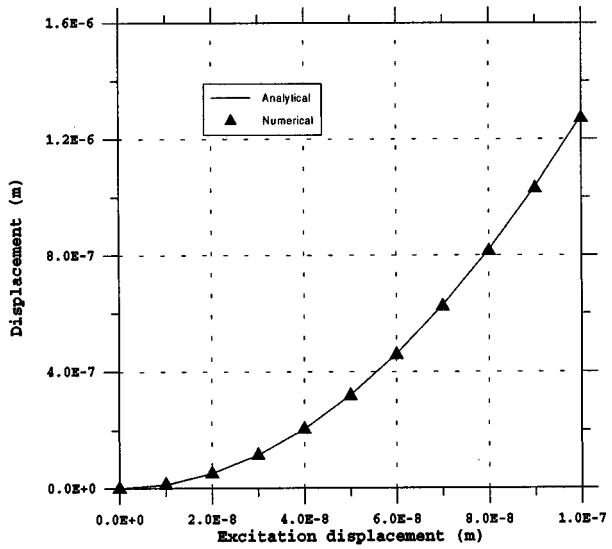

FIG. 15. Displacement of the $k=2$ component versus excitation level.

were obtained for a 1-kHz sinusoidal excitation and 0.1-μm displacement amplitude. The displacement distributions for $k=0,1,2$ are displayed separately. These results are plotted in terms of the rms displacement of the ith harmonic

$$\langle \xi_0 \rangle_{\mathrm{rms}} = g_0 , \tag{27a}$$

$$\langle \xi_i \rangle_{\mathrm{rms}} = \frac{\sqrt{g_i^2 + h_i^2}}{\sqrt{2}} \quad i=1,2. \tag{27b}$$

Figures 1–6 relate to the tube with a rigid end and Figs. 7–12 plot the results obtained assuming a pressure-release end. The length of the tube is adjusted to achieve either resonance or antiresonance

It can be seen from Figs. 1–12 that a good fit between analytical (continuous line) and numerical data (discrete points) is obtained. Establishing the number of elements needed to obtain accurate solutions is usually done by running the numeric algorithm with different meshes. An element length of $\lambda/4$ is often chosen for wave problems. This criterion gives for a nonlinear, second-order approach a minimum element length of $\lambda/8$. Figures 1–12 show that this criterion adequately describes the qualitative behaviour of the acoustic field but the absolute values obtained are not

TABLE I. Tube radii, absorption and tube length considered as a function of the driving frequency.

Frequency (Hz)	Tube radii (m)	Absorption coefficient σ	Tube length (m) first resonance
1000	0.049	0.00209	0.171
2000	0.024	0.00301	0.0856
3000	0.016	0.00369	0.0571
4000	0.012	0.00426	0.0428
5000	0.0099	0.00463	0.0342
6000	0.0083	0.00504	0.0285
7000	0.0071	0.00543	0.0244
8000	0.0062	0.00584	0.0214
9000	0.0055	0.00618	0.0190
10 000	0.0050	0.00646	0.0171

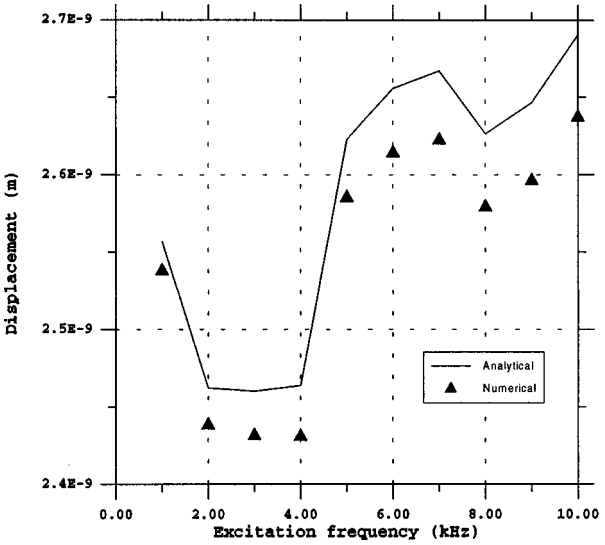

FIG. 16. Maximum displacement as a function of the frequency for the $k=0$ component.

accurate, which is due to the important changes caused by discretization near resonance conditions. This explanation is consistent with the results obtained which, for the antiresonance cases, converge faster than those for the cases of resonance. As was expected, the fundamental frequency displacement converges faster than the displacements relating to the rest of the frequency components. In any case, 30 elements per wavelength were enough to obtain accurate numerical data for the problems studied.

B. The effect of displacement amplitude of the excitation

Figures 13–15 show the relation between the amplitude of the excitation and the level obtained for the different harmonics. These results correspond to the maximum rms displacement inside the chamber when the rigid-end tube is excited at the resonance frequency (1 kHz).

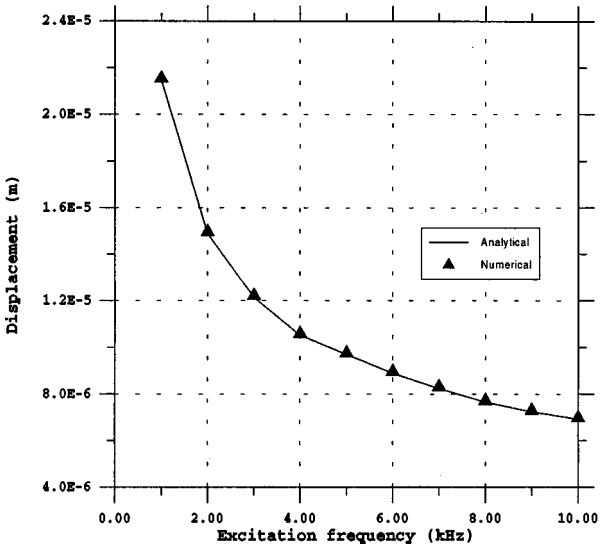

FIG. 17. Maximum displacement as a function of the frequency for the $k=1$ component.

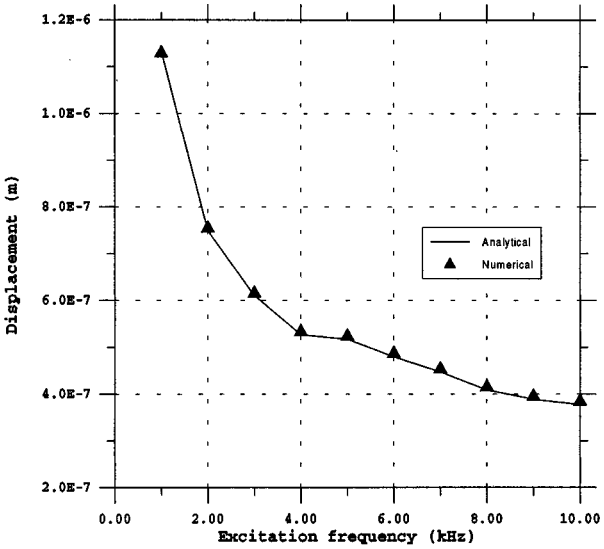

FIG. 18. Maximum displacement as a function of the frequency for the $k=2$ component.

It can be seen from these figures (13–15) that the relationship between the excitation level and the fundamental frequency displacement, follows a straight line. The other two components show a parabolic behavior related to the square exponent appearing in the corresponding Fourier coefficients [see Eqs. (21)].

C. The effect of absorption at high frequency

At higher frequencies, the absorption in the tube increases. This is a consequence of the frequency dependence of this coefficient. Besides this, the tube has to be narrower to avoid propagation of transverse modes. For small tube radii, the absorption increases even further (see Table I). Figures 16–18 show the pressure levels obtained at different frequencies for $k=0,1,2$. The resonance is kept by choosing an adequate tube length.

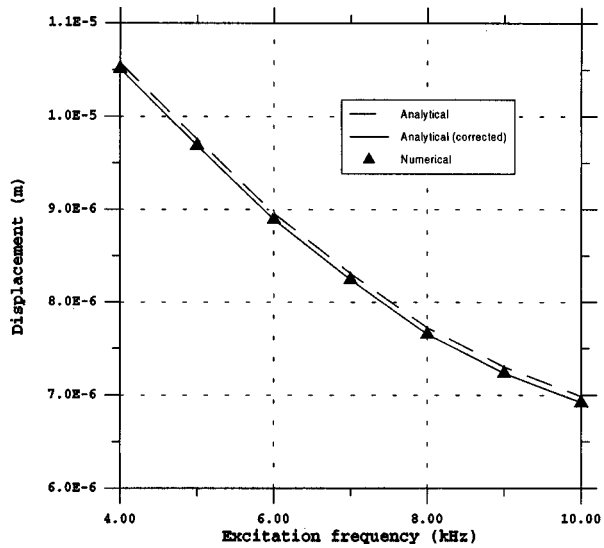

FIG. 19. Maximum displacement as a function of the frequency for the $k=1$ component.

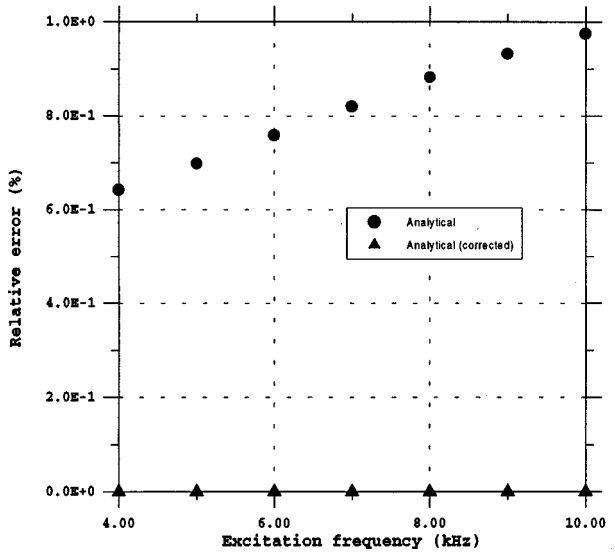

FIG. 20. Error in the numeric results when they are compared to the analytic solution or the analytic corrected one.

Discrepancies appear between the numerical and analytical results when the frequency (and the absorption) increases. Although the difference is obvious for $k=0$, a careful study shows that there are also differences between analytical and numerical data for the other two components. These discrepancies derive from the approximations made to obtain the analytical solutions [Eqs. (18)–(21)]. This can be easily shown for the fundamental, because in this case the exact solution can be calculated analytically [Eqs. (17)]. For the rest of the harmonics it is extremely complicated.

Figures 19 and 20 show these results. It can be seen that the difference between the corrected analytical solution and the approximated analytical solution increases with frequency. However, numerical data fit the former exactly, and there is no appreciable error.

V. CONCLUSIONS

A finite element algorithm was developed to describe nonlinear one-dimensional standing waves. The method incorporates perturbation techniques and it leads to the expression of displacement as a Fourier expansion. This numerical approach was checked against analytical solutions obtained for several special situations (resonance and antiresonance, with rigid and pressure-release boundary conditions), and proved to be accurate. The method can also be applied to problems where the tube is out of resonance or out of antiresonance and different boundary conditions are established at the end.

This numerical procedure is well suited for the study of high frequency standing fields, for which the effect of absorption leads to inaccurate analytic predictions (this inaccuracy was due to the approximations made to obtain these solutions).

Future work would give an expansion of the finite element method to simulate 2-D and 3-D nonlinear fields, where there are even fewer analytical results than in the 1-D case. It is precisely for these 2-D and 3-D problems where the finite element method is clearly advantageous over other numerical approaches, giving accurate solutions for a large number of different cases, no matter how irregular the geometry of the problem. For this reason, this method will probably play an important role in the study and design of finite-amplitude wave systems in the near future.

The acoustic radiation force in lossless fluids in Eulerian and Lagrangian coordinates

K. Beissner
Physikalisch-Technische Bundesanstalt, 38116 Braunschweig, Germany

(Received 21 November 1996; accepted for publication 7 February 1998)

A general theory of the (Langevin) acoustic radiation force in three-dimensional fields in lossless fluids in Eulerian and Lagrangian coordinates is given. It is based on Brillouin's approach of an acoustic radiation stress identified in Eulerian coordinates with the negative time average of the momentum flux density and in Lagrangian coordinates with the time average of the Piola–Kirchhoff–Boussinesq stress. It is shown in comparison to other statements from the literature that these stresses are not in general identical but that in the linear-acoustics approximation, the difference between the results in the two representations vanishes if the radiation force acting on an object entirely surrounded by the sound-propagating fluid is considered. It is just this situation which is of experimental relevance.

INTRODUCTION

The acoustic radiation force is the time-average force exerted by an acoustic field on an object (''target'') or on a boundary surface. In scientific practice it occurs as an unintentional effect under various circumstances, but its importance lies in its intentional and quantitative use for which at least three main areas can be identified, namely: (a) The radiation force on a large target as measured by a radiation force balance[1,2] and serving as a measure of the ultrasonic power; (b) the radiation force on a small target as measured by a sphere radiometer[3] and serving as a measure of the ultrasonic intensity; (c) the radiation force on small liquid and solid samples[4] for purposes of separation techniques and for levitation and positioning purposes, with the aim of a containerless processing.[5] In all these cases, it is important to theoretically and quantitatively understand the acoustic radiation force. This applies particularly to application (a) which is regarded as a primary measurement method and for which theoretical knowledge is necessary to obtain the ultrasonic power from the radiation force measured. This means that the acoustic radiation force theory is one of the cornerstones of the exposimetry of current medical ultrasonic equipment.

Lord Rayleigh,[6] Paul Langevin (as reported by P. Biquard[7]), Léon Brillouin,[8] and Gustav Hertz (in cooperation with H. Mende[9]) in particular influenced the early development of the acoustic radiation force theory. Hertz and Mende[9] introduced the formal distinction between the Rayleigh and the Langevin radiation force (cf. also Ref. 10). The former is defined as the force acting on the wall of a closed vessel containing the sound-propagating medium. The latter is defined as the force exerted on a target in an open vessel in which the general hydrostatic pressure (which is determined by the atmospheric pressure in this case) acts on both sides of the target and does, therefore, not enter into the radiation force result. The present paper deals with the time-average force exerted by an arbitrary, steady-state sound field on an arbitrary target entirely surrounded by the sound-propagating fluid. This situation falls under the Langevin case and covers all three application areas mentioned above. It should be noted that the field is here generally understood in the presence of the target. If this is to be traced back to the field in the absence of the target, a suitable calculation or conclusion has to be added, unless this is already contained in the results as, for example, in the so-called case 3 application below where $\hat{p}$ is the pressure amplitude of the incident wave. The present paper does not deal with particular field/target configurations but only with the fundamentals and with rather simple examples involving certain basic field types. The general results obtained can be applied to any specific problem of interest.

While radiation force methods based on the Langevin situation are in current use and the radiation force balance method (a) has been successfully tested in international intercomparisons,[11] the Rayleigh radiation force discussion so far appears to be in a more difficult state. A number of (controversial) plane-wave calculations based on particular field solutions under various boundary conditions have been made (for a review and a subsequent discussion, cf. Refs. 12 and 13), but the problem has not yet been solved by experiment and will not be dealt with here.

The fundamentals of the theory of the Langevin radiation force given in this paper are taken from Brillouin and, in a certain sense, from Langevin. According to the Brillouin approach,[8] the radiation force is due to an acoustic radiation stress (tensor) which is identified in Eulerian coordinates with the negative time average of the momentum flux density (with some terminological differences in the literature) and in Lagrangian coordinates with the time average of a quantity which has been referred to by Brillouin[8,14] as the Boussinesq stress and elsewhere[14–16] as the (first) Piola–Kirchhoff stress and which will here be simply regarded as the stress in Lagrangian coordinates and referred to as the Piola–Kirchhoff–Boussinesq stress. The latter quantity has been used so far in the radiation stress literature only for calculations concerning solids.[8,14] Most radiation force theories for

fluids have started from the Eulerian version of the Brillouin approach (see Sec. II below). The question of a Lagrangian radiation force theory for fluids according to the Brillouin approach has until now remained open[17] and will be answered here. The answer is not straightforward but makes it necessary to more closely consider the stress in Lagrangian coordinates and a number of formal relations important for the theory. In addition and as a reference, the Eulerian version will be given for comparison purposes.

The Eulerian (i.e., spatial) and the Lagrangian (i.e., material) description of fluid (and solid) motions both have specific advantages and disadvantages. The Lagrangian one is generally regarded as more cumbersome but may be advantageous if the boundary surface between two media moves in the Eulerian space but is at rest in Lagrangian coordinates. The Lagrangian version of Brillouin's radiation force theory for fluids is worked out here first, for having a complete theory in both representations and second, for comparing it with another Lagrangian radiation force theory which can sometimes be found in the literature and will be briefly quoted below and discussed in the Appendix.

The important comparison of the Eulerian with the Lagrangian results of the Brillouin approach will be dealt with in this paper but has also been discussed in the literature. Brillouin[8] found agreement between his plane-wave results for solids. This is in line with the plane-wave agreement found here (although the calculation methods are completely different) but it cannot be extended to arbitrary fields which Brillouin may have had in mind. Cantrell[14] postulated a general identity between the two versions of radiation stresses for arbitrary, three-dimensional fields.[18] The present paper, on the other hand, produces the result that the two versions of radiation stresses are in general different but that the difference becomes irrelevant if the radiation force acting on an object entirely surrounded by the sound-propagating fluid is considered.

The expressions obtained directly from the Brillouin approach are not sufficient for practical radiation force calculations as they contain in both representations (see below) the time-average acoustic pressure at least in the second-order approximation. Brillouin and a number of more recent authors in addition used certain plane-wave restrictions and boundary conditions[19] to arrive at practical results. It is better to use modifications of the field equations themselves in order to obtain results which are valid for any three-dimensional field type. This way of proceeding has been shown by the author for the Eulerian version[2,19,20] and it will here again be applied to the Lagrangian version, however along different lines, of course. The modified field equations to be used for this purpose go back to Langevin[7,21] and have on occasion[22] been referred to as ''Langevin's first relation'' for the Lagrangian version and as ''Langevin's second relation'' for the Eulerian version. So the general radiation force theory given below is a combination of the two representations of the Brillouin approach with Langevin's relations, but the benefits of such a combination were obviously not realized by the two authors themselves.[22]

Langevin[7] himself used his first relation in a different way. He considered the radiation force to be due to an acoustic radiation ''pressure'' and identified it with the Lagrangian time average of the acoustic pressure which according to his first relation is equal to the time average of the total acoustic energy density plus a constant which is not relevant to the Langevin situation. This approach has been repeated in the literature[12,23,24] and is briefly discussed in the Appendix.

This paper deals with a number of matrix quantities. The question of their behavior in a transformation of coordinates will not be discussed in detail but answered in summary. The paper does not consider curvilinear coordinates and covariant and contravariant vector and tensor components but only rectangular Cartesian coordinate systems. The tensor behavior in a transformation from one Cartesian system to another has been described, for example, in Refs. 25–27. Matrix quantities following these rules have been referred to as Cartesian tensors.[25,26] The following can be derived from the references mentioned: (1) The Cauchy stress[15,28] is known to be a tensor and thus also a Cartesian tensor, of course. (2) The determinant of a Cartesian tensor is an invariant. (3) The unit matrix is a Cartesian tensor. (4) The product of a scalar with a Cartesian tensor is a Cartesian tensor. (5) The product of two matrices each of which is a Cartesian tensor is also a Cartesian tensor. (6) The transpose of a Cartesian tensor is a Cartesian tensor. (7) The inverse of a Cartesian tensor is a Cartesian tensor. (8) The dyadic product of two vectors is a Cartesian tensor. (9) The gradient of a vector (cf. below) is a Cartesian tensor.

It follows from these rules that all the matrices appearing below, namely **B**, **B**′, **F**, **G**, **H**, **K**, **M**, **S**, **T**, and **U**, are Cartesian tensors.[29]

I. DEFINITIONS AND TERMINOLOGY

The physical quantities are understood here with reference to a (rectangular) Cartesian coordinate system whose axes are numbered from 1 to 3. Stresses are represented by matrices. For example, the Cauchy stress which is the usual mechanical stress in Eulerian coordinates is given by

$$\mathbf{T}=\begin{pmatrix} T_{11} & T_{12} & T_{13} \\ T_{21} & T_{22} & T_{23} \\ T_{31} & T_{32} & T_{33} \end{pmatrix}. \tag{1}$$

The indices are understood according to the following example:[27,28,30,but cf. 31] T_{12} is the force component in direction No. 2 per unit area of the surface perpendicular to direction No. 1. There are two implications of this convention. First, the infinitesimal force vector **df** exerted across an infinitesimal surface element which is characterized by its normal, infinitesimal vector **da** is given by

$$\mathbf{df}=\mathbf{da}\cdot\mathbf{T}, \tag{2}$$

i.e., the surface element vector is postmultiplied by the stress matrix. Second, this convention implies the special form of the vector gradient, the matrix divergence and the matrix curl given below. A different definition of the stress indices would imply different forms of these operators. The foregoing discussion might appear superfluous as the Cauchy stress is known to be symmetric, i.e., $\mathbf{T}=\mathbf{T}^T$ where the superscript T characterizes the transpose, but with respect to the other

stresses to be discussed, allowance is made for unsymmetric stresses, at least formally.

Products of physical quantities are represented here as follows. If at least one of the two factors is a scalar quantity, no multiplication symbol is used. If both factors are higher-rank quantities, the following symbols are used. The dot $\cdot$ characterizes the scalar product of two vectors or the product of a vector with a matrix[32] or the product of two matrices. The symbol $\otimes$ characterizes the dyadic product of two vectors. The symbol $\times$ characterizes the vector product of two vectors or the vector product of a vector with a matrix.

Let q be a general symbol for a scalar quantity, $\mathbf{q}$ for a vector quantity, and $\mathbf{Q}$ for a matrix, all being regarded as functions of the position vector $\mathbf{x}=(x_1,x_2,x_3)$. The well-known, conventional differential operators grad, div, and curl can be extended to a higher order by defining the gradient of a vector, grad $\mathbf{q}=\boldsymbol{\nabla}\otimes\mathbf{q}$, which is a matrix according to[25,33]

$$(\text{grad } \mathbf{q})_{ij}=\frac{\partial q_j}{\partial x_i}, \tag{3}$$

the divergence of a matrix, div $\mathbf{Q}=\boldsymbol{\nabla}\cdot\mathbf{Q}$, which is a vector according to[27,33]

$$(\text{div } \mathbf{Q})_j=\sum_i \frac{\partial Q_{ij}}{\partial x_i}, \tag{4}$$

and the curl of a matrix, curl $\mathbf{Q}=\boldsymbol{\nabla}\times\mathbf{Q}$, which is a matrix according to[33,34]

$$\text{curl } \mathbf{Q}=\begin{pmatrix} \frac{\partial Q_{31}}{\partial x_2}-\frac{\partial Q_{21}}{\partial x_3} & \frac{\partial Q_{32}}{\partial x_2}-\frac{\partial Q_{22}}{\partial x_3} & \frac{\partial Q_{33}}{\partial x_2}-\frac{\partial Q_{23}}{\partial x_3} \\ \frac{\partial Q_{11}}{\partial x_3}-\frac{\partial Q_{31}}{\partial x_1} & \frac{\partial Q_{12}}{\partial x_3}-\frac{\partial Q_{32}}{\partial x_1} & \frac{\partial Q_{13}}{\partial x_3}-\frac{\partial Q_{33}}{\partial x_1} \\ \frac{\partial Q_{21}}{\partial x_1}-\frac{\partial Q_{11}}{\partial x_2} & \frac{\partial Q_{22}}{\partial x_1}-\frac{\partial Q_{12}}{\partial x_2} & \frac{\partial Q_{23}}{\partial x_1}-\frac{\partial Q_{13}}{\partial x_2} \end{pmatrix}, \tag{5}$$

where $\boldsymbol{\nabla}$ is the nabla operator and where the vector product of a vector and a matrix is given by $(\mathbf{q}\times\mathbf{Q})_{ij}=\Sigma_m\Sigma_n\epsilon_{imn}q_mQ_{nj}$, with the Levi-Civita symbol ϵ representing the well-known third-order permutation tensor.[26,28]

The symbols grad, div, and curl will be used for both the conventional and the higher-order versions, so it is the order of the argument quantity which determines the true meaning of a differential operator symbol. Although it will not be shown in detail here, the following is true for the Cartesian transformation behavior of the quantities of Eqs. (3)–(5): The gradient of a vector is a Cartesian tensor. The divergence of a Cartesian tensor is a vector. The curl of a Cartesian tensor is a Cartesian tensor, but only in the case of a right-handed Cartesian system. In the case of a transition to a left-handed Cartesian system, the curl changes to its negative, which is similar to the behavior of the conventional vector curl. For this reason, the treatment is restricted to right-handed Cartesian systems.[35]

The following formulas, which are needed for this paper, can be derived from the above definitions by direct calculation:

$$(\text{grad } \mathbf{q})\cdot\mathbf{q}=\tfrac{1}{2}\text{ grad}(\mathbf{q}\cdot\mathbf{q}), \tag{6}$$

$$\tfrac{1}{2}\text{ grad grad } q^2=\text{grad}(q\text{ grad } q)$$
$$=\text{grad } q\otimes\text{grad } q+q\text{ grad grad } q, \tag{7}$$

$$\text{div}(q\mathbf{Q})=q\text{ div } \mathbf{Q}+(\text{grad } q)\cdot\mathbf{Q}, \tag{8}$$

$$\text{div}(q\mathbf{U})=\text{grad } q, \tag{9}$$

where $\mathbf{U}$ is the unit matrix with

$$U_{ij}=\delta_{ij}, \tag{10}$$

with δ_{ij} being the Kronecker delta,

$$\text{div}(\mathbf{q}\otimes\mathbf{q})=(\mathbf{q}\cdot\text{grad})\mathbf{q}+\mathbf{q}\text{ div } \mathbf{q}, \tag{11}$$

$$\text{curl grad } \mathbf{q}=0, \tag{12}$$

$$\text{div curl } \mathbf{Q}=0, \tag{13}$$

$$\text{curl curl}(q\mathbf{U})=\text{grad grad } q-\mathbf{U}\text{ div grad } q, \tag{14}$$

$$\text{adj}(\text{grad } \mathbf{q})=\tfrac{1}{2}\text{curl}(\mathbf{q}\times(\text{grad } \mathbf{q})^T)^T, \tag{15}$$

where the adjoint, adj, is the matrix of the cofactors[33] according to

$$\text{adj}(\mathbf{Q})=(\mathbf{Q}^T)^{-1}\text{ det } \mathbf{Q} \tag{16}$$

and, since grad $\mathbf{x}=\mathbf{U}$, Eq. (15) has a special application, namely

$$\text{adj}(\mathbf{U})=\mathbf{U}=\tfrac{1}{2}\text{curl}(\mathbf{x}\times\mathbf{U})^T, \tag{17}$$

and two algebraic identities can be derived from the usual vector and matrix calculus,

$$\mathbf{q}^{(a)}\cdot(\mathbf{q}^{(b)}\otimes\mathbf{q}^{(c)})=(\mathbf{q}^{(a)}\cdot\mathbf{q}^{(b)})\mathbf{q}^{(c)}, \tag{18}$$

$$(\mathbf{q}^{(a)}\cdot\mathbf{Q})\times(\mathbf{q}^{(b)}\cdot\mathbf{Q})=(\mathbf{q}^{(a)}\times\mathbf{q}^{(b)})\cdot\text{adj}(\mathbf{Q}). \tag{19}$$

The well-known Gauss and Stokes integral theorems can also be extended to a higher order.[33,34,36] Their extended meaning is: (Gauss:) The vectorial surface integral of a matrix over a closed surface is equal to the volume integral of the divergence of the matrix over the volume bounded by the surface. (Stokes:) The vectorial surface integral of the curl of a matrix is equal to the vectorial line integral of the matrix along the boundary line of the surface. The following helpful rule (mentioned in Ref. 37 in the nonextended meaning) can be derived from the Stokes integral theorem: The vectorial surface integral of the curl of a matrix over a closed surface is zero. To see this, consider a closed surface as, for example, a sphere, and a curve on it such as, for example, the equator. The curve divides the surface into two parts. The total surface integral is the sum of the surface integrals over the two parts. The Stokes integral theorem can be applied to both parts, thus the total surface integral of the curl of a matrix is given by a sum of two line integrals of the matrix over the same curve but in opposite directions. This is zero.[38]

The radiation force on an object (target) is the vectorial surface integral of the radiation stress over a closed surface enclosing the target. If the radiation stress is a zero-divergence quantity throughout the sound-propagating fluid, this has two important implications: First, the result is independent of the specific choice of the surface of integration, as

long as the entire target is contained in the interior of that surface. This means that the surface of integration can be freely chosen so as to minimize the calculation difficulties, even far away from the target or from the transducer (far-field approximation[39,40]). Second, if there is only fluid and no target inside the surface of integration, the result is zero, i.e., there is no net radiation force on the sound-propagating fluid itself.[41]

If, in addition, the radiation stress (or a certain part of it) can be expressed as the curl of some other quantity, the radiation force (or the corresponding part of it) is zero, even with a target inside the surface of integration. This means that any part of the radiation stress representing a curl can be regarded as ineffective and negligible for the Langevin radiation force. A radiation force which is zero can, therefore, be due to the following conditions: (a) The divergence of the radiation stress is zero and (b) the radiation stress can be formulated as a curl, but with an important difference: in case (a) the divergence must be zero everywhere inside the surface of integration (which means: no target), whereas the Stokes integral theorem does not refer to the volume bounded by the surface of integration, and so, in case (b), the condition that the radiation stress is the curl of something (and is divergenceless) need not be fulfilled everywhere inside the closed surface.[42]

Consideration is given to an isentropic motion of a lossless, nondispersive, compressible, sound-propagating fluid (gas or liquid) which is described by the primary field quantities pressure p, (mass) density ρ, and particle velocity $\mathbf{v}$ as functions of space and time. As usual in acoustics, these quantities are considered with reference to an initial state without sound field, characterized by constants p_0, ρ_0, and $\mathbf{v}_0$ with $\mathbf{v}_0=0$. The gravitational field is neglected. $p-p_0$ is the acoustic pressure. In addition, the specific enthalpy h is considered according to

$$dh=\frac{1}{\rho}\,dp, \quad h-h_0=\int_{p_0}^{p}\frac{dp}{\rho(p)}. \tag{20}$$

The equation of state is assumed in the usual Taylor-series form[43]

$$p-p_0=c_0^2(\rho-\rho_0)\pm\cdots, \tag{21}$$

where c_0 is the low-amplitude speed of sound and terms with higher powers $(\rho-\rho_0)^n$ and containing the nonlinearity parameters such as the Fox–Wallace nonlinearity parameter[44] can be neglected here.

In the following, certain secondary field quantities such as the energy densities and particularly the radiation stresses will be calculated as functions of the primary field quantities. There will be two types of formulas: (a) exact formulas which are strictly valid and for which the primary field quantities are understood to be exact solutions of the underlying, nonlinear differential equations given in the subsequent sections; (b) formulas for secondary field quantities valid up to and including the second order in the primary field quantities, i.e., containing products and powers up to the order of two. These type (b) equations will be characterized by (l.a.) standing for ''linear acoustics.'' For example, the exact expression for the kinetic energy density is

$$E_{\mathrm{kin}}=\tfrac{1}{2}\rho\mathbf{v}\cdot\mathbf{v}, \tag{22}$$

but its linear-acoustics approximation is

$$E_{\mathrm{kin}}=\tfrac{1}{2}\rho_0\mathbf{v}\cdot\mathbf{v}. \quad \text{(l.a.)} \tag{23}$$

The potential acoustic energy density in the linear-acoustics approximation is

$$E_{\mathrm{pot}}=\frac{(p-p_0)^2}{2\rho_0 c_0^2}. \quad \text{(l.a.)} \tag{24}$$

For its exact expression, cf. Ref. 43. The total acoustic energy density is $E=E_{\mathrm{pot}}+E_{\mathrm{kin}}$.

Another useful Taylor series now involving powers of $(p-p_0)$ should be given, namely

$$\rho_0(h-h_0)=p-p_0-E_{\mathrm{pot}}\pm\cdots, \tag{25}$$

which follows from Eqs. (20), (21), and (24) (cf. also Ref. 43).

The fluid motion can be described in Eulerian or Lagrangian coordinates and the terminology chosen here is as follows. If the definition of a physical quantity is the same in both representations (which can be regarded as the rule; for the exceptions, cf. below), the same symbol is used for this quantity in both descriptions. The difference lies, however, in the operations with respect to the coordinates. So $\partial/\partial t$ is used for the time derivative in the Eulerian representation, i.e., at constant Eulerian coordinates. The symbol D/Dt stands for the time derivative in the Lagrangian representation, i.e., at constant Lagrangian coordinates. The overbar is used for the temporal average in the Eulerian representation, i.e., at constant Eulerian coordinates. The pointed brackets $\langle\ \rangle$ are used for the temporal average in the Lagrangian representation, i.e., at constant Lagrangian coordinates. The operators grad, div, and curl are understood with reference to Eulerian coordinates. When understood as referring to Lagrangian coordinates, they are written as Grad, Div, and Curl. Everything written above about vectors and matrices is of course also valid for the Lagrangian representation, but with the formal difference that the Eulerian coordinates x_i should be replaced by the Lagrangian coordinates X_i. The infinitesimal vectorial surface element in the Eulerian space is referred to as **da**; the infinitesimal vectorial surface element in the Lagrangian space is referred to as **dA**.

For all those physical quantities which express a certain quantity per unit area or per unit volume, it must be distinguished whether the area or the volume is understood in the Eulerian or in the Lagrangian space. One group of such quantities is given by the energy densities. Strictly speaking, formulas (22)–(24) above refer to the energy per unit volume of Eulerian space. The Eulerian energy densities must be multiplied by ρ_0/ρ to obtain the corresponding expressions giving the energy per unit volume of Lagrangian space. So it can be seen, for example, that Eq. (23) gives the exact expression for the kinetic energy per unit Lagrangian volume. Strictly speaking, different names and different symbols should be used for the Eulerian and for the Lagrangian energy densities, but in this paper the energy densities will be used only in the linear-acoustics approximation. So the dif-

ferences between the Eulerian and the Lagrangian forms are negligible in this case and formulas (23) and (24) will be used throughout.

A closer examination, however, is advised when dealing with the stress. The Cauchy stress **T** describes the contact force per unit Eulerian area. The stress expressing the contact force per unit Lagrangian area is a different quantity and is here referred to as the Piola–Kirchhoff–Boussinesq stress **K**. Its relation with **T** will be studied in Sec. IV.

In both representations, a transition from a time-dependent quantity to its temporal average will often be necessary in the following. The paper is not restricted to sinusoidal waveforms but applies to arbitrary waveforms provided two conditions are fulfilled: (1) The time-average value exists. (2) The temporal average of a time derivative is zero (cf., for example, Ref. 7). The latter condition is referred to in the text by assuming that the quantity in question is ''in a steady state.'' This can, for example, be fulfilled by a periodic quantity. The fields from ultrasonic diagnostic instruments are periodic inasmuch as the pulses are repeated at a constant rate. ''Periodic'' does not necessarily mean that the quantity averages to zero, but its time derivative averages to zero.

II. THE RADIATION STRESS IN EULERIAN COORDINATES

In a lossless fluid, the Cauchy stress is determined by the scalar pressure according to

$$\mathbf{T}=-p\mathbf{U}. \tag{26}$$

The fundamental Eulerian field equations[28,45] are the equation of motion

$$\frac{\partial \mathbf{v}}{\partial t}+(\mathbf{v}\cdot\mathrm{grad})\mathbf{v}=\frac{1}{\rho}\,\mathrm{div}\,\mathbf{T}=-\frac{1}{\rho}\,\mathrm{div}(p\mathbf{U})=-\frac{1}{\rho}\,\mathrm{grad}\,p \tag{27}$$

[cf. Eq. (9)] and the equation of continuity (mass conservation law)

$$\frac{\partial \rho}{\partial t}=-\mathrm{div}(\rho\mathbf{v}), \tag{28}$$

which can be combined using Eq. (11) to yield the momentum conservation law

$$\frac{\partial(\rho\mathbf{v})}{\partial t}=-\mathrm{div}\,\mathbf{M}, \tag{29}$$

with **M** being the momentum flux density,[45]

$$\mathbf{M}=-\mathbf{T}+\rho\mathbf{v}\otimes\mathbf{v}=p\mathbf{U}+\rho\mathbf{v}\otimes\mathbf{v}. \tag{30}$$

If the momentum density $\rho\mathbf{v}$ is in a steady state, it follows from Eq. (29) that

$$\mathrm{div}\,\overline{\mathbf{M}}=0. \tag{31}$$

Following the Brillouin approach, we understand the radiation stress in Eulerian coordinates as the negative temporal average of the momentum flux density and thus arrive at the Brillouin stress **S** with

$$\mathbf{S}=-\overline{\mathbf{M}}+p_0\mathbf{U}=-\overline{(p-p_0)}\mathbf{U}-\overline{\rho\mathbf{v}\otimes\mathbf{v}}, \tag{32}$$

where the addition of $p_0\mathbf{U}$ does not change the result of the closed-surface integral, which is a trivial statement but can also be formally inferred from the fact that according to Eq. (17), the unit matrix **U** can be given as a curl. Owing to Eq. (31),

$$\mathrm{div}\,\mathbf{S}=0. \tag{33}$$

The radiation force **f** is given by the vectorial surface integral

$$\mathbf{f}=\oiint(\mathbf{da}\cdot\mathbf{S}) \tag{34}$$

over a closed surface which is at rest in the Eulerian space; the surface element vector is understood to point outward.[46]

S is at least of the second order and when passing to the linear-acoustics approximation, a second-order expression for $\overline{p-p_0}$ is needed. This is briefly derived here as follows. The equation of motion (27) can be reformulated with the help of a well-known formula from conventional vector analysis[33] and of Eq. (20) according to

$$\frac{\partial \mathbf{v}}{\partial t}+\frac{1}{2}\,\mathrm{grad}(\mathbf{v}\cdot\mathbf{v})-\mathbf{v}\times\mathrm{curl}\,\mathbf{v}=-\mathrm{grad}\,h=-\mathrm{grad}(h-h_0). \tag{35}$$

If this is time averaged and multiplied by ρ_0 and if it is assumed that **v** is in a steady state and that the fluid motion is irrotational, the following is obtained with the help of Eqs. (23) and (25):

$$\mathrm{grad}(\rho_0\overline{(h-h_0)}+\overline{E_{\mathrm{kin}}})=\mathrm{grad}(\overline{p-p_0}-\overline{E_{\mathrm{pot}}}+\overline{E_{\mathrm{kin}}})=0. \quad \text{(l.a.)} \tag{36}$$

This leads to the following second-order result for $\overline{p-p_0}$ (the exact version can be found in Ref. 43):

$$\overline{p-p_0}=\overline{E_{\mathrm{pot}}}-\overline{E_{\mathrm{kin}}}+\mathrm{const}, \quad \text{(l.a.)} \tag{37}$$

which is ''Langevin's second relation.'' [21,22] It has repeatedly been given in the literature, cf. the citations in Ref. 20. The free constant const is important when this result is compared with other results from the literature,[2,19] but it makes no contribution to the closed-surface integral and can be neglected for the Langevin radiation force. The final, linear-acoustics result for the Brillouin stress which is the acoustic radiation stress in the Eulerian representation then is[47]

$$\mathbf{S}=(\overline{E_{\mathrm{kin}}}-\overline{E_{\mathrm{pot}}})\mathbf{U}-\rho_0\overline{\mathbf{v}\otimes\mathbf{v}}. \quad \text{(l.a.)} \tag{38}$$

This result, given here with reference to Brillouin and Langevin, can also be found in the literature under different circumstances. It is referred to as the ''wave-stress tensor'' in Ref. 48 and also appears, either explicitly or implicitly, in Refs. 39, 49, and 50 which deal with small targets and the application areas (b) and (c) from the Introduction (cf. also Ref. 2). The result of Eq. (38) has been used in Refs. 20 and 51 to calculate the radiation force in nonplane fields for application area (a) from the Introduction.

III. EXAMPLES OF THE RADIATION STRESS IN EULERIAN COORDINATES

Equation (38) is applied to three basic field types as follows.

A. Case 1: Axial field

It is assumed that in the field point considered, the particle velocity vector **v** lies only in one direction (including its negative), namely in direction No. 1, so that $\nu_2=0$ and $\nu_3=0$ all the time, which means, $\overline{\nu_2^2}=0$ and $\overline{\nu_3^2}=0$. In this case

$$\overline{E_{\mathrm{kin}}}=\tfrac{1}{2}\rho_0\overline{\nu_1^2} \qquad \text{(l.a.)} \quad (39)$$

and therefore

$$\mathbf{S}=\begin{pmatrix} -\overline{E} & 0 & 0 \\ 0 & \overline{E_{\mathrm{kin}}}-\overline{E_{\mathrm{pot}}} & 0 \\ 0 & 0 & \overline{E_{\mathrm{kin}}}-\overline{E_{\mathrm{pot}}} \end{pmatrix}. \qquad \text{(l.a.)} \quad (40)$$

The negative of the normal stress S_{11} in the axial direction, i.e., in direction No. 1, is given here by the temporal average of the (total) acoustic energy density E, a classic result. Its limitations, however, should be clearly noted as follows.

First, this is not a scalar, omnidirectional radiation ''pressure'' but it applies only to normal incidence in the axial direction. Second, this applies only to restricted field types, namely to plane waves of the progressive, standing or mixed type, for example. It is also valid on the symmetry axis of a nonplane field of the rotationally symmetrical type.[20] It is not valid under oblique incidence and for general, three-dimensional fields (particularly in off-axis positions) where often phase differences between the particle velocity components occur so that the above conditions concerning the $\overline{\nu_i^2}$ cannot be fulfilled, not even locally or with a rotation of the coordinate axes.

In the following examples a continuous, sinusoidal waveform is assumed but only to simplify things. Other periodic waveforms are also possible, of course.

B. Case 2: Plane-progressive wave in an arbitrary direction

It is assumed that

$$p-p_0=\hat{p}\,\cos(\omega t-\mathbf{k}\cdot\mathbf{x}) \qquad \text{(l.a.)} \quad (41)$$

and

$$\mathbf{v}=\frac{\hat{p}}{\rho_0\omega}\,\mathbf{k}\,\cos(\omega t-\mathbf{k}\cdot\mathbf{x}), \qquad \text{(l.a.)} \quad (42)$$

where $\hat{p}$ is the pressure amplitude, ω the circular frequency, and **k** the wave propagation vector, with $|\mathbf{k}|=k=\omega/c_0$ being the circular wave-number. The final result is

$$\mathbf{S}=-\frac{\hat{p}^2}{2\rho_0 c_0^2}\,\frac{\mathbf{k}\otimes\mathbf{k}}{k^2}. \qquad \text{(l.a.)} \quad (43)$$

If the wave is incident on a plane-perfect absorber of arbitrary orientation as expressed by its surface element vector **da**, the infinitesimal radiation force following from Eq. (43) is, due to Eq. (18),

$$\mathbf{df}=\mathbf{da}\cdot\mathbf{S}=-\frac{\hat{p}^2}{2\rho_0 c_0^2}\,\frac{\mathbf{da}\cdot\mathbf{k}}{k}\,\frac{\mathbf{k}}{k}, \qquad \text{(l.a.)} \quad (44)$$

where the surface element vector is understood as pointing outwards from the target; at the target front surface, the scalar product $\mathbf{da}\cdot\mathbf{k}$ thus has a negative value. The force vector **df** of Eq. (44) is in the direction of **k**, not of **da**. This means that irrespective of the absorber orientation, the radiation force on a perfect absorber lies in the direction of the incident wave.[52] This reflects the tensorial character of the underlying theory, whereas any scalar radiation ''pressure'' theory would lead to the result that the radiation force is normal to the time-averaged target surface.

The dependence of the radiation force on the absorber orientation has been measured by Herrey,[53] confirming the tensorial theory and Eq. (44). Experimental evidence for this is also reported in Ref. 54.

The plane-wave result obtained here is in line with the formula used in radiation-force practice in the case of a perfect absorber.[1,2]

C. Case 3: Superposition of two oblique plane waves of equal amplitude

It is assumed that

$$p-p_0=\hat{p}\{\cos(\omega t-\mathbf{k}^{(a)}\cdot\mathbf{x})+\cos(\omega t-\mathbf{k}^{(b)}\cdot\mathbf{x}-\alpha)\} \qquad \text{(l.a.)} \quad (45)$$

and that

$$\mathbf{v}=\frac{\hat{p}}{\rho_0\omega}\,\{\mathbf{k}^{(a)}\,\cos(\omega t-\mathbf{k}^{(a)}\cdot\mathbf{x})+\mathbf{k}^{(b)}\,\cos(\omega t-\mathbf{k}^{(b)}\cdot\mathbf{x}-\alpha)\}, \qquad \text{(l.a.)} \quad (46)$$

where, in order to simulate a reflection at a plane $x_1=\text{const}$,

$$\mathbf{k}^{(a)}=(k\,\cos\,\gamma,k\,\sin\,\gamma,0)$$

and (l.a.) (47)

$$\mathbf{k}^{(b)}=(-k\,\cos\,\gamma,k\,\sin\,\gamma,0)$$

is chosen, with γ being the angle of incidence and α a phase constant to allow for hard and soft reflection. In this case the final result is

$$\mathbf{S}=-\frac{\hat{p}^2}{\rho_0 c_0^2}\begin{pmatrix} \cos^2\,\gamma & 0 & 0 \\ 0 & \sin^2\,\gamma+\cos\,\beta & 0 \\ 0 & 0 & \cos^2\,\gamma\,\cos\,\beta \end{pmatrix}, \qquad \text{(l.a.)} \quad (48)$$

where β is an abbreviation for $2kx_1\,\cos\,\gamma-\alpha$. It follows from the result that in contrast to an absorber, no tangential radiation forces are exerted on a perfect reflector (cf. Ref. 53). Although it will not be shown in detail, the result obtained here for the normal stress S_{11} on the reflecting surface is in line with the common perfect-reflector formula[1,2] which is well established in radiation-force practice.

IV. THE STRESS IN LAGRANGIAN COORDINATES

Consider the transition of a medium from a reference (''undeformed'') state to the actual (''deformed'') state. The position of a particle in the reference state is given by the (Lagrangian) position vector $\mathbf{X}=(X_1,X_2,X_3)$; the position

of that particle in the actual state is given by the (Eulerian) position vector $\mathbf{x}=(x_1,x_2,x_3)$. The transition from **X** to **x** is described by

$$\mathbf{x}=\mathbf{x}(\mathbf{X})=\mathbf{X}+\mathbf{s}(\mathbf{X}), \tag{49}$$

s being the displacement vector and Eq. (49) forming the basis for two matrices, namely the displacement gradient[16]

$$\mathbf{H}=\text{Grad }\mathbf{s} \text{ with } H_{ij}=\frac{\partial s_j}{\partial X_i} \tag{50}$$

and the deformation gradient[16,55]

$$\mathbf{F}=\text{Grad }\mathbf{x}=\mathbf{U}+\mathbf{H} \text{ with } F_{ij}=\frac{\partial x_j}{\partial X_i}=\delta_{ij}+H_{ij}. \tag{51}$$

Consider a material surface in the reference state of the medium, a point **X** on it and two infinitesimal vectors $\mathbf{dX}^{(a)}$ and $\mathbf{dX}^{(b)}$ tangent to the surface and defining the vectorial surface element $\mathbf{dA}=\mathbf{dX}^{(a)}\times\mathbf{dX}^{(b)}$. Consider the actual, deformed surface, the point **x** on it and the two corresponding vectors $\mathbf{dx}^{(a)}$ and $\mathbf{dx}^{(b)}$ now forming the actual surface element $\mathbf{da}=\mathbf{dx}^{(a)}\times\mathbf{dx}^{(b)}$. The transition $\mathbf{dX}\Rightarrow\mathbf{dx}$ of an infinitesimal vector is generally given by[33,56]

$$\mathbf{dx}=(\mathbf{dX}\cdot\text{Grad})\mathbf{x}=\mathbf{dX}\cdot\mathbf{F}. \tag{52}$$

The transition law for the surface element vector now follows from Eqs. (19) and (52) to be

$$\begin{aligned}\mathbf{da}&=\mathbf{dx}^{(a)}\times\mathbf{dx}^{(b)}=(\mathbf{dX}^{(a)}\cdot\mathbf{F})\times(\mathbf{dX}^{(b)}\cdot\mathbf{F})\\&=(\mathbf{dX}^{(a)}\times\mathbf{dX}^{(b)})\cdot\mathbf{G}=\mathbf{dA}\cdot\mathbf{G},\end{aligned} \tag{53}$$

with the transition matrix **G** being the adjoint of the deformation gradient, namely

$$\mathbf{G}=\text{adj}(\text{Grad }\mathbf{x})=\text{adj}(\mathbf{F})=(\mathbf{F}^T)^{-1}\text{ det }\mathbf{F} \tag{54}$$

or, in detail,

$$\begin{aligned}\mathbf{G}&=\begin{pmatrix}F_{22}F_{33}-F_{23}F_{32} & F_{23}F_{31}-F_{21}F_{33} & F_{21}F_{32}-F_{22}F_{31}\\ F_{13}F_{32}-F_{12}F_{33} & F_{11}F_{33}-F_{13}F_{31} & F_{12}F_{31}-F_{11}F_{32}\\ F_{12}F_{23}-F_{13}F_{22} & F_{13}F_{21}-F_{11}F_{23} & F_{11}F_{22}-F_{12}F_{21}\end{pmatrix}\\&=(1+\text{trace }\mathbf{H})\mathbf{U}-\mathbf{H}^T+\text{adj}(\mathbf{H}),\end{aligned} \tag{55}$$

where Eq. (51) has been used and where trace $\mathbf{H}=\text{Div }\mathbf{s}$.

If a stress **T** exists at the actual point **x**, the actual contact force **df** exerted across the actual surface element **da** is $\mathbf{df}=\mathbf{da}\cdot\mathbf{T}$. If, on the other hand, the actual force is to be described by a stress acting across the reference surface element **dA**, this leads to the Piola–Kirchhoff–Boussinesq stress **K** according to $\mathbf{df}=\mathbf{dA}\cdot\mathbf{K}$. A comparison with Eq. (53) immediately yields the result[57] $\mathbf{K}=\mathbf{G}\cdot\mathbf{T}$ or, more specifically,

$$\mathbf{K}(\mathbf{X})=\mathbf{G}(\mathbf{X})\cdot\mathbf{T}(\mathbf{x}(\mathbf{X})), \tag{56}$$

which, for a lossless fluid and due to Eq. (26), means that

$$\mathbf{K}=-p\mathbf{G}. \tag{57}$$

It can be seen that the stress in the Lagrangian representation in a lossless fluid does not in general reduce to a scalar quantity. So strictly speaking, the scalar pressure p remains a Eulerian quantity (=force per unit Eulerian area) even if used in the Lagrangian representation, i.e., if its value is considered as a function of Lagrangian coordinates.

The transition matrix **G** has the following properties: It is symmetric if the deformation gradient is symmetric. Due to Eqs. (15) and (54), it can be expressed as a Curl (i.e., its surface integral over a closed surface in the Lagrangian space vanishes); as a result and owing to Eq. (13),

$$\text{Div }\mathbf{G}=0 \tag{58}$$

which can also be directly obtained by applying Eq. (4) to Eq. (55).

V. THE RADIATION STRESS IN LAGRANGIAN COORDINATES

In the Lagrangian representation, the displacement vector **s** is considered to be the fourth primary field quantity in addition to pressure, density, and particle velocity. The basic relation reads

$$\mathbf{v}=\frac{D\mathbf{s}}{Dt}=\frac{D\mathbf{x}}{Dt}. \tag{59}$$

The fundamental field equations[26,28,37] are the equation of motion

$$\mathbf{F}\cdot\frac{D\mathbf{v}}{Dt}=-\frac{1}{\rho}\text{ Grad }p=-\text{Grad }h \tag{60}$$

and the equation of continuity

$$\rho\text{ det }\mathbf{F}=\rho_0. \tag{61}$$

When the equation of motion is premultiplied by $\mathbf{F}^{-1}$ and the equation of continuity and Eq. (54) are taken into account, the following relationship is obtained:

$$\begin{aligned}\frac{D\mathbf{v}}{Dt}&=-\frac{1}{\rho}\mathbf{F}^{-1}\cdot\text{Grad }p=-\frac{1}{\rho_0}(\text{Grad }p)\cdot(\mathbf{F}^T)^{-1}\text{ det }\mathbf{F}\\&=-\frac{1}{\rho_0}(\text{Grad }p)\cdot\mathbf{G}.\end{aligned} \tag{62}$$

Owing to Eqs. (8), (57), and (58), this equation can be reformulated:

$$\frac{D\mathbf{v}}{Dt}=-\frac{1}{\rho_0}\text{Div}(p\mathbf{G})=\frac{1}{\rho_0}\text{ Div }\mathbf{K}. \tag{63}$$

This equation is completely equivalent to its analogue in Eulerian coordinates, Eq. (27). The left-hand side of Eq. (27) contains the material time derivative of **v** in Eulerian coordinates, the left-hand side of Eq. (63) contains the (material) time derivative of **v** in Lagrangian coordinates. ρ in Eq. (27) is the mass per unit volume of Eulerian space. ρ_0 in Eq. (63) is the mass per unit volume of Lagrangian space. **T** in Eq. (27) is the Eulerian stress, and **K** in Eq. (63) is the Lagrangian stress.

If **v** is in a steady state (in the Lagrangian representation), it follows from Eq. (63) that

$$\text{Div}\langle\mathbf{K}\rangle=0. \tag{64}$$

Following the Brillouin approach, we understand the radiation stress in Lagrangian coordinates as the temporal average of the Piola–Kirchhoff–Boussinesq stress **K** and thus obtain the PKB stress **B** with[58]

$$\mathbf{B}=\langle\mathbf{K}\rangle+p_0\langle\mathbf{G}\rangle=-\langle(p-p_0)\mathbf{G}\rangle, \tag{65}$$

where, as **G** can be given as a Curl, the addition of $p_0\langle\mathbf{G}\rangle$ does not change the result of the closed-surface integral. Owing to Eqs. (58) and (64),

$$\text{Div } \mathbf{B}=0 \tag{66}$$

[Eq. (58) is valid at any instant and thus also on the temporal average]. The radiation force **f** is given by the vectorial surface integral

$$\mathbf{f}=\oiint (\mathbf{dA}\cdot\mathbf{B}) \tag{67}$$

over a closed surface which is at rest in the Lagrangian space; the surface element vector is again understood to point outward.

Equation (65) is exact. In order to get its second-order approximation to be used in linear acoustics, the first-order approximation of **G** is needed. Using Eq. (55) up to the first order, the following can be obtained for **B** up to the second order:

$$\mathbf{B}=-\langle p-p_0\rangle\mathbf{U}-\langle(p-p_0)\text{Div }\mathbf{s}\rangle\mathbf{U}+\langle(p-p_0)\mathbf{H}^T\rangle. \tag{68}$$

(l.a.)

For the first term of the right-hand side, the second-order approximation of $\langle p-p_0\rangle$ is needed. This can be derived as follows. As

$$\frac{D\mathbf{F}}{Dt}=\frac{D\mathbf{H}}{Dt}=\frac{D}{Dt}\text{ Grad }\mathbf{s}=\text{Grad }\mathbf{v} \tag{69}$$

and, due to Eq. (6) (and cf. Ref. 24),

$$\frac{D\mathbf{F}}{Dt}\cdot\mathbf{v}=(\text{Grad }\mathbf{v})\cdot\mathbf{v}=\frac{1}{2}\text{ Grad}(\mathbf{v}\cdot\mathbf{v}), \tag{70}$$

the equation of motion (60) can be reformulated as

$$\begin{aligned}\mathbf{F}\cdot\frac{D\mathbf{v}}{Dt}&=\frac{D}{Dt}(\mathbf{F}\cdot\mathbf{v})-\frac{D\mathbf{F}}{Dt}\cdot\mathbf{v}\\&=\frac{D}{Dt}(\mathbf{F}\cdot\mathbf{v})-\frac{1}{2}\text{ Grad}(\mathbf{v}\cdot\mathbf{v})\\&=-\text{Grad }h=-\text{Grad}(h-h_0).\end{aligned} \tag{71}$$

If this is time averaged and multiplied by ρ_0 and if it is assumed that $\mathbf{F}\cdot\mathbf{v}$ is in a steady state (in the Lagrangian representation), the following is obtained with the help of Eqs. (23) and (25):

$$\begin{aligned}\text{Grad}(\rho_0\langle h-h_0\rangle-\langle E_{\text{kin}}\rangle)&=\text{Grad}(\langle p-p_0\rangle-\langle E_{\text{pot}}\rangle\\&\quad-\langle E_{\text{kin}}\rangle)=0.\end{aligned} \tag{72}$$

(l.a.)

This leads to the following second-order result for $\langle p-p_0\rangle$:

$$\langle p-p_0\rangle=\langle E_{\text{pot}}\rangle+\langle E_{\text{kin}}\rangle+\text{Const}=\langle E\rangle+\text{Const}, \tag{73}$$

(l.a.)

which is ''Langevin's first relation.''[7,22,cf. also 12,24] The free constant Const does not make a contribution to the closed-surface integral and can thus be neglected for the Langevin radiation force. The linear-acoustics result for the PKB stress now reads

$$\mathbf{B}=-\langle E\rangle\mathbf{U}-\langle(p-p_0)\text{Div }\mathbf{s}\rangle\mathbf{U}+\langle(p-p_0)\mathbf{H}^T\rangle. \tag{74}$$

(l.a.)

This can be further simplified. Due to Eqs. (21), (50), (51), and (61), the following holds approximately (first-order approximation):

$$\text{Div }\mathbf{s}=\text{trace }\mathbf{H}=\det\mathbf{F}-1=\frac{\rho_0}{\rho}-1=-\frac{\rho-\rho_0}{\rho_0}=-\frac{p-p_0}{\rho_0 c_0^2} \tag{75}$$

(l.a.)

and therefore

$$(p-p_0)\text{Div }\mathbf{s}=-2E_{\text{pot}}. \tag{76}$$

(l.a.)

The final, linear-acoustics result for the PKB stress which is the acoustic radiation stress in the Lagrangian representation then is

$$\mathbf{B}=(\langle E_{\text{pot}}\rangle-\langle E_{\text{kin}}\rangle)\mathbf{U}+\langle(p-p_0)\mathbf{H}^T\rangle. \tag{77}$$

(l.a.)

Another remark should be made. In a lossless fluid, acoustic streaming usually does not occur, but it is interesting to consider the potential influence of such a streaming on the ''steady-state'' assumptions in the two representations. If the streaming itself is in a steady state, i.e., if it is temporally constant at constant Eulerian coordinates, the total field (acoustic field plus streaming) is in a steady state in the Eulerian sense, but not in the Lagrangian sense. In this case the fluid particles move through the field, which means through field points exhibiting different amplitudes of the acoustic quantities, and even leave the beam into a space where the acoustic quantities are practically zero, and so the Lagrangian time average of any field quantity is meaningless.[59] It might appear that this is an advantage of the Eulerian representation but it had to be assumed there that the field is irrotational and this is usually not the case in an acoustic streaming, strictly speaking.[60] Conditions of no streaming thus are obviously important for both of Langevin's relations.

VI. EXAMPLES OF THE RADIATION STRESS IN LAGRANGIAN COORDINATES

Equation (77) is applied to the three basic field types of Sec. III. Equivalent formulas where only $\mathbf{x}=(x_1,x_2,x_3)$ is to be replaced by $\mathbf{X}=(X_1,X_2,X_3)$ are not explicitly repeated. In addition, the displacement vector **s** has to be considered here as it appears in Eq. (77) in the displacement gradient **H**.

A. Case 1: Axial field

It is assumed that ν_1 and s_1 are the only nonzero components. It is also assumed that $H_{11}=\partial s_1/\partial X_1$ is the only

nonzero element of the displacement gradient, i.e., that all other elements vanish. This can be seen as follows. In the case of a (progressive or standing or mixed) plane wave in the X_1 direction, it is obvious. In the case of points on the symmetry axis of a nonplane rotationally symmetrical field, the derivatives with respect to X_2 and X_3 are zero for symmetry reasons. As s_2 and s_3 are zero on the axis, their derivatives with respect to X_1 vanish.

Consequently, $H_{11}=\text{trace}\ \mathbf{H}=\text{Div}\ \mathbf{s}$ here, and it follows from Eq. (76) that $(p-p_0)H_{11}=-2E_{\text{pot}}$. This leads to the final result

$$\mathbf{B}=\begin{pmatrix} -\langle E\rangle & 0 & 0 \\ 0 & \langle E_{\text{pot}}\rangle-\langle E_{\text{kin}}\rangle & 0 \\ 0 & 0 & \langle E_{\text{pot}}\rangle-\langle E_{\text{kin}}\rangle \end{pmatrix}. \qquad \text{(l.a.)} \quad (78)$$

B. Case 2: Plane-progressive wave in an arbitrary direction

In addition to the Lagrangian equivalents of Eqs. (41) and (42),

$$\mathbf{s}=\frac{\hat{p}}{\rho_0\omega^2}\,\mathbf{k}\,\sin(\omega t-\mathbf{k}\cdot\mathbf{X}) \qquad \text{(l.a.)} \quad (79)$$

is assumed. The final result is

$$\mathbf{B}=-\frac{\hat{p}^2}{2\rho_0 c_0^2}\,\frac{\mathbf{k}\otimes\mathbf{k}}{k^2}. \qquad \text{(l.a.)} \quad (80)$$

This is completely equivalent to Eq. (43) and so the orientation dependence of the radiation force here is completely equivalent to that of Eq. (44) which need not be repeated.

C. Case 3: Superposition of two oblique plane waves of equal amplitude

In addition to the Lagrangian equivalents of Eqs. (45) and (46),

$$\mathbf{s}=\frac{\hat{p}}{\rho_0\omega^2}\,\{\mathbf{k}^{(a)}\,\sin(\omega t-\mathbf{k}^{(a)}\cdot\mathbf{X})+\mathbf{k}^{(b)}\,\sin(\omega t-\mathbf{k}^{(b)}\cdot\mathbf{X}-\alpha)\} \qquad \text{(l.a.)} \quad (81)$$

is assumed. The final result is

$$\mathbf{B}=-\frac{\hat{p}^2}{\rho_0 c_0^2}\begin{pmatrix} \cos^2\gamma & 0 & 0 \\ 0 & \sin^2\gamma+(\sin^2\gamma-\cos^2\gamma)\cos\beta & 0 \\ 0 & 0 & -\cos^2\gamma\cos\beta \end{pmatrix}. \qquad \text{(l.a.)} \quad (82)$$

VII. INTERCOMPARISON AND UNIFIED RESULT

In the linear-acoustics approximation, the solutions for the primary field quantities in the Eulerian and Lagrangian representations are identical, cf. the linear wave equations (84) and (89) given below. The results obtained in the two representations can therefore be directly compared with each other. In case 2 which deals with the plane-progressive wave, the radiation stresses of Eqs. (43) and (80) have turned out to be identical. In cases 1 [Eqs. (40) and (78)] and 3 [Eqs. (48) and (82)], the normal stress numbered 11 which is relevant to the radiation force under the conditions assumed is also identical in the two representations, but the other normal stresses numbered 22 and 33 are not. So it appears that the Brillouin and the PKB stress are not in general identical but that fortunately, they differ only in ''unimportant'' details.[61] This can also be seen in other field examples which are not shown here for the sake of brevity. The reasons for this behavior will finally be clarified as follows.

The fluid motion is assumed to be irrotational and described by a velocity potential. Although this will only be considered in the linear-acoustics approximation, the formal distinction between the Eulerian and Lagrangian versions is maintained.

The first-order Eulerian velocity potential is ϕ with

$$p-p_0=\rho_0\,\frac{\partial\phi}{\partial t},\quad \mathbf{v}=-\,\text{grad}\ \phi \qquad \text{(l.a.)} \quad (83)$$

and the well-known linear wave equation

$$\frac{\partial^2\phi}{\partial t^2}=c_0^2\ \text{div grad}\ \phi, \qquad \text{(l.a.)} \quad (84)$$

which follows from Eqs. (27) and (28) by linearization. The following identity holds under the steady-state condition:[62]

$$\overline{\frac{\partial}{\partial t}\left(\phi\,\frac{\partial\phi}{\partial t}\right)}=\overline{\frac{\partial\phi}{\partial t}\,\frac{\partial\phi}{\partial t}}+\overline{\phi\,\frac{\partial^2\phi}{\partial t^2}}=0, \qquad \text{(l.a.)} \quad (85)$$

which, where some formulas from conventional vector analysis[33] and Eq. (84) are used, leads to

$$\begin{aligned}\overline{E_{\text{kin}}}-\overline{E_{\text{pot}}}&=\frac{1}{2}\,\rho_0\left\{\overline{\text{grad}\ \phi\cdot\text{grad}\ \phi}-\frac{1}{c_0^2}\,\overline{\frac{\partial\phi}{\partial t}\,\frac{\partial\phi}{\partial t}}\right\}\\ &=\tfrac{1}{2}\,\rho_0\{\overline{\text{grad}\ \phi\cdot\text{grad}\ \phi}+\overline{\phi\ \text{div grad}\ \phi}\}\\ &=\tfrac{1}{2}\,\rho_0\ \text{div}(\overline{\phi\ \text{grad}\ \phi})\\ &=\tfrac{1}{4}\,\rho_0\ \text{div grad}\ \overline{\phi^2}\end{aligned} \qquad \text{(l.a.)} \quad (86)$$

and, when Eqs. (7), (14), and (38) are made use of, to

$$\begin{aligned}\mathbf{S}&=\rho_0\{\tfrac{1}{4}\,\mathbf{U}\ \text{div grad}\ \overline{\phi^2}-\overline{\text{grad}\ \phi\otimes\text{grad}\ \phi}\}\\ &=\rho_0\{\overline{\phi\ \text{grad grad}\ \phi}-\tfrac{1}{4}\,\mathbf{U}\ \text{div grad}\ \overline{\phi^2}\\ &\quad-\tfrac{1}{2}\ \text{curl curl}(\overline{\phi^2}\mathbf{U})\}.\end{aligned} \qquad \text{(l.a.)} \quad (87)$$

The first-order velocity potential formally considered in Lagrangian coordinates is ψ with

$$p-p_0=\rho_0\frac{D\psi}{Dt},\quad \mathbf{v}=-\text{Grad }\psi \qquad \text{(l.a.)} \quad (88)$$

and the linear wave equation

$$\frac{D^2\psi}{Dt^2}=c_0^2\ \text{Div Grad}\ \psi \qquad \text{(l.a.)} \quad (89)$$

which follows from Eqs. (60) and (61) by linearization. The following identity holds under the steady-state condition:

$$\left\langle \frac{D}{Dt}(\psi\mathbf{H}^T)\right\rangle=\left\langle\frac{D\psi}{Dt}\mathbf{H}^T\right\rangle+\left\langle\psi\frac{D\mathbf{H}^T}{Dt}\right\rangle=0, \qquad \text{(l.a.)} \quad (90)$$

leading to

$$\begin{aligned}\langle(p-p_0)\mathbf{H}^T\rangle&=\rho_0\left\langle\frac{D\psi}{Dt}\mathbf{H}^T\right\rangle\\&=-\rho_0\left\langle\psi\frac{D\mathbf{H}^T}{Dt}\right\rangle\\&=-\rho_0\langle\psi(\text{Grad }\mathbf{v})^T\rangle. \qquad \text{(l.a.)}\end{aligned} \quad (91)$$

Due to Eq. (88) (right), the matrix Grad $\mathbf{v}$ is symmetric, and

$$\begin{aligned}\langle(p-p_0)\mathbf{H}^T\rangle&=-\rho_0\langle\psi\ \text{Grad}\ \mathbf{v}\rangle\\&=\rho_0\langle\psi\ \text{Grad Grad}\ \psi\rangle. \qquad \text{(l.a.)}\end{aligned} \quad (92)$$

On the other hand, exactly like Eqs. (85) and (86),

$$\langle E_{\text{pot}}\rangle-\langle E_{\text{kin}}\rangle=-\tfrac{1}{4}\rho_0\ \text{Div Grad}\langle\psi^2\rangle \qquad \text{(l.a.)} \quad (93)$$

and, making use of Eqs. (7), (14), and (77),

$$\begin{aligned}\mathbf{B}&=\rho_0\{\langle\psi\ \text{Grad Grad}\ \psi\rangle-\tfrac{1}{4}\mathbf{U}\ \text{Div Grad}\langle\psi^2\rangle\}\\&=\rho_0\{\tfrac{1}{4}\mathbf{U}\ \text{Div Grad}\langle\psi^2\rangle-\langle\text{Grad }\psi\otimes\text{Grad }\psi\rangle\\&\quad+\tfrac{1}{2}\text{Curl Curl}(\langle\psi^2\rangle\mathbf{U})\}. \qquad \text{(l.a.)}\end{aligned} \quad (94)$$

Equations (87) and (94) give the final results for the radiation stress in the Eulerian and Lagrangian representations in the linear-acoustics approximation. It can be seen that the difference between the two expressions is a curl, i.e., it is ''unimportant'' inasmuch as it is irrelevant to the radiation force on a target entirely surrounded by the sound-propagating fluid. The two results can be unified by adding or subtracting, respectively, a curl as follows, taking into account Eqs. (7) and (14):

$$\begin{aligned}&\mathbf{S}+\tfrac{1}{4}\rho_0\ \text{curl curl}(\overline{\phi^2}\mathbf{U})\\&\quad=\tfrac{1}{2}\rho_0\{\overline{\phi\ \text{grad grad}\ \phi}-\overline{\text{grad }\phi\otimes\text{grad }\phi}\},\\&\qquad\qquad\text{(l.a.)}\end{aligned} \quad (95)$$

$$\begin{aligned}&\mathbf{B}-\tfrac{1}{4}\rho_0\ \text{Curl Curl}(\langle\psi^2\rangle\mathbf{U})\\&\quad=\tfrac{1}{2}\rho_0\{\langle\psi\,\text{Grad Grad }\psi\rangle-\langle\text{Grad }\psi\otimes\text{Grad }\psi\rangle\}.\\&\qquad\qquad\text{(l.a.)}\end{aligned} \quad (96)$$

Equations (95) and (96) give the unified result for the (Langevin) acoustic radiation stress in a lossless fluid in the linear-acoustics approximation.[63]

APPENDIX: THE LANGEVIN APPROACH

According to the Langevin approach[7,12,24] and contrary to Eq. (65), the acoustic radiation stress in Lagrangian coordinates is assumed to be

$$\mathbf{B}'=-\langle p-p_0\rangle\mathbf{U} \quad (A1)$$

which represents the first term of Eq. (68) and which according to Eq. (73) is

$$\mathbf{B}'=-\langle E\rangle\mathbf{U} \qquad \text{(l.a.)} \quad (A2)$$

in the linear-acoustics approximation. Due to Eq. (9), its divergence is

$$\text{Div }\mathbf{B}'=-\text{Grad}\langle E\rangle, \qquad \text{(l.a.)} \quad (A3)$$

which indeed vanishes in a plane wave but is not in general zero in other fields, cf., for example, the fields from modern ultrasonic diagnostic instruments which are highly focussed and in which, as a result, the energy density is very different at different points in the field.

According to this approach, the radiation force is given by the integral[64]

$$\begin{aligned}\mathbf{f}=\oiint(\mathbf{dA}\cdot\mathbf{B}')&=-\oiint\langle p-p_0\rangle\mathbf{dA}\\&=-\oiint\langle E\rangle\mathbf{dA} \qquad \text{(l.a.)}\end{aligned} \quad (A4)$$

over the target surface.

Equation (A2) is applied to the three basic field types of Secs. III and VI as follows.

Case 1: Axial field

This is no special case of the Langevin approach, i.e., the general result of Eq. (A2) is retained. A comparison with Eqs. (40) and (78) shows that there is agreement in the ''important'' stress component which is the normal stress numbered 11. It is probably for this reason that the Langevin approach has been regarded as meaningful.

Case 2: Plane-progressive wave in an arbitrary direction

The result in this case is

$$\mathbf{B}'=-\frac{\hat{p}^2}{2\rho_0c_0^2}\mathbf{U}, \qquad \text{(l.a.)} \quad (A5)$$

to be compared with Eqs. (43) and (80). If the wave is incident on an absorber surface of orientation **dA** the infinitesimal radiation force is

$$\mathbf{df}=\mathbf{dA}\cdot\mathbf{B}'=-\frac{\hat{p}^2}{2\rho_0c_0^2}\mathbf{dA}, \qquad \text{(l.a.)} \quad (A6)$$

which means that the radiation force given here is normal to the absorber surface and not in the direction of the incident wave as in the corresponding results of Secs. III and VI.

Case 3: Superposition of two oblique plane waves of equal amplitude

The result in this case is

$$\mathbf{B}' = -\frac{\hat{p}^2}{\rho_0 c_0^2}(1+\sin^2\gamma\cos\beta)\mathbf{U}. \qquad \text{(l.a.)} \quad \text{(A7)}$$

It can be seen that with the exception of the special case $\cos\beta=-1$, there is no agreement with Eqs. (48) and (82), not even for the ''important'' stress component which is the normal stress numbered 11.

The Langevin approach is obviously in contradiction to important experimental facts (cf. also Ref. 53) and does not in general agree with the Brillouin approach worked out in this paper and shown in Sec. II to be in line with other radiation force theories of the literature.

Finally, the following is worth mentioning. In Ref. 20 the radiation stress of Eq. (38) has been integrated over a field cross section of infinite extent in a piston field including diffraction effects, in order to obtain a value for the radiation force on an absorber of infinite size as a theoretical reference result for practical radiation force measurements. If, however, the radiation stress according to the Langevin approach had been used for this purpose, no result would have been obtained as the improper integral would not exist, or in other words, any result might have been obtained if only the radius of the integration area had been chosen large enough.

[18] He stated that the closed surface integrals of the two versions of radiation stresses are both zero (in the no-target case) and then concluded that the radiation stresses themselves are equal to each other, but this conclusion is not necessarily true (zero-divergence quantities are not necessarily equal to one another; cf., for example, the various zero-divergence quantities appearing in this paper, including the unit matrix and, in addition, the zero matrix, too).

[37] H. Lamb, *Hydrodynamics* (Dover, New York, First American Edition 1945).

[38] Conditions for the applicability of the Stokes integral theorem are that the matrix and its curl exist, and are continuous, in a region containing the surface under consideration and its border line. The theorem is applied here twice, namely separately to both hemispheres (or generally, to both parts of the closed surface), and not to the whole sphere and its entire interior. So the rule mentioned is valid even with a target in the interior of the sphere (or generally, of the closed surface).

[40] K. Beissner, Acustica **62**, 255–263 (1987).

[41] *Nota bene:* as long as the radiation stress is a zero-divergence quantity which, in general, is not the case in lossy fluids, but this need not be discussed here as lossy fluids are not dealt with in this paper.

[42] The divergence of the radiation stress is assumed to be nonzero in the interior of the target or at its surface. The target usually represents a discontinuity with respect to the sound-propagating medium and its acoustic properties. The case that the divergence of the radiation stress is zero even throughout the target and its surface is trivial and is equivalent to the no-target case.

[44] F. E. Fox and W. A. Wallace, J. Acoust. Soc. Am. **26**, 994–1006 (1954). As far as Langevin's relations, Eqs. (37) and (73), are concerned, the Fox–Wallace nonlinearity parameter appears in their third-order approximation only or, on the other hand, it may appear in the constant which depends on the boundary conditions. When the Langevin case (where the

constant is zero or can be neglected) is considered up to the second order, the nonlinearity parameter is irrelevant.

[46] If it were understood as pointing inwards, a minus sign would appear as, for example, in Ref. 20.

[47] In the literature it is often stated that the potential acoustic energy density is equal to the kinetic one (their difference being zero) or in a more indirect way, that the total acoustic energy density is twice the kinetic one and so on. This is an indication that only plane waves and not general fields are dealt with in these cases.

[48] P. M. Morse and K. U. Ingard, *Theoretical Acoustics* (McGraw-Hill, New York, 1968). The wave-stress tensor appears as the wave momentum flux density in their Eq. (6.2.17), but then they speak of a radiation pressure (a vector in their notation) exerted by the wave, and associate it with the wave momentum density. Already Brillouin criticized Rayleigh for attributing the radiation forces to the momentum density and not to the momentum flux density. [In the present paper, the momentum refers to the fluid and not to the wave; cf. also M. E. McIntyre, J. Fluid Mech. **106**, 331–347 (1981)].

[52] In a lossless fluid the instantaneous contact force is of course normal to the instantaneous surface under consideration, but the orientation of a material surface is in general time dependent, and the time-average force is, therefore, not necessarily normal to the time-average surface, cf. Refs. 2 and 22 and J. Awatani, J. Acoust. Soc. Am. **27**, 278–281 (1955). Note in particular that the acoustic pressure is an alternating quantity. Consider the average of a positive force vector and a negative one, both being of the same order of magnitude but with a slightly different orientation. The superposition of these vectors leads to a small resultant vector whose direction depends on the details of the situation but can even be tangent to the surface (the radiation force is generally small in comparison with the force amplitudes of the instantaneous field).

[55] Grad $\mathbf{x}$ to be distinguished from grad $\mathbf{x}=\mathbf{U}$ and from Grad $\mathbf{X}=\mathbf{U}$.

[56] Equivalents of Eqs. (52) and (53/54) in a more generalized tensor notation can be found as Eqs. (20.10) and (20.8) in Ref. 15. Equivalents of Eqs. (56) and (63) in a more generalized tensor notation can be found as Eqs. (210.4) and (210.8) in Ref. 15, but here a different nomenclature and the different definition of the stress indices should be taken into account.

[57] Strictly speaking, this is one solution but not the only one. Any matrix $\mathbf{K}'$ for which $\mathbf{dA}\cdot\mathbf{K}'=0$ is valid can be added to $\mathbf{K}$. However, we are interested here in the resulting force values, and as these other matrices give no force contribution they can be ignored here.

[58] The symbols $\mathbf{F}$ and $\mathbf{H}$ have been adopted from Ref. 16. The symbols $\mathbf{K}$ and $\mathbf{B}$ stand for ''Kirchhoff'' and ''Boussinesq.'' The matrix symbols $\mathbf{H}$ and $\mathbf{B}$ here have nothing to do with the electromagnetic field vectors.

[59] In addition, the following may occur in an acoustic streaming: Fluid particles which were close together in the reference state may get more and more distant from one another with time. This leads to the Lagrangian spatial derivatives assuming increasingly higher values and therefore, $\mathbf{F}$ and $\mathbf{H}$ are not in a steady state.

[60] It may be, however, that in the temporal average of Eq. (35), the deviation of $\mathbf{v}\times\operatorname{curl}\mathbf{v}$ from zero in an acoustic streaming is only a higher-order effect, but this need not be discussed here.

[61] In the older literature the lateral stresses have sometimes been considered important for the ''boundary conditions'' mentioned in the Introduction. Note, however, that all results obtained here refer to the ''relaxed'' condition as set out in the discussions in Ref. 19 and that in this context the lateral stresses are unimportant for the radiation force on the target in the cases considered.

[62] It might appear that with the velocity potential being in a steady state, its time derivative, the acoustic pressure, should generally by zero on the time average. It should, however, be noted that Eq. (83) (left) is only valid in the first-order approximation and that in fact Eq. (37) [as well as Eq. (73)] does not contain first-order contributions to the time-average acoustic pressure.

[63] Equations (83) and (84) involve only temporal and spatial derivatives of the velocity potential, i.e., ϕ is indeterminate to the extent of an additive constant. In the first term in the curly brackets on the right-hand side of Eq. (95), however, ϕ itself appears. So it might appear that an additive constant in ϕ could have an influence on the radiation force, but this is not the case. If $\phi(\mathbf{x},t)$ is replaced by $\phi_0+\phi(\mathbf{x},t)$, with ϕ_0 being constant in space and time, it is easy to show with the aid of Eqs. (14) and (84) that all terms with ϕ_0 are unimportant for the radiation force as they either have the form of a curl or vanish in the time average, due to the steady-state condition. The similar applies to ψ and Eq. (96).

[64] Cf. Eqs. (A23) and (A26) of Ref. 23 (where, however, the minus signs do not appear as the surface element vector is understood there to point inwards).

Measurement and localization of interface wave reflections from a buried target

Applied Research Laboratories, The University of Texas at Austin, P.O. Box 8029, Austin, Texas 78713-8029

(Received 10 October 1996; revised 1 August 1997; accepted 31 December 1997)

It is demonstrated that seismic interface waves on the surface of a natural beach can be used to identify the position of a buried object. For this experiment, the waves were created with a sediment-coupling transducer and received on a three-element horizontal line array of triaxial geophones. The source and its coupling to the medium provided a high degree of signal repeatability, which was useful in improving signal-to-noise ratio. Reception of all three directions of particle velocity made it possible to augment conventional beamforming techniques with polarization filters to enhance interface-wave components. Reverberation in the beach was found to be large, though, and coherent background subtraction was required to isolate the component of the sound field reflected by the target. Propagation loss measurements provided comparisons of reflected signal power with predictions made previously, and the two were found to agree closely. [S0001-4966(98)03304-9]

INTRODUCTION

One approach to the problem of detecting and locating buried objects is echo location, using direct excitation and reception of seismic waves. Because it is basically an acoustic method, it offers an advantage over magnetic detection that it can be applied to nonmagnetic objects. At the same time, unlike applications based on fluid or bulk-medium sonars, it circumvents the complexity associated with transferring sound energy and information across a fluid/solid interface. Furthermore, seismic excitations can have shear as well as compressional components, so they comprise many independent degrees of freedom that can carry a rich spectrum of information.

Interface waves, such as the free-surface Rayleigh wave, are of particular interest in the context of seismic echo location, because they contain energy, and are sensitive to medium characteristics, near the surface of the solid in which they are excited. These are useful features for detection of shallowly buried objects in unconsolidated sediments, where restriction of the search field to the upper sediment region is appropriate, and attenuation in the sediment makes energy containment near the surface desirable.

It has been shown that interface waves propagating along the sea floor can be detected and processed with seismic arrays to clearly identify the direction of the source.[1] This demonstration incorporated beamforming techniques which correct for the dispersion that is a common feature of such waves. The work reported here extends many of the results of the previous investigation to include the interface-wave reflections from a passive target insonified with an active sonar.

In many applications, the buried objects of interest may be small compared to the wavelength of the excitations used. In this limit, it is possible to predict the scattering strength from such targets in terms of their material properties and those of the medium, using efficient algebraic expressions. A perturbative method for generating such predictions is presented in a companion article.[2]

Finite-element numerical calculations for similar systems have been made and show good agreement with the perturbative methods,[2,3] and hybrid boundary-element/global-matrix[4] and finite-difference methods[5,6] have been applied to the related problem of facet reverberation. Experimental investigations, similar in sensitivity and scale to that reported here, have previously been presented,[7–9] but prior to now experimental data have not been available in the literature to test the perturbative predictions in detail. The work reported here also differs from that of Refs. 7–9 in the nature of the source used, and in the employment of polarization filters to process received signals.

An experiment was performed in May 1995, on a beach of the Gulf of Mexico, to address these issues. The data presented here show that it is possible to extract the interface-wave reflections induced by a buried target from noise backgrounds, with sufficient precision to quantitatively test the predictions of the perturbative scattering theory.

For this experiment, an active seismo-acoustic interface-wave sonar was designed and implemented. Its source was an electromechanical transducer that coupled directly to the beach surface, and its receiver was a three-element line array of triaxial geophone sensors. Special signal processing methods were employed, to make use of the large amount of directional and phase information present in the three-dimensional particle velocity field provided by this seismic sensor array. The interface-wave reflections from the target were found to possess sufficient coherence that beamforming

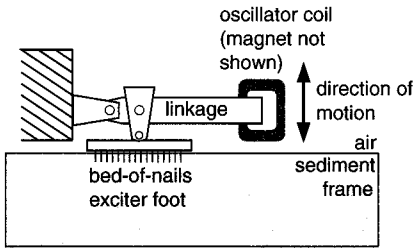

FIG. 1. Schematic of the transducer and coupling to the sediment.

methods could be used to produce a sonar output in plan position indicator (PPI) format, clearly identifying the target location. However, the seismic response of the beach led to a large reverberant component in the signal, and it was necessary to perform coherent background subtraction of a measured reverberation reference signal from measurements with a target present, to extract the target-induced reflection.

A second part of the experiment consisted of seismo-acoustic characterization of the medium with broadband sources. These were used to obtain information about dispersion, geometric spreading, and attenuation of seismic signals. The dispersion and attenuation characteristics were used to determine the preferred range of operating frequencies for the sonar, and the spreading and attenuation measurements were used to obtain transmission loss parameters for this site. With these, it was possible to compute interface-wave target strengths from the reflected signal power measured at the array. The resulting target strength values will be shown to be in good agreement with the results of the first-order perturbative calculation.

I. SOURCE AND SIGNAL CHARACTERISTICS

Two inertial impact sources and a specially designed electromechanical transducer were used as seismo-acoustic sources in this experiment. The impact sources will be described separately below. The transducer consisted of an electro-mechanical oscillator, linked to the sediment frame at the beach surface through an inverted ''bed of nails'' foot. Electrical inputs to the transducer were generated on a personal computer and amplified with a 500-W audio power amplifier. The oscillator and linkage assembly was mounted on one end of a cantilever, with the other end supported by a broad, acoustically buffered stabilizing platform that rested on the beach. The inertance for the oscillator was provided by the magnets and frame hardware.

The bed-of-nails foot was a reinforced rectangle of epoxy foam measuring 15 cm$\times$20 cm with a corrugated surface, from which thirty-eight 4-cm carpentry nails protruded in staggered rows, to embed in the beach. The corrugation and nail matrix served to distribute transducer stresses so that high power could be delivered to the beach surface without plastically deforming the sand matrix, to improve signal repeatability. A schematic of the transducer is given in Fig. 1.

The seismic output signal from the transducer, used for both *in situ* medium characterization and object detection, was chosen to be a Gaussian-enveloped cosine of center frequency 100 Hz. The full width at half-maximum of the signal envelope was chosen to equal one cycle period. Reasons for this choice of waveform and frequency band will be discussed below. The electrical input to produce the desired waveform was constructed in two steps, in an effort to remove as much of the transducer and medium response function as possible at the source. A broadband electrical test input was first applied, and the seismic waveform on a sensor 0.5 m from the source was recorded. The loaded response function of the transducer was obtained by dividing the Fourier transform of the measured seismic signal by that of the input. The Fourier transform of the desired output was then divided by the response function, and the result was inverse-Fourier transformed to obtain a time series for the desired electrical input.

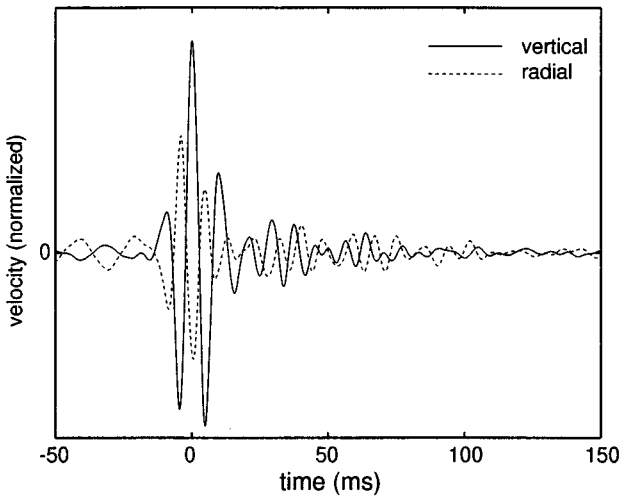

FIG. 2. A typical signal received on a geophone 0.5 m from the transducer foot. Solid (dashed) lines are vertical (radial) components of particle velocity.

In the ideal case, an electrical input produced with this method would pre-correct for the transducer response function, and reproduce the desired output. In realistic applications, the deconvolution of the response function tends to be unstable against noise. In this experiment, the seismic signal produced by pre-correction was found to acceptably approximate the desired output. The measured vertical and horizontal velocity signals produced at short range from the pre-corrected input are shown in Fig. 2.

The seismic sensors used in all measurements consisted of three 6-Hz geophones packaged in a balanced cylinder of epoxy foam to form a triaxial velocimeter. The sensor package had specific gravity 2.0 (comparable to that of saturated quartz sand[10]), height 5.6 cm and diameter 9.4 cm. When buried in the sand, the receiver packages appeared to be acoustically transparent to all of the signals used. Measurements with single sensors were used to obtain dispersion, time-of-flight and propagation loss measurements for *in situ* acoustic environment characterization, and the sensors were deployed in a linear array to form the receiver of the active sonar.

II. SITE CHARACTERIZATION AND SIGNAL PROPAGATION

The experimental site was the seaward beach of Mustang Island, a natural barrier island between Corpus Christi

bay and the Gulf of Mexico. Geologic studies have been conducted in the area, consisting of cores and detailed surface-sediment analysis.[11–13] The experiment described here was performed on the foreshore, defined in Ref. 14 as the region over which the surf travels between high and low tides. This region was very smooth and uniform, with a slope of roughly 3–6 degrees and width of 25–50 m. All measurements were carried out in a region of wet, but not wave-washed sediment, at times when the tide was below maximum.

Cores taken in the region[11] indicate that the top 30 m of the beach are composed of clean, well-sorted, and predominantly quartz sand, with some shell hash and other minerals. A grain size distribution of $\phi = 2.8 \pm 0.35$ was measured, where $\phi = -\log_2 D$ and D is the grain diameter in mm. While the sand is well sorted on small scales, cores showed some sedimentary layering, with layers of finer sand than that at the surface, from one to three meters thick, lying anywhere from 3 to 5 m subsurface. Layer depths and thicknesses varied among cores, though, and surface topography of the beach has been measured to vary by heights of roughly 1 m relative to mean sea level in the course of a year.[12] Thus the depths, thickness, or compositions of layers at a particular site are not precisely specified by existing records of geologic ground truth. The water table was estimated to lie roughly one meter below the beach surface while the current measurements were being taken.

In situ estimates of the effects of beach layering or sediment compaction with depth on acoustic propagation were obtained by measuring the dispersion curves of signals, created with a manual impact source, that propagated some 100 m along the surf line. The source was a cylindrical handle with a flat plate impactor welded to the end. The goal of these measurements was to determine what modes were created by sources at the beach surface, to assess their polarization and dispersion characteristics, and from these to identify optimal frequency ranges or signal processing methods for object detection.

Figure 3 shows Gabor matrix contour plots of the signals received on the horizontal and vertical geophones in the vertical plane looking from the receiver toward the source. A Gabor matrix is a time-frequency decomposition of the spectral density in a signal, plotted with frequency on the abscissa and time-of-flight on the ordinate. Figure 3 was produced by windowing the signal in the time domain with a sequence of Hanning windows, and plotting the spectra of the windowed segments, obtained as the absolute values of the fast Fourier transforms (FFT), as rows stacked according to the arrival time at the center of each window.

The group velocities of arriving pulses may be obtained from the Gabor plot by tracing along the maxima of the contours in regions of contiguous spectral density, and the phase velocities may be computed from this data.[1] The shear speed profile as a function of depth in the medium is then inferred by fitting the group velocity curve from a model profile to that measured from the Gabor plots. A simple two-layer shear speed model is shown as Fig. 3(c), and its associated group and phase velocities are plotted as the dashed and solid lines superimposed on the Gabor matrix plots. This

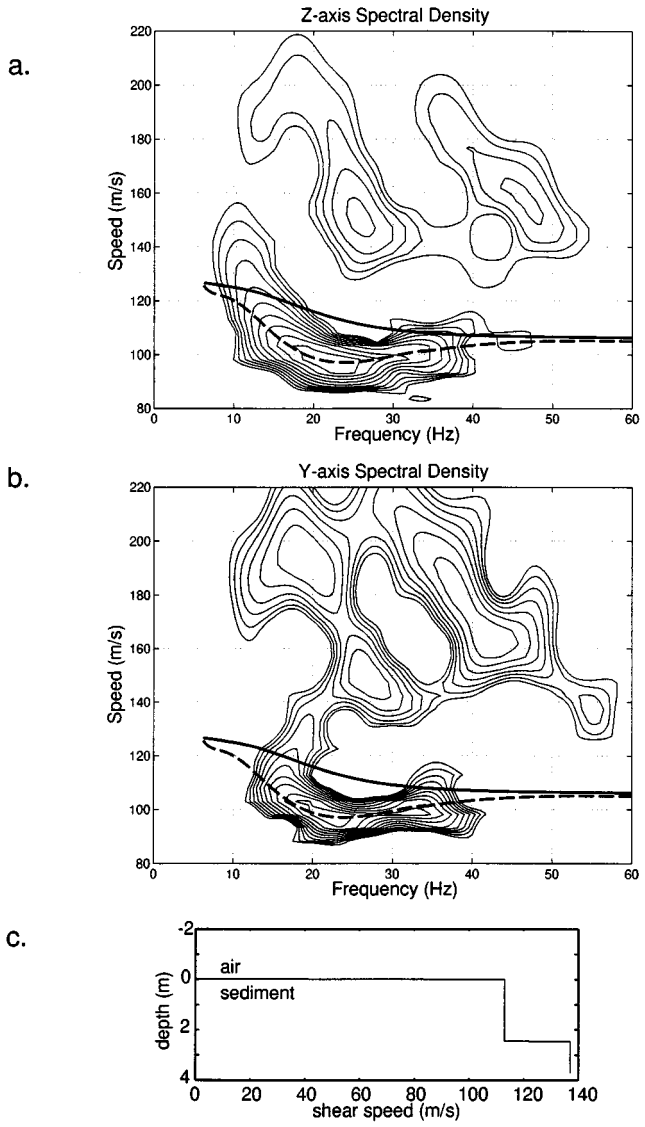

FIG. 3. Velocity-frequency decompositions (Gabor Matrix contour plots) from impacts, at 100-m source–receiver range along surf line. (a) radial; (b) vertical channels of particle velocity at receiver. Thick solid (dashed) lines are fits to phase (group) velocity from a model with an elastic layer over an elastic half-space. Shear speed profile for the model is shown in (c). Layer speed is 113 m/s, half-space speed 137 m/s, layer thickness 2.5 m. Compressional speeds are 1600 m/s in layer and half-space; model is insensitive to variations of compressional velocities as long as they are several times faster than shear speeds.

simple model of a homogeneous upper layer over a homogeneous half-space can be seen to match the measured group velocities within the uncertainty of the Gabor matrix contours above 15 Hz, which is the frequency range over which the Rayleigh wave propagation is controlled by the top 3 m or less of sediment.

The sequence of windows used in Fig. 3 was chosen so that the sum of all window values at any point in the time domain is unity. This makes it possible to decompose the Gabor matrix by ''cutting'' along boundaries between the modes, resumming the FFTs for all segments within a given cutting boundary and inverse Fourier transforming, to produce time series for the individual modes separately. When the modes are well separated, as they are in this case, this

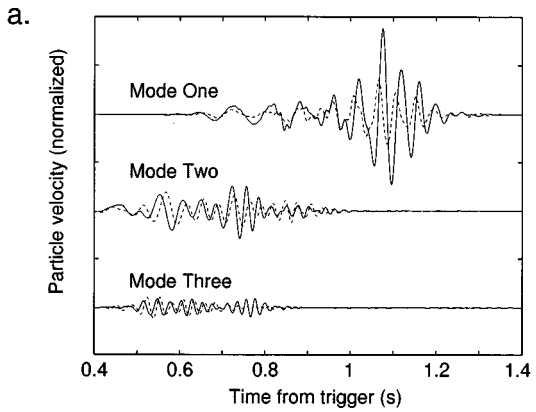

FIG. 4. Decomposition of the time series leading to Fig. 3 into modes, performed by summing FFT segments from contiguous regions of large spectral density in Gabor matrix. Solid (dashed) lines are vertical (radial) particle velocity components.

decomposition makes it possible to recover the individual mode time series with minimal corruption by either the window functions employed in the time domain, or those used to define the cutting prescription along rows in the Gabor matrix. The resulting modal time series for the three modes of Fig. 3 are shown in Fig. 4.

Plots of the horizontal signal versus the vertical signal yield hodograms (representations of actual particle velocity as the wave passes the receiver), which are shown for the three modes respectively in Fig. 5. The slowest mode, labeled ''Mode One,'' is vertical in aspect ratio and retrograde in sense of particle motion (polarization), which is consistent with the identification of this mode as the free-surface Rayleigh wave.[15] Both higher modes are prograde in polarization and more horizontal than the Rayleigh mode in aspect ratio.

Frequencies higher than 50 Hz were not visible above noise in the long-range dispersion analysis, so pulses from the transducer were used to examine higher-frequency propagation at closer ranges. Figure 6 shows received vertical time series and pulse envelopes for pulses propagated distances of 1, 5, and 10 m. The envelopes were obtained as the absolute values of the quadrature completions of the received time series. Center frequency of the pulses was 100 Hz. Time-of-flight estimates were made for these pulses by fitting a straight line to the maxima of the envelopes as a function of range. The mean pulse speed inferred by this method is 115 ± 5 m/s, consistent with the high-frequency asymptotic behavior shown in Fig. 3.

The *in situ* data were interpreted as indicating that an acoustically significant interface is present roughly 2 m below the beach surface (inferred from the layer model), forming a duct of nearly constant, slower shear speed between the beach surface and the lower interface. The cutoff frequency for shear modes in the duct coincides with the frequency of the group speed minimum for the Rayleigh wave, equal to roughly 25 Hz. Rayleigh waves of higher frequencies, being evanescent from the beach surface, involve particle motions almost entirely confined within the homogeneous upper layer and propagate effectively without dispersion.

To determine the geometric and dissipative losses characterizing high-frequency signals, a sequence of low energy,

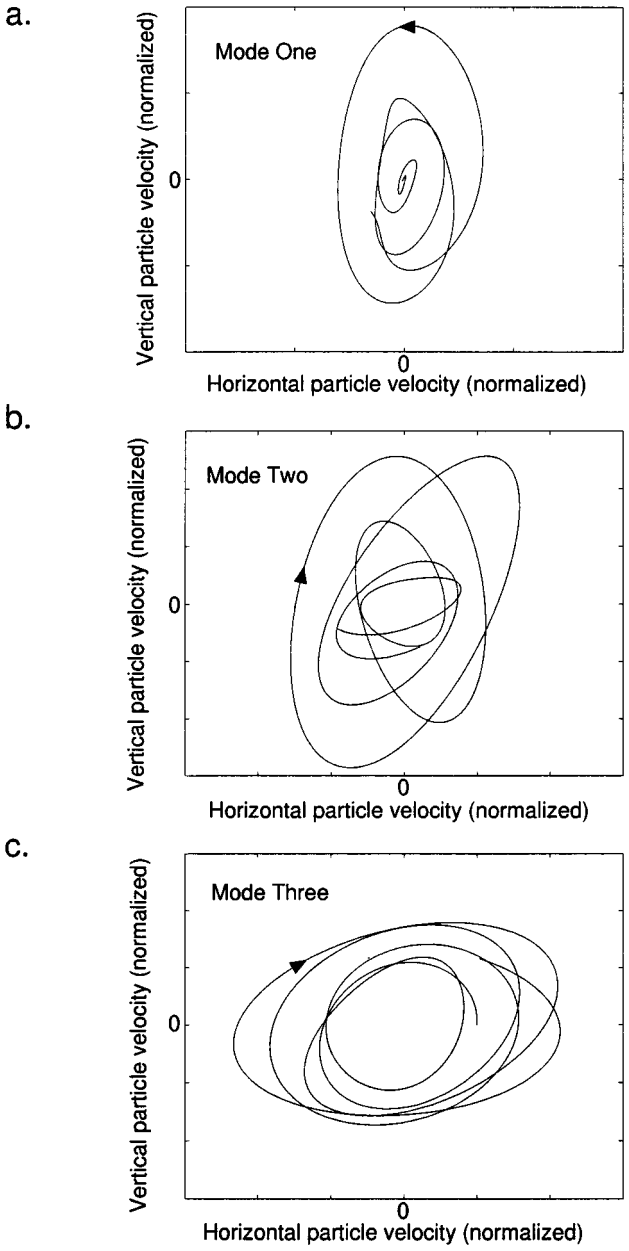

FIG. 5. Hodograms, or plots of particle velocity in the radial-vertical plane, for each of the time series shown in Fig. 4. Arrows indicate directions in which sediment frame traces the curves. Motion is retrograde for mode one, prograde for modes two and three.

calibrated impacts was used to produce broadband signals at ranges from 50 cm to 30 m from the receiver. The impacts were made by dropping an onyx sphere of diameter 8 cm from heights ranging from 10 cm to 2 m, to embed without bouncing in a region of wet but not saturated sand. The signals produced were found to scale in amplitude with the momentum of the drops, and were otherwise nearly independent of drop height. (This made it possible to vary drop height with range to optimize signal quality relative to noise, without overdriving the sensors. The spherical impactor provides very repeatable signals, unlike the plate impactor previously described.)

The received signals were band passed in 30-Hz bins and fitted to functions of the form $Ae^{-\kappa r}/r^{\alpha}$ in each bin.

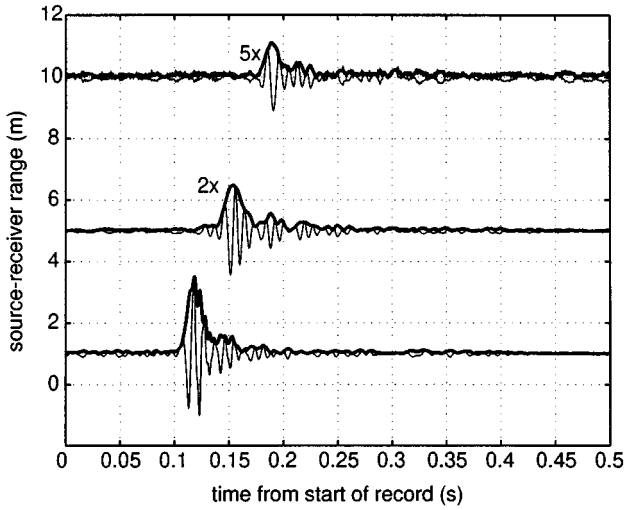

FIG. 6. Time series of pulses used in time-of-flight velocity measurement. Thin lines are vertical-channel geophone signals, and thick lines are rms amplitudes used to identify corresponding points in the group envelope at different ranges. Best-fit velocity for this population is 115 ± 5 m/s. Signals at 5-m and 10-m range have been multiplied by the indicated scale factors relative to the signal at 1 m, to aid visibility.

Data and fit for the bin from 90 to 120 Hz are shown in Fig. 7. The best-fit value of the power law for geometric spreading is $\alpha = 0.55$, and the best-fit dissipation factor is $\kappa = 0.912$ dB/m. The population shown represents the dominant frequency content for these impacts; results were similar, but scatter in the data was larger, in the bins at both higher and lower frequencies. These data confirm that the signal is carried by a cylindrically spreading wave, and the dissipation is consistent with values previously reported for clean sand.[10]

The results of these measurements were used to identify an optimal frequency range for the object-detection experiments. The best range resolution possible was desired, which recommended single-cycle pulses. A resolution of order 1 m could be obtained from pulses of center frequency 100 Hz. Such pulses were sufficiently bandlimited that most of the signal energy propagated in the high-frequency asymptotic part of the Rayleigh wave dispersion curve indicated in Fig. 3. Significantly higher frequencies were found to damp out too quickly to provide useful signal strengths over propagation paths of even 5–10 m, while lower frequencies than 100 Hz produced wavelengths longer than 1 m and could not be enveloped in single-cycle pulses without leading to significant dispersion of their lower-frequency components.

III. SIGNAL PROCESSING METHODS

Extraction and localization of seismic interface wave signals can employ a number of signal processing methods that are not available for simpler pressure-wave acoustic signals. This is because interface waves are vector excitations, containing a dominant shear component. In the case of Rayleigh waves, the radial component of the particle motion in the wave is collinear with its direction of travel. Further, interface waves, by their nature as evanescent waves that decay with distance from an interface, generically have phase offsets between the horizontal and vertical components of their particle motion. These phase offsets cause the particle motion to be elliptical, or *polarized*, in the radial-vertical plane, as appears in the hodograms of Fig. 5. It is possible to filter for this polarization, preferentially selecting interface-wave components of a signal, over in-phase components associated with bulk motion in the solid or the air. Both techniques were combined with traditional beamforming methods to create a signal-processing algorithm for an active seismic sonar, as described below.

The sonar source and targets were deployed along a line parallel to the surf line. Targets were placed at several ranges along this line, and a linear receiving array of three triaxial geophones was buried, with their top surfaces flush with the beach surface, and with the center element 0.5 m in front of the source. The receiving array was offset in angle, so that the source–target line was 22.6-deg off-broadside, and the element spacing used was 1.08 m. The nine directional signals from the array elements were received and stored, along with copies of the output signal that were used to specify a zero-time for pings.

Processing of the array signals to yield a PPI sonar plot was performed in three stages. First, for each position in the search field, a look direction was defined from each element. Because the distances between source, target and array elements were all comparable to the wavelengths used, exact look directions, rather than far-field approximations, were used. To define the planes of interest for imaging a cylindrically spreading Rayleigh wave, the vertical signal and a steered radial signal,

$$r_i(t,\mathbf{x}) \equiv x_i(t)\cos\,\theta_i(\mathbf{x}) + y_i(t)\sin\,\theta_i(\mathbf{x}), \tag{1}$$

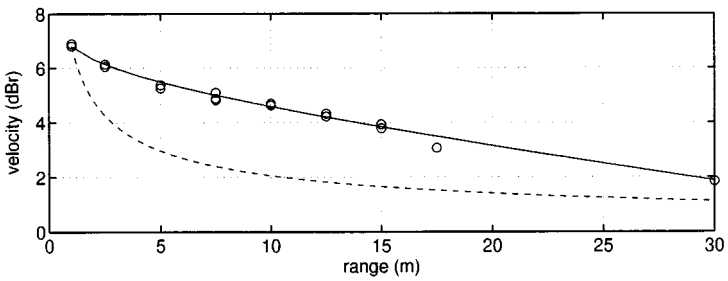

FIG. 7. Fit of bandpass-filtered packet envelopes, for a population of spherical impactor drops, to the function $Ae^{-\kappa r}/r^{\alpha}$, with r in meters. Pass band is 90–120 Hz. A is a normalization and fit parameters shown are $\alpha = 0.55$, $\kappa = 0.912$ dB/m. (Dashed line shows cylindrical spreading without dissipation, for reference.)

were retained. Here, $\mathbf{x}$ is the position in the search field, $x_i(t)$ and $y_i(t)$ are the two received time series on the horizontal geophones, at element i in the array, and $\theta_i(\mathbf{x})$ is the angle to position $\mathbf{x}$ from the ith element relative to the x sensor direction.

The vertical and radial signals from all three elements were multiplied by element shadings σ_i between 0 and 1, and the steered signals for each search position were summed with appropriate time-of-flight delays for that position to produce a two-channel array output:

$$v_{\text{array}}(t,\mathbf{x}) \equiv \sum_i \sigma_i v_i(t - t_i(\mathbf{x}),\mathbf{x});$$
$$r_{\text{array}}(t,\mathbf{x}) \equiv \sum_i \sigma_i r_i(t - t_i(\mathbf{x}),\mathbf{x}). \tag{2}$$

Here, $t_i(x)$ is the time delay between the central and ith element for search position $\mathbf{x}$, and v_i is the vertical signal measured on element i. The two components v_{array} and r_{array} sum constructively for the outgoing vertical and radial components that would be produced by a cylindrically spreading Rayleigh wave reflected from a target at position $\mathbf{x}$.

Polarization filtering for this application is the process of extracting, from a radial-vertical signal pair, the component of the crossed signal power that comes from the elliptical particle motion of the wave. It was performed on the radial and vertical array signals defined in Eq. (2) as follows: Each real-valued time series was Fourier transformed to produce a complex spectrum. Negative-frequency components of this spectrum were zeroed; positive-frequency components were multiplied by two; the resulting spectrum was inverse-Fourier transformed. This produces a quadrature completion of the real time series, the positive-frequency complex signal whose real part is the measured signal. The completed signals r and v will be denoted r_C and v_C (for ''Complex'').

A complex, crossed power function in the time domain, denoted P_{rv}, was then formed from r_C and v_C as

$$P_{rv}(t,\mathbf{x}) \equiv r^*_{\text{array } C}(t,\mathbf{x}) \times v_{\text{array } C}(t,\mathbf{x}), \tag{3}$$

where * denotes complex conjugation. P_{rv} contains the in-phase and out-of-phase power components that can be extracted from the signal pair, as its real and imaginary parts. If r_C and v_C happen to be two copies of the same signal, then P_{rv} is a purely real quantity, proportional to the rms power in the signal pulse. Other in-phase motions differ only by an overall scale factor, determined by the relative projections of the wave into the radial and vertical axes.

For an interface-wave pulse arriving at the receiver, the two quadrature-completed signals are again copies of the same time series, but the phase delay in the particle motions appears as a relative *complex* phase in the complex waveforms. P_{rv} is again proportional to the rms pulse power, but deflects in the complex plane along an axis defined by the phase angle.

Therefore, the imaginary component of P_{rv} projects out purely in-phase arriving signals, and deflects positively or negatively for polarized signals, according to whether the polarization is prograde or retrograde. An example of the process of polarization filtering is shown in Fig. 8.

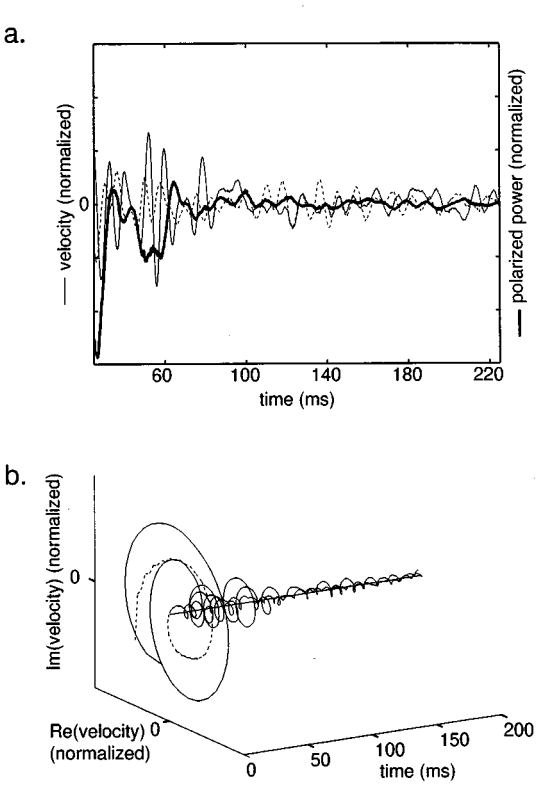

FIG. 8. Polarization filtering and crossed power in the time domain. (a) Vertical (solid-thin) and radial (dashed-thin) time series obtained by subtracting a 10-signal average of events with no target from a 10-signal average with a target present, received on the central array geophone of the active sonar apparatus. (b) The quadrature completions obtained from the real-valued time series in part (a). Using r to denote the complex radial time series (dashed), and v the complex vertical (solid), the crossed radial-vertical power is defined as the product $P_{rv} \equiv r^* \times v$ in the time domain. Its polarized component, $\text{Im}(P_{rv})$, is plotted as the heavy line superimposed on the time series in part (a).

This imaginary part of P_{rv}, representing the polarized power component, is plotted versus position $\mathbf{x}$ in the search field to produce the PPI output. Because the signal can deflect either positively or negatively, a linear scale is used, and the sign of the deflection gives an additional form of visual information about the arrival. For instance, if the arriving signal is known by some other means to be a Rayleigh wave, the sign of the polarized component resolves the forward-backward ambiguity of the linear array. Alternatively, if the direction of arrival is known, the polarization provides information about the type of mode that carried the signal.

An example of the sonar plot produced by this method is shown in Fig. 9. The inputs to the algorithm were the raw geophone signals measured with a target buried 3 m in front of the source, at bearing -22.6 deg from array broadside. A population average over ten ''pings'' was used to reduce random noise. The target used was a titanium cylinder of height 20 cm and diameter 22.5 cm, weighing 35.4 kg. It was buried with the cylinder axis vertical and its top surface flush with the beach surface. (For wavelengths larger than the typical target dimensions, this orientation is not expected to affect reflection signatures.[2]) The scale used for $\text{Im}(P_{rv})$ was chosen to normalize the polarized power of the outgoing

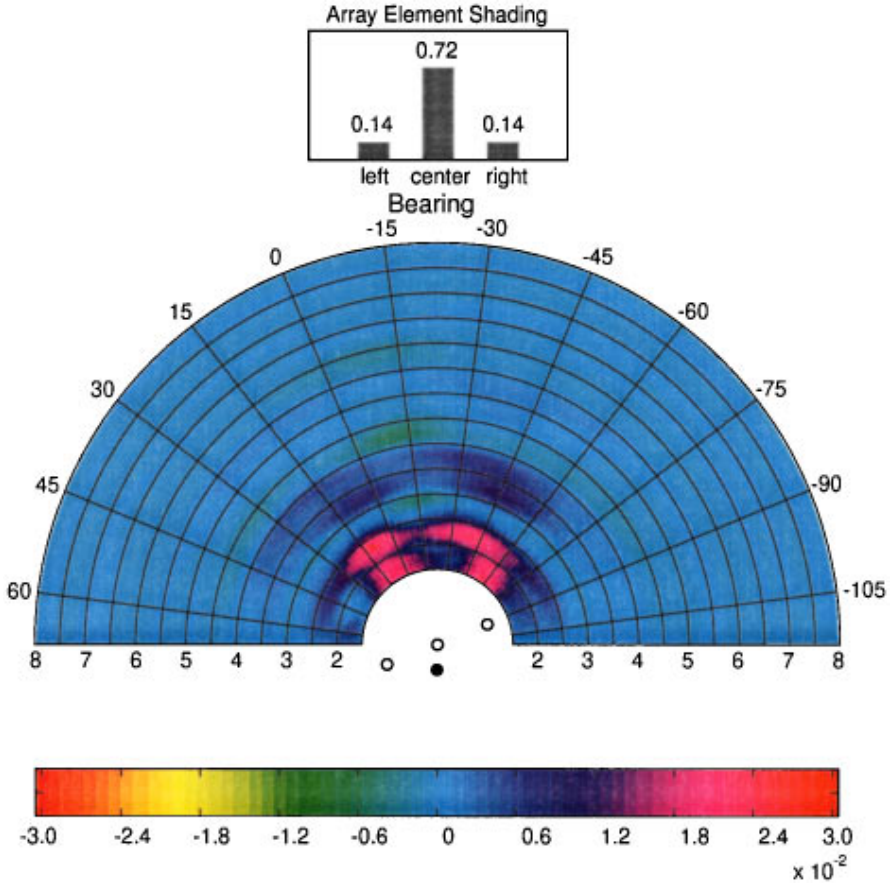

FIG. 9. Example sonar plot of a signal from a buried target before subtraction of reverberant backgrounds. Polarized component of the crossed radial-vertical power, $\mathrm{Im}(P_{rv})$, shown with linear color scale. Blank region in the center of the display shows source and receiver locations. Solid circle is the source position, and outlined circles are the array element positions. Plot produced with element shadings depicted, and mode velocity 113 m/s.

direct arrival to unity at 1 m (i.e., source level of 0 dB). No evidence of a target reflection is visible at the expected location, but numerous artifacts of order $\pm 2\%$ are present.

IV. ANALYSIS OF BACKGROUND AND NOISE FEATURES

In Fig. 2, deviation from the desired output is largest immediately following the main signal pulse. To understand the nature of this deviation, as well as the origin of the features in Fig. 9 and their relation to statistical and systematic components of noise, the signal creating a slice through the PPI plot, looking along the chosen source–target line, was analyzed in the following ways.

Figure 10(a) shows the autocorrelation of the vertical (quadrature completed) signal, defined as

$$\left| \int dt v^{*}_{\text{array } C}(t) \times v_{\text{array } C}(t-\tau) \right| \Big/ \int dt |v_{\text{array } C}(t)|^2,$$

as a function of offset time τ. Because of the form of the signal, shown in Fig. 2, the large direct arrival dominates the correlation, acting as a matched filter to extract copies of itself appearing later in the time series. Because the full complex signal is used, these can appear with any phase offset, relative to the direct arrival. The magnitude of peaks gives, to linear order, the *amplitude* of the reflected copies, because the main weight of the filter function is invariant.

A complicated series of peaks can be seen in the autocorrelation. Once the constructive interference of the direct arrival with itself is past, though, the maxima of the peaks fall nearly on a line, with most peaks in the series forming a regular sequence (indicated by the arrows). If these are interpreted as a sequence of reflections from a subsurface interface, the associated ray diagram for the four indicated peaks is shown in Fig. 10(b). Using the reference distance of 0.5 m from the source to the central receiver element, and the measured value of the shear speed, the inferred depth of the reflecting interface is 2 m, consistent with the value obtained from the dispersion analyses of Fig. 3. It is therefore concluded that a large component of the signal background is due to reverberation within the beach, with an amplitude reflection coefficient of roughly 0.5 indicated by the straight line in Fig. 10(a).

Because of the pre-correction process used to produce these signals, it is likely that reverberation signatures are present both directly and indirectly via the response-function deconvolution. This does not compromise the signal processing methods applied here, and it may explain why the sequence of peaks seen in Fig. 10(a) is more complex than the simplest single-layer model predicts.

To identify whether the form of these time series was stable or slowly variable, autocorrelations were computed for all shots in a ten-shot population, and their average graphed as a function of separation within the population in Fig. 11.

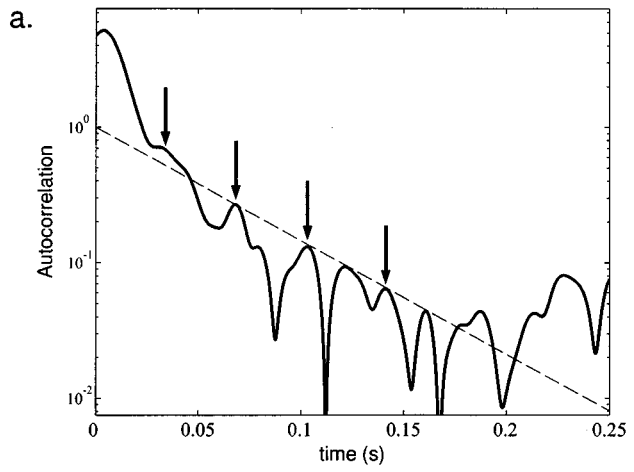

FIG. 10. Reverberation identification from the signal autocorrelation. (a) Absolute value (solid line) of the autocorrelation, from the quadrature completion of a typical vertical geophone signal with no target, as a function of time offset. Signal was measured on a geophone 0.5 m from the source. Dashed line is the exponential decay corresponding to a series of reflections with constant reflection coefficient 0.4. Arrows indicate first four reflected arrivals. (b) Ray diagram leading to the reflections marked in (a). Layer thickness implied for shear reflections at 113-m/s shear speed is 2.0 m.

Roughly, each shot in the population was recorded 2 min after the one preceding it. It should be noted that, for a population of ten shots, there are nine autocorrelation values contributing to the population average at separation 1, and only one value at separation 9, so the autocorrelations at large separation are more sensitive to individual deviant shots, or outliers, than those at small separations.

Autocorrelations were computed over three time intervals, to compare the repeatability of the direct arrival with that of longer time series containing more reverberation. For the shorter two intervals, centered on the direct arrival, there is no convincing evidence for a signal drift with time. Autocorrelations for separation intervals 1–7 and 9 are comparable. While the autocorrelation at separation 8 is lower, it may not be significant because it represents only a two-event average. For the longer time period, comprising the whole signal shown, there appears to be a small systematic decay of the autocorrelation, representing a change in medium response over the period of 20 min sampled. It is therefore concluded that the reverberation may be subject to a systematic drift over these time scales, which is larger than that for the direct arrival.

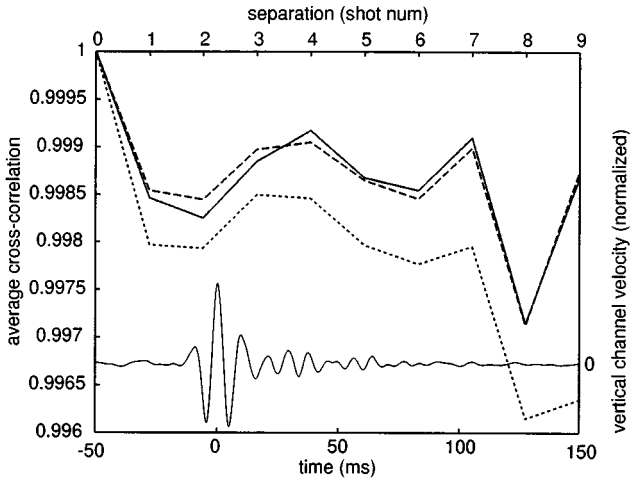

FIG. 11. Averaged crossed correlations for pairs of vertical geophone velocity signals from a 10-shot population, as a function of separation in shot numbers. Separation between events in the population is roughly 1–2 min per event number. Zero separation denotes the autocorrelation, normalized to unity. Nine correlation values are averaged to produce the 1-index result, and one value for the 9-index separation. Time series (thin line) plotted for reference. Heavy solid line is the correlation average for time-interval $(-20,30)$ ms, dashed is $(-20,80)$ ms, and dotted $(-50,150)$ ms, indicating a greater relative decay of correlation with time among shots including more of the reverberation with the direct arrival.

A final measure, of the statistical rather than systematic variation of shots, is a point-by-point signal-to-noise ratio (SNR) in the time domain, shown in Fig. 12. It is computed as $-20\log_{10}$ of the standard deviation obtained from the absolute values of differences among the quadrature-completed signals in the population. This measure incorporates both magnitude and phase errors in a mutually consistent way. The value of roughly 25 dB in the main pulse of the signal time series corresponds to an expected two-shot coherence of 0.997, which is comparable to the values given

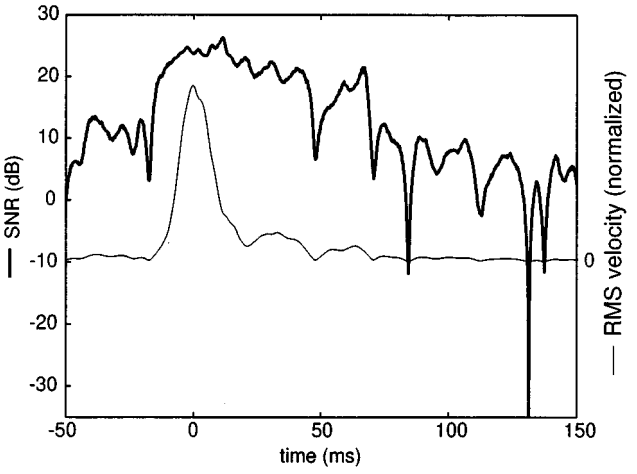

FIG. 12. Pointwise signal/noise ratio (SNR) as a function of time for the vertical channel of the central geophone, from a population of ten recorded pulses with no target present. rms signal amplitude (thin line, shown for reference), is the absolute value of the mean of the quadrature completion of the ten signals. SNR is computed from the absolute mean square deviation of the quadrature-completed signals, thus incorporating both phase and magnitude errors.

by the autocorrelation in Fig. 11, further suggesting that most of the loss of coherence in the autocorrelation of the direct arrival is statistical in nature, and not systematic.

The absolute signal level and the SNR at 55–65 ms, where the target reflection is expected, define the noise floor, relative to which subtraction of backgrounds should make a reflected signal visible. The central limit theorem relates the SNR of 10 dB for two individual pings, from Fig. 12, to an expected SNR of 15 dB for the difference of two ten-shot population averages, which will be used below. It then follows, from the signal level of roughly -24 dB in this range, *re*: the direct arrival at 1 m, that the noise floor is -39 dB. Thus a target reflection larger than -39 dB relative to source level can be expected to be recovered by subtraction of backgrounds from signals with the target present.

V. COHERENT SUBTRACTION AND TARGET LOCALIZATION

Both incoherent and coherent subtractions of backgrounds are possible in computations of the polarized power component, as for any quadratic function of the signal. Figure 13 shows the output of both differencing methods. The raw input containing reverberation, with the target present, is the same ten-shot average used to produce Fig. 9. Backgrounds alone are given by the average of ten shots produced with the same sonar deployment, immediately prior to burying the target in the beach. Figure 13(a) shows the vertical components v_{array} for the two populations, and the difference amplitude between them.

Figure 13(b) shows the corresponding polarized power values, $\text{Im}(P_{rv})$, for the signal and background, and also the difference of the power values (incoherent subtraction) and the power value produced from the signal difference (coherent subtraction). The polarized power produced by coherent subtraction (multiplied by 10 for visibility in the figure) is much smaller than the incoherently subtracted value. Also, whereas the incoherent subtraction leaves numerous features in the time series, coincident with large reverberant signatures in the background, the coherently subtracted power has only one large, retrograde feature at 3-m range, corresponding to the known position of the target.

The PPI output from the coherently subtracted signal is shown in Fig. 14. A clear retrograde signal is visible at the target location, with magnitude -34 dB. Array sidelobes of the same sign are also visible at bearings 30 deg and -75 deg, with strengths of -38 dB.

The array shadings used in Fig. 14 were chosen to produce the least cluttered sonar plot when three elements are included, and also the most consistent two-element outputs when any single element is zeroed. The output of the array with these indicated shadings, using real data, was similar to that predicted from *uniform* shadings for an idealized reflection. The origin of this deviation in array performance from the idealized case is not known at this time, but we conjecture that it is related to the close proximity of the large static load created by the transducer foot, which is centered 0.5 m from the center receiving element.

Because it was of interest to compare the reflected signal strength to predictions, the reflection was also measured using the central array element alone, with unit shading. The single-element reflected power was found to be within 0.5 dB of the value for the array shown in Fig. 14, where the array weights sum to unity. Deviation within the main body of the pulse was roughly 0.5 dB for the single-element signal, so the two values are taken to agree within measurement error.

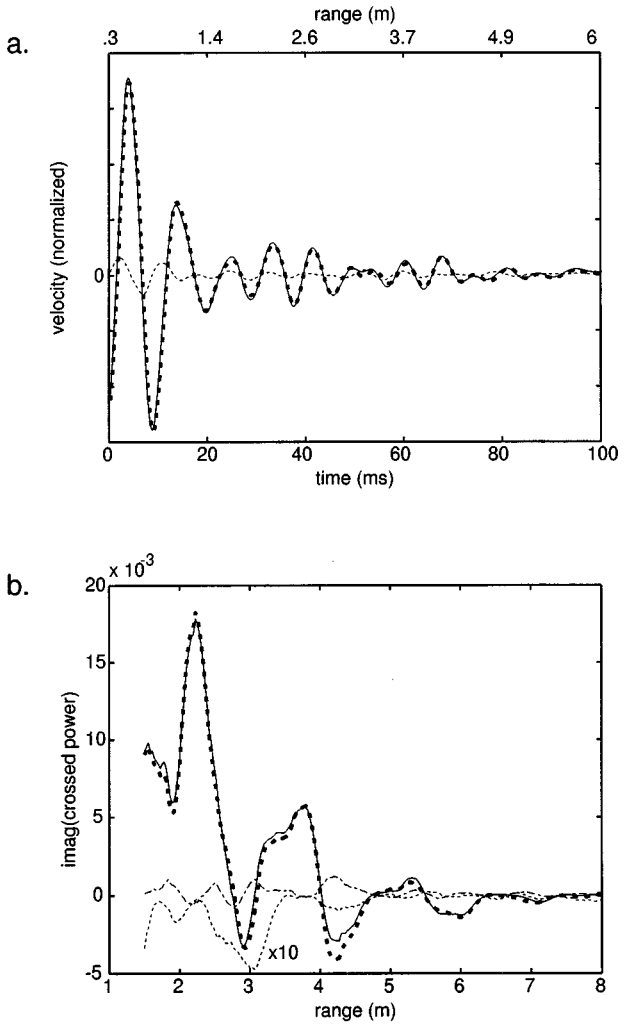

FIG. 13. Typical signal and polarized crossed power component for coherent and incoherent subtractions. (a) Center-geophone vertical component for 10-event population averages of signal with target present (solid), reverberation measured without target (heavy, dashed) and target signal with background subtracted (dotted). (Range label on top axis provided for reference.) (b) Sections through the PPI plot, looking at the target, for different input signals. 10-event average with target (solid), reverberation only (dashed), the difference of the power values, (incoherent subtraction, dash-dot), and the polarized power component obtained from the amplitude differences (coherent subtraction, dotted). The coherent subtraction is multiplied by 10 to aid visibility. All other values are shown with the normalization used in the PPI plots.

VI. COMPARISON TO PREDICTIONS

A perturbative method for approximating the scattering of interface waves from small buried objects is presented in a companion article.[2] Prior to now it has not been possible to test the predictions of this method. The perturbative method is analytic rather than numerical, and the first-order perturbative result, which is expected to be valid for weak scatter-

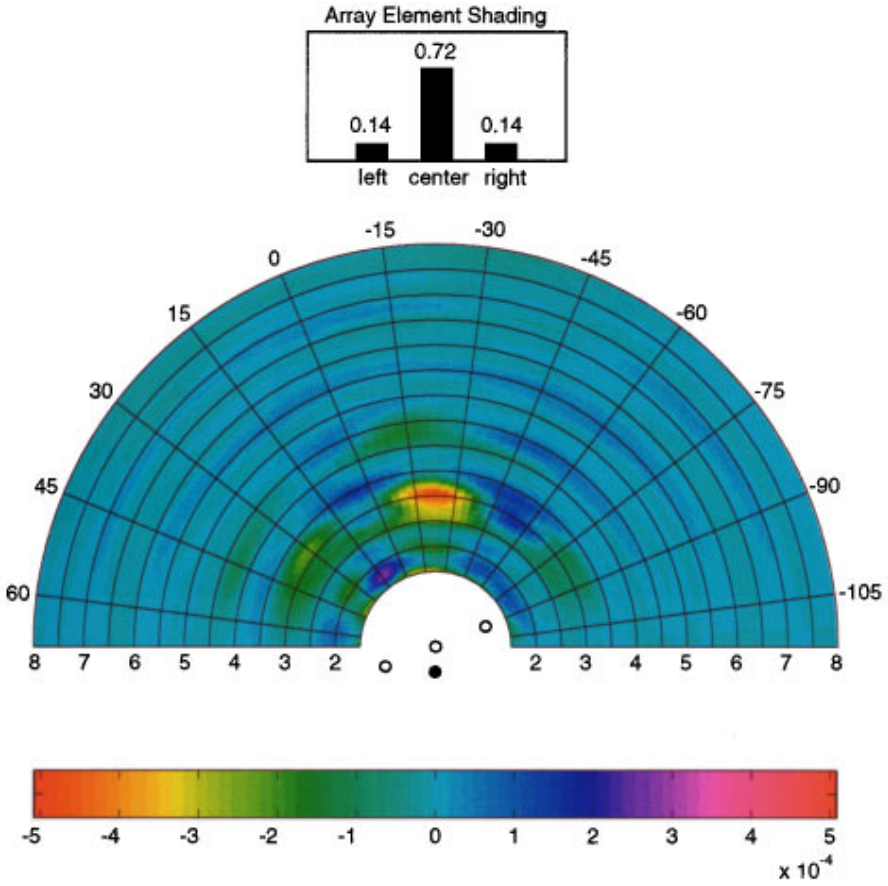

FIG. 14. Example of a sonar plot produced from measurements taken with target buried at 2.5-m range and -22.5 deg bearing, after coherent subtraction of backgrounds measured without target. Element shadings and speed are the same as those of Fig. 9.

ing from inclusions much smaller than the interface-wave wavelength, is computed algebraically. Therefore this method, when it can be used, is much less costly than finite-difference computation, or other numerical methods for treating the scatterer boundary conditions explicitly.

The perturbative computation predicts that scattering from the target used here, in an unconsolidated sediment medium, should be dominated by the discontinuity created by the target mass. The pointlike-scatterer approximation also should be valid for this target, because all of its characteristic dimensions are smaller than than $1/2\pi$ times the wavelength at 100 Hz. Using a density of 2 g/cm^3 for the sand, first-order perturbation theory predicts a target strength of -21.6 dB for the conversion of a plane-fronted Rayleigh wave incident on the target to a cylindrical outgoing Rayleigh wave at 1 m.

The transmission loss (TL) associated with the propagation path for this system is drawn from the acoustic medium characterization. Using the observed geometric spreading as $r^{-0.55}$ and the dissipation of 0.912 dB/m, the combined TL for the two paths, 1 m from the source to the target, and one meter from the target to the central receiver, is -11 dB. The resulting predicted reflection strength is -32.6 dB, which compares favorably with the measured value of -34 dB.

VII. CONCLUSIONS

The experimental results presented here show that it is possible to identify the reflection from a passive buried target insonified with an active, seismic interface-wave sonar, and to process the reflection to recover the position of the target.

Seismic-array signal processing was performed by combining dipole steering, time-delay beamforming, and polarization filtering techniques in a single algorithm. This type of processing enhances interface-wave components relative to in-phase seismic excitations, and provides polarization as well as amplitude information in the resulting PPI sonar plot.

The signals produced for echo location were found to contain a significant component of medium-induced reverberation, and it was necessary to coherently subtract the reverberant background from sonar pings with a target present, in order to isolate the target-induced reflection. Because the source produced repeatable signals, and statistical variation of backgrounds was found to be much smaller than the reverberation level, coherent subtraction was effective, rendering a reflection of -34 dB at the receiver clearly visible. Developing reliable differential signal processing methods that can be used under less idealized circumstances remains an important outstanding problem.

Simple algebraic methods based on perturbation theory can be used to predict interface-wave scattering strengths under the experimental conditions studied here. Prior to now, though, it has not been possible to test the perturbative predictions directly with measured data. The reflection strengths measured in this experiment, combined with transmission loss data for the site, were found to yield a target strength

that agrees closely with the value predicted by first-order perturbation theory.

Scattering of interface waves from pointlike obstacles

Eric Smith
Applied Research Laboratories, The University of Texas at Austin, P.O. Box 8029, Austin, Texas 78713-8029

(Received 10 October 1996; revised 1 August 1997; accepted 31 December 1997)

A method is presented for efficiently computing or estimating low-order elastic wave scattering, from a pointlike inhomogeneity in a bounded medium, into interface as well as bulk modes. The particular system considered is a half-space of fluid overlying a half-space of a linear elastic solid, with the obstacle placed in the solid very near the interface. Boundary constraints are enforced as an improvement to the bulk scattering vertex, so that the stratified-medium Green's function is used to propagate scattered waves at each perturbative order. Analytic approximation of the first-order scattering amplitude, based on the symmetries of the scattering vertex and the interface-wave pole structure, makes it easy to identify the qualitatively different components of the scattered wave, and their dependence on medium properties. © *1998 Acoustical Society of America.* [S0001-4966(98)03404-3]

INTRODUCTION

Relatively few phenomena involving interface-wave excitation can be treated efficiently with current computational models of acoustic propagation and conversion. Yet problems occur for which efficient computational techniques would be useful. For instance, because interface waves confine energy entirely within a small spatial region around a particular interface, their scattering can be used to identify and characterize defects or inhomogeneities at the interface itself, while suppressing sensitivity to features of the surrounding bulk media. In designing effective search methods to make use of interface-wave reflection, it is desirable to be able to search a large parameter region to identify what effects are possible, and in many cases very precise solution is not as important as the ability to qualitatively identify the origins and parameter dependence of signal features.

Another application involving interface-wave conversion concerns its presence as a loss mechanism in otherwise range-independent environments. While global-matrix codes[1] automatically account for the excitation of interface waves in response to placed sources, they necessarily omit secondary scattering, which occurs at isolated defects on the interface itself. Range-dependent enhancements of these methods[2] incorporate interface-wave production at explicit points of change, but are not efficient for modeling the presence of many such inclusions in an otherwise homogeneous medium.

Totally incoherent scattering into interface modes can be treated phenomenologically,[3] but scattering at isolated obstacles, even simple ones, requires augmentation of range-independent algorithms, preferably without adding great computational complexity.

This last application is of interest because ocean-bottom sensors have been used to monitor waterborne noise sources,[4,5] and the ability to estimate the importance of isolated obstacle-induced conversion, under the wide variety of ocean-bottom conditions that occur, is necessary to correctly interpret the results of such measurements. A finite-difference analysis of this problem has recently been presented, which can serve as a benchmark for analytic solutions based on the approach given here.[6,7]

It is therefore useful to have available a simple representation of the scattering amplitude into interface as well as bulk modes, from obstacles located near or on the interface itself. The representation that will be derived here is a perturbative multipole scattering expansion for a pointlike discontinuity of density, compressibility, and rigidity, located near a boundary in a homogeneous, isotropic elastic solid. The important feature of the calculation is the use of the stratified-medium Green's function to propagate scattered waves at intermediate orders of perturbation theory. For a dilute collection of obstacles, the discrete states induced by boundary conditions may be expected to dominate multiple as well as single scattering near the interface, so it is efficient to incorporate the boundary constraints as correction terms to the simple bulk scattering vertex. Because interface waves exist at a only a few allowed values of horizontal slowness (for practical purposes, often only one), the multipole expansion at lowest order can be reduced to an algebraic rather than integral form. This can be used as the basis for an algebraic perturbation expansion in interface-wave scattering, rather than one requiring wave number integrals. The closed-form first-order scattering amplitude reduces to a simple set of constants, which depend on medium parameters and give the proportionality between the relative strengths of radiated monopole, dipole and quadrupole interface mode excitation and the material inhomogeneity represented by the point defect. This approach is intended to be complementary to numerical techniques such as finite-element calculations that have been performed for equivalent physical systems.[8]

The primary motivation to perform the calculation in this way comes from an application of interface wave scattering to detect buried obstacles in unconsolidated sediments.[9] Experimental results on measurement and localization of such reflections are presented in a companion article.[10] The following two sections present the definition and construction of the scattering amplitude, and then its analysis and evaluation in a particular instance. The last sec-

tion provides a conversion from the the language of the scattering vertex to the notion of a target strength, and comments.

I. CONSTRUCTION OF THE SCATTERING THEORY

Point-obstacle perturbation theory, for a number of realistic problems, gives the ability to trade refinement of the solution, either of resolution or magnitude approximation, for computational efficiency. The basic perturbative building block is an amplitude for homogeneous waves, incident on a pointlike obstacle, to scatter into a basis of radiated continuum (bulk) and discrete (interface) modes. Because the scatterer is represented as a point, the elementary scattering vertex can be computed analytically, which makes it relatively easy to identify contributions from discrete and continuum modes, which can have very different propagation characteristics, to the scattered density of states. Complex or distributed scatterers may be modeled as collections of points at whatever resolution is appropriate to a given application, by means of a Huygens' construction of the scattered wave. Because the presence of the interface is represented as part of the elementary scattering vertex, any truncated perturbative order may be used to approximate the exact solution, and resummation techniques traditional in perturbation theory remain viable if coherent effects, such as resonant scattering, are important. This section contains the computation of the perturbative scattering amplitude in a simple system, chosen because it demonstrates the techniques and results of interest, but otherwise restricts attention to a relatively simple scattered spectrum.

A. General definitions and notation

Acoustic disturbances in a layered system of linear elastic solids or fluids are characterized by the displacement from equilibrium of the points of each of the media, denoted in each layer by a vector field **u**. It is convenient to decompose **u** as a sum of a gradient and a curl by writing

$$\mathbf{u}=\boldsymbol{\nabla}\phi+\boldsymbol{\nabla}\times\mathbf{A}, \tag{1}$$

where ϕ is a complex scalar field and **A** a complex vector field. The ambiguity of **A**, up to addition of an arbitrary gradient, can be removed by imposing the transversality condition

$$\boldsymbol{\nabla}\cdot\mathbf{A}=0. \tag{2}$$

If **A** has components A_i, and the gradient $\boldsymbol{\nabla}$ components $\boldsymbol{\nabla}_i$, with spatial index $i\in\{1,2,3\}$, the strain tensor $\boldsymbol{\epsilon}$ of the medium has components $\boldsymbol{\epsilon}_{ij}$ given by

$$\boldsymbol{\epsilon}_{ij}=\boldsymbol{\nabla}_i\boldsymbol{\nabla}_j\phi+\tfrac{1}{2}[\boldsymbol{\nabla}_i(\boldsymbol{\nabla}\times\mathbf{A})_j+\boldsymbol{\nabla}_j(\boldsymbol{\nabla}\times\mathbf{A})_i]. \tag{3}$$

The wave equation for the medium may be written in terms of the trace of the strain tensor $\mathrm{Tr}(\boldsymbol{\epsilon})\equiv\Sigma_i\boldsymbol{\epsilon}_{ii}$, and its transverse part $\boldsymbol{\epsilon}^T$, with components ${\boldsymbol{\epsilon}^T}_{ij}\equiv\boldsymbol{\epsilon}_{ij}-\delta_{ij}\,\mathrm{Tr}(\boldsymbol{\epsilon})$, as

$$\partial_t{}^2(\rho\mathbf{u})=\boldsymbol{\nabla}\cdot[2\mu\boldsymbol{\epsilon}^T]+\boldsymbol{\nabla}[(\lambda+2\mu)\mathrm{Tr}(\boldsymbol{\epsilon})]. \tag{4}$$

Here, λ and μ are the Lamé parameters, and ρ the density of the medium. The density and moduli are assumed to be time independent but spatially varying.

The particular case considered here will be that of a uniform isotropic half-space of fluid overlying a uniform isotropic half-space of elastic solid, with a scatterer located in the solid at ignorable distance below the interface. Because interface excitations are to leading order independent of system characteristics away from the interface that supports them, many of the important features which occur in a general case also appear in this very simple system. As a discontinuity of the solid, the scatterer can couple fully to its shear as well as to its compressional modulus and density. A rich structure of interface modes arises from the boundary conditions at the fluid–solid interface, which is sufficient to contain the features of interest in the companion application,[10] but simpler to compute than the most general case of layers of fluid and adjoining elastic solids. The description of this system will thus exclude phenomena such as scattering into Love modes[11] or more complicated normal modes trapped among multiple layers, but because these are simply additional discrete states of possible systems, they can be readily included either analytically at the price of more algebra, or with wave number integration[1] or mode codes,[12] using the vertex from the pointlike scatterer to provide the strengths of an effective source located in one of the media.

The fluid layer will be described by a homogeneous density ρ_f and zero shear modulus. All fluid parameters will be expressed in terms of ρ_f and the fluid sound speed c_f. The solid layer will be described by homogeneous and isotropic parameters except at a point, which must then be parametrized to represent the scatterer. While it may be natural to think of a small massive buried object as a point perturbation of the density with respect to wavelengths longer than the size of the object, it is less clear that pointlike perturbations in the moduli are meaningful. Physically, changes in moduli occur by finite amounts in macroscopic domains of the medium. Therefore, the perturbations of the moduli, while treated as pointlike, will be labeled with strengths which denote a finite change in modulus over some characteristic volume labeled R^3. The scaling with frequency of the resulting scattering amplitude will be used to argue that this representation is valid for perturbations smaller in extent than the relevant wavelengths. For weak scattering (i.e., in the Born approximation), it should then also be possible to represent larger regions of inhomogeneity with a distribution of pointlike scatterers.

The forms thus taken to describe the lower half-space with a single scatterer are

$$\rho(\mathbf{x})=\rho_0+M\,\delta^3(\mathbf{x}-\mathbf{x}_0), \tag{5}$$

$$\lambda(\mathbf{x})=\lambda_0+\Delta\lambda R^3\delta^3(\mathbf{x}-\mathbf{x}_0), \tag{6}$$

$$\mu(\mathbf{x})=\mu_0+\Delta\mu R^3\delta^3(\mathbf{x}-\mathbf{x}_0). \tag{7}$$

The compressional speed in the lower medium will be denoted by c and is given in terms of the background parameters by $c^2=(\lambda_0+2\mu_0)/\rho_0$, and the shear speed s by $s^2=\mu_0/\rho_0$. Because buried obstacles provide a physically natural application for low-order perturbative calculations, the density defect has been expressed in terms of a mass M of such an obstacle.

B. Solution of the wave equation

It is notationally convenient to treat the scalar and vector displacement potentials in each medium as elements of a four-component column vector ψ defined as

$$\psi \equiv \begin{bmatrix} \phi \\ \mathbf{A} \end{bmatrix}. \tag{8}$$

ψ will be taken to have a single frequency component and time dependence $e^{i\omega t}$ in all that follows. The Helmholtz equations for the scalar and vector potentials in a homogeneous medium are obtained by acting, respectively, with the gradient and curl operators on wave equation (4). The pair of operations can be represented as a matrix acting on the components of ψ which, after separation of the homogeneous from the inhomogeneous terms, takes the form

$$(\boldsymbol{\nabla}^2)\begin{bmatrix} (c^2\boldsymbol{\nabla}^2+\omega^2) & \\ & (s^2\boldsymbol{\nabla}^2+\omega^2)\mathbf{1} \end{bmatrix}\psi$$

$$= \sum_{\alpha=1,2} \mathbf{P}_1^{(\alpha)}(\boldsymbol{\nabla})[\mathbf{P}_2^{(\alpha)}\delta^3(\mathbf{x}-\mathbf{x}_0)(\mathbf{P}_3^{(\alpha)}(\boldsymbol{\nabla})\psi)]. \tag{9}$$

In this expression the $\mathbf{P}_i^{(\alpha)}$ are matrices with polynomial coefficients in components of the gradient operator and the perturbation strengths. The values $\alpha=1,2$ correspond, respectively, to perturbations in density or the moduli, which involve different orders of spatial derivatives. Explicit expressions for the $\mathbf{P}_i^{(\alpha)}$ are given in Appendix A, and $\mathbf{1}$ is the unit diagonal. This form for the equations of motion lends itself to a perturbative treatment in which the inverse of the operator on the left-hand side is the Green's function for the homogeneous medium and the polynomial expression on the right-hand side is the vertex associated with the perturbation.

To solve Eq. (9) perturbatively, one divides the wave ψ into parts $\psi=\psi_0+\delta\psi$, requiring that

$$(\boldsymbol{\nabla}^2)\begin{bmatrix} (c^2\boldsymbol{\nabla}^2+\omega^2) & \\ & (s^2\boldsymbol{\nabla}^2+\omega^2)\mathbf{1} \end{bmatrix}\psi_0 \equiv 0. \tag{10}$$

The homogeneous wave operator is invertible in a wave number basis, defined by the relation

$$\psi_{\mathbf{x}} \equiv \int d^3k e^{-i\mathbf{k}\cdot\mathbf{x}}\psi_{\mathbf{k}}. \tag{11}$$

The solution of the full equations of motion may be generated in two steps. The first is to compute an expression for the wave that would be scattered from the same pointlike perturbation in the lower medium in the *absence* of a boundary constraint. Denoted $\delta\psi_{\mathbf{k}_{\text{n.b.}}}$, this part of the scattered wave follows from inversion of Eq. (9), using Eq. (10),

$$\delta\psi_{\mathbf{k}_{\text{n.b.}}} = \frac{-1}{(2\pi)^3}\begin{bmatrix} \dfrac{1}{(\omega^2-c^2\mathbf{k}^2)} & \\ & \dfrac{1}{(\omega^2-s^2\mathbf{k}^2)}\mathbf{1} \end{bmatrix}\frac{1}{\mathbf{k}^2}\int d^3k'$$

$$\times \sum_{\alpha=1,2} \mathbf{P}_1^{(\alpha)}(-i\mathbf{k})\mathbf{P}_2^{(\alpha)}\mathbf{P}_3^{(\alpha)}(-i\mathbf{k}')e^{i(\mathbf{k}-\mathbf{k}')\cdot\mathbf{x}_0}\psi_{\mathbf{k}'}. \tag{12}$$

The function ψ appearing in the integrand is the solution to the complete equations of motion, including the constraint from the boundary. The scalar product $\mathbf{k}\cdot\mathbf{k}$ is denoted $\mathbf{k}^2$ to distinguish it from the scalar product of the two-component horizontal wave vector, which will be used explicitly in later steps.

The vertex strength is parametrized in terms of three ratios with the dimensions of volume, defined, respectively, for compression, density, and shear as

$$\mathbf{C} \equiv \frac{(\Delta\lambda)R^3}{(\lambda_0+2\mu_0)}, \tag{13}$$

$$\mathbf{D} \equiv \frac{M}{\rho_0}, \tag{14}$$

$$\mathbf{S} \equiv \frac{\Delta\mu R^3}{\mu_0}. \tag{15}$$

The inhomogeneous term in Eq. (12) may be written in terms of these, as

$$\sum_{\alpha=1,2} \mathbf{P}_1^{(\alpha)}(-i\mathbf{k})\mathbf{P}_2^{(\alpha)}\mathbf{P}_3^{(\alpha)}(-i\mathbf{k}')$$

$$= -c^2\mathbf{C}\begin{bmatrix} \mathbf{k}^2\mathbf{k}'^2 & 0 \\ 0 & 0 \end{bmatrix} + (\omega^2\mathbf{D} - 2s^2\mathbf{S}(\mathbf{k}\cdot\mathbf{k}'))$$

$$\times\begin{bmatrix} \mathbf{k}\cdot\mathbf{k}' & \mathbf{k}\times\mathbf{k}' \\ -\mathbf{k}\times\mathbf{k}' & [(\mathbf{k}\cdot\mathbf{k}')\mathbf{1}-\mathbf{k}'\mathbf{k}] \end{bmatrix}$$

$$+ s^2\mathbf{S}\begin{bmatrix} 0 & 0 \\ 0 & [(\mathbf{k}\times\mathbf{k}')(\mathbf{k}\times\mathbf{k}')+(\mathbf{k}\cdot\mathbf{k}')((\mathbf{k}\cdot\mathbf{k}')\mathbf{1}-\mathbf{k}'\mathbf{k})] \end{bmatrix}, \tag{16}$$

in which the products $(\mathbf{k}\times\mathbf{k}')(\mathbf{k}\times\mathbf{k}')$ and $\mathbf{k}'\mathbf{k}$ are to be understood as dyadics. The symmetry decomposition of this bulk scattering vertex is performed in Appendix B. It is shown that from arbitrary incoming waves satisfying the transversality condition (2), the vertex produces scattered monopole, dipole and quadrupole components, with expansions in terms of respectively zeroth, first, and second level spherical harmonics in a basis defined by the direction and polarization of the incoming wave. The symmetries of the bulk vertex are slightly different from those that will result from projection onto interface waves, because dipole components normal to the interface appear isotropic in the horizontal plane.

The boundary constraint is next implemented by solving for the wave that must be added to $\delta\psi_{\text{n.b.}}$ for the sum to obey the boundary conditions. The boundary-induced correction will be expressed as an improvement to the bulk vertex, thus producing a perturbation series for the solution which satisfies the boundary constraint order by order. The scatterer will be taken to lie at a small finite distance z_0 below the interface, with $|z_0|$ larger than any infinitesimals ϵ needed to define contour prescriptions in wave vector integrals. z_0 will then be taken to zero at the end of the calculation.

The constraint is represented as follows. A general incident wave satisfying the homogeneous wave equation at a given frequency is decomposed into a sum of plane waves

indexed by the horizontal wave number $\vec{k}$ and a polarization for the vector shear wave in the solid. (The corresponding vertical wave numbers are fixed by the wave equation.) The transversality condition $\nabla\cdot\mathbf{A}=0$ is satisfied without loss of generality in this system if the vector potential is canonically chosen to have polarization $\mathbf{A}\propto\hat{\mathbf{z}}\times\mathbf{k}$, where $\hat{\mathbf{z}}$ is the unit normal to the interface and $\mathbf{k}$ is the shear wave vector with horizontal component $\vec{k}$.

A set of arbitrarily normalized basis functions $\{\varphi^f_{\vec{k}},\varphi_{\vec{k}},\mathbf{a}_{\vec{k}}\}_{\rm in}$, $\{\varphi^f_{\vec{k}},\varphi_{\vec{k}},\mathbf{a}_{\vec{k}}\}_{\rm out}$ is introduced for respectively incoming and outgoing scalar components in the two layers, and the vector component in the solid. Square roots for the $\hat{\mathbf{z}}$ wave numbers are chosen so that outgoing radiative roots continue to evanescent roots bounded away from the interface, and incoming radiative roots to unbounded evanescent roots. This is the correct prescription because, with the scatterer in the bulk, the scattered wave incident on the interface is characterized by unbounded or in-radiative roots, whereas the physical Green's function propagating solutions from the interface selects entirely out-radiative or bounded roots. The no-boundary solution $\delta\psi_{\mathbf{k}_{\rm n.b.}}$ of Eq. (12) provides incoming components $\phi^f_{\rm in}$, $\phi_{\rm in}$, $\mathbf{A}_{\rm in}$ for an expansion of the full scattered wave in terms of the basis functions:

$$\begin{aligned}
\phi^f_{\vec{k};\rm in,out}&=\gamma^f_{\rm in,out}\varphi^f_{\vec{k};\rm in,out},\\
\phi_{\vec{k};\rm in,out}&=\gamma_{\rm in,out}\varphi_{\vec{k};\rm in,out},\\
\mathbf{A}_{\vec{k};\rm in,out}&=\sigma_{\rm in,out}\mathbf{a}_{\vec{k};\rm in,out}.
\end{aligned}\tag{17}$$

The outgoing components will be fixed by the boundary constraints.

The differential fluid–solid interface conditions, continuity of vertical motion and the vertical components of the stress tensor, may be written by means of the basis expansion (17) as algebraic constraints on the coefficients γ,σ. Expressed collectively as matrices acting on vectors of the coefficients, these may be arranged to read

$$\begin{aligned}
&\begin{bmatrix}\sqrt{\omega^2/c_f^2-k^2} & \sqrt{\omega^2/c^2-k^2} & -k^2\\ -\dfrac{\rho_f}{\rho}\left(\dfrac{\omega}{s}\right)^2 & -(2k^2-\omega^2/s^2) & -2k^2\sqrt{\omega^2/s^2-k^2}\\ 0 & 2\sqrt{\omega^2/c^2-k^2} & -(2k^2-\omega^2/s^2)\end{bmatrix}\\
&\quad\times\begin{bmatrix}\gamma^f_{\rm out}\\ \gamma_{\rm out}\\ \sigma_{\rm out}\end{bmatrix}\\
&=\begin{bmatrix}\sqrt{\omega^2/c_f^2-k^2} & \sqrt{\omega^2/c^2-k^2} & k^2\\ \dfrac{\rho_f}{\rho}\left(\dfrac{\omega}{s}\right)^2 & (2k^2-\omega^2/s^2) & -2k^2\sqrt{\omega^2/s^2-k^2}\\ 0 & 2\sqrt{\omega^2/c^2-k^2} & (2k^2-\omega^2/s^2)\end{bmatrix}\\
&\quad\times\begin{bmatrix}\gamma^f_{\rm in}\\ \gamma_{\rm in}\\ \sigma_{\rm in}\end{bmatrix}.
\end{aligned}\tag{18}$$

Square roots denote the out-radiative/bounded branch (which has opposite signs in the fluid and solid), and k^2 is the scalar product $\vec{k}\cdot\vec{k}$ of the horizontal wave vector.

Values of the transverse wave vector for which the first constraint matrix in Eq. (18) is degenerate admit outgoing waves which may exist with nonzero amplitude even if the incoming waves vanish. These, of course, are the interface wave states. With correct treatment of such degenerate cases, the first constraint matrix may be inverted to express the outgoing coefficients in terms of the incoming, in which case a solution, having the same incoming components as $\delta\psi_{\mathbf{k}_{\rm n.b.}}$, but satisfying the boundary conditions, is given by

$$\begin{aligned}
\phi^f_{\vec{k};\rm full}&=\gamma^f_{\rm in}\varphi^f_{\vec{k};\rm in}+\gamma^f_{\rm out}\varphi^f_{\vec{k};\rm out},\\
\phi_{\vec{k};\rm full}&=\gamma_{\rm in}\varphi_{\vec{k};\rm in}+\gamma_{\rm out}\varphi_{\vec{k};\rm out},\\
\mathbf{A}_{\vec{k};\rm full}&=\sigma_{\rm in}\mathbf{a}_{\vec{k};\rm in}+\sigma_{\rm out}\mathbf{a}_{\vec{k};\rm out}.
\end{aligned}\tag{19}$$

The coefficients are related by a product of the constraint matrices which may be treated as a Jacobian from the incoming to the outgoing basis:

$$\begin{aligned}
&\begin{bmatrix}\gamma^f_{\rm out}\\ \gamma_{\rm out}\\ \sigma_{\rm out}\end{bmatrix}\\
&=\begin{bmatrix}\sqrt{\omega^2/c_f^2-k^2} & \sqrt{\omega^2/c^2-k^2} & -k^2\\ -\dfrac{\rho_f}{\rho}\left(\dfrac{\omega}{s}\right)^2 & -(2k^2-\omega^2/s^2) & -2k^2\sqrt{\omega^2/s^2-k^2}\\ 0 & 2\sqrt{\omega^2/c^2-k^2} & -(2k^2-\omega^2/s^2)\end{bmatrix}^{-1}\\
&\quad\times\begin{bmatrix}\sqrt{\omega^2/c_f^2-k^2} & \sqrt{\omega^2/c^2-k^2} & k^2\\ \dfrac{\rho_f}{\rho}\left(\dfrac{\omega}{s}\right)^2 & (2k^2-\omega^2/s^2) & -2k^2\sqrt{\omega^2/s^2-k^2}\\ 0 & 2\sqrt{\omega^2/c^2-k^2} & (2k^2-\omega^2/s^2)\end{bmatrix}\\
&\quad\times\begin{bmatrix}\gamma^f_{\rm in}\\ \gamma_{\rm in}\\ \sigma_{\rm in}\end{bmatrix}\equiv\left[\frac{\partial(\gamma^f_{\rm out},\gamma_{\rm out},\sigma_{\rm out})}{\partial(\gamma^f_{\rm in},\gamma_{\rm in},\sigma_{\rm in})}\right]\begin{bmatrix}\gamma^f_{\rm in}\\ \gamma_{\rm in}\\ \sigma_{\rm in}\end{bmatrix}.
\end{aligned}\tag{20}$$

For application to the companion experiment,[10] as well as to ocean-bottom seismometry, the receiver as well as the obstacle will be taken to be anchored in the solid at the interface, so the motion of the fluid is not directly of interest. Since the incident wave from the scatterer consists entirely of components in the solid layer, it is sufficient to consider only the Jacobian $[\partial(\gamma_{\rm out},\sigma_{\rm out})/\partial(\gamma_{\rm in}\sigma_{\rm in})]$ which is the projection of the matrix defined in Eq. (20) onto the coefficients of the basis functions that describe the solid.

The full scattered wave in Eq. (19) may now be expressed in terms of the incoming component generated by Eq. (12). Fourier transforming solutions (17) of the wave equation back to a full three-dimensional plane wave representation, taking care with the Fourier transforms that relate incoming to outgoing $\hat{\mathbf{z}}$ wave numbers in the basis functions, gives the representation

$$\delta\psi_{\vec{k},\lambda}=\frac{-1}{(2\pi)^3}\begin{bmatrix}\dfrac{1}{(\omega^2/c^2-k^2-\lambda^2)} & \\ & \dfrac{1}{(\omega^2/s^2-k^2-\lambda^2)}\,\mathbf{1}\end{bmatrix}\int d\lambda'\left\{\delta(\lambda-\lambda')+\frac{i}{\pi}\begin{bmatrix}\sqrt{\omega^2/c^2-k^2} & \\ & \sqrt{\omega^2/s^2-k^2}\,\mathbf{1}\end{bmatrix}\right.$$
$$\left.\times\left[\frac{\partial(\gamma_{\rm out},\sigma_{\rm out})}{\partial(\gamma_{\rm in},\sigma_{\rm in})}\right]\begin{bmatrix}\dfrac{1}{(\omega^2/c^2-k^2-\lambda'^2)} & \\ & \dfrac{1}{(\omega^2/s^2-k^2-\lambda'^2)}\,\mathbf{1}\end{bmatrix}\right\}\begin{bmatrix}\dfrac{1}{c^2} & \\ & \dfrac{1}{s^2}\,\mathbf{1}\end{bmatrix}$$
$$\times\frac{e^{i\lambda'\epsilon}}{\mathbf{k}'^2}\int d^3k''\sum_{\alpha=1,2}\mathbf{P}_1^{(\alpha)}(-i\mathbf{k}')\mathbf{P}_2^{(\alpha)}\mathbf{P}_3^{(\alpha)}(-i\mathbf{k}'')e^{i(\mathbf{k}'-\mathbf{k}'')\cdot\mathbf{x}_0}\psi_{\mathbf{k}''}. \tag{21}$$

In expression (21) the transverse and vertical components of the wave vector are denoted explicitly. Three-component wave vectors are defined as $\mathbf{k}=(\vec{k},\lambda)$ and $\mathbf{k}'=(\vec{k},\lambda')$. The integral over λ' relates the incoming to the outgoing basis states used to implement the boundary condition in Eq. (19), and the term $e^{i\lambda'\epsilon}$ defines the prescription for selecting poles of the argument $1/\mathbf{k}'^2$. This additional integral may be taken as the improvement of the vertex term to one which automatically produces an outgoing state respecting the boundary conditions.

The physics of solution (21) may be better understood by decomposing the Jacobian into two very simple terms. Specifically, it is possible to write

$$\left[\frac{\partial(\gamma_{\rm out},\sigma_{\rm out})}{\partial(\gamma_{\rm in},\sigma_{\rm in})}\right]$$
$$=\begin{bmatrix}1 & 0\\ 0 & -\mathbf{1}\end{bmatrix}-\frac{2}{\rm Det}\begin{bmatrix}(2k^2-\omega^2/s^2)\\ 2\sqrt{\omega^2/c^2-k^2}\hat{\mathbf{z}}\times\mathbf{k}\end{bmatrix}[(2k^2-\omega^2/s^2)$$
$$-2\sqrt{\omega^2/s^2-k^2}\hat{\mathbf{z}}\times\mathbf{k}], \tag{22}$$

where

$$\text{Det}\equiv\frac{\rho_f}{\rho}\left(\frac{\omega}{s}\right)^4\frac{\sqrt{\omega^2/c^2-k^2}}{\sqrt{\omega^2/c_f^2-k^2}}+(2k^2-\omega^2/s^2)^2$$
$$+4k^2\sqrt{\omega^2/c^2-k^2}\sqrt{\omega^2/s^2-k^2} \tag{23}$$

is the appropriately scaled determinant of the constraint matrix acting on the outgoing coefficients in Eq. (18). Thus the values of the wave vector for which the outgoing constraint becomes degenerate are the zeros of the determinant, which produce poles in the density of states that make possible scattering of finite energy into discretely indexed modes.

The first term in decomposition (22), together with the incident wave preserved by the $\delta(\lambda-\lambda')$ in Eq. (21), produces a symmetric sum of in-going and out-going modes which has identically zero vertical motion (and vertically directed shear stress). The second term may be checked to be an out-going wave which satisfies the constraint of zero vertically directed shear, multiplied by a projector which acts on the state produced by the scatterer. All sensitivity to properties of the upper fluid layer is contained in the first summand in the determinant, which is a ratio of the mechanical impedances of the upper and lower compressional modes times a ratio of the vertical components of their velocities. Taking the impedance of the fluid to infinity effectively removes the term proportional to 1/Det, leaving only the zero-vertical motion state consistent with an immovable upper fluid layer. Taking the same impedance to zero produces the limiting Rayleigh solution. For finite impedance of the upper layer, corrections to the symmetric sum provided by the first term in Eq. (22) come from the wave vector integrals around the branch cuts induced by square roots in the term containing the determinant, and the strength of scattering into any bound states is given by the residues of its poles, because all other terms are explicitly regular.

It is desirable to separate various terms from the scattering integral according to the range dependence of the scattered wave components they contribute. Physically, one expects modes radiating into the bulk to die off as a larger power of distance from the scatterer than modes trapped at the interface. To leading order at long range, the scattered wave should therefore include only the trapped Scholte pole on the physical sheet of the complex wave vector plane (for realistic values of Poisson's ratio in granular sediments[13]). For systems with additional layers or gradients that refract toward the interface, however, the situation may be more complicated. Normally ignorable poles representing ''Leaky Scholte modes'' may be brought from unphysical to physical sheets as frequency is varied. Yet this emergence of an additional pole from what was formerly a branch integral results from a continuous deformation of parameters. The qualitative separation of modelike from bulk-radiative effects is thus not clearly defined. In what follows, branch integrals will not be evaluated explicitly. However, it is important to note that in addition to spherically spreading waves which are less important at long range, those integrals may contain resonances arising from ''partial contour integrals'' around nearby leaky poles, in which case the strength of scattering into such poles may be estimated analytically from complete contour integrals enclosing them, even when they are not located at physical wave number values.

II. EVALUATION OF THE SCATTERING MATRIX

The first step in evaluating Eq. (21) is to perform the λ' integration, so the fields satisfy the homogeneous wave equation in the bulk. The Green's function appearing in the full solution (21) contains more poles than would be expected from the physical degrees of freedom of the theory. These are created by the term $1/\mathbf{k}'^2$, and arise because the fields being propagated are not the physical degrees of freedom, but rather their scalar and vector potentials. The only such integral which will be evaluated here is the one involving the determinant, because the other, which leads to a factor of $1/\mathbf{k}^2$ in the outgoing state, affects only the symmetric, bulk-radiative term. The determinant itself is a function only of the horizontal wave vector, so in fact the only effect of the integration over λ' is to induce appropriate projections of the the terms involving $\mathbf{k}'$ in the vertex integral over $\mathbf{k}''$.

At this point a great simplification is obtained by using the fact that the perturbation series defined by Eq. (21) satisfies the boundary conditions at each order. This feature makes it possible to restrict attention to terms $\psi_{\mathbf{k}''}$ in the integrand which satisfy the boundary conditions, without concern for whether these are intended to represent the full solution or intermediate orders of perturbation theory in an iterative approximation. The general projection of such a wave onto the components of the lower half-space is given in the position representation by

$$\psi_{\mathbf{x}_{\text{b.c.}}} = \int d^2k\ e^{-i\vec{k}\cdot\vec{x}} \begin{bmatrix} (2k^2-\omega^2/s^2)e^{i\sqrt{\omega^2/c^2-k^2}z} \\ 2\sqrt{\omega^2/c^2-k^2}\hat{\mathbf{z}}\times\mathbf{k}e^{i\sqrt{\omega^2/s^2-k^2}z} \end{bmatrix} \psi_{\vec{k}}. \tag{24}$$

The three-vector $\mathbf{k}$ appearing in the cross product is defined to have as its horizontal component $\vec{k}$, and the remaining density $\psi_{\vec{k}}$ need not be further restricted at this point.

Evaluating the two integrals (over λ' and λ'', the vertical component of $\mathbf{k}''$), reduces solution (21) to a form

$$\begin{aligned}\delta\psi_{\vec{k},\lambda} &= \delta\psi_{\vec{k},\lambda,\text{symmetric bulk}} \\ &+ \frac{1}{(2\pi)^3} \begin{bmatrix} \dfrac{\sqrt{\omega^2/c^2-k^2}}{(\omega^2/c^2-k^2-\lambda^2)} & \\ & \dfrac{\sqrt{\omega^2/s^2-k^2}}{(\omega^2/s^2-k^2-\lambda^2)}\mathbf{1} \end{bmatrix} \\ &\times \begin{bmatrix} (2k^2-\omega^2/s^2) \\ 2\sqrt{\omega^2/c^2-k^2}\hat{\mathbf{z}}\times\mathbf{k} \end{bmatrix} \left(\frac{2}{\text{Det}}\right) \\ &\times \frac{1}{\sqrt{\omega^2/c^2-k^2}} \int d^2k''\ e^{i(\vec{k}-\vec{k}'')\cdot\vec{x}_0} [\mathbf{C}\ \mathbf{D}\ \mathbf{S}] \\ &\times \left[\frac{\partial(\mathscr{M},\mathscr{D},\mathscr{Q})}{\partial(\mathbf{C},\mathbf{D},\mathbf{S})}\right] \begin{bmatrix} 1 \\ (\vec{k}\cdot\vec{k}'') \\ (\vec{k}\cdot\vec{k}'')^2 \end{bmatrix} \psi_{\vec{k}''}. \end{aligned} \tag{25}$$

The first (diagonal) matrix in Eq. (25) may be recognized as the full three-vector Green's function for the compressional and shear Helmholtz equations in the solid. The column vector is the polarization vector for waves satisfying the boundary conditions, and the matrix $[\partial(\mathscr{M},\mathscr{D},\mathscr{Q})/\partial(\mathbf{C},\mathbf{D},\mathbf{S})]$ is the transformation that relates the perturbation strengths to the amplitudes of scattered components proportional to the zeroth, first and second powers of in-plane scattering angle.[14] The only nonzero components of this matrix are given in terms of the incoming and outgoing horizontal wave numbers as

$$\frac{\partial\mathscr{M}}{\partial\mathbf{C}} = -\frac{\omega^2}{c^2}(2k^2-\omega^2/s^2)(2k''^2-\omega^2/s^2),$$

$$\begin{aligned}\frac{\partial\mathscr{M}}{\partial\mathbf{D}} &= -2\frac{\omega^2k^2}{s^2}\left(1-\frac{i\sqrt{\omega^2/s^2-k^2}}{|k|}\right) \\ &\times\sqrt{\omega^2/c^2-k^2}\sqrt{\omega^2/c^2-k''^2},\end{aligned}$$

$$\begin{aligned}\frac{\partial\mathscr{M}}{\partial\mathbf{S}} &= 2\frac{s^2k^2}{\omega^2}\left(1-\frac{i\sqrt{\omega^2/c^2-k^2}}{|k|}\right)\left(\frac{i\sqrt{\omega^2/c^2-k^2}}{|k|}\right) \\ &\times(2k^2-\omega^2/s^2)\{(2k''^2-\omega^2/s^2)(k''^2-\omega^2/c^2) \\ &+2k''^2\sqrt{\omega^2/c^2-k''^2}\sqrt{\omega^2/s^2-k''^2}\},\end{aligned} \tag{26}$$

$$\begin{aligned}\frac{\partial\mathscr{D}}{\partial\mathbf{D}} &= \left(1-\frac{i\sqrt{\omega^2/c^2-k^2}}{|k|}\right)(2k^2-\omega^2/s^2) \\ &\times[(2k''^2-\omega^2/s^2)+2\sqrt{\omega^2/c^2-k''^2}\sqrt{\omega^2/s^2-k''^2}],\end{aligned}$$

$$\begin{aligned}\frac{\partial\mathscr{Q}}{\partial\mathbf{S}} &= -2\frac{s^2}{\omega^2}\left(1-\frac{i\sqrt{\omega^2/c^2-k^2}}{|k|}\right)(2k^2-\omega^2/s^2) \\ &\times[(2k''^2-\omega^2/s^2)+2\sqrt{\omega^2/c^2-k''^2}\sqrt{\omega^2/s^2-k''^2}].\end{aligned}$$

Density perturbation contributes a component isotropic in the plane, because of the large vertical component of interface wave motion, and the fact that dipole scattering oriented normal to the surface looks monopolar from the point of view of interface waves. Otherwise the symmetry of in-plane scattering respects that of the three-vector vertex (16) in the bulk.

In a dilute-scatterer approximation, where interface modes are expected to dominate, the appropriate expansion of the scattered wave is in terms of outgoing radial functions. Further, for weak scattering, where self-interaction of the scattered wave is expected to be small, it is sufficient to consider the effects of a plane incident wave satisfying the boundary conditions at a single wave number, in which case $\psi_{0,\mathbf{x}}$ takes the form (24), with

$$\psi_{0,\vec{k}} = \varphi_0\delta^2(\vec{k}-\vec{k}_0). \tag{27}$$

The wave number integral for the incident part of the full wave in this case becomes trivial.

Performing the wave number integrations, evaluating the residues at any poles of the determinant by Cauchy's theorem, and keeping explicit only leading lowest order terms in the far field gives the result

$$\delta\psi_{\mathbf{x}}=(\delta\psi_{\mathbf{x},\text{bulk}}+\delta\psi_{\mathbf{x},\text{higher order}})+\sum_{\text{poles}} e^{i(k\hat{x}-\vec{k}_0)\cdot\vec{x}_0}$$
$$\times\begin{bmatrix}(2k^2-\omega^2/s^2)e^{i\sqrt{\omega^2/c^2-k^2}z}\mathrm{J}_0^+(kx)\\ 2\sqrt{\omega^2/c^2-k^2}e^{i\sqrt{\omega^2/s^2-k^2}z}i\mathrm{J}_1^+(kx)k\hat{\mathbf{z}}\times\hat{\mathbf{x}}\end{bmatrix}\varphi_0$$
$$\times\left(2\sqrt{\omega^2/c^2-k^2}\,\frac{\partial\ \mathrm{Det}}{\partial k^2}\right)^{-1}[\mathbf{C}\ \ \mathbf{D}\ \ \mathbf{S}]$$
$$\times\left[\frac{\partial(\mathscr{M},\mathscr{D},\mathscr{Q})}{\partial(\mathbf{C},\mathbf{D},\mathbf{S})}\right]\begin{bmatrix}1\\ (k\hat{x}\cdot\vec{k}_0)\\ (k\hat{x}\cdot\vec{k}_0)^2\end{bmatrix}. \tag{28}$$

The three-vector $\mathbf{x}\equiv(\vec{x},z)$, with $x\equiv|\vec{x}|$ and $\hat{\mathbf{x}}\equiv(\vec{x}/x,0)\equiv(\hat{x},0)$. Similarly, $k\equiv|\vec{k}|$. In the expansion in leading terms, it has been assumed that the distance from the origin of coordinates to the scatterer $|\vec{x}_0|\ll x$. J_i^+ denotes the outgoing complex component of the Bessel function of order i, and as required the vector component in the scattered wave takes value zero at the origin, removing the orientation singularity of the vector polarization. The magnitude k is to be evaluated at the position of the pole in each term in the sum, and in the final factor, the wave vectors $\vec{k}$ and $\vec{k}''$ of Eq. (25) are evaluated as $k\hat{x}$ and $\vec{k}_0$, respectively.

Recalling the form of input wave (24), the first term is simply the outgoing radial wave with the same normalization at the origin as the incident plane wave, so the coefficients that follow give the relative magnitudes of the incident and scattered waves as a function of the wave numbers of each. The phase assigned to the component from each pole is simply that obtained by tracing along rays in a geometric-optics description, so when the scattered amplitude is perturbatively small, a representation of a distributed scatterer by Huygens' construction is consistent. The scattering strengths may be nondimensionalized by grouping a factor of $(\omega/s)^3=(2\pi/\lambda_{\text{shear}})^3$ with the perturbation strengths $[\mathbf{C}\ \mathbf{D}\ \mathbf{S}]$ to give the small-parameter vector $(2\pi R/\lambda_{\text{shear}})^3[\Delta\lambda/(\lambda_0+2\mu_0)\ M/(R^3\rho_0)\ \Delta\mu/\mu_0]$, and separating the norms k and $|\vec{k}_0|$ from their respective powers of the direction cosine $\hat{k}_0\cdot\hat{x}$. The vertex is thus expressed in terms of a matrix of dimensionless scattering strengths relating equivalently normalized planar incident and radial scattered waves at first order. Denoted $\mathbf{V}^{(1)}$, this matrix is given by

$$\mathbf{V}^{(1)}\equiv\left(2\sqrt{\omega^2/c^2-k^2}\,\frac{\partial\ \mathrm{Det}}{\partial k^2}\right)^{-1}\left(\frac{s}{\omega}\right)^3\left[\frac{\partial(\mathscr{M},\mathscr{D},\mathscr{Q})}{\partial(\mathbf{C},\mathbf{D},\mathbf{S})}\right]$$
$$\times\begin{bmatrix}1 & & \\ & (kk_0) & \\ & & (kk_0)^2\end{bmatrix}. \tag{29}$$

The definition of a pointlike scatterer is that the combination $(2\pi R/\lambda_{\text{shear}})^3$ be less than or comparable to unity, and the remaining specifications of the perturbation strengths are then expressed as fractional changes relative to the background values.

The detailed behavior of the first-order vertex depends on the choice of poles used for incident and scattered waves, and on parameter values. However, it has several features, including the general order of magnitude and the relative dependence of scattering on density and modular perturbations, which are qualitatively parameter independent. These may be represented by giving the values of $\mathbf{V}^{(1)}$ for the scattering of Rayleigh→Rayleigh waves, in the absence of dissipation, when the compressional speed is assumed much larger than the shear speed. For this case, the position and residue of the pole is asymptotically independent of the compressional speed. The prefactor in the scattering amplitude term of Eq. (28), including the residue from the determinant, contributes a nearly parameter-independent suppression of magnitude $\sim(0.1)$ (true also for scattering into the leaky Rayleigh pole). All vertex elements in Eq. (26) are bounded above on the physical sheet at order unity, but for this range of cases all except the coefficient $\partial\mathscr{M}/\partial D$ are suppressed by a factor of s^2/c^2. Supposing for example a shear speed of 200 m/s and a compressional speed of 1800 m/s yields a first-order vertex

$$\mathbf{V}^{(1)}_{\text{Rayleigh}\to\text{Rayleigh}}=\begin{bmatrix}-0.0019i & & \\ 0.1795i & 0.0004i & \\ 0.0009i & & -0.0010i\end{bmatrix}. \tag{30}$$

Thus increases in density by a factor of 2 or more across substantial fractions of a shear wavelength are expected to be visible at the 10% level in *amplitude* near the target. While changes in shear modulus much larger than unity are realistic, e.g., for hard inclusions in unconsolidated sediments, the difficulty of coupling such discontinuities to the sediment frame may make realizable scattering strengths smaller than this vertex would indicate. Also, contributions from realizable variations in compressibilities, as well as density-driven in-plane dipole scattering, are suppressed by powers of the compressional speed, corresponding to the smaller magnitude of compressional motion relative to that of shearing.

III. APPLICATION AND COMMENTS

An application for low-order perturbative scattering amplitudes is the location and characterization of objects buried in unconsolidated sediments.[10] Since this is essentially a sonar application, it conventionally employs a description of the scattering amplitude in terms of a target strength, defined as[15]

$$\mathrm{TS}\equiv 10\log_{10}\left(\frac{I_r(1\ \mathrm{m})}{I_i}\right), \tag{31}$$

where $I_r(1\ \mathrm{m})$ is the scattered (radiated) intensity at a distance of 1 m from the scatterer, and I_i in the incident intensity of the insonifying plane wave. Because the scatterer is a point source, the acoustic center from which distances are measured is simply its location.

For small scattered amplitude, the first-order perturbative result should be a useful approximation to the full scattered amplitude. In the respective limits of long and short wavelength, this approximation defines a first-order bistatic target strength as a function of the wavelengths of the inci-

dent and scattered waves and the angle θ between the direction of incidence and the direction of reception from the target, with the forms:

$$\mathrm{TS}^{(1)}(\lambda_i,\lambda_r,\theta) = \left\{ \begin{array}{ll} \lambda_r \gg \pi^2(\mathrm{m}); & -20\log_{10}(2) \\ \lambda_r \ll \pi^2(\mathrm{m}); & -20\log_{10}(2\pi)+10\log_{10}\left(\dfrac{\lambda_r}{1m}\right) \end{array} \right\} + 20\log_{10}\left(\left(\frac{\omega}{s}\right)^3 [\mathbf{C}\ \ \mathbf{D}\ \ \mathbf{S}]\ \ \mathbf{V}^{(1)}\Big|_{\lambda_i,\lambda_r,\theta} \begin{bmatrix} 1 \\ \cos\theta \\ \cos^2\theta \end{bmatrix} \right). \tag{32}$$

The scattering amplitude in the logarithm scales as ω^3, which may be recognized as the scaling of the Rayleigh cross section ($\sim\omega^{d+1}$) for $d=2$. Thus though the obstacle was introduced formally as a feature of the bulk, projection onto the interface-wave pole yields the characteristics of wave scattering from pointlike obstacles two dimensions. The combination of this scaling, for all perturbations, with the angular dependence of the scattered wave that distinguishes compressional, shear, and density coupling, shows how small finite regions may be consistently treated as point perturbations.

As an example, scattering of 1-m Rayleigh waves from a density mismatch of 100% occupying a $(1\ \mathrm{m}/2\pi)^3$ volume gives a monopole contribution at -31 dB. In unconsolidated sand of density 2 g/cm^3, this would describe a 16-kg buried object. When propagation characteristics are included, these numbers compare favorably to experimental results for density inclusions.[10]

A similar computation for a shear-only diffractor has been performed with finite-element methods in the point-scatterer limit.[8] The parameters for that system were 250-m/s background shear speed and 30-Hz signal, with a diffractor of volume roughly 1.5 m^3 buried 1 m below a solid–fluid interface in a model resembling a surf zone. The water overlayer at the position of the diffractor was very thin, and will be ignored here. The first-order perturbative calculation predicts almost identical monopole and quadrupole scattered Rayleigh wave components at one wavelength, of magnitude -63 dB relative to the wave impinging on the target. When this value is corrected for propagation loss terms, it appears to under-predict scattering by roughly 6 dB relative to the numerical result. This discrepancy is consistent, at one estimated standard deviation, with the approximations made in computing propagation loss and the difficulty of specifying the shape and effective radius of the inclusion in the coarse-grained, higher order finite-element scheme.[16] The perturbative prediction of comparable monopole and quadrupole components in the scattered wave also appears consistent with angular dependence shown in the numerical result.

Nominally, the target strength (32) is direction dependent. But, as noted, for a wide range of realistic parameter values the scattered amplitude is dominated by the monopole term coupled to density defects, so for practical purposes any directionality in the bistatic target strength is likely to be dominated by the spatial distribution of the target itself.

APPENDIX A: MATRIX EXPANSION OF THE INTERACTION TERMS

The inhomogeneous terms appearing in wave equation (9) may be written as a matrix of scattering vertex operators of the form

$$\sum_{\alpha=1,2} \mathbf{P}_1^{(\alpha)}(\boldsymbol{\nabla})[\mathbf{P}_2^{(\alpha)}\delta^3(\mathbf{x}-\mathbf{x}_0)(\mathbf{P}_3^{(\alpha)}(\boldsymbol{\nabla})\psi)] = \begin{bmatrix} V^{\phi\phi} & V^{\phi\mathbf{A}} \\ V^{\mathbf{A}\phi} & V^{\mathbf{AA}} \end{bmatrix} \psi. \tag{A1}$$

The action of these elements on the scalar and vector potential components will be indexed as

$$\begin{bmatrix} \delta\phi \\ \delta\mathbf{A}_l \end{bmatrix} = \begin{bmatrix} V^{\phi\phi} & V_k^{\phi\mathbf{A}} \\ V_l^{\mathbf{A}\phi} & V_{lk}^{\mathbf{AA}} \end{bmatrix} \begin{bmatrix} \phi \\ \mathbf{A}_k \end{bmatrix}, \tag{A2}$$

where spatial vector indices $k,l\in\{1,2,3\}$, and repeated indices are summed. The matrix product (A1) implicitly involves inner products over internal spatial indices, which will be denoted explicitly in the factors given below. In this Appendix only it is necessary to use this index convention to write the factorization of the operator in a manageable form. The unit diagonal matrix is implied wherever **P** operators are denoted as scalars. ϵ_{ijk} is the totally antisymmetric symbol, and δ_{ij} is the Kronecker delta.

The $\alpha=1$ term in Eq. (A1) involves only density perturbations, and is quadratic in spatial derivatives. Its factors are

$$\begin{aligned} [\mathbf{P}_1^{(1)}\ (\boldsymbol{\nabla})]_i &= \boldsymbol{\nabla}_i, \\ [\mathbf{P}_2^{(1)}]_{ip} &= \left(\frac{-M\omega^2}{\rho_0}\right) \begin{bmatrix} \delta_{ip} & \epsilon_{ipk} \\ -\epsilon_{ipl} & \epsilon_{mil}\epsilon_{mpk} \end{bmatrix}, \\ [\mathbf{P}_3^{(1)}\ (\boldsymbol{\nabla})]_p &= \boldsymbol{\nabla}_p. \end{aligned} \tag{A3}$$

The $\alpha=2$ term is quartic in derivatives, and comprises perturbations in both compressional and shear moduli. Its factors are

$$\begin{aligned} [\mathbf{P}_1^{(2)}\ (\boldsymbol{\nabla})]_{ij} &= \boldsymbol{\nabla}_i\boldsymbol{\nabla}_j, \\ [\mathbf{P}_2^{(2)}]_{ijpq} &= \left\{ \left(\frac{-\Delta\lambda R^3}{\rho_0}\right) \begin{bmatrix} \delta_{ij}\delta_{pq} & 0 \\ 0 & 0 \end{bmatrix} - \left(\frac{2\Delta\mu R^3}{\rho_0}\right) \times \begin{bmatrix} \delta_{ip}\delta_{jq} & \epsilon_{ipk}\delta_{jq} \\ -\epsilon_{ipl}\delta_{jq} & \tfrac{1}{2}\epsilon_{mil}[\epsilon_{mpk}\delta_{jq}+\epsilon_{jpk}\delta_{mq}] \end{bmatrix} \right\}, \\ [\mathbf{P}_3^{(1)}\ (\boldsymbol{\nabla})]_{pq} &= \boldsymbol{\nabla}_p\boldsymbol{\nabla}_q. \end{aligned} \tag{A4}$$

Contraction of these terms, after transformation to a wave number basis, gives the expansion of Eq. (16).

APPENDIX B: SYMMETRIES OF THE SCATTERING VERTEX

The symmetry decomposition of the scattering vertex (16) is performed by fixing the wave vector $\mathbf{k}'$ of input fields ϕ, $\mathbf{A}$, and identifying the dependence of the various components of the scattered wave,

$$\sum_{\alpha=1,2} [\mathbf{P}_1^{(\alpha)}(-i\mathbf{k})\mathbf{P}_2^{(\alpha)}\mathbf{P}_3^{(\alpha)}(-i\mathbf{k}')]\cdot\begin{bmatrix}\phi\\ \mathbf{A}\end{bmatrix}_{\mathbf{k}'},$$

on the angle of the output wave vector $\mathbf{k}$.

For $\mathbf{A}$ satisfying the transversality condition (2), the polarization of the shear wave defines a unit vector $\hat{\mathbf{p}}$ as $\mathbf{A} \equiv |\mathbf{A}|(\hat{\mathbf{p}}\times\mathbf{k}')/|\mathbf{k}'| \equiv |\mathbf{A}|(\hat{\mathbf{p}}\times\hat{\mathbf{k}}')$. Without loss of generality, $\hat{\mathbf{p}}$ may be taken to satisfy $\hat{\mathbf{p}}\cdot\hat{\mathbf{k}}'=0$. An orthonormal basis is therefore defined by the three unit vectors

$$\hat{\mathbf{e}}_1=\hat{\mathbf{p}}\times\hat{\mathbf{k}}', \quad \hat{\mathbf{e}}_2\equiv\hat{\mathbf{p}}, \quad \hat{\mathbf{e}}_3\equiv\hat{\mathbf{k}}'. \tag{B1}$$

Denoting $\hat{\mathbf{k}}\equiv\mathbf{k}/|\mathbf{k}|$, and introducing angles θ, φ for an expansion in spherical harmonics $Y_{mn}^{e,0}(\theta,\varphi)$,[17] such that

$$\begin{aligned}
&\hat{\mathbf{k}}\cdot\hat{\mathbf{k}}' \equiv \cos\,\theta = Y_{01}^e,\\
&\hat{\mathbf{k}}\cdot(\hat{\mathbf{p}}\times\hat{\mathbf{k}}') \equiv \cos\,\varphi\,\sin\,\theta = Y_{11}^e,\\
&\hat{\mathbf{k}}\cdot\hat{\mathbf{p}} \equiv \sin\,\varphi\,\sin\,\theta = Y_{11}^0,
\end{aligned} \tag{B2}$$

the components of the scattered wave may be grouped according to the level of their representation of the rotation algebra.

Identities useful in computing the action of the matrix proportional to $\mathbf{D}$ are

$$\begin{aligned}
&(\hat{\mathbf{k}}\times\hat{\mathbf{k}}')\cdot(\hat{\mathbf{p}}\times\hat{\mathbf{k}}') = Y_{11}^0,\\
&-(\hat{\mathbf{k}}\times\hat{\mathbf{k}}') = -\hat{\mathbf{e}}_1 Y_{11}^0 + \hat{\mathbf{e}}_2 Y_{11}^e,\\
&[(\hat{\mathbf{k}}\cdot\hat{\mathbf{k}}')\mathbf{1}-\hat{\mathbf{k}}'\hat{\mathbf{k}}]\cdot(\hat{\mathbf{p}}\times\hat{\mathbf{k}}') = \hat{\mathbf{e}}_1 Y_{01}^e - \hat{\mathbf{e}}_3 Y_{11}^e.
\end{aligned} \tag{B3}$$

Similar useful identities for the terms proportional to $\mathbf{S}$ are

$$\begin{aligned}
&(\hat{\mathbf{k}}\cdot\hat{\mathbf{k}}')^2 = \tfrac{1}{3}Y_{00}^e + \tfrac{2}{3}Y_{02}^e,\\
&(\hat{\mathbf{k}}\cdot\hat{\mathbf{k}}')(\hat{\mathbf{k}}\times\hat{\mathbf{k}}')\cdot(\hat{\mathbf{p}}\times\hat{\mathbf{k}}') = \tfrac{1}{3}Y_{12}^0,\\
&-(\hat{\mathbf{k}}\cdot\hat{\mathbf{k}}')(\hat{\mathbf{k}}\times\hat{\mathbf{k}}') = -\hat{\mathbf{e}}_1\tfrac{1}{3}Y_{12}^0 + \hat{\mathbf{e}}_2\tfrac{1}{3}Y_{12}^e,\\
&(\hat{\mathbf{k}}\cdot\hat{\mathbf{k}}')[(\hat{\mathbf{k}}\cdot\hat{\mathbf{k}}')\mathbf{1}-\hat{\mathbf{k}}'\hat{\mathbf{k}}]\cdot(\hat{\mathbf{p}}\times\hat{\mathbf{k}}') = \hat{\mathbf{e}}_1(\tfrac{1}{3}Y_{00}^e + \tfrac{2}{3}Y_{02}^e) - \tfrac{1}{3}\hat{\mathbf{e}}_3 Y_{12}^e,\\
&(\hat{\mathbf{k}}\times\hat{\mathbf{k}}')(\hat{\mathbf{k}}\times\hat{\mathbf{k}}')\cdot(\hat{\mathbf{p}}\times\hat{\mathbf{k}}') = \hat{\mathbf{e}}_1(\tfrac{1}{3}Y_{00}^e - \tfrac{1}{3}Y_{02}^e - \tfrac{1}{6}Y_{22}^e) - \tfrac{1}{6}\hat{\mathbf{e}}_2 Y_{22}^0.
\end{aligned} \tag{B4}$$

Substituting these expansions into Eq. (16) gives an expression for the scattered wave in terms of the magnitudes of the inputs ϕ and $\mathbf{A}$,

$$\begin{aligned}
&\sum_{\alpha=1,2} [\mathbf{P}_1^{(\alpha)}(-i\mathbf{k})\mathbf{P}_2^{(\alpha)}\mathbf{P}_3^{(\alpha)}(-i\mathbf{k}')]\cdot\begin{bmatrix}\phi\\ \mathbf{A}\end{bmatrix}_{\mathbf{k}'}\\
&= \left\{ -\left(c^2\mathbf{C} + \frac{2s^2\mathbf{S}}{3}\right)\mathbf{k}^2\mathbf{k}'^2\begin{bmatrix} Y_{00}^e & 0\\ 0 & 0\end{bmatrix} + \omega^2\mathbf{D}|\mathbf{k}||\mathbf{k}'|\begin{bmatrix} Y_{01}^e & Y_{11}^0\\ -\hat{\mathbf{e}}_1 Y_{11}^0 + \hat{\mathbf{e}}_2 Y_{11}^e & \hat{\mathbf{e}}_1 Y_{01}^e - \hat{\mathbf{e}}_3 Y_{11}^e\end{bmatrix}\right.\\
&\left. - \frac{s^2\mathbf{S}}{6}\,\mathbf{k}^2\mathbf{k}'^2\begin{bmatrix} 8Y_{02}^e & 4Y_{12}^0\\ -4\hat{\mathbf{e}}_1 Y_{12}^0 + 4\hat{\mathbf{e}}_2 Y_{12}^e & \hat{\mathbf{e}}_1(6Y_{02}^e + Y_{22}^e) + \hat{\mathbf{e}}_2 Y_{22}^0 - 2\hat{\mathbf{e}}_3 Y_{12}^e\end{bmatrix}\right\}\begin{bmatrix}\phi\\ |\mathbf{A}|\end{bmatrix}_{\mathbf{k}'}.
\end{aligned} \tag{B5}$$

Both $\mathbf{C}$ and $\mathbf{S}$ contribute to isotropic, or monopole scattering, with constant angular dependence $Y_{00}^e \equiv 1$. $\mathbf{D}$ multiplies only components $Y_{m1}^{e,0}$, and thus gives rise to pure dipole scattering. Finally, $\mathbf{S}$ contributes additional terms in $Y_{m2}^{e,0}$, representing quadrupole scattering, as would be expected from the symmetry of shear deformations.

A fast integral equation approach to acoustic scattering from three-dimensional objects using a natural basis set

D. T. Moroney and P. J. Cullen
Department of Electronic and Electrical Engineering, Trinity College Dublin, Dublin 2, Ireland

(Received 1 February 1996; revised 29 December 1996; accepted 31 December 1997)

Boundary value integral equations and the moment method solution technique provide a succinct and elegant strategy for the solution of acoustic surface scattering problems. This paper explores the application of a subdomain basis set, based on the phase of the incident radiation, which is used to solve for the unknown normal pressure gradient on the surface of the scatterer using the moment method. The advantage of this basis set lies in the fact that it can accurately represent the fast phase character of the pressure gradient on the surface of the scatterer. This allows for far fewer discretizations/basis elements in the moment method formulation and therefore significantly reduces the density of unknowns that must be numerically computed. The main contribution of this paper is to show how to efficiently employ this natural basis and to explore the physical justification for using this approach. The method is compared with other techniques including the Kirchhoff solution technique, high frequency single scattering techniques, the Nussenzveig–Fock technique, and the parabolic equation approximation. Unlike these methods no approximation to the physical system need be introduced. © *1998 Acoustical Society of America.* [S0001-4966(98)02904-X]

INTRODUCTION

The problem we shall address is the efficient computation of the scattered field caused by the presence of an irregular, three-dimensional, pressure-release scatterer, embedded in free space and irradiated by a source with wave number k. The starting point of our analysis will be the Helmholtz integral equation. If we consider a two-dimensional surface S with Dirichlet boundary conditions the total acoustic pressure $p(\boldsymbol{\rho})$ that results from an incident field $p_{\text{inc}}(\boldsymbol{\rho})$ interacting with S is given by

$$p(\boldsymbol{\rho}) = p_{\text{inc}}(\boldsymbol{\rho}) - \int_S \Psi(\boldsymbol{\rho},\boldsymbol{\rho}') \frac{\partial p(\boldsymbol{\rho}')}{\partial n'} dS'. \tag{1}$$

Here, $\partial p(\boldsymbol{\rho}')/\partial n'$ is the unknown normal pressure gradient at the surface which we will hereafter denote as J_n, $\Psi(s,s',t,t')$ (s and t parametrize the boundary surface) is the free-space Green's function

$$\frac{\exp(-ikR)}{4\pi R} \tag{2}$$

with R the distance between points on the surface and integration points, and dS' is a surface element (see Fig. 1). Using the boundary condition $p(\boldsymbol{\rho}_s)=0$, where $\boldsymbol{\rho}_s$ is a point on the surface, we arrive at an integral equation for $J_n(\boldsymbol{\rho}_s)$

$$p_{\text{inc}}(s,t) = \int_S \Psi(s,s',t,t') J_n(s',t') dS', \tag{3}$$

where s and t parametrize the boundary surface.

The moment method solves boundary value problems (BVPs) described as surface integral equations over finite domains by converting continuous integral equations into systems of algebraic equations. In the case where N Dirac testing functions are used (point collocation) such systems can be written as

$$\mathcal{Z}\mathbf{a} = \mathbf{P}_{\text{inc}}, \tag{4}$$

where $\mathbf{P}_{\text{inc}}$ is the vector consisting of the incident field at the collocation points, $\mathcal{Z}$ is the $N\times N$ kernel of the discretized integral equation (which we will refer to as the impedance matrix), and $\mathbf{a}$ is the unknown vector containing the coefficients a_n of the expansion of the pressure gradient over the basis $b_n(s,t)$

$$\hat{J}_n(s,t) = \sum_{n=1}^{N} a_n b_n(s,t). \tag{5}$$

Once the a_n are determined Eq. (5) provides an approximation to the exact solution of the integral equation.

The moment method is usually considered a low frequency method[1,2] because the size N of the moment matrix increases with frequency. To accurately model the fast moving phase we must discretize the surface pressure gradient at a rate of at least four surface patches (triangular patches are most commonly used) per wavelength in any direction on the surface. Moreover the impedance matrix $\mathcal{Z}$, where N is the total number of surface elements, is full and has complex entries.

Over the past few years a number of methods have been proposed to reduce the number of unknowns in the formulation of integral equation problems. Recent approaches to speed up iterative solutions include the fast multipole method and its variants[3–5] as well as the matrix decomposition algorithm.[6] The impedance matrix localization method[7] can reduce solution complexity by creating a very sparse impedance matrix. The factoring out of either the physical optics pressure gradient (or current in the electrical case) or its phase factor have been suggested by James.[8] The use of the phase factor of the physical optics current to construct a basis set for the unknown surface current density has been suggested in Refs. 9 and 10. It is this technique which we

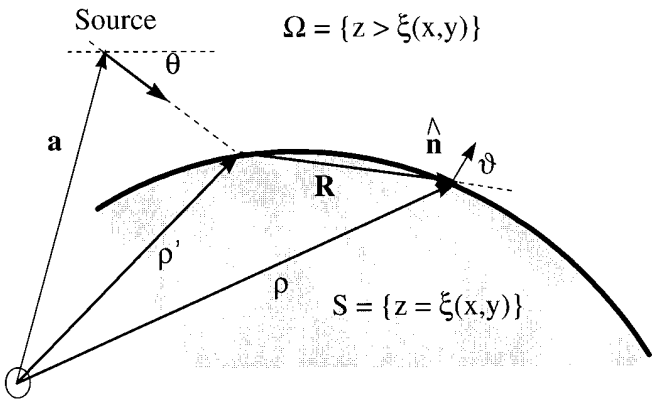

FIG. 1. Scattering geometry.

shall explore in this paper. Incidentally, the relationship between this method and some of the aforementioned techniques is considered in Ref. 11 and more recently in Ref. 12. In the latter citation very high speed iterative methods which are more robust than the natural basis method, for the case of multiple scattering, are outlined for the two-dimensional electromagnetic case.

Any physical knowledge we may have of the solution of a scattering problem can be used to inform the construction of a good basis set. The more we can inform the basis, the less numerically intensive will be our task of finding the exact solution. This paper is concerned with a particular, and rather natural, case of this general approach. The optimum basis function for the unknown pressure gradient in a moment method formulation of a scattering problem is of course, the trivial one that tends towards the unknown gradient itself.

We have mentioned James[8] who constructed a modified integral equation called the High Frequency Panel Method, for uniform plane wave excitation by dividing the surface into linear segments (panels) and assuming that the phase of the surface current on the panels could be expressed in terms of the phase of the physical optics current. The resulting integral equation where a piecewise constant basis function was assumed was solved for the residual function and a reduction in the density by a factor of between 20 and 100 was claimed as possible and a reduction nearer 20 was actually demonstrated. The essence of our approach is the same, we use the normalized incident field (the field divided by its magnitude, i.e., the physical optics phase-factor) as a basis.

Moroney and Cullen in Ref. 9 introduced the idea of a natural basis for two-dimensional terrain scattering. This basis is a set of linearly independent subdomain complex valued functions defined to be the phase of the incident radiation as a function of arclength (they consider the 2-D case) on the surface boundary of the scatterer. This basis set can greatly reduce the number of unknowns N and thus provide a method suitable for many very large scattering problems. A reduction of N by a factor of 1000 has been demonstrated for a practical terrain propagation problem where the scatterer was of the order $10^5\lambda$ in total arclength, allowing the scattered field to be calculated in a few seconds on a desktop computer.

Abregg and Peterson,[10] taking their lead from James, describe a method where the phase of the physical optics current is used to construct a moment method basis for the unknown current. They also employ an edge basis function for some of the cases they consider and their surface elements are considered to be parabolic. Aberegg and Peterson call their method the integral equation asymptotic phase (IE-AP) technique. A reduction in the density of unknowns to less than one sample per wavelength was achieved.

In this paper we consider the application of the natural basis to three-dimensional problems. The main contribution of this paper is the solution methodology (in particular, the construction of the matrix operator) and the exploration of the physical justification of this approach. This is important because it is required to understand under what conditions we can expect significant computational savings to be had using the natural basis.

Computationally, the numerical scattering problem can be divided into four elementary steps: (1) Preprocessing—surface discretization, physical parameter input. (2) Matrix fill. (3) Inversion/pseudo-inversion to calculate the unknown $\hat{J}_n$. (4) Calculation of total field using $\hat{J}_n$. It will be seen that using the natural basis set can speed up each of the steps with the exception of preprocessing; and although the analysis will rely on the Helmholtz integral[13] with pressure-release boundary condition, i.e., $p=0$ on the surface of the scatterer, the extension to the condition $\partial p/\partial n=0$ on the surface of the scatterer will be evident. It appears likely that the method can also be applied to lossy homogeneous isotropic scatterers, this is certainly the case for two-dimensional scattering by dielectrics which is considered in Ref. 14.

I. A NATURAL BASIS SET IN THREE DIMENSIONS

The natural basis set is extracted from the high frequency complex function $\phi(\boldsymbol{\rho}_s)=p_{\text{inc}}(\boldsymbol{\rho}_s)/|p_{\text{inc}}(\boldsymbol{\rho}_s)|$. Writing J_n as $J_n=\overline{J_n}\cdot\phi$ we argue that, for a significant class of problems, ϕ contains the fast moving phase of the true surface pressure gradient J_n. Whenever this is true we can significantly reduce the size of the impedance matrix $\mathcal{Z}$. Generally if $\overline{J_n}$ is in any way slower moving than J_n then, of course, a computational speedup can be achieved.

Expressing $\overline{J_n}$ in terms of the incident and scattered field gradients

$$\overline{J_n}=\hat{n}\cdot\nabla(p_{\text{inc}}+p_{\text{sca}})/\phi$$

and assuming that the incident field magnitude will typically be slowly varying in practical applications, we see that if $\overline{J_n}$ is to be slowly varying on the surface then

$$F=[\nabla\Phi(p_{\text{sca}})A(\boldsymbol{\rho})-i\nabla A(\boldsymbol{\rho})]$$

must be also be slowly varying where we have expressed the scattered pressure $p_{\text{sca}}=A(\boldsymbol{\rho})\exp(-i\Phi(p_{\text{sca}}(\boldsymbol{\rho})))$ and we use the function $\Phi(x)=x/|x|$ to extract its phase factor. Computational gain requires that F be piecewise slowly varying in amplitude and phase over regions that are large compared to a wavelength.

For computational purposes we rely on the weaker assumption that $\overline{J_n}$ can be represented as a set of low order

polynomials over disjoint subdomains. We assume that there exist suitable conditions such that $\Phi(J_n)$ can be well approximated, in local areas, with possibly some constant phase shift as $\Phi(p_{\text{inc}}(s))$. This occurs when the phases and amplitudes of the function F, restricted to the surface of the scatterer, are quasiconstant in local basis areas. Specifically the complex basis set is

$$b_n(s,t)=\begin{cases} e^{-i\Phi(p_{\text{inc}}(s,t))}, & s,t\in\Delta S_n \\ 0, & s,t\notin\Delta S_n \end{cases} \tag{6}$$

defined over *large* subdomains $s,t\in\Delta S_n$ of the surface. None of the elements $b_n(s,t)$ lie in the space spanned by $\{b_m(s,t)\}_{m=1,m\neq n}^{N}$ thus $\{b_n(s,t)\}_{n=1}^{N}$ is a linearly independent set. The restriction on the set is that it forms a complete set in the domain of the operator $\mathscr{Z}$ (Ref. 15) i.e., $\{b_n(s,t)\}_{n=1}^{N}$ should satisfy the boundary conditions and any differentiability condition of the problem.

We may supplement the complex basis set with a real set $\{r_n\}_{n=1}^{N}$ to better approximate the change in amplitude and phase over a basis element on ΔS_n giving a basis set $\{b_n r_n\}_{n=1}^{N}$ over the same subdomains ΔS_n. The subdomains ΔS_n over which the basis functions are defined are, of course, variable in length for each n.

II. RELATION OF THE NATURAL BASIS TO OTHER SOLUTION TECHNIQUES

We will now produce evidence to suggest that $\overline{J_n}$ varies slowly relative to ϕ, for a certain class of problems. We will first consider the formulation of our problem in terms of a second kind integral equation exploring the contribution of the integral term in the case of large smooth scatterers. We then examine the behavior of the first few terms of the Born series solution to justify our thesis that $\overline{J_n}$ can be a slowly varying function. We will then consider in turn the Nussenveig–Fock correction, the Green's function perturbation method (GFPM), and the parabolic wave approximation in each case to support our thesis that when we remove ϕ that $\overline{J_n}$ is slowly varying.

A. Second kind integral equation

Consider first (in the two-dimensional case), the modified Helmholtz equation (second kind integral equation) with Dirichlet boundary condition

$$J_n=2J_n^i-\frac{1}{2i}\int_S(\hat{n}\cdot\hat{R})G'(s,s')J_n ds', \tag{7}$$

to help gauge the validity of our representation of ϕ. J_n^i is the incident pressure derivative on the surface and we can identify $2J_n^i$ as the Kirchhoff approximation J_K for the pressure gradient. The geometry is illustrated in Fig. 1. For ease of use we rewrite Eq. (7) as $J_n=J_K+I$. These two right hand terms can be interpreted as the Kirchhoff–tangent plane approximation J_K and all corrections I to this approximation. In Ref. 16 Poggio and Miller make the observation that due to geometrical factors in the kernel of I, namely $\hat{n}\cdot\hat{R}=\cos\vartheta$, for large smooth conductors the contribution from I is only of second order importance. The phase $\Phi(J_K)$ of the Kirchhoff term J_K is directly calculable and so we postulate that J_n can be written as $\overline{J_n}\Phi(J_K)$. This is trivially true when S is a flat plate because $\cos\vartheta$, and hence I, is zero everywhere. Thus our thesis is supported for large smooth scatterers.

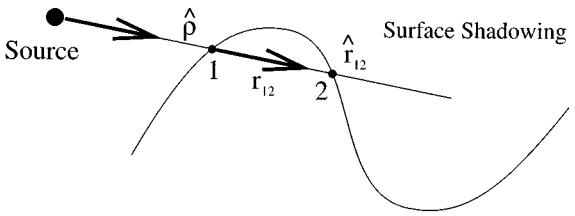

FIG. 2. Geometrical interpretation of a surface shadowing event.

B. Born series: Multiple scattering

Writing the Born (the Born or Neumann series is sometimes referred to as the Meecham series for the specific case of the acoustic analog of the magnetic field integral equation) series for Eq. (7)[17]

$$J_n=J_K-\mathscr{Z}J_K+\mathscr{Z}^2J_K-\cdots+\mathscr{Z}^NJ_K-\cdots \tag{8}$$

we can explore the contribution of terms after the tangent plane pressure gradient approximation J_K to the induced pressure gradient J_n. An evaluation of the contribution to J_n of the term $\mathscr{Z}J_K$ in the limit $k\to\infty$ is studied using the method of stationary phase by Liszka and McCoy[18] for the two-dimensional case where the Green's function $G(s,s')$ is given by the Hankel function $H_0^{(2)}$. However, the analysis extends, quite naturally, to the case where $G(s,s',t,t')=\exp(-ikR)/(4\pi R)$. They found that when the addition to the integral (7) from the local region $kR\leqslant 1$ is negligible, two stationary points exist. The domain of integration is divided into local $kR\leqslant 1$ and outer $kR>1$ so that asymptotic forms of the Hankel function $H_0^{(2)}$, for small and large arguments, can be used in the analysis. Referring to the geometry of Figs. 2 and 3 stationary points are given by

$$\hat{\boldsymbol{\rho}}=-\hat{r}_{12}, \tag{9}$$

where $\hat{\boldsymbol{\rho}}$ is the unit vector from the radiating source to an observation point 1, on the surface, and $\hat{r}_{12}$ is a unit vector, equivalent to $\hat{R}$, along the vector joining the observation point 1 and any other point 2 indicating surface shadowing and

$$\hat{\boldsymbol{\rho}}\cdot\hat{t}_2=-\hat{r}_{12}\cdot\hat{t}_2, \tag{10}$$

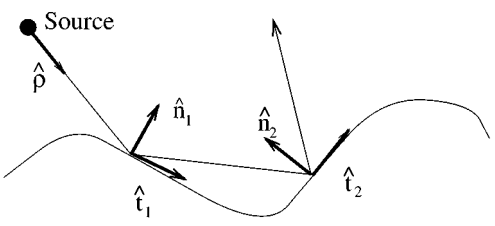

FIG. 3. Geometrical interpretation of a single scattering event.

where $\hat{t}_2$ is the unit tangent vector at a point 2, indicating a double reflection. What is most important about these two instances is that their contribution to J_n is a piecewise scalar multiple of J_K, thus the phase of J_n is equal to the phase of J_K. Again we find $J_n = \overline{J_n}\Phi(J_K)$ and our requirement is satisfied for surfaces with up to double scattering events (see Fig. 3) where the dimensions of the surface are large compared to the dimension of the incident wavelength.

C. Born series: Second term

The contribution from local regions, where $kR \leqslant 1$, is considered by Voronovich.[19] He limits himself to surfaces that can be represented, in the local area $kR \leqslant 1$ about the observation point $\boldsymbol{\rho}$, by $\xi(x,y) \approx x^2/2\rho_x + y^2/2\rho_y$ where ρ_x and ρ_y are the radii of curvature in the xz and yz planes at (x,y). He shows, in the case of an incident plane wave, that the addition, from local areas, to J_n from the second term in the Born series is

$$J_K\left(\frac{i}{2k\rho_x \sin^3\theta} + \frac{i}{2k\rho_y \sin\theta}\right), \tag{11}$$

where θ is the angle of incidence. Thus the contribution to the phase from local areas, other than that from J_K, in the second term of the Born series, is from the purely complex function $i(1/(2k\rho_x \sin^3\theta) + 1/(2k\rho_y \sin\theta))$ whose phase angle is zero. Once again this lends support to our thesis.

D. Green's function perturbation method

Alternative evidence can be had by considering the most general form of convolutional approximate solution to the boundary operator problem is introduced as a Green's function perturbation method (GFPM) in Refs. 20 and 21.

The difference in phase of the normal derivative of the pressure calculated by convolution $\Phi(P_c)$, using the GFPM, and $\Phi(J_K)$ is

$$\Phi\left(\mathscr{F}^{-1}\left[\frac{\mathscr{F}[p_{\text{inc}}(s,t)]}{\mathscr{F}[G(g(s,s',t,t'))]}\right]\right) - \frac{2J_n(s,t)}{|2J_n(s,t)|}, \tag{12}$$

where $s = \int_0^x \sqrt{1 + (dy/dx)^2 (dz/dx)^2}\, dx$ and $g(s,t)$ is judiciously chosen. It is a straightforward task to show that again, in this case, $\overline{J_n}$ is slowly varying. As an example, $g(s,t)$ may be defined by $g(s,t) = \langle \mathbf{d}(s',t',s'-s,t'-t)\rangle_{s,t}$ where $\langle\cdot\rangle_{s,t}$ defines the average function $1/L\int_S \cdot\, ds\, dt$ and $\mathbf{d}(\cdot,\cdot)$ is the Euclidean distance function.

E. Nussenveig–Fock correction

Fock[22] considered another general set of surfaces, namely the set of paraboloids of revolution, in order to investigate diffraction into shadowed regions. (A point is *shadowed* if it is not geometrically visible to the source.) He found that he could express the current (pressure gradient) J_n as

$$J_n = J_K G(\zeta,0), \tag{13}$$

where

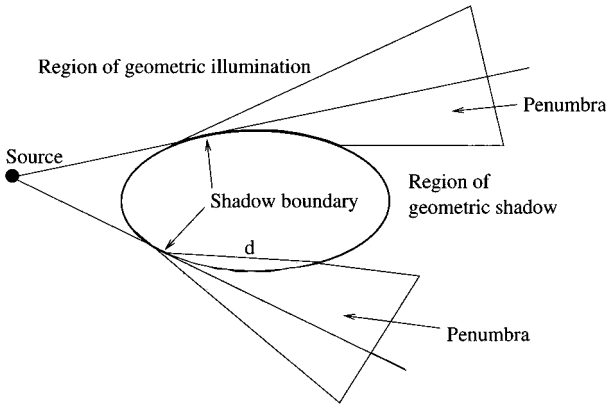

FIG. 4. Geometry for the Nussenzveig–Fock correction.

$$G(\zeta,0) = \exp\left(i\frac{\zeta^3}{3}\right)\frac{1}{\sqrt{\pi}}\int_c \frac{\exp(i\zeta t)}{w'(t)}\, dt \tag{14}$$

with $\zeta = \pm ld$, where l is the distance from the geometrical shadow boundary and the sign convention is $+$ in the geometrical shadow and $-$ otherwise, d is the width of the transition region from illumination to shadow (see Fig. 4), w is the complex Airy function and c is a contour in the complex t plane. He called his method the principle of the local field in the penumbra region (the *penumbra* is that region which, heuristically, can be defined as the finite transition region from illumination, according to geometrical optics, to total shadow). The function G tends to a limit in amplitude of 2, for ζ negative and large; and exponentially to zero, for ζ positive; thus showing the physical requirements of diffraction and reflection. For our purposes, the most important trait is that G, for the paraboloids of revolution, was found to be a slowly varying function of position. This agrees with our postulation exactly. The functions G are difficult to evaluate and so Fock envisaged a lookup table with G evaluated asymptotically over individual scatterers. This approach is often used as a post-process in improving the Kirchhoff approximation and is referred to as the Nussenzveig-Fock correction.[23] We, on the other hand, evaluate the Fock functions implicitly in the moment method.

F. Parabolic equation

The parabolic equation (PE) approach to solving an approximate form of the Helmholtz equation was first introduced by Leontovich and can be found in Ref. 22. Leontovich was primarily concerned with propagation around the earth, first considered as a plane and then as a sphere. Tappert[24] is regarded as the first to use the PE method for complex scattering problems. Physically the PE requires that energy propagates in a forward direction away from the source and that an insignificant amount is backscattered from any obstacle along the path of propagation. In terms of the pressure p, satisfying $\nabla^2 p + k^2 p = 0$, we write p as $W\exp(ik_0(R\cdot\hat{x}))/\sqrt{(R\cdot\hat{x})}$, where W is a slowly varying envelope about the fast phase component $\exp(ik_0 x)/\sqrt{x}$. The PE is given by[24]

TABLE I. Subdomain integration types.

d_1 ↓	d_2→	Monotonic increasing	Monotonic decreasing
monotonic increasing		*A*	*B*
monotonic decreasing		*B*	*A*

$$\frac{\partial^2 W}{\partial z^2}+\frac{1}{r^2}\frac{\partial^2 W}{\partial \theta^2}+2ik_0\frac{\partial W}{\partial x}+k_0(n^2-1)W=0. \tag{15}$$

Note that k_0 is a nominal wave number but is usually taken to be $2\pi/\lambda$ where λ is the mean wavelength of the illuminating radiation source. The symbol n is the refractive index of the propagating medium which may be a function of position. Within the bounds of the PE approximation n is considered close to constant. The conditions necessary for the validity of the PE are

$$\frac{\partial^2 W}{\partial x^2}\ll 2ik_0\frac{\partial W}{\partial x} \tag{16}$$

indicating that the change in the envelope W is small over a wavelength and

$$k_0 x\gg 1 \tag{17}$$

demanding observations far from the source. Tappert continues by indicating that the rapidity of changes in W depend on n and the boundary conditions and that for variations that are much more gradual in the horizontal, compared to the vertical, the step size needed to solve Eq. (15) is much greater than a wavelength. Methods that are often used to solve the PE are finite difference[25,26] and finite element.[27] It is evident that with $W\exp(ikR\cdot\hat{x})/\sqrt{R\cdot\hat{x}}$ on the surface on the scatterer

$$J_n=W\varphi\phi. \tag{18}$$

If φ is a low frequency function then problems that can be solved by the PE method can be solved using the natural basis set.

III. COMPUTATIONALLY EFFECTIVE ADAPTIVE MATRIX FILL

An extra advantage of the complex basis set in Eq. (6) arises in the calculation of the subintegrals required to fill the moment matrix. A naïve approach,[28] using small basis functions with compact support, would sample the subdomains for each matrix slot by at least four samples per wavelength along the arclength of the scatterer and then apply some numerical integration scheme. James in Ref. 29 considers a range of asymptotic methods for speeding the calculation of matrix elements.

Here we follow a different approach which is physically inspired and particularly well suited to grazing incidence scattering from undulating surfaces. Subintegrals of collocation type in the moment method with the derived basis set (6) take the following form

$$\int_{\Delta S} G(s,s',t,t')\exp(-i\Phi(p_{\text{inc}}(s',t'))dS'. \tag{19}$$

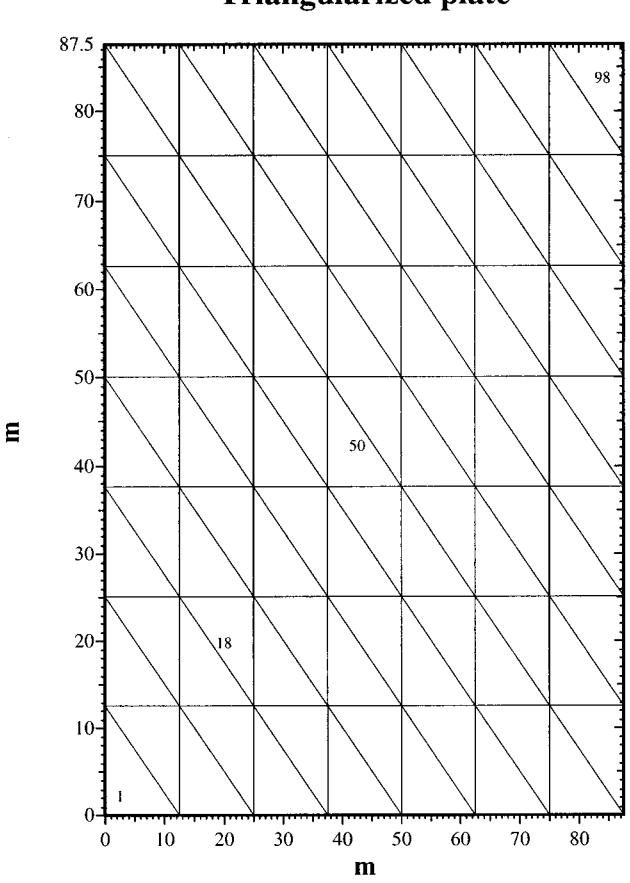

FIG. 5. Triangularization of flat plate.

Equation (19) is a generalized Fourier integral dependent on the two distance functions $d_1=|\boldsymbol{\rho}-\boldsymbol{\rho}'|$, via the Green's function, and $d_2=|\mathbf{a}-\boldsymbol{\rho}'|$, via the basis, as illustrated in Fig. 1, where **a** is a vector describing the position of the point source.

Over any surface S the oscillation in the subintegral is characterized by the function $D(s',t')=d_1+d_2$ and the distance functions can be divided into segments where d_1 and d_2 are, respectively, monotonic in the variables s,t. The four possible interactions of these functions shown in Table I produce two different integral types. Integrations of type *A* have integrands that oscillate more rapidly than the Green's function $\exp(-jkR)/(4\pi R)$ and integrands of type *B* oscillate more slowly than the Green's function. The specific oscillation rates over subdomains are calculated by the respective partial derivatives in s and t of D.

As an example consider the scattering of the field due to a point source by a flat plate: a thin screen of dimensions 87.5×87.5 m with leftmost position at the origin, see Fig. 5. The (x,y,z) coordinates of the source (the wavelength is $\lambda=1$ m) are $(-10,-10,4)$m. The plate is triangulated as in Fig. 5. We will consider the contributions from basis subdomains

$$\Delta S_1=\{(0,0,0),(12.5,0,0),(0,12.5,0)\}, \tag{20}$$

$$\Delta S_{18}=\{(25,12,5,0),(25,25,0),(12.5,25,0)\}, \tag{21}$$

$$\Delta S_{98}=\{(87.5,75,0),(87.5,87,5,0),(75,87.5,0)\}, \tag{22}$$

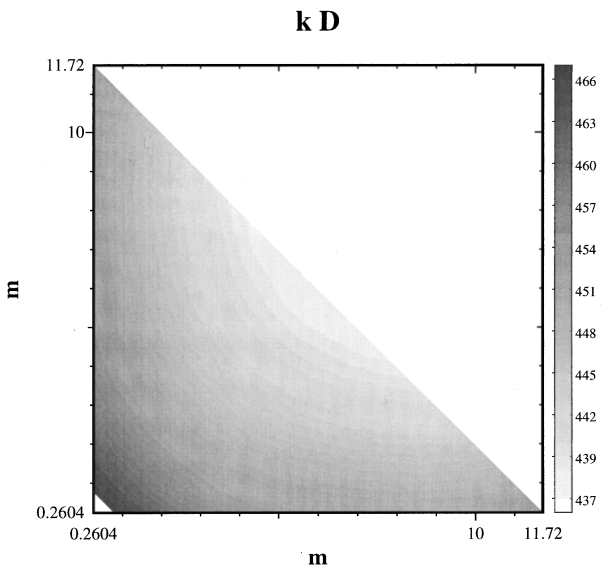

FIG. 6. The function kD in basis ΔS_1.

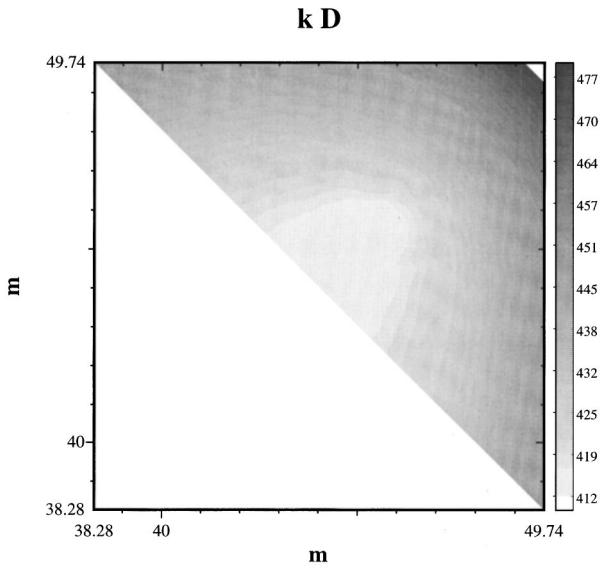

FIG. 8. The function kD in basis ΔS_{50}.

and the basis self-term

$$\Delta S_{50}=\{(50,37.5,0),(50,50,0),(37.5,50,0)\} \tag{23}$$

to the integration point $P=(45.83,45.83,0)$ indicated in Fig. 5. We note that the subscript i in subdomains ΔS_i is a label to a triangle where labeling is left to right and then bottom to top. Each ΔS_i is characterized by its three corners. The basis subdomains are each 12.5×12.5 m in area (i.e., greater than $156\lambda^2$).

The first case, where the phase of the contribution to integration point P is from ΔS_1, has the distance functions d_1 and d_2, where d_1 is monotonically decreasing and d_2 is monotonically increasing. The integration over this element is therefore of type B with kD, the sum of distance functions times wave number is shown in Fig. 6. kD is quasiconstant indicating that the integrand behaves very much like $|G(|\boldsymbol{\rho}-\boldsymbol{\rho}'|)|$. A second similar case is noted for ΔS_{18} in Fig. 7. When Eq. (19) represents a slowly oscillating function a low order Gaussian[30] or Simpson rule can be used to calculate the integration.

The third case, where the phase contribution to integration point P is from ΔS_{98}, has the distance functions d_1 and d_2 whose sum times wave number is shown in Fig. 9. In this case both d_1 and d_2 are monotonically increasing and the integration over this element is of type A. The accumulated distance function D has a very large slope indicating that the integrand is oscillating at a fast rate.

Figure 8 shows the case of the phase of the contribution to P from the self-term ΔS_{50}. The transition from integration of type A to type B at the point P is evident. When Eq. (19) represents a very quickly oscillating function an asymptotic technique[31] can be used in a fixed number of operations to a particular order once a truncation criterion for the asymptotic series is fixed. A specific and simple method for expanding a rapidly oscillating integral in terms of wave number k is repeated integration by parts.

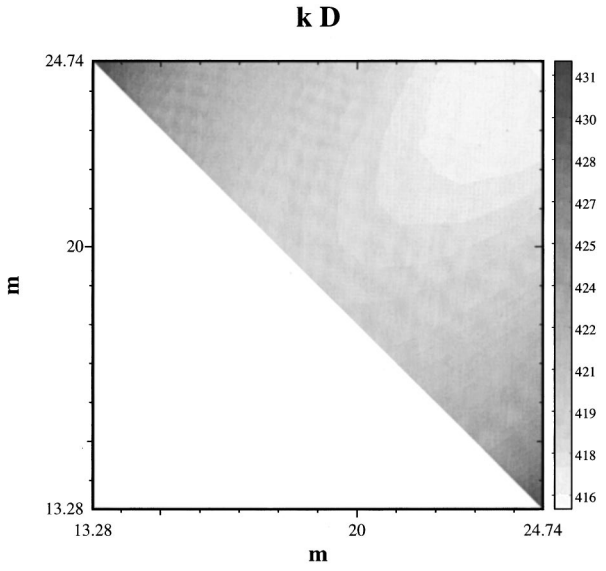

FIG. 7. The function kD in basis ΔS_{18}.

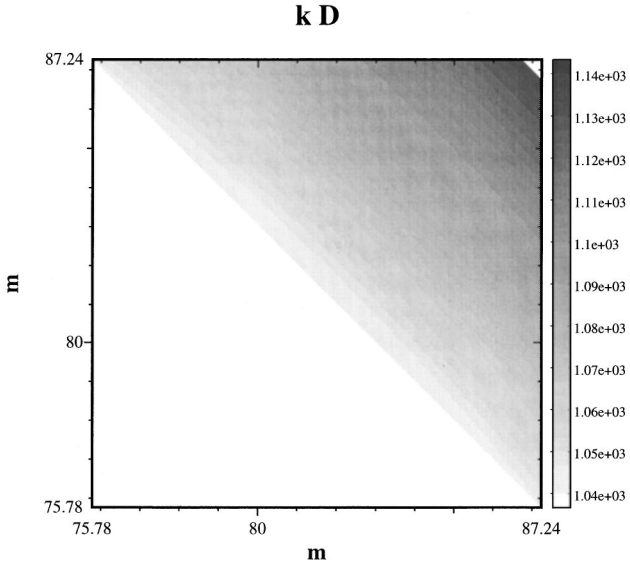

FIG. 9. The function kD in basis ΔS_{98}.

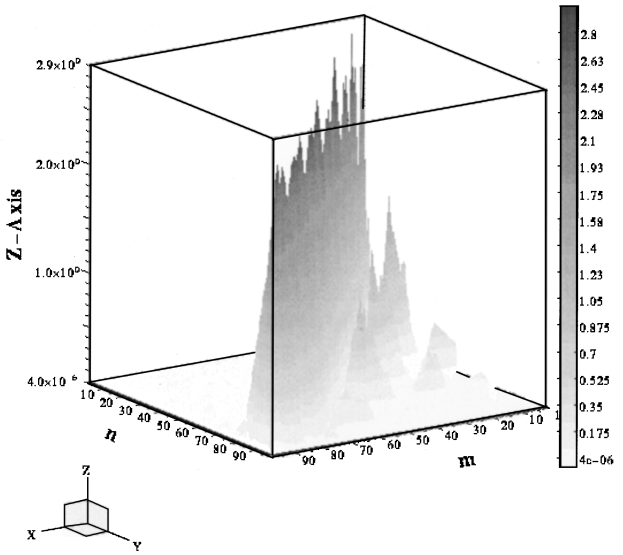

FIG. 10. Absolute value of matrix entries for the double wedge with a source at (100,45,16) with basis size (12.5×12.5).

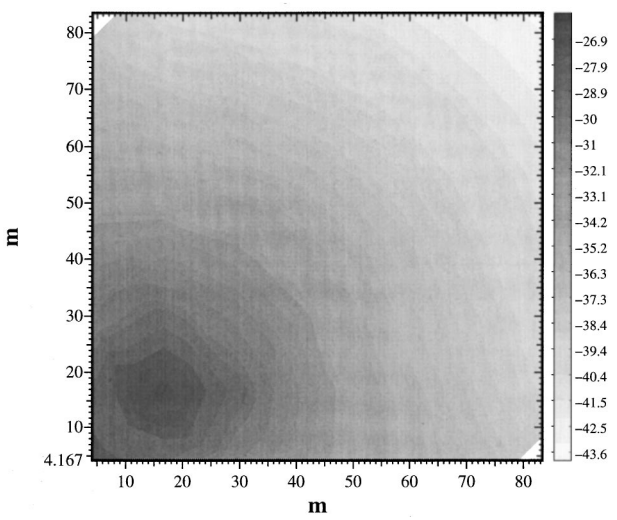

FIG. 11. Total field in dB 2.4 m above a 87.5×87.5 m flat plate.

The generalized Fourier integral can be represented as

$$I(k)=\int_{a_t}^{b_t}\int_{a_s}^{b_s} f(s',t')\exp(ikh(s',t'))ds'dt' \tag{24}$$

$$=\int_{a_t}^{b_t}\left[\int_{a_s}^{b_s}\frac{f(s',t')}{ik(d/ds')\,h(s',t')}\,\frac{d}{ds'}e^{ikh(s',t')}ds'\right]dt'. \tag{25}$$

Thus the integral (19) can be written as Eq. (25) with

$$f=\frac{1}{k\pi d_2} \tag{26}$$

and

$$h=-(d_1+d_2) \tag{27}$$

giving

$$I(k)=-\int_{\Delta t}\left[\int_{\Delta s} f\left[ik\frac{d}{ds'}(d_1+d_2)\right]^{-1}\times e^{-ik(d_1+d_2)}ds'\right]dt'. \tag{28}$$

Integration by parts yields,

$$I(k)=-\int_{\Delta t}\left[\left[\frac{\sqrt{2/k\pi d_2}[ik(d/ds')(d_1+d_2)]^{-1}}{ik(d/ds')(d_1+d_2)}e^{ikh(s')}\right]_{a_s}^{b_s}-\int_{a_s}^{b_s}\frac{d}{ds'}\left[\frac{\sqrt{2/k\pi d_2}[ik(d/ds')(d_1+d_2)]^{-1}}{ik(d/ds')(d_1+d_2)}\right]\times e^{-ik(d_1+d_2)}ds'\right]dt'. \tag{29}$$

Clearly, continued integration creates a series in inverse powers of k for each integration variable. We note the restriction that $\nexists\xi\in[a,b]$ s.t. $h'(\xi)=0$. When $h'(\xi)=0$ the method of stationary phase[32] should be used. This is in no way prohibitive since, if $h'(\xi)<\varepsilon$ (i.e., when d_1 and d_2 are almost collinear in the specific or coplanar in the general), where ε is small, an integration of type B would be in order and a quadrature rule may be used. The functions $h'(s')$ and $f(s')$ give the information needed to pick the order. The error produced in the asymptotic integration is[32] $\mathcal{O}(k^{-(n+1)})$ when n terms of the asymptotic series are retained.

In the case of terrain propagation, where the angle of incidence of the propagating wave is small and the terrain undulating (i.e., with hills and mountains) the integrands relating to forward propagation are very slowly oscillating and may even be thought of as pseudo-linear allowing low order Gaussian rule to be used to evaluate the integrals, while the integrands relating to backward propagation are very quickly oscillating (of the order twice that of the forcing frequency) and are ideal candidates for asymptotic integration. Diagonal terms, as illustrated in Fig. 8, exhibit both forward and backward characteristics about the match point.

The natural basis set (6) has the property that integrands over domains that produce a significant contribution to the kernel using (6) are low frequency (slowly oscillating) and integrands over domains that are less significant are high frequency (quickly oscillating).

An interaction is defined by the contribution from a basis element subdomain to a point

$$\int_{\Delta S_n} G(s,t,s',t')(\beta|\boldsymbol{\rho}-\boldsymbol{\rho}'|)b_n(s',t')dS'. \tag{30}$$

In particular, each entry $\mathcal{Z}_{mn}$ in the moment matrix represents the contribution from the domain of the nth basis function to the mth match point for collocation (or mth basis domain for Galerkin's method). These interactions over basis elements explicitly show, by means of amplitude $|\mathcal{Z}_{mn}|$, the areas of significant physical interaction. Thus in a system where we expect forward scattering to be a dominant factor the lower triangular section of the moment matrix dominates the operator. This triangular matrix fits the criteria for suitable preconditioners. It is easily invertible, its inverse is

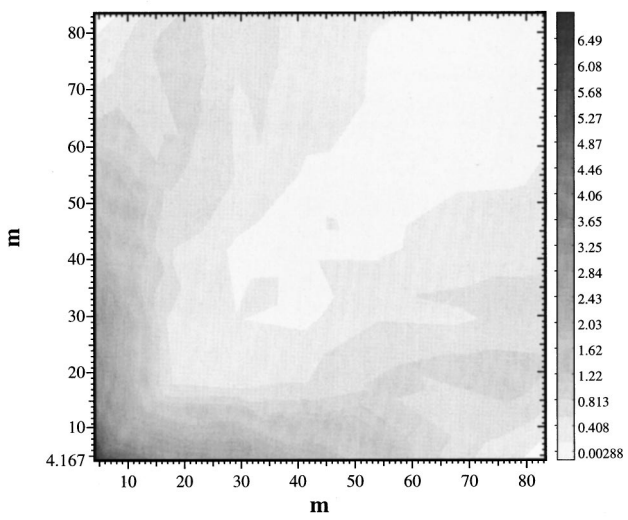

FIG. 12. Absolute difference in dB between the natural basis method and the image method.

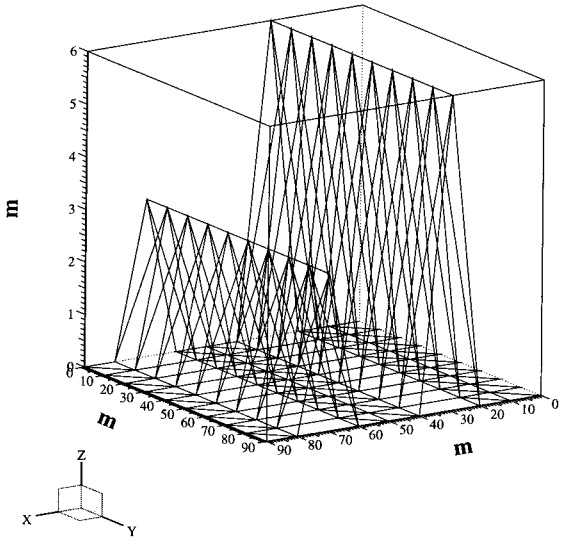

FIG. 14. Geometry of three dimensional double wedge.

close to $\mathscr{Z}^{-1}$ and, importantly, it is easily found, both by means of physical understanding (using a forward propagation assumption for example) and by a simple numerical scheme that removes values that fail a certain tolerance criterion. Figure 10 shows the amplitudes of the matrix kernel, for the double wedge problem illustrated in Fig. 14 with a radiating source of $\lambda = 0.5$ m situated at (100,45,16). It clearly shows that the operator discriminates in the forward scattering direction (by having large values of $|\mathscr{Z}_{mn}|$ when $m \leqslant n$ and small values of $|\mathscr{Z}_{mn}|$ for $m > n$). It also shows us that truncation to lower triangular matrix will produce a preconditioner $\mathscr{P}^{-1}$. For operators that are not solely forward scattering the same heuristic can be used to drop values in a well conditioned operator that fail a tolerance criterion.

IV. ANALYSIS AND RESULTS OVER CANONICAL BOUNDARIES

In this section we will discuss the results found, using the complex basis set (6), over some canonical boundaries. A canonical boundary is one that is considered a standard structured boundary. The canonical boundaries that we investigate are the flat plate and the wedge. Series type solutions for these simple shapes can be found in Bowman *et al.*[33]

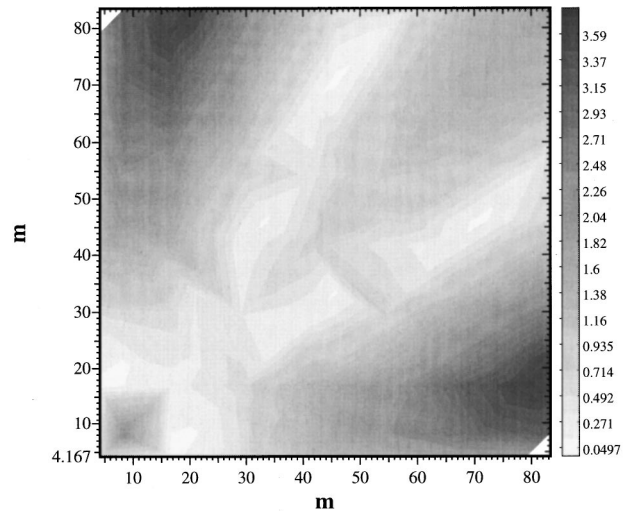

FIG. 13. Absolute difference in dB between the natural basis method and the physical optics method.

A. The flat plate

Figure 11 shows the total field in dB 2.4 m above a 87.5 $\times$87.5 m flat plate irradiated by a line source at $\lambda = 1$ m, positioned at (0,0,10) m calculated by three different methods; the method of images, which is our reference solution (it can be considered quite accurate for the example chosen) and the Helmholtz integral using the natural basis set as described in Eq. (6). The basis dimensions were 12.5$\times$12.5 m. It should be noted that, neglecting edge effects, the natural basis set is an exact representation of the phase of the induced pressure gradient for any orientation of the plate. The size of the moment matrix used is 98$\times$98 whereas the accepted published norm[34] with discretizations of at least four samples per wavelength would create a matrix of order $1.225\times10^5\times1.225\times10^5$. The core storage saving is then greater than 1.5625×10^8%. An algorithm consistent answer is assured by using the conjugate gradient squared (CGS) algorithm and its condition number is 5.8345, using the $\|\cdot\|_2$ norm, indicating fast convergence even without preconditioning.

Figure 12 shows the absolute dB difference between the natural basis method and the method of images. Figure 13 shows the absolute dB difference between the natural basis method and the Kirchhoff/physical optics method. In both cases the differences are small. The edge effect due to the location of the source is clearly visible in the comparison with the image method.

B. The double wedge

One of the most studied canonical boundaries is the wedge. Solutions in the form of infinite series (see Bowman[33] and Balanis[35] where the wedge is considered infinite in one coordinate direction) are well known as are high frequency asymptotic solutions.[36] Series solutions suffer,

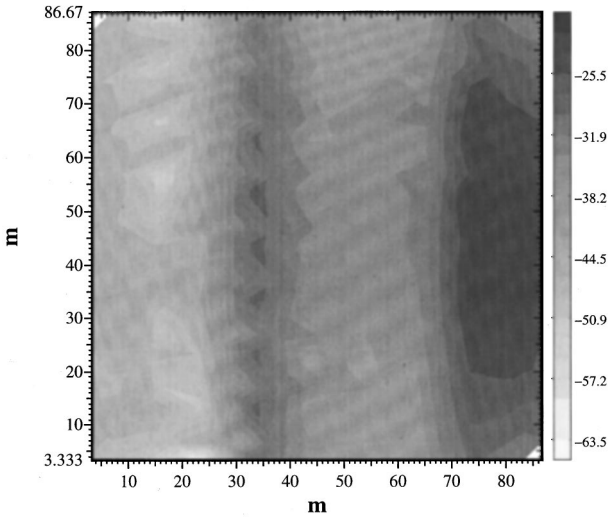

FIG. 15. Total field in dB 2.4 m above the three-dimensional double wedge.

computationally, from poor convergence characteristics and high frequency asymptotic methods such as the geometrical theory of diffraction,[36] which is used for terrain scattering problems,[37] have convergence difficulties when multiple wedges have apexes in shadow regions.[38] In this section we will consider an example of a double wedge configuration as illustrated in Fig. 14. The incident radiation is from a point source positioned at (100,45,16), as indicated in the figure and the radiating frequency is $\lambda = 0.5$ m.

Figure 15 illustrates the total field, in dB, 2.4 m above the surface of the scatterer. Figure 16 shows the absolute difference of the total fields, in *dB*, between the natural basis and the Kirchhoff method. Typically, the Kirchhoff method overestimates the field strength in the shadowed region. The absolute value of the kernel for this problem is illustrated in Fig. 17 and shows how many of the entries are close to zero. Its condition number, using the $\|\cdot\|_2$ norm, is 14.7082.

C. A box on a plane

Another interesting scattering problem is that of a box on a plane as illustrated in Fig. 18. In this example the source

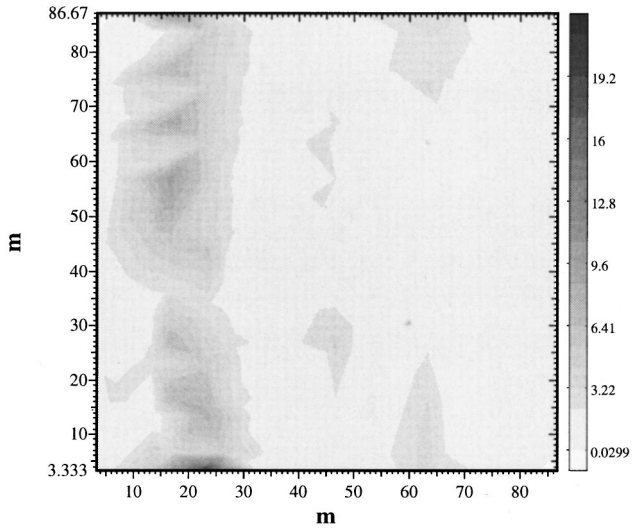

FIG. 16. Absolute difference, in dB, between the natural basis and Kirchhoff method for the three-dimensional double wedge.

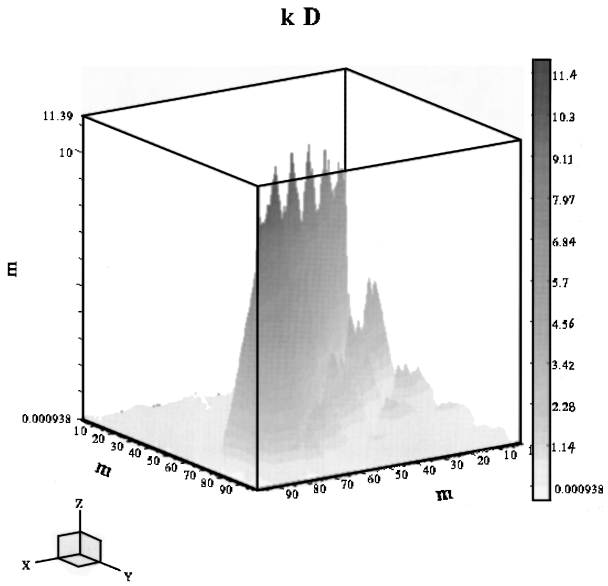

FIG. 17. Absolute values of the kernel $\mathcal{Z}$ for the three dimensional double wedge.

is situated at (0,0,10) and the frequency of the incident radiation is $\lambda = 0.33$ m. Figure 19 shows the magnitude, in dB, of the total field 5.0 m above the scatterer. A comparison with the Kirchhoff method is made in Fig. 20 where the absolute difference, in dB, between the Kirchhoff method and the natural basis method is given. Again, the overestimation, by the Kirchhoff method, of the field strength in the shadowed region is evident.

V. CONCLUSIONS

In this paper we have explored the application of a natural basis moment method to acoustically large objects achieving a large reduction in computational complexity. A reduction of three orders of magnitude in the density of unknowns over the direct approach has been demonstrated for grazing propagation over undulating surfaces, which is of significance for rough surface scattering.

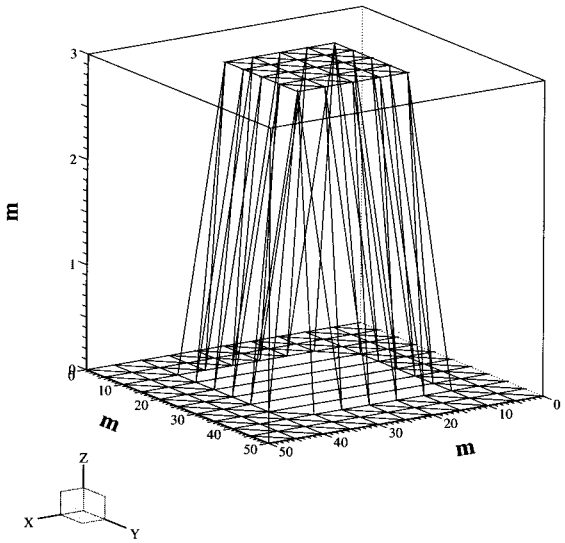

FIG. 18. Triangularization of box on plate.

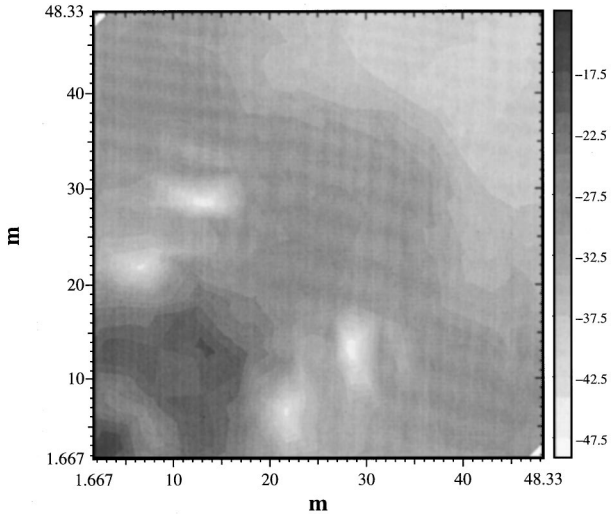

FIG. 19. Total field, in dB, 4.0 m above the surface given in Fig. 18.

We have demonstrated how to substantially increase the computational efficiency of the matrix fill integrations using a low order method for the forward scattering terms and an asymptotic method to solve the generalized Fourier integral for the backscattering terms. We have also suggested a heuristic for the construction of a preconditioner.

We have carefully compared the natural basis method to a number of other completely different methods including: (i) Born or Neumann series, (ii) The Green's function perturbation method, (iii) The Nussenzveig–Fock correction to the Kirchhoff approximation, and (iv) The parabolic equation method. In making these comparisons we have provided guidelines on the applicability of the method and provided a physical justification for the choice of basis function.

The method described can be applied to any integral equation where we have to calculate the unknown pressure gradient. It is directly applicable to the Dirichlet and Von Neumann boundary condition cases. It is probably applicable to scattering from lossy penetrable media although to date, we have only verified this in the lossy electrical dielectric case in two dimensions.

Acoustical properties of end-initiated explosive line charges

William J. Marshall
BBN Technologies, Union Station, New London, Connecticut 06320

(Received 15 July 1997; accepted for publication 6 February 1998)

Acoustic radiation produced by end-fired explosive line charges is examined experimentally and theoretically. Three explosive compositions are studied: PETN detonating cord, RDX detonating cord, and thin ribbons of HLX. Specific output levels are formulated for each of the three explosive materials over the four 1-oct bands spanning 50–800 Hz. Bubble period relationships are derived for each material and compared to previous studies. In terms of directivity effects, long line charges are found to behave like beam-steered continuous arrays over moderately wide bands. A math model is developed which predicts acoustic levels and spectrum shapes for the shock wave component over a wide range of view angles and linear charge densities. This model is driven by two parameters which are extracted from the experimental data for the three compositions studied. The result is a practical means of designing explosive line arrays to desired source levels, bandwidths, and beam patterns. © *1998 Acoustical Society of America.* [S0001-4966(98)05305-3]

INTRODUCTION

Explosives have a long history of use in underwater acoustics, their main advantages over modulatable sources being short pulse lengths/wide bandwidths (for good time resolution) and high source levels (for long-range propagation and deep bottom penetration), all at modest expense. Fairly accurate performance predictions are possible for a number of explosive compositions,[1–5] but only when arranged in compact, omnidirectional configurations. Spatially extended configurations, particularly line charges, are also of interest because of their directivity and ease of fabrication. The main benefit of directivity is that sound is focused in desired directions and away from undesired directions. An important secondary benefit is that impressive far-field source levels may be achieved with comparatively small near-field pressures (that is, less environmental impact). For these reasons it is desirable to have data and techniques available for designing this type of explosive source.

The library of papers on acoustical properties of line charges is fairly sparse. Slifko[6] devised procedures for calculating spectra and beam patterns for the shock wave component. Since his aim was to find scaling laws for end-initiated lines, the actual composition of his charges was not identified and his data are of limited usefulness in designing new sources. Wentzell *et al.*[7] studied the bubble periods from point and line charges made of Composition A3 (waxed RDX). Sari and Nelson[8] reported on measurements of long vertical lines of PETN detonating cord, finding that the interplay of shock wave and bubble pulse characteristics caused tilting and splitting of the beam patterns. Their experiments explored a variety of cord charge densities and depths, and observed a bubble period coefficient significantly different from Wentzell's.

The present work describes a series of at-sea measurements of vertical top-fired line charges and develops a model describing shock wave radiation for this class of sources. The composition, charge density, length, and depth of the test objects were varied in order to investigate variations in parameters across these four dimensions. Three explosive compositions were used: HLX ribbon (an RDX-based flexible explosive equivalent to SX-2), PETN detonating cord, and RDX detonating cord. Acoustic measurements were made using a semivertical array of 13 hydrophones at a nominal test distance of 400 m.

Experimental results in the following categories are presented: maximum energy source level (ESL) and beamwidth, by band; energy spectral density (ESD) versus vertical view angle; bubble period versus depth; and impulse and shock wave decay time on the maximum response axis (MRA).

Definitions of ESL and ESD can be found in Ref. 9.

Empirical parameters required for the math model are extracted from the database. The model is generally consistent with Slifko's findings, but offers three advantages over his method: (1) closer agreement with measured data, particularly for modern flexible explosives, (2) a gradual rather than abrupt transition between view angle regimes, and (3) a time domain description. Since all measurements were made at a single range, direct verification of range-dependent line charge parameters is not possible with these data.

I. MEASUREMENTS

A. Test description

1. Geometry, technique, and environment

The test configuration consisted of a receiver platform suspending a bottom weighted 13-element vertical array of hydrophones, tethered downwind from a moored source deployment platform. Water depth at the test site was approximately 520 m. In addition to deploying the explosives, the source ship suspended three shallow hydrophones to monitor waveforms above the source. Since the test took place in a high current area (Straits of Florida), considerable tilting and bowing of both source and hydrophone arrays was inevitable. To account for this effect each explosive line array was augmented with small charges placed near its upper and lower end. These charges (called marker pops) were initiated

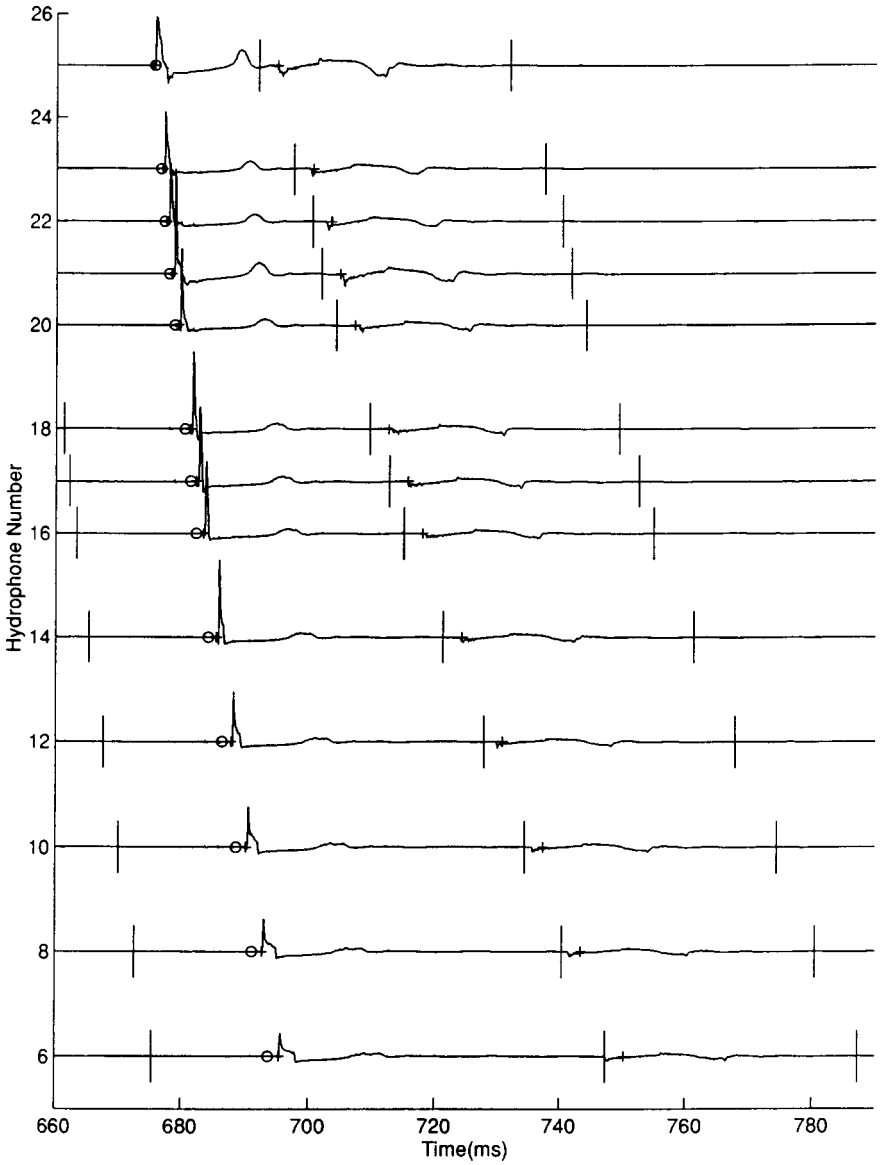

FIG. 1. Display used to determine source tilt and hydrophone locations by matching predicted and actual marker pop signals. Vertical spacing of traces is proportional to hydrophone spacing (Event C3-10).

a fraction of a second before the main charge, thus providing timing marks to determine range and relative angle from each end of the source to each hydrophone. This technique compensated well for tilts of both arrays and for hydrophone array bowing, but not for source bowing which remains an uncertainty in these measurements.

The hydrophone array included depth gauges at top and bottom. During data reduction the test geometry for each event was reconstructed by plotting a cascade of hydrophone signals (Fig. 1) and superimposing on each trace predicted marker pop arrivals, via direct (open circle) and surface reflected (plus sign) paths, for pops at known depths (calculated from their bubble periods) but displaced laterally in accordance with a variable source tilt angle. Varying source tilt in the simulation caused changes in perceived hydrophone locations and simulated marker pop arrival times. Comparing top and bottom hydrophone depths against the two depth gauge readings while monitoring simulated marker pop arrival times led to the optimum tilt value. The three vertical bars on each trace in Fig. 1 are analysis region boundaries for direct and surface-reflected portions of the signal. Figure 2 shows typical geometries observed for each of the three source lengths.

Data were recorded on 16-channel digital audio tape recorders with a useable bandwidth of 5 kHz (12-kHz sampling rate per channel). To synchronize recordings, the composite detonating signal for main charge and marker pops was telemetered from source to receiver ship and recorded at both locations.

The sound velocity profile (SVP) at the receiver ship featured a sharp thermocline but remained steady over the 2 days of the test. A typical SVP from this period, with lengths and depths of sources added, is given in Fig. 3. A constant sound speed of 1530 m/s was used for all data reduction and modeling purposes.

2. Objects tested

Table I gives a list of sources tested and shows the parameter variation plan. C1–C4 were compared to study the

effect of varying linear charge density, C5–C7 plus C3 to study depth variation, C8 and C9 plus C3 to study length variation, and so forth. C3, the standard configuration, was a 20-m (65-ft) length of HLX ribbon, top initiated at a mid-

C16	RDX	160	20	101.3	3

depth of 92.8 m. The HLX material is extruded initially into a flat noodle having a thickness of 3.2 mm (0.125 in.) and a width of 18 mm (0.72 in.) in which shape it has an effective linear charge density (excluding nonexplosive binders) of 400 grain/ft (0.085 kg/m). Smaller sizes are then formed by slitting this ribbon in halves, quarters, and eighths to achieve charge densities of 200, 100, and 50 grain/ft. The smallest of these was near the critical lateral dimension for this material and did not propagate reliably, so C1 results were not analyzed.

Detonating cord samples for the smaller charge densities were single strands of cord; multiple strands were placed side by side and taped at 1 ft intervals to form the larger sizes, 2×100, 4×100, and 2×80 grain/ft. All charges were initiated by duPont SSS blasting caps augmented with 6 g slip-on boosters.

B. Test results

Consider the typical set of waveforms shown in Fig. 1. The first disturbance in each trace is the initial shock wave. At view angles away from the shock axis this has the form of a triangular or rectangular impulse with a peaked leading edge. Nearer the MRA it narrows and grows in height until, exactly on the MRA, it becomes a brief sharp spike. The shock wave phase is followed by a period of slightly negative pressure and then a broad positive hump associated with collapse of the gas bubble formed by the explosion. (Occasionally a second bubble rebound can be seen in traces near the MRA.) The shape and relative position of the bubble hump is fairly consistent from phone to phone, indicating that this phenomenon has little directionality for these source sizes and depths. The last features are long-duration negative polarity impulses which follow the previous groups at ever longer delays on deeper hydrophones. These are surface-reflected echoes of the shock wave and usually display the low plateau seen far from the shock axis, but inverted due to having been reflected from a pressure release surface. Sometimes this feature overlaps the bubble pulse on shallower hydrophones.

Analysis of data for the 60 events in Table I is divided into three categories:

(1) angular variation of spectra and levels of total acoustic energy;
(2) dependence of bubble rebound period on depth; and
(3) derivation of MRA signal parameters used in the math model.

When designing a line source for given acoustical requirements the information in items (1) and (2) may be used for initial top level choices, then the math model described in Sec. II can be used to obtain more detailed spectra and band level energy predictions for the shock wave portion of the signal.

1. Energy spectra and beam patterns

Data reduction methods will be described using the C3 series as an example. For each hydrophone the shock wave and first bubble rebound portions of the waveforms are spectrum analyzed and the spectra summed over four 1-oct bands and one 4-oct band to obtain bandlimited ESLs. Plotting these values against hydrophone view angle (defined from hydrophone to source array center, with zero at broadside and positive angles toward the surface) produces the energy beam patterns in Fig. 4(a)–(e). Overlaying beam patterns from several events provides an improved picture of source behavior since the different measurement geometries sample different angles and angular regions. Note that one shot in Fig. 4 was at an extreme tilt angle so that only the sector from $-34°$ to $-60°$ was captured, thus providing useful information about the lower edge of the pattern. Beams become narrower in successively higher 1-oct bands, as expected, but higher bands also have higher peak levels because the on-axis spectrum rolls off at less than 3 dB per octave so there is a net energy gain in the higher bands. The 4-oct band has even higher levels [note the scale change in Fig. 4(e)].

Patterns in the higher bands consistently peak near $-10°$, while the lowest band, though it has little directivity and therefore an indistinct peak, seems to be spread fairly evenly between $+5°$ and $-10°$. Like the lowest band, the 100–200 Hz band shows considerable shot-to-shot variability, however, the sample having the highest output has a well-shaped peak aimed between $0°$ and $-5°$. Including the bubble rebound in the analyzed waveform generally adds 2 to 3 dB to wideband ESLs below about 500 Hz, and less at higher frequencies. Including the bubble also makes the source less directive, but only in the band containing the bubble frequency fundamental. The last panel in Fig. 4 demonstrates this by comparing spectra of signals measured on the hydrophone nearest the MRA, with and without the bubble portion of the waveform. Energy levels in narrow bands surrounding peaks of the bubble spectrum can exceed those of the shock wave-only case by as much as 6 dB.

Beam pattern results may be condensed and related to source properties by characterizing the maximum of each pattern by three metrics: angle of maximum response, maximum ESL value, and beamwidth. An MRA curve fitting procedure, described in the Appendix, is used to derive these three parameters for every test group in Table I, then these values are used to explore each family of sources.

The MRA direction for the early, shock wave portion of the emission is normal to the shock front. Calling v the detonation velocity and c the small-amplitude speed of sound, the Mach number, $M=v/c$, determines ϕ_s, the MRA angle measured from broadside, through

$$\sin\ \phi_s = 1/M. \tag{1}$$

ϕ_s ranges between $11.0°$ and $11.7°$ for these materials and test conditions.

Directivity effects are an antenna property (i.e., related to the spatial distribution of radiating elements) and should be the same for each of the three source materials. Let L be line charge length and λ the wavelength in water. For continuous line arrays the theoretical narrow-band 3-dB beamwidth of the broadside beam is $0.886\lambda/L$, and this relationship continues to hold for moderately wide bands if the spectrum is flat and λ is interpreted as the wavelength at the arithmetic band center. For beams steered away from broadside the theoretical relationship[10] changes to

$$B_{-3} = \sin^{-1}(0.443\lambda/L + \sin\ \phi_s) + \sin^{-1}(0.443\lambda/L - \sin\ \phi_s). \tag{2}$$

Fitted beamwidths are plotted against λ/L in Fig. 5. These charts show that measured beamwidths, in both 1- and 4-oct bands, follow the curve given by (2). Greater shot-to-shot variations and departures from theory are seen for the broader beams (shorter L's, lower frequencies) because these have little directivity which makes the beamwidth more difficult to measure.

Acoustic output in a given band is determined by three factors: composition of the energetic material, quantity of that material, and array directivity. Directivity is accounted for by recognizing that the effect of concentrating an omnidirectional energy level E_0 into an axisymmetric fan beam B radians wide is to raise the apparent level seen on the MRA by the factor $1/\sin(B/2)$. For small B this factor can be approximated by $2/B$, with the approximation error less than 0.1 dB for $B<40°$. If the spectrum is fairly flat over a band, then the acoustical energy in that band will be directly proportional to the net explosive weight, W,

$$E_{\max} = E_0 W(2/B) \tag{3}$$

or, expressed in decibels,

$$\mathrm{ESL_{MRA}} = \mathrm{ESL_0} + 10\log\ W + 3 - 10\log\ B, \tag{4}$$

where $\mathrm{ESL_0}$, interpreted as the omnidirectional source level per kg of active material, varies with explosive composition and band. By normalizing output by explosive weight and beamwidth, (4) condenses the measured source level data to a set of $\mathrm{ESL_0}$ values which are presented in Table II.

Constants in Table II were obtained by solving (4) for $\mathrm{ESL_0}$ and averaging over the set of measurements for each material. Because of the large scatter in measured beamwidths seen in Fig. 5, lower $\mathrm{ESL_0}$ variances were obtained using theoretical beamwidths from (2) rather than measured

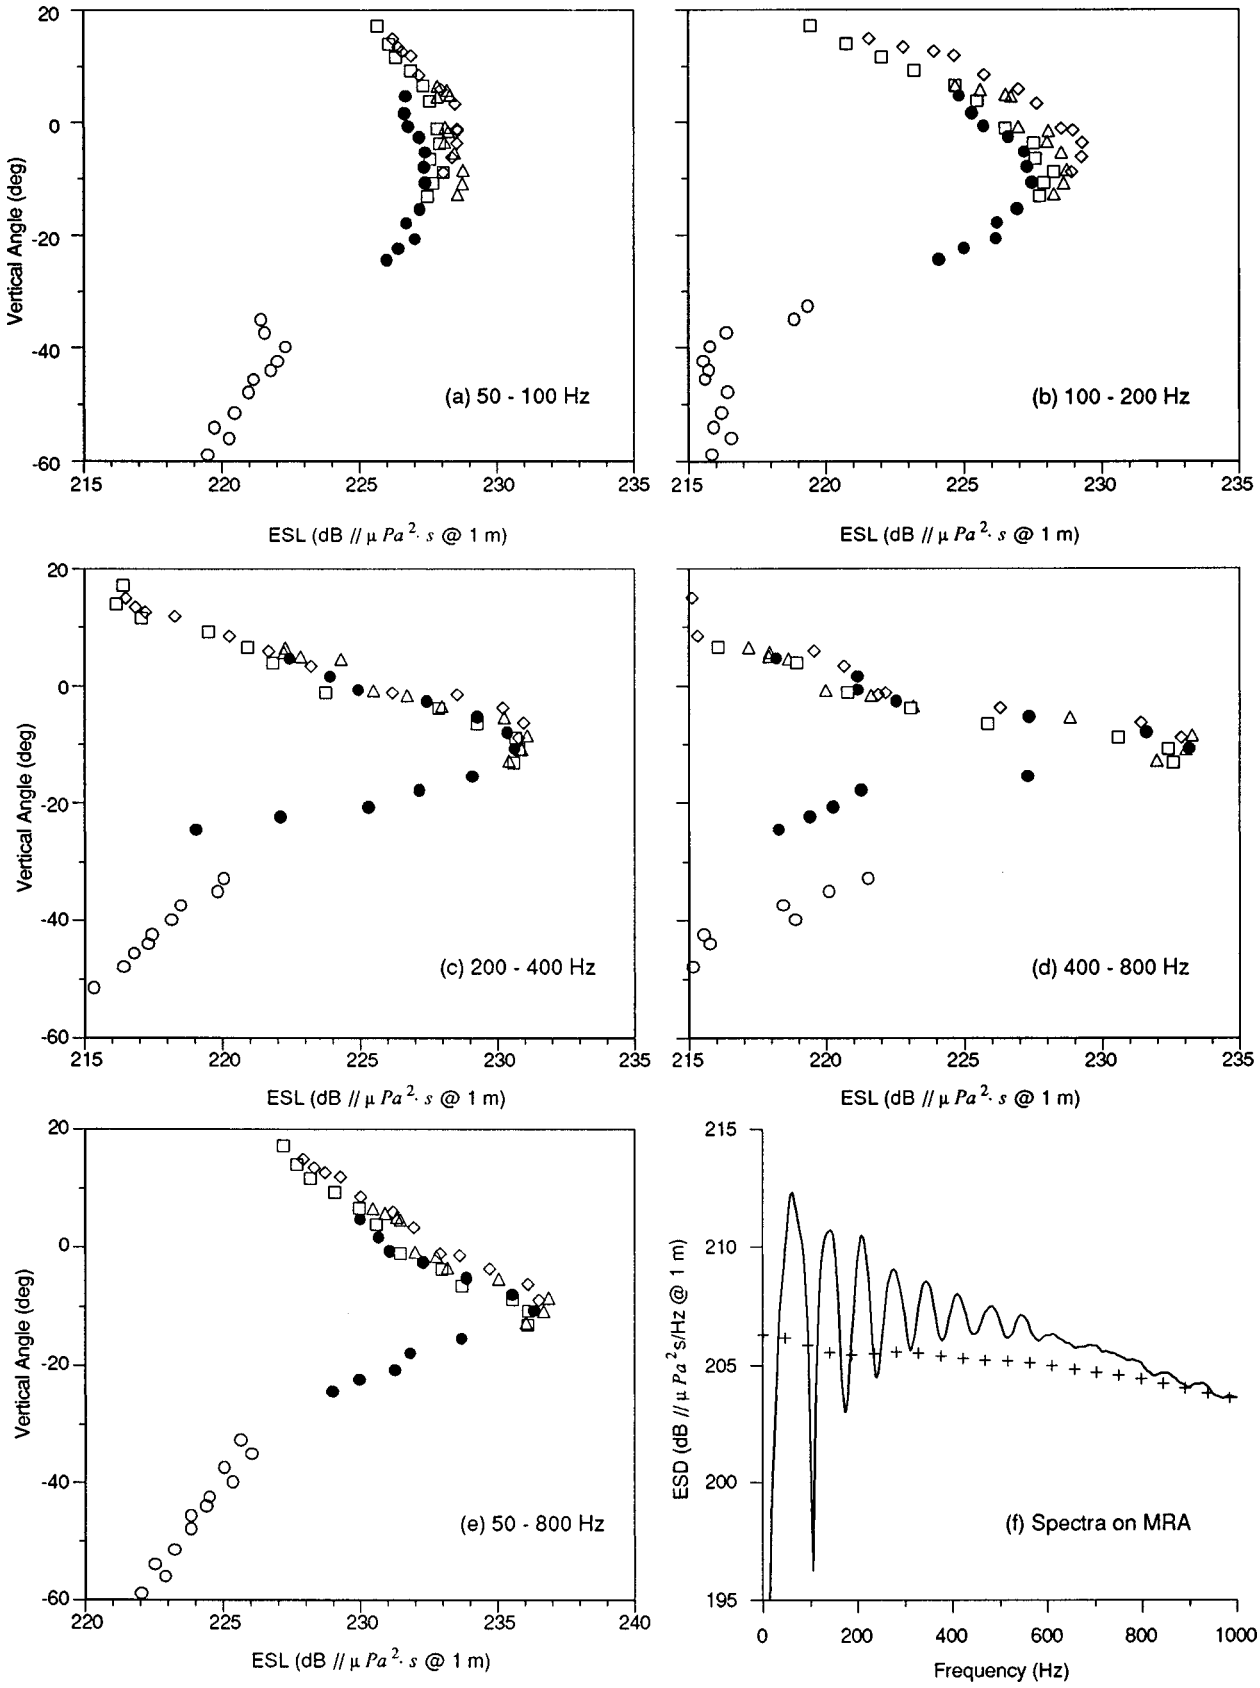

FIG. 4. (a)–(e) Superposition of ESL beam patterns for five C3 events. (f) Spectra from hydrophone nearest the MRA for C3-2 (solid line: complete direct path waveform, +: shock wave portion only). C3-2 is plotted with □ symbols in (a)–(e).

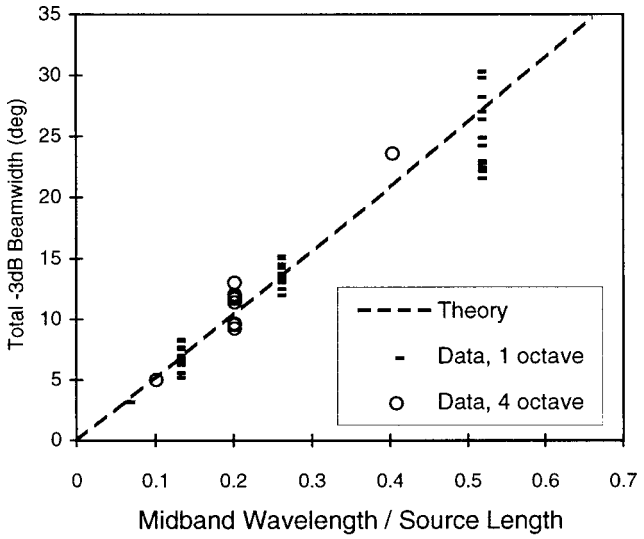

FIG. 5. Measured and theoretical beamwidths. Dashed line is the theoretical narrow-band curve for a continuous line steered 11° off broadside [Eq. (2)].

ones. By connecting source level to predicted directivity, this choice enhances the use of Table II and Eqs. (2) and (4) as a design tool.

Two trends are seen in Table II. First, frequency dependence over the four 1-oct bands is weak except for HLX which shows significantly higher output in the lowest band. This is due to the bubble effect which adds energy to the band containing the bubble frequency. For HLX samples this frequency remains in the lowest band consistently for all test conditions, thus raising the average level in that band. For the two detonating cord samples, depending on cord density and depth, the bubble frequency can fall into either of the lowest two bands, which lowers its impact on either one. The second trend noted in Table II is that, comparing the three materials, PETN cord has the largest acoustic output per active weight, about 2 dB greater than HLX ribbon.

2. Bubble period

For the depths and charge sizes used in these tests, oscillation of the gas bubble generally produces nearly omnidirectional radiation (the wavelength associated with the bubble period is usually longer than the charge length), and the bubble period can be measured most conveniently on a near-MRA waveform where a clear shock wave peak is present. Observed bubble rebounds vary from consistent, sharp, well-defined peaks to weak, broad, and sometimes double humped features. No bubble data was taken for the C5 series (the shallowest) because the surface reflection of the shock wave obscured the bubble rebound.

TABLE II. Average values of ESL_0, by band, in dB//μPa^2 s/kg at 1 m. The uncertainty span represents the standard deviation for HLX and PETN (8 and 4 samples, respectively) and the half range to extrema for RDX (2 samples).

Band	HLX	PETN	RDX
50–100 Hz	225.1±1.5	225.9±1.3	225.2±1.6
100–200 Hz	222.8±0.8	225.0±0.7	225.1±0.7
200–400 Hz	222.3±0.5	224.0±0.2	223.1±0.1
400–800 Hz	221.5±0.8	223.3±0.2	222.6±0.0
50–800 Hz	229.2±0.6	231.2±0.4	230.5±0.1

Wentzell[7] has shown that the first bubble period for line charges is directly proportional to the square root of the linear charge density and inversely proportional to the hydrostatic pressure,

$$T_B = K_1 (W/L)^{1/2}/(H+10), \tag{5}$$

where H is the center depth of the charge, in m, and K_1 is a material-specific constant to be determined experimentally. With the limited range of depths available in this data set, the best method for finding K_1 is to rearrange (5) into

$$H+10 = K_1 \frac{(W/L)^{1/2}}{T_B} \tag{6}$$

and form a scatter plot of hydrostatic depth against the reciprocal of reduced bubble period. K_1 is the slope of the best straight line from the origin through the resulting cluster of points.

Seven sets of HLX points and a straight line fit through these data are plotted in Fig. 6(a). The C9 data points have the greatest deviation, presumably because it is the longest array. For the RDX and PETN data in Fig. 6(b), two curve fits are shown. The RDX slope matches that for HLX, while most of the PETN data shows a higher K_1 (longer period, lower bubble frequency) than HLX and RDX. The smallest charge density PETN cord, C10, has lower bubble periods than the remaining three cases. These results are tabulated and compared to prior measurements in Table III. The present measurements agree with Sari and Nelson's[8] value for PETN cord, but show an RDX value some 40% larger than that obtained by Wentzell for Composition A-3 pressed into long thin-walled aluminum cylinders. (Composition A-3 is 91% RDX by weight.) Some of this difference can be attributed to the inertial effect of the aluminum casing, but most of it remains unexplained.

3. Shock wave decay time constant and impulse

The model to be developed in Sec. II requires two empirical parameters related to the MRA waveform, shock wave decay rate and either peak pressure or impulse. Ideally, the far-field pressure waveform of a line charge resembles that of a point charge when viewed on the shock axis: a nearly instantaneous rise to a sharp peak followed by a steady, and initially exponential, decay. In the present experiment, bowing of the source line prevents the MRA waveform from achieving ideal form, and this complicates finding the peak parameters.

Figure 7 shows a one-sided impulse with exponential decay, sampled at evenly spaced time steps. Call M_n $(n=-1,0,1,...)$ the time series for this waveform. Assume the ideal form for the impulse and let it reach its peak value at time t_p. Then the nth measurement during the decaying portion of the signal is

$$M_n = p_0 \exp(-(t_n - t_p)/\tau). \tag{7}$$

Taking the ratio of any two successive readings eliminates both p_0 and the start time t_p yielding an estimate of τ alone

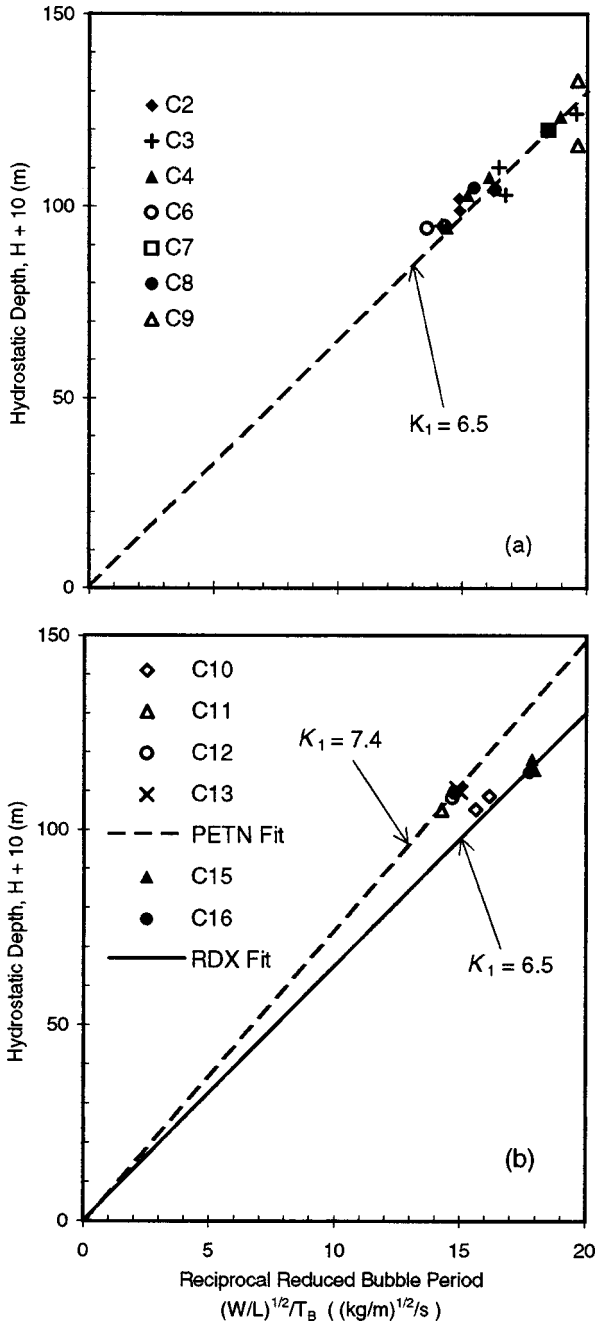

FIG. 6. Bubble period data with lines from Eq. (6) drawn through clusters. (a) HLX ribbon, (b) PETN and RDX cord.

$$\tau_n = \frac{\Delta t}{\ln(M_n/M_{n+1})}, \tag{8}$$

where $\Delta t = t_{n+1} - t_n$ is the sampling interval. Usually the estimate formed from the first two large values in the sequence is used.

It follows from the principle of similarity that τ for spherical charges is proportional to $W^{1/3}(W^{1/3}/R)^{\alpha}$, where R is the measurement distance and α an experimentally determined parameter given by Arons[2] as -0.22 (for TNT and Pentolite) and, more recently, by Chapman[11] as -0.14 (for Cyclotol). In the near field of a line charge the type of wave changes as it propagates, and there is no similitude equation for time constant in this case;[12] however, transition to spherical propagation occurs at about $R \approx L/2$ so at our test distances ($10L$ for the longest specimen) a simple scaling law can be found for τ as observed on the MRA. The scaling variable, however, is not explosive weight but linear charge density, W/L.

TABLE III. First bubble period constants (MKS units: $m^{3/2}\,kg^{-1/2}\,s$, English units: $ft^{3/2}\,lb^{-1/2}\,s$).

Material	Data source	K_1 (MKS)	K_1 (English)
Comp A-3	Wentzell *et al.*	4.5	18
RDX	This paper	6.5	26
HLX	This paper	6.5	26
PETN	Sari/Nelson	7.4	30
PETN	This paper	7.4	30

For the remainder of the paper let τ without a subscript denote the decay time constant of a line charge, as observed on the MRA. To find the form of $\tau(W/L)$, consider the line charge to be a series of independent bits of explosive strung end to end. A sensible choice for the length of these bits is something proportional to the distance the detonation moves along the line in time τ, say $Av\tau$. Taking Chapman's τ formula as the most accurate recent measurement for an underwater point charge we have, using MKS units,

$$\begin{aligned}\tau &= 8.12(10)^{-5} W^{(1-0.14)/3} R^{0.14} \\ &= 8.12(10)^{-5} ((W/L)Av\tau)^{0.86/3} R^{0.14},\end{aligned} \tag{9}$$

which reduces to

$$\tau = 1.84(10)^{-6} (Av)^{0.402} (W/L)^{0.402} R^{0.196}, \tag{10}$$

suggesting that an exponent of about 0.4 on charge density might describe line charge τ data.

Figure 8 displays near-MRA τ measurements at constant R plotted against W/L. The large τ variation at each W/L arises from two causes: not being exactly on the shock axis, and curvature of the source in the plane containing the hydrophone. Both of these factors cause observed values to exceed true values, so the smallest of a set is that closest to the desired value. The power law that best fits the minimal PETN τ's in Fig. 8(a) is $\tau = 15.2(W/L)^{0.4}$ with τ in microseconds and W/L in the traditional linear charge density units, grains/ft. The good match of the slope of this line to that of the locus of data minima justifies treating the line

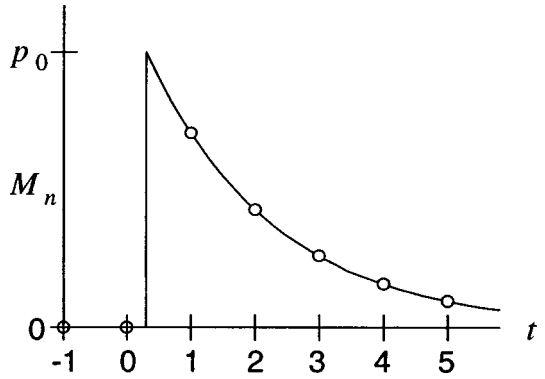

FIG. 7. Shock wave front pressure samples taken at regular time intervals.

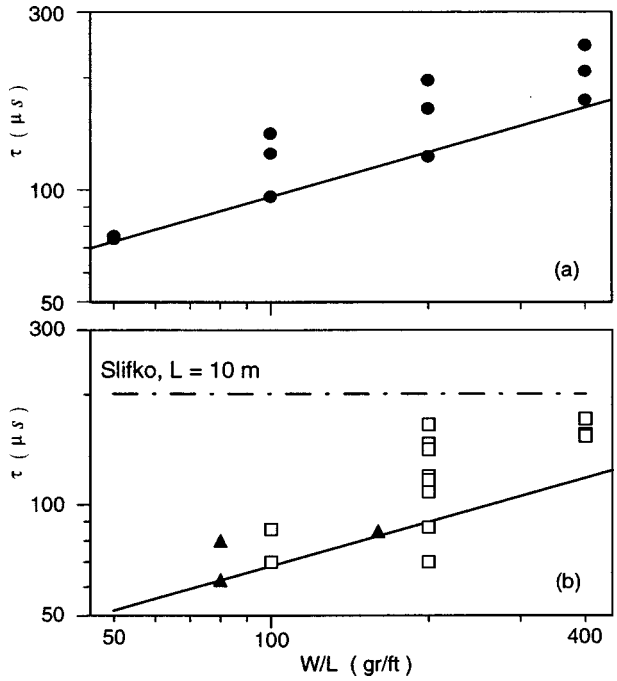

FIG. 8. Shock wave decay time constant near MRA, measured data and curves of the form $K(W/L)^{0.4}$, with W/L in grains/ft. (a) circles: PETN cord, line: $K=15.2$. (b) squares: HLX ribbon, triangles: RDX cord, solid line: $K=10.8$.

charge as a series of independent bits. Finding the appropriate value of A will be addressed after the impulse measurements are evaluated.

The τ data for the other two materials are given in Fig. 8(b). The tall spread of data points for 200 gr/ft HLX samples can be divided into three groups: the lowest cluster for the shortest arrays (C8), the middle group for the standard 10-m lengths (C7), and the highest group for the longest lengths (C9). Although a definite trend toward longer τ for heavier ribbons can be seen, the locus of minima does not form a straight line, so an empirical line is not given for the HLX data. The very limited amount of RDX data, however, does seem consistent with a 0.4 power law, and the line which passes through the lowest RDX point is given by $\tau = 10.8(W/L)^{0.4}$.

Slifko's experiments[6] on short horizontal lengths of cord (composition unspecified) measured decay rate as a function of deviation from the shock axis. His on-axis result, at $R = 8L$ and for two very different cord densities, 120 and 1400 gr/ft, was that τ did not obey a power law like $(W/L)^{\alpha}$ but, rather, was independent of W and directly proportional to L: $\tau = 0.031(L/c)$. That result, plotted in Fig. 8(b) for a 10-m line length, is completely incompatible with our data. One might think having τ proportional to L is a reasonable result: the time for the detonation to travel the length of cord is L/v, and that certainly influences waveform duration when away from the shock axis, and even on axis when in the near field. However, the shock front from the entire line arrives at one instant when viewed in the far field on the MRA, so L cannot have a strong influence on τ in this case.

Impulse is defined as $\int p(t)dt$ with the integration extending over the positive portion of the pressure waveform. The impulse of an ideal shock wave (7) is simply $p_0\tau$, therefore p_0 for an exponentially decaying transient can be inferred from a measurement of its impulse. Impulse is computed from time series data by

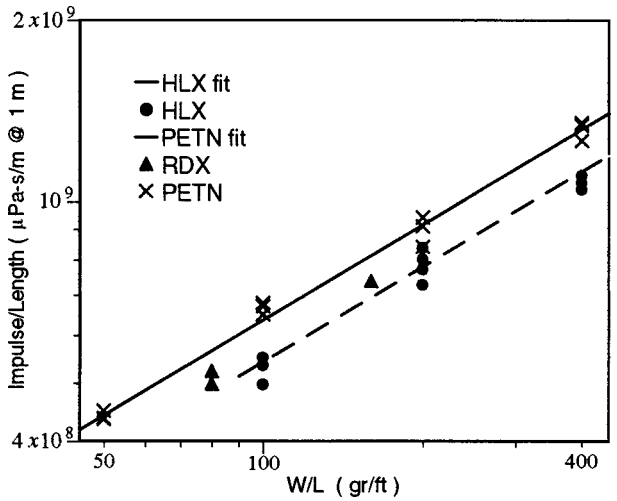

FIG. 9. Shock wave impulse per unit length, near MRA. Solid line: $5.65 \times 10^7\ (W/L)^{0.526}$, dashed line: $4.81 \times 10^7\ (W/L)^{0.526}$ (W/L in grains/ft).

$$I = \Delta t \sum M_n \tag{11}$$

with the summation taken over contiguous positive M_n surrounding the peak.

To determine the dependence of line charge impulse on source parameters, start with Chapman's formula for the peak pressure of a single isolated charge of weight W/N

$$p_0 = C_0(W/N)^{0.377}/R^{1.13} \tag{12}$$

and, as before, regard the line as $N = L/Av\tau$ independent bits whose shock waves add coherently to a peak pressure of Np_0 on the MRA. The impulse on the MRA is then

$$I = \tau N p_0 = \frac{LC_0}{Av}\left(\frac{W}{L}Av\tau\right)^{0.377} R^{-1.13}$$

$$= C_0 L (Av)^{0.377-1}\left(\frac{W}{L}\tau\right)^{0.377} R^{-1.13}. \tag{13}$$

Replacing τ in (13) by (10) results in

$$I = C_1 L (C_2 (W/L)^{1.402} R^{0.196})^{0.377} R^{-1.13}$$

$$= C_3 L (W/L)^{0.529} R^{-1.056}, \tag{14}$$

where C_0, C_1, C_2, and C_3 are various proportionality constants.

Experimental values of impulse per unit length are plotted against W/L in Fig. 9. A least-squares fit of logarithms of the PETN data (solid line) gives a power law exponent of 0.526, in excellent agreement with (14). The dashed line in Fig. 9 is that curve with the same exponent which best fits the HLX data. The coefficient for the HLX line is 0.85 times that for the PETN line, or -0.7 dB. It is clear from the graph that the sparse RDX data would fall near a third line between and parallel to the first two. Experimental determination of the R dependence of I is not possible with constant distance measurements, but it is interesting to note that the exponent

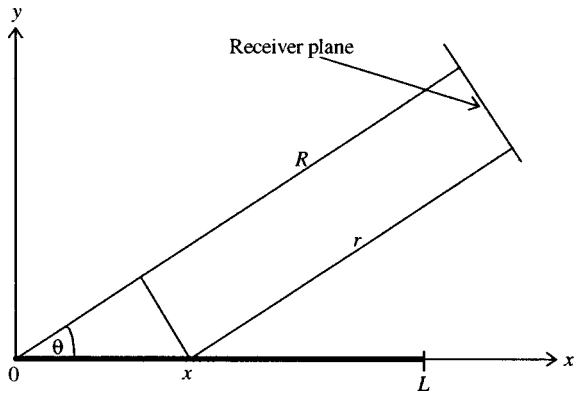

FIG. 10. Notation for model of radiation from an end-fired line charge.

of R reported by Cole[13] for the impulse of Pentolite point charges is -1.05, in close agreement with (14).

Preserving the A dependence of C_3 in (14) and using $v=8000$ m/s one finds that (14) matches the experimental I/L curve for PETN when A is close to 1, as hypothesized. Inserting this A in (10) predicts τ's about half as large as those from the minimal τ curve in Fig. 8(a). We conclude, therefore, that τ's predicted by (10) are a lower bound for those realized on long, curved cords.

II. MODEL

A. Derivation

Consider the geometry of Fig. 10 where a line of length L is detonated at the origin at time $t'=0$, and the detonation travels along the positive x axis with velocity v, reaching position $x=vt'$ at t'. Assume the shock wave pressure observed at a distant field point (R,θ) can be found by adding the pressures developed by successive sections of a cylinder of radius a and infinitesimal length dx. Then

$$p(t')=\frac{\rho}{4\pi}\int_{x_1}^{x_2}\frac{2\pi a\ddot{a}(x,t'-r/c)}{r}\,dx, \tag{15}$$

where ρ is the undisturbed water density, $\ddot{a}$ the radial acceleration of the cylinder's surface at the moment of detonation, and the limits of integration are functions of t' to be determined presently. Assume that each cord element emits a pressure pulse like that of a small point charge,

$$\ddot{a}(x,t')=\begin{cases}\alpha\,\exp(-(t'-x/v)/\tau), & 0<x<vt'\\ 0, & x\leqslant 0,\ x\geqslant vt'\end{cases}, \tag{16}$$

where α and τ are experimentally determined properties of the charge. Using (16) and $r=R-x\cos\theta$ from Fig. 10, (15) becomes

$$p(t')=\frac{\rho a\alpha}{2}\int_{x_1}^{x_2}\frac{\exp(-[t'-(R/c)+(x/c)\cos\theta-x/v]/\tau)}{R-x\cos\theta}\times dx. \tag{17}$$

Now make the usual far-field simplification that when $R\gg L$, variations in the argument of the exponential function have a strong influence on the integral, while variations in the denominator do not. Then the denominator can be replaced by R and (17) reduces to

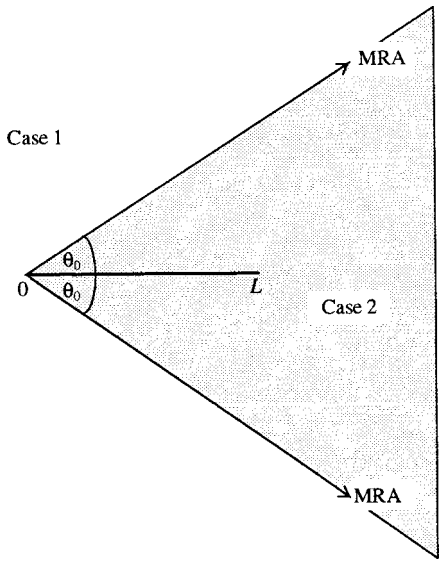

FIG. 11. Two regions are distinguished: behind (case 1) and in front of (case 2) the MRA.

$$p(t')=\frac{\rho a\alpha}{2R}\,\Phi(t'-t_0)\times\exp\left(-\frac{(t'-t_0)}{\tau}\right)\int_{x_1}^{x_2}\exp\left(\frac{\beta}{\tau}\frac{x}{v}\right)dx, \tag{18}$$

where Φ is the Heaviside step function, $t_0=R/c$ is the travel time from the origin to R, and $\beta=1-M\cos\theta$. Finally, shifting the time variable to $t=t'-t_0$ (so time is measured from the instant sound from the detonator reaches R) and evaluating the definite integral, (18) becomes

$$p(t)=\frac{\rho a\alpha}{2R}\frac{v\tau}{\beta}\,\Phi(t)\exp\left(-\frac{t}{\tau}\right)\times[\exp(\beta x_2/v\tau)-\exp(\beta x_1/v\tau)]. \tag{19}$$

Two cases are evident (see Fig. 11). Case 1 is when $\beta>0$ or $\theta>\cos^{-1}(1/M)$, the region behind the shock axis, and case 2, with $\beta<0$, the smaller region forward of the shock axis.

In case 1, $x<v(t'-r/c)=v(t'-t_0)+xM\cos\theta$ so that $x(1-M\cos\theta)<v(t'-t_0)$ or $x<vt/\beta$. The first sound to reach R arrives from the detonator end of the line at $t=0$ and $x_1=0$. During the interval $0<t<\beta L/v$ the upper limit follows $x_2=vt/\beta$ as the detonation progresses down the line. After the detonation reaches L, x_2 remains fixed at L for $t\geqslant\beta L/v$.

In case 2, $x<v(t_0-t')/(-\beta)=vt/\beta$ with both β and t negative. The first sound to reach R arrives from the end of the line opposite the detonator at $t=\beta L/v$ and $x_2=L$. During the interval $\beta L/v<t<0$ sound from earlier positions on the line arrives and the lower limit follows $x_1=vt/\beta$ until after $t\geqslant 0$ when it stays fixed at $x_1=0$.

Evaluating (19) with these limits produces the general waveform

$$p_{1,2}(t)=\frac{\rho a\alpha}{2R}\frac{v\tau}{\beta}G_{1,2}(t)\exp(-t/\tau) \tag{20}$$

with the subscript indicating case 1 or 2 and

$$G_1(t)=\begin{cases}0, & t\leqslant 0\\ 1-e^{t/\tau}, & 0<t<L\beta/v\\ 1-e^{L\beta/v\tau}, & t\geqslant 0\end{cases}$$
$$G_2(t)=\begin{cases}0, & t\leqslant L\beta/v\\ e^{t/\tau}-e^{-L\beta/v\tau}, & L\beta/v<t<0\\ 1-e^{-L\beta/v\tau}, & t\geqslant 0.\end{cases} \tag{21}$$

Exactly on the MRA neither form can be used, however, direct evaluation of (18) with $\beta=0$, $x_1=0$, and $x_2=L$ yields

$$p_{\mathrm{MRA}}=\frac{\rho a\alpha}{2R}L\Phi(t)\exp(-t/\tau), \tag{22}$$

which has the form of a point charge shock wave, as expected.

The impulse calculated from this model is independent of θ,

$$I_0=\frac{\rho a\alpha}{2R}L\tau \tag{23}$$

and this is confirmed experimentally. (For instance Slifko reports[6] that, at ranges beyond $1.5L$, measured line charge impulse varies little with emission angle.) Therefore data measured on the MRA may be used to establish the two parameters needed in the model: time constant, directly from the empirical equations in Fig. 8, and amplitude, through (23) and the impulse equations in Fig. 9. For example, for PETN detonating cord we have

$$\tau_{\mathrm{PETN}}=15.2(10)^{-6}(W/L)^{0.4} \tag{24}$$

and

$$\left.\frac{\rho a\alpha}{2R}\right|_{\mathrm{PETN}}=\frac{(I_0/L)}{\tau}=\frac{5.65(10)^7(W/L)^{0.526}}{15.2(10)^{-6}(W/L)^{0.4}}$$
$$=3.72(10)^{12}(W/L)^{0.26}. \tag{25}$$

Typical waveforms produced by this model are shown in Fig. 12. Away from the shock axis the impulse is long and flat-topped. Nearer the axis it becomes shorter and grows in height, maintaining the area under the curve (impulse) constant. All examples in Fig. 12 are from the region behind the MRA (case 1); curves for positive deviations (case 2) have the same size and shape but are displaced to the right and begin at $t=0$.

B. Model/data comparisons

The model has been validated by comparing predictions to data for much of the data reported in Sec. I. This is illustrated for a subset of view angles for one example, C8-2, in Fig. 13. Characteristics of unit C8-2 used in the model were

$$L=9.9\ \mathrm{m},\quad M=5.33,\quad \tau=80\ \mu\mathrm{s},$$

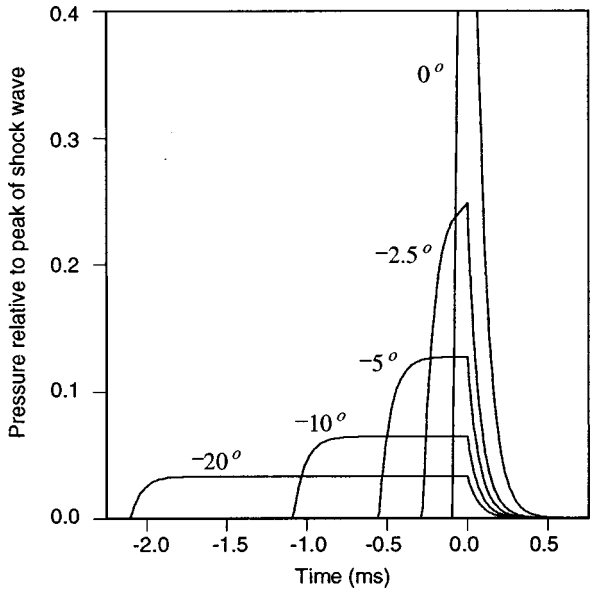

FIG. 12. Modeled line charge waveforms at indicated angles relative to the shock axis, normalized by peak pressure exactly on the shock axis ($M=5.33$).

$$I_0=8.31\times 10^9\ \ \mu\mathrm{Pa\ s\ at\ 1\ m}$$

and model time was discretized at 12 kHz, the same rate used in the measurement. All spectra were cut off at the Nyquist frequency, 6 kHz.

Of the five angles depicted in Fig. 13, (b) is the closest to the theoretical shock axis angle of 79.2° for this M. The other angles span the measurement extremes for this unit. It was found that the match improved if the angle used in the model was tweaked slightly from the value derived from marker pop analysis. This adjustment varied from a few tenths of a degree near the MRA to 2° at the maximum view angle, and is believed to be due to uncertainty in M, angle measurement errors, and source curvature.

Overall the agreement is quite good, and major features of the measurement are predicted well in both time and frequency domains. The negative phase following the shock wave is not modeled, but this feature affects only the very low-frequency end of the spectrum.

III. CONCLUSIONS

(1) Directivity effects for explosive line arrays can be approximated over moderately wide bands by continuous array methods.

(2) Ranking the three materials by specific acoustic output per active weight, PETN cord is the strongest, RDX cord intermediate, and HLX ribbon weakest. The difference between PETN and HLX is about 2 dB.

(3) Bubble period data in this experiment agreed with Sari and Nelson's result for PETN cord, but deviated significantly from Wentzell's result for RDX.

(4) A model of shock wave acoustics for end-initiated line charges has been developed and validated. Scaling laws which relate τ and I, the two parameters controlling the model, to linear charge density are based on the hypothesis that a line charge may be treated as a string of independent

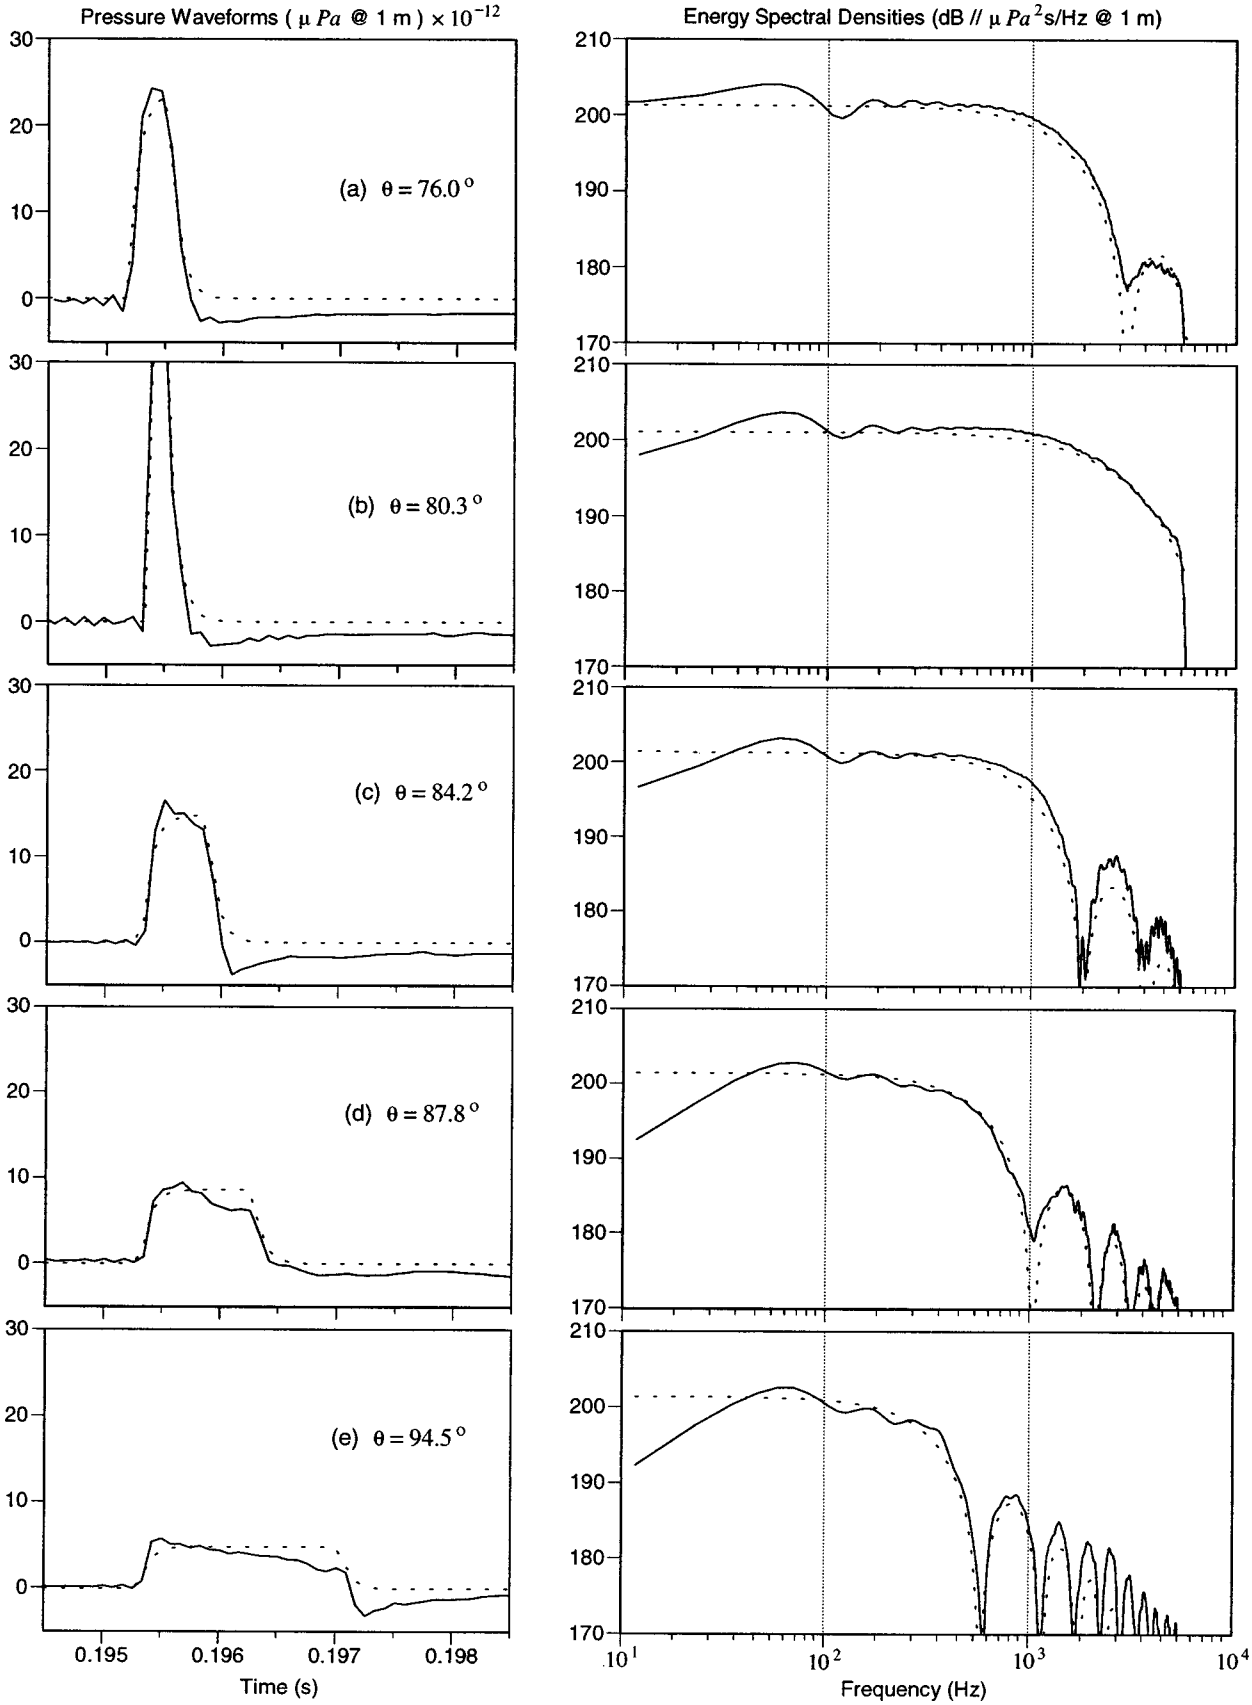

FIG. 13. Model results (dashed lines) compared to measured data (solid lines) for unit C8-2 at indicated view angles θ. Model parameters used are given in the text.

discrete charges if the length of each discrete bit is the distance the detonation travels in time τ. Finding that measured τ and I follow predicted trends confirms the hypothesis.

(5) Of the two parameters driving the model, impulse is easier to measure because it is substantially independent of view angle and, therefore, relatively unaffected by source curvature. The on-axis decay time constant is hard to measure on long cords because small amounts of curvature can increase apparent τ by a factor of 2 or more. The best model predictions result from using actual τ's.

ACKNOWLEDGMENTS

The author wishes to thank J. Barger for suggesting the mathematical method employed in Sec. II and, in particular, the idea of discretizing the line into bits of length $v\tau$. T. Farrell designed and wrote the data reduction procedures used in locating the hydrophones from marker pop arrival times. This work was sponsored by the Tactical Technology Office (TTO) of the Defense Advanced Research Projects Agency (DARPA).

APPENDIX: BEAM PATTERN CURVE FITTING

Assume the energy beam pattern of a directive source is the same as that of a continuous line,

$$\begin{aligned} \mathrm{ESL}(\theta) &= \mathrm{ESL}_0 + 20\log\left|\frac{\sin x}{x}\right|, \\ x &= \pi(L/\lambda)(\cos\theta - \cos\theta_0), \end{aligned} \tag{A1}$$

where θ_0 is the MRA direction, ESL_0 the maximum value on the peak of the pattern, and angles are measured from end-fire. Express L/λ in terms of the beamwidth,

$$\pi(L/\lambda) = 50.4\pi/\beta = 158/\beta, \tag{A2}$$

where β is the total beamwidth between the -3-dB points, in degrees. On the main lobe of the pattern (θ near θ_0) the x-dependent term can be expanded in a Taylor's series,

$$20\log\left|\frac{\sin x}{x}\right| = -1.45\left(1+\frac{x^2}{30}\right)x^2 + \cdots . \tag{A3}$$

Dropping the fourth power term in x, the peak of the pattern reduces to a parabola,

$$\mathrm{ESL}(\theta) = \mathrm{ESL}_0 - 1.45x^2, \tag{A4}$$

where

$$x = \frac{158}{\beta}(\cos\theta - \cos\theta_0). \tag{A5}$$

Pairs of (ESL,θ) near the MRA are least-squares fitted to this equation to obtain the three parameters, ESL_0, β, and θ_0, which best describe the peak. The nonlinear fit is done using a Mathcad solve block.

(Received 11 January 1996; revised 29 January 1997; accepted 24 November 1997)

Nonlinear scattering due to bubble oscillations was theoretically and experimentally investigated for bubble size distribution measurements in water. If two primary acoustic waves of different frequencies are incident on a bubble, the difference frequency component of primary waves is produced in the scattered field. The incoherent scattering at the difference frequency from bubbles was theoretically studied. It was shown that the difference frequency amplitude is proportional to the density of bubbles having resonance frequencies close to the difference frequency. It allows the use of difference frequency measurements to determine the bubble density in water. For experimental investigations two focused transducers were used to increase the levels of primary waves in the interaction zone. One of the primary frequencies was kept constant 2.25 MHz while another was changed from 2.22 to 1.93 MHz, so that the observed difference frequency was varied from 30 to 320 kHz. This frequency band corresponds to the resonant bubble radii from 109 to 10 μm. For the bubble clouds produced in a laboratory tank by an electrolysis-type and a slit-type bubble maker the bubble densities were well estimated with the present nonlinear acoustic method. INTRODUCTION

It is well known that the ocean surface layer is very inhomogeneous and full of entrapped air bubbles. In the ocean there are various bubble-generating mechanisms. The breaking of surface waves is one of the most likely generating mechanisms. The bubble clouds can be formed in the upper layer and be transported down to depths of tens of meters in the ocean by Langmuir circulation, turbulence, and so on.[1] Such bubble clouds influence the gas flux between atmosphere and ocean[2] and also play significant roles in sound propagation as well as sound generation.[3–6] Bubble clouds have been also experimentally confirmed as one of the most likely sources of underwater ambient noise in the ocean over wide frequency ranges.[7,8]

Measurements of bubble size and density in a sound propagating medium require understanding of the acoustic characteristics of the medium. Even the presence of a small number of bubbles makes enormous changes to acoustic properties in water. Since bubbles are good resonant scatterers and absorbers of sounds in the ocean, sound scattering and attenuation data are used in acoustic bubble sizing methods and for bubble cloud observations.[1,3,5]

For bubble diagnostics in the ocean nonlinear acoustic methods have been lately attracting increasing attention. Since a bubble is a highly nonlinear scatterer, the acoustic scattered fields from a bubble also show highly nonlinear properties. Such scattered fields from a bubble are easily observed at the second or higher harmonics as well as at the fundamental frequency. If two primary acoustic waves of different frequencies are incident on a bubble, the scattered fields at the sum and the difference frequencies of the primary waves also arise. These nonlinear acoustic responses make nonlinear acoustic diagnostics possible for bubble sizing in water. The usage of the nonlinear acoustic techniques easily allows one to distinguish a bubble from the other scatterers since nonlinear scattering from a bubble is much stronger than the other scatterers such as solid particles or any other inhomogeneities in fluid.

One of the early experimental investigations with a method of second harmonic measurements was an observation of gas emboli in divers' tissues during decompression.[9] A method based on second harmonic observation was also developed for estimating bubble distribution in the ocean[10,11] and tested for bubble detection in pipelines.[12] A difference frequency method was developed with dual primary transmitting waves.[13,14] For this difference frequency observation the primary frequencies are taken as those higher than bubble resonance frequencies. The difference frequency is chosen around bubble resonance. Another nonlinear acoustic technique is a modulation method based on modulation of a high-frequency probe wave by a low-frequency primary wave.[15,16] The modulation level increases if the primary frequency becomes close to the bubble resonance frequency. Another modulation technique is a method based on the modulation of a probe wave by the subharmonic frequency of primary wave.[17] In the above-mentioned experiments the nonlinear scattering from a single bubble was mainly studied.

When sound waves propagate in the ocean, acoustic scattering from many bubbles usually takes place. Such scattering consists of coherent and incoherent parts. The coherent component arises when there is spatial temporal correla-

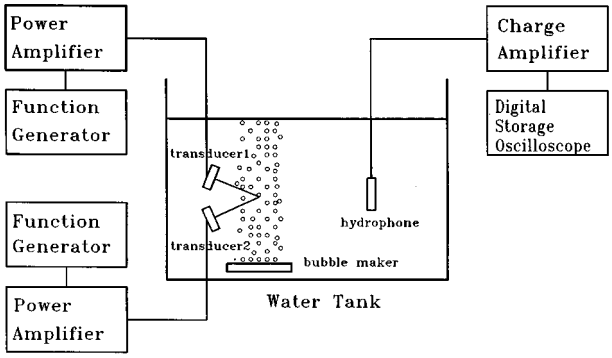

FIG. 1. Schematic diagram of experimental setup.

tion between scattered and incoming waves. It takes place, for example, for forward scattering when the coherent scattering yields distortion in sound velocity and sound attenuation. Measurements of these parameters are used in linear acoustic bubble sizing methods. The coherent technique based on sound velocity measurements was applied for total void fraction estimation,[3] and the sound attenuation measurement technique was used for bubble density determination.[18,19] The incoherent components in the scattered signals exist when phases of scattered signals from scatterers are stochastically distributed. Such a case usually occurs in a subsurface bubble layer in the ocean when the backscattering signal is investigated. The incoherent methods of bubble sizing[6,20,21] are much more widely used than the coherent methods.

The nonlinear scattering signal consists not only of coherent but also of incoherent components. Nonlinear coherent scattering can take place for the waves scattered in a forward direction or as a result of nonlinear reflection from the ocean surface layer. Such nonlinear coherent scattering from bubble layers has been observed in laboratory measurements.[22,23] Nonlinear incoherent scattering can take place in a backward direction. Such scattering was investigated when the bubble resonance occurred at the primary frequencies.[10,11,21] In Ref. 21 such nonlinear scattering was considered as a disturbance factor for conventional linear measurements of bubble cloud spatial distribution.

In this paper nonlinear incoherent scattering of the difference frequency for a wide function of bubble size distribution is theoretically investigated for the case that individual bubble resonance frequencies are within the variation range of difference frequencies. The parameters of nonlinear scattering are related to a bubble size distribution that permits measurement of the bubble density. Experimental verification of the present method was carried out in a laboratory facility.

I. EXPERIMENTAL SETUP

The experimental measurements were carried out in a laboratory tank of dimensions 0.30 m×0.91 m×0.45 m. A schematic diagram of the experimental setup is shown in Fig. 1. Anechoic lining rubber plates were placed in the tank opposite to the transmitters to reduce the reflection from tank walls.

Two different bubble makers were used in the measurements. An electrolysis-type bubble maker was composed of nets of wires for a positive and a negative electrode. A positive constant electric voltage about 20 V was applied at the positive electrode. Hydrogen bubbles were generated from the positive electrode to the water surface. The negative electrode was placed near the tank wall to avoid the influence of oxygen bubbles produced by itself in an acoustical field. Much higher bubble concentrations were created with a slit-type bubble maker. The slit-type bubble maker consisted of a porous plate and a compressed air supply system. Bubbles can be generated through the plate made from pressed cardboards with compressed air. The compressed air from an air tank was fed to the bubble maker through a flow control system. The size of the plate was 9 cm×14 cm. The flow rate Q of gas volume fed to the bubble maker was measured with a flow meter, and the bubble rising speed V_r was also determined by direct measurements of time and distance of bubble rising. The total void fraction β of the bubble layer produced by the bubble maker was estimated from the gas volume flow rate Q and the average speed V_r of rising bubbles as follows:

$$\beta = \frac{Q}{SV_r},$$

where S is the effective cross-sectional area for bubble generation of the slit-type bubble maker.

Two high-frequency primary beams were generated by two separate focused transducers (Panametrics type A304S) to make more interactions of the primary waves in the beam-crossing region. Each transducer has a resonance frequency around 2.25 MHz, a radius $a=12.7$ mm, and a focal length $F=101.6$ mm. Each transducer was calibrated with a reference source by the comparison method.[4] It was observed that the amplitude of the acoustic wave near the transmitter was about 6.6×10^4 Pa near a resonance frequency. For this pressure field measurement a tone burst signal was generated and its reflection signal from a water surface was used. The primary acoustic power radiated by each transducer was about 1.5 W. The radiation amplitude decreased when the frequency was off from the resonance. The size of the interaction zone can be approximated to the diameter of the focal spot. In our case this diameter d can be estimated by a formula[24]

$$d = 1.21\lambda F/a,$$

where λ is the wavelength of the pump wave. In the present case the diameter of the focal spot was about 6.4 mm. More details of the acoustic pressure distribution near the focal point are described in Sec. II.

One of the primary frequencies was kept constant at 2.25 MHz, and another was varied from 2.22 to 1.93 MHz to get difference frequencies from 30 to 320 kHz. Such difference frequency variation allowed measurements of bubble size distribution in the range from 109 to 10 μm of bubble radius. The two primary beams intersected in the region near their focal spots. The positions of both primary pump radiators were tuned with a spherical steel ball of 3 mm in diameter placed at the center of interaction zone. A tone burst

signal was radiated by one transducer as a transmitter and was received by another transducer as a receiver. The locations of both transducers were adjusted to reach the maximum amplitude of signals reflected from the steel ball at the intersection point. A bubble maker was placed under the beam-crossing interaction zone. As bubbles rose and passed through the interaction zone, the difference frequency wave was generated in the interaction zone. The signal was received by a hydrophone situated at approximately 130 mm from the focal point. It was amplified with a preamplifier (Panametrics model 5678) and analyzed by a digital storage oscilloscope (LeCroy 9310M).

The measurements of the difference frequency radiation signal were carried out by using continuous wave (cw) primary waves for different frequencies. Since the interaction zone of the primary waves was very small, bubbles randomly passed through the interaction zone and fluctuations of the received signal were observed. To get their mean value the averaging of the received signal intensities for a time period of 60 s at each difference frequency was used. Even though anechoic lining rubber plates were used, all the influence of tank resonance could not be avoided in the case of the electrolysis-type bubble maker, where the attenuation of the acoustic wave was not enough to suppress such reverberation due to tank resonance. Since the attenuation was rather strong for the slit-type bubble maker, the effects of reverberation in the tank were not observable in this case. To reduce tank resonance effects in the measurements the following two methods were applied to the data processing:

(1) The frequency dependence of received signals reveals tank resonance when the frequency is swept. To avoid such interference due to the tank resonance a frequency averaging method was used. In our experiments the levels of five different frequency signals near every chosen frequency were determined and these intensities were averaged. The step between the main frequency points was 10 kHz and a step of 1 kHz was used to measure the levels around the main point for averaging.
(2) Beside such an averaging method the tank resonance effect was also estimated by using a small spherical omnidirectional radiator of which volume was close to the volume of interaction zone. This radiator was centered in the interaction zone, so that it can be considered as a reference source for absolute measurements of the sound produced by bubbles in the interaction zone. The transfer function $K(\Omega)$ from a reference radiator to a hydrophone is defined as the ratio of the electric input voltage amplitude U_1 into the radiator to the electric received voltage amplitude U_2 from the hydrophone, i.e., as $K(\Omega)=U_1/U_2$ for an observed difference frequency.

In our experiments the electric output amplitude U of the hydrophone at a difference frequency produced by bubbles was measured. To recalculate that amplitude for the free field condition the transfer function $K(\Omega)$ was used. Since the transmitting sensitivity S of the radiator is known, the acoustic pressure P_Ω of the difference frequency radiated by bubbles in a free field at the distance 1 m from the interaction zone was estimated by

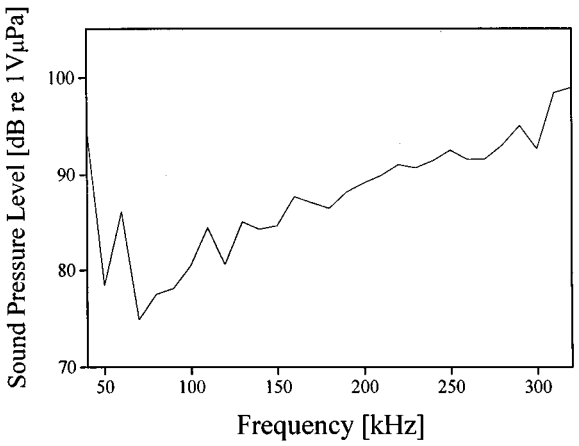

FIG. 2. Frequency dependence of the difference frequency field generated through the bubble layer from the slit-type bubble maker.

$$P_\Omega = S(\Omega)K(\Omega)U. \tag{1}$$

The frequency dependence of the received difference frequency signals is presented in Figs. 2 and 3 for bubble clouds from the respective bubble makers, respectively.

To calculate bubble density function from such measurements we also need to take account of the attenuation of the primary high-frequency waves in a bubbly medium. The attenuation coefficients for the primary pump waves were determined by the insertion loss measurements with a bubble layer. A hydrophone was placed behind the bubble layer as a receiver. The received amplitudes of primary frequency waves through the bubble layer were measured and compared with the amplitudes without the bubble layer. The attenuation coefficient α in dB per m can be estimated from such measurements as follows:

$$\alpha = \frac{\ln(U_0/U_b)}{l},$$

where U_0 is the received amplitude of the primary wave without the bubble layer, U_b is the received amplitude with the bubble layer, and l is the length of the acoustic path inside the bubble layer.

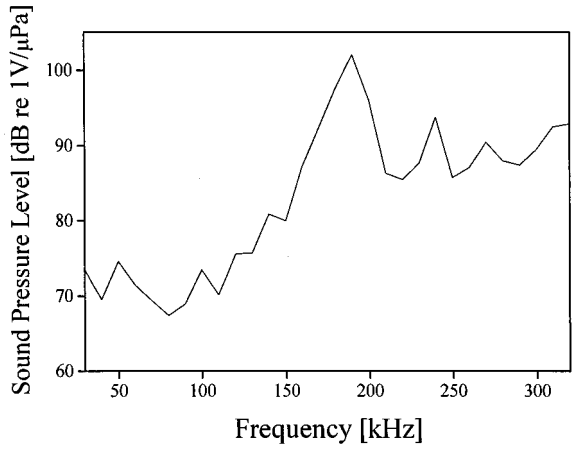

FIG. 3. Frequency dependence of the difference frequency field generated through the bubble layer from the electrolysis-type bubble maker.

II. THEORETICAL CONSIDERATION

For a theoretical description of the nonlinear incoherent scattering it is necessary to start from nonlinear scattering by a single bubble. The formula for a nonlinear scattered field at the combination frequencies can be derived by two typical approaches in the literature. One is the volume displacement approach[25] and another is the radial displacement approach.[12,15,26] In Refs. 26 and 27 both approaches were compared and their authors had different conclusions. In Ref. 26 it was concluded that the volume displacement approach was not correct, and in Ref. 27 it was pointed out the errors taken in the Ref. 26. The opinion of the authors of the present paper is that the approach of Zabolotskaya and Soluyan[25] is valid.

The derivation of the formulas will be given below following the concept of Zabolotskaya and Soluyan[25] but from more fundamental equations.

The first equation of movement, i.e., the Euler equation which has a form for spherically symmetric motion, is described as follows:

$$\frac{\partial U}{\partial t}+U\frac{\partial U}{\partial r}=-\frac{1}{\rho_o}\frac{\partial p}{\partial r}, \tag{2}$$

where U is the fluid velocity at the distance r from the center of a bubble, p is the pressure, and ρ_o is the ambient equilibrium fluid density.

The second equation is the linear wave equation in terms of a velocity potential φ:[28]

$$\nabla^2\varphi-\frac{1}{c^2}\frac{\partial^2\varphi}{\partial t^2}=0, \tag{3}$$

where c is the sound velocity. The fluid velocity is given by the velocity potential as follows:

$$U=\nabla\varphi. \tag{4}$$

Since the nonlinear disturbances due to bubble oscillations are much higher than the distortion of acoustic waves in a pure fluid surrounding a bubble, the higher-order terms of acoustic nonlinearity of fluid can be neglected. The Rayleigh equation for bubble oscillations can be derived from Eqs. (2)–(4). The solution of the wave equation for radially symmetric motion is written in the form

$$\varphi=\frac{A(t-r/c)}{r}, \tag{5}$$

where A is an arbitrary function. Since only small bubbles are under consideration, that is, the radii R are much smaller than the acoustic wavelength λ, the parameter $R/\lambda\ll 1$ for the asymptotic expansion of the sound wave equation can be used and the following assumption is valid:

$$\frac{|(1/c^2)(\partial^2\varphi/\partial t^2)|}{|\nabla^2\varphi|}\sim\left(\frac{R}{\lambda}\right)^2\ll 1.$$

Therefore, the sound wave equation can be written in the following formula;

$$\nabla^2\varphi=0, \tag{6}$$

that is, the equation of continuity for an incompressible liquid in terms of the velocity potential. Equation (6) has a solution of

$$\varphi=\frac{A(t)}{r}, \tag{7}$$

where A is the arbitrary function of time.

The same result can be obtained directly from Eq. (5) for the distance $r\ll\lambda$. With the velocity potential φ for radial motion

$$U=\frac{\partial\varphi}{\partial r},$$

the Euler equation, Eq. (2), becomes

$$\frac{\partial^2\varphi}{\partial t\partial r}+\frac{1}{2}\frac{\partial}{\partial r}\left(\frac{\partial\varphi}{\partial r}\right)^2=-\frac{1}{\rho_o}\frac{\partial p}{\partial r}. \tag{8}$$

Let us integrate the last equation from r to r_1, where $R\ll r_1\ll\lambda$. It gives

$$\frac{\partial\varphi}{\partial t}+\frac{1}{2}\left(\frac{\partial\varphi}{\partial r}\right)^2=-\frac{p-P_o-p_a}{\rho_o}, \tag{9}$$

where p_a is the applied acoustic pressure produced by external sources, and P_o is the ambient equilibrium fluid pressure. It is assumed that at the distance $r_1\gg R$ the acoustical pressure disturbance produced by a bubble is small. The boundary conditions at the bubble surface are given as follows:

$$\dot{R}=\left.\frac{\partial\varphi}{\partial r}\right|_{r=R},\quad p_g=p|_{r=R}, \tag{10}$$

where p_g is the gas pressure inside the bubble. After substitution of Eq. (7) to the first boundary condition of Eq. (10), the velocity potential can be described as

$$\varphi=\frac{A}{r}=-\frac{R^2\dot{R}}{r}. \tag{11}$$

Substituting Eq. (11) in Eq. (9) one can obtain the well-known Rayleigh equation:

$$R\ddot{R}+\frac{3\dot{R}^2}{2}=\frac{p_g-P_o-p_a}{\rho_o}. \tag{12}$$

Since the surface tension effect is neglected, Eq. (12) might be good for the bubbles larger than several microns in radius. Neglecting the heat exchange between the bubble and the medium, the adiabatic gas law can be used as the equation of state:

$$p_g=P_o\left(\frac{V_o}{V_o+V}\right)^{\gamma}, \tag{13}$$

where V is the volume variation of single bubble, $\gamma=1.4$ is the specific heat ratio of the gas in a bubble, and P_o is the static pressure in a bubble. The subscript ''o'' denotes the quantity in a state of equilibrium. For small bubble oscillations, i.e., $V\ll V_o$, substituting Eq. (13) into Eq. (12) and keeping all the terms up to $(V/V_o)^2$ order, the Rayleigh equation, Eq. (12), becomes[25]

$$\ddot{V}+\omega_o^2 V+\nu\dot{V}-\frac{1}{8\pi R_o^3}\left[3(\gamma+1)\omega_o^2 V^2+2\dot{V}V+(\dot{V})^2\right]$$

$$=\frac{-4\pi R_o}{\rho_o}\,p_a, \tag{14}$$

where R_o is the equilibrium bubble radius and ω_o is the bubble resonance frequency known by the Minnaert formula as

$$\omega_o=\frac{1}{R_o}\sqrt{\frac{3\gamma P_o}{\rho_o}}. \tag{15}$$

The energy dissipation term is included phenomenologically in Eq. (14) and ν is the loss factor. For a time harmonic wave the loss factor ν can be written as $\nu=\omega/Q$ or as $\nu=\omega\delta$, where Q is the quality factor and δ is the bubble damping constant. The damping constant is made up of the damping constants due to reradiation or scatter, plus shear viscosity and thermal conductivity.[3,29] Equation (14) describing the forced bubble oscillations under acoustic pressure p_a up to the quadratic nonlinearity terms was first derived and investigated by Zabolotskaya and Soluyan in Ref. 25.

The substitution of Eq. (11) to Eq. (9) allows us to find the pressure around a bubble:

$$p(r)=P_o+p_a+\frac{\rho_o[R^2(t_r)\ddot{R}(t_r)+2\dot{R}^2(t_r)R(t_r)]}{r}$$

$$-\frac{\rho_o}{2}\frac{\dot{R}^2(t_r)R^4(t_r)}{r^4}, \tag{16}$$

where a retarded time $t_r=t-r/c$ is used instead of t to take into account that the pressure disturbances produced by a bubble propagate with a finite velocity, i.e., sound velocity. The pressure field consists of two parts: the far-field component which depends on r as $1/r$, and the near-field component which decreases with r as $1/r^4$. For the distance $r\gg R$ the near-field component becomes negligibly small, and the acoustic pressure scattered by a bubble, p_s, is defined by the third term:

$$p_s=\frac{\rho_o[R^2(t_r)\ddot{R}(t_r)+2\dot{R}^2(t_r)R(t_r)]}{r}=\frac{\rho_o\ddot{V}(t_r)}{4\pi r}, \tag{17}$$

where $V=(4\pi/3)(R^3-R_o^3)$ is the bubble volume variation. Equations (14) and (17) are the basic equations to determine the processes of nonlinear scattering by bubbles. These equations were the same as those in Ref. 25 and the derivation made in the present paper shows that the volume displacement approach is correct. It is interesting to consider why another solution has been obtained in the paper of Du and Wu.[26] The point of disagreement with the radial displacement approach[12,15,26] is in the form of pressure pulsation near a small bubble. Du and Wu used the acoustic pressure field in the form

$$p=\frac{B(t-r/c)}{r}, \tag{18}$$

but the correct formula, Eq. (16), contains also the near-field component, which is very essential for the nonlinear bubble oscillations, and the near-field component cannot be neglected.

Let us investigate the bubble radiation field at the difference frequency. In the case of biharmonic waves, which consist of two frequency components ω_1 and ω_2 with the pressure amplitudes P_1 and P_2, respectively, the pressure field of scattered wave at the difference frequency $\Omega=\omega_1-\omega_2$ can be determined by the bubble volume variation at this frequency. The acoustic radiation field is expressed with the bubble volume variation V_Ω as follows:

$$P_\Omega=\frac{\rho_o\Omega^2 V_\Omega}{4\pi r}, \tag{19}$$

where r is the distance from a bubble to an observation point. Relation between the volume variation at the difference frequency and the pressure amplitude in an incident wave can be obtained from Eq. (14). It leads to an easy solution for the bubble volume variation V_Ω by the perturbation method for a given pressure of an external wave and small additions due to nonlinearity (see Ref. 25):

$$V_\Omega=\frac{2\pi[3(\gamma+1)\omega_o^2-\omega_1^2-\omega_2^2+\omega_1\omega_2)]P_1P_2}{\rho_o^2R_o[\omega_o^2-\omega_1^2+i\delta\omega_1^2][\omega_o^2-\omega_2^2-i\delta\omega_2^2][\omega_o^2-\Omega^2+i\delta\Omega^2]}, \tag{20}$$

where $i=\sqrt{-1}$. Assume that there is no bubble with radius less than 1.4 μm, which has a resonance at the primary frequency around 2.3 MHz. It allows one to simplify Eq. (20) and for a very low difference frequency compared with the primaries, i.e., $\Omega\ll\omega_1,\omega_2$, the amplitude of the bubble volume variation at the difference frequency can be written as

$$V_\Omega=\frac{2\pi P_1P_2}{\rho_o^2R_o\omega_1^2[\omega_o^2-\Omega^2+i\delta\Omega^2]}. \tag{21}$$

It is common procedure to describe the scattering strength by an effective scattering cross section. Let us introduce the nonlinear scattering cross section σ_n, which is defined as the ratio of the total intensity of nonlinearly scattered waves to that of the incident wave in the free space:

$$P_\Omega^2=\sigma_n P_1P_2/4\pi r^2. \tag{22}$$

From Eqs. (19), (21), and (22) the nonlinear scattering cross section σ_n at the difference frequency can be expressed as

$$\sigma_n=\frac{\pi\Omega^4P_1P_2}{\rho_o^2R_o^2\omega_1^4[(\omega_o^2-\Omega^2)^2+\delta^2\Omega^4]}. \tag{23}$$

The nonlinear scattering cross section depends on the amplitudes of incident waves, while the linear scattering cross sec-

tion does not. It seems noteworthy that the above relations were obtained with the perturbation method assuming the amplitude of nonlinear scattered signal is much smaller than that of the linear one. Equations (22) and (23) give the information on the difference frequency signal produced by a single bubble. In our experiments the time-averaged intensity of received signals was used as described in Sec. I.

Bubbles randomly pass through the interaction zone. Since the interaction zone is small, the probability that more than one bubble exists in this zone at the same moment is also small. The time-averaged signal from the small size interaction zone can be considered as a model for the larger size interaction zone where many bubbles can exist at the same moment. Such a situation can take place in ocean bubble measurements with transducers of larger sizes than those in the laboratory experiments. Let us consider a small volume element dv in the interaction zone. In the processing of the received signal the time-averaged level of the power spectrum was measured, that is, the time-averaged intensity of the signal produced by bubbles. The mean intensity can be found by using the function of bubble size distribution $n(r)$. This function determines the probability W that the bubble having radii from R to $R+dR$ is located in a volume dv as $W=n(r)dRdv$. Thus, the averaged signal produced by a volume element dv is

$$dP_{\Omega}^2=\frac{S_n P_1 P_2\, dv}{4\pi r^2}, \tag{24}$$

where

$$S_n=\int_{R_{\min}}^{R_{\max}}\sigma_n(r)n(r)dR. \tag{25}$$

Here S_n is the nonlinear scattering coefficient, which is equal to the effective nonlinear scattering cross section per unit volume of a medium. A similar linear backscattering coefficient is well known in underwater acoustics.[3,4] The nonlinear backscattering coefficient can be found in the same manner as the linear one by integrating the scattering cross section of an individual bubble over the radius with the bubble density function. Equation (25) is mainly contributed by the resonant bubbles and can be calculated with the same approximation method, which is usually used for determining the absorption coefficient and the linear scattering coefficient:[3]

$$S_n=\frac{\pi^2 n(R_\Omega)P_1P_2}{2\rho_o^2\delta\omega_1^4 R_\Omega}, \tag{26}$$

where R_Ω is the bubble radius having the resonance frequency of Ω. Equations (24) and (26) give the information on the acoustical signal produced by the bubbles passing through the volume element dv. Any bubbles passing through the interaction zone Δv make a contribution to the received signal. For this contribution Eq. (25) should be integrated through the beam interaction zone, where the nonlinear scattering from bubbles originates. When the dimension of the interaction volume element Δv is much smaller than the distance r from the interaction zone to the hydrophone, the nonlinear scattering field can be described as

$$P_\Omega^2=\frac{\pi n(R_\Omega)}{8\rho_o^2\delta\omega_1^4 R_\Omega r^2}\int_{\Delta v}P_1^2P_2^2\,dv. \tag{27}$$

Equation (27) relates the intensity of the difference frequency field with the concentration of bubbles in the scattering volume which are resonant at the difference frequency. This equation allows the measurements of bubble density and size distribution for various difference frequencies. The intensity distributions of the primary beams in the scattering volume are considered to be known.

In a laboratory experiment the focused transducers were used as the primary beam transmitters. For such a case the integration in Eq. (27) can be analytically solved by considering the acoustic pressure distribution near the focal point of the transmitter for the primary pressure fields.[24] The transmitter axis is chosen with the x axis, and then the distance from the transmitter axis is given as $\sqrt{y^2+z^2}$. For this transmitter whose focal distance F is much larger than its radius a, i.e., $F\gg a$, it is possible to neglect the pressure variation along the x axis for the distance from the focal point much less than $\lambda F^2/a^2$, where λ is the wavelength of the primary wave. In the interaction zone the primary pressure field is described as the following formula:

$$P_1(x,y,z)=\frac{A_1\pi a^2 J_1(2X)}{\lambda F X}\,e^{-\alpha l}, \tag{28}$$

where A_1 is the acoustic pressure near the transmitter, α is the attenuation coefficient for the primary wave, l is the length that the primary wave passes inside of the bubble cloud, and

$$X=\frac{\pi a\sqrt{y^2+z^2}}{\lambda F}. \tag{29}$$

If two primary beams are perpendicular to each other, we can choose the y axis for the second transmitter axis and the field near focal point P_2 is determined by a similar equation with A_2 the acoustical pressure amplitude near the second transducer. With the primary beams of Eq. (28), Eq. (27) for the difference frequency can be easily calculated:

$$P_\Omega^2=\frac{\pi^2 a^5\chi A_1^2A_2^2 n(R_\Omega)}{8\rho_o^2\lambda F\delta\omega_1^4R_\Omega r^2}\,e^{-4\alpha l}, \tag{30}$$

where

$$\chi=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\left[\frac{J_1(2\pi\sqrt{X^2+Z^2})}{\pi\sqrt{X^2+Z^2}}\right]^2\left[\frac{J_1(2\pi\sqrt{Y^2+Z^2})}{\pi\sqrt{Y^2+Z^2}}\right]^2 \times dX\,dY\,dZ\approx 0.11. \tag{31}$$

It is seen that the nonlinear scattering field is proportional to the bubble density function with the bubble resonance radius at the difference frequency. From Eqs. (1) and (30) the bubble density function $n(R_\Omega)$ can be described as follows:

$$n(R_\Omega)=\frac{8\rho_o^2K^2S^2U^2\delta\omega_1^4R_\Omega\lambda F e^{4\alpha l}}{\pi^2a^5\chi A_1^2A_2^2}. \tag{32}$$

This makes it possible to determine bubble density from direct measurements.

Let us derive the conditions for Eqs. (32) and (27) to be valid. It is evident that Eq. (32) is applicable for the case that the probability of more than one resonant bubble existing in the interaction zone is small. Such a condition can be written in the form:

$$n(r)\,\delta R\Delta v \ll 1. \tag{33}$$

In the present paper Eq. (32) can be applicable even for higher bubble density when Eq. (33) is not satisfied and many bubbles can be situated in the scattering volume. Since the bubbles in a liquid move due to floating force and turbulence, the scattered signals fluctuate with time. Therefore, the averaged values of such an ensemble scattering only have physical meanings. There are two components in the resulting signal after averaging. One is the coherent component that appears when the averaged signal amplitude does not become zero. It can be if there is spatial–temporal correlation in bubble distribution such as bubble layers. Forward scattering also gives the coherent component. Another is the incoherent part that has a meaning of pure stochastic scattering. The intensity of incoherent field is equal to the total intensity of the fields scattered by all the bubbles. The incoherent scattering field is described by Eqs. (27) and (32). The incoherent scattering from many bubbles in the interaction zone takes place if the angle between two incident beams is not small because the scale of the phase variation is about the primary pump wavelength. In other words, the phases of nonlinear scattered signals depend on the phases of primary waves at the scatterer positions. Different bubbles which stay in the interaction zone not closer from each other than the wavelength of pump waves have very different phases in the scattered field at the difference frequency. It means that the distance between bubbles must be more than the wavelength of pump waves and the condition of applicability of difference frequency incoherent scattering becomes smoother:

$$n(r)\,\delta R\lambda^3 \ll 1. \tag{34}$$

If this condition is not satisfied in a system of scatterers, it is necessary to take into account the processes of multiple scattering[30–33] and mutual interference.[34] However, the multiple scattering effect is essential mainly for the coherent scattering and very high bubble concentrations with void fraction of order 10^{-2}.[33] Such a high void fraction can hardly exist in the ocean. It is a reason why the processes of multiple scattering are not taken into account in the linear backscattering theory.[3,4] The interference effect was considered in Ref. 34 only for the case of planar distribution of scatterers.

III. RESULTS OF MEASUREMENTS

The experimentally determined bubble densities are presented in Fig. 4 for the bubble clouds produced by the slit-type bubble maker and in Fig. 5 for the bubble clouds produced by the electrolysis-type bubble maker. The slit-type bubble maker can produce a much higher bubble concentration than the electrolysis-type bubble maker. The peak bubble radius in the bubble size distribution for the electrolysis-type bubble maker was near 20 μm. For the bubble clouds produced by the slit-type bubble maker the bubble density increases with bubble radius. Bubble densities presented in Figs. 4 and 5 were calculated by using Eq. (32). Equation (32) includes the parameters of the transducers such as the focal distance F, the radius a of the transducer, the pressure A_1, A_2 at the transducer surface, the frequencies $\omega_{1,2}$ of the primary beams, the transfer function $K(\Omega)$, and the transmitting sensitivity $S(\Omega)$ of the reference radiator at the difference frequency. In Eq. (32) R_Ω is the radius of a bubble having a resonance at frequency Ω defined by the Minnaert formula, Eq. (15). Here $U=U(\Omega)$ is an experimentally measured output voltage at the hydrophone at the difference frequency Ω. The total gas void fraction β can be easily calculated from the bubble density function:

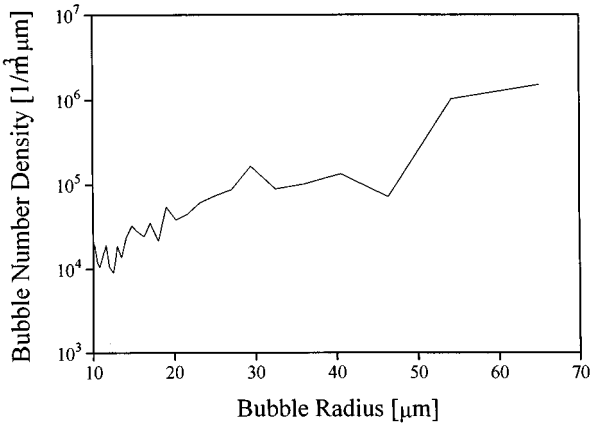

FIG. 4. Bubble density as a function of bubble radius for the bubble layer of the void fraction 7.2×10^{-3} produced by the slit-type bubble maker.

$$\beta = \int_{R_{\min}}^{R_{\max}} \frac{4\pi R^3 n(r)}{3}\, dR. \tag{35}$$

For numerical calculations $\delta \approx 0.1$ was used for the damping constant.[29] The estimated void fraction for the bubble clouds produced by the slit-type bubble maker was $\beta \approx 7.2\times10^{-3}$. It agreed very well with the directly measured void fraction $\beta \approx 7.1\times10^{-3}$. For the bubble clouds produced by the electrolysis-type bubble maker the void fraction was estimated as $\beta \approx 6.0\times10^{-5}$.

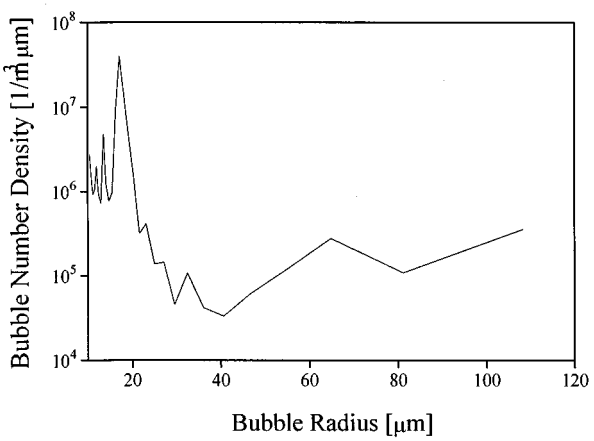

FIG. 5. Bubble density as a function of bubble radius for the bubble layer of the void fraction 6.0×10^{-5} produced by the electrolysis-type bubble maker.

IV. CONCLUSION

In this paper a nonlinear acoustic bubble sizing method based on the incoherent scattering of the difference frequency by bubbles from the intersecting zone of two high-frequency primary acoustic beams was theoretically investigated. This nonlinear acoustic method allows the measurements of the very low bubble density case, which is almost impossible to be measured by a linear acoustic method. The present nonlinear method was verified in the laboratory measurements for bubbles produced by two types of bubble makers. This nonlinear method seems very attractive to the ocean application because it provides high selectivity of bubbles from the other types of ocean scatterers which do not have such large nonlinear response as bubbles. It also provides a rather wide frequency band by relatively small changes of the frequency for one of the primary beams.

(Received 9 May 1997; accepted for publication 21 January 1998)

The pressure dependence of the resonance frequency of several resonant ultrasound spectroscopy modes in a sample of fused silica has been measured at UCLA in atmospheres of air, helium, and argon near ambient temperature. For both compressional and torsional modes, the radiation resistance is linearly dependent upon pressure and increases with the molecular mass of the surrounding gas. The effects are larger for breathing modes than for torsional modes. They also increase with the molecular mass of the gas. A radiation impedance model is presented which explains some of these data qualitatively and quantitatively. © *1998 Acoustical Society of America.* [S0001-4966(98)00505-0]

INTRODUCTION

The adiabatic elastic moduli of solids, and the pressure and temperature dependencies of these moduli, are important for a wide range of problems relevant to solid state physics and geophysics. The pressure dependencies of the elastic moduli are related to the third-order elastic constants and are important in developing theoretical models of solid state properties since they provide information about the interatomic potentials.[1] We emphasize that information about the third-order elastic constants reveals much about the fundamental physics of a solid since the third-order constants are obtained by taking appropriate derivatives of the free energy.[2,3] Indeed, some theoretical attempts to predict solid phase transformations and/or solid–liquid phase changes involve consideration of large strains, i.e., a few percent, in the crystalline lattice.[4–9] Consideration of strains of this magnitude means that anharmonic effects, i.e., nonlinearity in the elastic constants, must be understood. The third-order elastic constants are also required for accurate equations of state used in the investigation of solid material under pressure.[1] Accurate equations of state at low pressure are critical when making extrapolations to the megabar range as is done in studies of planetary interiors. Of prime importance in these equations of state is a particularly simple third-order elastic constant, the pressure dependence of the adiabatic bulk modulus.

There is a long, fruitful history of using ultrasonic techniques in measuring elastic properties and their pressure and temperature dependencies. Two methods in particular have been used in these ultrasonic experimental studies on single crystals. The first is the pulse-echo method, and various versions of it, all based on principles of interferometry. The second is resonant ultrasound spectroscopy (RUS). The RUS method has been used extensively in the study of the temperature dependencies of elastic properties up to temperatures of 1500–1800 K.[10–12]

Virtually all ultrasonic experimental work on the pressure dependencies of elasticity, i.e., on some of the third-order elastic constants, has been done using interferometry. Although interferometry is a powerful experimental tool, there remain questions regarding the effects of bonds between the specimen and the transducers. One advantage of the RUS technique is that RUS requires no bonds between the transducers and the specimen. Even though advances during the past few years have been realized using interferometry techniques[13,14] the effect of bonds required to couple the acoustic energy to the specimen continues to be problematic. In describing their state-of-the-art GHz-ultrasonic interferometer apparatus, Spetzler *et al.*[14] provide a lengthy discussion of theoretical and experimental approaches to problems originating with the bonds in high precision ultrasonic experiments. They state, ''...conclusive results on the nature and the effect of the bonds are still lacking.'' In view of the experimental uncertainties noted above, it is appropriate to develop alternative ultrasonic methods by which the third-order elastic properties of materials are determined experimentally.

We propose using the RUS technique to determine the third-order elastic constant of solids. This will be done by measuring the pressure dependence of the resonance peaks of appropriately shaped samples. Isotropic pressure is exerted by a surrounding gas of helium, air, or argon. Different gases are used in order to experimentally determine the effect of the molecular mass of the gas on the resonance peaks, exclusive of the intrinsic effect of the pressure on the resonance peaks via the third-order elastic constants. Once experimental data were obtained on a fused silica sample in the shape of a rectangular parallelepiped, it became obvious that a theoretical model had to be developed in order to account for the effect of radiation impedance on the resonance frequency

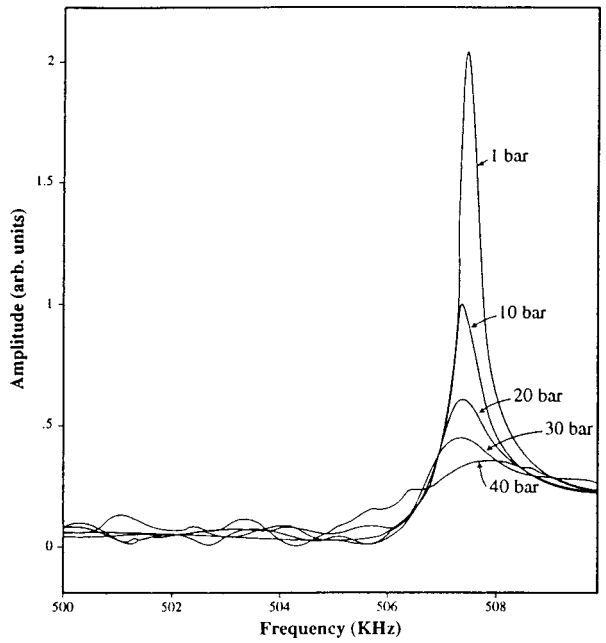

FIG. 1. Resonant peaks of torsional mode A_{1u} measured in fused silica in air at a temperature of 24 °C at various pressures.

of the sample. However, since the resonance frequency could be affected by both the third-order elastic constants and by the mass loading due to the surrounding gas, it was imperative to check the accuracy of the theoretical model by comparing the theoretical results with another experimentally obtained quantity which was negligibly dependent upon the pressure dependence of the intrinsic properties of the sample. Such a quantity is the quality factor of the resonance peaks, Q. It is assumed that the changes in Q being produced by the changes in the applied pressure are principally produced by the energy radiated into the surrounding gas, the intrinsic change in attenuation in the sample itself produced by the compression being negligible.

The RUS measurements reported here were performed on a rectangular crystal of fused silica. The resonant lines of two vibrating modes, identified as torsional mode (A_{1u}) and compressional mode (A_{1g}), were monitored when the sample was in three different surrounding gases, helium, air, and argon, and the pressure of the surrounding gas was changed from 1 bar up to 100 bar. For both modes, it was found that the quality factor of the resonance, Q_r, where the subscript r refers to energy loss due to radiation impedance, decreased when the pressure increased, and decreased with increasing molecular mass of the surrounding gas. For the torsional mode in all three gases, the resonant line was shifted to lower frequency when the pressure was increased, while for the compressional mode, it was shifted to lower frequency in helium but higher in argon.

In our theoretical analysis, we use a two-dimensional model to solve the resonance problem for a bar, and we calculate the sound radiation impedance for each face of the rectangular parallelepiped sample assuming a response similar to that for a vibrating piston mounted in an infinite baffle. The two-dimensional model is applicable because the sound wavelength in the surrounding gas is much smaller than the

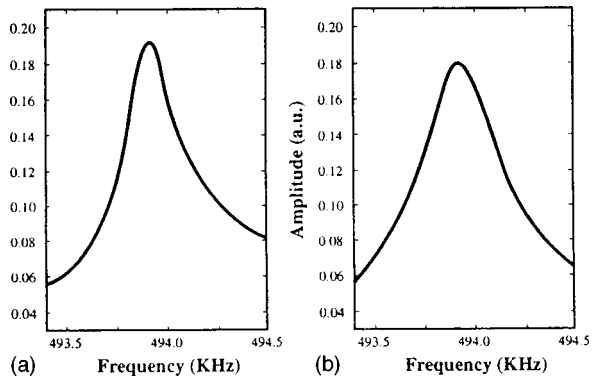

FIG. 2. Lorentzian resonant peaks obtained before (a) and after a background subtraction (b).

dimensions of the rectangular faces of the crystal, and, therefore, the directivity of the sound beams is mostly in the forward direction.

I. EXPERIMENTAL RESULTS

The resonance peaks of the torsional A_{1u} and the compressional A_{1g} modes of a fused silica crystal with dimensions of $0.3194\times0.3083\times0.2491$ cm^3 and a mass of 0.0545 g were measured under various pressures of surrounding gases of helium, air, or argon. A typical result for the A_{1u} mode in air at room temperature, 23.8 °C, is given in Fig. 1. It can be seen that, as the pressure is increased from 0 to 40 bar, the resonant peak becomes broader and shifts to lower frequencies at higher pressures. Since the resonant peaks do not always display a symmetric Lorentzian shape due to cross talk between the two transducers used in the experiment, a background needs to be subtracted in order to determine the resonant center frequency and the quality factor accurately. The original data resonant peak has the form

$$\left|\frac{a_1}{a_2^2-x^2-ia_3x}+a_4\right|^2,$$

where x is the frequency and the coefficients a_1, a_2, and a_3 are real. The coefficient a_4 is complex and arises from coherent background noise, including electromagnetic and mechanical pickup. After removal of the background term a_4, one obtains the Lorentzian-like peak of the form

$$\frac{a_1^2}{(a_2^2-x^2)^2+a_3^2x^2},$$

where a_1 is the amplitude, a_2 is the center frequency of the peak, and a_3 is the width of the peak. The computer code used to analyze the data was obtained from A. Migliori.[15] Figure 2 shows one of the resonant peaks before and after the background subtraction.[16]

It was assumed that the total quality factor Q_t obtained after the background subtraction was composed of two loss mechanisms, one due to radiation impedance Q_r and the other due to the sample support and electronic losses Q_0. These latter losses are assumed to remain constant as a function of pressure. Therefore,

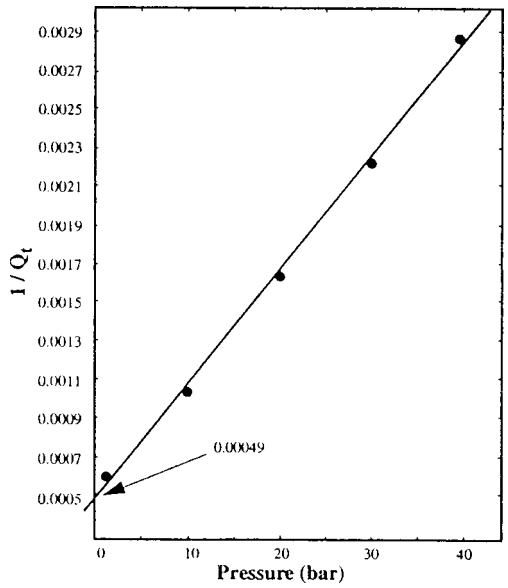

FIG. 3. Inverse total quality factor Q_t versus pressure for fused silica in argon (torsional mode).

$$\frac{1}{Q_t}=\frac{1}{Q_r}+\frac{1}{Q_0},$$

where Q_t is the Q factor measured from the corrected resonant peak using the background subtraction described above (using a_3), and $1/Q_0$ is a constant (y intercept) obtained by extrapolating the $1/Q_t$ versus pressure curve to zero pressure, as shown in Fig. 3, which plots $1/Q_t$ versus pressure for the torsional mode in argon. In Fig. 4, we have plotted the resulting values for $1/Q_r$ as a function of pressure for the torsional mode in helium, air, and argon. Similar values for the compressional mode in helium and argon are shown in Fig. 5. It is clearly seen that for both modes in the various gases, $1/Q_r$ is proportional to the pressure of the surrounding gases. In Fig. 6, we plot $1/Q_r$ at 1 atm as a function of molecular mass M of the surrounding gas on a log–log scale for both modes, and find that the slope is proportional to M^{γ}, with $\gamma=0.9$ for the torsional mode and $\gamma=0.5$ for the compressional mode.

The frequency of the resonant peak (a_2) obtained from the Lorentzian-like peak after the background subtraction

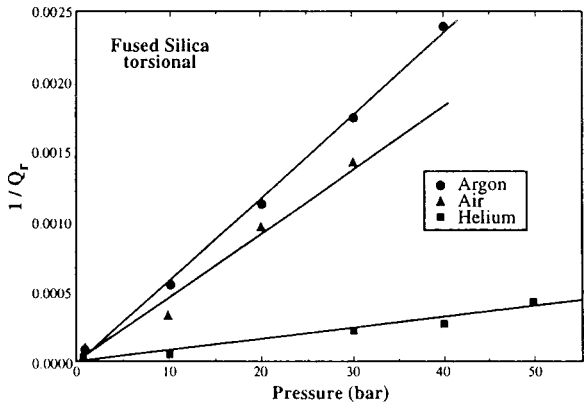

FIG. 4. Inverse radiation quality factor Q_r versus pressure for fused silica in helium, air, and argon (torsional mode).

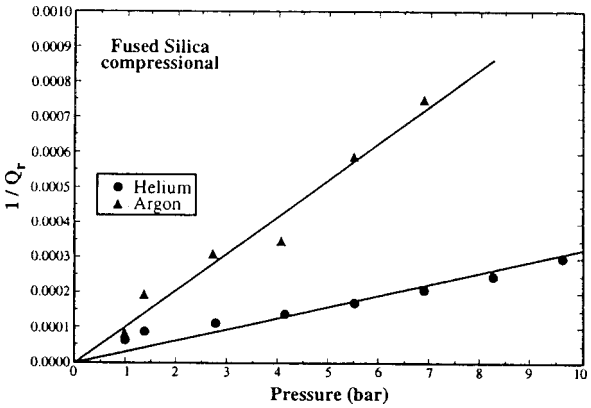

FIG. 5. Inverse radiation quality factor Q_r versus pressure for fused silica in helium and argon (compressional mode).

was plotted as a function of pressure in Fig. 7 for the torsional mode in helium, air, and argon, and in Fig. 8 for the compressional mode in helium and argon. The resonant peak shifts to lower frequencies at higher pressures in all cases except for the compressional mode in argon. Such a shift to lower frequencies would be expected as a result of the third-order elastic constants. However, before final conclusions can be drawn about the value of the third-order elastic constants, we need to estimate the mass loading effect due to the acoustic radiation reactance from the surrounding gas in order to determine its contribution to the frequency shift.

In the following two sections, we will carry out theoretical calculations of radiation impedance for a rectangular parallelepiped sample in two resonant modes, and compare the calculated Q_r factor and resonant frequency shift to the above experimental results.

II. THEORETICAL CALCULATION OF RADIATION IMPEDANCE

A. Two-dimensional model

Consider a solid bar of length l with a linear density of ρ_l, and with its two ends exposed to surrounding media, as

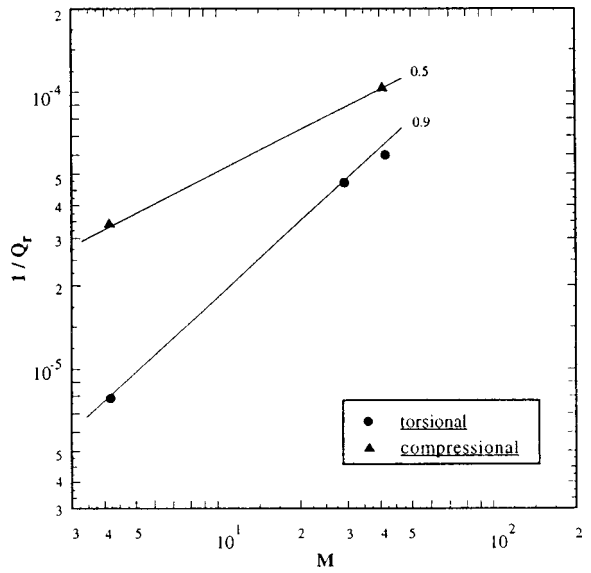

FIG. 6. Inverse radiation quality factor Q_r versus molecular mass of the surrounding gases for fused silica (torsional and compressional modes).

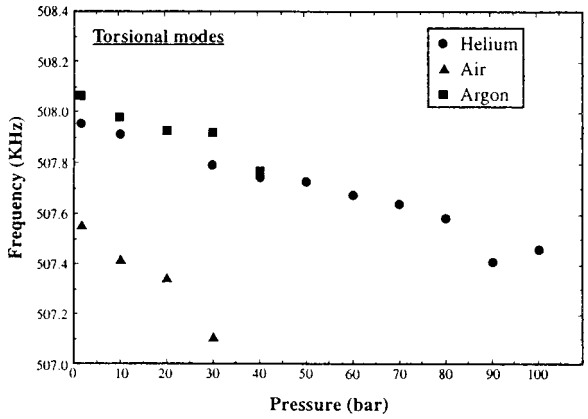

FIG. 7. Resonant frequency versus pressure for fused silica in helium, air, and argon (torsional mode).

shown in Fig. 9. The radiation impedances through the media at each end of the bar are Z_{m0} and Z_{ml}, respectively, and the sound velocity in the solid medium is v. The resonant frequencies of this bar can be obtained by solving the following transcendental equation:[17]

$$\tan Kl = \frac{i(Z_{m0}/\rho_l v + Z_{ml}/\rho_l v)}{1+(Z_{m0}/\rho_l v)(Z_{ml}/\rho_l v)}, \tag{1}$$

where $K=\omega/v$, with ω being the angular frequency of vibration.

For our case, the media at both ends are the same, and we may therefore take

$$Z_{m0}=Z_{ml}=Z_m=R_m+iX_m,$$

which allows Eq. (1) to be expressed as

$$\tan Kl = \frac{2iZ_m/\rho_l v}{1+(Z_m/\rho_l v)^2}. \tag{2}$$

It can be assumed that for our samples and the surrounding gases used, the following conditions hold: $R_m \ll \rho_l v$ and $X_m \ll \rho_l v$. Therefore, Eq. (2) simplifies to the following form:

$$\tan Kl = 2i\,\frac{Z_m}{\rho_l v}. \tag{3}$$

Now the remaining problem is to find Z_m for the three pairs of opposite faces of our rectangular parallelepiped sample.

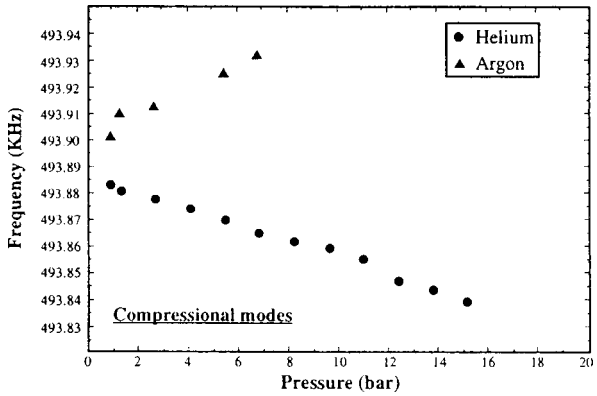

FIG. 8. Resonant frequency versus pressure for fused silica in helium and argon (compressional mode).

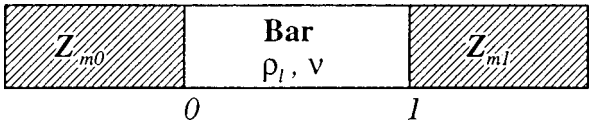

FIG. 9. A bar with a linear density of ρ_l, a length of l, sound velocity v, and radiation impedances of Z_{m0} and Z_{ml} at each end, respectively.

B. Radiation impedance of a vibrating piston

Before determining the radiation impedance of a rectangular piston with the surface moving uniformly or as a sine or cosine function, we shall review the procedure for evaluating the radiation impedance of a circular piston, moving uniformly in an infinite baffle.

1. Circular piston with uniform motion

When a piston is vibrating, it will set up acoustic pressure waves in a surrounding medium which will lead to reaction forces exerted by the medium on the driving surface (the piston itself). This causes an additional impedance for the vibration of the piston. In calculating the reaction force, let us consider an infinitesimal area dS of the surface of the piston as shown in Fig. 10. The increment in pressure that the motion of dS produces in the medium at a point adjacent to some other element of area of the piston, dS', can be written as[18]

$$dp = (i\rho ck/2\pi r)U_0\, dS\, \exp(i(\omega t - kr)), \tag{4}$$

where ρ is the density of the medium, c is the sound velocity in the medium, $k=\omega/c$ is the wave vector of the acoustic wave in the medium, r is the distance along the surface of the piston between dS and dS', U_0 is the amplitude of the piston velocity, and ω is the angular frequency of the vibration. The total acoustic pressure p in the medium adjacent to dS' can then be obtained by integrating expression (4) over the surface of the piston:

$$p \int\int \frac{i\rho ck}{2\pi r}\, U_0\, \exp(i(\omega t - kr))\, dS. \tag{5}$$

Now the total reaction force acting on the piston due to the medium can be obtained by integrating p over the piston:

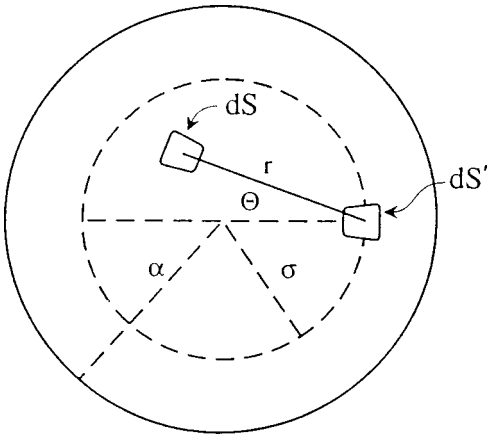

FIG. 10. A circular piston mounted on an infinite baffle with uniform motion in the z direction.

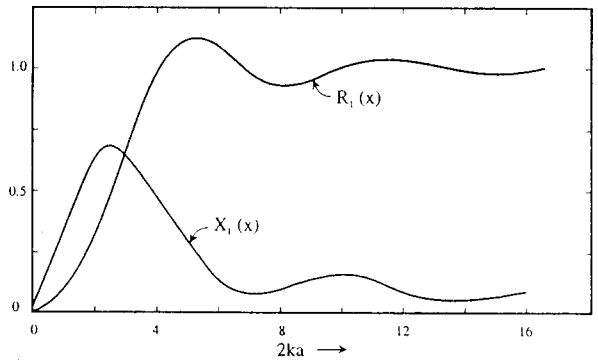

FIG. 11. Radiation resistance function $R_1(2ka)$ and radiation reactance function $X_1(2ka)$ for a cylindrical piston undergoing uniform motion.

$$f_m = -\int\int p\, dS' = -\frac{i\rho ck}{2\pi} U_0 \exp(i\omega t) \cdot \int\int dS' \int\int \frac{\exp(-ikr)}{r}\, dS. \tag{6}$$

Since the reaction force acting on the element dS' due to the motion of dS is the same as the force acting on dS due to the motion of dS', the result of the double integration in Eq. (6) will be twice as much as what would be obtained if the limits of integration were chosen to include the force due to each pair of elements only once. The choice of integration limits shown in Fig. 10 will considerably simplify the problem and therefore the resulting integral needs to be multiplied by a factor of 2:

$$f_m = -\frac{i\rho ck}{\pi} U_0 \exp(i\omega t) \int_0^a \sigma\, d\sigma \int_0^{2\pi} d\psi \int_{-\pi/2}^{\pi/2} d\theta \times \int_0^{2\sigma\cos\theta} \exp(-ikr)\, dr, \tag{7}$$

where a is the radius of the piston. The above integration results in

$$f_m = -\rho c\pi a^2 U_0 \exp(i\omega t)[R_1(2ka) + iX_1(2ka)], \tag{8}$$

where $R_1(x)$ and $X_1(x)$ are piston impedance functions defined as

$$R_1(x) = \frac{x^2}{2\cdot 4} - \frac{x^4}{2\cdot 4^2\cdot 6} + \frac{x^6}{2\cdot 4^2\cdot 6^2\cdot 8} - \cdots, \tag{9}$$

$$X_1(x) = \frac{4}{\pi}\left(\frac{x}{3} - \frac{x^3}{3^2\cdot 5} + \frac{x^5}{3^2\cdot 5^2\cdot 7} - \cdots\right). \tag{10}$$

A common way of defining the radiation impedance of the piston is to set it equal to the ratio of the force exerted by the piston on the medium to the velocity of the piston. When the force and velocity vary over the piston, however, the impedance should be evaluated from the (complex) power divided by the square of the velocity amplitude averaged over the piston area. For the special case of a uniformly moving piston, this approach yields the same impedance as the simple force-to-velocity ratio since the velocity can be factored out of the integrals. We shall first use the simple approach in what follows, and then use the power to evaluate Z_m for the square piston. Thus, for the uniformly moving cylindrical piston in an infinite baffle, we write

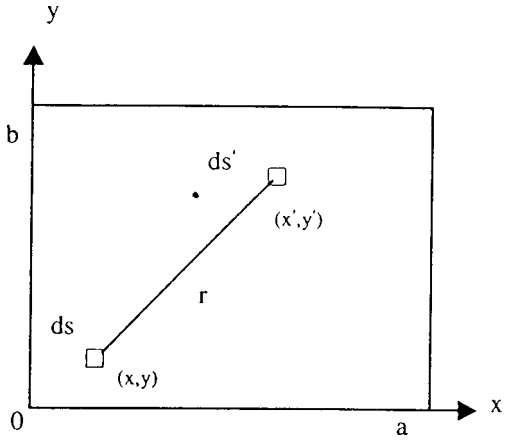

FIG. 12. A rectangular piston with dimensions of $a\times b$, and its surface vibrating in various modes in the z direction.

$$Z_m = \frac{-f_m}{U_0 \exp(i\omega t)} = \rho c\pi a^2[R_1(2ka) + iX_1(2ka)]. \tag{11}$$

The functions $R_1(2ka)$ and $X_1(2ka)$ are plotted in Fig. 11. The real part of the radiation impedance Z_m is called the radiation resistance R_m and the imaginary part the radiation reactance X_m. Therefore, for a circular piston mounted in an infinite baffle, we have

$$R_m = \rho c\pi a^2 R_1(2ka) \tag{12}$$

and

$$X_m = \rho c\pi a^2 X_1(2ka). \tag{13}$$

Notice that these are just equal to the piston impedance functions multiplied by the area of the pistons πa^2 and the acoustic impedance of the medium ρc.

Although the material that was presented in this section is well known, it was presented in order to acquaint the reader with the mathematical devices used to solve the circular baffle problem and which will be used for the rectangular piston in the following section. Other authors have used somewhat different approaches.[19,20]

2. Rectangular piston with motion in different modes

The radiation of sound from a vibrating rectangular piston has been addressed by several researchers.[21–25] However, the authors are not aware of any work which explicitly calculates the complex impedance for the nonuniform motion of a rectangular piston. Let us consider a rectangular piston which is vibrating in a particular mode in the z direction, as shown in Fig. 12. The velocity in the z direction of the area element dS located at position (x,y) is denoted by $U(x,y)\exp(i\omega t)$, and the distance between the element dS and dS' is

$$r = \sqrt{(x-x')^2 + (y-y')^2}. \tag{14}$$

Similar to the case of the circular piston, the increment in pressure that the motion of dS produces in the medium at dS' can be written as

$$dp = \frac{i\rho ck}{2\pi} U(x,y) \frac{\exp(i(\omega t - kr))}{r} dS. \tag{15}$$

Since the motion of the piston in the z direction is no longer uniform, the total pressure exerted by the medium at position (x',y') due to the vibration of the whole piston is

$$p(x',y') = \int\int \frac{i\rho ck}{2\pi} U(x,y) \frac{\exp(i(\omega t - kr))}{r} dS, \tag{16}$$

where, in contrast to Eq. (5), the velocity is not uniform but is allowed to vary with position.

As mentioned in the paragraph preceding Eq. (11), instead of calculating the total force exerted by the medium on the piston as in the case of the circular piston in uniform motion, one should consider the total power radiated by the vibrating rectangular piston in order to obtain the radiation impedance. The complex power radiated is given by the product of the complex pressure amplitude times the velocity amplitude, i.e.,

$$P = -\int\int U(x',y') p(x',y') dS', \tag{17}$$

where it is understood that the factor $\exp(i\omega t)$ is now dropped in $p(x',y')$. Substituting Eq. (16) into Eq. (17), one obtains

$$P = -\frac{i\rho ck}{2\pi} \int\int U(x',y') dS' \int\int U(x,y) \times \frac{\exp(-ikr)}{r} dS. \tag{18}$$

In evaluating the integral in Eq. (18), one needs the velocity of the area element on the piston located at (x,y) for various modes. For simplicity, here we consider only two modes: the torsional mode A_{1u} and the compressional mode A_{1g}, as illustrated in Fig. 13. For comparison, the integral is also evaluated for uniform motion of the piston. It can be seen from Fig. 13 that, for the torsional mode,

$$U(x,y) = U_0 \sin(\alpha x)\sin(\beta y) \tag{19}$$

is a good approximation[26] for the velocity of area element dS at (x,y), where U_0 is a constant and α and β are wave vectors in the piston with $\alpha = \pi/a$ and $\beta = \pi/b$. Similarly, for the compressional mode,

$$U(x,y) = U_0 \cos(\alpha x)\cos(\beta y); \tag{20}$$

and for uniform motion,

$$U(x,y) = U_0. \tag{21}$$

In the Cartesian coordinates shown in Fig. 12, the integral to be evaluated for a rectangular piston with dimensions of a and b $(a > b)$ has the following form:

$$I(k) = -ik \int_{-a/2}^{a/2} dx' \int_{-b/2}^{b/2} dy' \int_{-a/2}^{a/2} dx \int_{-b/2}^{b/2} dy\, U(x',y') U(x,y) \frac{\exp(-ik\sqrt{(x-x')^2+(y-y')^2})}{\sqrt{(x-x')^2+(y-y')^2}}. \tag{22}$$

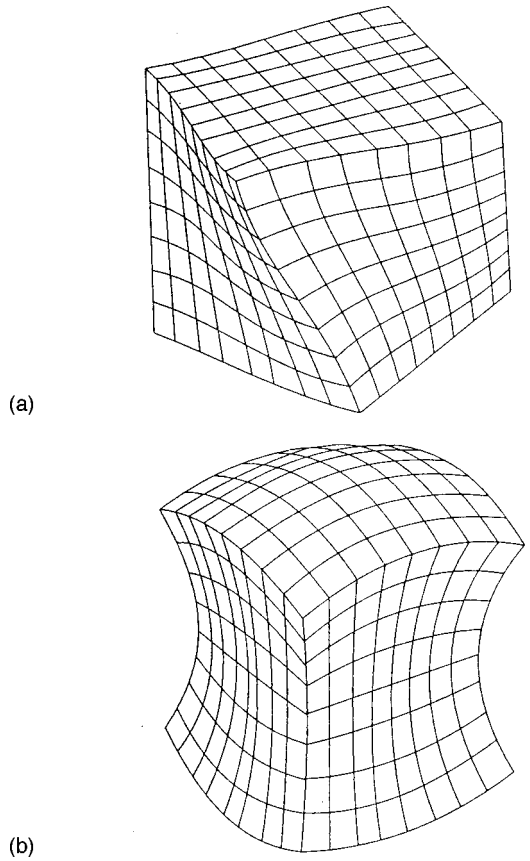

FIG. 13. Resonances of a cubic sample in (a) torsional mode A_{1u} and (b) compressional mode A_{1g}.

The analytical evaluation of the integral in Eq. (22) could be rather difficult, especially for the two nonuniform modes. In the following, we will show how to evaluate this integral numerically. It should be noticed that the integrand diverges at the origin of the Cartesian coordinates, and it is quite computer-time consuming to numerically carry out this fourfold integral. Therefore, a change of variables was undertaken in order to get around the divergence and to permit the analytical integrations which reduce the integral from fourfold to twofold. First, it can be shown that by letting

$$z = x \pm x', \quad z' = y \pm y',$$

and introducing

$$f(|z|,|z'|) = \frac{\exp(-ik\sqrt{z^2+z'^2})}{\sqrt{z^2+z'^2}},$$

we can rearrange the integral over x and x' and integrate analytically to obtain

$$\int_{-a/2}^{a/2} dx' \int_{-a/2}^{a/2} dx\; U(x,x') f(|x-x'|,|z'|) = U_0 \int_0^a dz\; f(|z|,|z'|) g_\alpha(a,z),$$

where

$$g_\alpha(a,z)=(a-z)\left(\cos(\alpha z)\mp\frac{\sin(\alpha(a-z))}{\alpha(a-z)}\right),$$

with the $-$ sign taken for the torsional mode, and the $+$ sign taken for the compressional mode. [For the uniform mode, $g_\alpha(a,z)\equiv 1$.] Thus, the fourfold integral in Eq. (22) is replaced by

$$I(k)=-ikU_0^2\int_0^b dz'\int_0^a dz\; g_\alpha(a,z)g_\beta(b,z')f(|z|,|z'|), \tag{23}$$

which is a twofold integral and requires much less computing time for numerical evaluation.

The straightforward numerical integration over z and z' in the above equation is frustrated by the $\rho=\sqrt{z^2+z'^2}$ factor in the denominator of the integrand which causes the integrand to diverge at the origin. For the circular piston this factor is cancelled by the same factor in the cleverly chosen differential surface element. We can take advantage of the same clever procedure by employing circular coordinates ρ and θ such that $z=\rho\cos\theta$ and $z'=\rho\sin\theta$. Using these variables, we can cast Eq. (23) into the form

$$\begin{aligned}I(k)=-ikU_0^2\Bigg(&\int_0^{\theta_0}d\theta\int_0^{a/(\cos\theta)}d\rho\\&\times\exp(-i\rho k)g_\alpha(a,\rho\cos\theta)g_\beta(b,\rho\sin\theta)\\&+\int_0^{\pi/2-\theta_0}d\phi\int_0^{b/(\cos\phi)}d\rho\\&\times\exp(-i\rho k)g_\alpha(a,\rho\sin\phi)g_\beta(b,\rho\cos\phi)\Bigg),\end{aligned} \tag{24}$$

where $\theta_0=\tan^{-1}(b/a)\leqslant\pi/4$ and $\phi=\pi/2-\theta$.

It is convenient to express $I(k)$ in terms of dimensionless impedance functions $R(ka)$ and $X(ka)$, as follows:

$$I(k)=2\pi CU_0^2ab(R(ka)+iX(ka)), \tag{25}$$

where we choose $C=1$ for the uniform mode [Eq. (21)] and $C=\frac{1}{4}$ for the sine and cosine modes [Eqs. (19) and (20)]. Although we have written R and X as explicit functions of ka, they also depend implicitly upon the aspect ratio a/b. The functions $R(ka)$ and $X(ka)$ for one face of the sample are shown in Figs. 14 and 15. Note that the introduction of the coefficient C in Eq. (25) results in $R(ka)$ having an asymptotic value equal to 1 for all modes.

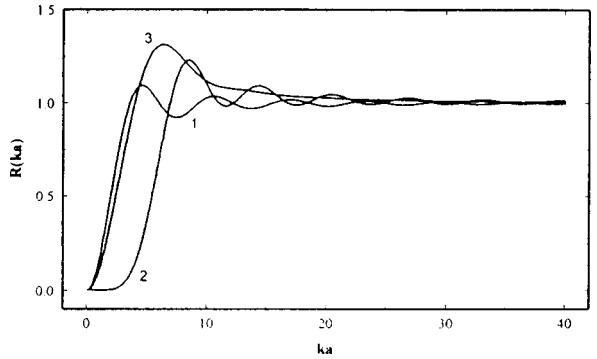

FIG. 14. Radiation resistance function $R(ka)$ for (1) $U(x,y)=U_0$, (2) $U(x,y)=U_0\sin(\alpha x)\sin(\beta y)$, and (3) $U(x,y)=U_0\cos(\alpha x)\cos(\beta y)$. As seen in Eqs. (30) and (31), $R(ka)$ is related to the energy radiated into the surrounding gas.

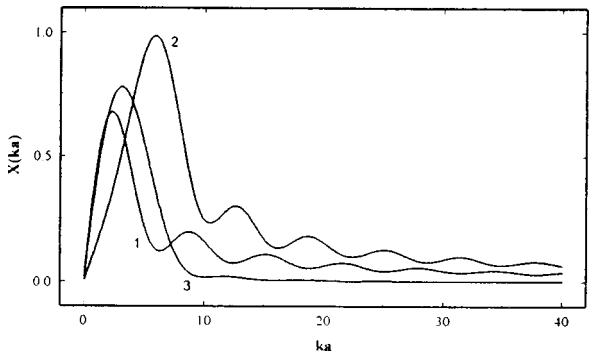

FIG. 15. Radiation reactance function $X(ka)$ for (1) $U(x,y)=U_0$, (2) $U(x,y)=U_0\sin(\alpha x)\sin(\beta y)$, and (3) $U(x,y)=U_0\cos(\alpha x)\cos(\beta y)$. As seen in Eq. (33), $X(ka)$ is related to the frequency shift due to mass loading by the surrounding gas.

The radiation impedance, Z_m, is related to $R(ka)$ and $X(ka)$ by the expression

$$Z_m=\rho cab(R(ka)+iX(ka)), \tag{26}$$

which follows directly from the prescription that the impedance is the complex power P divided by the square of the velocity amplitude $U(x,y)$ averaged over the area of the piston. This prescription is equivalent to calculating the impedance as the ratio F/U_0, where F is the amplitude of the force in mode pattern (α,β). For example, in the case of torsional modes, if we expand the pressure pattern as

$$p(x,y)=\sum_{n,m}p_{nm}\sin\left(\frac{n\pi x}{a}\right)\sin\left(\frac{m\pi y}{b}\right), \tag{27}$$

then $F=-p_{11}ab$ for the mode of interest in which $\alpha=\pi/a$ and $\beta=\pi/b$. From Eqs. (17) and (27) it is then easy to show that $P/(\int U(x,y)^2\,dxdy/ab)=F/U_0$. Note that Eq. (26) is similar to Eq. (11) for the case of the circular piston, and that the radiation impedance is proportional to ρc times the area of the piston, regardless of the mode of vibration.

The results shown in Figs. 14 and 15 are somewhat unexpected. In Fig. 14 the asymptotic value of $R(ka)$ for all three cases is 1. If we were to plot the values obtained for the integral $I(k)$ from Eq. (24), the asymptotic values would be four times larger for the uniform mode than for the sine and cosine modes. However, we are not interested in these values *per se*, but in the values of Z_m that are obtained by dividing the complex power by the square of the velocity averaged over the area of the piston. The complex power is equal to $\rho cI(k)/2\pi$, but the velocity average gives U_0^2 for the uniform mode and $\frac{1}{4}U_0^2$ for the sine and cosine modes. Thus, after the division, one obtains the same asymptotic value for all three cases.

There are features in the individual curves which are also interesting. For instance, we have the following:

(1) The R values for the sine curves are negligibly small up to values of $ka \simeq 2$, while the other curves increase as $(ka)^2$.
(2) The R and X values for both the uniform and sine modes exhibit gradually decaying oscillations for ka values larger than 15, while the cosine mode shows no perceptible oscillations past this value of ka.
(3) The period of the oscillation appears to be $ka = 2\pi$.

The first feature is related to the fact that the sine mode is antisymmetric and therefore the four quarters of the rectangular faces are effectively vibrating as a quadrupole source, which cancels the power radiation for large wavelengths or small values of ka, apparently up to $ka \simeq 2$. The last two features are interrelated. The piston faces are assumed to be vibrating in a semi-infinite baffle. Only the cosine mode does not exhibit a discontinuity in velocity and displacement at its boundaries with respect to the semi-infinite baffle. It is discontinuities that usually provoke oscillations in response functions. Therefore, the smooth transition of the cosine mode eliminates oscillations in the Fourier transform into frequency space. The integrals that are being performed are effectively Fourier transforms of the displacement functions (weighted by a $1/r$ factor). Following this line of reasoning, then, one may say that the oscillations in X and R for the sine and uniform modes are associated with the Fourier transform of the displacement of the faces and the discontinuities at the boundaries. The period of the modulation then should go as 2π, similar to the results for a cylindrical piston, which exhibit Bessel function dependence for large values of ka. Notice also that the piston impedance functions shown in Fig. 11 have the same period with respect to kd, where $2a = d$, the diameter of the piston.

The oscillations observed in Figs. 11, 14, and 15 may also be understood from an argument based on Babinet's principle. According to this principle, the pressure field above a vibrating piston that is contained in an infinite baffle is equal to the pressure field due to an entire vibrating plane minus the pressure field due to the (fictitious) vibrations of the infinite planar region consisting of only the baffle, with the piston regarded as stationary. Now, the pressure field from the entire vibrating plane equals $\rho c U(x,y)$ at the piston. This contribution by itself results in values of R and X appropriate to the asymptotic regime, namely $R(ka) = 1$ and $X(ka) = 0$. Departures from these values must therefore arise from the pressure field due to the (fictitious) vibrating infinite baffle. However, this pressure field in the region of the piston that is well away from the baffle is small because the distance to the baffle is much greater than the wavelength in the gas, and hence there is a great deal of cancellation due to the $r^{-1} \exp(-ikr)$ factor modulating the various contributions. [See, for example, Eq. (15).] On the other hand, the vibrating baffle creates a substantial pressure field near the edge of the piston because the $r^{-1} \exp(-ikr)$ factor will not effectively cancel-out contributions at positions within a few wavelengths, $2\pi/k$, from the edge. It follows that the significant departures from the asymptotic $R(ka)$ and $X(ka)$ values arise predominantly from regions within a few wavelengths from the edge of the piston. These contributions are relatively large when the piston (and hence, the fictitious baffle) has a relatively large displacement at the edge. This effect is further magnified because the $R(ka)$ and $X(ka)$ are proportional to the real and imaginary parts of the complex power, respectively, and the latter is found by integrating the product of pressure and velocity over the piston area. It follows that modes for which the displacement field is relatively large at the edge of the piston will have relatively large oscillations in $R(ka)$ and $X(ka)$. This is in qualitative agreement with the patterns observed in Figs. 11, 14, and 15.

In the next section we will use our calculated impedances for each face of the vibrating rectangular parallelepiped sample. In effect we are treating the six faces of the sample as independently vibrating pistons. This simple approach is justified because the wave vector α on the faces of the parallelepiped is about an order of magnitude smaller than the wave vector k in the gas. That is, the wavelength of the sound radiated in the gas is about an order of magnitude smaller than the dimensions of the faces of the parallelepiped since the sound velocity in the gas is about an order of magnitude smaller than in fused silica. Thus, we may think of the faces as independently vibrating pistons because their directivity pattern is mostly in the forward direction in the $ka \gg 1$ regime, which is the regime appropriate to the experimental measurements.

III. COMPARISON WITH EXPERIMENTAL RESULTS

In order to compare the above theoretical results to the experimental data, one needs to calculate the attenuation coefficient α, or the quality factor Q_r due to the radiation resistance, and the mass loading Δm, or the frequency shift Δf due to the radiation reactance. We start with the transcendental equation (3) obtained earlier in the two-dimensional model:

$$\tan Kl = 2i(Z_m/\rho_l v),$$

which, for $|Kl - n\pi| \ll 1$, becomes

$$\tan Kl \simeq Kl - n\pi = 2i(Z_m/\rho_l v),$$

and therefore

$$Kl = 2i(Z_m/\rho_l v) + n\pi. \tag{28}$$

Since K and Z_m are complex, one may let

$$K = K + i\alpha,$$

and with

$$Z_m = R_m + iX_m$$

Eq. (28) becomes

$$Kl + i\alpha l = -2X_m/\rho_l v + n\pi + 2iR_m/\rho_l v. \tag{29}$$

From the imaginary part of Eq. (29), one obtains

$$\alpha = 2R_m/\rho_l l v = 2R_m/M_B v,$$

where M_B is the mass of the bar. Since α is the attenuation coefficient per unit length, we find that the attenuation coefficient per unit time is given by

$$\alpha' = 2R_m/M_B.$$

The quality factor Q_r can now be calculated as the ratio of the angular frequency ω over $2\alpha'$, which gives

$$Q_r = \omega M_B / 4R_m.$$

Now, from Eq. (26) we have for the rectangular piston,

$$R_m = \rho c a b R(ka)$$

and (30)

$$X_m = \rho c a b X(ka).$$

Therefore,

$$Q_r = \frac{\omega M_B}{4R_m} = \frac{\omega M_B}{4\rho c a b R(ka)}, \tag{31}$$

and, since $R(ka)$ is approximately constant for values of $ka > 10$ (this is the range of values for ka in the experimental data presented in Sec. I), we see that

$$1/Q_r \propto \rho c, \tag{32}$$

where ρ is the density of the medium and c is the sound velocity in the medium. From the above relation, it is easy to see that the pressure dependence of the Q factor is

$$1/Q_r \propto p$$

since ρ is proportional to the pressure p of the surrounding gas, and c is independent of p. This is in agreement with the data shown in Figs. 4 and 5. In addition, one also finds that

$$1/Q_r \propto M^{1/2}$$

as ρ is proportional to the molecular mass of the surrounding gas M, and c is proportional to $\sqrt{1/M}$. This result is in agreement with the data shown for the compressional mode in Fig. 6.

From the real part of Eq. (29), one may calculate the mass loading due to the radiation reactance X_m as follows. The real part of Eq. (29) gives

$$Kl = -2X_m/\rho_l v + n\pi,$$

which results in a shift in the wave vector ΔK:

$$\Delta K l = -2X_m/\rho_l v.$$

Thus, we have

$$\Delta K = -\frac{2X_m}{\rho_l l v} = -\frac{2X_m}{M_B v} = -\frac{2X_m K}{M_B \omega}$$

or

$$\frac{\Delta K}{K} = -\frac{2X_m}{M_B \omega} = -\frac{2\Delta m}{M_B},$$

where $\Delta m = X_m/\omega$ is the mass loading. From the relation

He	2.98×10^4	3.14×10^4

$$\frac{\Delta K}{K} = \frac{\Delta\omega}{\omega} = \frac{\Delta f}{f},$$

we may calculate the resonant frequency shift Δf as

$$\frac{\Delta f}{f} = -\frac{2\Delta m}{M_B}$$

or

$$\Delta f = -\frac{X_m}{\pi M_B} = -\frac{\rho c a b X(ka)}{\pi M_B}. \tag{33}$$

To obtain the quality factor Q_r and the frequency shift Δf for the rectangular parallelepiped sample, we note that Eqs. (31) and (33) take into account the effects of a single pair of opposite faces of the sample. Therefore, to incorporate contributions due to all sets of faces, we average the Δf and $1/Q_r$ results over each of the three pairs of opposite faces. (An alternative approximation scheme would weigh the contributions from each pair of faces by the fraction of the total energy residing in the displacement field associated with each pair of faces. The final result would not be significantly different, however.) The reason that an average is required rather than a sum is that the vibration of each set of faces is associated with a different component of velocity. Therefore, the vibrations associated with each additional set of faces contributes both power radiated *and* energy stored. However, since $1/Q_r$ is proportional to the total power radiated divided by the total energy stored per cycle, it follows that an average of the contributions from each set of faces is the relevant quantity.[27] Similarly, the frequency shift can be understood as a mass loading on each face, but the net effect on the dynamics of the rectangular parallelepiped sample is approximated by a simple average within our two-dimensional model.

Now let us compare the quality factor of resonance Q_r and the frequency shift Δf measured experimentally to those calculated using Eq. (31) and Eq. (33) and the simple averaging process described in the previous paragraph. Table I gives the results of Q_r for the torsional mode for three different surrounding gases, and Table II shows the results for the compressional mode. It can be seen that the Q_r's calculated from Eq. (31) have the same order of magnitude as those of the experimental results for both modes, but the

result of the torsional mode in helium agrees the best. Table III summarizes the results of Δf for the torsional mode for three different surrounding gases, while Table IV is the result for the compressional mode. For the compressional mode, the model predicts Q's that are within a few percent of the experimentally obtained ones and the changes in resonance frequency are one or two orders of magnitude lower than the measured ones. Therefore, for this mode it may be assumed that mass loading does not affect the values that would be deduced for the third-order elastic constants. However, the results are different for the torsional mode, where the theoretical Q's are as much as three and a half times lower than seen experimentally, and the theoretical changes in frequency are somewhere between a quarter and a twelfth of the experimental ones. Therefore, a better model has to be developed for these modes, since it appears that mass loading could make a significant contribution to the estimated third order elastic constant.

Since the typical ka values for the experiment are in the range $ka \approx 10$ to $ka \approx 35$, our calculated values of the frequency shifts are somewhat sensitive to the oscillations in the $X(ka)$ curves. It therefore follows from our discussion at the end of Sec. II concerning the sources of these oscillations that before definitive statements can be made about the effects of radiation impedance on the observed frequency shifts, calculations have to be performed for unbaffled pistons, and a better theoretical model has to be developed for the vibrating rectangular parallelepiped. However, it can be safely said that the present model accurately predicts the pressure dependence for the inverse of Q, and also predicts an increase in $1/Q$ with the increasing molecular mass of the surrounding gas.

At present, data are being collected on a spherical sample, which is more amenable to the actual calculation of the radiation impedance in three dimensions. The authors are also performing an *ab initio* calculation of the resonant modes of a sphere in a gas atmosphere and are developing a three-dimensional model for determining the radiation impedance of a rectangular parallelepiped.

[26] The trigonometric function forms are used for the piston displacements in order to clearly demonstrate the consequences of the symmetries involved. These trigonometric functions are the leading terms of a series expansion of the exact solutions of the motion of the individual surfaces. However, it is felt that in view of the nature of the approximations used, the summation of the entire series is not warranted since the corrections produced by the absence of the summation would be comparable to those incurred by assuming a baffled solution.
[27] In an accurate calculation of Q, one would use the actual displacement field at each point within the sample to compute the total energy stored. Our more approximate approach avoids the necessity of dealing with the precise details of the displacement field inside the sample.

A new approximation method for thermoacoustic calculations

Richard Raspet, James Brewster, and Henry E. Bass
National Center for Physical Acoustics and Department of Physics and Astronomy, University of Mississippi, University, Mississippi 38677

(Received 27 November 1996; revised 21 January 1998; accepted 24 January 1998)

In many cases, it is convenient to have approximate relations to evaluate thermoacoustic gain and efficiency. G. W. Swift [J. Acoust. Soc. Am. **84**, 1145–1180 (1988)] has provided such relations for short stacks in a standing wave. This paper describes an approximation method based on a finite difference form of the thermoacoustic equations and provides results for thermoacoustic engines or refrigerators for both standing and traveling waves. The short stack assumption is retained. The method is limited at present to linear temperature gradients across the stack. The calculations are compared to measurements and in the appropriate limits to Rott's boundary conditions for a temperature discontinuity [N. Rott, Adv. Appl. Mech. **20**, 135–175 (1980)]. The approximation is applied to both thermoacoustic prime movers and thermoacoustic refrigerators. © *1998 Acoustical Society of America.* [S0001-4966(98)03605-4]

INTRODUCTION

Swift's short stack approximation[1] has found wide application in explaining thermoacoustic phenomena in resonant tubes. In short, a uniform standing wave is assumed, and the work per unit volume is calculated using the gas properties at the center of the stack. This method has not been successfully applied to traveling wave devices or devices with both standing and traveling waves since there is no *a priori* way to apportion the work between the transmitted and reflected waves.

Atchley *et al.*[2] modeled the acoustic gain in a resonant thermoacoustic system by treating the second-order differential equation for acoustic pressure as a wave equation with constant coefficients. The free space wave number was used to calculate the complex compressibility. The results are readily expressed in terms of waves traveling in opposite directions. This approach leads to good predictions of quality factor and resonant frequency as a function of temperature difference across the stack. Atchley[3] reexamined the data from Ref. 2 using an energy-based standing wave short stack approximation which incorporated changes in gas properties through the stack, and improved the fit of theory to data.

Raspet *et al.*[4,5] developed an energy-based short stack traveling wave approximation and applied this theory to measurements on a traveling wave tube. Subsequent research demonstrated that this method failed in the Stirling regime.[6] We have attempted to apply and extend the calculational method of Ref. 2, only to find the method failed as the pore size was decreased. Other wave-based approximations we developed were valid for small stack pores, but failed for wider pore spaces. The goal of this paper is to develop an approximate method which will provide quick estimates of thermoacoustic performance while retaining the concept of counter-propagating waves necessary to develop an understanding of the relation between standing wave and traveling wave thermoacoustics. As such, this paper is a continuation of the research begun in Ref. 2 and for consistency will utilize the experimental results of that paper.

I. THEORY

The calculations of this paper are based on the formulation of Arnott *et al.*,[7] which express the thermoacoustic equations in terms of the thermoviscous function $F(\lambda)$, commonly used in the literature of sound propagation through porous media. This notation is chosen rather than Rott's since the notation and relevant approximations have been well developed in the analysis of sound propagation through a wide variety of porous media.[8] The translation between the porous media notation used and Rott's notation is presented in Appendix A. For parallel plate stacks with spacing y_0, $F(\lambda)=1-(2/\lambda\sqrt{-i})\tanh(\sqrt{-i}\lambda/2)$, where $\lambda=y_0(\rho\omega/\eta)^{1/2}$ is the shear wave number and $\lambda_T=y_0(\rho\omega c_p/\kappa)^{1/2}$ is the thermal wave number. The physical parameters of the gas are the density ρ, viscosity η, thermal conductivity κ, and specific heat per unit mass at constant pressure c_p. In small pores, the acoustic pressure is constant across the pore cross section and is a function only of axial distance along the pore. Also, the radial velocity is small with respect to the axial velocity. With these restrictions, an equation for the area-averaged complex axial particle velocity in terms of the pressure gradient is

$$\hat{v}(z)=\frac{d\hat{p}(z)/dz\ F(\lambda)}{i\omega\rho(z)}, \tag{1}$$

where $\rho(z)$ is the density, ω is the angular frequency, and $\hat{p}(z)$ is complex acoustic pressure amplitude.[7] The other equation necessary for our development relates the average axial velocity gradient to the average axial velocity and acoustic pressure. This equation can be developed by combining Eqs. (13) and (28) of Ref. 7 to give

$$\frac{d\hat{v}}{dz}+\frac{1}{T}\frac{dT}{dz}\left[\frac{F(\lambda_T)/F(\lambda)-1}{1-\sigma}\right]\hat{v}+\frac{F(\lambda)}{i\omega\rho(z)}k^2\hat{p}=0, \tag{2}$$

where we have substituted the ideal gas relationship $\beta=1/T$ for the coefficient of thermal expansion. Here k is the wave number in a pore and is given by

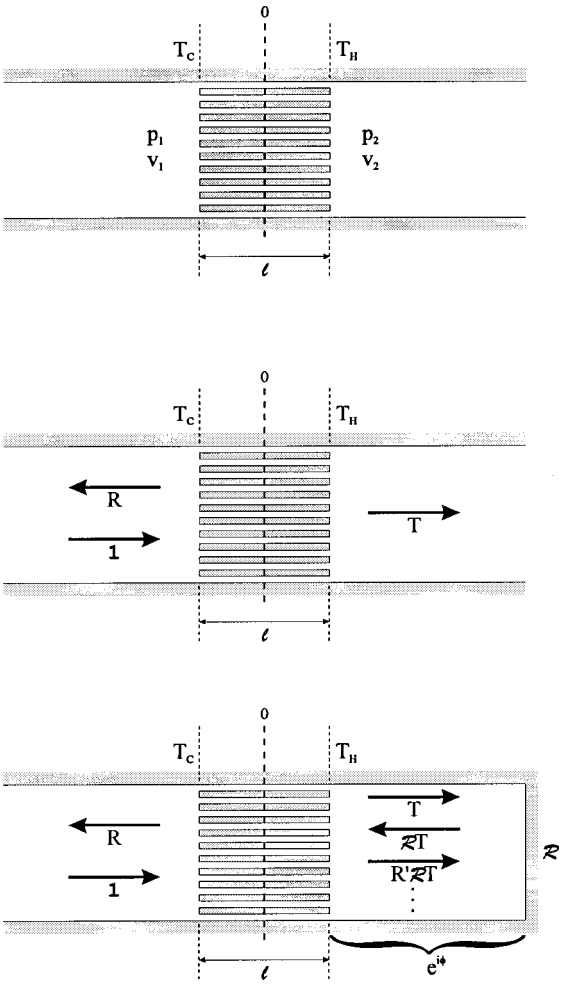

FIG. 1. Idealization of the stack in a thermoacoustic device with (a) the notation used for the finite difference scheme; (b) the notation used for reflection and transmission coefficients for traveling waves; and (c) the notation used for the standing wave gain calculation.

$$k^2=\frac{\omega^2}{c^2}\frac{[\gamma-(\gamma-1)F(\lambda_T)]}{F(\lambda)}, \tag{3}$$

where c is the adiabatic speed of sound in the free field, γ is the ratio of specific heats, and σ is the Prandtl number. Note that this wave number corresponds to the wave number in the pores of the stack and can be much larger than the wave number in free space. Equations (1) and (2) are convenient for an Euler finite difference solution for propagation in the stack. The stacks are typically very short with respect to a wavelength in the porous material, so a single-step Euler calculation can provide a reasonable estimate.

Consider the finite difference form of Eqs. (1) and (2) using average values at the center of the stack [see Fig. 1(a)]:

$$\frac{\hat{p}_2-\hat{p}_1}{l}=iA\frac{\hat{v}_1+\hat{v}_2}{2}, \tag{4}$$

$$iA\frac{(\hat{v}_2-\hat{v}_1)}{l}+iAB\frac{(\hat{v}_2+\hat{v}_1)}{2}+k^2\frac{\hat{p}_1+\hat{p}_2}{2}=0, \tag{5}$$

$$A=\omega\rho/F(\lambda), \tag{6}$$

and

$$B=\frac{1}{T}\frac{dT}{dz}\left[\frac{F(\lambda_T)/F(\lambda)-1}{1-\sigma}\right], \tag{7}$$

where l is the length of the stack. Here A, B, and k^2 are evaluated at the center of the stack, consistent with finite difference methods.

To adjust for the relative porosity of the stack, Ω, we replace $\hat{v}$ with $\hat{v}/\Omega$. Equations (4)–(7) can now be solved to form an impedance translation formula through the stack,

$$\frac{\hat{p}_1}{\hat{v}_1}=\frac{A}{k\Omega}\frac{\left[\frac{\hat{p}_2}{\hat{v}_2}\left(1-\frac{Bl}{2}-\frac{k^2l^2}{4}\right)-i\frac{A}{k\Omega}(kl)\right]}{\left[-i\frac{\hat{p}_2}{\hat{v}_2}kl+\frac{A}{k\Omega}\left(1-\frac{k^2l^2}{4}\right)+\frac{A}{k\Omega}\frac{B}{2}l\right]}. \tag{8}$$

Two ideal cases help us to interpret Eq. (8). The first is the case when $dT/dz=0$; there is no thermoacoustic effect. Then Eq. (8) becomes

$$\frac{\hat{p}_1}{\hat{v}_1}=\frac{A}{k\Omega}\frac{\left[\frac{\hat{p}_2}{\hat{v}_2}\left(1-\frac{k^2l^2}{4}\right)-i\frac{A}{k\Omega}(kl)\right]}{\left[-i\frac{\hat{p}_2}{\hat{v}_2}kl+\frac{A}{k\Omega}\left(1-\frac{k^2l^2}{4}\right)\right]}. \tag{9}$$

Comparison of Eq. (9) with the impedance translation theorem,[9]

$$Z_1=Z_{\text{int}}\frac{[Z_2\cos(kl)-iZ_{\text{int}}\sin(kl)]}{[Z_{\text{int}}\cos(kl)-iZ_2\sin(kl)]}, \tag{10}$$

demonstrates that the finite difference calculation is correct to first order in kl with $Z_{\text{int}}=A/k\Omega$, $Z_1=\hat{p}_1/\hat{v}_1$, and $Z_2=\hat{p}_2/\hat{v}_2$.

A second case is that of a vanishingly short stack with a fixed temperature difference. This corresponds to Rott's boundary condition for a temperature discontinuity.[10] In this limit

$$\lim_{l\to 0} Bl\to\frac{\Delta T}{T_m}\left[\frac{F(\lambda_T)/F(\lambda)-1}{(1-\sigma)}\right], \tag{11}$$

remains finite, and depends only on the total temperature change, while kl approaches zero.

Equation (8) then becomes

$$\frac{\hat{p}_1}{\hat{v}_1}=\frac{\hat{p}_2}{\hat{v}_2}\frac{(1-Bl/2)}{(1+Bl/2)}, \tag{12}$$

where Bl is given by Eq. (11). At the discontinuity, the pressure is continuous so that the boundary condition on particle velocity is

$$\hat{v}_2=\hat{v}_1\frac{(1-Bl/2)}{(1+Bl/2)}. \tag{13}$$

For positive ΔT, Bl has negative real and imaginary parts and therefore $\hat{v}_2$ is greater than $\hat{v}_1$; the wave is amplified in propagating from the cold side to the hot side of the stack.

Rott's boundary condition for a temperature discontinuity can be expressed as

$$\hat{p}_2=\hat{p}_1 \tag{14}$$

and

$$\hat{v}_2 = \hat{v}_1 e^{-B'l}, \tag{15}$$

where

$$B' = \frac{1}{l}\int_0^l \left[\frac{F(\lambda_T)/F(\lambda)-1}{1-\sigma}\right]\frac{1}{T}\frac{dT}{dz}\,dz. \tag{16}$$

The Rott impedance relation is then

$$\frac{\hat{p}_1}{\hat{v}_1} = \frac{\hat{p}_2}{\hat{v}_2}\,e^{-B'l}. \tag{17}$$

Here B' has negative real and imaginary parts for ΔT positive so that Eq. (15) produces a gain in particle velocity for propagation in the direction of positive temperature gradient. For thermoacoustic prime movers with the cold side near room temperature, the thermoviscous functions are slowly varying and the stack length is small with respect to a wavelength. For these conditions Eq. (16) can be approximated by

$$B' \cong \frac{1}{l}\,\frac{F(\lambda_T)/F(\lambda)-1}{1-\sigma}\cdot\frac{\Delta T}{T_m} = B, \tag{18}$$

where the gas properties are evaluated at the center of the stack.

The close agreement between the Euler form for the impedance change due to a short stack [Eq. (12)] and Rott's form [Eq. (17)] can be understood by comparing the series expansion of $(1-x/2)/(1+x/2)$ and e^{-x} with $x=Bl$:

$$\frac{1-x/2}{1+x/2} = 1-x+\frac{x^2}{2}-\frac{x^3}{4}\cdots, \tag{19a}$$

$$e^{-x} = 1-x+\frac{x^2}{2}-\frac{x^3}{6}\cdots. \tag{19b}$$

In the limit of very short stacks, the single-step finite difference agrees with Rott's boundary condition to second order in Bl, and the third-order term differs only by a factor of 1.5.

For Stirling devices, λ is small and

$$\frac{F(\lambda_T)/F(\lambda)-1}{1-\sigma} \approx -1. \tag{20}$$

Rott's integral becomes

$$B' = -\frac{1}{l}\int_0^l \frac{1}{T}\cdot\frac{dT}{dx}\,dx = -\frac{1}{l}\ln\left(\frac{T_H}{T_C}\right). \tag{21}$$

Equation (17) then yields

$$Z_1 = Z_2\,\frac{T_H}{T_C}. \tag{22}$$

An impedance relation similar to Eq. (22) has been derived by Ceperley for Stirling engines.[11]

The single-step finite difference method well approximates three analytic limits for short stacks and moderate $\Delta T/T_m$. In the thermoacoustic regime Bl is about 0.75 for $\Delta T/T_m = 1$; the difference between the expansions in Eqs. (19a) and (19b) is only 4%. In the Stirling limit Bl is close to 1 for $\Delta T/T_m = 1$, but the finite difference method reproduces the Stirling result exactly. The Euler method can be improved by subdividing the stack, and applying the finite difference calculation to the subsections. In the next section, we will compare results from a single-step Euler approximation to results using multiple steps for two realistic examples.

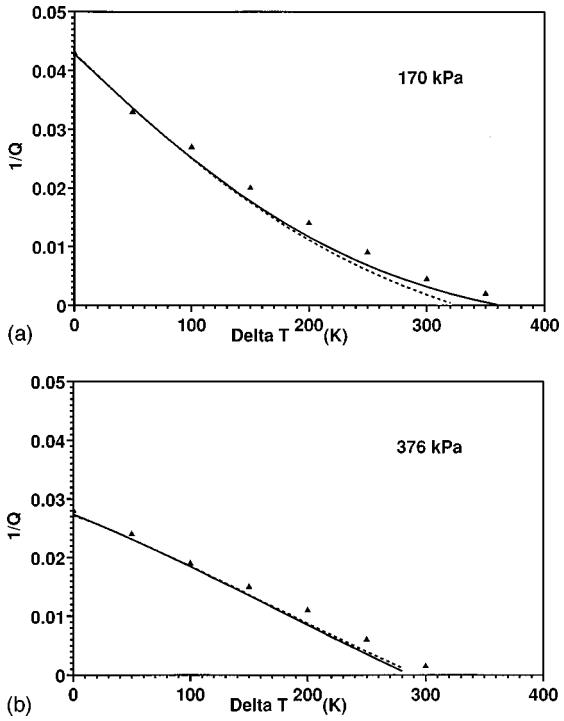

FIG. 2. Graph of $1/Q$ versus the temperature difference across the stack for a prime mover filled with helium. The symbols represent experimental data (Ref. 1). ——— Prediction using the single step Euler approximation for the stack. --- Prediction with two steps. (a) Mean pressure 170 kPa. (b) Mean pressure 376 kPa.

II. APPLICATIONS

A. Prime mover

We demonstrate the accuracy of the single-step Euler's method solution by comparison with a multiple step integration of the equations and previously published experimental data. Atchley *et al.*[2] measured the quality factor of a resonator containing a thermoacoustic prime mover as a function of the temperature gradient across the stack. The apparatus consisted of a cylindrical tube, 1.0 m long and 3.8 cm in diameter, filled with pressurized helium. The stack was 3.5 cm in length and sandwiched between heat exchangers with its hot end located 6.3 cm from the end of the tube.

We calculated the frequency response of this resonator in the following manner. In sections other than the stack, the temperature is uniform and the solution to Eqs. (1) and (2) is

$$p(x) = A^+ e^{+ikx} + A^- e^{-ikx}. \tag{23}$$

In the stack, Eqs. (4) and (5) are applied, either in a single step or in multiple iterations with the stack divided into sections of equal length. The boundary conditions between sections of the device were that the pressure and volume velocity be continuous. The impedance at the ends was taken to be to that of a solid wall.[9]

Figure 2(a) and (b) shows comparison of this calculation to experimental results taken from Ref. 2 in which the am-

bient pressures are 170 and 376 kPa, respectively. The calculation was performed using one step, and two steps to span the stack.

In general, the Euler method approximation predicts the behavior of the experimental data. The prediction overestimates the quality factor as the system approaches onset. The direction of this error is consistent with extra losses in the experiment or a nonzero temperature difference between the heat exchanger and the stack. The error is comparable for both cases displayed. The 170-kPa case [Fig. 2(a)] displays a significant but small difference between the one-step and two-step Euler methods. Calculations with three steps cannot be distinguished from the two-step calculation. As a diagnostic, the magnitude of kl and Bl were printed out. The one-step and two-step results differ noticeably only when $|kl| > 0.3$. The single-step approximation is still useful for initial design purposes when $|kl| \cong 0.5$.

In Atchley *et al.*,[2] the authors reduced the porosity of the stack from its true value of 0.76 to an effective value of 0.53. This was justified on the basis that the pores of the stack and its neighboring heat exchangers did not form continuous ducts but were offset. The value chosen for the porosity reflected the estimated extent of the blockage resulting from this offset. The reduced porosity provided better agreement between measurements and calculations, especially near onset. The calculations reported here agree with experimental results reasonably well without using a modified porosity.

In a later paper,[3] Atchley reanalyzed this data using an extension of Swift's short stack approximation involving integrals of the varying gas properties through the stack. The success of the single-step approximation reported here indicates that changing gas properties in the stack are a small perturbation.

B. Refrigeration

The finite difference approach to thermoacoustics can also be applied to the analysis of refrigeration stacks. The temperature gradient is typically less than that in a prime mover but the stack is often longer. Refrigeration technology is not limited to stacks driven by standing waves and we will demonstrate that the single-step approximation extends to cases where there is a significant traveling wave component present. Hofler has reported on a similar analysis using a different calculational method.[12]

Consider the general case of a thermoacoustic refrigeration stack. We wish to determine the coefficient of performance (CoP), defined by

$$\mathrm{CoP} = \frac{Q_C}{W_C - W_H}, \tag{24}$$

where Q_C is the heat flow at the cold end and W_H and W_C are the work flows at the hot and cold ends, respectively. In any particular device, the amplitude and phase of the pressure and velocity on each side of the stack are determined by the design of the resonator and driver in addition to the response of the stack. Here the problem is approached in a more general manner by taking the pressure and velocity to be known at one end. If the pressure and velocity are known, then the heat and work flows can be found by substitution into Eqs. (11), (47), and (48) of Ref. 7:

$$W = \frac{A_{\mathrm{res}}}{2} \mathrm{Re}(\hat{v}\hat{p}^*), \tag{25}$$

$$Q = \frac{A_{\mathrm{res}}}{2} \frac{1}{1+\sigma} \mathrm{Re}\left(\hat{v}\hat{p}^*\left(\frac{F^*(\lambda_T)}{F(\lambda)} - 1\right)\right) - \frac{A_{\mathrm{res}}}{2} \frac{dT}{dx} \frac{c_p}{\omega} \left(\left|\frac{\hat{v}}{F(\lambda)}\right|\right)^2 \frac{\rho}{1-\sigma^2} \mathrm{Im}(F^*(\lambda_T) + \sigma F(\lambda)), \tag{26}$$

where W is the work flow, Q is the heat flow, A_{res} is the cross-sectional area, and c_p the heat capacity at constant pressure. For the purpose of this demonstration the porosity is set equal to unity so the velocity can be assumed continuous between the stack and its surroundings. If we choose the cold end to be the end at which the pressure and velocity are known, then the only quantity in Eq. (24) dependent on the propagation model employed to span the stack is W_H.

Arguments based on similitude[13] show that for a given value of λ_T the results are independent of the frequency if the stack length is expressed in units of the wavelength at a fixed reference temperature. This temperature is chosen to be that of the hot end. The coefficient of performance is also independent of area.

The acoustic field on the cold side of the stack is described by the superposition of a unit traveling wave with a reflected wave of arbitrary real amplitude and phase:

$$p = e^{ikx} + Ae^{i\phi}e^{-ikx}. \tag{27}$$

The cold end of the stack is located at $x=0$. We define a ''standing wave ratio'' (SWR) in terms of A:

$$\mathrm{SWR} = \frac{1+A}{1-A}. \tag{28}$$

The amplitude A ranges from 0 for a pure traveling wave to the right to $+\infty$ for a pure traveling wave to the left. The inverse standing wave ratio then indicates the relative extent to which the wave is a standing wave; 1/SWR is equal to $+1$ for a traveling wave moving into the stack, 0 for a standing wave and -1 for a traveling wave moving away from the cold end of the stack.

To demonstrate the use of the finite difference method for refrigeration with arbitrary traveling and standing waves, we calculate the relative coefficient of performance of two example refrigerators as a function of the inverse of the standing wave ratio. The relative coefficient of performance is the coefficient of performance divided by the Carnot coefficient of performance $T_C/(T_H - T_C)$.

First, we calculate the relative coefficient for a helium-filled thermoacoustic refrigerator operating between 290 K and 270 K. The plate spacing is such that $\lambda_T = 2.9$ and the length of the stack is 0.02 wavelengths in free space. These are evaluated at 290 K. The phase is set to 0.225π, which gives the largest maximum relative coefficient of performance. Figure 3(a) displays the results of the calculation for

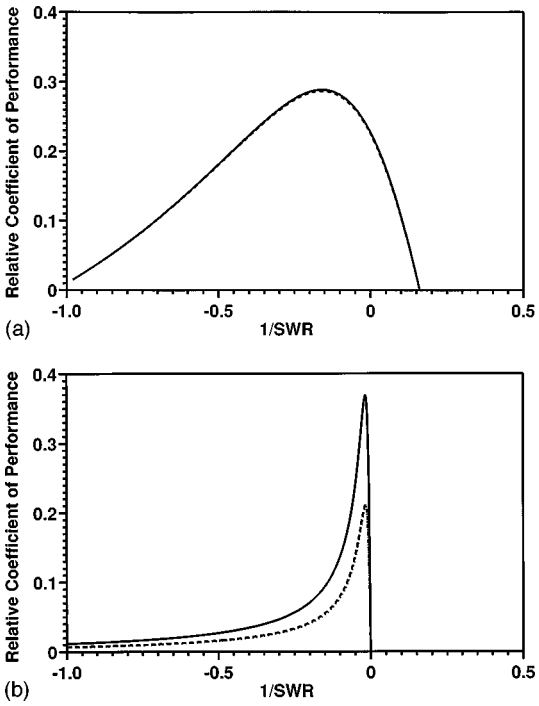

FIG. 3. Relative coefficient of performance for example refrigerators versus inverse standing wave ratio. (a) A thermoacoustic refrigerator for temperature span 290 K to 270 K, $\lambda_T = 2.9$. ——— one step, --- two steps. (b) A Stirling regime cryo-cooler for temperature span 270 K to 70 K, $\lambda_T = .035$. ——— one step, --- two steps.

one step and two steps. The results are nearly indistinguishable. For this case $|kl|$ and $|Bl|$ are 0.19 and 0.05, respectively, and the one-step method is sufficient.

The next case will use parameters more like a Stirling or pulse tube refrigerator. To investigate the limits of the discrete step method we choose a temperature span typical of cryo-coolers: the hot side is held at 270 K and the cold side at 70 K. The stack plate spacing is such that $\lambda_T = 0.035$ and the stack length is 0.002 wavelengths in free space evaluated in the hot end. This corresponds to a $k_0 l$ value of 0.013 rad, where k_0 is the free space wave number. The phase, ϕ, is set to 0.

The results are displayed in Fig. 3(b) for one step and two steps. The results for three steps agree with the two-step calculation to within the lines used in Fig. 3(b). Although the approximation is very poor for the one-step calculation, it quickly converges for two and three steps. The single-step calculation fails since both $|kl|$ and $|Bl|$ are greater than 1. Surprisingly, the two-step calculation is sufficient (agrees with the three-step calculation) although $|kl| = 0.62$ and $|Bl| = 0.455$.

Note that $|kl|$ is much larger than the ''free space'' value of 0.013 rad. The wave number in finely divided porous media can be orders of magnitude larger than the free space value. Calculations with half the stack length or half the temperature span used in Fig. 3(b) indicate that the restriction on $|kl|$ is the principle restriction on the single-step accuracy, not the value of $|Bl|$. For small λ_T, large $|kl|$ implies large acoustic losses since the real and imaginary parts of the wave number are equal. The losses in our example cryo-cooler may be larger than losses in an optimized realistic device.

As noted by Hofler,[12] the highest coefficient of performance for a thermoacoustic refrigerator is achieved when there is a significant traveling wave component in the refrigerator. Note also that the coefficient of performance of the Stirling device is zero for a pure standing wave.

III. A TRAVELING WAVE INTERPRETATION OF THERMOACOUSTIC GAIN

The finite difference model derived above can be used to develop a traveling wave interpretation of thermoacoustic gain. Referring to Fig. 1(b), a traveling wave of complex pressure amplitude 1 is incident on a stack comprised of a porous material supporting a linear temperature gradient. A portion of the wave is reflected and a portion is transmitted. We denote the complex reflection coefficient by R and the complex transmission coefficient by T when the wave is incident on the stack in the direction of increasing temperature and by R' and T' when the direction of the incident wave opposes the temperature gradient.

The impedance seen by the incident wave (Z_1) given a traveling wave on the right-hand side can be calculated using Eq. (9) and

$$Z_2 = \hat{p}_2 / \hat{v}_2 = \rho(T_H) c(T_H), \tag{29}$$

the traveling wave impedance. The reflection factor from the left-hand side of the stack is given by

$$R = e^{-ik_1 l}\left(\frac{z_1 - 1}{z_1 + 1}\right), \tag{30}$$

where z_1 is the impedance Z_1, normalized by $\rho(T_C)c(T_C)$. The factor $e^{-ik_1 l}$ results from choosing the center of the stack as the zero of the coordinate system when evaluating R. This means that k_1, the free space wave number, is evaluated at temperature T_C.

The transmission coefficient is evaluated by solving Eqs. (4) and (5) for $\hat{p}_2$ in terms of $\hat{p}_1$ and $\hat{v}_1$,

$$T = e^{-ik_3(l/2)} \frac{\left[\hat{p}_1\left(1 + \frac{Bl}{2} - \frac{k^2 l^2}{4}\right) + \hat{v}_1 \frac{iAl}{\Omega}\right]}{1 + \frac{Bl}{2} + \frac{k^2 l^2}{4}}, \tag{31}$$

where k_3 is the wave number at temperature T_H. The effect of stack porosity has been incorporated into Eq. (31). Figure 4 displays the transmission coefficient as a function of thermal wave number, λ_T, for a parallel plate stack 3.5 cm long with 0.77-mm spacing and porosity 0.76, with helium at 170 kPa as the working fluid. The cold end is held at 300 K and the hot end is 300, 400, 500, and 600 K for the curves displayed. The traveling wave gain for waves propagating from the cold side to the hot side is largest for λ_T small, the Stirling regime. In any resonant device, there are traveling waves propagating from the cold side of the stack to the hot side and vice versa. Also displayed in Fig. 4 is the transmitted intensity for a unit intensity traveling wave incident on the hot end for a 300-K temperature difference.

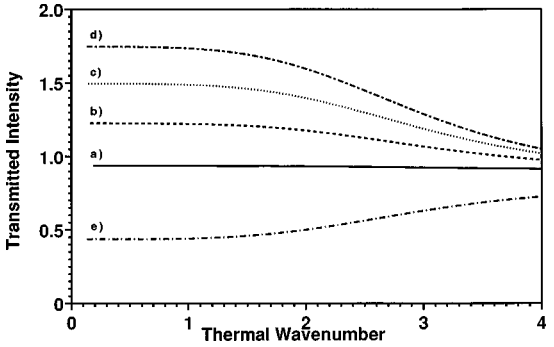

FIG. 4. Transmitted intensity relative to an incident intensity of one versus thermal wave number for the example stack. Transmitted intensity from the cold side at 300 K to the hot side at (a) 300 K ———, (b) 400 K – – –, (c) 500 K ···, and (d) 600 K ——–. (e) Transmitted intensity from the hot side at 600 K when the cold side is held at 300 K -·-·-.

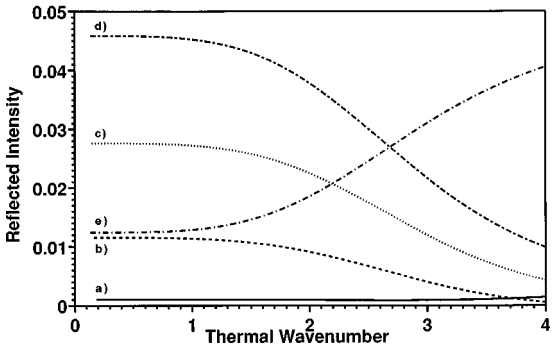

FIG. 6. Reflected intensity from the cold end of the stack at 300 K versus thermal wave number for a hot end temperature of (a) 300 K ———, (b) 400 K – – –, (c) 500 K ···, and (d) 600 K ——–. (e) Reflected intensity from the hot end of the stack at 600 K when the cold end is held at 300 K -·-·-.

A crude model for a resonant device is a traveling wave incident on the cold side of the stack transmitted to the hot side, reversed in direction and then transmitted from the hot side to the cold side without reflections off the stack. For this perfect reflectionless device, the total gain is the product of the intensity gain in propagating from the cold side of the stack to the hot side of the stack times the intensity loss in propagating from hot side to cold side. The calculated two-way intensity for our example stack as a function of λ_T is illustrated in Fig. 5. The net gain for the ideal device is less than 1 for all values of λ_T. There is a maximum near $\lambda_T = 2.7$, but this maximum still represents a net loss of 20% of the incident intensity. The product of the transmitted intensity increases with increasing temperature difference from cold to hot but still remains less than 1. Evidently, the energy reflected from the stack faces must also contribute to the intensity gain for thermoacoustic prime movers to operate.

The reflected intensities for the same temperature differences used in Fig. 4 are plotted in Fig. 6. These are small with respect to the transmitted intensities and are in fact smaller than would be calculated for a temperature discontinuity without a stack. For future use, the phase of the transmitted and reflected waves are displayed in Fig. 7. Note that the phase of the reflection coefficient from the cold side differs by approximately π from the phase of the reflection coefficient from the hot side of the stack.

A simple calculation which takes the reflected wave contributions into account will clarify the relationship between traveling wave gain and onset of standing wave devices. Consider the wave contribution in Fig. 1(c). A wave of amplitude 1 is incident on the cold side of the stack. A portion is reflected with complex coefficient R and a portion is transmitted with complex transmission coefficient T. The transmitted wave is reflected from the tube termination with reflection coefficient $\Re$. We will consider $\Re$ as real and incorporate any phase change on reflection into the phase factor ϕ. If the reflection factor of the termination is real and positive, ϕ is the free space phase change from the end of the stack to the termination at the hot end temperature. This is a completely general description of a passive termination of a resonance tube. A portion of this reflected wave is transmitted with coefficient T' and a portion reflected with coefficient R'. The net gain received at the left-hand side of the stack is expressed by the series

$$G = R + T\Re e^{i2\phi} + T\Re e^{i2\phi} R' \Re e^{i2\phi} T' + \cdots \tag{32}$$

or

$$G = R + T\Re T' e^{i2\phi}(1 + R'\Re e^{i2\phi} + (R'\Re e^{i2\phi})^2 + \cdots)$$

$$= R + \frac{T\Re T' e^{i2\phi}}{1 - R'\Re e^{i2\phi}}. \tag{33}$$

The series clearly converges since $\Re$ and R' are less than 1.

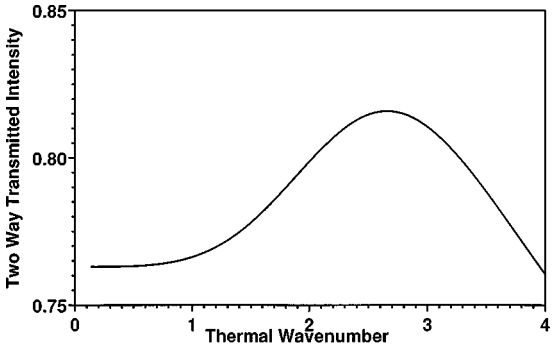

FIG. 5. Product of the transmitted intensities versus thermal wave number λ_T for the example stack with the cold end at 300 K and the hot end at 600 K.

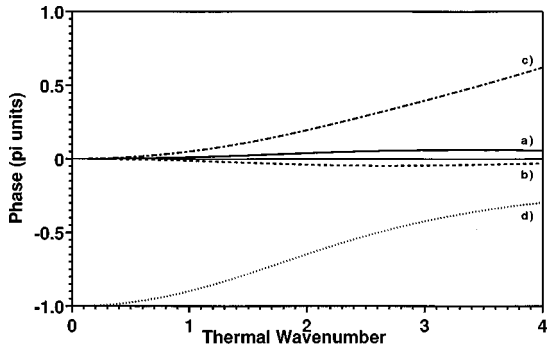

FIG. 7. The phase of the transmitted and reflected waves in fractions of π as a function of thermal wave number for (a) ——— transmitted wave for wave incident on cold side; (b) – – – transmitted wave for wave incident on the hot side; (c) -·-·- reflected wave for a wave incident on the cold side; and (d) ··· reflected wave on an incident wave on the hot side.

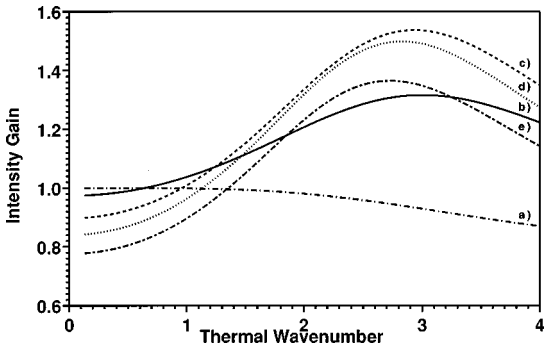

FIG. 8. Gain [Eq. (33)] as a function of thermal wave number for the example stack with ϕ given by (a) -·-·-, 0.0π; (b) ———, $0.10\ \pi$; (c) – – –, 0.20π; (d) ···, $0.25\ \pi$; and (e) ————, $0.30\ \pi$.

Note that the total gain produced by the stack plus resonance tube end is maximized when $\Re\, R' e^{i2\phi}$ is real and when the phase of R matches the phase of $e^{i2\phi}$. This is illustrated in Fig. 8 which displays the total gain of the example stack in a lossless resonator. The optimum phase change ($2\phi = 0.4\pi$) corresponds closely to the phase of the reflected wave from the cold end of the stack and also is close to the negative of the phase of the reflection from the hot end of the stack.

The total gain in the resonant system is strongly dependent on the phase and magnitude of the reflected waves. In the Stirling limit (small λ_T) the magnitude and phase of the reflection coefficients are small and the magnitude of the product TT' is always less than 1 so that it is not possible to construct a resonant device with net gain. The large traveling wave gain predicted in the Stirling limit cannot be exploited in a resonant device. The thermoacoustic engine ($\lambda_T \approx 3.0$) has smaller traveling wave gains but also has relatively smaller traveling waves losses against the temperature gradient. The reflected waves also contribute in phase to the gain in a properly designed resonance tube, so that instability can occur even when the product of the transmission coefficients is less than 1.

This analysis does not include annular resonators that are being studied by others,[14,15] but the methods described above can be adapted to such devices.

IV. CONCLUSIONS

The finite difference approximation method developed in this paper is useful for initial design estimates for thermoacoustic engines and refrigerators. This method may also be used for devices operated in the Stirling regime, with some care. All approximations in this calculation are clearly understood.

The approximation has been tested by use of a multistep extension of the finite difference method for three example systems; a thermoacoustic engine below onset and a refrigerator in the thermoacoustic and Stirling regimes. The accuracy of the calculations is determined by the size of $|kl|$ and $|Bl|$. We have found that the limiting factor for refrigerators is usually $|kl|$ exceeding 0.5, while the limiting factor for typical engines is $|Bl|$ exceeding 0.5. For Stirling devices, large wave numbers in the porous stacks are a limiting factor on the computational method. It is emphasized that this calculation is limited to a linear stack temperature gradient.

A traveling wave interpretation of thermoacoustic engines has been presented, which explains gain in thermoacoustic resonators in terms the interactions of traveling wave contributions, and demonstrates that the reflected components are a significant contributor to thermoacoustic gain. Optimum phasing is shown to be determined by the phase of the reflected waves relative to the incident waves.

APPENDIX A: RELATION OF POROUS MEDIA NOTATION TO ROTT'S NOTATION FOR THERMOACOUSTICS

The relation between shear wave number, λ, and viscous penetration depth, δ_v is given by

$$\lambda = 2^{1/2} R/\delta_v, \tag{A1}$$

and the relation between thermal disturbance number, λ_T, and the thermal boundary layer thickness, δ_κ, is given by

$$\lambda_T = 2^{1/2} R/\delta_\kappa, \tag{A2}$$

where R is the hydrodynamic radius defined as twice the pore area divided by the pore perimeter.

The relations between $F(\lambda)$ and $F(\lambda_T)$ and the Rott functions f_ν and f_κ are given by

$$F^*(\lambda) = 1 - f_v, \tag{A3}$$

$$F^*(\lambda_T) = 1 - f_\kappa. \tag{A4}$$

The complex conjugate arises due to our use of $e^{-i\omega t}$ notation, rather than Rott's $e^{i\omega t}$ notation.

APPENDIX B: TRANSMISSION AND REFLECTION COEFFICIENTS CALCULATED USING ROTT'S BOUNDARY CONDITION

Analogous expressions to Eqs. (30) and (31) can be developed from the impedance of a short stack calculated from Rott's boundary condition for a temperature discontinuity.

The substitution of $Z_1 = \hat{p}_1/\hat{v}_1$ and $Z_2 = \hat{p}_2/\hat{v}_2$ into Eq. (17) yields

$$z_1 = z_2 \frac{\rho(T_H)c(T_H)}{\rho(T_C)c(T_C)}\, e^{-B'l}, \tag{B1}$$

where z_1 and z_2 are the normalized impedances.

The reflection coefficient calculated by assuming a traveling wave on the right-hand side is

$$R = \frac{z_1 - 1}{z_1 + 1} = \frac{\sqrt{T_C/T_H}\, e^{-B'l} - 1}{\sqrt{T_C/T_H}\, e^{-B'l} + 1}. \tag{B2}$$

The reflection coefficient for a wave incident on the left-hand side can be calculated by exchanging T_C and T_H in Eq. (B2) and yields $R' = -R$, so the reflection coefficient from the hot

side has a π phase shift with respect to the reflection coefficient from the cold side as observed approximately in Fig. 7.

The transmission coefficients are easily calculated since pressure is continuous across the discontinuity:

$$T = 1 + R \tag{B3}$$

and

$$T' = 1 + R' = 1 - R. \tag{B4}$$

These may be used in Eq. (33) to yield results for the gain of a short lossless stack.

Focusing and steering through absorbing and aberrating layers: Application to ultrasonic propagation through the skull

Mickaël Tanter, Jean-Louis Thomas, and Mathias Fink
Laboratoire Ondes et Acoustique, ESPCI, Université Paris VII, U.R.A. C.N.R.S. 1503, 10 rue Vauquelin, 75005 Paris, France

(Received 9 May 1997; accepted for publication 20 January 1998)

The time-reversal process is applied to focus pulsed ultrasonic waves through the human skull bone. The aim here is to treat brain tumors, which are difficult to reach with classical surgery means. Such a surgical application requires precise control of the size and location of the therapeutic focal beam. The severe ultrasonic attenuation in the skull reduces the efficiency of the time reversal process. Nevertheless, an improvement of the time reversal process in absorbing media has been investigated and applied to the focusing through the skull [J.-L. Thomas and M. Fink, IEEE Trans. Ultrason. Ferroelectr. Freq. Control **43**, 1122–1129 (1996)]. Here an extension of this technique is presented in order to focus on a set of points surrounding an initial artificial source implanted in the tissue volume to treat. From the knowledge of the Green's function matched to this initial source location a new Green's function matched to various points of interest is deduced in order to treat the whole volume. In a homogeneous medium, conventional steering consists of tilting the wave front focused on the acoustical source. In a heterogeneous medium, this process is only valid for small angles or when aberrations are located in a layer close to the array. It is shown here how to extend this method to aberrating and absorbing layers, like the skull bone, located at any distance from the array of transducers. © *1998 Acoustical Society of America.* [S0001-4966(98)04904-2]

INTRODUCTION

A number of recent studies have demonstrated the feasibility of the practical clinical realization of noninvasive surgery using high intensity focal ultrasound.[1,2] Such surgical applications require precise control of the size and location of the focal of the therapy beam. However, most ultrasonic therapeutic systems do not take into account the inhomogeneities of the human tissues: The acoustic velocity is assumed to be constant, while steering and focusing the acoustic energy. In fact, the spatial variations of the speed of sound (from approximately 1440 m s^{-1} in fat to 1580 m s^{-1} in muscle) induce a phase and amplitude distortion of the wave front propagating in the medium. These aberrations degrade the spatial resolution, which can reduce the therapeutic performance. Furthermore, in the particular case of the skull, a large discrepancy in acoustic velocities between brain tissue and skull tissue (about 1500 m s^{-1} vs 3000 m s^{-1}, respectively) and a severe attenuation of ultrasound in the skull bone severely degrade the beam shape. This problem was first discovered by White *et al.* (1967)[3] during investigation into brain imaging.

There have been many investigations into the effects of biological tissue heterogeneities upon resolution and imaging quality. O'Donnell and Flax[4] have measured *in vivo* phase and amplitude distortions of the wave front in subjects producing low and high image quality. They have shown that the inhomogeneities can be modeled like a phase screen close to the array. Most investigations in correction of ultrasonic beam degradation have restricted their means of compensation to time shift in the receiving aperture, although it is not a complete solution of the aberration correction problem. Zhu and Steinberg[5,6] have shown that the wave front distortion due to breast tissue is not only described by a phase distortion, but also an amplitude distortion. Important improvements in breast imaging are made by phase aberration correction, but even when all phase errors are corrected, the sidelobes are higher than in homogeneous medium.

The inability of time shift compensation in the receiving aperture to correct perfectly for the effect of a phase screen that is not near the receiving aperture has been shown experimentally[7] and explained by our group.[8] Recently, Liu and Waag[9] have modeled the aberrating medium as a phase screen placed some distance from the receiving aperture. They removed amplitude and phase distortion by backpropagating the wave front before applying the time shift compensation. Optimal focusing in any heterogeneous nonabsorbing medium requires taking into account all the information received on the array from the point source. For a monochromatic signal, this information corresponds to the amplitude and phase modulation recorded on each element of the array. For a pulsed echo, each spectral component of the wave front is subject to different phase and amplitude distortions: Then, all the temporal waveforms need to be recorded.

Time reversal[10–12] represents an original way to compensate for distortion due to various inhomogeneous media. Time-reversal mirrors (TRM) take advantage of the invariance of the wave equation in a lossless medium under a time-reversal operation. This means that if focusing through any inhomogeneous medium is the objective, the distorted wave field coming from a source (active or passive) located at the desired focal point should be recorded and then transmitted in time reversed form. The time-reversed wave field back propagates through the inhomogeneities and optimally focuses on the source. Such an adaptive system is locked on

the pointlike reflector position or on the brightest point of an extended target. Usually, in a practical situation, such an acoustic source is not available in the region of interest. Nevertheless, for hyperthermia, invasive methods using implantable acoustic sensors inside tumors for acoustic feedback have been proposed.[13]

In this paper, we first show the limit of the time reversal process in focusing an implantable point source through an absorbing and aberrating layer, like the skull. Section I illustrates with a new experiment the main results previously shown in Ref. 14. Then, we review how to combine time reversal with an amplitude compensation procedure to improve the focusing, when the skull can be modeled as a thin absorbing layer close to the array of transducers. We discuss and justify this assumption of thin absorbing layer. We review also how a numerical backpropagation extends this technique, when the skull is located at some distance of the array.

Then, in Sec. II, the time-reversal technique improvement by the amplitude compensation and numerical backpropagation is extended to focus not only on the initial source, but also on other points surrounding the implanted source. Ultrasonic beam steering through heterogeneous nonabsorbing layers with a time reversal mirror has been recently treated by Dorme and Fink.[15] We generalize their results to absorbing media. In most ultrasonic therapeutic and imaging systems, conventional steering consists of tilting the wave front focused on the initial source in order to focus nearby. For our purposes, if the skull is close to the array, conventional steering and amplitude compensation of the time-reversed signals coming from the initial source give a good focusing quality around the new desired focal point. However, this focusing degrades as soon as the array-skull distance increases. We apply the numerical backpropagation of the wave front received from the initial point source before steering and amplitude compensation.

I. TRANSMIT FOCUSING THROUGH THE SKULL

In this section, we review the results previously obtained in Ref. 14. First, the analytical derivation is extended to medium with density, sound velocity, and absorption heterogeneities. Second, new experimental materials along with more detailed description of the effects induced by the skull are presented. Third, the method used to extend the time reversal processing into the case of absorbing layer and its limitations are reviewed.

The basic theory of the time-reversal process is based on an elementary property of wave equations in a lossless medium: The time derivative appears only at the second order in this wave equation. Indeed, in a fluid nonabsorbing medium with a sound velocity $c(r)$, a density $\rho(r)$ that varies with space, the acoustic pressure field $p(r,t)$ satisfies:

$$\rho(\mathbf{r})\mathrm{div}\left(\frac{\mathbf{grad}(p(\mathbf{r},t))}{\rho(\mathbf{r})}\right)-\frac{1}{c(\mathbf{r})^2}\frac{\partial^2 p(\mathbf{r},t)}{\partial t^2}=0. \tag{1}$$

Whatever the medium, the wave equation contains only a second-order time-derivative operator: Thus if $p(r,t)$ is a solution of Eq. (1), then $p(r,-t)$ is also another solution. If $p_{r0}(r,t)$ is the resulting pressure field that propagates from a single source located in the nonabsorbing medium, the optimal way to focus on this source consists of a time-reversal operation in the whole 3D volume, generating $p_{r0}(r,T-t)$ in the medium, where T is a time delay that ensures causality. Using Huygen's principle we reduce the time-reversal operation on the 3D volume to a time-reversal operation on a two-dimensional closed surface, and develop there the concept of closed time-reversal cavity.[16] However, a closed cavity is difficult to realize experimentally. A compromise consists in applying the time-reversal process to a portion of the cavity such as a two-dimensional piezoelectric transducers array.

However, this property becomes obsolete in an absorbing medium: Acoustic losses are taken into account in the wave equation by a first derivative in time and are not time-reversal invariant. Indeed, one way to introduce losses is to modify the equation of state to allow for a delay between the application of a sudden pressure change and the attainment of the resulting equilibrium condensation.[17] This modification yields a third term in the wave equation for an absorbing fluid medium:

$$\rho(\mathbf{r})\left(1+\tau(\mathbf{r})\frac{\partial}{\partial t}\right).\mathrm{div}\left(\frac{\mathbf{grad}(p(\mathbf{r},t))}{\rho(\mathbf{r})}\right)-\frac{1}{c(\mathbf{r})^2}\frac{\partial^2 p(\mathbf{r},t)}{\partial t^2}=0, \tag{2}$$

where τ is the relaxation time of the medium.

Time reversal of the initial wave front is no longer the optimal solution to focus on the source. However, in a particular case, when the aberrating and absorbing medium can be modeled as a thin layer placed at some distance from the transducers array, it is possible to take into account the amplitude modulation originating from acoustic losses and so, to improve the quality of TRM focusing. This assumption of very thin absorbing layer will be discussed and justified in the next part. Afterward, we assume that this condition is fulfilled by the skull.

A. Degradation of time-reversal focusing induced by the skull

In this paper, experimental data have been obtained with a real time electronic prototype previously described in Ref. 14. This electronic prototype is used with a prefocused 1-D cylindrical array of transducers. It is made of 128 piezoelectric elements working at 1.5 MHz. Each transducer element is prefocused in elevation at 100 mm and its aperture is 1 mm wide and 25 mm high. The array pitch is 1.2 mm and the elements are set out on a spherical backing of 100 mm radius of curvature. The total aperture of the array of transducers is thus equal to 140 mm. The time-reversal experiments were performed using a rectangular transducer, 1 mm wide and 10 mm high, as an active transmitting line source. This same monoelement was used in receive mode as a hydrophone to scan the pressure field. The array of transducers and the monoelement were immersed in a water tank.

The time reversal process was performed in two steps: In the first step, the monoelement worked in transmit mode. The pressure field generated by this source was recorded on the 128 transducers of the array. In a second step, the signals

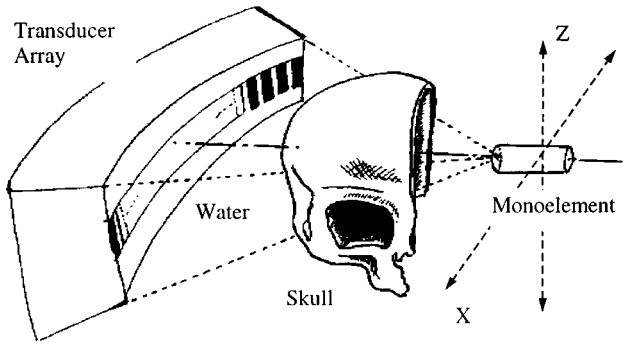

FIG. 1. Experimental setup.

recorded were time reversed and transmitted simultaneously by the 128 elements. The monoelement was then used as a hydrophone to scan the pressure field along the x axis (Fig. 1). It was moved by stepper motors to 30 mm on each side of the initial location of the source with a 0.3-mm scanning step, in order to plot the directivity pattern which represents the maximum of the pressure field for each location of the hydrophone.

In a first experiment, the optimal focusing quality of our system was measured. For this purpose a TRM experiment was conducted in homogeneous medium. In this case, time-reversal process was only used to compensate the geometrical distortion, if any, of the array of transducers. Figure 2(a) shows the waveforms received in homogeneous medium. Signal amplitude is shown linearly on a gray scale, the horizontal axis is the transducer number, and the vertical axis is the evolution in time. As the monoelement was placed at the center of curvature of the transducers array, all signals arrive at the same time on the transducers.

Figure 3 shows the directivity patterns (gray line) with the time-reversal procedure in homogeneous medium (pure water). One can notice the sharp focusing obtained with a background level at -40 dB and a beamwidth at -6 dB of 1.2 mm.

In the next experiments the source was observed through a half-skull (human). The dried skull was cut in the midsagittal plane. Afterward, it was degased and stored in a water tank. The skull was set between the source and the array of transducers, its outer side at a distance of 40 mm from the array. Conventional focusing consists in applying time shifts on each transducers of the array when assuming the medium to be homogeneous. In order to evaluate the beam degradation induced by the skull, when the conventional focusing is applied, the signals recorded in homogeneous medium were time reversed and transmitted a second time. The resulting wave front was distorted by the skull and the directivity pattern obtained is shown in Fig. 3 (dashed line). We can observe a 1-mm shift of the focus and the beam is widely spread. The -6-dB lateral resolution is about 4.8 mm and the side lobe level is very high.

Finally, in order to compare conventional and time-reversal focusing through the skull, a complete time-reversal experiment was performed: The monoelement was used as an active acoustic source. The generated wave front propagated through the skull and was distorted. The signals measured by the 128 transducers are presented in gray scale [Fig. 2(b)]. One can notice the strong phase and amplitude aberration induced by the skull. The sound velocity in the skull is greater than in water: Hence, the most attenuated part of the signal passed through a thicker part of the bone and arrived first at the transducers. This wave front was time reversed and transmitted through the skull. The directivity pattern is

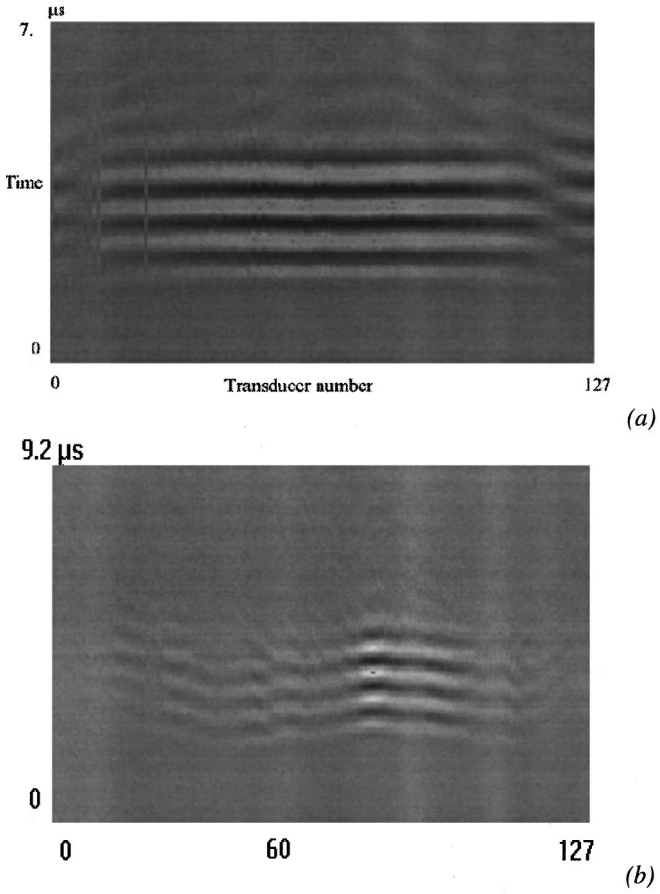

FIG. 2. Waveforms received on the transducers array: (a) in homogeneous medium; (b) through the skull. Signal amplitude is shown linearly on a gray scale, the horizontal axis is the transducer number, and the vertical axis is the evolution in time.

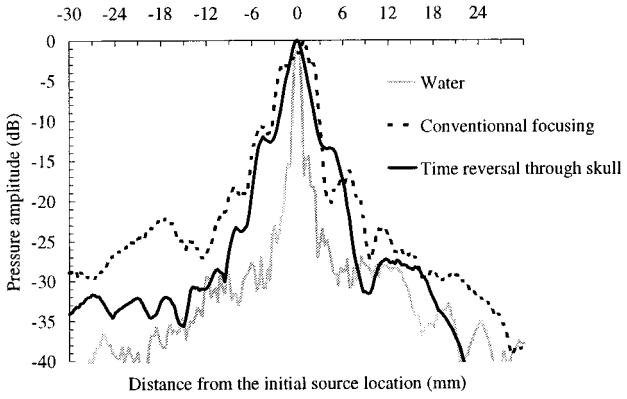

FIG. 3. Directivity patterns obtained by time reversal through pure water (gray line), time reversal through the skull of signals recorded in water (dashed line) and time reversal through the skull (solid line).

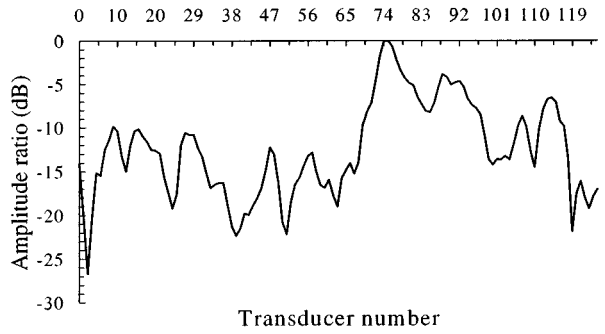

FIG. 4. Amplitude ratio between the waveforms received through the skull and the waveforms obtained in pure water.

shown Fig. 3 (solid line). This experiment shows that TRM focusing is slightly better than conventional focusing but remains far from the optimum. Indeed, the previous focus shift has been removed and the sidelobes level has been reduced, but the beam remains very large; the -6-dB beamwidth is about 3.6 mm.

We have seen that the acoustic losses induced by the skull are not time reversal invariant, and thus degrade the quality of time-reversal focusing. In practice, a transducer that received a weak signal was located in front of a strongly absorbing area of the skull. After the time-reversal operation, this weak signal backpropagated through the same area of the skull and hence, the amplitude modulation of the wave front was increased by a power of two. Thus the amplitude aberration due to the absorption in the skull was not compensated by the time-reversal process. At this point, Fig. 4 presents the amplitude ratio between the wave front propagated through the skull [Fig. 2(b)] and the one obtained through water only [Fig. 2(a)]. It shows that the losses due to absorption in the skull can vary on a scale of 25 dB.

B. Improvement of time-reversal focusing by amplitude compensation

It has been shown in a previous paper[14] that to obtain a good quality of focusing through the skull an amplitude compensation could be added to the time reversal processing. We will now review this method and the assumption it is based on. A comparison between the signals received in homogeneous medium [Fig. 2(a)] and those recorded through the skull [Fig. 2(b)], shows that the main qualitative difference is a varying time shift and attenuation. Particularly, there is no visible replica of the wave front and hence multiple scattering inside the skull is negligible. In these conditions, the simplest modeling of the skull is to assume it to a thin time shifting and absorbing layer. Thus the first method developed in Ref. 14 to compensate for this layer is to add to the time-reversal process a pretreatment taking partially into account the absorption. However, in all this paper, the absorption is assumed to be constant over the whole bandwidth of the transducers. In others words, only the spatial dependence of the absorption is taken into account. Without this strong approximation a compensation of the absorption at each frequency would be required, i.e., a deconvolution in the time domain, and the method would have to deal with the numerical instability encountered in both inverse problems: temporal and spatial.

Under these assumptions skull crossing does not modify the shape of the wave field. In other words, *if the skull is located close to the array*, the signals $s_i(t)$ received on each transducer i from an initial point source are only time delayed with a time shift τ_i, and multiplied by an absorption factor a_i, in comparison with the signals $s_i^h(t)$ that would be received in a homogeneous medium:

$$s_i(t)=(a_i\cdot\delta(t-\tau_i))\otimes s_i^h(t), \tag{3}$$

$$s_i(t)=a_i\cdot s_i^h(t-\tau_i). \tag{4}$$

This assumption of very thin layer—''phase and amplitude screen''—can now be quantitatively justified. For our purposes, Eq. (4) can be rewritten in the Fourier domain:

$$\mathbf{S}_i(f)=a_i\cdot\mathbf{S}_i^h(f)\cdot e^{j2\pi f\tau_i}. \tag{5}$$

Then, one can remark that the phase of the Fourier transform $\mathbf{S}_i(f)$ of each signal $s_i(t)$, namely, $\phi_i(f)$, has to depend linearly on the frequency f in comparison with $\phi_i^h(f)$, phase of the Fourier transform $\mathbf{S}_i^h(f)$ of the signals obtained in homogeneous medium $s_i^h(t)$:

$$\Delta\phi_i(f)=\phi_i(f)-\phi_i^h(f)=2\pi f\tau_i. \tag{6}$$

This phase difference at each frequency f was experimentally measured for each channel i and was found linearly dependent on the frequency in the limited bandwidth of the transducers. The mean standard deviation for the experimental phase difference $\Delta\phi_i(f)$ with a fitted straight line is equal to 0.118 rads.

This deviation is very small ($\sim T/50$) and we can conclude that the signals received on the array after propagation through the skull are strongly correlated with the ones obtained in the same conditions in homogeneous medium. The assumption of skull as a very thin layer is then justified.

Now, how can we correct the aberrations (a_i,τ_i) induced by the skull? The phase aberration correction is automatically accomplished by the time-reversal process and we can take into account the amplitude aberration due to attenuation by inverting the amplitude modulation of the wave field received on the array of transducers. For this purpose, the amplitude modulation a_i due to skull attenuation was estimated by comparison with the reference waveform obtained in the same conditions in homogeneous medium: Accordingly to Eq. (4), we deduce $a_i=\max_t\{|s_i(t)|\}/\max_t\{|s_i^h(t)|\}$ a ratio between the amplitudes of the wave packets (another choice could be $|\mathbf{S}_i(f=f_0)|/|\mathbf{S}_i^h(f=f_0)|$, where f_0 is the central frequency of the transducers). These estimates were then employed to invert the amplitude modulation a_i and gave the new set of corrected signals $s_i^c(t)$ to be reemitted:

$$s_i^c(t)=\overbrace{\frac{\max_t\{|s_i(t)|\}^2}{\max_t\{|s_i^h(t)|\}^2}}^{\text{Amplitude Compensation}}\cdot\underbrace{s_i(T-t)}_{\text{time reversal}}, \tag{7}$$

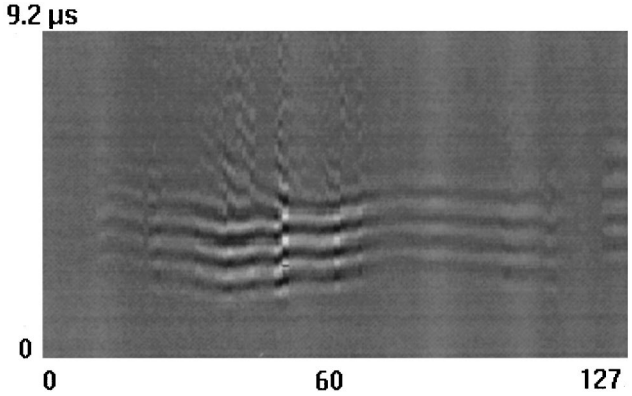

FIG. 5. Waveforms previously presented in Fig. 3 after amplitude compensation.

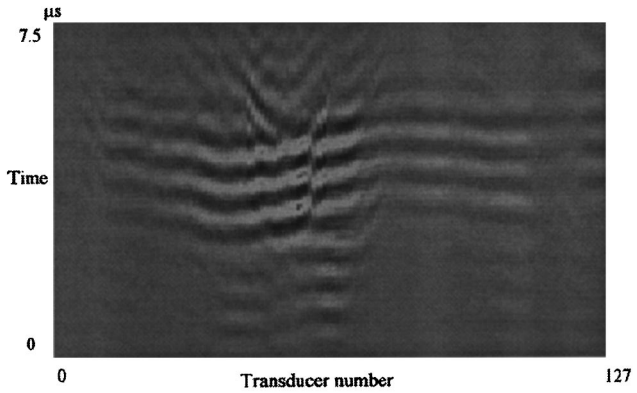

FIG. 6. Waveforms previously presented in Fig. 2(b) after numerical propagation and amplitude compensation.

$$s_i^c(t) = \frac{1}{a_i^2} \cdot s_i(T-t) = \frac{1}{a_i} \cdot s_i^h(T-t-\tau_i), \tag{8}$$

where T ensures the causality.

These new signals are reemitted by the 128 transducers of the array. As the distorting thin layer is located close to the array, the signal reemitted by each transducer i is immediately modified and became a set $s_i^{a,s}(t)$ after passing through the skull:

$$s_i^{a\,s}(t) = a_i \cdot \delta(t-\tau_i) \otimes s_i^c(t), \tag{9}$$

$$s_i^{a\,s}(t) = s_i^h(T-t). \tag{10}$$

Now we come back to a time-reversal operation in a nondissipative medium and according to the time-reversal invariance, this wave front propagates in homogeneous medium and optimally focuses on the initial source point. Figure 5 shows the wave front, recorded during the previous experiment and presented in Fig. 2(b), after this amplitude compensation.

The amplitude compensation improves the focusing and the beamwidth is perfectly corrected up to -14 dB (Fig. 7, dotted line). Nevertheless, this amplitude compensation is quite efficient only when the absorbing medium is a layer *located close to the array*. In fact, the skull-array distance was about 40 mm in this experiment and hence, additional amplitude and shape distortions may develop as the wave front propagates in the homogeneous and lossless medium after passing through the skull. These amplitude distortions are automatically compensated by the time-reversal processing and so must not be taken into account a second time in the pretreatment. The idea is to simulate a virtual array of transducers located close to the skull. For this purpose, the original diverging wavefront represented by $s_i(t)$ was time reversed and numerically backpropagated from a 100 mm to a 60 mm radius of curvature cylindrical surface respectively corresponding to the array aperture and the skull surface.[18] Indeed, since the medium between the array and the skull is lossless, the time-reversal processing achieves an inverse wave field propagator. Moreover this time-reversal processing can be easily computed as soon as the medium is assumed to be homogeneous. Amplitude distortion was then estimated on the virtual array and the estimates were used to compensate for the backpropagated field. This compensated and converging waveform can now be time reversed and numerically propagated from the approximated skull surface to the array aperture. This method, by simulating a virtual array located close to the skull, allows discrimination between these two kinds of amplitude modulations, respectively, due to the absorption in the skull and the propagation from the skull to the array. Thus we obtained a new set of 128 signals adapted to focus through the skull at the initial source location (Fig. 6).

These signals were time reversed and transmitted in the medium. A comparison of the focusing results obtained with amplitude compensation in the aperture (Fig. 7, dotted line) and with amplitude compensation after backpropagation (Fig. 7, solid line) can be made.

The focusing is now optimal up to -16 dB and the sidelobes level has been strongly decreased. This quality of focusing seems quite good for hyperthermia where the heating pattern contrast is proportional not to the pressure amplitude but rather to the ultrasound energy.

II. STEERING THROUGH THE SKULL

Although time reversal is only self-focusing onto the artificial source implanted inside the treatment volume, we

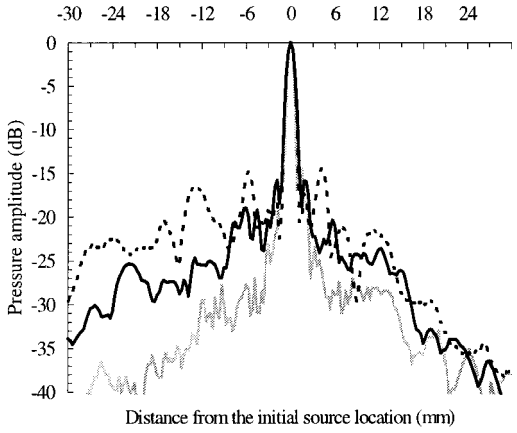

FIG. 7. Directivity patterns obtained by time reversal through pure water (gray line), time reversal with amplitude compensation (dotted line), and time reversal with backpropagation and amplitude compensation (solid line).

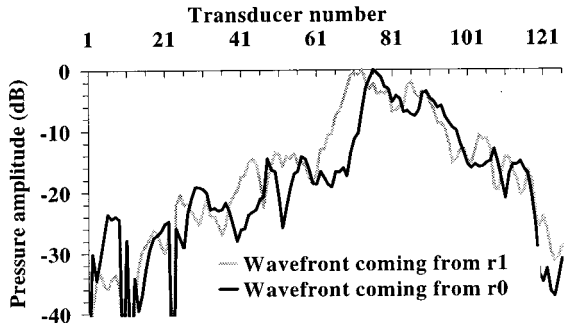

FIG. 8. Comparison between the amplitude modulation of the wave front coming from the new focal point r_1 [presented in Fig. 9(a)] and the wavefront coming from the initial source location r_0 [previously presented in Fig. 2(b)].

show how the array can be steered on points surrounding this beacon. In homogeneous medium, conventional beamsteering modifies the wave front focused on the artificial source by applying a time delay law and apodization factors, taking into account the distances between the new focus location and the array elements. Note, this process requires only to know the sound speed of the medium. However, in heterogeneous medium, this process is only valid for small angles or when the aberrations are located in a layer close to the array. Indeed, if the aberrating layer is modeled as a thin layer located close to the array, the aberrations (a_i, τ_i) induced by the skull are independent of the source location, and then the Green's functions of two different points r_0 and r_1 implanted in the medium only differ from the same time shifts and apodization factors as in homogeneous medium. On the other hand, if the thin aberrating layer is now located at some distance from the array of transducers, the two Green's functions associated to r_0 and r_1 are different: The propagation between the layer and the array modifies in a different way for these two wave fronts. The wave front coming from r_0, the artificial source location, was previously presented in Fig. 2(a) [the one coming from r_1, when located 10 mm away from r_0, is presented in Fig. 9(a)]. One can remark, as shown in Fig. 8, that the amplitude modulation of these two wave fronts are different. The two amplitude modulations, which represent the maximum of pressure measured on each transducer, are very similar, but translated in space. This translation can be easily understood by a ray theory approach.

In order to estimate the time of arrival error introduced by conventional steering, the wave front coming from r_0 was steered on r_1 assuming that the heterogeneities are located close to the array. (The difference between the time of arrival of the wave front coming from r_0 tilted to focus on r_1 and the genuine wave front coming from r_1 is presented in Fig. 11, gray line.) This time of arrival error is measured by intercorrelation between the two wave fronts, and the variance of the error is equal to 0.16 μs (to be compared with the central frequency of the signal, which is equal to 0.66 μs^{-1}). Thus as soon as the skull is not located close to the array, conventional steering of an initial wave front is not efficient if we want to construct the Green's function associated to a new point of interest.

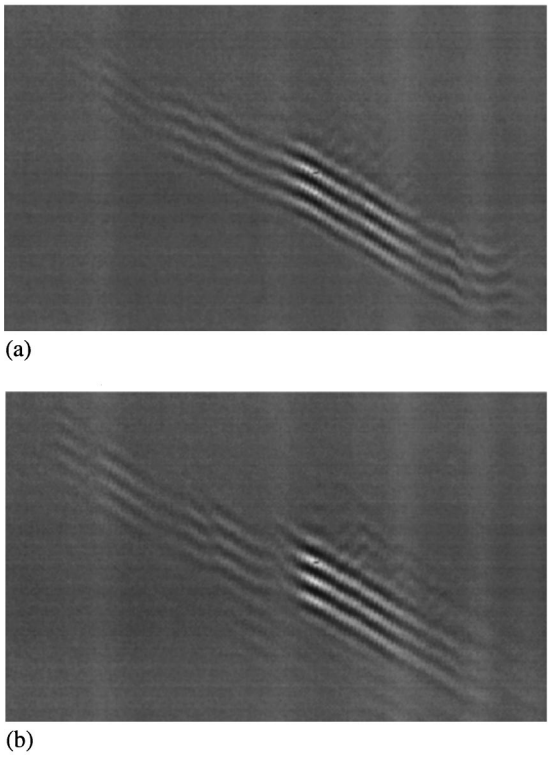

FIG. 9. Comparison between (a) the acquired Green's function of the new point of interest r_1 and (b) this Green's function calculated from the knowledge of the wavefront coming from the initial source location r_0.

Nevertheless, as well as for the amplitude compensation presented in the second part, numerical backpropagation can extend the conventional steering to aberrating layers located at any distance from the array:[15] The initial wave front coming from r_0 [Fig. 2(b)] was numerically backpropagated from the array to the surface of the skull. This wave front was then tilted in order to focus on r_1, time reversed, and numerically backpropagated from the skull to the array. Thus from the knowledge of the Green's function associated to the initial point r_0, we obtained a new calculated Green's function associated to r_1 [Fig. 9(b)].

As previously, we can compare the acquired and calculated Green's function associated to r_1. As shown in Fig. 10, their amplitude modulations are very similar. Furthermore, the variance of the time delay error is equal to 0.05 μs, and

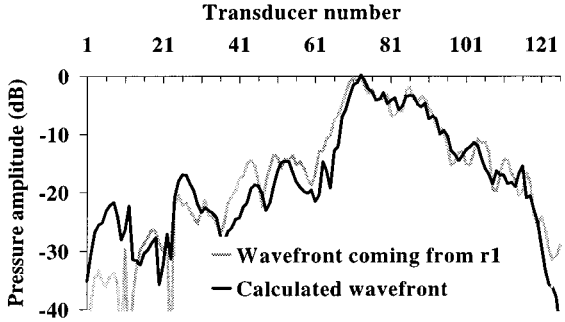

FIG. 10. Comparison between the amplitude modulation of the wave front coming from the new focal point r_1 [Fig. 9(a)] and the wave front calculated in order to focus on r_1 [Fig. 9(b)].

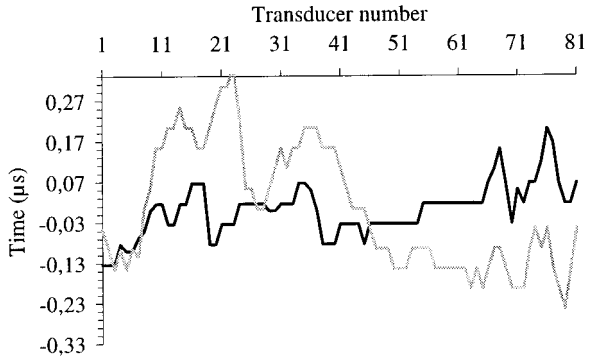

FIG. 11. Time shift error measured on each transducer of the array between the acquired wavefront coming from r_1 and this wavefront calculated without backpropagation (gray line) and with backpropagation (black line) from the knowledge of the wavefront coming from the initial source location.

thus is three times better than the variance obtained without backpropagation. One can notice that a maximum variance of $T/8$ (0.08 μs) is required to ensure a nice focusing. The time delay law error between the acquired and calculated wave fronts is presented in Fig. 11 (black line).

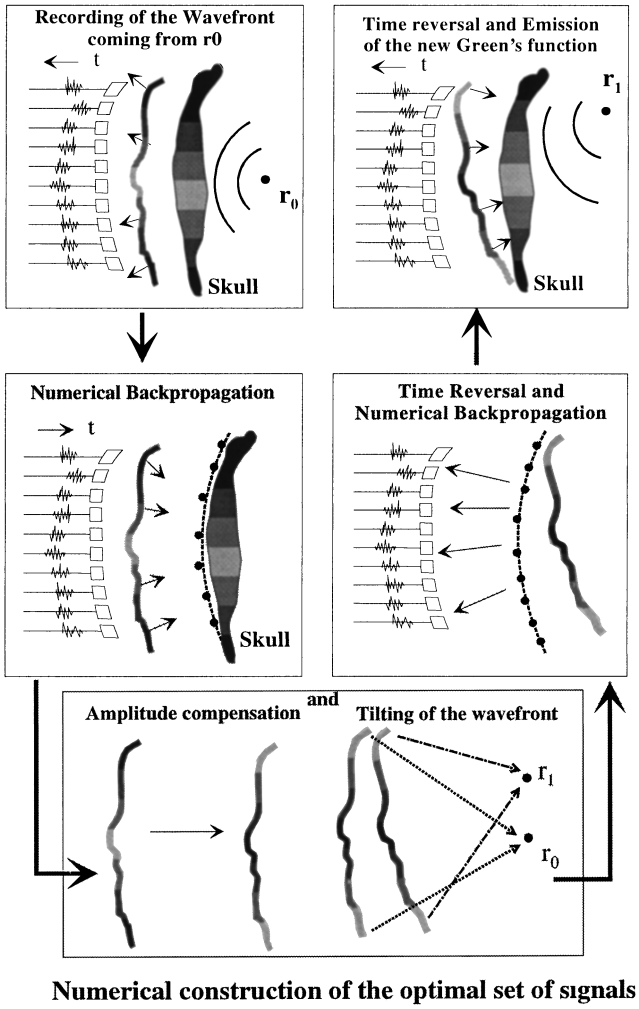

FIG. 12. Numerical construction of the Green's function associated to the point r_1 from the knowledge of the Green function associated to the initial point location r_0.

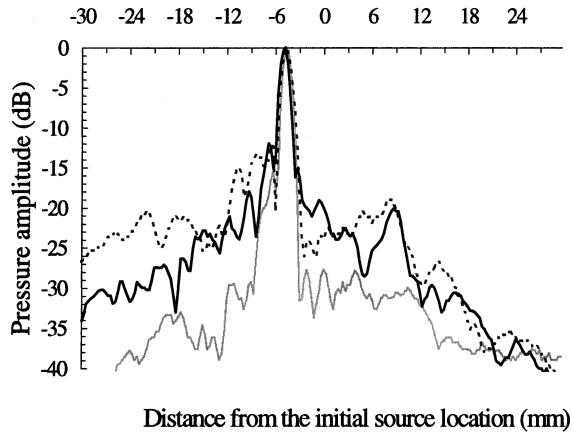

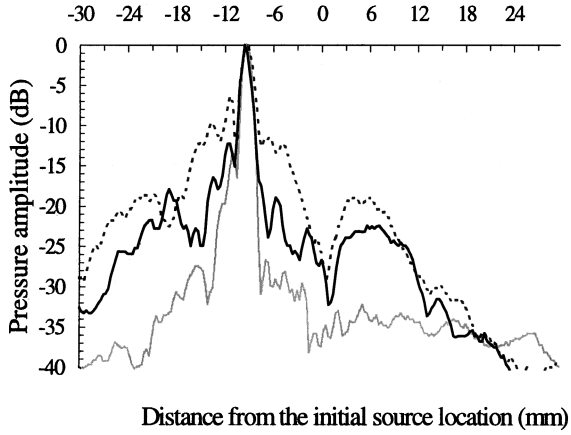

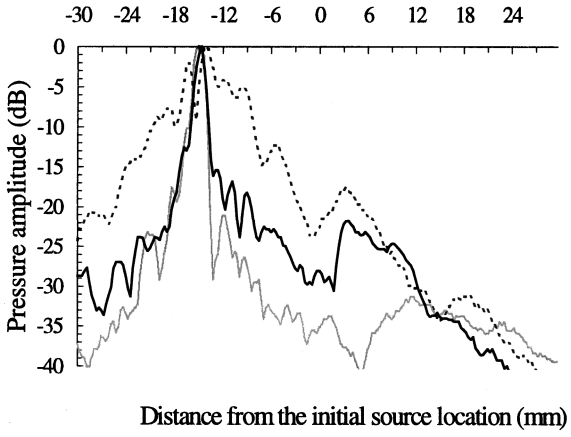

FIG. 13. Directivity patterns obtained by tilting the wavefront received from the initial point source at a distance of (a) 5 mm, (b) 10 mm, and (c) 15 mm: Tilting through pure water (gray line), time reversal of the signal received through the skull with amplitude compensation (dotted line), time reversal of the amplitude compensated signal after backpropagation (solid line).

By combining the amplitude compensation presented in the second part and the steering of the wave fronts presented in this third part, we were now able to construct the optimal set of signals in order to focus around the initial source location (Fig. 12). This process was applied to focus at 5, 10, and 15 mm away of the initial source location. We compared focusing obtained by tilting of the wave front in homogeneous medium with, on the one hand, tilting and amplitude

compensation of the wave front in the array aperture and, on the other hand, tilting and amplitude compensation of the wave front after numerical backpropagation to the skull. Directivity patterns are presented in Fig. 13. Without backpropagation, the focusing was quickly degraded as the distance from the initial source location was increased, thus sidelobes appeared, respectively, at -12 dB, -6 dB, and -2 dB (Fig. 13, dotted line). On the other hand, the focusing remained quite good when backpropagation to the skull-array distance was applied before amplitude compensation and tilting of the wave front (Fig. 13, solid line). Now, sidelobes appeared, respectively, at -12 dB, -12 dB, and -14 dB. Thus conventional beamsteering that consists of tilting the wave front without backpropagation is no longer efficient when the aberrating and absorbing layer is located some distance away of the array of transducers. Beside this limit of 15 mm, the focusing degrades more and more, even in homogeneous medium. This degradation is due to the directivity of each tranducer of the array, and we attain the maximum steering abilities of the array. Moreover in our experiment the skull is not a perfect thin layer and refraction effects are neglected which limits the maximum steer angle. Thus we are able to focus the ultrasonic beam in an area of 15 mm on each side of the initial source location in the lateral direction. Moreover, a depth of 30 mm on each side of the initial source in the axial direction can be investigated.

III. CONCLUSION

In this paper, we have shown that focusing and steering of an ultrasonic beam through the skull is possible in spite of the severe ultrasonic attenuation of the bone. We propose a method of steering combined with an amplitude compensation to improve the time-reversal focusing when an artificial acoustic source is available in the medium. Thus although time reversal is only self-focusing onto this initial source implanted inside the treatment volume, we learn how to focus the ultrasound beam onto many new others focal points in order to investigate the whole tumor. A new set of signals is calculated from the knowledge of the initial ones corresponding to the artificial source location. The proposed method is valid when the inhomogeneities can be modeled as a thin screen varying in absorption and time delay, located at any depth from the array. Experimental results show that this assumption can be done in the case of the skull.

This method could be easily improved. First, our numerical backpropagation could be improved by the acquisition of the real skull surface with a MRI or x-ray system. Second, although we used in this study only a one-dimensional array and since significant aberration exists both in elevation and azimuth, aberration correction should be performed in both dimension to be most effective. It will be done in our further work.

We want now to apply this adaptive focusing method to a new time-reversal mirror developed in our laboratory. This time-reversal mirror will be able to produce high intensity ultrasonic beams.

(Received 10 July 1997; accepted for publication 27 January 1998)

An electromagnetic acoustic transducer has been developed for line-focusing the shear-vertical (*SV*) wave in a metal. The EMAT consists of a permanent magnet to supply the bias magnetic field normal to the surface, and a meanderline coil to induce the dynamic field and eddy currents in the surface region of the sample. The meanderline spacing is continuously changed so that the generated *SV* waves from all segment sources become coherent on the focal line after traveling oblique paths. The printed circuit technique enables the fabrication of such a functionally spaced meanderline coil within 1-μm accuracy. The directivity is measured using a half-cylindrical sample of an aluminum alloy, which shows a much sharper radiation pattern of the focusing EMAT than the EMAT having a meanderline coil of constant spacings. This EMAT is then tested through detecting a shallow notch. The scattered signal from the notch is received by the same EMAT, which shows enough strength even for the notch of 0.2-mm depth. © *1998 Acoustical Society of America.*

INTRODUCTION

Electromagnetic acoustic transducers (EMATs)[1–5] have definite advantages for the noncontact inspection and characterization of electrically conductive materials. They excite and detect the elastic waves through the electromagnetic transduction and they are free from any mechanical coupling, which eliminates the measurement errors associated with the contact transduction. An EMAT consists of permanent magnets (or electromagnets) to supply the bias magnetic field, and the driving coil element to excite the eddy currents and the dynamic fields. Their configuration depends on the mode of elastic wave desired.

An EMAT, however, has two basic disadvantages; the weak transduction efficiency and the broad radiation pattern of elastic waves into a solid. However, the sensitivity of the EMAT has been dramatically improved owing to the recent advances in the electronics and signal processing techniques, the permanent magnet such as the Nd–Fe–B sintered magnet, and the printed circuit techniques to fabricate the printed coils. Especially, the use of an EMAT in the ultrasonic resonant technique[6–9] overcame the low transduction efficiency by receiving highly and coherently overlapping echoes at a resonant state. On the other hand, the elastic waves generated by an EMAT propagate nearly all possible directions in the sample, which is undesirable for flaw detection purposes. For example, Fig. 1 illustrates the elastic-wave radiation by the EMAT built with a meanderline coil and a permanent magnet. The EMAT generates the logitudinal wave and the shear-vertical (*SV*) wave propagating obliquely in the sample, and the Rayleigh wave along the surface. They are generated at the same time for both sides with the broad directivity patterns and will be reflected not only by flaws but also by the sample edges. It is often difficult to distinguish the flaw signal from others. Moreover, the broad radiation decreases the ultrasonic energy to be concentrated on the target flaw.

This paper presents a technique to sharpen the directivity by line-focusing the *SV* waves. The major radiation direction by the EMAT in Fig. 1 depends on the driving frequency, the meanderline spacings, and the wave modes.[10] We choose to focus the *SV* waves at a fixed frequency by continuously changing the meanderline spacing so that the excited *SV* waves become coherent on a focal line.

Another technique is possible for focusing the shear-horizontal (*SH*) wave by the periodic-permanent-magnet EMAT (PPM-EMAT),[5] which consists of the elongated spiral coil and the periodically arrayed thin permanent magnets. The direction of the *SH* wave is governed by the spatial period of the magnet array and the frequency. The *SH* wave can be concentrated on a focal line by changing the magnet thickness. However, this method for focusing the *SH* wave is impractical for many purposes, because the megahertz-range *SH* wave needs the magnets thinner than 1 mm, which are intolerable to even a small liftoff. Besides, the present focusing technique is superior at two points. One is the high accuracy for making the meanderline coil. Unlike the permanent magnet case, the spacing of the meanderline coil can be decreased as small as the fabrication accuracy. The recent printed circuit technique makes it possible to produce the meanderline coil of theoretically generated unequal spacing within 1-μm accuracy. The second advantage is in the use of the *SV* wave itself. The *SV* wave radiated from a line source

[a]Electronic mail: ogi@me.es.osaka-u.ac.jp

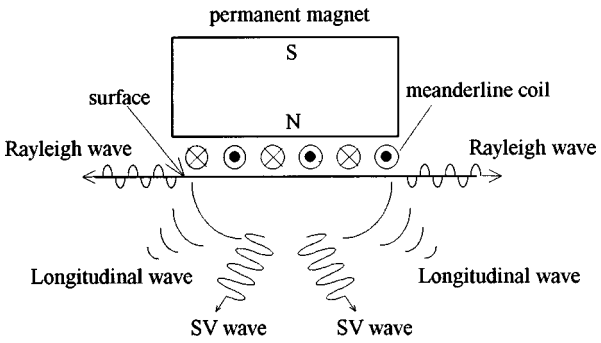

FIG. 1. Typical elastic wave radiation by an EMAT with a permanent magnet and a meanderline coil with equal spacings.

has a sharp directivity,[11] unlike the broad radiation patterns of other elastic modes.

I. DESIGN OF THE MEANDERLINE COIL

We consider a two-dimensional space, where the half-space of $z>0$ is filled with an electrically conducting material and the x-y plane coincides with the surface (Fig. 2). A meanderline coil and a permanent magnet are located near the surface. When the coil is driven by a current, the shearing forces parallel to the surface arise mainly under the straight parts of the coil due to the Lorentz force, the magnetization force, and the magnetostriction effect.[4,5] Only the Lorentz force is the possible source in a nonmagnetic metal, but all three contribute to producing the shearing force in a ferromagnetic metal.

When the meanderline coil has a constant spacing l, the angle θ for the major radiation is determined so that the elastic wave originated from each source becomes coherent:[10]

$$\sin\theta=\frac{c}{2lf}, \tag{1}$$

where c is the longitudinal or shear wave velocity and f is the frequency of the driving current. On the basis of this relation, we intend to focus the SV wave to a line in the sample using the variable spacing. Figure 3 illustrates the

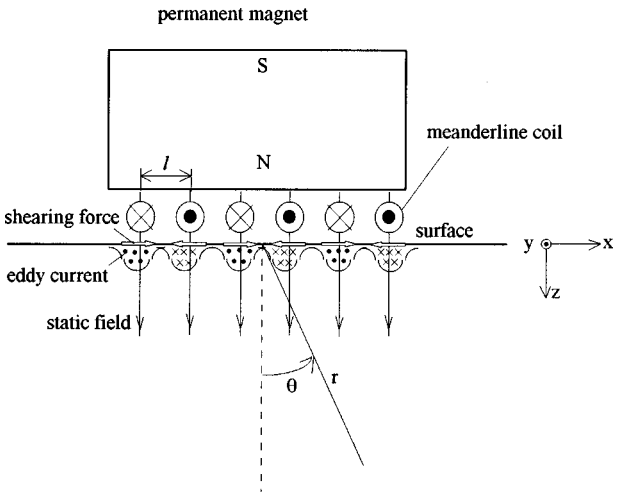

FIG. 2. Two-dimensional field for analyzing the radiation of the EMAT. Only Lorentz force is considered for simplicity.

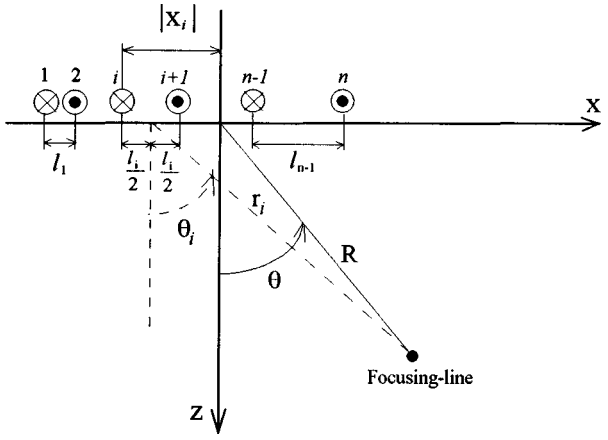

FIG. 3. Determination of the meanderline configuration.

determination of the meanderline spacing. First, we set the frequency, a focal line in the sample, and the edge of the coil at the most left side (i.e., setting f, θ, R, and x_1). The location of $(i+1)$th line (x_{i+1}) is determined so that the spacing l_i locally satisfies Eq. (1):

$$\sin\theta_i=\frac{c_S}{2l_if}=\frac{|R\sin\theta-x_i-l_i/2|}{\sqrt{(R\cos\theta)^2+(R\sin\theta-x_i-l_i/2)^2}}, \tag{2}$$

where c_S is the shear wave velocity. Equation (2) is solved for l_i by Newton's method with known x_i and then we can determine the detailed configuration of the meanderline coil. In this study, we set $f=4$ MHz, $\theta=40°$, $R=100$ mm, $x_1=-30.88$ mm, and $n=98$ with $c_S=3.2$ km/s. Figure 4 shows the meanderline spacings calculated for the above parameters.

We have fabricated the meanderline coil by printing copper on a polyimide sheet and then etching the copper following the designed pattern. This technique allows us to make a high-impedance coil of an arbitrary geometry with the accuracy of 1 μm. The liftoff of the sheet coil is only 25 μm, improving the weak coupling efficiency of the EMAT.

II. NUMERICAL SIMULATION OF RADIATION DIRECTIVITY

A numerical simulation is possible for estimating the radiation pattern of the EMAT. Considering a nonmagnetic

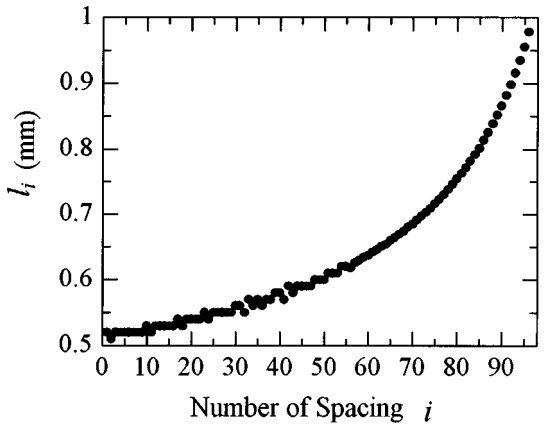

FIG. 4. Variable of the meanderline coil.

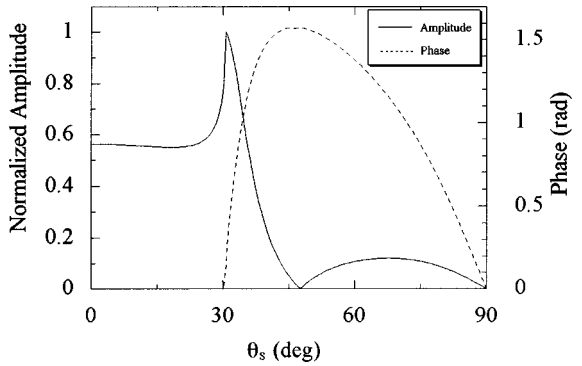

FIG. 5. Directivity of the amplitude and the phase of the *SV* wave radiated from the single strip source.

metal, the EMAT shown in Fig. 2 excites the shearing Lorentz force in the x direction in the surface region. When the sample material has a good conductivity, the shearing force takes place in the surface skin and can be considered as the traction force on the x-y plane.[12] Thompson[5] derived the Fourier transform expression for the periodic traction force and, by taking up the fundamental component, showed that it is proportional to $\cos(\pi x/l)$. We apply this formula to the small part of the coil, assuming the local uniformity of the spacings. On the surface region between the ith and $(i+1)$th lines, we approximate the traction force by the cosine curve with the characteristic length l_i (spatial frequency of $\pi x/l_i$).

We then digitize the traction-force distribution to a large number of strip sources at equal intervals to calculate the amplitude and the phase of the *SV* wave radiated from the EMAT. Each element source oscillates with the strength and phase prescribed by the cosine function. When a strip source, lying along the y axis at $x=0$ and having a very narrow width compared with the wavelength, vibrates along the x axis, the displacement u_θ perpendicular to the propagation direction of the excited *SV* wave is generated:[11]

$$u_\theta(r,\theta_S) = \frac{C}{\sqrt{r}} \frac{(\lambda+2\mu)\cos 2\theta_S \cos\theta_S}{2\mu \sin 2\theta_S \sin\theta_L \cos\theta_L + (\lambda+2\mu)\cos^2 2\theta_S} \times e^{j[(3/4)\pi - k_S r]}, \tag{3}$$

$$\cos^2\theta_L = 1 - \left(\frac{\lambda+2\mu}{\mu}\right)\sin^2\theta_S, \tag{4}$$

at a far distance r from the source. Here C is a constant, λ and μ are Lame's constants, $k_S(=\omega/c_S)$ is the wave number of the *SV* wave, and θ_S is the propagation direction of the *SV* wave. Figure 5 shows the normalized amplitude and the relative phase referring to $\theta_S=0°$ of the *SV* wave radiated from the single strip source as functions of θ_S for $c_S=3.2$ km/s, $\mu=26$ GPa, and $\lambda=58$ GPa. We see that the amplitude directivity has a sharp peak around $\theta_S=30°$, which corresponds to the critical angle of the longitudinal wave ($\theta_L=90°$), and all the exciting energy is directed toward the shear wave generation. Therefore, it is beneficial to locate the focal line so that all the sources take the angle θ_i centered around this angle, although Eq. (1) must be satisfied. The angle θ_i ranges from 23° to 51° with the meander-line coil designed in this study (Fig. 4).

By applying Eq. (3) to all the strip sources and numerically integrating their contributions,[13] we map the amplitude and the phase of the *SV* wave in the two-dimensional region. Figure 6 shows the result for the line-focusing EMAT (LF-EMAT) with the coil designing of Fig. 4 and, for comparison purposes, the constant-spaced EMAT (CS-EMAT) of $l=0.65$ mm. Attenuation is not included. The results are normalized by the maximum amplitude in the LF-EMAT case. We find that the LF-EMAT successfully focuses the *SV* wave at the position as expected ($x=64.2$ mm, $z=76.6$ mm), while the CS-EMAT produces the broad radiation pattern

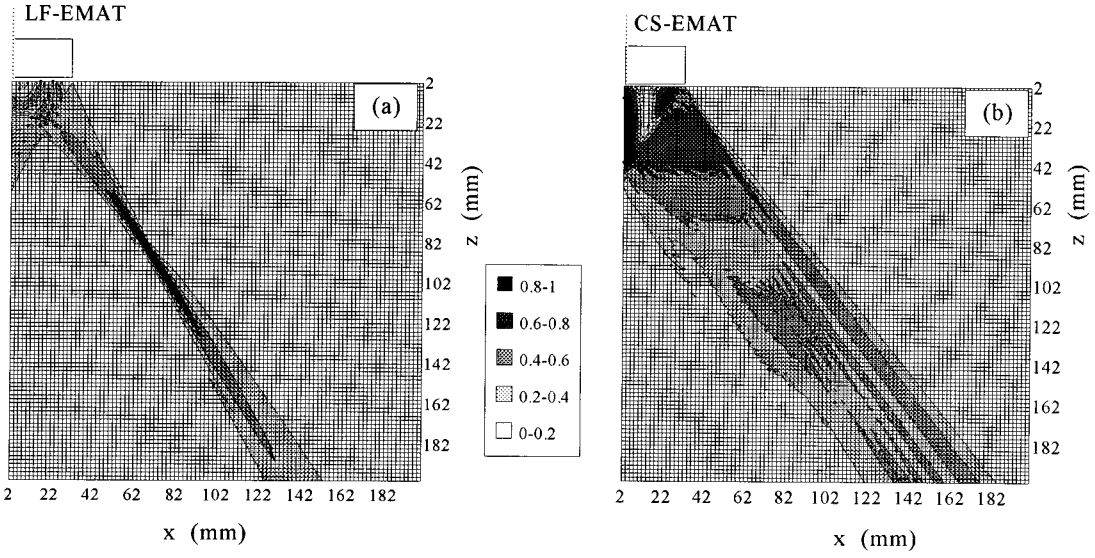

FIG. 6. Simulation of the two-dimensional distribution of the *SV*-wave amplitude radiated by (a) the LF-EMAT and (b) the CS-EMAT.

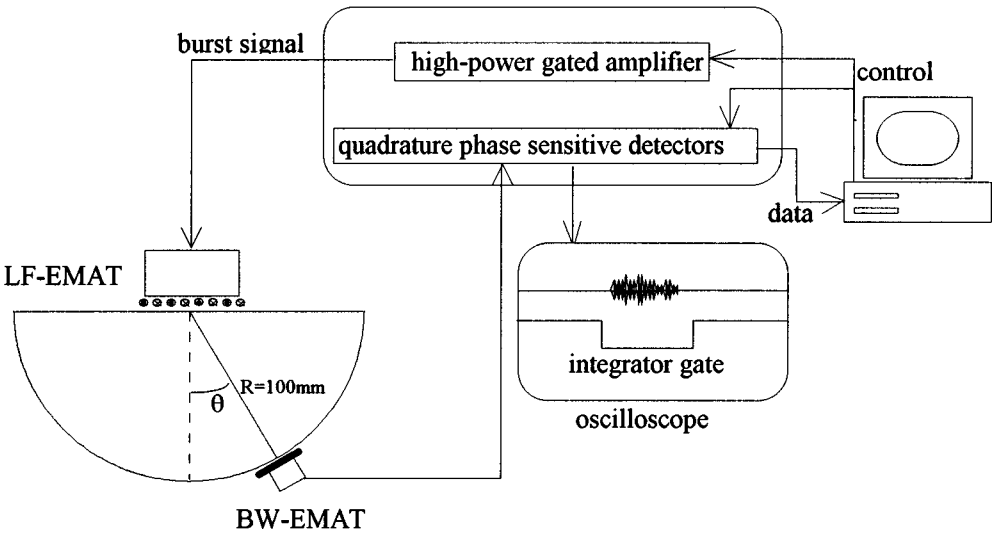

FIG. 7. Measurement setup for the directivity of the *SV*-wave amplitude.

and naturally the peak amplitude is smaller than the LF-EMAT case.

III. MEASUREMENT OF DIRECTIVITY

Figure 7 sketches the measurement setup for the radiation pattern of the EMATs. We use a half-cylindrical sample of an aluminum alloy (Al2017), whose diameter is 200 mm and axial length is 100 mm. The EMAT is located on the middle of the flat surface and is driven by high-power burst signals of 8-μs duration. The *SV* waves generated by the EMAT are received by the bulk-wave EMAT[6,8] located on the cylindrical surface. To produce a good spatial resolution for the directivity measurement, the coil face of the bulk-wave EMAT is shielded with copper sheets to make a 1-mm-wide aperture. The received signal is fed to the quadrature phase detectors to extract the in-phase and out-of-phase outputs relative to the driving signal by analog-integrator gates of 30-μs width. The amplitude is determined from the root of their squares. The details of electronics are found in the pervious work.[6]

The measurements have been performed for two EMATs, the LF-EMAT and the CS-EMAT ($l=0.65$ mm). Figure 8 shows the amplitude distribution as a function of the propagation direction. This includes the results of the numerical simulation, which shows a good agreement with the measurement, indicating the validity for estimating the radiation pattern. It is clear that the LF-EMAT is much superior to the CS-EMAT in the directivity sharpness. We also show the measured directivity pattern when the LF-EMAT is driven at 2.5 MHz. As the driving frequency decreases, the amplitude peak moves to larger angle region. This is easily understood from Eq. (1), but the directivity shows the sharpest peak at the designed angle and frequency.

We show the as-received signals at 4 MHz for three angles in Fig. 9. They also indicates the good directivity of the LF-EMAT. The signal from the LF-EMAT at the focusing angle ($\theta=40°$) is not flat, which is attributed to the transit time difference from the sources. The meanderline coil was about 60 mm long. The maximum difference occurs between the edge sources and it is estimated to be 12 μs. In the measurement, we used an 8-μs burst signal. Therefore, they are partially superimposed and the received signal takes the shape of a larger duration.

IV. DETECTION OF SHALLOW NOTCH

The LF-EMAT was then used for detecting the shallow notch on the opposite surface of an aluminum block (76-mm hight, 60-mm width, and 500-mm length) introduced by the electrodischarge technique. The notch was 20 mm long, 1.0 mm wide, and 0.2 mm deep. The notch was located at the distance of 111.5 mm from the edge of the block. The focal line of the EMAT lays on the opposite surface. By moving the EMAT on the upper surface in the length direction, we measure the amplitude of the scattering signal from the notch.

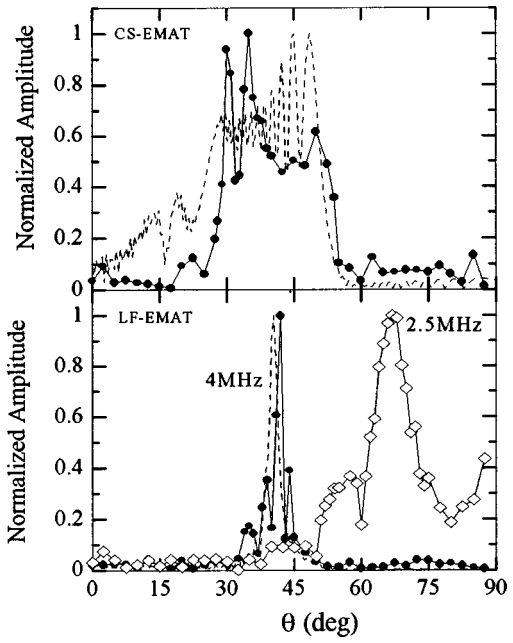

FIG. 8. Measurement and calculation of the directivity of the *SV*-wave amplitude. The solid circles are the data at 4 MHz and the open lozenges at 2.5 MHz. The broken lines show the calculation results at 4 MHz.

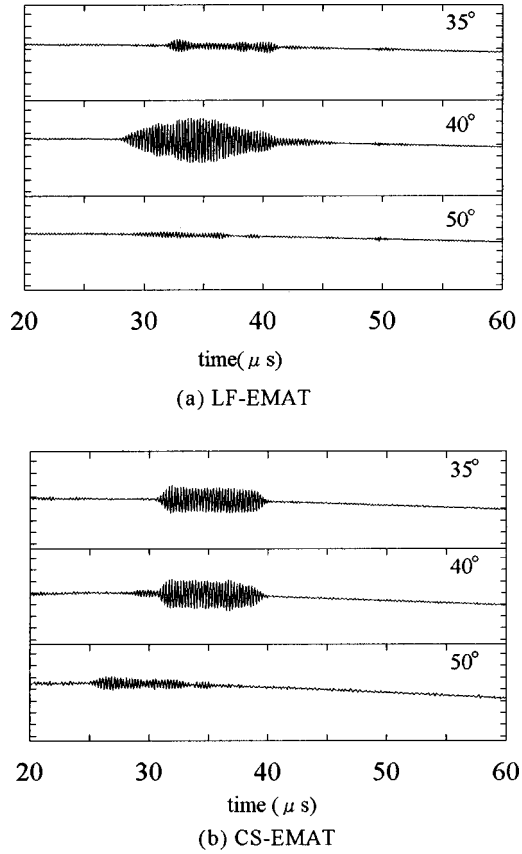

FIG. 9. Wave forms received at three angles for (a) the LF-EMAT and (b) the CS-EMAT.

The same EMAT receives the signals. The result is plotted in Fig. 10. If the focal line is away from the notch, the amplitude is as small as the noise level. Approaching the notch, the amplitude increases and, after taking the peak, it suddenly decreases back to the noise level. We show the maximum scattering signal in Fig. 11, where the signal has the flat shape and the duration is comparable to that of the input burst signals of 16 μs, unlike the previous case in Fig. 9(a). This can be explained as follows. The directivity pattern of the *SV* wave generated from the single source (Fig. 5) is also applicable to express the efficiency directivity in the receiving stage. The total transduction efficiency is governed by the square of this pattern and the peak around $\theta_S = 30°$ is much more enhanced. Therefore, the coil parts located near

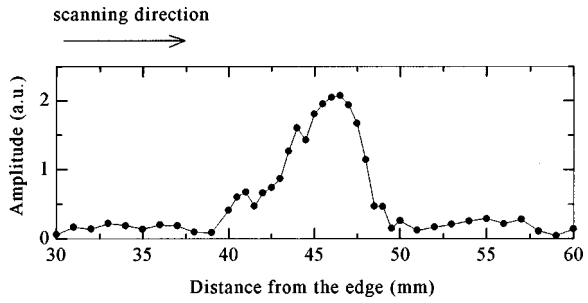

FIG. 10. Amplitude of the scattering echo from the notch detected by the LF-EMAT at 4 MHz.

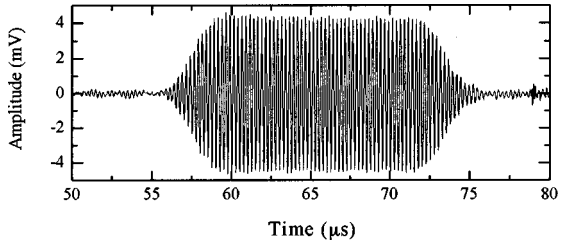

FIG. 11. Scattered echo from the notch of 0.2 mm deep.

this angle primarily contribute to the received signal. Considering only these parts, the transit time is approximately the same, which makes such a flat signal. We measured the transit time of the received signal through the phase[14] and obtained 57.8 μs. The distance between the line source located at $\theta_S = 33°$ and the notch bottom was 91.7 mm, and the transit time of the round trip is then calculated to be 57.3 μs with $c_S = 3.2$ km/s. This agreement supports the above explanation.

V. CONCLUSIONS

The line-focusing EMAT has been developed for concentrating the *SV* wave in a metal by designing the variable spacing of the meanderline coil. Owing to the high accuracy of fabricating the printing coil and the unique radiation pattern of the *SV* wave, the line-focusing EMAT establishes a sharper directivity pattern. The numerical simulation has been used for predicting the radiation pattern of the EMAT, which showed a good agreement with the measurement. The directivity measurement proved a sharper amplitude peak of the focusing EMAT than the EMAT with an equal-spacing coil. The measurement also indicated that the location of the focal line can be controlled through the frequency, though the directivity is broadened.

The line-focusing EMAT showed a pronounced sensitivity for detecting the shallow notch of 0.2-mm-depth on the opposite surface of a block. The echo from the notch was large enough and it will be measurable even for smaller notches. The line sources having the angle near 30° to the focal line give the largest contribution to the flaw detection.

(Received 13 August 1997; accepted for publication 28 January 1998)

Among the various techniques available, ultrasonic Lamb waves offer a convenient method of evaluating composite materials. Since the Lamb wave velocity depends on the elastic properties of a structure, an effective tool exists to monitor damage in composites by measuring the velocity of these waves. Lamb wave measurements can propagate over long distances and are sensitive to the desired in-plane elastic properties of the material. This paper describes two studies which monitor fatigue damage and two studies which monitor thermal damage in composites using Lamb waves. In the fatigue studies, the Lamb wave velocity is compared to modulus measurements obtained using strain gage measurements in the first experiment and the velocity is monitored along with the crack density in the second. In the thermal damage studies, one examines samples which were exposed to varying temperatures for a three minute duration and the second includes rapid thermal damage in composites by intense laser beams. In all studies, the Lamb wave velocity is demonstrated to be an excellent method to monitor damage in composites. © *1998 Acoustical Society of America.* [S0001-4966(98)02705-2]

INTRODUCTION

Composite materials are being more widely used today by aerospace, automotive, sports equipment, and a number of other commercial industries because of their advantages over conventional metals. Composites have a high strength-to-weight ratio and can be constructed to meet specific design needs. In addition to satisfying the design specifications, composites offer weight savings over traditional metals without sacrificing strength. With the advantages of composite materials, their use is continually increasing and becoming more widespread to a variety of fields.[1–3]

O'Brien *et al.*[4] and Charewicz and Daniel[5] have examined the fatigue behavior of laminates and proposed lifetime prediction models based on fatigue factors such as increased matrix cracking, delamination growth, and stiffness loss. Ogin *et al.*[6,7] and Lim and Hong[8] have modeled the stiffness reduction in composites due to the effects of matrix cracking. Laws and Dvorak[9] have investigated the progression of matrix cracking as well as stiffness loss due to transverse cracking.

In addition to fatigue damage, thermal degradation of composites is of concern. Street *et al.*[10] have examined how composites respond to thermal damage of temperatures up to 350 °C for short durations, as well as exposure times as long as 30 min for temperatures of 225 °C. Herakovich and Hyer[11] and Ermer and Mall[12] have studied the effects on composites which were thermally cycled. The temperature range used was −157 °C–+121 °C in Ref. 11 and 149 °C–427 °C in Ref. 12. Stansfield and Pritchard[13] have subjected composites to rapid changes in temperature. These fluctuations, similar to the flight profile of supersonic aircraft, can lead to moisture absorption and matrix cracking.

Traditional nondestructive evaluation (NDE) techniques used on metals are often not easily adaptable to composites due to the inhomogeneous and anisotropic nature of these materials. Finding an effective means of nondestructively monitoring damage in composites is a challenging task, but it is extremely important to the safety and reliability of such structures. Several techniques are available to nondestructively evaluate damage in materials.[14–16] Salkind[14] and Stinchcomb[15] detail various methods used for damage detection in composites such as ultrasonics, x-ray radiography, thermography, and holography. In addition, Daniel *et al.*[16] examined the use of ultrasonic backscatter to monitor crack density and compared the results to those obtained using x-ray radiography.

Among the various techniques available, ultrasonic Lamb waves offer a convenient method of evaluating these composite materials. As a material is damaged, the elastic parameters of the structure change. Since the Lamb wave velocity depends on these properties, an effective tool exists to monitor damage in composites by measuring the velocity of these waves. Additionally, Lamb wave measurements are better than conventional through-the-thickness ultrasonic measurements because they can propagate over long distances and are sensitive to the desired in-plane elastic properties of the material.

[a)]Current address: NASA Langley Research Center, Mail Stop 231, Hampton, VA 23681.

Studies have been conducted which show a reduction in Lamb wave velocity due to a loss of stiffness caused by matrix cracking.[17–19] All of the authors noted that the in-plane properties of a composite are affected by cracking and that they can be monitored through the use of Lamb waves, which travel perpendicular to the crack direction. Dayal and Kinra[17] showed that for through-the-thickness measurements, the attenuation is sensitive to cracking, while the velocity is not. For Lamb wave propagation in the plane of the plate, both wave speed and attenuation were found to be sensitive to cracking. Tang and Henneke[18] noted that Lamb waves provide information about the in-plane properties of a plate, and this type of measurement is more useful due to the fact that composites are commonly designed to carry in-plane loads. Similarly, Dayal *et al.*[19] noted that the Lamb wave interaction with cracks is much stronger in the plane of the plate and, thus, provides an effective method to detect damage due to transverse matrix cracking.

Given the ability to nondestructively monitor materials using guided waves, studies have been conducted which use Lamb waves to monitor a variety of material properties in composite structures. Karim *et al.*[20] and Mal *et al.*[21] have used inversion techniques to determine the material parameters of composites from experimental Lamb wave data. Habeger *et al.*[22] studied the use of plate waves to monitor the strength of paper for the purpose of monitoring quality control on line for the paper industry. Several authors[23–25] have used Lamb waves to inspect adhesively bonded joints. Lamb wave techniques have also been used to study delaminations,[26–29] porosity,[29,30] and fiber misalignment.[30] Recently, Lamb waves have even been used by Lee *et al.*[31] to measure the temperature of silicon wafers during processing and by Pei *et al.*[32] for *in situ* measurements of thin film thickness. Both of these techniques would be of interest to the semiconductor processing industry.

While numerous studies exist which examine fatigue damage in composites using nondestructive techniques, few, if any, have been conducted which monitor thermal damage using ultrasonic nondestructive evaluation techniques. In the studies mentioned earlier,[10–13] the effects of thermal damage were measured using mainly mechanical tests and microscopic observation. This work will focused on the use of Lamb waves to nondestructively monitor fatigue as well as thermal damage in composite structures.

The following sections describe two experimental studies which monitor fatigue damage in composites using Lamb waves. In the first study, the Lamb wave velocity was compared to modulus measurements obtained using strain gage measurements. Additionally, experimental dispersion curves are compared for damaged and undamaged specimens. In the second study, the Lamb wave velocity was monitored along with the crack density. For both studies, the Lamb wave velocity measurements showed a significant decrease as the samples underwent increasing amounts of damage.

In addition to the fatigue studies, two studies were also conducted which monitor thermal damage in composites using the Lamb wave technique. The first study involves samples which were heated to varying temperatures for a three minute duration. The second study examined rapid thermal damage in composites. These samples were subjected to a very short duration (0.5 and 1.0 s) laser source. In both studies, the Lamb wave velocity was demonstrated to be an excellent method to monitor thermal damage in composite materials.

I. FATIGUE DAMAGE 1

In this experiment, studies have been conducted which monitor fatigue damage in composite samples using strain gage measurements as well as Lamb wave velocity measurements. A description of the test samples is followed by the results of two different measurements of Lamb wave velocity. The first technique is a contact measurement done at a single frequency, while the second involved an immersion study of Lamb waves in which dispersion curves were obtained. The results of the Lamb wave method for monitoring fatigue damage are compared to the damage progression measured using strain gages.

The composite samples studied were AS4/3501-6 graphite/epoxy with a stacking sequence of $[0/90_3]_S$. Two 30.5-by 38.1-cm plates were manufactured and C-scanned prior to being cut into specimens to check for any abnormalities. The scans revealed a 5%–7% level of porosity in the samples. The plates were then cut into 28-by 3.8-cm coupons. The finished coupons had an average thickness of 0.12 cm. Two 0.635-cm strain gages were attached to each sample: one axial and one transverse. From the values measured for the stress, axial strain, and transverse strain, one can obtain Young's modulus and Poisson's ratio for the sample.

Before the fatiguing process, two samples were loaded quasi-statically to failure to obtain Young's modulus, Poisson's ratio, and ultimate strength. Each of these coupons was loaded from 0 to 3250 microstrain and back twice. On the third run, the samples were loaded to failure. The modulus and Poisson's ratio were obtained by averaging the values measured for each of the three load cycles described above. The ultimate strength was defined as the load at which the samples failed.

The specimens were subjected to tension–tension fatigue in a 55-kip capacity load frame. The samples were fatigued at a frequency of 10 Hz and at an R value (minimum load/maximum load) of 0.3. The upper load was taken to be 33% of the ultimate strength, which had a value of 160 MPa. The specimens were successively raised to higher fatigue cycle values. The velocity of the lowest order symmetric Lamb mode was measured and the modulus obtained from strain gage measurements both before and after each cyclic loading. The samples were removed from the load frame at intermediate values of fatigue cycles in order to make the contact measurements.

Lamb modes can be generated by placing a longitudinal contact transducer on a plate and driving it with a sine wave tone burst. Ditri *et al.*[33] showed that periodic loading normal to the surface of a plate, as produced by a longitudinal transducer, will excite Lamb waves at distances away from the source which are large compared to the wavelength of the Lamb mode. Lamb waves are generated in most materials at a distance of roughly 1 cm or less. Since measurements are

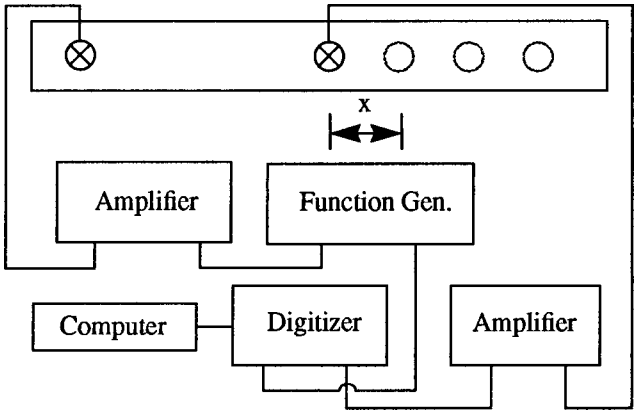

FIG. 1. Experimental arrangement for the contact measurement.

normally done anywhere from 5 to 10 cm away from the source, this does not create any difficulties in generating and measuring Lamb modes using this technique.

A Lamb wave was generated by using a 2-cycle, 0.5-MHz sine wave to excite the sending transducer. The signal was received at various positions, digitized at 10 MHz, and the waveforms saved on a computer. Both the sending and receiving transducers were broadband longitudinal wave transducers with a nominal center frequency of 1.0 MHz and a diameter of 1.27 cm. A coupling gel was used between the transducers and the plate. The experimental arrangement is shown in Fig. 1.

The time differences were measured by imposing a computational delay on the first signal to overlap the signals received at greater distances. The small thickness of the plates combined with the low frequency used to generate the Lamb wave yield a frequency–thickness product of 0.6 MHz·mm. In this region, only the S_0 and A_0 modes propagate. Therefore, the leading part of the wave was identified as the lowest order symmetric Lamb wave, which is not very dispersive. The trailing portion of the signals contained the dispersive antisymmetric wave as well as edge reflections. The distances were measured to an accuracy of 0.01 cm using a sonic ranger. A least-squares fit from a plot of time and distance was performed to obtain the velocity of the prompt S_0 mode.

As the samples underwent increasing amounts of fatigue, an increasing number of cracks developed in the 90° plies. These cracks degrade the modulus. Photomicrographs at different magnifications were taken of the edge of a fatigued composite and are shown in Fig. 2. For the lowest magnification, the fibers from the 0° laminas are the vertical bright streaks on the outer edges and the six 90° laminas are what appear as dots in between the outer layers. The ends of the fibers for these laminas is seen quite clearly at the higher magnification shown in Fig. 2(d). The size of the crack shown is approximately 1 μm.

The composite samples exhibited a decrease in the velocity as the modulus degraded due to increasing fatigue. Both the modulus and velocity squared follow the same general trend with increasing fatigue cycles. This is shown schematically in Fig. 3. In the plot, the velocity was normalized to the velocity measured before fatiguing. The normalized

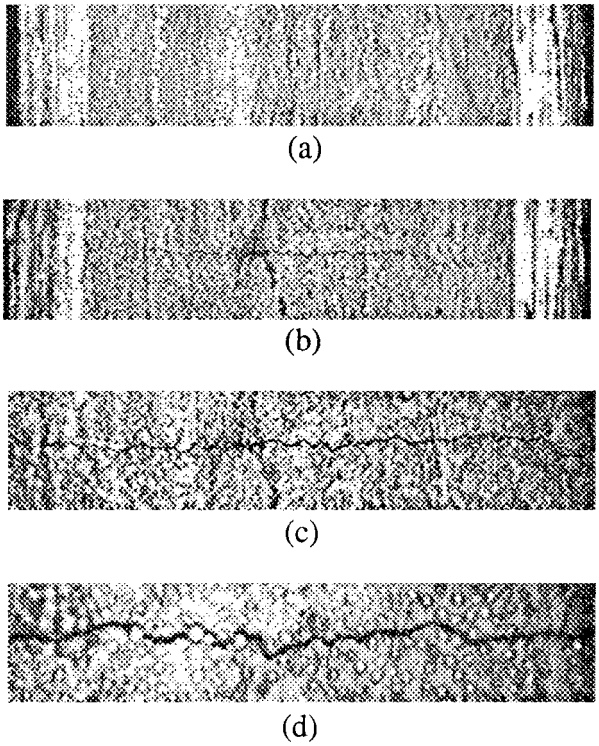

FIG. 2. Photomicrographs of the edge of a composite sample: (a) without a crack and (b)–(d) with a transverse matrix crack. The magnification for each was: (a) 5.5; (b) 5.5; (c) 11.0; and (d) 28.0. The thickness of the sample is 0.12 cm.

modulus was obtained in a similar manner. The velocity squared error bars are an estimate of the total error due to the uncertainties in the distance measurement and the digital signal overlap used to obtain the time differences. Some of values for the three measurements on the individual samples varied as much as 8%–10% from the average. Using a similar technique, Tang and Henneke[18] have reported deviations as great as 10% from the average of three measurements as well.

The velocity of the lowest order symmetric mode depends on the square root of the modulus for isotropic plates and the square root of the in-plane stiffness values for unidirectional composites.[34] Since the modulus shown in the plot was obtained from strain gage measurements of the in-

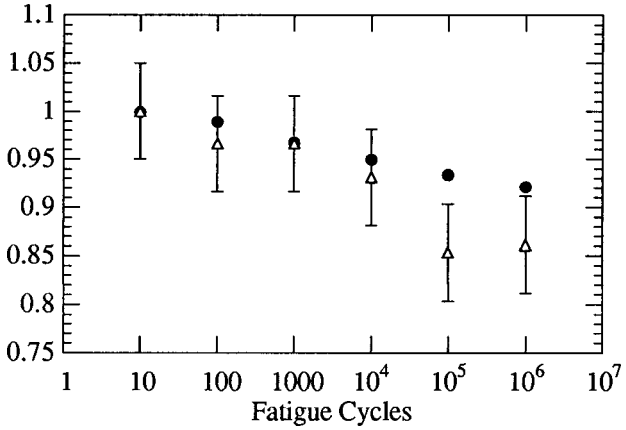

FIG. 3. Plot of normalized modulus (solid circles) and normalized velocity squared (open triangles) versus fatigue cycles for a fatigued sample.

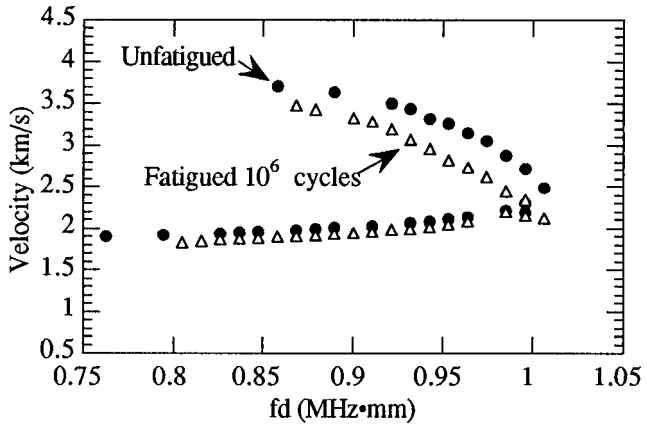

FIG. 4. Plot of the lower modes of the experimental dispersion curves for a sample which is undamaged (solid circles) and one which has been fatigued 10^6 cycles (open triangles).

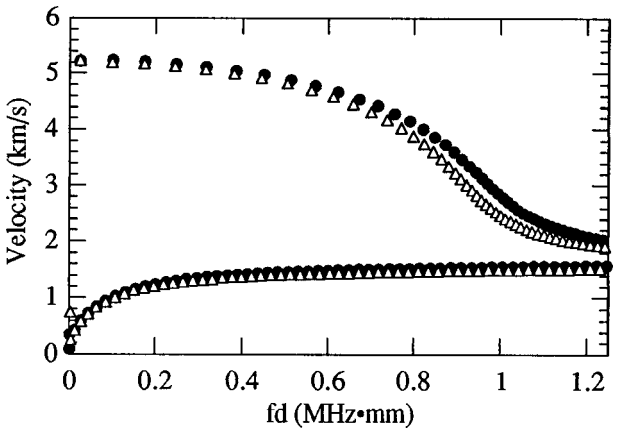

FIG. 5. Comparison of lower modes of numerical curves using full parameters (solid circles) and with c_{33} reduced by 5% (open triangles).

plane stiffness, the square of the velocity was chosen to plot against the number of fatigue cycles for convenience.

In addition to the contact measurements, which were done at a single frequency, an immersion method was used to obtain dispersion curves for two samples. The experimental arrangement for this type of measurement is detailed by Balasubramaniam *et al.*[35] In this method, the sample was immersed in water, which serves as the couplant between the transducer and the plate, and the same transducer was used to generate and receive the ultrasonic signal. An aluminum block served as a reflector for the input pulse as the specimen was rotated about the corner. When a Lamb wave is excited in the plate, part of the total energy is converted to a propagating Lamb mode. Due to this loss of energy, a minimum in the frequency spectrum of the reflected signal corresponds to the frequency at which a Lamb mode is propagating.

The reflected waveform at each angle was saved for later analysis of the frequency content. The velocity can be determined from Snell's law using the fact that only a longitudinal wave is supported in water and that the Lamb mode is propagating in the plate. After determining the frequency of the minimum for each angle, the velocity verses the frequency–thickness product can be plotted to obtain the dispersion curve. The frequency range is determined by the bandwidth and frequency of the transducer used.

In this experiment, an immersion transducer with a nominal center frequency of 1.0 MHz and diameter of 2.86 cm was used in a pulse-echo arrangement. The specimen was rotated 0.4°–60° in steps of 0.4° and the reflected waveform at each angle was saved for later analysis of the frequency content. After determining the frequency of the minimum for each angle, the velocity (from Snell's law) verses the frequency–thickness product was plotted to obtain the dispersion curves. This technique was used to obtain dispersion curves for an undamaged sample as well as one which had one million fatigue cycles. The results are shown in Fig. 4.

The dispersion curves for the fatigued sample is clearly shifted from the undamaged sample for both of the lower modes. The curves have roughly a 7% difference in velocity for the symmetric mode. This is in good agreement with the contact result for the same sample, which had a 7.2% relative decrease in velocity after one million fatigue cycles. It is also noted in the figure that the A_0 mode velocity variation was much less than that of the S_0 mode. This can be understood by examining how the velocity relates to the modulus. The velocity changes as the square root of the stiffness for the symmetric mode, but as the fourth root of the stiffness for the antisymmetric mode.[34] Therefore, the A_0 mode velocity will change less than the S_0 mode velocity for a given decrease in modulus.

For propagation across the fibers, where the 1-axis is in the fiber direction and the 3-axis is perpendicular to the fibers, a decrease in the elastic stiffness parameter c_{33} alters the dispersion curves. This is due to the fact that c_{33} is the modulus across the fibers. The transverse matrix cracks (due to fatigue damage) should, therefore, lead to a decrease in the elastic stiffness constant c_{33}. To examine the effect of the matrix cracking, a through-the-thickness finite element model, detailed in Dong and Huang[36] and Datta *et al.*,[37] is used to generate dispersion curves in laminated composites. Numerical dispersion curves were calculated in which the value of c_{33} was reduced by 5% in only these layers. A comparison was done for the numerical dispersion curves for the lower modes. The curves for the lower modes calculated using the full elastic parameters and those calculated using c_{33} reduced by 5% in the 90° layers are shown in Fig. 5. When compared in the region where the experimental data was obtained ($0.75 \leqslant fd \leqslant 1.05$ MHz·mm), the numerical results (see Fig. 5) are in good agreement with the experimental dispersion curves shown in Fig. 4. For the theoretical curves in this region, the S_0 velocity shows roughly a 7% decrease and the A_0 mode variation is much less than the S_0 velocity change. These are exactly the characteristics which were observed in the experimental curves.

It has been noted by Charewicz and Daniel[5] that strain gages only measure a local change in modulus and do not measure a global change in the specimen. Since the strain gages used in this study had a gauge length of 0.635 cm, they may not give an accurate account of damage throughout the entire plate. This would be especially true at the lower fatigue levels where very few cracks were observed in the samples. As the samples were damaged further, the cracking

became more uniform. Thus a Lamb wave technique at low frequencies used to track the modulus as a function of fatigue history may provide improved global interrogation over the propagation length of the wave.

II. FATIGUE DAMAGE 2

Additional composite samples of the same material, AS4/3501-6, and same architecture, $[0/90_3]_S$, were obtained in order to conduct a second fatigue damage study. The new composites were loaded to greater levels in order to induce damage more quickly in the samples. Two composite plates identical to those used in the previous study were obtained. The new composite plates were C-scanned prior to cutting them into coupons to check for porosity. The images were very uniform and, therefore, no large scale areas of porosity were expected. The plates were then cut into 18 3.8-by 28-cm coupons. The edges were polished and photomicrographs were taken. No appreciable amounts of porosity were found.

Similar to the first study, the specimens have been subjected to tension–tension fatigue. The samples were fatigued at a frequency of 10 Hz and at an R value of 0.35. For this study, however, the upper load was taken to be 45% of the ultimate strength, which has a value of 200 MPa. The samples were fatigued for a range of 10^n cycles ($n=3$, 4, and 5). As before, the samples were removed from the load frame at intermediate values of fatigue cycles and the velocity of the lowest order symmetric Lamb mode was measured. In addition to loading these samples at higher levels, the crack density was also monitored during the process.

A Lamb wave was generated by using a 6-cycle, 0.5-MHz sine wave to excite a longitudinal wave transducer with a nominal center frequency of 0.5 MHz and a diameter of 1.27 cm. The signal was received at various positions by an array of pinducers with active elements of 0.135 cm. The pinducers were placed in a holder at a fixed separation distance of 1.0 cm between each transducer. This receiving arrangement greatly reduces the error in the measurement of the velocity due to the uncertainty in the distance between the transducers. Since a differential measurement is being made, fixing the transducers in a holder virtually eliminates the distance error. A coupling gel was used between the transducers and the plate.

The signals were digitized at 10 MHz, averaged, and the waveforms saved to the computer. In an effort to reduce the error incurred in the time measurement by human judgement of the overlap region, the time differences between the pinducers were measured by performing a cross correlation. The leading part of both waves, which is identified as the lowest order symmetric Lamb wave, was used in the correlation. The distances between the five pinducers in the array were held fixed at 1, 2, 3, and 4 cm, respectively. The velocity of the prompt S_0 mode was obtained by a least-squares fit from a plot of time and distance.

To measure the crack density, a 2.5-cm section in the middle of the plate was marked. This was done in order to count the number of cracks occurring in the same 2.5-cm length in the sample. Keeping the same measurement area is especially important at the lower cycle levels where the cracking is not very uniform. The number of cracks was counted by examining the edges of the coupons under a microscope. The velocity measurements described above were centered over the same region where the crack density was monitored.

The influence of fatigue cycles on transverse matrix cracking and Lamb wave velocity was examined for five different samples. The velocity and crack density were obtained after each cyclic loading. Each velocity was obtained from the average of three measurements. The standard deviation for all of the samples was less than 5% from the average of the three measurements and most were within 2.5% of the average for each individual sample. Thus the reproducibility of the measurements is quite good and provides an improvement over the technique used in the first fatigue study. Also, these results are similar to those obtained by Tang and Henneke,[18] who report a variation of 1.5% using a similar technique.

As expected, the crack density for these samples increased with increasing cycles and, as with the previous study, the velocity squared decreased with fatigue cycles. Since strain gages were not used on these samples, the decrease in modulus will be estimated from the crack density. An expression which relates reduced modulus to crack density is given in Caslini *et al.*[38] For a $[0_m/90_n]_S$ laminate, the stiffness loss is given by[38]

$$\frac{E}{E_0}=\left[1+\frac{nE_2}{mE_1}\frac{\tanh(\lambda/2D)}{(\lambda/2D)}\right]^{-1}, \tag{1}$$

where

$$\lambda^2=\frac{3G_{12}E_0}{h^2E_1E_2}\frac{(n+m)}{n^2m}. \tag{2}$$

In the above equations, E and E_0 are the values of the modulus for the damaged and undamaged laminate, respectively. E_1, E_2, and G_{12} are the moduli (longitudinal, transverse, and shear, respectively) for each individual unidirectional lamina in the plate. D is the crack density, h is the lamina thickness, and m and n are the number of 0° and 90° layers, respectively, in the half-thickness of the plate.

For the case presented here, $m=1$, $n=3$, and $h=0.15$ mm. The value for the undamaged modulus, E_0, was obtained from the average of the four modulus measurements for the samples which were loaded to failure. The engineering constants for AS4/3501-6, are taken to be[1]

$$E_1=142.0,\ E_2=10.34,\ G_{12}=7.17,$$

where all values are listed in GPa.

The reduced stiffness as a function of crack density was calculated from the parameters given above using Eqs. (1) and (2). Figure 6 shows a comparison of the calculated reduced stiffness and the normalized velocity squared for all of the samples in this study. The velocity was normalized in a similar manner as described previously. Since the uncertainty in the distance and time measurements in this study is less than that of the earlier study, the velocity error bars are not as large as were previously shown. Due to the possibility of overlooking a small crack under the microscope, the error in calculation of the crack density is assumed to be a ± 1 error in the total number of cracks counted in the 2.5-cm

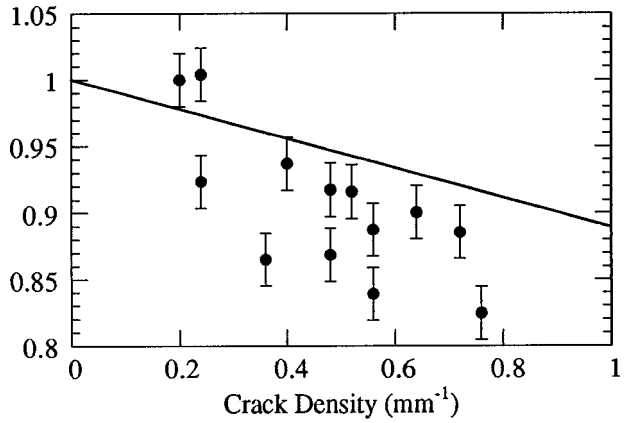

FIG. 6. Calculated normalized modulus (solid line) versus normalized velocity squared (solid circles) as a function of crack density for all samples.

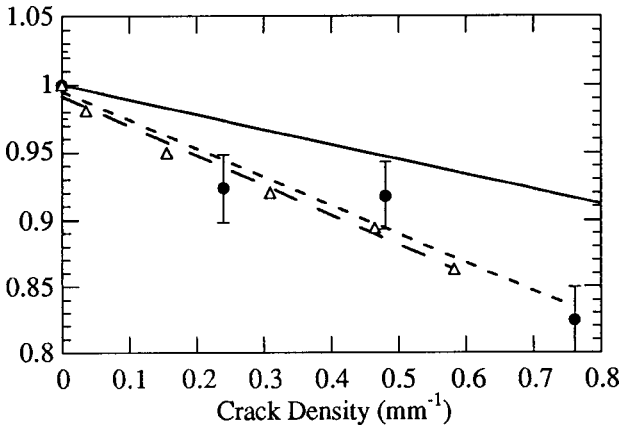

FIG. 7. A plot of the normalized velocity squared for a fatigued sample (solid circles) versus data from Dayal *et al.* (Ref. 19) (open triangles). Curve fits are shown for the data in this study (short dashes) and for the data of Dayal *et al.* (Ref. 19) (long dashes). The solid line is the theoretical modulus reduction described in the text.

length. However, for clarity, the error bars for the crack density have been omitted in the figure. Figure 6 shows a larger decrease for the normalized velocity squared than for the normalized modulus which was calculated from the crack density. Although not as pronounced as the results shown in Fig. 6, this behavior was evident in the previous study when the modulus was measured using strain gages (see Fig. 3).

These results are also in agreement with those found by Dayal *et al.*,[19] who examined the modulus degradation of an AS4/3502, $[0/90_3]_S$ composite using velocity measurement of the lowest order symmetric Lamb mode. The architecture and the fibers (AS4) of the samples used by Dayal *et al.*[19] are identical to the ones studied here. The epoxy matrix used (3502) is slightly different than the one used here, but the material properties of the two samples are very close.

Similar to the measurements done here, the tests by Dayal *et al.*[19] were also done at a frequency of 0.5 MHz. The velocity of the S_0 mode, measured using a different technique, and the crack density, measured using edge replication, were monitored as the samples underwent increasing damage. The modulus was calculated directly from the velocity measurement using the relation[19]

$$E = \rho v^2, \tag{3}$$

where E is the modulus, ρ is the density, and v is the velocity of the S_0 Lamb mode. Given this relation, the normalized modulus will also be equal to the normalized velocity squared. The results from Dayal *et al.*[19] are presented, along with the results for a representative sample from this study, in Fig. 7.

In the figure, the solid line represents the theoretical reduced modulus previously calculated using the material parameters for AS4/3501-6. However, as mention earlier, the parameters for this type of composite are extremely close to those of AS4/3502. Therefore, the theoretical curve shown in the figure is representative of the composites used in both studies. Another interesting feature in the figure involves the comparison of the two velocity measurements. Both sets of data show a larger decrease in normalized velocity squared than what is theoretically predicted for the modulus reduction. Dayal *et al.*[19] reported similar results when the modulus reduction measured using the Lamb wave technique was compared with the results of analytical modeling and static stiffness measurements conducted by other authors. Thus the Lamb wave velocity technique may provide a more sensitive method of damage detection than modulus reduction measurements.

Presented in the second fatigue study are the results of a different technique than that which was used in the previous study for determining the Lamb wave velocity in composites. Due to a reduction in the uncertainty in the distance and time measurements, the error in the velocity measurements were found to be less using this technique than those found in the first study. The crack density was also monitored as a function of fatigue cycles. A decrease in normalized velocity squared with increasing fatigue cycles was noted. This was expected and agrees with the results presented in the initial study.

The main difference between this study and the initial fatigue study was the monitoring of the crack density with fatigue cycles. The crack density was observed to increase with an increasing number of cycles, as is to be expected, and the Lamb wave velocity exhibited a decrease with increasing crack density. This drop in velocity as a function of crack density was compared with the results of Dayal *et al.*,[19] who saw a similar velocity decrease.

As was mentioned before, strain gages only measure a local change in modulus and do not measure a global change in the specimen. The strain gages used in the previous study had a gauge length of 0.635 cm and therefore, may not have given an accurate account of damage throughout the entire plate. It was shown in Caslini *et al.*[38] that the crack density can be theoretically related to stiffness reduction. Since the crack density was monitored over a 2.5-cm length, this becomes the effective gauge length for measuring the modulus reduction via the crack density.

The modulus reduction, calculated from the crack density, was compared to the results obtained using the Lamb wave velocity measurements. A more dramatic decrease was observed in the velocity measurements than in the theoretical modulus reduction. Thus a Lamb wave technique used to track damage in composites may provide improved interro-

gation of the effective stiffness of a structure over the propagation length of the wave.

III. THERMAL DAMAGE

Determining the response of composites to thermal damage is necessary for a complete understanding of the total use environment of these materials. Heat damaged samples, which simulate typical thermal damage on carbon/epoxy aircraft structures, were provided by McDonnell Douglas Aerospace. These 15.24-by 15.24-cm specimens were fabricated as 16-ply, uniaxial plates of AS4/977-3 and had an average thickness of 3.07 mm. All samples had received different levels of heat damage, had been C-scanned, and had Barcol hardness readings performed. The exposure temperatures ranged from 288 °C to 538 °C for a duration of 3 min and included a sample which was exposed to 316 °C for 10 min.

Lamb waves were generated and received with the same techniques described in the second fatigue study. The only differences were that the transmitting transducer had a nominal center frequency of 1.0 MHz and the receiving transducers had fixed separations of 4, 5, 6, and 7 cm. The signal was received at various positions and digitized at 10 MHz. The time differences were measured by imposing a computational delay on the first signal to overlap the signals received at greater distances. A least-squares fit from a plot of time and distance was performed to obtain the velocity of the prompt S_0 mode.

As in the fatigue studies, the velocity of the lowest order symmetric Lamb mode was measured. The results of the velocity measurements in the fiber direction for ten different thermally damaged samples are plotted in Fig. 8. The error bars are an estimate in the velocity error and are mainly due to uncertainty in the digital channel alignment. The decrease in velocity with increasing thermal damage is quite dramatic. The variation in velocity is on the order of 18% for the two extremes of temperature exposure. The correlation with extended temperatures is excellent and provides a method to assess thermal damage. Although the velocity showed a large change with thermal damage, the Barcol hardness numbers provided by McDonnell Douglas showed little variation over this temperature range. Therefore, measurement of the Lamb wave velocity could provide a better technique to assess thermal damage than conventional methods.

A model calculation[36,37] to determine the dispersion curves for this material system was computed using engineering constants supplied by McDonnell Douglas. The four standard engineering values (E_1, E_2, G_{12}, and ν_{12}) can be used to calculate the corresponding five elastic stiffness parameters (c_{11}, c_{13}, c_{23}, c_{33}, and c_{55}) using various techniques.[1] Since a value for G_{23} was not available, the value of c_{44} [where $c_{44}=(c_{22}-c_{23})/2$] must be estimated using common values for polymer matrix/graphite fiber composites.[39] The value of c_{44} typically ranges from 3.5 to 4.0 GPa, so a median value of 3.75 GPa was chosen for the calculation. The density of the material was taken to be 1560 kg/m^3. A five layer model calculation of the dispersion curves for propagation in the fiber direction is shown in Fig. 9.

From the dispersion curve, one can see that the S_0 mode is almost completely nondispersive for the lower frequency–thickness products. Also, the S_0 velocity in this region is around 9 km/s, which is exactly the velocity that was measured for the samples with little or no damage. Thus the model compares well with the experimentally determined velocity.

Theoretical dispersion curves were also calculated for AS4/977-3 using reduced stiffness constants. The effect of reducing different c_{IJ}'s by 20% on the low frequency, nondispersive region of the lowest order symmetric mode ($0.0 \leqslant fd \leqslant 1.0$ MHz·mm) was investigated. The only parameter which altered the velocity of the S_0 mode in this region for propagation along the fibers is c_{11}.

Figure 10 shows a plot of the experimentally determined normalized velocity versus exposure temperature, where the normalized velocity is the velocity in the damaged sample divided by the velocity in an undamaged control sample. Also plotted is the normalized velocity of the S_0 mode with reduced values of c_{11}. Here, the normalized velocity is the velocity with c_{11} reduced divided by the velocity with the full values of the elastic stiffness constants. Both velocities were taken at a constant frequency–thickness product of 0.5 MHz·mm on the dispersion curve. Theoretical calcula-

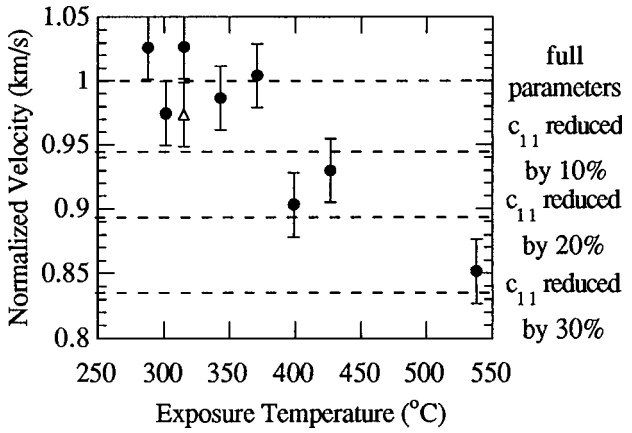

FIG. 10. Plot of the normalized S_0 velocity of samples exposed to different temperatures. The duration times are 3 min (solid circles) and 10 min (open triangle). Also shown (dashed lines) is the theoretically determined normalized S_0 velocity with reduced values of c_{11}, as described in the text.

tions with reduced values of c_{11} show that a 25%–30% reduction in this parameter lowered velocities of the S_0 mode by 15%. This value corresponds to the velocity reduction of the sample which saw an exposure temperature of 538 °C.

IV. LASER DAMAGE

The three laser damaged samples examined were fabricated as quasi-isotropic plates with a stacking sequence of $[0/+45/-45/90]_S$. The fiber/matrix used on two of the samples was IM7/SP500 and the remaining sample was IM7/PEEK. All three samples were irradiated at 100 W/cm^2. The IM7/SP500 samples were subjected to the laser source for durations of 0.5 and 1.0 s. The IM7/PEEK sample was subjected to the laser source for 0.5 s.

In this study, Lamb wave velocities were measured using the same technique described in the second fatigue study. The velocity of the lowest order symmetric Lamb mode was measured in the 0° direction in both the undamaged and damaged regions of each of the samples. The velocities as well as the damage level for each of the different samples are shown in Table I. The listed velocities are the average of three measurements performed in each region. For each of the three measurements in a particular region, the values of the velocity varied less by less than 5% from the average.

As can be seen from the data, the velocity actually increases in the area which was subjected to the laser source. This is contrary to what was seen in the thermally damaged samples discussed earlier in this paper. The main difference between the laser damage and the thermal damage previously mentioned is that the laser subjects the sample to an extremely rapid thermal cycle. This type of heating could actually cause embrittlement of the sample, which would serve to increase the velocity of the Lamb wave in that region.

TABLE I. Data for laser damaged samples.

Sample	Irradiation (W/cm^2)	Time (s)	Fluence (J/cm^2)	Undamaged Vel. (km/s)	Damaged Vel. (km/s)
IM7/SP500	100	0.5	50.0	6.01	6.10
IM7/SP500	100	1.0	100.0	5.91	6.33
IM7/PEEK	100	0.5	50.0	6.50	6.56

V. CONCLUSION

The Lamb wave velocity measurements in this study were conducted at long wavelengths. This was done for several reasons. First, if the wavelength is large compared to the diameter of the fibers, composites can be treated as homogeneous. Second, only the lowest order modes propagate in the frequency range where the contact measurements were conducted. Finally, the effective elastic properties of the material can be measured because local defects, which scatter high frequency waves, will not be observed at long wavelengths.

Lamb waves offer a useful technique for characterizing many forms of damage in composite materials. Lamb wave velocity measurements are better than conventional ultrasonic measurement schemes (i.e., through-the-thickness measurements) because they can propagate over long distances and are sensitive to the desired in-plane elastic properties of the material. The propagation of Lamb waves depends on a variety of material properties: elastic stiffness constants, density, and thickness. As a material is damaged in some fashion, one or more of these material properties are altered. Since the Lamb wave velocity is directly related to these parameters, an effective tool exists to monitor damage in composites by measuring the velocity of these waves.

The Lamb wave velocity is a quantitative measurement and it has been shown by this work to be an effective tool in monitoring both fatigue and thermal damage in composites. Thus the Lamb wave method can be used to verify the integrity of a composite structure over the service life of a component. This is an important measurement for flight qualified composite materials that may have undergone some measure of nonvisible damage, which could seriously degrade the performance of the structure. Since the Lamb wave velocity depends on a variety of material properties, an ideal technique exists to monitor composites as damage is incurred. With the continued development of damage assessment techniques such as the Lamb wave method, the safety of such structures can be assured.

ACKNOWLEDGMENTS

The authors would like to thank John Masters of Lockheed Engineering and Sciences for providing the samples used in the fatigue studies. They would also like to thank Kevin Slattery of McDonnell Douglas Aerospace for providing the thermally damaged samples and Bill Laughlin of Physical Sciences, Inc. for providing the laser damaged samples. This work was supported in part by NASA Grant No. NAG-1-1063 and NASA Task Assignment No. NAS1-19656.

(Received 3 June 1997; accepted for publication 4 February 1998)

This paper investigates the influence of structural parameters on the performance of an optical fiber wound mandrel hydrophone by using the finite element method (FEM). A hydrophone should exhibit the highest possible sensitivity, the widest possible flat frequency response, and an omni-directional sensitivity pattern within the frequency range. The parameters studied included the mandrel geometry, the thickness of the molding coated over the fiber, and the material properties of the constituent parts of the hydrophone. The analysis results showed that the pressure sensitivity of a hydrophone increases in relation to the length of the mandrel and the thickness of the molding. A higher pressure-sensitivity also requires a mandrel or molding material with a relatively low Young's modulus and Poisson's ratio. On the other hand, the flat frequency response of a hydrophone increases when either the mandrel length is shortened or the mandrel material is hardened. The omni-directional characteristic is also improved with a shorter mandrel. Therefore, a hydrophone with the best performance must balance the tradeoff between the geometrical and material parameters. The analysis discussion is focused on a representative specification of a frequency range of up to 5 kHz. © *1998 Acoustical Society of America.* [S0001-4966(98)03905-8]

INTRODUCTION

Interferometric optical fiber hydrophones exploit the changes in an optical path length induced by sound in the optical fibers. One of the major areas of application for hydrophones is in underwater acoustic sensing. There are numerous reasons for this interest which range from cost and performance to the geometric versatility of the sensing head. There are two main approaches to coupling an acoustically induced phase shift in an optical fiber to the detection process: a mandrel sensor or a coated fiber sensor.[1–3] Both of these approaches are viable up to ~50 kHz. In coated fiber sensors the optical fiber is wound in a coil as a sensing element and the size is comparatively large. Since the acousto-optic coupling of the fiber is weak, a long fiber is generally used to increase the induced phase change. Pressure sensitivity is a complex function of a Young's modulus, a bulk modulus, and the cross-sectional area of a secondary coating.[2] In the case of a mandrel sensor, a thin jacket fiber is typically wrapped around a compliant mandrel. The optical fiber then measures the pressure-induced strain in the mandrel. It is important to maximize the scale factor or the acoustic phase response of the sensor in order to maintain a high sensitivity and a flat acoustic response for its frequency range. Mandrel sensors appear to be ideal for point sensors even though they have somewhat limited geometrical versatility.

This paper investigates the influence of structural parameters on the performance of a mandrel hydrophone by using the finite element method (FEM). Acoustic response characteristics such as pressure sensitivity, bandwidth, and directivity depend upon geometry and the material properties of the sensor element. Previous research on mandrel sensors have analytically analyzed and concentrated on compliant plastic mandrels, typical examples being nylon and Teflon.[1,4] Africk analytically determined sensor response by calculating a pressure response term which neglected the cylinder-end response by separately determining the term associated with the radial strain of the mandrel.[4] His results demonstrate a very good agreement between theory and experiment for the case of a relatively hard mandrel like Teflon. However, the calculated results are significantly higher than the experimental results. This is attributed to the neglect of the circumferential deformation of the mandrel. In this paper, the full three-dimensional behavior of a mandrel hydrophone is analyzed by using the FEM without any prior assumptions or simplifications of the structure. A hydrophone should exhibit the highest possible sensitivity, the widest possible flat frequency response, and an omni-directional sensitivity pattern within the frequency range. However, to facilitate a more practical discussion of the analysis results, the frequency range was restricted to 5 kHz as a representative case. The parameters studied included the mandrel geometry, the molding thickness, and the material properties of the constituent parts of the hydrophone. The pressure sensitivity, the frequency range, and the directivity pattern of the hydrophone were analyzed as a function of the structural parameters, and the results discussed.

FIG. 1. Schematic structure of the optical fiber wound mandrel hydrophone.

I. PRESSURE SENSITIVITY OF A MANDREL HYDROPHONE

In a fiber wound mandrel sensor, a thin jacket fiber is typically wrapped around a compliant mandrel and a thin polymer, less than 1 mm thick, is coated over the fiber as protection during operation. The optical fiber measures the pressure-induced strain in the mandrel and protecting layer. Mandrel sensors are important because they are easy to produce and they exhibit a high sensitivity and an amenability to spatial shading.

Consider the mandrel sensor shown in Fig. 1(a). A homogeneous cylindrical mandrel of length L_m and radius R_m is radially wrapped with a single-mode fiber of length l over a length L. The molding layer is assumed to be only coated on the fiber layer and has a thickness of less than 1 mm. Assuming that the fiber sensor response is driven solely by the mandrel response, it is clear that a circumferential change in the mandrel couples directly to a length change in the fiber. The phase of light propagating through an optical fiber is defined as

$$\phi=\beta\star l=n\star k_0\star l, \tag{1}$$

where β is the propagation constant in the fiber length direction, l is the total fiber length wrapped around the mandrel equal to $2\pi R^*N$, N is the number of fiber windings round the mandrel, R is the distance from the center of the mandrel to that of the fiber as denoted in Fig. 1(b), n is the refractive index of the fiber core, and k_0 is the free space propagation constant. The change in the optical phase of the fiber which is subjected to a unit of pressure may be written as

$$\Delta\phi=\beta\star\Delta l+\frac{d\beta}{dn}\star\Delta n\star l+\frac{d\beta}{dD}\star\Delta D\star l, \tag{2}$$

where D is the fiber diameter.[5,6] The change Δl in the fiber length using the cylindrical coordinate system is written as

$$\Delta l=l\star(\varepsilon_r+\varepsilon_\theta), \tag{3}$$

where ε_r is the radial strain, and ε_θ is the axial strain in the fiber with the axis convention with respect to the mandrel in Fig. 1. Since the refractive indices of the core and cladding differ only slightly, one can use the approximation of

$$\frac{d\beta}{dn}\approx k_0. \tag{4}$$

The change in the refractive index Δn can be written in terms of the change in the optical indicatrix given by the well-known expression[7,8]

$$\Delta\left(\frac{1}{n^2}\right)_i=\sum_{j=1}^{3}P_{ij}\varepsilon_j, \quad i,j=1,2,3, \tag{5}$$

where p_{ij} are elements of the strain optic tensor and ε_j are principal strains. Since fluid pressure is transmitted to the hydrophone only at right angles to its boundary at every point, the components containing a shear strain have been assumed to be zero in Eq. (5). A typical optical fiber consists of a core and a cladding fabricated from glasses which have similar properties. Hence, the fiber may be considered homogeneous and isotropic, leading to

$$p_{ij}=\begin{bmatrix} p_{11} & p_{12} & p_{12} \\ p_{12} & p_{11} & p_{12} \\ p_{12} & p_{12} & p_{11} \end{bmatrix}. \tag{6}$$

Thus, the Δn in Eq. (2) for the light propagating in the z direction[6] is

$$\begin{aligned}\Delta n_z&=-\frac{n^3}{2}\star\Delta\left(\frac{1}{n^2}\right)_{x,y}\\&=-\frac{n^3}{2}\star[(p_{11}+p_{12})\star\varepsilon_r+p_{12}\star\varepsilon_\theta].\end{aligned} \tag{7}$$

The third term in Eq. (2) can be shown to be negligible compared with the first two.[9]

Therefore, the acoustic sensitivity of the mandrel sensor per unit of sound pressure becomes

$$\begin{aligned}\frac{\Delta\phi}{\phi}&=\sum\varepsilon_r+\sum\varepsilon_\theta\\&\quad-\frac{n^2}{2}\left[p_{11}\star\sum\varepsilon_r+p_{12}\star\left(\sum\varepsilon_\theta+\sum\varepsilon_r\right)\right].\end{aligned} \tag{8}$$

Equation (8) means that the phase change of the mandrel sensor can be found once we determine the appropriate strain distribution in relation to the unit of applied pressure, which then leads to the analysis of the hydrophone performance. In this paper, the strain distribution is calculated by using the finite element method. Equation (8) is written in the form of a summation of the strains distributed over all the discrete elements in the finite element model. The following values

$$p_{11}=0.121, \quad p_{12}=0.27.$$

II. COMPUTATIONAL CONSIDERATIONS AND STUDIED PARAMETERS

A typical optical fiber consists of a core and a cladding fabricated from glasses which have similar properties. The single-mode optical fiber under investigation in this paper is composed of a fused silica core with traces of GeO_2 and a cladding of 5% B_2O_3- and 95% of SiO_2. This glass waveguide is coated first with an inner soft elastomer and then with an outer hard polymer jacket to preserve some level of fiber strength.

The core diameter is about 4 μm, while the clad diameter about 125 μm.[5,6,10,11] The fiber inner and outer jackets consist of 60-μm layers of silicon and PMMA polymer, respectively. The composition and the geometry of the fiber are kept constant throughout this paper. If the optical fiber is precisely described in the finite element modeling of the mandrel sensor and includes a circular cross section of the fiber, there are too many elements in the model and it is quite time consuming to get any results. Hence, the fiber layer has been modeled as an isotropic tube with a flat cross section possessing the same material properties as a fiber composite which adheres to the mixture rule of a volumetric fraction for each contributor. Table I lists the material properties as well as the geometry of the fiber and its equivalent tube.

In this study, the mandrel sensor is assumed to have a frequency range of up to 5 kHz. The optical fiber has a constant length of 10 m. The parameters studied in order to satisfy the frequency range requirement and to realize the highest sensitivity are the geometry, the material properties of the mandrel, and the molding. Before rigorous investigation, some preliminary analysis is performed so that the range of the main calculation is established even though a rough estimate. Above all, the fundamental resonance frequency of the mandrel should be at least higher than 10 kHz considering the fact that the operating frequency range of a nonresonant type sensor is usually less than half of the resonance frequency. Hence, the maximum length of the mandrel is determined where its fundamental mode frequency reaches 10 kHz. Typically, a mandrel is more compliant than the optical fiber, and, when wrapped by the fiber, the resonance frequency of the whole sensor will increase. Thus this is a rather safe and conservative way of preserving the resonance frequency above 10 kHz. Figure 2(a) shows the variation of the fundamental mode frequency of a mandrel in relation to its length for a representative radius and material. For the material, we selected one of the most compliant materials reported as appropriate for fabricating a mandrel, Teflon.[12] The fundamental mode frequency of a Teflon mandrel of 2-cm radius and 5.1-cm height is about 10 kHz. Therefore, the maximum length of the cylindrical mandrel is 5.1 cm. The minimum length $L_{\min}$ is determined to be equal to the length of the optical fiber winding over the mandrel as shown in Eq. (9) where the fiber is supposed to be wound as a single layer:

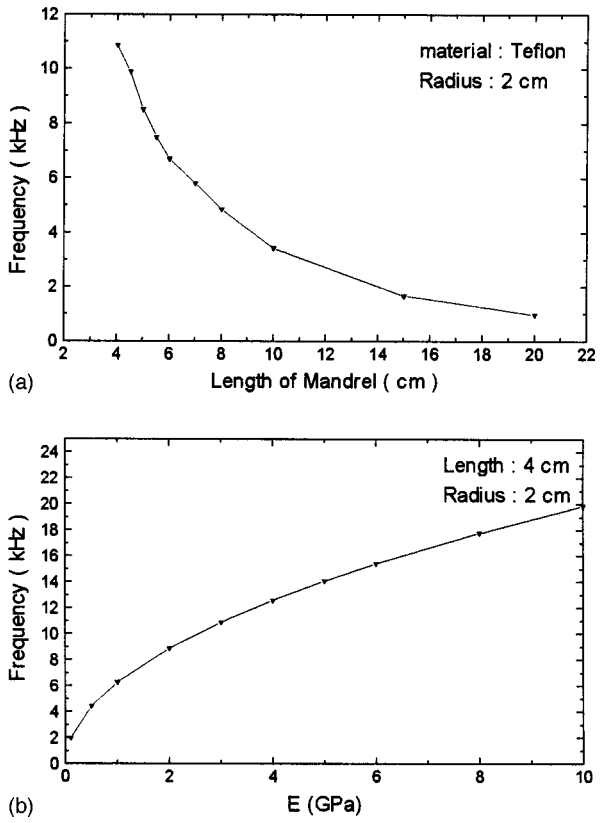

FIG. 2. Variation of the fundamental resonance frequency of a mandrel in relation to its length and Young's modulus. (a) Fundamental resonant frequency versus mandrel length. (b) Fundamental frequency versus Young's modulus of the mandrel.

TABLE II. Studied parameters of a mandrel hydrophone.

Name	Constitutional parts	Parameters
Geometry	Mandrel	Length=1.56–5.1 cm Radius=0.75–2.5 cm
	Molding	Thickness=0–1 mm
Material properties	Mandrel	Young's modulus=1–5 GPa Bulk modulus=0.5–8 GPa Poisson's ratio=0.2–0.45
	Molding	Young's modulus=0.1–5 GPa Poisson's ratio=0.2–0.45

$$L_{\min}=\frac{l\star D}{2\star\pi\star(R_m+D/2)}. \tag{9}$$

For example, if the mandrel radius is 2.5 cm, its minimum length must be 1.6 cm to achieve a constant fiber length of 10 m. On the other hand, the maximum diameter of a mandrel must be equal to its maximum length to achieve a resonance frequency of not lower than 10 kHz. The minimum diameter corresponds to the case in Eq. (9) where the mandrel length is at its maximum because the fiber length is constant.

The material parameters of the acoustic sensing part are a Young's modulus, a bulk modulus, and a Poisson's ratio. However, the independent variables of the material are either a Young's modulus and a bulk modulus, or a Young's modulus and a Poisson's ratio due to the cross-relationships of these parameters. Typical mandrel materials are Teflon, Nylon, Si, and rubber, while the molding materials are polyethylene, polypropylene, PVC, and rubber.[1,2,5,12] The Young's modulus of these materials lies between 0.1 and 6 GPa, and the bulk modulus between 1 and 8 GPa. The density of these materials has a nearly constant value of about 1500 kg/m^3. Figure 2(b) shows a variation of the fundamental mode of a mandrel that has a length of 4 cm and a radius of 2 cm as the representative geometry. The mandrel with a Young's modulus of 1 GPa has a fundamental mode around 10 kHz. Therefore, the variation range of a Young's modulus is selected from 1 to 6 GPa. All the literature reports Poisson's ratio as ranging from 0.2 to 0.45. Therefore, the bulk modulus of a mandrel automatically ranges from 0.5 to 8 GPa due to the elastic inter-relationships between the parameters.

For the molding parts working as a protection layer for the fiber, the range of Young's modulus is set from 0.1 to 5 GPa as they are generally more flexible than the mandrel. We assume that the thickness of the molding is less than or equal to 1 mm. Table II summarizes all of the above concerning the materials, the geometry parameters, and their variation range for designing a fiber wound mandrel sensor.

III. FINITE ELEMENT MODELING AND ANALYSIS

To analyze the response of a mandrel hydrophone in an underwater environment, two separate finite element models were constructed. The first model, shown in Fig. 3, analyzes the transient and frequency response of the hydrophone. The second model, shown in Fig. 4, analyzes the directional pattern of the mandrel sensor. Due to the symmetrical characteristics of the sensor, only a quarter of the whole sensor is

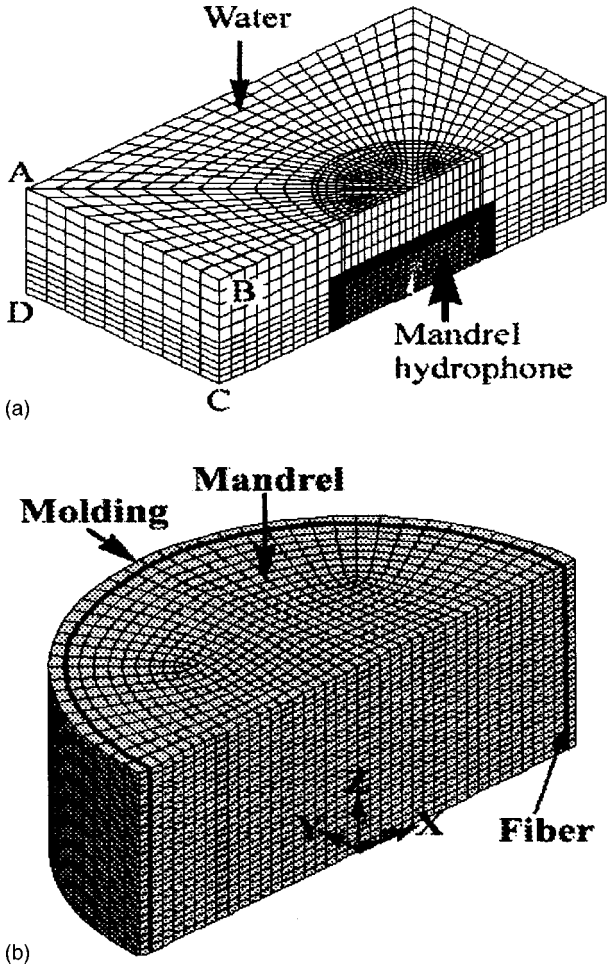

FIG. 3. Finite element model of a mandrel hydrophone for a pressure sensitivity and a frequency response spectrum analysis. (a) Course model. (b) Sub-model.

modeled. The modeling and analysis is carried out using the commercial finite element analysis software, ANSYS, which employs a particular modeling technique of substructuring in order to achieve an acceptable accuracy with the minimum computer processing time. First, a coarse three-dimensional model is constructed that includes the acoustic fluid and describes the hydrophone as a simple cylinder. Then the mandrel sensor is fine meshed again as a submodel and its response is analyzed in detail based on the calculation results of the coarse model. In Fig. 3, the wall ABCD works as a plane wave source and applies a 1-kHz acoustic pressure to the sensor. Figure 3(b) is an enlarged view of the hydrophone model showing the mandrel/fiber/molding area as described in detail in Fig. 1(b). In Fig. 4, each point P along the fluid boundary works as a point source and applies 5 kHz of acoustic pressure. To overcome the limitation given by the finite dimension of the fluid medium, a pressure relief condition is applied to all the fluid boundaries. In this analysis, no artificial constraint or simplification has been made on the deformation of the hydrophone. All the possible strain components, including the shear parts of the hydrophone, are calculated first and then their principal values are determined by means of an internal calculation function of the ANSYS. A sensitivity computation is carried out with the principal strains of the optical fiber using Eq. (8).

IV. RESULTS AND DISCUSSION

A. Influence of the mandrel on the hydrophone sensitivity

For the mandrel, the material parameters that have an effect on the pressure sensitivity are the bulk modulus, Young's modulus, and Poisson's ratio. Figures 5 and 6 show the variations of pressure sensitivity for material properties with fixed mandrel geometries of a 5-cm length and a 3-cm diameter. Teflon is molded over the fiber with a thickness of 1 mm. In Fig. 5, with a Young's modulus E, the pressure sensitivity decreases until a certain point, after which it starts to increase until it eventually reaches a saturation point. However, a mandrel with a low bulk modulus shows the opposite trend. With a bulk modulus, the sensitivity decreases in the high-E range, while in the low-E range, especially between 1 and 2 GPa, no general trend is observed. On the other hand, Fig. 6 shows a stable trend, i.e., the pressure sensitivity decreases while either Poisson's ratio or Young's modulus increases. When considering the cross-relationships of the elastic parameters, the complicated behavior in the low bulk modulus region of Fig. 5 could be explained as an

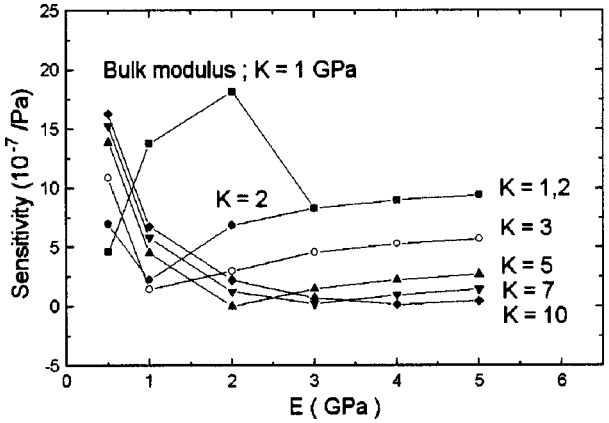

FIG. 5. Variation of pressure sensitivity of a hydrophone in relation to the Young's modulus and the bulk modulus of the mandrel at 1 kHz (length=5 cm, diameter=3 cm).

inconsistent change of Poisson's ratio. From this point of view, the bulk modulus is thus an inefficient parameter for controlling the performance of the hydrophone. It is, therefore, concluded that a hydrophone with the highest sensitivity requires a mandrel that possesses both the lowest Poisson's ratio and the lowest Young's modulus.

The effect of mandrel geometry on pressure sensitivity is shown in Figs. 7 and 8. The results reflect a mandrel of constant properties, a Young's modulus of 2 GPa, and a Poisson's ratio of 0.2. Figure 7 shows the variation of sensitivity in relation to a change of mandrel diameter. The change in diameter does not seem to have much influence on the pressure sensitivity, but it does not show any consistent relationship. Thus the diameter of a mandrel is also not an efficient parameter which improves the performance of a hydrophone. Figure 8 shows the pressure sensitivity changes in relation to mandrel length. The sensitivity steadily increases with the mandrel length to a certain level and then converges to a constant value. Therefore, the length of a mandrel is more efficient as a parameter that can improve sensitivity, and it would appear that the mandrel should be as long as possible unless it violates the flat frequency response requirement of up to 5 kHz.

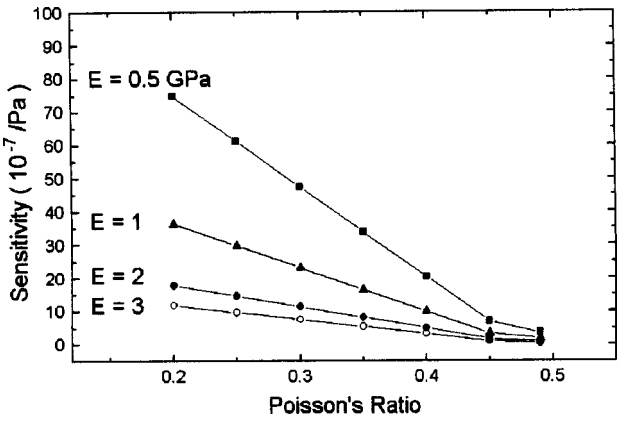

FIG. 6. Variation of pressure sensitivity of a hydrophone in relation to the Poisson's ratio and the Young's modulus of the mandrel at 1 kHz (length=5 cm, diameter=2.5 cm).

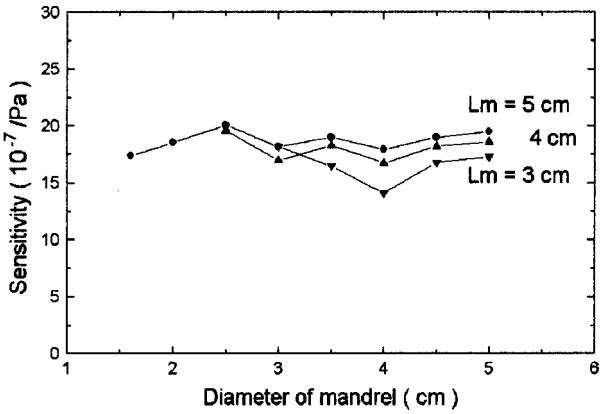

FIG. 7. Variation of pressure sensitivity of a hydrophone in relation to the diameter of the mandrel (Lm=mandrel length).

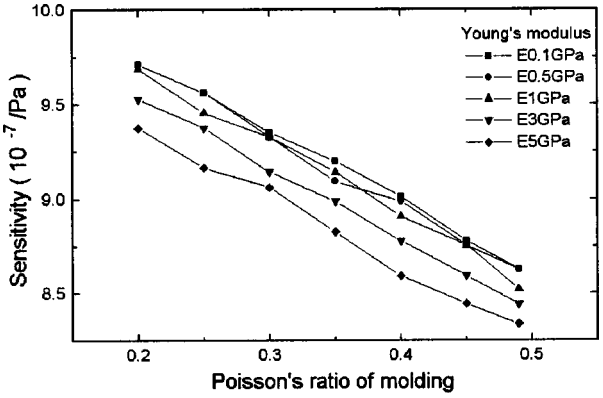

FIG. 9. Variation of the pressure sensitivity of a hydrophone in relation to the Poisson's ratio and Young's modulus of the molding.

B. Influence of the molding layer on the hydrophone sensitivity

The influence of the molding layer on the sensitivity of a hydrophone is represented in Figs. 9 and 10. Figure 9 is the variation of the sensitivity in relation to Poisson's ratio, and Fig. 10 in relation to the thickness of the molding layer. Figure 10 has been drawn for two representative values of E. The calculations have been performed fixing all the parameters of the mandrel at exemplary values, that is, a length of 3.15 cm, a diameter of 2.5 cm, a Young's modulus of 2 GPa, and a Poisson's ratio of 0.3. As shown in Fig. 9, the hydrophone has higher sensitivity with the decrease of both Young's modulus and Poisson's ratio. The pressure sensitivity also increases with the thickness in Fig. 10, although not to any great amount. These results indicate that the more flexibility in the molding layer, the more deformation induced in the optical fiber. Therefore, the molding layer with the lowest Young's modulus and Poisson's ratio should be coated as thickly as possible in order to improve the pressure sensitivity of a hydrophone.

C. Frequency response characteristics and directivity patterns

Using the above results, that is, the geometry and material properties of the constituent parts, we then analyzed the frequency response and the directivity pattern of a hydrophone. The frequency response analysis employs the model in Fig. 3 and investigates the sensor response from 500 Hz to 15 kHz. As a representative case the mandrel geometry is selected at a 4-cm length and a 2.5-cm diameter, and its material properties as a Young's modulus of 2 GPa and a Poisson's ratio of 0.3. A molding layer was selected with a 1-mm thickness, a Young's modulus of 1 GPa, and a Poisson's ratio of 0.3. Figure 11 is the result. The first resonance frequency of the hydrophone is 11.5 kHz, and it satisfies the requirement of a flat response of up to 5 kHz. The pressure sensitivity is about 27×10^{-7} per pascal up to 7 kHz, and then shows a rather unstable characteristic above that frequency. In the case when a wider frequency range is desired, the resonance frequency should then be increased. A higher resonance frequency requires a shorter mandrel and a higher Young's modulus as shown in Fig. 2. However, a higher Young's modulus has the undesirable effect of decreasing the sensitivity of the sensor, and therefore the selection should be made carefully.

An analysis of the sensitivity of the directivity pattern of a hydrophone used the finite element model in Fig. 4. The mandrel geometry and material properties are the same as those used in the frequency response analysis. Figure 12 is the directivity pattern of a hydrophone at 5 kHz. The hydrophone has the sensitivity of $(30\pm3)\times10^{-7}$ per pascal in all the directions and shows a nearly omni-directional pattern at

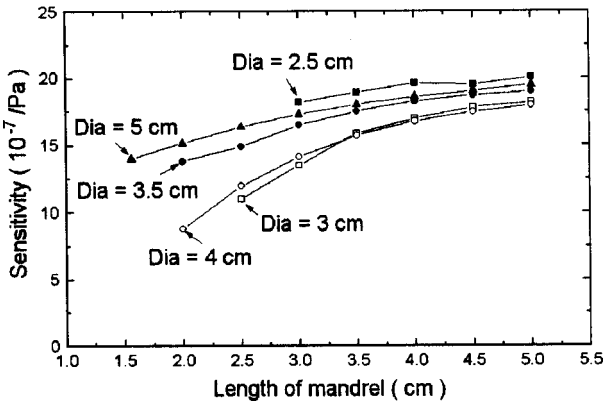

FIG. 8. Variation of pressure sensitivity of a hydrophone in relation to the length of the mandrel.

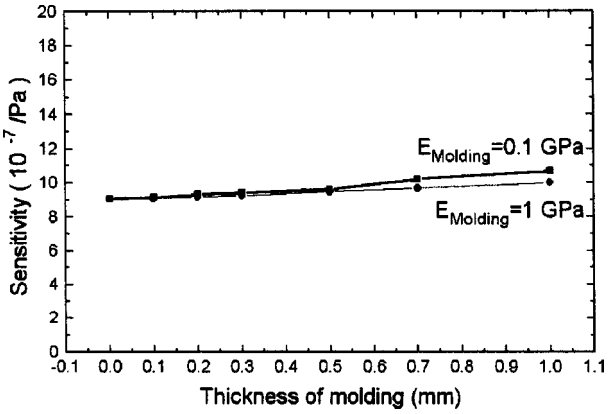

FIG. 10. Variation of the pressure sensitivity of a hydrophone in relation to the thickness of the molding.

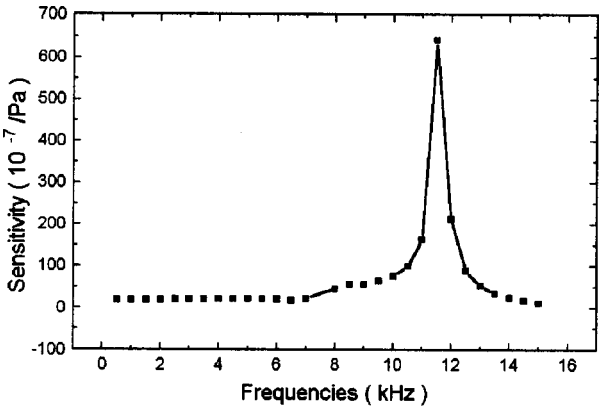

FIG. 11. Frequency response characteristics of a hydrophone.

5 kHz. Within the geometrical variation range in Table II, all the models have similar patterns with a directional fluctuation of less than 10%. If a more nearly uniform omnidirectionality is desired, a smaller geometry should be employed. However, a smaller geometry will reduce the sensitivity of the sensor as shown in Fig. 8.

V. CONCLUSION

This paper has investigated the influence of the structural parameters of an optical fiber wound mandrel hydrophone on its sensitivity by using the finite element method. A hydrophone should have as high a sensitivity as possible, a flat frequency response of up to 5 kHz, and an omnidirectional sensitivity pattern within the frequency range. The parameters studied include the mandrel geometry, the molding thickness, and the material properties of the constitutional parts of a hydrophone. The analysis results show that the pressure sensitivity of a hydrophone increases as both the mandrel length and the molding thickness increase. Also a higher pressure sensitivity requires a mandrel or a molding material with both a low Young's modulus and a low Poisson's ratio. On the contrary, a flat frequency response increases as either the mandrel length is shortened or the mandrel becomes harder. A shorter mandrel also provides a better omni-directional characteristic, that is, when a wider frequency range or a more nearly uniform omnidirectionality is desired, the structural parameters must be selected at the expense of sensitivity. These results indicate that the best sensitivity for a hydrophone is accomplished when the mandrel length and the molding thickness are as large as possible and when its constituent materials are as compliant as possible unless it violates the flat response requirement up to a given frequency range. The results of the present work are thought to provide valuable tools for making the optimum selection of structural parameters for a mandrel-type fiber optic hydrophone.

Ultrasonic three-dimensional probe modeling in anisotropic solids

A. Jonas Niklasson
Division of Mechanics, Chalmers University of Technology, S-412 96 Göteborg, Sweden

(Received 12 March 1996; revised 11 December 1997; accepted 30 January 1998)

Three-dimensional wave propagation and probe modeling in a homogeneous, linear elastic, anisotropic half-space is discussed. The probe is modeled by modifying the traction vector at the interface between an isotropic half-space and an anisotropic half-space. The traction vector is obtained by considering a plane wave in the isotropic solid incident upon the interface. The probe can be of any type, angle, frequency, and size. The probe is attached to an anisotropic half-space and the wave propagation problem is solved by means of Fourier transform techniques. Numerical examples illustrate some of the properties of the probe model and wave propagation in anisotropic solids. © *1998 Acoustical Society of America.* [S0001-4966(98)02905-1]

INTRODUCTION

Nondestructive testing (NDT) is a vital part of the security and maintenance of, for example, nuclear power plants. A widely used testing method is ultrasonic NDT. The method has proven to be very successful when dealing with isotropic solids where a lot of intuitive knowledge can be used. In the last decades, the use of anisotropic materials has increased rapidly. When these materials are introduced a lot of the intuitive knowledge is lost, one reason being that the phase and group velocities no longer coincide. This makes it difficult to perform and evaluate ultrasonic NDT on components made of anisotropic materials. Therefore, there are good reasons to model test situations for anisotropic materials.

Wave propagation in isotropic solids has been studied for a long period of time and there are numerous results (both theoretical and numerical) in the literature. The number of work dealing with wave propagation in anisotropic materials is significantly lower. Some basic theorems and results are given by Wheeler.[1] Auld[2] reviews the theory of wave propagation in anisotropic solids and discusses different types of materials. Van der Hijden[3] discusses propagation of transient elastic waves in stratified anisotropic media using the method of Cagniard–de Hoop. Lord *et al.*[4] use FEM to solve mainly two-dimensional (2-D) wave propagation problems in various media. Green's functions in anisotropic solids are derived by Wang and Achenbach.[5]

In order to simulate complete test situations, models of probes and various defects are needed. In the isotropic case, complete models are given by, for example, Boström and Wirdelius[6] and Chapman.[7] In the anisotropic case little has been done in this area. A 2-D *SH* model, including a probe and a striplike interface flaw, is given by Mattsson and Niklasson.[8] Rajapakse and Gross[9] study the transient response of an orthotropic medium with a cavity. The model is 2D and the waves are generated by a point force. Fellinger *et al.*[10] use the elastodynamic finite integration technique (EFIT) to solve mainly 2-D wave propagation in various materials containing defects. Wave propagation through a bimetallic weld is studied by Minachi *et al.*[11] and Nouailhas *et al.*[12] Minachi *et al.*[11] study beam propagation and compare the Gauss–Hermite beam model and a finite element method. Nouailhas *et al.*[12] compare a ray tracing code and a finite element code and use various experiments to validate the codes. In both of these last two papers, the computations are performed in 2D.

Probe modeling in isotropic solids has been done by, for example, Boström and Wirdelius,[6] Kažys and Mažeika,[13] and Schmerr and Sedov.[14] The probe by Boström and Wirdelius[6] prescribes the traction on an isotropic half-space. Schmerr and Sedov[14] use a similar approach in their modeling, but the transducer is restricted to have a circular shape. Kažys and Mažeika[13] use spatial impulse responses and FEM to model the field inside the probe. In the anisotropic case, a 2-D *SH* probe is modeled by Niklasson.[15] This probe is modeled in the same way as the probe by Boström and Wirdelius.[6]

The plan of the present paper is as follows. In Sec. I, some basic results in wave propagation in anisotropic solids are reviewed. The probe is modeled by the traction it is causing on the surface of an anisotropic half-space in Sec. II. The approach here is similar to the approaches by Boström and Wirdelius[6] and Niklasson.[15] The traction is obtained by considering a plane wave in an isotropic half-space incident upon an anisotropic half-space. The probe is modeled by a modification of the traction at the interface. The probe is attached to an anisotropic half-space in Sec. III and the corresponding wave propagation problem is solved by means of Fourier transform techniques. Various numerical examples are presented in Sec. IV which illustrate some of the probe characteristics and properties of wave propagation in anisotropic solids.

I. PRELIMINARIES

Consider a homogeneous, lossless, anisotropic solid. The existence of a strain energy function is assumed. The equations of motion in the absence of body forces are

$$\nabla \cdot \sigma = \rho_A \ddot{\mathbf{u}}, \tag{1}$$

where $\mathbf{u}$ is the displacement vector, σ is the (symmetric) stress tensor, and ρ_A is the (constant) density and dot denotes

partial differentiation with respect to time t. Since a strain energy function is assumed to exist, Hooke's law in abbreviated indices is

$$\begin{pmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{zz} \\ \sigma_{yz} \\ \sigma_{xz} \\ \sigma_{xy} \end{pmatrix} = \begin{pmatrix} C_{11} & C_{12} & C_{13} & C_{14} & C_{15} & C_{16} \\ C_{12} & C_{22} & C_{23} & C_{24} & C_{25} & C_{26} \\ C_{13} & C_{23} & C_{33} & C_{34} & C_{35} & C_{36} \\ C_{14} & C_{24} & C_{34} & C_{44} & C_{45} & C_{46} \\ C_{15} & C_{25} & C_{35} & C_{45} & C_{55} & C_{56} \\ C_{16} & C_{26} & C_{36} & C_{46} & C_{56} & C_{66} \end{pmatrix} \begin{pmatrix} \epsilon_{xx} \\ \epsilon_{yy} \\ \epsilon_{zz} \\ 2\epsilon_{yz} \\ 2\epsilon_{xz} \\ 2\epsilon_{xy} \end{pmatrix}, \tag{2}$$

where $C=(C_{ij})$ is the positive definite stiffness matrix and

$$\epsilon_{ij}=(u_{i,j}+u_{j,i})/2, \quad i,j=x,y,z, \tag{3}$$

is the strain tensor. If Eqs. (1)–(3) are combined, the wave equations expressed in the components of $\mathbf{u}$ are obtained.

A plane wave is defined by $\mathbf{u}=A\mathbf{d}e^{i(qx+py+hz-\omega t)}$, where A is the amplitude, $\mathbf{d}$ is the polarization vector, q,p,h are the wave numbers in the x,y,z directions, respectively, and ω is the circular frequency. Direct insertion into the equations of motion leads to the homogeneous linear system of equations called the Christoffel equation[2]

$$D\mathbf{d}=0 \quad \text{where} \quad D=LCL^T-\rho_A\omega^2 I,$$

$$L=\begin{pmatrix} q & 0 & 0 & 0 & h & p \\ 0 & p & 0 & h & 0 & q \\ 0 & 0 & h & p & q & 0 \end{pmatrix}, \tag{4}$$

where I is the 3-by-3 identity matrix and the superscript T denotes transpose. If q, p, and ω are known, Eq. (4) splits up into

$$\begin{aligned} &\text{I. Find } h \text{ such that } \det D=0. \\ &\text{II. Given } h \text{ from I, find } \mathbf{d} \text{ such that } D\mathbf{d} \\ &\quad =0 \text{ and } |\mathbf{d}|=1. \end{aligned} \tag{5}$$

If wave propagation in, for example, a half-space is considered, three values of h and $\mathbf{d}$ are admissible. These values corresponds to different types of waves in the half-space. One talks about quasi P (qP) and quasi S (qS) waves since these waves in general are mixtures of P and S waves. The relation $\det D=0$ is the characteristic equation for the anisotropic solid. From this relation, the group velocity $\mathbf{v}$, which is equal to the energy velocity in a homogeneous lossless medium, is easily obtained[2]

$$\mathbf{v}=-\frac{\nabla_k(\det D)}{\partial(\det D)/\partial\omega}, \quad \nabla_k F=\left(\frac{\partial F}{\partial q},\frac{\partial F}{\partial p},\frac{\partial F}{\partial h}\right). \tag{6}$$

The group velocity plays an important role when wave propagation in infinite bodies is considered. Then, the admissible values of h are selected from radiation conditions on the energy (see below).

II. THE PROBE MODEL

Consider an anisotropic, homogeneous half-space. On the surface of the half-space, an ultrasonic probe is attached. The origin of the coordinate system (x,y,z) is located on the surface (see Fig. 1). In this section the aim is to model a

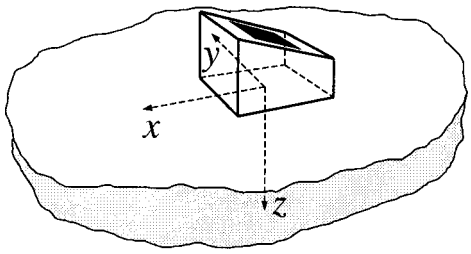

FIG. 1. A probe on a half-space.

piezoelectric contact probe. The probe model will prescribe the traction beneath the probe and not the displacement. This approach has the advantage that the boundary condition on the surface of the half-space will not be mixed. This simplifies the calculations a great deal when Fourier methods are used. The approach in this paper is similar to the approaches by Boström and Wirdelius[6] and Niklasson.[15]

Consider the case when the probe is embedded in an isotropic half-space made of the same material as the wedge of the probe (see Fig. 2). λ and μ are the Lamé constants and ρ_1 the density of the wedge and the isotropic half-space. The surface S is the part of the xy plane which is affected by the field in the wedge. In order to model the probe, a plane wave in the isotropic half-space incident upon the interface is considered. The main purpose of considering a plane wave is to obtain the phases and relative amplitudes of the different waves which are transmitted into the anisotropic half-space (one qP wave and two qS waves). The direction of propagation of the plane wave is normal to the piezoelectric crystal. If the wave is propagating in the xz plane then

$$\begin{aligned} &\mathbf{u}^{(i)}=\mathbf{u}^{(0)}=A_0(d_x^{(0)},d_y^{(0)},d_z^{(0)})e^{i\eta_0}, \\ &\eta_0=k_0(\sin\,\theta_0 x+\cos\,\theta_0 z)-\omega t. \end{aligned} \tag{7}$$

Here, three types of incident waves are considered

$$\begin{aligned} &P \text{ wave } (P \text{ probe}): \quad k_0=\omega\sqrt{\rho_I/(\lambda+2\mu)}, \\ &\qquad\qquad\qquad\quad \mathbf{d}^{(0)}=(\sin\,\theta_0,0,\cos\,\theta_0). \end{aligned} \tag{8a}$$

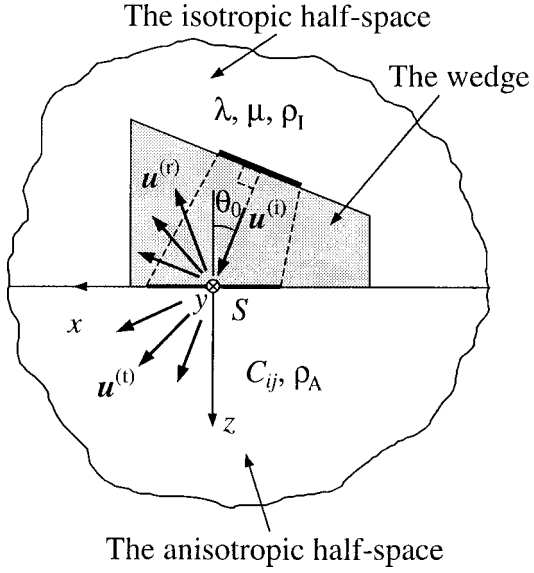

FIG. 2. The embedded probe.

$$SV \text{ wave } (SV \text{ probe}): \quad k_0=\omega\sqrt{\rho_1/\mu}, \quad \mathbf{d}^{(0)}=(\cos\theta_0,0,-\sin\theta_0). \tag{8b}$$

$$SH \text{ wave } (SH \text{ probe}): \quad k_0=\omega\sqrt{\rho_I/\mu}, \quad \mathbf{d}^{(0)}=(0,1,0). \tag{8c}$$

By choosing an incident P, SV, or SH wave, it is possible to model a P, SV, or SH probe, respectively. The following ansatz is made for the reflected and transmitted fields

$$\mathbf{u}^{(r)}=\mathbf{u}^{(1)}+\mathbf{u}^{(2)}+\mathbf{u}^{(3)}, \quad z<0, \tag{9a}$$

$$\mathbf{u}^{(t)}=\mathbf{u}^{(4)}+\mathbf{u}^{(5)}+\mathbf{u}^{(6)}, \quad z>0, \tag{9b}$$

where

$$\mathbf{u}^{(1)}=A_1(\sin\theta_1,0,-\cos\theta_1)e^{i\eta_1}, \quad \eta_1=k_1(\sin\theta_1 x-\cos\theta_1 z)-\omega t, \tag{10a}$$

$$\mathbf{u}^{(2)}=A_2(\cos\theta_2,0,\sin\theta_2)e^{i\eta_2}, \quad \eta_2=k_2(\sin\theta_2 x-\cos\theta_2 z)-\omega t, \tag{10b}$$

$$\mathbf{u}^{(3)}=A_3(0,1,0)e^{i\eta_3}, \quad \eta_3=k_3(\sin\theta_3 x-\cos\theta_3 z)-\omega t, \tag{10c}$$

$$\mathbf{u}^{(4)}=A_4(d_x^{(4)},d_y^{(4)},d_z^{(4)})e^{i\eta_4}, \quad \eta_4=q^{(4)}x+h^{(4)}z-\omega t, \tag{10d}$$

$$\mathbf{u}^{(5)}=A_5(d_x^{(5)},d_y^{(5)},d_z^{(5)})e^{i\eta_5}, \quad \eta_5=q^{(5)}x+h^{(5)}z-\omega t, \tag{10e}$$

$$\mathbf{u}^{(6)}=A_6(d_x^{(6)},d_y^{(6)},d_z^{(6)})e^{i\eta_6}, \quad \eta_6=q^{(6)}x+h^{(6)}z-\omega t. \tag{10f}$$

Since $\mathbf{u}^{(1)}$, $\mathbf{u}^{(2)}$, and $\mathbf{u}^{(3)}$ correspond to a reflected P, SV, and SH wave, respectively, the following hold

$$k_1=\omega\sqrt{\rho_I/(\lambda+2\mu)}, \quad k_2=k_3=\omega\sqrt{\rho_I/\mu}. \tag{11}$$

The transmitted fields cannot be interpreted in the same simple fashion.

If perfect (welded) contact between the half-spaces is assumed, the following hold at the interface

$$\mathbf{u}^{(i)}+\mathbf{u}^{(r)}=\mathbf{u}^{(t)}, \quad z=0, \tag{12a}$$

$$(\sigma^{(i)}+\sigma^{(r)})\cdot\mathbf{e}_z=\sigma^{(t)}\cdot\mathbf{e}_z, \quad z=0, \tag{12b}$$

where $\mathbf{e}_z$ is the unit vector in the z direction. If the fields (7) and (9) are inserted into (12) it is concluded that

$$\sin\theta_1=(k_0/k_1)\sin\theta_0, \quad \sin\theta_2=(k_0/k_2)\sin\theta_0, \quad \theta_2=\theta_3, \quad q^{(4)}=q^{(5)}=q^{(6)}=k_0\sin\theta_0. \tag{13}$$

The values of $h^{(j)}$ and $\mathbf{d}^{(j)}$ $(j=4,5,6)$ are obtained as the solutions of (5) combined with radiation conditions on the energy. The radiation conditions are

$$\mathbf{v}\cdot\mathbf{e}_z>0, \quad \text{Im } h=0, \tag{14a}$$

$$\text{Im } h>0, \quad \text{Im } h\neq 0. \tag{14b}$$

where Im means the imaginary part as usual. In addition, insertion into (12) yields a system of equations for the amplitudes A_j $(j=1,...,6)$ expressed in the amplitude of the incident wave A_0. When this system of equations is solved the reflected and transmitted fields are determined.

At this point, the double spatial Fourier transform and the temporal Fourier transform are introduced as

$$\hat{f}(q,p)=\int\int_{\mathbf{R}^2} f(x,y)e^{-i(qx+py)}\,dx\,dy, \quad \tilde{f}(\omega)=\int_{\mathbf{R}} f(t)e^{i\omega t}\,dt, \tag{15a}$$

and their inverses as

$$f(x,y)=\frac{1}{4\pi^2}\int\int_{\mathbf{R}^2}\hat{f}(q,p)e^{i(qx+py)}\,dq\,dp, \quad f(t)=\frac{1}{2\pi}\int_{\mathbf{R}}\tilde{f}(\omega)e^{-i\omega t}\,d\omega, \tag{15b}$$

where $\mathbf{R}$ denotes the set of real numbers. As mentioned above, the main purpose of considering the plane wave incident upon the interface was to obtain the phases and relative amplitudes of the waves transmitted into the anisotropic half-space. In order to model the probe, the traction caused by the plane waves above at the interface $z=0$ is modified. The expression for the modified traction is

$$\begin{aligned}(\tilde{\sigma}\cdot\mathbf{e}_z)_{z=0}=i\{&\mu(k_0A_0(d_x^{(0)}\cos\theta_0+d_z^{(0)}\sin\theta_0)\\&-k_1A_1\sin 2\theta_1-k_2A_2\cos 2\theta_2)\delta_x\mathbf{e}_x\\&+\mu(k_0A_0d_y^{(0)}\cos\theta_0-k_3A_3\cos\theta_3)\delta_y\mathbf{e}_y\\&+[k_0A_0(\lambda(d_x^{(0)}\sin\theta_0+d_z^{(0)}\cos\theta_0)\\&+2\mu d_z^{(0)}\cos\theta_0)+k_1A_1(\lambda+2\mu\cos^2\theta_1)\\&-\mu k_2A_2\sin 2\theta_2]\delta_z\mathbf{e}_z\}e^{ik_0\sin\theta_0 x}g(x,y)\tilde{f}(\omega).\end{aligned} \tag{16}$$

The probe model (16) is obtained from the traction in (12b), in this case the traction expressed in the fields in the isotropic half-space, multiplied with $\tilde{f}$ and g. The factor $e^{-i\omega t}$ is omitted and the traction is taken as the temporally Fourier transformed traction. The function $g(x,y)$ in Eq. (16) models the spatial distribution of the traction on the surface and its support is the surface S. $\tilde{f}(\omega)$ models the frequency spectrum of the probe. The constants δ_x, δ_y, and δ_z allow weighing of the components of the traction. The contact is perfect if $\delta_x=\delta_y=\delta_z=1$. Another important special case is when $\delta_x=\delta_y=0$ and $\delta_z=1$. This corresponds to (inviscid) fluid contact between the probe and the half-space. In this case, the traction is

$$\begin{aligned}(\tilde{\sigma}\cdot\mathbf{e}_z)_{z=0}=i\{&k_0A_0(\lambda(d_x^{(0)}\sin\theta_0+d_z^{(0)}\cos\theta_0)\\&+2\mu d_z^{(0)}\cos\theta_0)+k_1A_1(\lambda+2\mu\cos^2\theta_1)\\&-\mu k_2A_2\sin 2\theta_2\}e^{ik_0\sin\theta_0 x}g(x,y)\tilde{f}(\omega)\mathbf{e}_z.\end{aligned} \tag{17}$$

The constants A_1 and A_2, in this case, are determined by the boundary conditions governing a smooth contact between the half-spaces

$$(\mathbf{u}^{(i)}+\mathbf{u}^{(r)})\cdot\mathbf{e}_z=\mathbf{u}^{(t)}\cdot\mathbf{e}_z, \quad z=0, \tag{18a}$$

$$((\sigma^{(i)}+\sigma^{(r)})\cdot\mathbf{e}_z)\cdot\mathbf{e}_z=(\sigma^{(t)}\cdot\mathbf{e}_z)\cdot\mathbf{e}_z, \quad z=0, \tag{18b}$$

$$((\sigma^{(i)}+\sigma^{(r)})\cdot\mathbf{e}_z)\cdot\mathbf{e}_x=(\sigma^{(t)}\cdot\mathbf{e}_z)\cdot\mathbf{e}_x=0, \quad z=0, \tag{18c}$$

$$((\sigma^{(i)}+\sigma^{(r)})\cdot\mathbf{e}_z)\cdot\mathbf{e}_y=(\sigma^{(t)}\cdot\mathbf{e}_z)\cdot\mathbf{e}_y=0, \quad z=0, \tag{18d}$$

which replace the boundary conditions (12).

As mentioned earlier, the approach above is similar to the approach by Boström and Wirdelius.[6] In fact, the probe model reduces to the probe model by Boström and Wirdelius[6] if the anisotropic half-space is taken as isotropic and the material of the wedge is identical to the material of the anisotropic half-space. As seen above, the labeling of the probe types is only related to the type of incident plane wave in the wedge. This does not mean, for example, that a *P* probe always generates *P* waves in an isotropic half-space since the angle θ_0 may exceed the critical angle for the transmitted *P* wave.

III. FORMAL SOLUTION

In this section, the wave propagation problem in an anisotropic half-space, subjected to the probe model discussed in the previous section, is solved. The solution is obtained by means of Fourier transform techniques.

Applying the Fourier transforms (15a) to Eqs. (1)–(3) and solving for $\hat{\tilde{\mathbf{u}}}$ yields the general solution as

$$\hat{\tilde{\mathbf{u}}}=B_1\mathbf{d}_1e^{ih_1z}+B_2\mathbf{d}_2e^{ih_2z}+B_3\mathbf{d}_3e^{ih_3z}, \tag{19}$$

where $\mathbf{d}_j$ and h_j are obtained from (5) subjected to radiation conditions on the energy (14). Applying the spatial Fourier transform to Eq. (16) yields

$$\begin{aligned}(\hat{\tilde{\sigma}}\cdot\mathbf{e}_z)_{z=0}=i\{&\mu(k_0A_0(d_x^{(0)}\cos\theta_0+d_z^{(0)}\sin\theta_0)-k_1A_1\sin 2\theta_1-k_2A_2\cos 2\theta_2)\delta_x\mathbf{e}_x\\&+\mu(k_0A_0d_y^{(0)}\cos\theta_0-A_3k_3\cos\theta_3)\delta_y\mathbf{e}_y+(k_0A_0(\lambda(d_x^{(0)}\sin\theta_0+d_z^{(0)}\cos\theta_0)+2\mu d_z^{(0)}\cos\theta_0)\\&+k_1A_1(\lambda+2\mu\cos^2\theta_1)-\mu k_2A_2\sin 2\theta_2)\delta_z\mathbf{e}_z\}\hat{g}(q-k_0\sin\theta_0,p)\tilde{f}(\omega).\end{aligned} \tag{20}$$

If the traction is calculated from (19) for $z=0$ and combined with (20), a linear system of equations for the B_j's is obtained. When this is solved, the transformed solution is obtained.

When the Fourier transformations are to be inverted some problems arise. In the qp plane, there may exist a large number of branch points and in some cases poles. Here, the integration is carried out using polar coordinates in the qp plane, i.e., $q=k_pr\cos\phi$ and $p=k_pr\sin\phi$ with k_p defined below. The integration path for r is deformed into the complex r-plane (in order to avoid the possible Rayleigh-like pole) as $r=s(1-i\alpha e^{-\beta s})$ where α and β are positive parameters and $s\in[0,\infty)$. The minimum of the imaginary part is attained at $s=1/\beta$ with $\mathrm{Im}\,r=-(\alpha/\beta)e^{-1}$. Here, the choices $\beta=1/r_b$, where r_b is the (real) radius at the outmost branch point, and $\alpha=\epsilon\beta$ (with ϵ between 0.01 and 0.1) are made. When q and/or p are complex, the radiation condition differs from the usual one.[3] Therefore, along the complex contour the admissible wave numbers h_j $(j=1,2,3)$ are selected by means of continuity provided that the integration starts on a physical Riemann sheet. This is easily accomplished for large values on s.

IV. NUMERICAL EXAMPLES

The complicated nature of the problem makes it in general impossible to perform analytical calculations. Therefore, it is important to have good numerical algorithms for root finding, solution of linear systems of equations and quadrature. The root finding is carried out using Laguerre's method and the linear systems of equations are solved using Gaussian elimination. The integration in the qp plane is performed using Gaussian quadrature and polar coordinates. The integration in r is carried out as described above with approximately 500 quadrature points in s and the integration in ϕ is carried out with approximately 300 quadrature points. The ω integration is performed with 100 quadrature points and the trapezoidal rule.

In the numerical examples below, a transversely isotropic graphite–epoxy composite is considered. The stiffness matrix, expressed in the crystal axes system with the z axis as the symmetry axis, is given by[16]

$$C=\begin{pmatrix}13.92 & 6.92 & 6.44 & 0 & 0 & 0\\ 6.92 & 13.92 & 6.44 & 0 & 0 & 0\\ 6.44 & 6.44 & 160.73 & 0 & 0 & 0\\ 0 & 0 & 0 & 7.07 & 0 & 0\\ 0 & 0 & 0 & 0 & 7.07 & 0\\ 0 & 0 & 0 & 0 & 0 & 3.50\end{pmatrix}\ \text{GPa}, \tag{21}$$

and the density is $\rho_A=1578\ \mathrm{kg/m^3}$. The wedge of the probe is made of polymethyl methacrylate (PMMA) which is assumed to be isotropic and lossless. The material properties of the wedge are $\lambda=2.6$ GPa, $\mu=2.1$ GPa, and $\rho_I=1180\ \mathrm{kg/m^3}$. The normalized slowness surfaces for the graphite–epoxy are shown in Fig. 3(a) in the plane $p=0$ and the corresponding normalized wave surfaces are shown in Fig. 3(b) in the plane $v_y=0$. In the figures, $c_p=\sqrt{C_{11}^c/\rho_A}$, $k_p=\omega/c_p$ and the material is considered in the crystal axes system with h as the wave number along the symmetry axis (the z axis). C_{11}^c is element (1,1) of the stiffness matrix expressed in the crystal axes system, i.e., $C_{11}^c=13.92$ GPa in

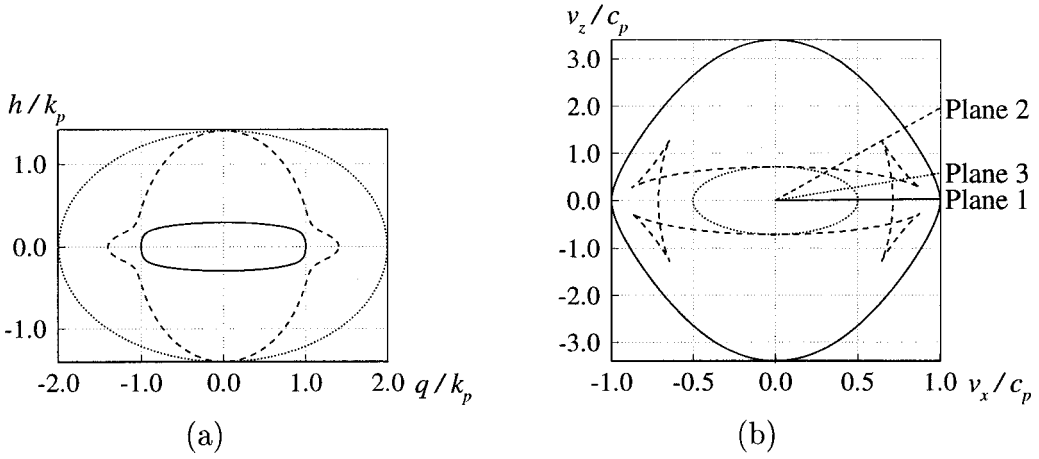

FIG. 3. The slowness and wave surfaces of the graphite-epoxy. (a) The slowness surfaces. (b) The wave surfaces.

this case. The slowness surfaces are obtained from the characteristic equation (5) and the three surfaces represent different waves. The three wave surfaces are obtained from the group velocity expression Eq. (6). In the figures, the solid curve is the quasi P (qP) wave, the dashed is the quasi SV (qSV) wave and the dotted is the SH wave. Pure SH waves exist due to the material symmetry considered, i.e., transverse isotropy. The complete slowness and wave surfaces are obtained as the surfaces of revolution around the h and v_z axes, respectively, due to this material symmetry. In Fig. 3(b), three straight lines are included. These lines are only included in the figure as aid in the identification of the waves (see Fig. 10) and they are not part of the wave surfaces. If the coordinate system (x,y,z) does not coincide with the crystal axes system, the elastic constants must be transformed. This is done with Bond matrices[2] and Euler angles. The Euler angles φ_1, φ_2 and φ_3 are defined according to Fig. 4. In Fig. 4, (X,Y,Z) represents the crystal axes system and (x,y,z) the probe system as before.

Two simple and convenient choices of the effective probe surface S are

$$S_1=\{(x,y)|(x,y)\in[-a,a]\times[-b,b]\},$$
$$S_2=\{(x,y)|(x/a)^2+(y/b)^2\leqslant 1\}, \tag{22}$$

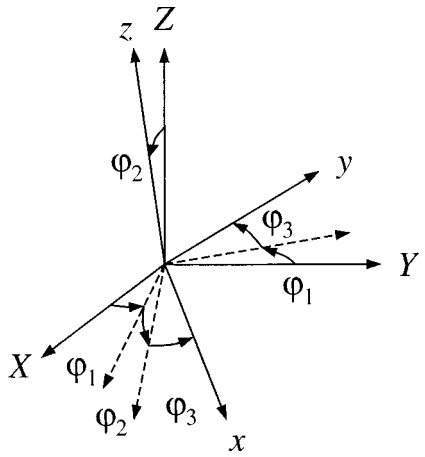

FIG. 4. The Euler angles.

i.e., a rectangular and an elliptical surface. If the characteristic function of a set A is introduced as

$$\chi_A=\begin{cases}1, & x\in A,\\ 0, & x\notin A,\end{cases} \tag{23}$$

some suitable choices of the spatial shape function $g(x,y)$ are

$$g_1(x,y)=\chi_{S_1},\quad g_2(x,y)=\sqrt{1-(x/a)^2)(1-(y/b)^2}\,\chi_{S_1},$$
$$g_3(x,y)=\chi_{S_2},\quad g_4(x,y)=\sqrt{1-(x/a)^2-(y/b)^2}\,\chi_{S_2}. \tag{24}$$

These choices of $g(x,y)$ are such that they can be Fourier transformed analytically and seem realistic. In the numerical examples, however, only $g_1(x,y)$ (the piston model with rectangular support) is used. This shape function is the simplest and the most widely used. In addition, the support is restricted to a square with side $2a$. This means that the probe is situated at $(x,y)\in[-a,a]\times[-a,a]$. The spatially Fourier transformed g_1 is (when $b=a$)

$$\hat{g}_1(q,p)=4\sin(qa)\sin(pa)/qp. \tag{25}$$

The frequency spectrum $\tilde{f}(\omega)$ is chosen as

$$\tilde{f}(\omega)=\sin^2\left(\frac{|\omega|-\omega_1}{\omega_2-\omega_1}\,\pi\right)\chi_\Omega,$$
$$\Omega=\{\omega|\omega\in[-\omega_2,-\omega_1]\cup[\omega_1,\omega_2]\}. \tag{26}$$

The reason for this choice of $\tilde{f}(\omega)$ is that it has a compact support and can approximate a pulse rather well.

In the figures, the displacement is represented in either the frequency domain as $|\mathrm{Re}\,\tilde{\mathbf{u}}|$ or in the time domain as $|\mathbf{u}|$. The fields are presented in contour plots consisting of 15 levels with black representing the largest value in each figure. The nondimensional frequency $\bar{\omega}$ and the nondimensional time τ are introduced as

$$\bar{\omega}=k_pa=\omega a\sqrt{\rho_A/C_{11}^c},\quad \tau=c_pt/a=(t/a)\sqrt{C_{11}^c/\rho_A}, \tag{27}$$

with a as above and all lengths are normalized with a. This means that the probe is about 7.1 S (SV or SH) wavelengths and 3.9P wavelengths wide at $\bar{\omega}=10$. Note that these are

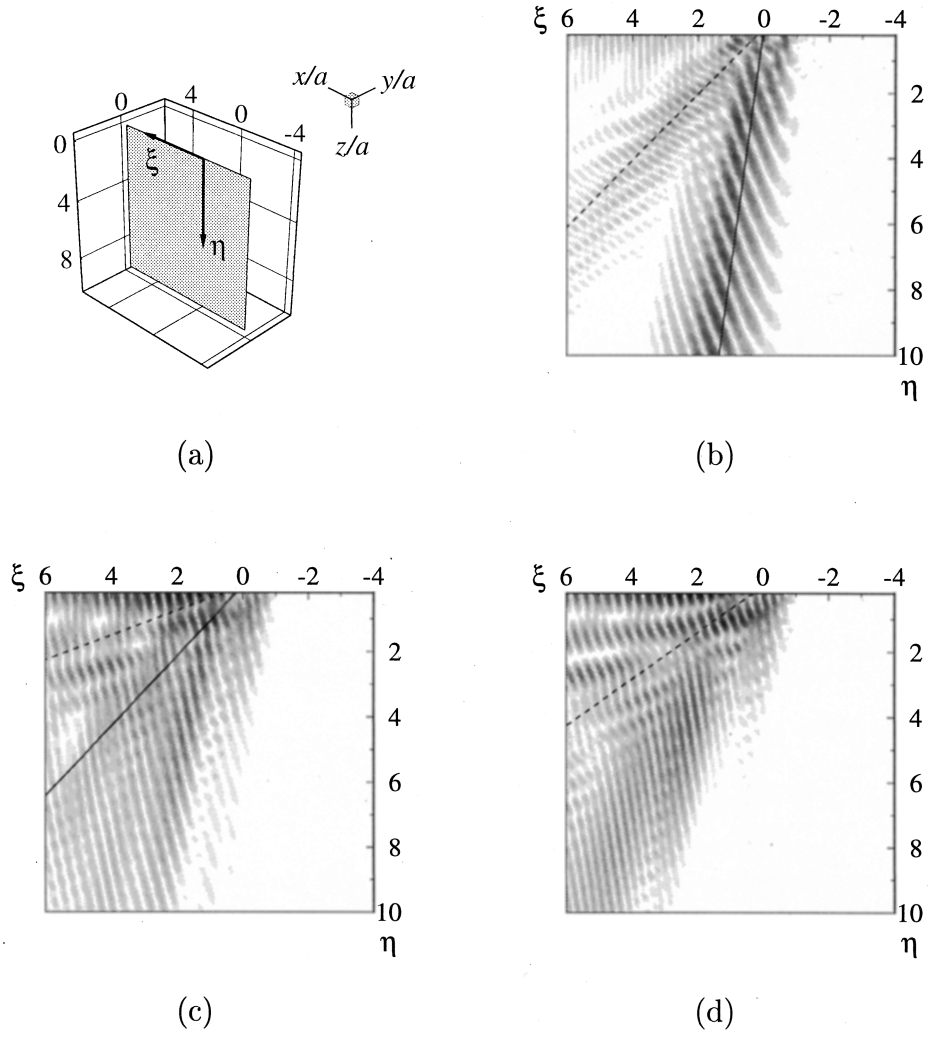

FIG. 5. $|\mathrm{Re}\,\tilde{\mathbf{u}}|$ for a P probe when $\theta_0=30°$, 50°, 60°, and $\bar{\omega}=10$. (a) The plane. (b) $\theta_0=30°$. (c) $\theta_0=50°$. (d) $\theta_0=60°$.

wavelengths in the isotropic wedge. The plot planes are chosen as the planes spanned by the group velocities belonging to the probe model (the transmitted plane waves) and the z axis. Here it is worth noting that there may be less than three group velocities. This is the case when the angle of incidence is larger than one or more of the critical angles. In the planes spanned by the group velocities, the coordinates ξ and η are used. They are defined by

$$\xi=\sqrt{x^2+y^2}/a, \quad \mathbf{e}_\xi=\mathbf{v}^{xy}/|\mathbf{v}^{xy}|,$$
$$\mathbf{v}^{xy}=(\mathbf{v}\cdot\mathbf{e}_x)\mathbf{e}_x+(\mathbf{v}\cdot\mathbf{e}_y)\mathbf{e}_y, \qquad \eta=z/a, \quad \mathbf{e}_\eta=\mathbf{e}_z. \tag{28}$$

Note that the probe will not be situated at $\xi\in[-1,1]$ unless the ξ axis coincides with the x or the y axis. In each of the different cases (but not in all of the figures), a plot showing the orientation of the planes is included. In addition, lines (solid, dashed or dotted) are included to indicate the group velocity directions of the main waves generated by the probe as rays originating from the origin.

In Fig. 5, the displacement in the frequency domain for a P probe is shown for three different values of the probe angle θ_0. The contact is perfect, i.e., $\delta_x=\delta_y=\delta_z=1$, the frequency is $\bar{\omega}=10$ and (x,y,z) coincides with the crystal axes system. The symmetry axis of the material is parallel to the z axis which means that the stiffness matrix is given by (21). The result is that the group velocities of the plane waves associated with the probe all lie in the xz plane and the $\xi\eta$ axes and the xz axes coincide. In the figures the solid lines indicate the group velocity direction of the qP wave and the dashed ones the direction of the qSV wave. Since the xz plane is a plane of elastic symmetry, no SH waves exist in this plane for a P probe. In the case when $\theta_0=30°$, which is far away from the critical angle, the direction of the qP wave is close to the axis of the greatest stiffness, i.e., the z axis. Here, the waves coincide very well with the group velocity directions in the figure and the difference in the direction of the phase and group velocity is very well illustrated. As θ_0 is increased, the directions of the waves are getting closer to the probe surface and it gets difficult to identify distinct waves. When θ_0 is 50° and 60°, large parts of the field are located close to the probe surface. Finally, when $\theta_0=60°$, $q/k_p=(k_0/k_p)\sin\theta_0=1.07$, and the critical angle for the qP wave is exceeded [see Fig. 3(a)]. Therefore only one ray (dashed) representing the qSV wave is included in the last plot.

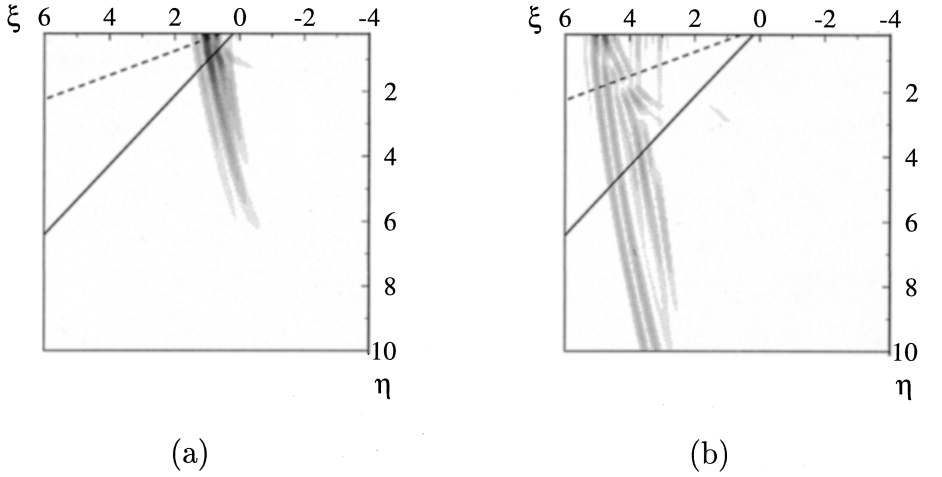

FIG. 6. Snapshots of $|\mathbf{u}|$ in the same situation as in Fig. 5(c). (a) $\tau=1$. (b) $\tau=5$.

The same situation as in Fig. 5(c) is considered in Fig. 6. Here, two snapshots of $|\mathbf{u}|$ are shown when $\tau=1$ and $\tau=5$. The lower and upper frequencies are $\overline{\omega_1}=1$ and $\overline{\omega_2}=19$, respectively. In Fig. 6(b), two waves can be identified, a qP wave with 80° between the phase velocity and the η axis (with group velocity along the solid line) and a qSV wave with 57° between the phase velocities and the η axis (with group velocity along the dashed line). Note that the angles of the phase velocity of the qP and the qSV waves are measured along the solid and dashed lines, respectively. It is evident from the figure that the high degree of anisotropy ''stretches'' the wave front a great deal.

In Fig. 7, fields from the two remaining probe types, the SV and SH probes, are shown in the frequency domain. These figures should be compared to the field in Fig. 5(b), which is the same situation for a P probe. Again, the symmetry of the material result in no SH waves for the SV probe and no qP and qSV waves for the SH probe in the xz plane. In the case of an SV probe, $q/k_p=(k_0/k_p)\sin\theta_0=1.11$ and the critical angle for the qP wave is exceeded [see Fig. 3(a)]. Therefore only one ray (solid) representing the qSV wave is included in the field from the SV probe. Note that as in the case with a P probe a large part of the field is located near the surface. For the SH probe one very distinct SH wave is identified (traveling along the solid line). Since the SH wave decouples from the two other waves in this case, this is expected. In Fig. 7(b) the near and far field are very nicely illustrated. When the distance to the probe is greater than approximately $3a$ the field seems to be radiated from a point source located at the origin.

In Fig. 8, wave propagation for a P probe is shown in the frequency domain for $\theta_0=30°$, $\delta_x=\delta_y=\delta_z=1$, and $\overline{\omega}=10$. Here, the crystal axes system does not coincide with (x,y,z). The transformation from the crystal axes system to the (x,y,z) system is accomplished with the Euler angles $\varphi_1=0°$, $\varphi_2=60°$, and $\varphi_3=45°$ (see Fig. 4). The transformed stiffness matrix is given by

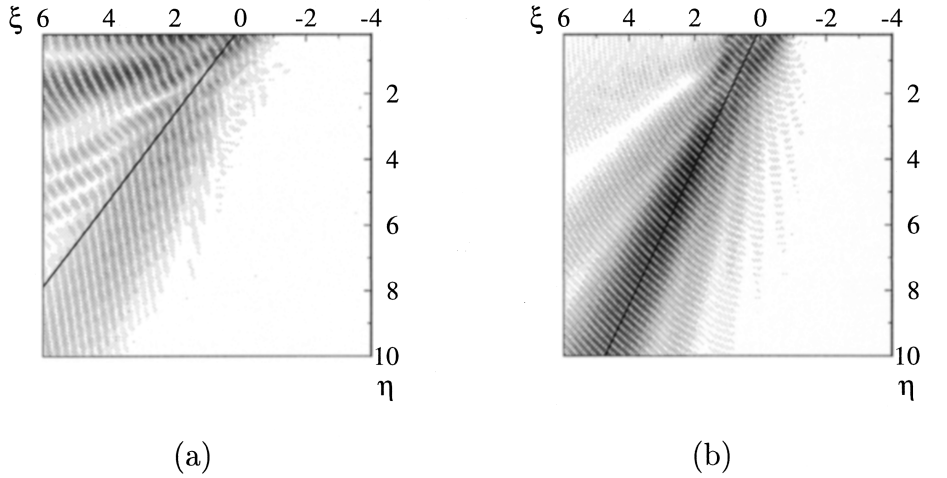

FIG. 7. $|\mathrm{Re}\,\tilde{\mathbf{u}}|$ for an SV and SH probe with $\theta_0=30°$ and $\overline{\omega}=10$. (a) SV probe. (b) SH probe.

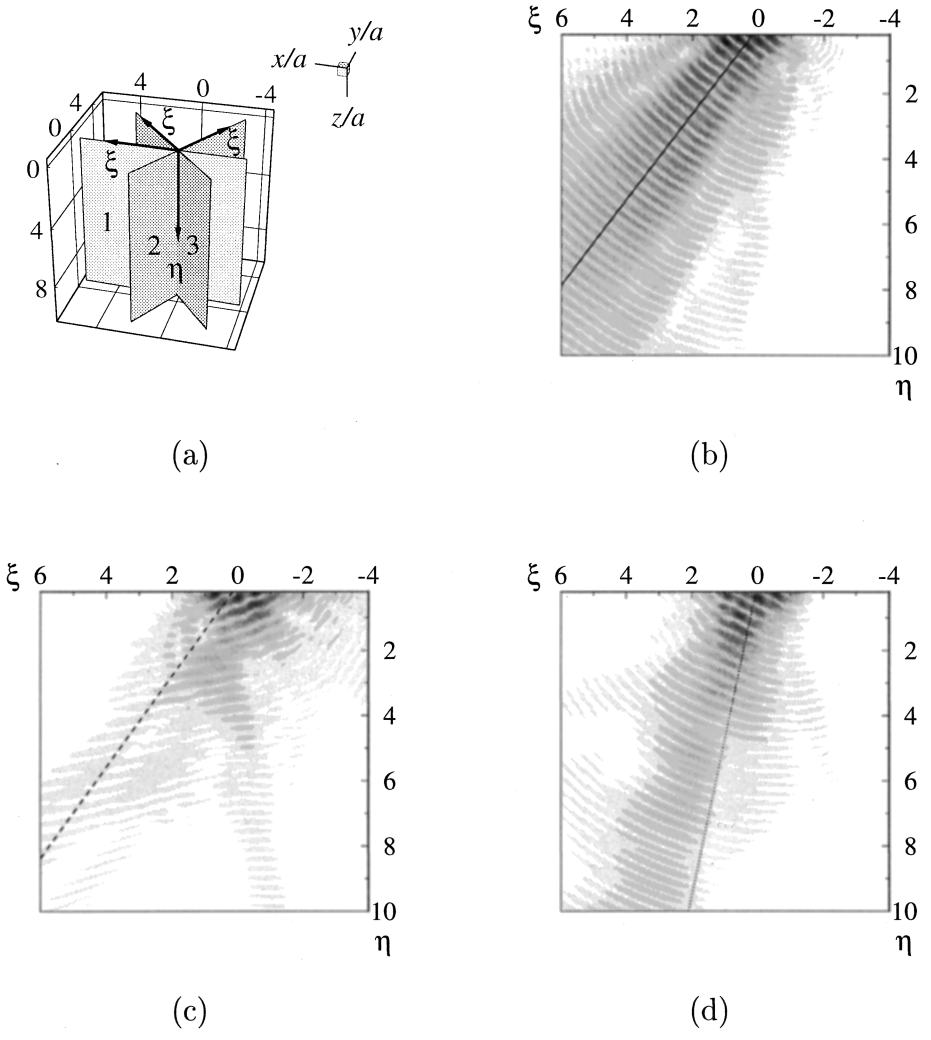

FIG. 8. $|\mathrm{Re}\,\tilde{\mathbf{u}}|$ for a P probe when $\theta_0=30°$, $\bar{\omega}=10$, $\varphi_1=0°$, $\varphi_2=60°$, and $\varphi_3=45°$. (a) The planes. (b) Plane 1. (c) Plane 2. (d) Plane 3.

$$C=\begin{pmatrix} 37.69 & 25.33 & 19.13 & 15.18 & -17.37 & -21.27 \\ 25.33 & 37.69 & 19.13 & 17.37 & -15.18 & -21.27 \\ 19.13 & 19.13 & 25.59 & 12.26 & -12.26 & -12.33 \\ 15.18 & 17.37 & 12.26 & 18.25 & -13.85 & -16.42 \\ -17.37 & -15.18 & -12.26 & -13.85 & 18.25 & 16.42 \\ -21.27 & -21.27 & -12.33 & -16.42 & 16.42 & 24.95 \end{pmatrix} \text{ GPa.} \tag{29}$$

Since (x,y,z) does not coincide with the crystal axes system, the three group velocities do not lie in one plane and the figure consists of the field plotted in three different planes. Plane 1 is spanned by the group velocity of the qP wave and the z axis, plane 2 by the group velocity of the qSV wave, and the z axis and plane 3 by the group velocity of the SH wave and the z-axis. In addition, the wave types do not decouple as they do in Figs. 5–7 and all three types will in general be present at the same time. In all of the figures, the solid line is the group velocity direction of the qP wave, the dashed line the direction of the qSV wave and the dotted line the direction of the SH wave. In all of the figures, a dominant part is seen close to the surface. Since this contribution comes from the qP wave, the field is largest in plane 1 where the qP wave is strongest. In plane 2, a weak qSV wave seems to be traveling along the dashed line. The third wave type, the SH wave, is much more difficult to identify.

In Fig. 9, the same situation as in Fig. 8 is considered except that the contact is inviscid, i.e., $\delta_x=\delta_y=0$ and $\delta_z=1$. This means that the directions of the main waves are the same here as in Fig. 8. Since Figs. 8 and 9 look very much alike, the normal part of the traction should be the dominat-

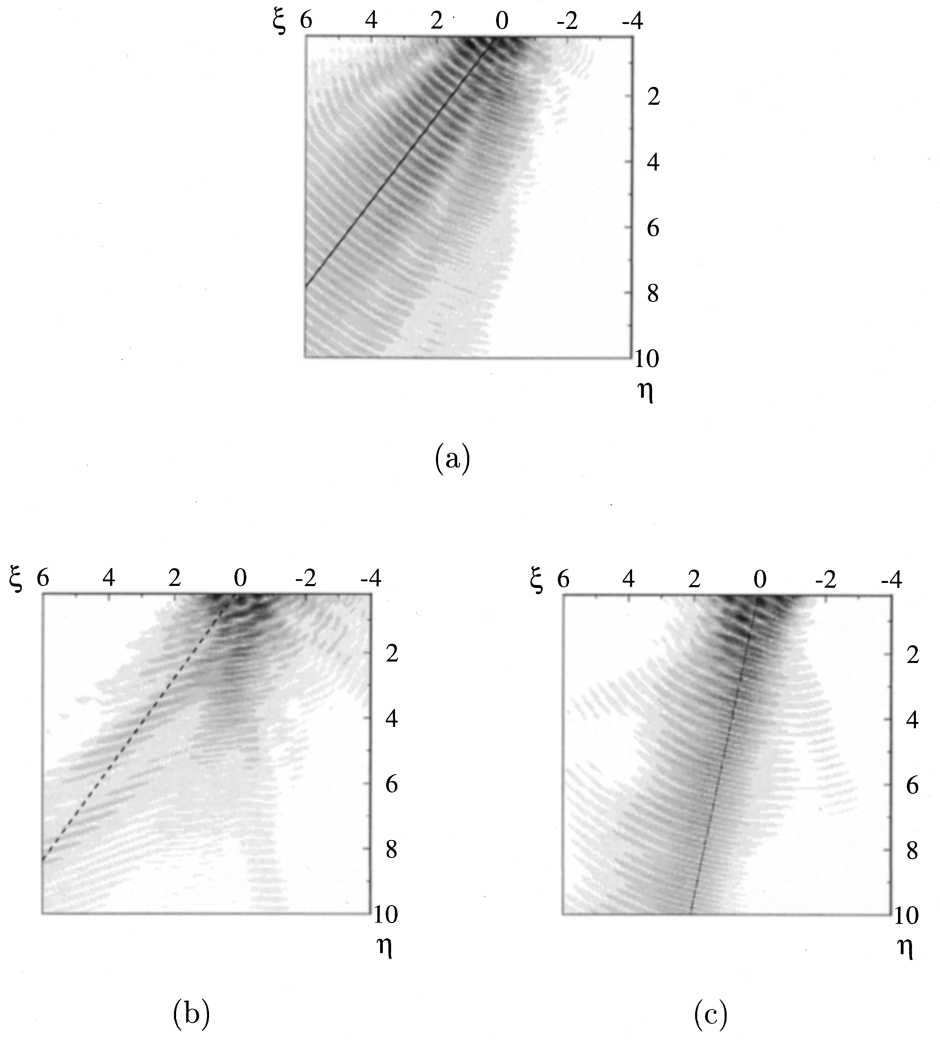

FIG. 9. $|\mathrm{Re}\,\tilde{\mathbf{u}}|$ for the same situation as in Fig. 8 except for $\delta_x=\delta_y=0$ and $\delta_z=1$. (a) Plane 1. (b) Plane 2. (c) Plane 3.

ing generator of the field in these case. Contrary to the case in Fig. 8, it is possible to identify the *SH* wave propagating along the dotted line in plane 3.

The same situation as in Fig. 8 is shown in Fig. 10 but in the time domain instead of the frequency domain. The field is shown at $\tau=3$ and $\tau=6$. The lower and upper frequencies are $\overline{\omega_1}=1$ and $\overline{\omega_2}=19$, respectively. The planes used and the directions of propagation are the same as in Fig. 8. Here, it is seen that the field is strongest in plane 1 and very weak in plane 2, as would be expected from Fig. 8. In order to identify the main waves, the absolute values and the directions of the group velocities are used. The directions of the main waves shown in the figures are also shown as straight lines in Fig. 3(b) (note that the directions are transformed to the crystal axes system). If the values of $|\mathbf{v}|$ where the straight lines cross the wave surfaces are multiplied with $\tau=6$, the result is the following:

Plane 1: *qP* at $(\xi,\eta)\approx(3.6,4.8)$;

qSV at $(\xi,\eta)\approx(2.6,3.4)$;

SH at $(\xi,\eta)\approx(1.8,2.4)$.

Plane 2: *qP* at $(\xi,\eta)\approx(6.1,8.4)$;

qSV at $(\xi,\eta)\approx(5.0,6.9)$;

SH at $(\xi,\eta)\approx(2.3,3.1)$.

Plane 3: *qP* at $(\xi,\eta)\approx(1.4,6.6)$;

qSV at $(\xi,\eta)\approx(1.2,5.6)$,

$(\xi,\eta)\approx(1.1,5.2)$,

$(\xi,\eta)\approx(1.1,4.9)$;

SH at $(\xi,\eta)\approx(0.7,3.2)$.

With this information at hand it is possible to identify the main waves from the figures. Note that, for example, only the main part of the *qP* wave will be located at the point calculated in plane 1. The other two waves will possibly prefer other directions of propagation but there will still be contributions at the calculated points which enables identification of the waves. Also note that due to the cusps in Fig. 3(b), three *qSV* waves are obtained along the dotted line. Moreover, contributions to the field apart from the main

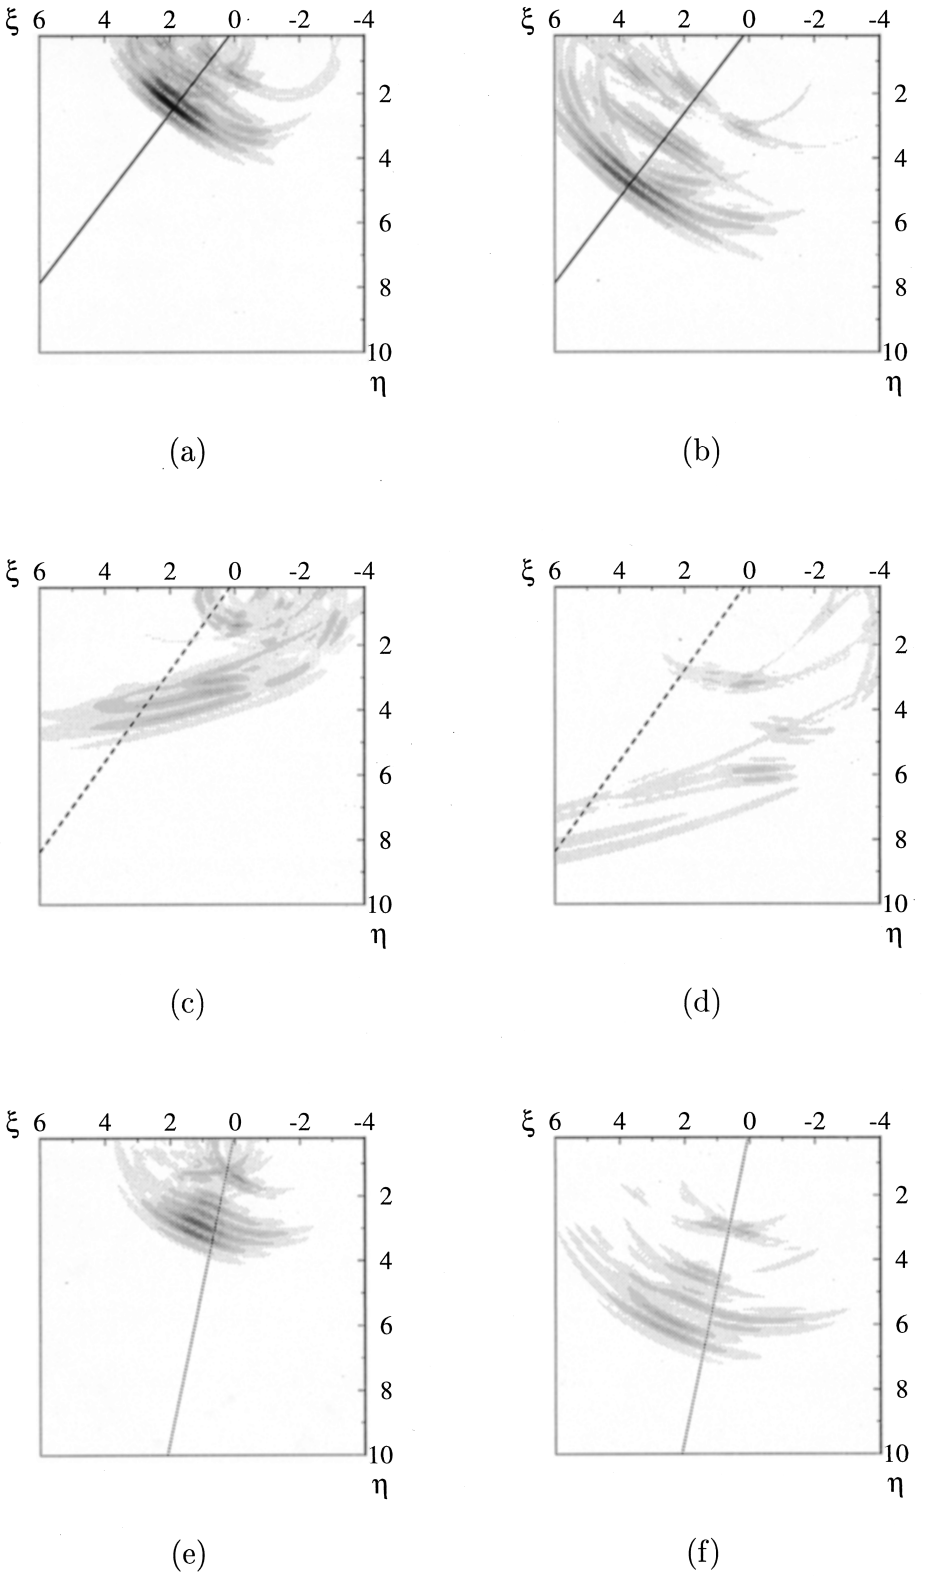

FIG. 10. Snapshots of $|\mathbf{u}|$ for the same situation as in Fig. 8. (a) $\tau=3$ in plane 1. (b) $\tau=6$ in plane 1. (c) $\tau=3$ in plane 2. (d) $\tau=6$ in plane 2. (e) $\tau=3$ in plane 3. (f) $\tau=6$ in plane 3.

waves are seen. From the figures, it is seen that these contributions come from the edges of the probe.[6,14] This is not surprising since the piston model implies a discontinuity in the traction here. This effect is somewhat reduced if the shape function is chosen as $g=g_2$ since this function has a tapering off at the edges.

V. CONCLUDING REMARKS

In this paper, a three-dimensional (3D) piezoelectric contact probe of *P*, *SV*, or *SH* type for anisotropic media is modeled. The model prescribes the traction beneath the probe and one advantage of the model is its simplicity. The

approach is especially suitable when Fourier methods are used. The model includes three parameters, δ_x, δ_y, and δ_z, and two functions, $g(x,y)$ and $\tilde{f}(\omega)$.

The probe is attached to an anisotropic half-space and the wave propagation problem is solved by means of Fourier transform techniques. The nature of the problem does not allow many analytical calculations, i.e., almost everything has to be calculated by means of numerical algorithms. Another property of wave propagation in anisotropic solids, which further complicates the situation, is the fact that the group velocities of the three wave types do not in general span one plane. This results in visualization problems and the fields are represented in 1–3 planes in this paper. It also results in interpretation problems since the different wave types are strongly mixed.

In the numerical examples, a transversely isotropic material and the piston model are used. There are examples of *P*, *SV*, and *SH*, probes, but mainly *P* probes are used. Radiated fields are shown in both the frequency and time domain. In the figures it is evident that the wave separation problem is large. This problem is somewhat reduced if the fields are examined in the time domain, but even here it can be hard to identify different waves. The mixing should make evaluation of ultrasonic test results much more difficult than in the isotropic case.

Modal excitation and control of membrane waves on cylindrical shells

Joseph E. Bondaryk
Department of Ocean Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

(Received 24 June 1997; revised 10 November 1997; accepted 19 January 1998)

A set of in-air experiments were made on two, thin, cylindrical shells to understand and control the propagation of membrane waves, which are primary determinants of target strength in the mid-frequency, high-aspect angle regimes. A circumferential source array was used to drive single modes in all wave types, compressional, shear, and flexural. Resulting waves were collected using an axial line array of laser Doppler velocimeter measurements and the wave types separated by array processing. Comparison between a clean plastic shell and a steel shell with a keel-like feature suggest on the order of 10-dB reduction of compressional wave response via coupling into higher order flexural waves by the nonaxisymmetric discontinuity. The conversion coupled with subsequent damping of the resulting flexural waves makes this a potentially useful mechanism for control of membrane waves. © *1998 Acoustical Society of America.* [S0001-4966(98)01705-6]

INTRODUCTION

Recent structural acoustics research on finite-length submerged shells has quantified the importance of quasi-shear and quasi-compressional membrane waves in radiation and scattering. For example, Fig. 1 shows the monostatic target strength in dB *re:* 1 m versus nondimensional frequency and aspect angle of a thin, finite cylindrical shell, collected for MIT by the Acoustic Scattering Group at the Naval Research Laboratory in 1991. It has been shown[1,2] that the strong features in the frequency range, $2<ka<12$, where k is the water wave number and a is shell radius, and in the aspect-angle range $60°>\phi>85°$ are due to reradiation of trace-matched membrane waves. On this empty shell, flexural waves are poorly coupled to the acoustic medium, due to the absence of periodic frames.

Only major changes to the shell can alter the membrane wave behavior. Their long wavelengths tend to ''ride over'' small and local treatments. For example, small periodic frames induce flexural Floquet waves,[3] which contribute to scattering at higher ka, but leave the membrane wave region relatively unaffected. An example of the effect of a major modification is shown in Fig. 2, the monostatic target strength in dB *re:* 1 m for the same shell with four, unequally spaced, axisymmetric stiffeners. These are major discontinuities, with the mass of the stiffeners equal to mass of shell. Note that the membrane wave region has been extended by at least 10°.

The ultimate objective of this research is to explore various modifications to the basic shell structure that might provide a designer with options in optimizing a hull for combined hydrostatic strength, shock resistance, and acoustic performance. Specifically, those modification schemes appropriate to the control of membrane waves in the above frequency and aspect-angle range are being studied experimentally. These include heavy bulkheads, neckdown sections, and keel-like structures.

Section I of this paper describes the experimental setup and methodology used to understand membrane wave propagation on shells. A novel source array configuration allows single mode excitation of shells. The resulting data are collected at an array of shell locations, which allows the separation of wave types via array processing. With this approach, single mode propagation as well as wave type and mode coupling can be studied in detail. The experiments described here were conducted in air for simplicity. Complexities such as water-mass loading and acoustic-resistive coupling can be appended to the results analytically via reasonably well known physics. Section II describes data derived from experimentation including observation of the source-selected modes propagating on a plastic shell. Section III describes several strategies for the control of membrane waves and some preliminary data on a steel shell with a keel-like feature. Data suggests significant reduction of the compressional response, on the order of 10 dB, via coupling of energy into higher order flexural modes.

I. EXPERIMENTAL SETUP AND PROCESSING

The overall experimental setup is comprised of three major systems: (1) the cylindrical shell itself; (2) the source array; and (3) the receiver array. The particular shell under test will be discussed in Secs. II and III, the latter two systems are described here.

The sources are 6.35×10^{-3} m (1/4 in.) o.d. piezoceramic rings made of lead zirconate titanate 5500 by Channel Industries. P holes were drilled into the shell at $360°/P$ intervals around the shell circumference and the rings bonded in with epoxy, as shown in Fig. 3 for the example of $P=12$. When a voltage is applied to the inner and outer surface of the ring, it expands radially and tends to excite compressional waves in the shell. A workstation is used to drive each source signal independently via 12-bit D/A cards. The elements were driven in a swept-sine mode, 256 frequencies over the range 0–25 kHz for ≈100-Hz resolution, coherently with amplitude shading over element number to

achieve modal excitation. The pth amplitude shading is given by $a(p)=\cos(2\pi Mp/P)$, where P is the total number of source elements and M is the desired mode number. The voltages of these signals are then amplified by $10\times$ via step-up transformers, since the piezoceramic rings are capacitive in nature, and sent on to the ring sources.

With this driving system, it is possible to drive single modes in all wave types on the shell. By the Nyquist sampling theorem, P sources around the circumference can drive single unaliased modes up to $M=P/2$. As we shall see, this discrete mode drive must excite modes at higher harmonics. Specifically, for a P element source, exciting mode M, where $M<P/2$, the excited modes are modes M, $(l\times P)+M$ and $(l\times P)-M$ for $l=1,2,3,....$ A mode will only exist if the frequency is above the cutoff frequency for that mode. This is seldom the case for the higher order membrane waves in the frequency range of interest but is usually the case for the flexural waves, due to their dense frequency spacing. In theory, all wave types with the excited mode number should be generated by this circumferential source array. However, the sources elements themselves are compressional in nature and thus the array tends to excites compressional waves primarily.

Output velocity is measured at points on the shell by a single-axis Polytec PI laser Doppler velocimeter (LDV),

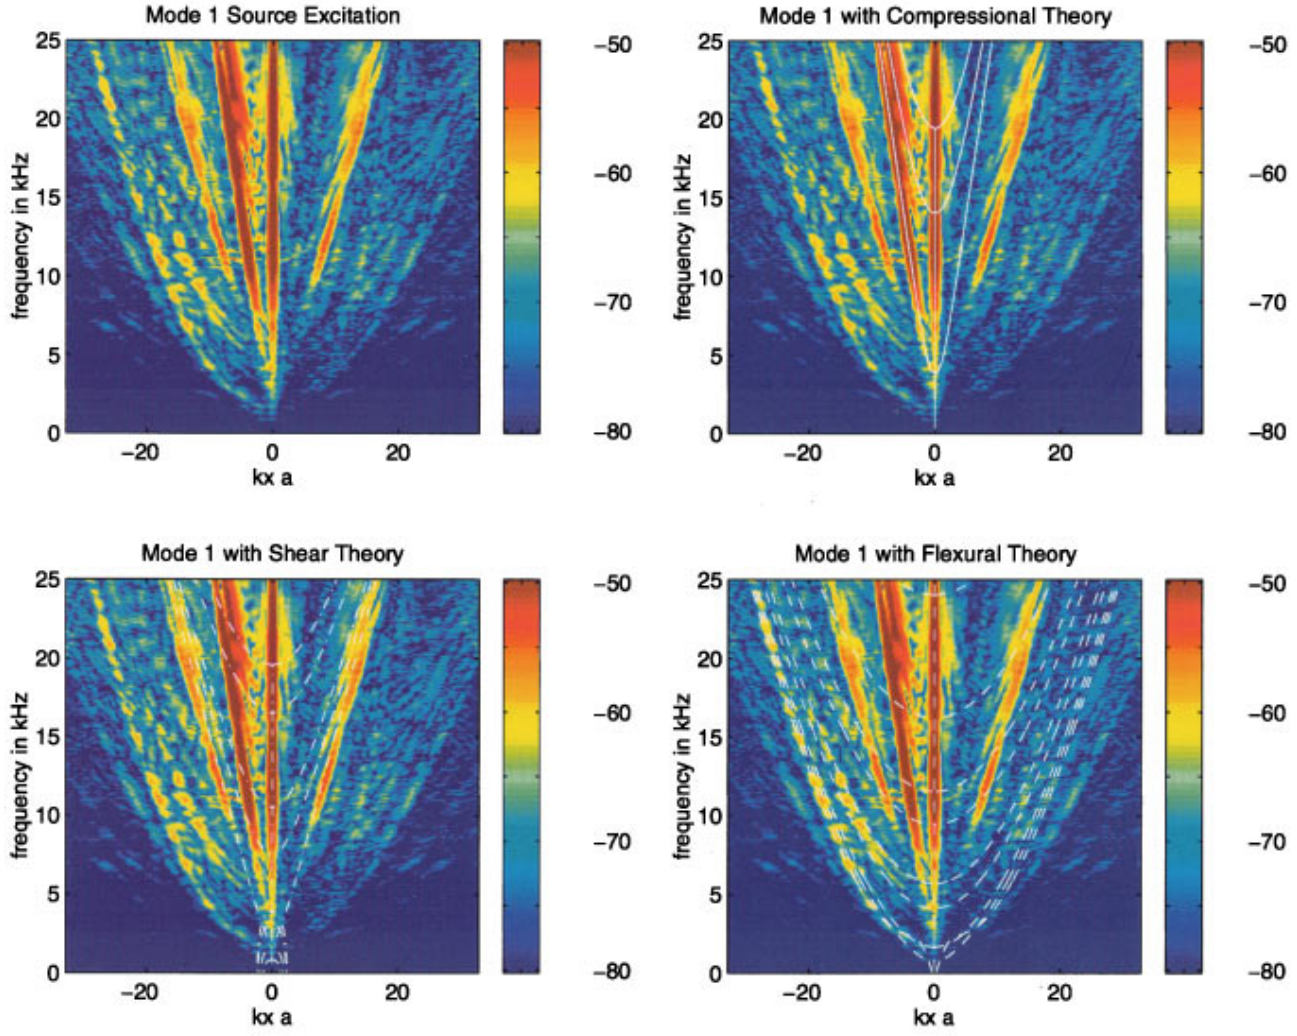

FIG. 5. Frequency wave number spectrum in dB *re:* 1 m/s^2/V_{in} for PVC shell. Mode $M=1$ source excitation with overlays of thick shell theory for dispersion relations of three wave types—compressional, shear, and flexural.

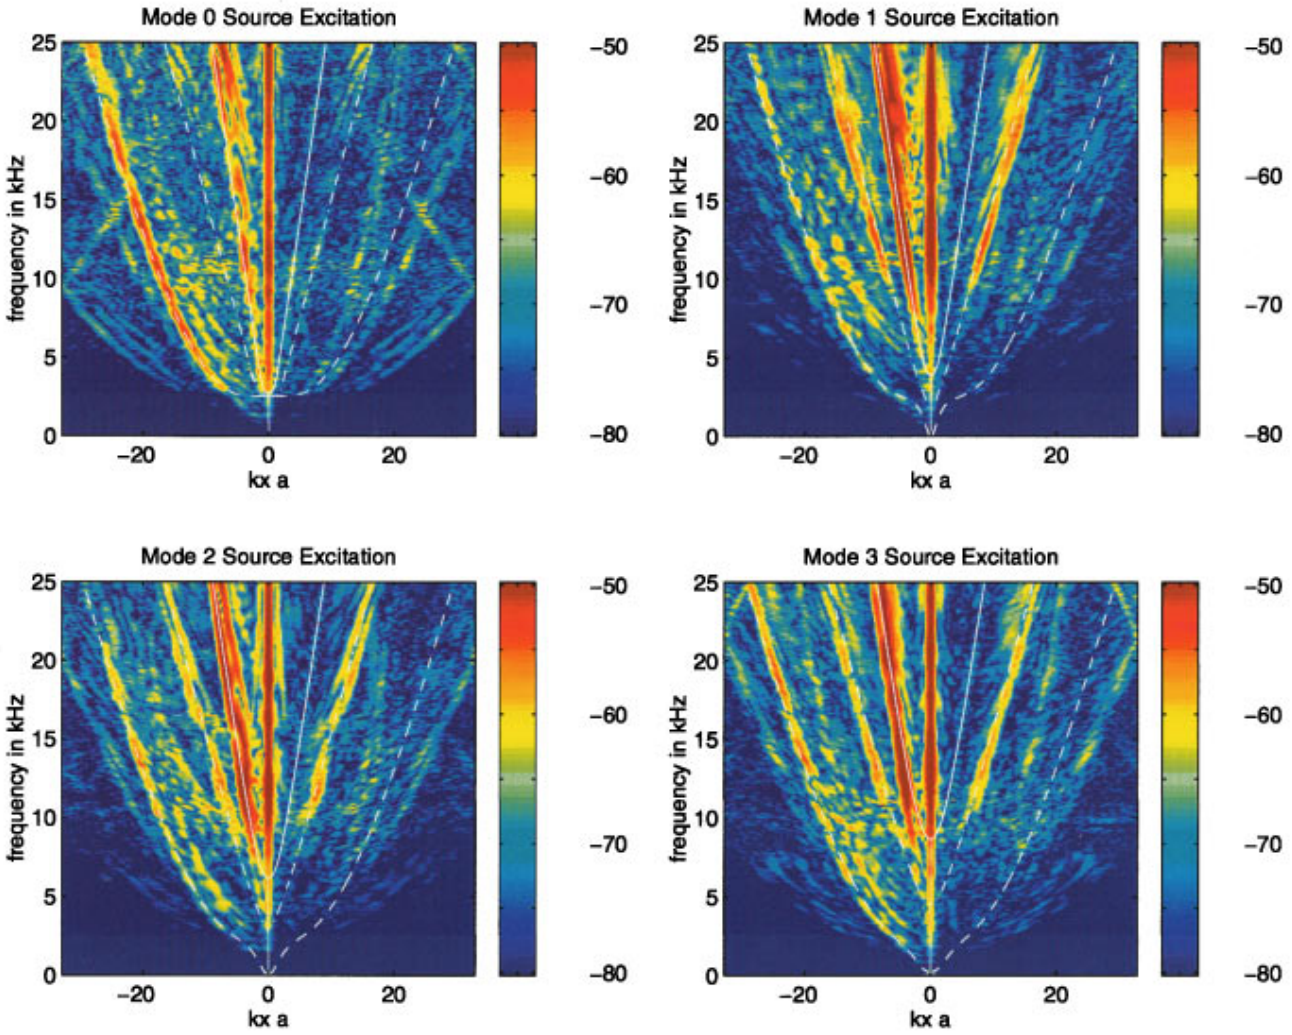

FIG. 6. Frequency wave number spectrum in dB *re:* $1\ \mathrm{m/s^2}/V_{\mathrm{in}}$ for PVC shell. Mode $M=0-4$ source excitation with overlays of thick shell theory for dispersion relations of three wave types—compressional (solid), shear (dot-dashed), and flexural (dashed).

OFV353 laser head and OFV3001 controller. The system is capable of measuring velocity along the beam over a velocity spectral range of $0.5\ \mu\mathrm{m/s}\sqrt{\mathrm{Hz}}-10\ \mathrm{m/s}\sqrt{\mathrm{Hz}}$ and a frequency range of 0.5 Hz–1.5 MHz. Radial velocity measurements are made by aiming the beam at 90° to the shell, axial velocity measurements are made by aiming the beam at 45° to the shell axis, and transverse velocity measurements are made by aiming the beam at 45° to the shell transverse axis. The latter two measurements contain both the desired and radial components. These components are not separated by subtracting laser data directly. Rather, subsequent array processing is used to separate wave types in frequency wave number space. Thus the measurements represent scaled wave amplitudes, rather than particle velocity in a particular direction.

The workstation is used to acquire the LDV output and the shell input signal via a 12-bit A/D board. Data are antialias filtered, sampled at 50 kHz and cross spectra between the LDV output and shell input signal are acquired over 100 ensembles.

A Parker linear positioning table under control of the workstation is used to move the LDV beam along a line down the shell axis by an increment of dx. This increment controls spatial aliasing, which occurs at an axial wave number of $k_x=\pi/dx$. The above measurements are made at each of the N array positions. For a given dx to control aliasing, N determines the array length. The spatial frequency resolution is inversely proportional to array length, L.

For each frequency, the N complex spectral values are collected into vector $\mathbf{x}(f)=[x_1(f)w_1,\ldots,x_N(f)w_1]$, where w_n is a standard Hanning taper function and $x_n(f)$ is the complex spectral value at frequency f from position z_n. The spectral matrix is formed via $S_x(f)=\mathbf{x}(f)\mathbf{x}^{\dagger}(f)$, where ''†'' denotes complex conjugate transpose. The array is then steered over axial wave number, k_x in the unaliased axial wave number range $-\pi/dx<k_x<\pi/dx$. The steering vector $\mathbf{e}(k_x)[e^{j2\pi k_x\cdot z_1},\ldots,e^{j2\pi k_x\cdot z_N}]$ is applied to the data for all k_x to form the output frequency wave number surface, $P(f,k_x)=\mathbf{e}^{\dagger}(k_x)S_x(f)\mathbf{e}(k_x)$. This results in a $\geqslant$30 dB SNR over the frequency range $100\ \mathrm{Hz}<f<25\ \mathrm{kHz}$. As will be shown in the next section, the three wave types overlap completely in frequency, but are well separated in axial wave number, k_x.

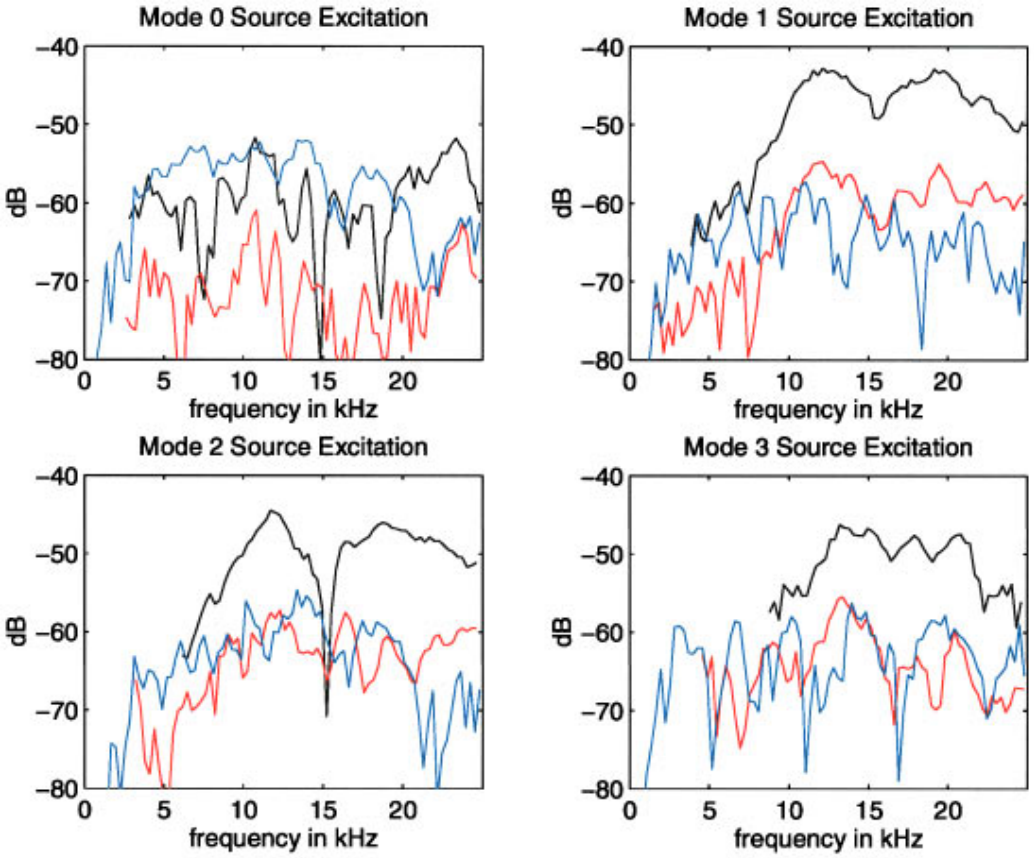

FIG. 7. Spectral amplitude of right-going waves on PVC shell by wave type in dB *re:* $1\ \mathrm{m/s^2}/V_{\mathrm{in}}$ for modes $M=0-3$. Black line is compressional, red is shear, and blue is flexural level. 300-Hz band average.

II. RESULTS—CLEAN SHELL

For this section, testing was conducted on a 1.525 m (5 ft) section of radius 0.1 m (4 in.), 4.76×10^{-3} m (3/16 in.) thick, type I, PVC pipe. The shell has flat-plate endcaps of 6.35×10^{-3} m (1/4 in.) thick, type I, PVC attached with epoxy. The measured compressional wave speed was 1660 m/s and Poisson's ratio was assumed to be $\nu=0.4$. The shell was suspended from a wooden frame by bungie straps, which provide vibrational isolation above approximately 10 Hz. The source and receiver array locations are shown in Fig. 4. The source array has $P=6$ elements at 60° spacing and the receiver array has $N=101$ elements at $dx=1$ cm spacing.

Figure 5 shows the resulting data for a mode $M=1$ source excitation, measured by an axial/radial measurement. The upper left plot shows the acceleration level on the shell surface versus frequency in kHz on the y axis and normalized axial wave number, k_xa on the x axis, where a is the shell radius. Negative values of k_xa indicate propagation from left to right w.r.t. Fig. 4, positive values of k_xa indicate propagation from right to left. Color levels are in dB *re:* $1\ \mathrm{m/s^2}/V_{\mathrm{in}}$, where V_{in} is the input voltage to the piezo sources. The other three plots of Fig. 5 show the same data overlayed with theoretical dispersion curves for the expected fundamental and higher order aliased modes separated by wave type. Hermann–Mirsky thick shell theory[4] with the above parameters was used to generate these curves. The compressional overlay shows modes 1, 5, and 7. Higher modes cutoff above this frequency range. The shear overlay shows these modes plus modes 11 and 13. The flexural overlay shows these modes plus modes 17, 19, 23, and 26. The strong line at $k_xa=0$ is due to electronic leakage of the extremely high voltages used to drive the sources into the acquisition system and should be ignored.

For the compressional wave, data matches theory for the entire mode 1. Mode 5 is clearly present above 20 kHz. Mode 7 is not seen. Note, that propagation for this wavetype is limited to the negative k_xa range. The plastic shell has high intrinsic damping. Auxiliary measurements over the 25-kHz range indicate $\eta=0.2$ for compressional waves. This is the direct wave from the source, the wave reflected from the far end of the shell has decayed too much to be observed in the data.

The shear wave mode 1 data matches theory above 10 kHz. There is a hint of modes 5 and 7, but not higher modes. This wave type seems to propagate both forward and backward on the shell. This seems unlikely due to the high damping of the shell. However, since the data must be correlated with the source to appear in the plot at all and since anomalies caused by array processing problems would apply equally to all wave types, this must be true phenomenon. The damping for shear waves in this plastic shell is under investigation. The flexural wave shows strong negative k_xa propagation in modes 1, 5, and 7.

Figure 6 shows the data for this shell for source excitation of modes $M=0-3$. The theoretical overlays are shown only for the fundamental excited mode for the three wave

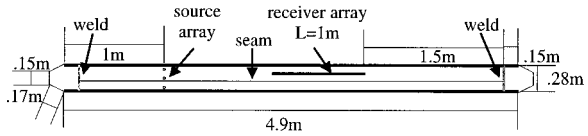

FIG. 8. Steel test shell with conical endcaps and keel-like feature with array locations.

types. Note that there is good agreement between the data and the theoretical dispersion curves. This plot shows that single mode excitation of the cylindrical shell has been achieved. As expected for mode $M=0$ excitation, there is a sharp reduction in energy below about 2.7 kHz, which is the ring frequency for this shell. The compressional wave is the strongest wave present in all modes, which is consistent with the compressional nature of the source elements. Note that the shear wave is not present in $M=0$ as expected, but is present for higher order M. This supports the above statement that the data shows a true shear wave and not a processing or measurement anomaly. Most easily seen in mode 0 is a wave which exists outside of the flexural ''U'' and aliases at about 9 kHz. Since the flex wave is the slowest structural wave which exists on this shell, this must be some other phenomenon. Analysis indicates that this very slow wave is the air-borne duct mode inside the closed pipe.

For a more quantitative view the data, consider Fig. 7. It shows the spectral acceleration level in dB *re:* 1 m/s^2/V_{in} for each of the wave types on the PVC shell. These curves were made from Fig. 6 by extracting the values of the data under the theoretical curve for the fundamental mode in the right-going direction only. The black curve represents the compressional level, red is shear and blue is flexural level. Notice that the compressional wave is most directly excited in modes $M=1$, 2, and 3 with 10 dB of separation from the other curves. This will be in contrast to the behavior of the shell with a keel in the next section.

III. MEMBRANE WAVE CONTROL—SHELL WITH KEEL

Membrane wave control could be achieved by taking advantage of one or several basic wave phenomenon: (1) damping; (2) dispersion; (3) path blocking; and (4) wave conversion. Damping is difficult to achieve against membrane waves, since their particle velocities are mostly unaffected by traditional constrained layer or bulk fill damping

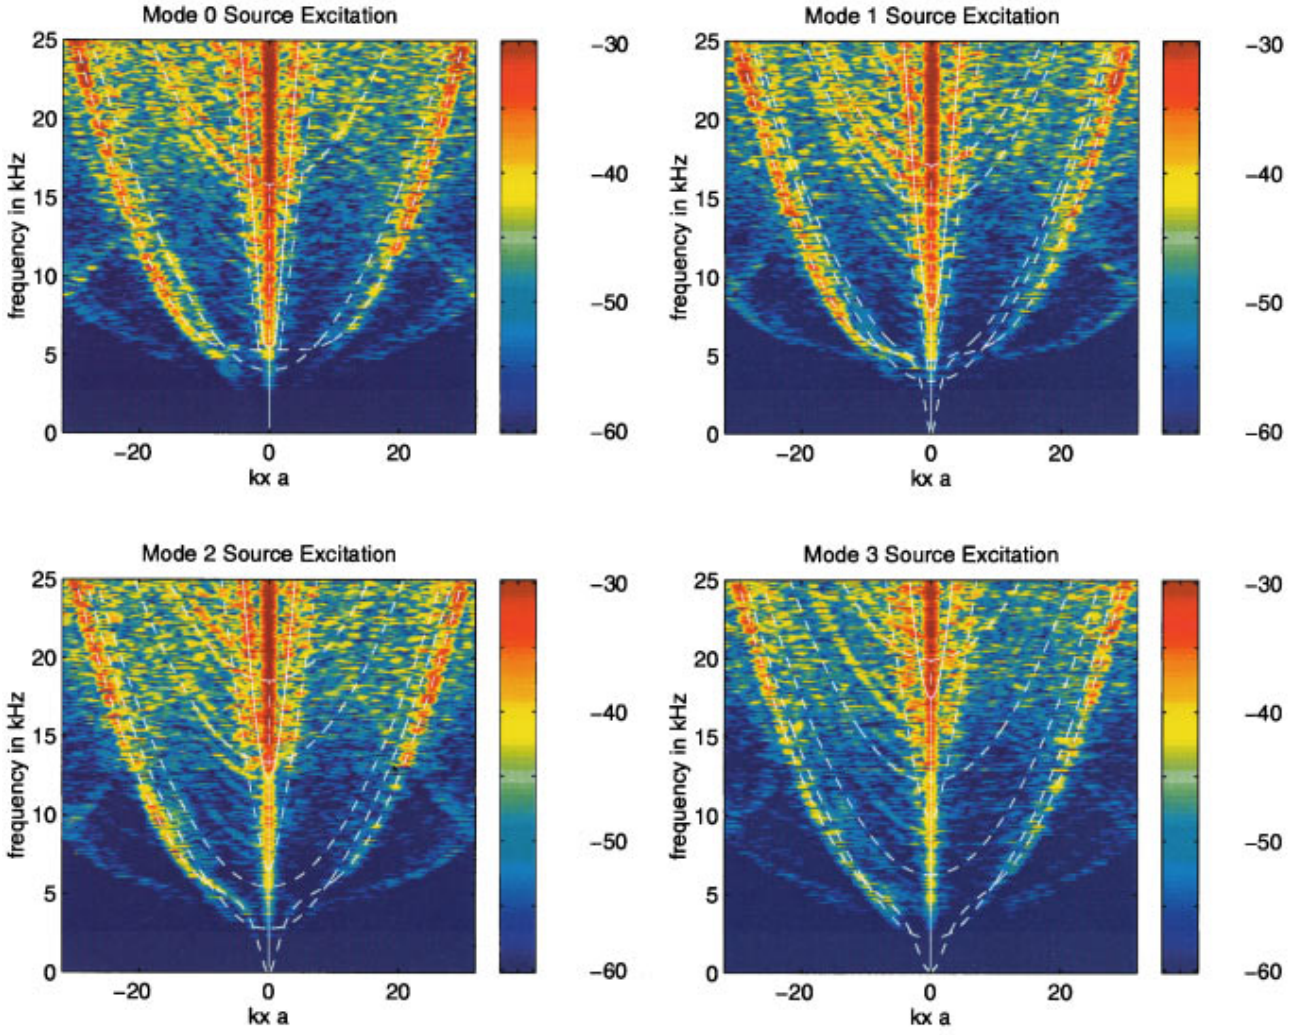

FIG. 9. Frequency wave number spectrum in dB *re:* 1 m/s^2/V_{in} for steel shell. Modes $M=0-4$ source excitation with overlays of thick shell theory for dispersion relations of three wave types—compressional (solid), shear (dot-dashed), and flexural (dashed).

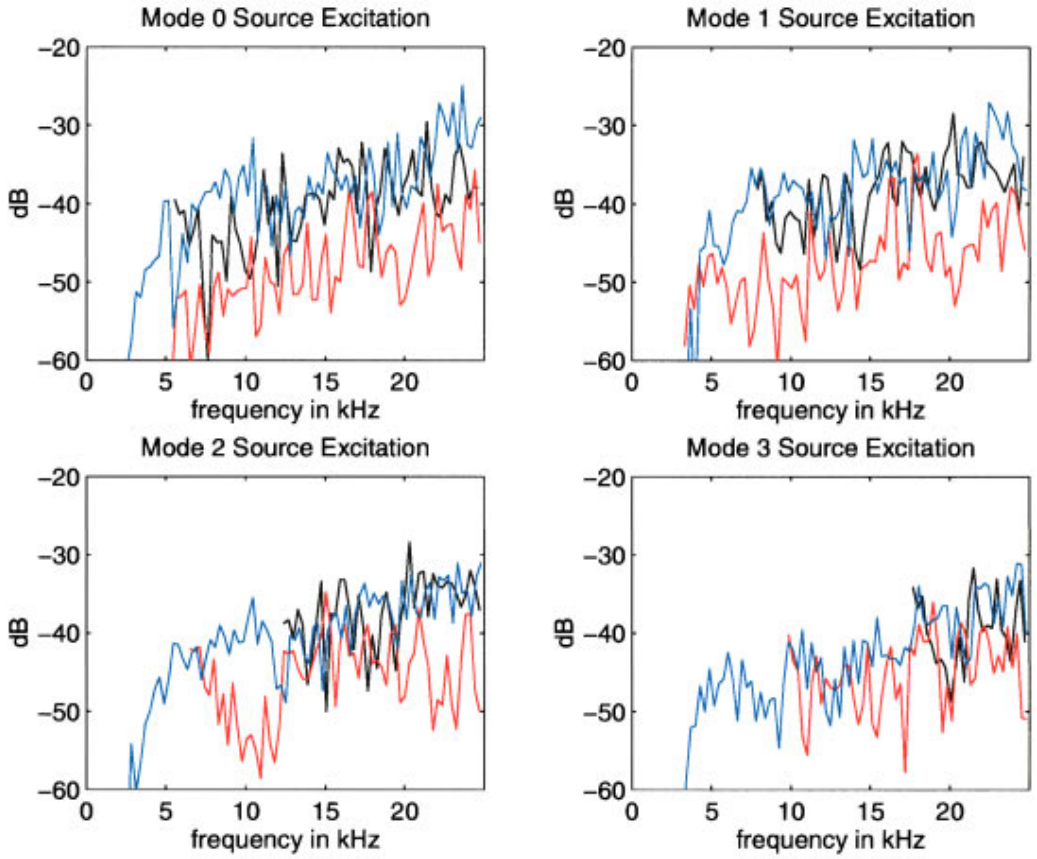

FIG. 10. Spectral amplitude of right-going waves on steel shell by wave type in dB *re:* 1 m/s^2/V_{in} for modes $M=0-3$. Black line is compressional, red is shear, and blue is flexural level. 300-Hz band average.

approaches. These waves are also nondispersive. This leaves the latter two approaches. An example of a major modification which should cause such behavior is a nonaxisymmetric axial discontinuity or ''keel'' in the shell.

The testing described in this section was conducted on the steel pipe depicted in Fig. 8. The shell radius is 0.152 m (6 in.) and is 2.54×10^{-3} m (0.1 in.) thick with a measured compressional wave speed of 5048 m/s and assumed Poisson's ratio of $\nu=0.35$. This cylindrical shell has a keel-like feature in the form of a cusped weld seam along its axis, about twice the thickness of the shell itself. The shell has open conical endcaps. The conical sections have a material and slope discontinuity where they meet the straight cylinder section, but are axisymmetric. The shell was suspended from a wooden frame by bungie straps which provide vibrational isolation above 10 Hz. The source array has $P=12$ elements at 30° spacing and the receiver array has $N=67$ elements at $dx=1.5$ cm.

Figure 9 shows the frequency wave number response of the steel shell for a source excitation of modes $M=0-3$. Since there are $P=12$ sources in this shell, the spacing between the expected aliased modes is larger. Only the fundamental compressional and shear waves are below their cutoff in this frequency range. The theoretical dispersion curves for the fundamental compressional and shear modes are overlayed on the plots as well as the those for *all* expected flexural modes in the frequency range. The thick shell theory is approximate here since the shell is no longer axisymmetric, but is reasonable as the keel's effect on wave speed is probably small. Again the line at $k_xa=0$ is due to electronic noise and should be ignored. Due to the low intrinsic damping of steel, acceleration levels per input volt on this shell are 20 dB higher than those found on the PVC shell. This also accounts for the fact that waves propagate in both directions as evidence by high levels seen in both the $+k_xa$ and $-k_xa$ sides of the plots. Excited waves reflect many times at both endcaps before decaying into the ambient noise level.

Coupling between wave types at the endcaps is certainly occurring as it did in the plastic shell. However, since all endcaps are axisymmetric, this coupling should be restricted to the same circumferential order, M. Indeed, energy in all wave types is 5–10 dB higher above the fundamental compressional mode cutoff frequency than below, seen most easily in the plots for excited modes $M=2$ and 3. The sources primarily excites the compressional mode, M. This mode could couple into the same mode, M, in shear and flexure at the endcaps. However, there are many higher order flexural waves excited, besides the expected directly excited and aliased modes. These are seen as the series of ''U''-shaped curves stacked in frequency, which are not overlayed by theoretical lines. These modes are coupled by the keel either directly from the fundamental compressional mode generated at the source or indirectly from the secondary shear and flexural modes generated at the endcaps. Either way, the energy equilibrium that exists with these higher order flexural

modes, must reduce the energy of the primary compressional wave.

Further evidence of coupling can be found in Fig. 10. This figure shows the spectral acceleration level in dB *re:* $1\ \mathrm{m/s^2}/V_{\mathrm{in}}$ for each of the wave types on the steel shell. These curves were made from Fig. 9 by extracting the values of the data under the theoretical curve for the fundamental mode in the right-going direction only. The black curve is for the compressional wave, red is for shear and blue is for flexural level. The compressional and flexural levels are fairly close across frequency and mode, there are no longer the 10-dB differences seen in the clean shell. This is consistent with the theory that compressional energy is being wicked away into the higher order flexural modes. This preliminary evidence suggests that the keel may be an effective coupling mechanism between these wave types. More direct comparisons, i.e., the same shell with and without a variety of keel configurations, are underway to investigate coupling mechanisms and their controlling parameters. If proven, this mechanism for the coupling of membrane energy into flexural waves is potentially beneficial, as this wave type can be controlled effectively by classical damping treatments.

IV. CONCLUSIONS

This paper has shown that the experimental procedure of synthetic LDV array measurements and subsequent frequency wave number processing are sufficient to measure and separate membrane and flexural wave types on cylindrical shells. It is possible to excite a select few modes on a cylindrical shell through the use of a properly shaded discrete circumferential array. The characteristics of the these experimentally measured modes agree well with theoretical thick-shell dispersion curves.

Experiments were conducted on a clean shell and a shell with a keel-like feature. It was suggested that there is on the order of 10-dB reduction of the excited compressional mode by the keel through coupling into higher order flexural modes. These initial results are encouraging, since flexural modes can be effectively damped by conventional methods, constrained layer for example. This could provide a useful mechanism for the control of membrane wave propagation on cylindrical shells. The coupling mechanisms and important parameters of this coupling, for example whether the mass or bending stiffness of the keel of is of primary importance, are topics of continuing research.

Sound radiation by a simply supported unbaffled plate

B. Laulagnet
Laboratoire Vibrations Acoustique, Institut National des Sciences Appliquées de Lyon, 20, avenue Albert Einstein, 69621 Villeurbanne Cedex, France

(Received 14 October 1996; revised 23 September 1997; accepted 4 February 1998)

Sound radiation by a simply supported unbaffled plate is presented using a double layer integral representation of the acoustic pressure. Both the pressure jump and the plate displacement are developed in series of the simply supported plate modes. This leads to modal coupling coefficients, which are numerically calculated for this specific unbaffled problem. The unbaffled problem is then transformed in the presentation of the baffled one which allows us to define original modal radiation impedance coefficients to the unbaffled plate. Baffled and unbaffled radiation impedances are then compared versus nondimensional frequency, in real and imaginary parts for a set of representative modes. An approximate expression for the direct unbaffled radiation impedance is presented, which is useful for light fluid loading. Finally, the influence of the baffle on sound radiation both in light and in heavy fluid, on the acoustic radiated power, the plate velocity, and the radiation factor is investigated. © *1998 Acoustical Society of America.* [S0001-4966(98)04105-8]

INTRODUCTION

Plate sound radiation has been a problem of practical interest for many years. As a matter of fact, a lot of industrial structures can be modeled, to a first approximation, as a finite flat plate.

Usually, one of the simplest models available is the one of the baffled, simply supported plate. The simply supported plate is chosen because of the simplicity of the eigenmodes, which can be analytically determined. The rigid baffle allows us to transform the double layer integral representation into a simple one and it renders the vibroacoustical problem solvable. Nevertheless, in most of the practical cases, a rigid infinite baffle does not exist.

Early in the 1960s and 1970s, some authors studied the radiated sound from a baffled, simply supported, plate. First, Maidanik[1] investigated a single-mode radiation resistance of a finite, simply supported baffled plate, and Wallace[2] obtained an expression for the real part of the radiation coefficients versus frequency, for only the diagonal terms. Maidanik[3] gave an asymptotic formula for these coefficients which is still useful and widely used. Davies in Refs. 4 and 5 gave an approximate formula for the imaginary part of the radiation coefficient to allow for the calculation of the fluid added modal mass effect. This formula is widely used, when for example, a heavy fluid is considered and when one wants to calculate a first approximation of the resonance frequencies of a baffled plate in water. More recently, Graham[6] gave an approximate formula for the cross-modal radiation impedance terms in order to calculate sound radiation by a simply supported baffled plate excited by a turbulent boundary layer.

These radiation coefficients have been calculated for simply supported baffled cylindrical shells by Harari and Sandman,[7] Stepanishen,[8] and Laulagnet and Guyader[9] for heavy fluid radiation. In Ref. 8, the cross-modal radiation terms are derived. In Ref. 9, a comprehensive study of the radiation phenomenon in air and in water was investigated. Finally Sandman, in Ref. 10, investigated the influence of the baffle on the radiation coefficients for a cylindrical shell. His conclusion is that the baffle is of little influence on the sound radiation, and hence on the radiation coefficients. Although this conclusion is drawn from radiation impedances, rather than in impedance levels, the sound radiated by a cylindrical shell is not representative of the one for a flat plane.

Recently, Attala *et al.*[11] investigated the sound radiation by an unbaffled plate with general boundary conditions, using a light fluid assumption, i.e., neglecting the pressure jump when calculating the plate velocity. The pressure jump and the plate displacement are expanded in polynomial series. This allows the authors to describe analytically any boundary condition on the plate's edge, which renders the method attractive. However, the numerical implementation of the method suffers from instabilities, which leads to an overestimate of the unbaffled radiation efficiency of the plate with increasing frequency. However, in the low-frequency range, theory and experiment are presented which show a good agreement in radiation efficiency for an unbaffled free plate.

The objective of this paper is to address the sound radiation problem for an unbaffled plate with simply supported end conditions when submerged in light or heavy fluid without neglecting the pressure jump in the plate velocity, and to resolve the question of the influence of the baffle on the acoustic radiation, in a wide frequency range. The original set of cross-modal radiation impedance of the simply supported unbaffled plate are plotted versus a wide range of nondimensional frequencies.

In the first part of the paper, the equations of the vibroacoustic problem are presented and are solved using a modal decomposition for both the pressure jump and the plate displacement. This leads to the definition of the acoustical modal coupling coefficient of the unbaffled plate problem. In the second part, the equations are transformed in order to compare those coefficients with those of the baffled problem.

Then, the set of cross-modal radiation impedance coefficients are deduced for the unbaffled plate and compared to a baffled one. Numerical comparisons are presented which exhibit the differences in behavior between the two plates. Approximate formulas for the unbaffled coefficients are presented, which can be useful, in practical cases of light fluid loading.

In the last part of this paper, the influence of the rigid baffle is evaluated for a light fluid like air and in a heavy fluid like water. The plate is a 1-m^2 steel plate and represents a normalized case of the ''commission de validation des logiciels,'' a French organization supported by the French Acoustical Society and the French Mechanical Engineering Society[12] charged with validation of vibroacoustical software of simple basic cases. For this normalized case, the influence of the baffle is evaluated in terms of the sound radiated power, the plate velocity, and the radiation efficiency.

I. GOVERNING EQUATIONS

Consider a thin plate, excited by a harmonic driving force of angular frequency ω, located in the plane $z=0$. The plate is unbaffled, simply supported, with a surface S_p. The acoustic medium is infinite. The force is normal to the plate producing flexural waves governed by the classical equation:

$$D\nabla^4 w(x,y) - m\omega^2 w(x,y) = F(x,y) + \overline{p}(x,y), \tag{1}$$

where D is the rigidity modulus, m the mass per unit area, $w(x,y)$ the transverse displacement, $F(x,y)$ the driving force, and $\overline{p}(x,y)$ the difference of the acoustic surface pressure. The expression of the pressure jump due to the transverse motion of the plate is given by

$$\overline{p}(x,y) = p^-(x,y) - p^+(x,y), \tag{2}$$

where $p^-(x,y)$ and $p^+(x,y)$ are, respectively, the surface pressures on the side z negative and z positive of the plate.

The acoustic pressure is governed by the classical homogeneous Helmholtz equation:

$$\nabla^2 p(x,y,z) + k^2 p(x,y,z) = 0, \tag{3}$$

where $p(x,y,z)$ is the acoustic pressure anywhere in the acoustic fluid, k the acoustic wave number, ω/c, c the sound velocity, and ∇^2 the Laplacian operator.

The continuity between the normal acceleration of the plate and the fluid particle is given by Euler's equation:

$$\left.\frac{\partial p(x,y,z)}{\partial z}\right|_{z=0} = \rho_0 \omega^2 w(x,y), \tag{4}$$

where ρ_0 is the fluid density.

II. INTEGRAL REPRESENTATION FOR THE ACOUSTIC PRESSURE

Applying the Green's formula to a volume entirely closing the plate, one can write for the pressure anywhere in the volume: (cf. Fig. 1)

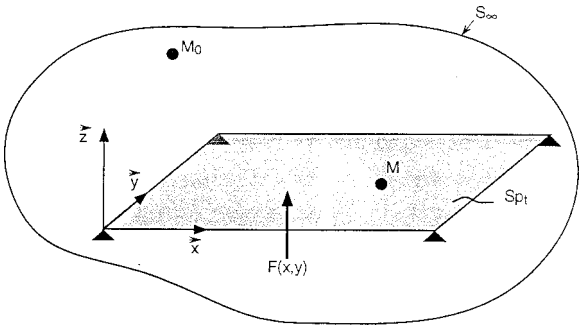

FIG. 1. Schematic view of the supported plate in the infinite medium.

$$p(M_0) = \int_{S_T} \left(\frac{\partial G}{\partial n_M}(M,M_0) p(M) - \frac{\partial p}{\partial n_M}(M) G(M,M_0) \right) dS_T, \tag{5}$$

where M_0 belongs to V, $\mathbf{n}_M$ is the normal to the total surface taken at M composed by S_{p_t} and S_∞ pointing outward, and $G(M,M_0)$ is the Green's function satisfying:

$$\nabla^2 G(M,M_0) + k^2 G(M,M_0) = \delta(x-x_0)\delta(y-y_0) \times \delta(z-z_0), \tag{6}$$

where δ is the Dirac delta distribution. The expression for the Green's function can be found using the bidimensional spatial Fourier transform of Eq. (6):

$$G(x,x_0,y,y_0,z,z_0) = \frac{j}{8\pi^2} \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \frac{e^{jk_x(x-x_0)} e^{jk_y(y-y_0)} e^{jk_z|z-z_0|}}{k_z} \times dk_x\, dk_y, \tag{7}$$

where k_z is

$$k_z = \sqrt{k^2 - k_x^2 - k_y^2}, \tag{8}$$

where k_x, k_y are the real Fourier's variables in the bidimensional wave-number domain. To ensure that G, when $|z-z_0|$ tends to infinity, is finite, the definition of k_z is taken as

$$\begin{aligned} k_z &= \sqrt{k^2 - k_x^2 - k_y^2} \quad \text{if } k^2 \geqslant k_x^2 + k_y^2, \\ k_z &= j\sqrt{k_x^2 + k_y^2 - k^2} \quad \text{if } k^2 \leqslant k_x^2 + k_y^2. \end{aligned} \tag{9}$$

In the following, the expression of the pressure in Eq. (5) will be simplified if we consider that there is no reflected wave from the surface S_∞. Since the acoustical sources are located on the plate, the surface integral will be reduced to S_{p_t}, where S_{p_t} is the whole surface S_{p+} plus S_{p-} (cf. Fig. 2).

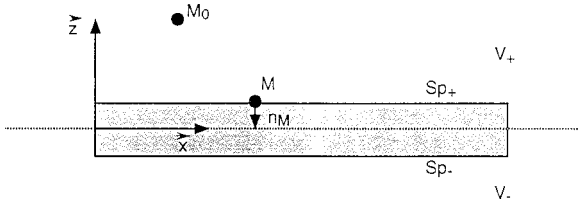

FIG. 2. Detail of the contour of integration on the plate.

In order to calculate the pressure at M_0, we need to know the relative location of M_0 vs M which belongs to the plate surface. Two cases appear which determine the sign of the absolute value in the G function (7):

$$\begin{aligned} &e^{-jk_z(z-z_0)} \quad \text{if } z_0 \geqslant z=0, \\ &e^{jk_z(z-z_0)} \quad \text{if } z_0 \leqslant z=0. \end{aligned} \tag{10}$$

In the following it is sufficient to estimate the pressure at a point M_0 always located above the plate. Consequently we will calculate the Green's function with the first inequality defined in Eq. (10). (The problem is an antisymmetric problem and to know the pressure in the half-space $z_0 \leqslant 0$ one has only to change the sign of the pressure calculated in the half-space $z_0 \geqslant 0$.)

Identifying the normal $\mathbf{n}_M$ to $\mathbf{z}$ or $-\mathbf{z}$ depending on which side of the plate is being considered, Eq. (5) can be decomposed as

$$\begin{aligned} p(M_0) = &\int_{S_{p^+}} -\frac{\partial G}{\partial z_M}(M,M_0)p^+(M)dS_{p^+} \\ &+ \int_{S_{p^-}} \frac{\partial G}{\partial z_M}(M,M_0)p^-(M)dS_{p^-} \\ &+ \int_{S_{p^+}} \frac{\partial p^+}{\partial z}(M)G(M,M_0)dS_{p^+} \\ &- \int_{S_{p^-}} \frac{\partial p^-}{\partial z}(M)G(M,M_0)dS_{p^-}, \\ &M_0 \in V^+, \end{aligned} \tag{11}$$

where V^+ is the half-space located ''above'' the plate.

Since both $G(M,M_0)$ and the gradiant of the acoustic pressure are continuous functions on the plate midsurface S_p, the simple layer contribution vanishes when S_{p+} and S_{p-} tend to S_p:

$$\int_{S_p} \left(\frac{\partial p^+(M)}{\partial z} - \frac{\partial p^-(M)}{\partial z} \right) G(M,M_0)dS_p = 0, \quad M \in S_p. \tag{12}$$

Substituting (1) into (11), one can write the following double layer integral of the pressure:

$$\begin{aligned} p(M_0) = &\int_{S_p} [D\nabla^4 w(M) - m\omega^2 w(M) - F(M)] \\ &\times \frac{\partial G}{\partial z_M}(M,M_0)dS_p, \quad M \in S_p, \quad M_0 \in V^+. \end{aligned} \tag{13}$$

The integral representation (13) depends on two unknown fields, the acoustic field $p(M_0)$ and the vibratory field of the plate $w(M)$. These fields can be connected using Euler's equation in the plane of the plate at $z=0$:

$$\begin{aligned} \left. \frac{\partial p}{\partial z}(M_0) \right|_{z=0} &= \rho_0 \omega^2 w(M_0) \\ &= \int_{S_p} [D\nabla^4 w(M) - m\omega^2 w(M) - F(M)] \\ &\quad \times \frac{\partial^2 G_{(M,M_0)}}{\partial z_M \, \partial z_{M_0}} dS_p, \\ &\quad M_0 \in S_p, \quad M \in S_p, \end{aligned} \tag{14}$$

where $\partial/\partial z_M$ and $\partial/\partial z_{M_0}$ denote, respectively, the partial derivatives versus $\mathbf{z}$ at M and M_0. Equation (14) allows us to find a solution for the displacement field, by eliminating the pressure.

III. SOLUTION FOR THE INTEGRAL REPRESENTATION USING THE MODAL BASIS OF THE SIMPLY SUPPORTED PLATE

Let us expand the shell displacement in a series of the plate modes:

$$w(x,y) = \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} a_{nm} \phi_{nm}(x,y), \tag{15}$$

where a_{nm} is the displacement modal amplitude and $\phi_{nm}(x,y)$ is the modal shape given by

$$\phi_{nm}(x,y) = \sin \frac{n\pi x}{a} \sin \frac{m\pi y}{b}. \tag{16}$$

The same kind of expansion can be written for the driving mechanical force:

$$F(x,y) = \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} F_{nm} \phi_{nm}(x,y), \tag{17}$$

where F_{nm} is the generalized force density.

Substituting the series (15) and (16) into (14) and using the properties of the function ϕ_{nm} versus the bi-Laplacian operator (cf. Appendix A), one can transform (14) as follows:

$$\begin{aligned} &\rho_0 \omega^2 \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} a_{nm} \phi_{nm}(x_0,y_0) \\ &= \int_{S_p} \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} [m(\omega_{nm}^2 - \omega^2) a_{nm} - F_{nm}] \phi_{nm}(x,y) \\ &\quad \cdot \frac{\partial^2 G}{\partial z \, \partial z_0}(x,x_0,y,y_0,z=z_0=0)dx \, dy, \end{aligned} \tag{18}$$

where ω_{nm} is the resonance frequency of the mode n,m. The density of the generalized force is fairly simple to calculate, in the case of a driving point force applied at M_e of coordinates (x_e,y_e):

$$\begin{aligned} F_{nm} &= \frac{4}{S_p} \int F_0 \delta(x-x_e)\delta(y-y_e)\phi_{nm} dx \, dy \\ &= \frac{4F_0}{S_p} \phi_{nm}(x_e,y_e), \end{aligned} \tag{19}$$

where F_0 is the amplitude of the point force.

To find the set of unknowns a_{nm}, it is necessary to project Eq. (18) on a particular modal shape ϕ_{pq}. After the use of the orthogonality relationships one obtains:

$$\rho_0\omega^2 \frac{S_p}{4} a_{pq} = \sum_{n=1}^{\infty}\sum_{m=1}^{\infty} (m(\omega_{nm}^2-\omega^2)a_{nm} - F_{nm})\gamma_{pq\,nm}, \tag{20}$$

where $\gamma_{pq\,nm}$ are coupling terms defined as

$$\gamma_{pq\,nm} = \int_{S_p}\int_{S_p} \phi_{pq}(x_0,y_0) \frac{\partial^2 G}{\partial z\ \partial z_0}(x,x_0,y,y_0,z=z_0=0) \times \phi_{nm}(x,y)dx\ dx_0\ dy\ dy_0. \tag{21}$$

Introducing the G function in (21) leads to the following formula for the $\gamma_{pq\,nm}$ terms once the two integrals over S_p are done:

$$\gamma_{pq\,nm} = \frac{j}{8\pi^2} \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} k_z \tilde{\phi}_{pq}^*(k_x,k_y)\tilde{\phi}_{nm}(k_x,k_y)dk_x\ dk_y, \tag{22}$$

where $\tilde{\phi}_{nm}(k_x,y_y)$ denotes the Fourier transform of the modal shape $\phi_{nm}(x,y)$ and $\tilde{\phi}_{pq}^*$ is the conjugate transform defined by

$$\tilde{\phi}_{nm}(k_x,k_y) = \int_0^a\int_0^b \sin\frac{n\pi x}{a}\sin\frac{m\pi y}{b} e^{-jk_x x}e^{-jk_y y}dx\ dy \tag{23}$$

whose calculation can be made analytically (cf. Appendix B). One has to note that when we deal with the analog problem of the sound radiation by a baffled plate, the modal radiation impedance terms (cf. Refs. 1–6) are derived by the same integral formula as (22) but where the k_z term appears in the denominator. This is due to the fact that the integral representation is a ''simple layer one.'' Consequently the Green's function is not differentiated at all. Here the Green's function is differentiated twice.

The $\gamma_{pq\,nm}$ terms are the acoustical cross-modal coupling terms. Similar to the cross-modal radiation impedances terms of a baffled plate, these are symmetric and they have the same properties versus the mode's parity. They vanish when the modes are of different parities. They are only different from zero in the following parity cases: odd odd odd odd, even even even even, even odd even odd, and odd even odd even.

Consequently, similar to the baffled plates, the acoustic radiation leaves the modes of different parities independent, and renders those of same parity dependent.

The calculation of the expression (22) can be completed and one finds for modes of same parity:

$$\gamma_{nm\,pq} = \gamma_{pq\,nm} = \frac{2jS_p^2}{pq\ nm\ \pi^6} \int_0^\infty\int_0^\infty \frac{\sqrt{k^2-k_x^2-k_y^2}(1-(-1)^p\cos k_x a)(1-(-1)^q\cos k_y b)}{(a^2k_x^2/n^2\pi^2-1)(a^2k_x^2/p^2\pi^2-1)(b^2k_y^2/q^2\pi^2-1)(b^2k_y^2/m^2\pi^2-1)} \cdot dk_y\ dk_x. \tag{24}$$

To obtain expression (24) one notes that the integrand is even both in k_x and k_y, reducing the domain of integration only to the first quadrant of the k_x,k_y plane.

We present in Appendix B the numerical method for calculating these cross-coupling terms, namely the numerical criteria which allows us to overcome these rather difficult oscillating infinite integrals in the k_x,k_y domain.

Once the $\gamma_{pq\,nm}$ terms are numerically evaluated, one can find a solution for the modal amplitudes, solving the following linear system:

$$[\gamma_{pq\,nm}]\{m(\omega_{nm}^2-\omega^2)a_{nm}\} - \rho_0\omega^2\frac{S_p}{4}[I]\{a_{nm}\} = [\gamma_{pq\,nm}]\{F_{nm}\}, \tag{25}$$

where $[I]$ is the identity matrix of size N by N, and $[\gamma_{pq\,nm}]$ is the matrix of the cross-coupling terms.

The size N of this linear system depends, as in modal methods, on the truncation order of the series, which must be high enough to ensure the convergence of the pressure and the vibratory fields of the plate. In a light fluid, it is well known that this size N can be determined by the criteria of the resonant mode at the current frequency of excitation ω. That is to say, all modes whose eigenfrequencies are smaller or equal to ω must be taken into account in the calculation. This gives the size N of modes to be included. In the FORTRAN algorithm, it is convenient to increase the current frequency to the range $\omega+\Delta\omega$, where $\Delta\omega$ is an adjustable frequency band which allows us to improve the accuracy of the criteria, taking into account the small contribution of stiffness modes.

When the fluid is heavy, like water, the resonant mode criteria is no more sufficient, since it is based on the plate in vacuum resonance frequency which does not take into account the added modal masses.

Nevertheless, in the algorithm, it is easy to increase the adjustable frequency band $\Delta\omega$, to take into account heavy fluid loading. Thus the size N will be larger in the case of the water loading than air loading for a given plate. Numerical examples of water loading and air loading will be presented later.

Using the parity case property, one can solve independently four linear systems of smaller size, one for each type of parity. These linear system are solved using a classical

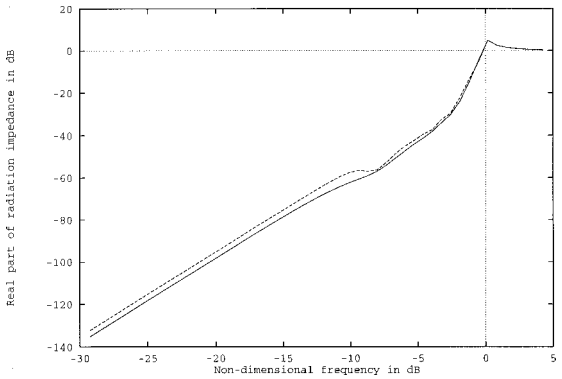

FIG. 3. Comparison between the exact and approximated calculation in the real part of the unbaffled radiation impedance; ——— approximated, -------- exact.

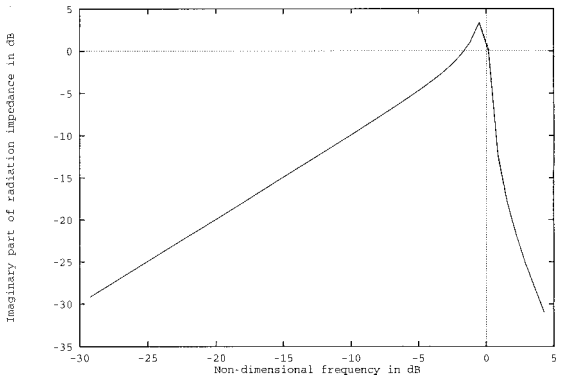

FIG. 4. Comparison between the exact and approximated calculation on the imaginary part of the unbaffled radiation impedance; ——— approximated, -------- exact.

Gauss algorithm program. Numerical examples will be presented in the following.

IV. DEFINITION OF THE CROSS-MODAL RADIATION IMPEDANCE TERMS FOR AN UNBAFFLED SIMPLY SUPPORTED PLATE AND COMPARISON WITH THE BAFFLED ONES

The goal of this section is to define a new set of radiation impedances for the unbaffled, simply supported plate and to compare it with the well-known baffled plate. Although it is not necessary to define these unbaffled radiation impedances to solve the linear system (25), it is interesting to calculate them in order to exhibit the main difference that occurs versus frequency.

Inverting the linear system (25), one can write:

$$[I]m(\omega_{nm}^2-\omega^2)\{a_{nm}\}-\rho_0\omega^2(S_p/4)[\gamma_{pq\,nm}]^{-1}\{a_{nm}\} =\{F_{nm}\}. \tag{26}$$

Multiplying by the constant $S_p/4$, it is possible to identify the equivalent baffled modal equations, cf. Refs. 1–6:

$$-\rho_0\omega^2\left(\frac{S_p}{4}\right)^2[\gamma_{pq\,nm}]^{-1}\{a_{nm}\}=[Z^0_{pq\,nm}]\{j\omega a_{nm}\}. \tag{27}$$

The linear system (27) allows us to define the cross-modal radiation impedance terms for the unbaffled plate from the $\gamma_{pq\,nm}$ coefficients as

$$[Z^0_{pq\,nm}]=j\omega\rho_0\left(\frac{S_p}{4}\right)^2[\gamma_{pq\,nm}]^{-1}. \tag{28}$$

Finally it is now possible to define the matrix normalized to $\rho_0 c\ S_p/4$ and to define the normalized cross-modal radiation impedance terms for a simply supported unbaffled plate:

$$[z^0_{pq\,nm}]=jk\,\frac{S_p}{4}\,[\gamma_{pq\,nm}]^{-1}. \tag{29}$$

As in the baffled case, the $z^0_{pq\,nm}$ terms are complex. The real part is associated with acoustic radiation and the imaginary part is the added mass to the plate, which is responsible for the decrease of the resonance frequencies of the plate. The coupling between modes is introduced by the off-diagonal terms of (29), but is limited to modes of the same parity.

Contrary to the baffled case where the radiation impedance formula appears directly in the equations to be solved, the $z^0_{pq\,nm}$ terms do not appear directly. It is necessary, first to calculate the $\gamma_{pq\,nm}$ terms and second, to invert this matrix.

Consequently, the quality of the $z^0_{pq\,nm}$ terms presented below depends on the accuracy of the calculation of the $\gamma_{pq\,nm}$ terms themselves but also on the size of the matrix of $\gamma_{pq\,nm}$ to be inverted. Tests of convergence have been done which show that the diagonal terms $z^0_{pq\,pq}$ are not sensitive to the size of the matrix $[\gamma_{pq\,nm}]$ to be inverted. The off-diagonal terms are sensitive and their calculation must be performed with particular care.

These last remarks allow us to think, since the diagonal terms can be calculated to a first approximation without the long computation needed for the off-diagonal terms $\gamma_{pq\,nm}$, they can be deduced from the simple approximate formula:

$$z^0_{pq\,pq}\approx jk\,\frac{S_p}{4}\,\frac{1}{\gamma_{pq\,pq}}. \tag{30}$$

This formula renders the calculation of the diagonal terms very easy, as easy as for the baffled case, which do not necessitate a matrix inversion. The formula (30) can be used to approximate the radiation of an unbaffled plate, neglecting, the cross-modal coupling writing independently for each mode (p,q):

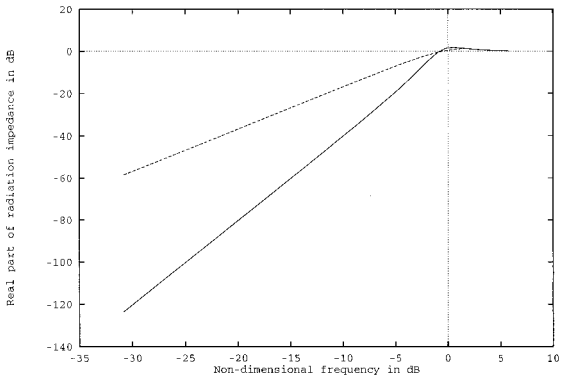

FIG. 5. Radiation impedance in the real part of the mode (1,1); ——— unbaffled, -------- baffled.

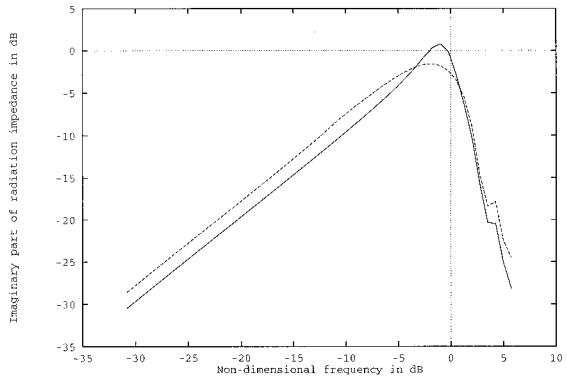

FIG. 6. Radiation impedance in the imaginary part of the mode (1,1); ——— unbaffled, -------- baffled.

$$m_{pq}(\omega_{pq}^2-\omega^2)a_{pq}-\rho_0\omega^2\left(\frac{S_p}{4}\right)^2\frac{1}{\gamma_{pq\,pq}}a_{pq}=\mathscr{F}_{pq}, \tag{31}$$

where m_{pq} and $\mathscr{F}_{pq}$ denote, respectively, the generalized mass and the generalized force of the mode (p,q) (cf. Appendix A).

It will be shown in the next section that the solution (31) when compared to the exact solution (25) is a very good approximation in air and a not so bad approximation in water.

Moreover, what is interesting in the approximate solution (31) is it allows us to substitute in a program the baffled impedance routine library and the unbaffled one. This program is a powerful tool, in industrial applications, for one of the more commonly encountered cases; in which the plate cannot be considered as baffled.

Finally to render the problems of the baffled and unbaffled plates equivalent, we have either to multiply by two the baffled radiation impedances, since they take into account only the fluid loading on one side of the plate, or to divide by two the $z^0_{pq\,nm}$ terms since the unbaffled plate is loaded on its two sides. The second option has been chosen.

Figures 3 and 4 deal with the comparison between an exact calculation using (29) and the approximate one using (30), respectively, for the real and imaginary part of the radiation impedance of the mode (7,7) for an unbaffled plate. In these figures and all the subsequent figures, the normalized radiation impedances are in dB and plotted versus the

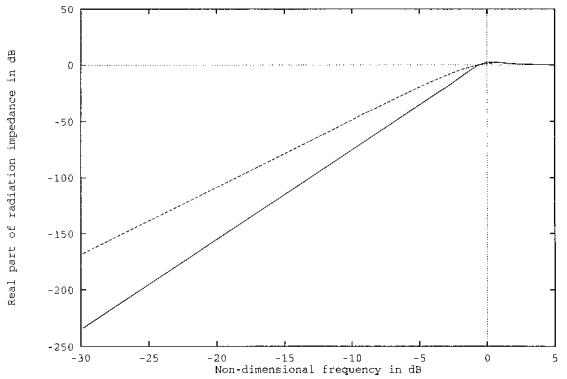

FIG. 7. Radiation impedance in the real part of the mode (2,2); ——— unbaffled, -------- baffled.

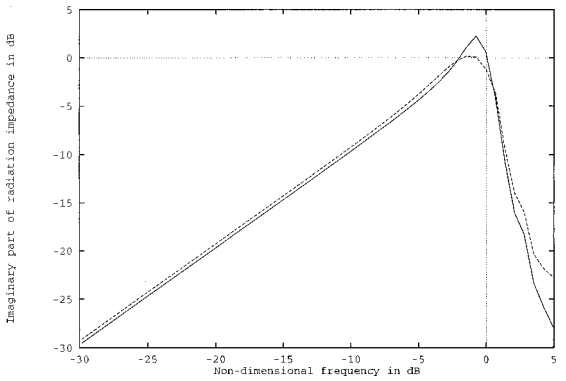

FIG. 8. Radiation impedance in the imaginary part of the mode (2,2); ——— unbaffled, -------- baffled.

nondimensional wave number k/k_{nm} in dB, where k is the acoustical wave number and k_{nm} is the mechanical modal wave number defined by

$$k_{nm}=\left[\left(\frac{n\pi}{a}\right)^2+\left(\frac{n\pi}{b}\right)^2\right]^{1/2}, \tag{32}$$

where a and b denote the dimensions of the plate. It can be seen that differences occur in the real part to within 3 dB. However, the difference between the exact and ''diagonal approximation'' is not sensitive in the imaginary part over the whole frequency range considered.

As was mentioned above, the diagonal terms can be easily calculated to a first approximation using the approximate formula (30), which neglects the cross-modal terms of the matrix $\gamma_{pq\,nm}$.

Figures 5 and 6 show the comparison of the radiation impedance when the plate is baffled and not baffled, for the direct diagonal term of the mode (1,1). The calculation of the unbaffled terms, in these comparisons, is not approximate. It can be seen that, at low frequencies, large differences do occur (more than 60 dB in the real part at a nondimensional frequency of -30 dB). Consequently, as is well-known experimentally, the baffle raises the radiation loading at low frequencies. This is due to the transformation of the equivalent monopole source of the mode (1,1) into a pure dipole source. Removing the baffle renders the mode a particularly ineffective radiator, increasing considerably the short-circuit effect, from one side to the other side of the plate.

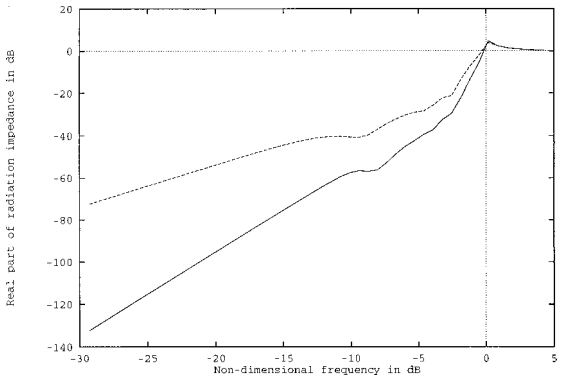

FIG. 9. Radiation impedance in the real part of the mode (7,7); ——— unbaffled, -------- baffled.

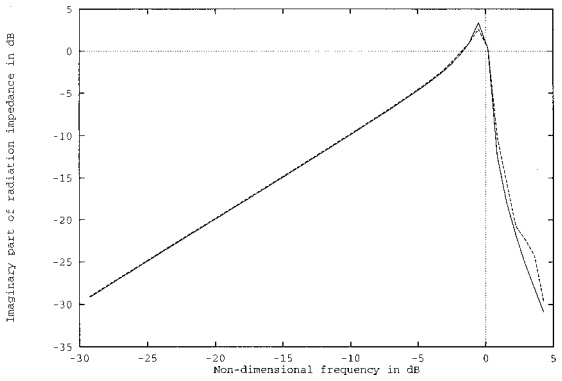

FIG. 10. Radiation impedance in the imaginary part of the mode (7,7); ——— unbaffled, -------- baffled.

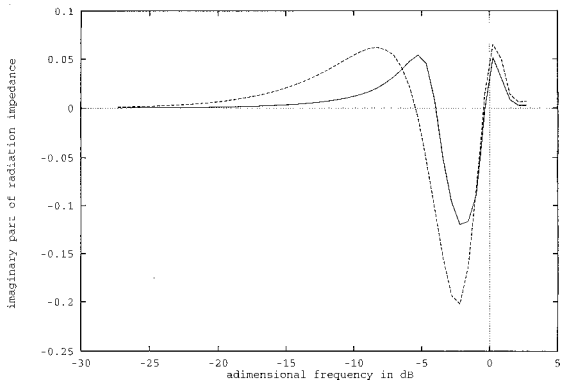

FIG. 12. Cross-modal radiation impedance in the imaginary part of the modes 11 13; ——— unbaffled, -------- baffled.

Conversely, the differences vanish at high frequencies and for the baffled plate the real part of the unbaffled radiation term tends to unity. The differences in the imaginary parts are not so strong since only 4 dB can be seen around the maximum value. Since the imaginary part is related to an added mass phenomenon, i.e., nonpropagating acoustical waves in the near-field of the plate, the presence or absence of the baffle strongly affects the propagating waves at low frequencies but only slightly the nonpropagating ones. Nevertheless, one can say that removing the baffle decreases a little the added mass phenomenon. This will be obvious in the computed velocity results of a plate immersed in water.

Figures 7 and 8 deal with the same kind of impedances but for the mode (2,2) to check the influence of the parity of the mode on the conclusions deduced from the first odd-odd mode. The behavior is the same: a large difference at low frequencies in the real part and little difference for the imaginary part. As for the baffled plate, the even-even modes radiate less than the odd-odd modes of the unbaffled plate.

Figures 9 and 10 show the results for the odd-odd mode of order (7,7). The same conclusions can be reached for both the real and the imaginary parts. Nevertheless, the differences on the imaginary part are now negligible over the whole frequency range $[-30,5]$ dB. Consequently, the differences in the imaginary part vanish when one increases the order of the mode.

Finally the study would not be complete without examining the cross-modal coefficients of the real part in Fig. 11 and the imaginary part in Fig. 12. These terms can be positive or negative. So, they are presented in linear versus the nondimensional modal wave number. Since the cross-modal coefficients involve two modes [here the modes (1,1) and (1,3)], the mechanical wave number chosen to render the wave number axis nondimensional is the larger. [In this example it is the mode (1,3)].

Although the behavior is the same, it can be seen that differences do occur between the baffled and the unbaffled plates, both in the real and the imaginary parts. What the figures do not exhibit, because of the linear presentation, is that, at low frequencies, the differences are of most importance, but the coefficients themselves tend to zero rapidly.

V. INFLUENCE OF THE BAFFLE ON THE SOUND RADIATED BY A SIMPLY SUPPORTED PLATE IN AIR AND IN WATER

A. Radiation simulation in heavy fluid

The interest of this simulation is that it allows us to check the whole set of modal coupling coefficient $\gamma_{pq\,nm}$, since all the coefficients (diagonal and off-diagonal, in real or imaginary parts) need to be calculated to get the correct simulation. The plate under consideration is the one defined in the organization (commission de validation des logiciels en acoustique) (cf. Ref. 12), i.e., a square 1-cm-thick steel plate, of $1\,\mathrm{m}^2$, excited at (0,7,0,2) by a 1 N driving point force. The damping coefficient η of the plate is fixed to be 10^{-2}. The water characteristics are a fluid density of

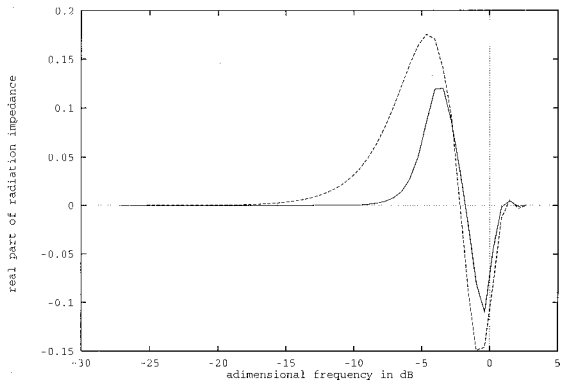

FIG. 11. Cross-modal radiation impedance in the real part of the modes 11 13; ——— unbaffled, -------- baffled.

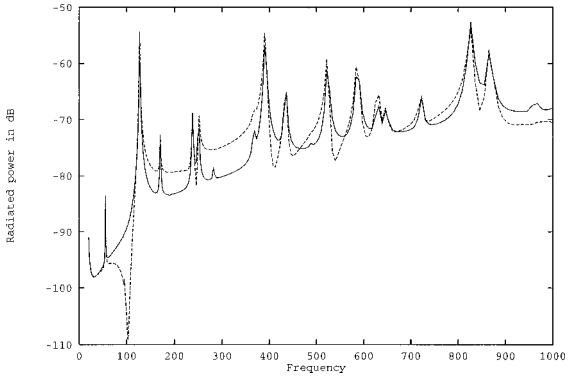

FIG. 14. Radiated power for the unbaffled plate in water; ——— approximated, -------- exact.

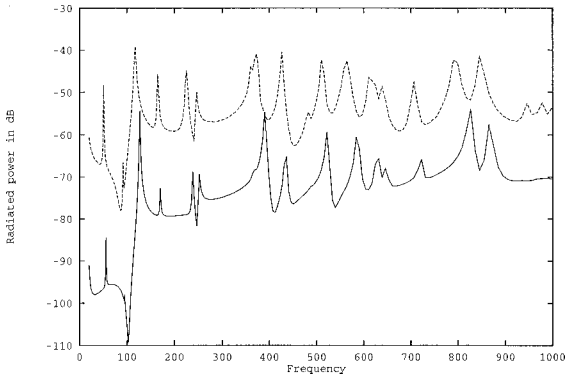

FIG. 16. Radiated power of the plate in water; ——— unbaffled, -------- baffled.

1000 kg/m^3 and a sound velocity of 1500 m/s. The solution is derived from the linear system (25) for the exact solution and from (31) for the approximate, diagonal-only solution. The structural damping is introduced in both systems by making complex the eigenfrequencies as follows:

$$\omega_{pq}^{2*} = \omega_{pq}^2 (1 + j\,\eta). \tag{33}$$

To reach the 1000-Hz frequency range and to take into account the fluid added mass, about 90 modes of the *in-vacuo* simply supported plate are needed to converge reasonably. Definitions of the acoustical radiated power, normal quadratic velocity, and radiation factor are given in Appendix C.

The two solutions are compared in Fig. 13 for the velocity and in Fig. 14 for the radiated power, the diagonal solution is computed by not calculating the off-diagonal terms $\gamma_{pq\,nm}$ and making them zero. As for the baffled problem, exact and diagonal solutions give similar results in velocity. However, there is a great sensitivity in the radiated power with and without the off-diagonal terms. Nevertheless it seems not to affect the frequency location of the peaks, but only the levels (both in negative and positive offsets).

This numerical simulation gives an estimation of the error introduced by neglecting the off-diagonal terms for an unbaffled plate in water, leading to 7 or 8 dB error in some frequency range only in the radiated power, while the velocity levels are not quite as affected. These remarks were already true for the baffled plate (cf. Ref. 12).

Figure 15 for the velocity, Fig. 16 for the radiated power, and Fig. 17 for the radiation factor show the comparison of the baffled and unbaffled plate, using the exact solution in both cases. One has to say that, to render this comparison meaningful, the baffled plate has to be loaded on its two sides. This is done in the FORTRAN program by multiplying by two the radiation impedance of the baffled plate (cf. Ref. 12). It can be seen that the velocity of the plate is quite similar. One can see that the resonance frequencies of the baffled plate are a little lower than the one of the unbaffled plate. This is due to the small differences between the imaginary parts of the radiation impedances in Figs. 6 and 8. Consequently, the fluid loading is a little smaller when unbaffled. On the contrary, the radiated power is much lower when unbaffled.

This difference is very important because the relative position of the excitation frequency to the critical frequency of the plate is given by

$$f_c = \frac{c^2}{2\pi h}\sqrt{\frac{12\rho(1-\nu^2)}{E}}, \tag{34}$$

where ρ, ν, E, and h are, respectively, the density, the Poisson ratio, the Young's modulus, and the thickness of the plate. The plate's critical frequency in water is about 23 kHz. Consequently, one can consider calculating the ratio of the current frequency at 1000 Hz to f_c (equal to about 4%), we are in a very low-frequency range in terms of sound radiation. The big decrease in radiated power (more than 20 dB in

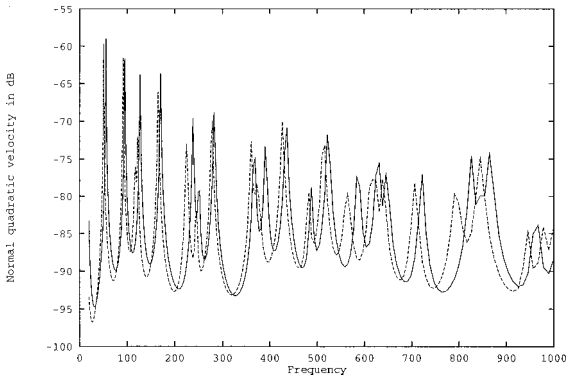

FIG. 15. Normal quadratic velocity for the plate in water; ——— unbaffled, -------- baffled.

average) is explained by the same proportional decrease in the radiation factor.

B. Radiation simulation in light fluid

The case under study is a plate immersed in air of fluid density 129 kg/m^3 and of sound velocity 340 m/s. For the purpose of light fluid simulation, only the diagonal approximation (31) is used. The exact solution (25) gives exactly the same numerical results for this 1-cm steel plate under consideration. The diagonal solution is, what is called, a ''good approximation.'' Obviously, in air, it can be seen that the velocity is not affected by the baffle, Fig. 18.

The plate critical frequency in air is about 1200 Hz. The ratio of the current frequency to the critical frequency is much higher in air than in water, belonging to [0,01,0,8]. Consequently, the power decrease in air when unbaffled is smaller than in water, only 5 dB at 1000 Hz, Fig. 19. The decrease of the radiation efficiency of the plate is in the same proportion, Fig. 20.

In conclusion, the acoustic power decrease is sensitive below the plate critical frequency, both in air and in water which is intuitively well corroborated.

VI. CONCLUSION

A model of acoustic radiation from an unbaffled simply supported plate has been presented and compared to the well-known baffled problem both in light and heavy fluid. Removing the baffle decreases the radiation efficiency of the plate and its radiated power, but is of little effect on its velocity, even in heavy fluid. The radiation impedances of the unbaffled plate have been presented and compared to the well-known baffled ones. Large differences appear in the real part, and smaller differences in the imaginary part.

The influence of the modal coupling is exhibited both in air and in water. For the baffled problem, the modal coupling in air is of small effect. Conversely, the modal coupling in water is very important, including small errors in velocity but large errors in the acoustic radiated power.

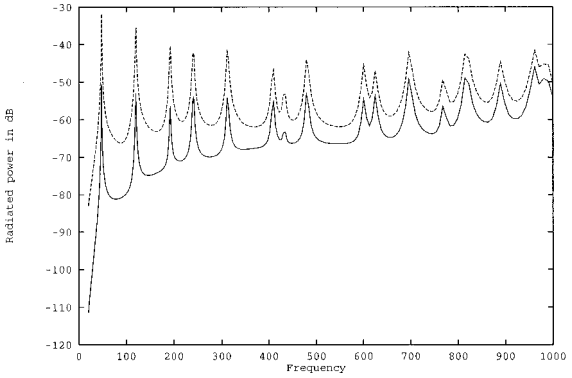

FIG. 19. Radiated power of the plate in air; ——— unbaffled, -------- baffled.

APPENDIX A

The modes $\phi_{nm}(x,y)$ are the modes of the unloaded simply supported plate. They satisfy:

$$D\nabla^4\phi_{nm}(x,y)=m\omega_{nm}^2\phi_{nm}(x,y), \tag{A1}$$

where ∇^4 is defined by

$$\nabla^4=\frac{\partial^4}{\partial x^4}+\frac{2\partial^4}{\partial x^2\,\partial y^2}+\frac{\partial^4}{\partial y^4} \tag{A2}$$

and where ω_{nm} is the *in-vacuo* eigenfrequency of a simply supported mode given by

$$\omega_{nm}=\left(\frac{D}{m}\right)^{1/2}k_{nm}^2, \tag{A3}$$

where k_{nm} denotes the modal mechanical wave number of the mode (n,m):

$$k_{nm}=\left[\left(\frac{n\pi}{a}\right)^2+\left(\frac{m\pi}{b}\right)^2\right]^{1/2}, \tag{A4}$$

(a,b) being the dimensions of the rectangular plate.

The orthogonality relationship is the following:

$$\int_{S_p}D\nabla^4\phi_{nm}\cdot\phi_{pq}dS_p=\int_{S_p}m\omega_{nm}^2\phi_{nm}\cdot\phi_{pq}dS_p$$

$$=m\,\frac{S_p}{4}\,\omega_{pq}^2\delta_{np}\delta_{mq}, \tag{A5}$$

where δ denotes here the Kronecker's delta.

The product $m(S_p/4)$ denotes also the generalized mass of the mode, which for a simply supported plate is independent of the order of the mode:

$$m_{pq}=m\cdot\frac{S_p}{4},\quad \forall_p\forall_q. \tag{A6}$$

The generalized force of the mode (p,q) can be calculated using:

$$\mathscr{F}_{pq}=\int_{S_p}F(x,y)\,\phi_{pq}(x,y)dx\;dy. \tag{A7}$$

This leads to the following relationship when a driving mechanical point force F_0 is applied at M_e at coordinates (x_e,y_e):

$$\mathscr{F}_{pq}=F_0\phi_{pq}(x_e,y_e)=\frac{S_p}{4}F_{pq}. \tag{A8}$$

Force and density of force (here a pressure) are related by the constant $S_p/4$.

APPENDIX B

The calculation of the Fourier transforms of the modal shapes $\phi_{pq}(x,y)$:

$$\tilde{\phi}_{pq}(k_x,k_y)=\int_0^a\int_0^b\sin\frac{n\pi}{a}x\,\sin\frac{m\pi}{b}y e^{-jk_xx}e^{-jk_yy}dx\;dy \tag{B1}$$

are evaluated analytically:

$$\tilde{\phi}_{pq}(k_x,k_y)=ab\pi^2pq\,\frac{[(-1)^pe^{-jk_xa}-1]}{a^2k_x^2-p^2\pi^2}\,\frac{[(-1)^qe^{-jk_yb}-1]}{b^2k_y^2-q^2\pi^2} \tag{B2}$$

and for the conjugate form of order (n,m):

$$\tilde{\phi}^*_{nm}(k_x,k_y)=ab\pi^2nm\,\frac{[(-1)^ne^{jk_xa}-1]}{a^2k_x^2-n^2\pi^2}\,\frac{[(-1)^me^{jk_yb}-1]}{b^2k_y^2-m^2\pi^2}. \tag{B3}$$

From the definition of $\gamma_{pq\,nm}$:

$$\gamma_{pq\,nm}=\frac{j}{8\pi^2}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}k_z\tilde{\phi}_{pq}(k_x,k_y)\tilde{\phi}^*_{nm}(k_x,k_y)dk_x\;dk_y \tag{B4}$$

it can be seen that the integrand is odd with respect to k_x if the orders (n,p) versus the x direction are of different parity and that the integrand is odd with respect to ky for the same reasons versus the mode orders (q,m). It can be seen the integrand is even in the remaining cases of parity. This leads to the following properties:

$$\gamma_{pq\,nm}=\frac{j}{2\pi^2}\int_0^\infty\int_0^\infty k_z\tilde{\phi}_{pq}(k_x,k_y)\tilde{\phi}^*_{nm}(k_x,k_y)dk_x\;dk_y,$$

when p and n of same parity, and q and m of same parity. (B5)

$$\gamma_{pq\,nm}=0 \text{ when } p \text{ and } n \text{ of different parity, or } q \text{ and } m \text{ of different parity.} \tag{B6}$$

Finally, when the parity is the same one can write for the $\gamma_{pq\,nm}$ terms:

$$\gamma_{pq\,nm}=\frac{2ja^2b^2}{pq\;nm\;\pi^6}\int_0^\infty\int_0^\infty\sqrt{k^2-k_x^2-k_y^2}\times\frac{(1-(-1)^p\cos k_xa)}{(a^2k_x^2/n^2\pi^2-1)(a^2k_x^2/p^2\pi^2-1)}\times\frac{(1-(-1)^q\cos k_yb)}{(b^2k_y^2/q^2\pi^2-1)(b^2k_y^2/m^2\pi^2-1)}\,dk_x\;dk_y. \tag{B7}$$

Substituting the square root dependence given in Eq. (9), one can write the imaginary part as

$$\mathrm{Im}(\gamma_{pq\,nm})=\frac{2a^2b^2}{pq\;nm\;\pi^6}\int_0^k dk_x\int_0^{\sqrt{k^2-k_x^2}}\sqrt{k^2-k_x^2-k_y^2}\times\frac{(1-(-1)^p\cos k_xa)}{(a^2k_x^2/n^2\pi^2-1)(a^2k_x^2/p^2\pi^2-1)}\times\frac{(1-(-1)^q\cos k_yb)}{(b^2k_y^2/q^2\pi^2-1)(b^2k_y^2/m^2\pi^2-1)}\,dk_y \tag{B8}$$

and the real part as

$$\mathrm{Re}\{\gamma_{pq\,nm}\}=\frac{-2a^2b^2}{pq\;nm\;\pi^6}\int_0^\infty dk_x\int_{\sqrt{k^2-k_x^2}\geqslant 0}^\infty\sqrt{k_x^2+k_y^2-k^2}\times\frac{(1-(-1)^p\cos k_xa)}{(a^2k_x^2/n^2\pi^2-1)(a^2k_x^2/p^2\pi^2-1)}\times\frac{(1-(-1)^q\cos k_yb)}{(b^2k_y^2/q^2\pi^2-1)(b^2k_y^2/m^2\pi^2-1)}\,dk_y. \tag{B9}$$

These two integrals are evaluated numerically using the criteria which will be described below.

The numerical integration over the singularities of the denominators in (B8) and (B9) is done using the following asymptotic formulas:

if $n=p$

$$\begin{cases}\dfrac{1-(-1)^p\cos k_xa}{[a^2k_x^2/n^2\pi^2-1]^2}\to\left(\dfrac{p\pi}{2}\right)^2\\ k_x\to\dfrac{n\pi}{a},\end{cases} \tag{B10}$$

if $q=m$

$$\begin{cases} \dfrac{1-(-1)^q \cos k_y b}{[b^2k_y^2/m^2\pi^2-1]^2} \to \left(\dfrac{m\pi}{2}\right)^2 \\ k_y \to \dfrac{m\pi}{b}, \end{cases} \tag{B11}$$

if $n \neq p$

$$\begin{cases} \dfrac{1-(-1)^p \cos k_x a}{[a^2k_x^2/n^2\pi^2-1][[a^2k_x^2/p^2\pi^2-1]]} \to 0 \\ \text{if } k_x \to \dfrac{n\pi}{a} \text{ or } k_x \to \dfrac{p\pi}{a}, \end{cases} \tag{B12}$$

if $m \neq q$

$$\begin{cases} \dfrac{1-(-1)^q \cos k_y b}{[b^2k_y^2/q^2\pi^2-1][[b^2k_y^2/m^2\pi^2-1]]} \to 0 \\ \text{if } k_y \to \dfrac{q\pi}{b} \text{ or } k_y \to \dfrac{m\pi}{b}. \end{cases} \tag{B13}$$

To ensure the numerical convergence of these oscillating integrals both the k_x and the k_y domains have to be discretized based on wavelength criteria. In this paper, the criteria are fixed to six points per wavelengths in k_x and k_y. These lead to the following mesh:

$$\Delta k_x = \frac{2\pi}{a} \cdot \frac{1}{6} = \frac{\pi}{3a}, \quad \Delta k_y = \frac{2\pi}{b} \cdot \frac{1}{6} = \frac{\pi}{3b}. \tag{B14}$$

Criteria (B14) allows us to ensure good accuracy in the results and a good ratio accuracy to time consuming.

An additional criterion must be stated to limit the domain of integration which must be truncated to a finite value, both in k_x and k_y. From (B9) it can be seen that the integrand tends to zero when k_x tends to infinity or k_y tends to infinity, respectively (following an $O(k_x^{-3})$ or an $O(k_y^{-3})$). Thus the domain is limited versus k_x and k_y at values such as

$$k_x^{\text{stop}} = \frac{n\pi}{a} + K\,\frac{n\pi}{a}, \quad k_y^{\text{stop}} = \frac{m\pi}{b} + K\,\frac{m\pi}{b}, \tag{B15}$$

where K is an arbitrary integer and n or m is the majorant of the couples of integer (n,p) or (q,m). In the numerical results presented here K is fixed to 4 which is sufficient to give a good accuracy. A similar process of integration has already been used for the calculation of the radiation impedances of a simply supported baffled plate which involves very similar integrands (the k_z term is at the denominator and not at the numerator).

APPENDIX C

The radiated power is defined by

$$W = \frac{1}{2} \int_{S_{Pt}} R_e\{p \cdot \mathbf{v}^*\}\mathbf{n}\, dS_{p_t}, \tag{C1}$$

where S_{p_t} denotes S_{p+} plus S_{p-}. Splitting the integral (C1) this gives:

$$W = \frac{1}{2} \int_{S_{p+}} R_e\{p^+ \cdot \mathbf{v}^*\}\mathbf{n}\, dS_{p+} + \frac{1}{2} \int_{S_{p-}} R_e\{p^- \cdot \mathbf{v}^*\}\mathbf{n}\, dS_{p-}. \tag{C2}$$

Since $\mathbf{n}$ denotes the normal to the surfaces pointing inward to V, we can associate $\mathbf{n}$ to $\mathbf{z}$ or $-\mathbf{z}$ depending on the side of the plate under consideration giving:

$$W = \frac{1}{2} \int_{S_p} R_e\{\{p^- - p^+\}v_z^*\}dS_p, \tag{C3}$$

where v_z denotes the velocity component along $\mathbf{z}$ of a point on the plate.

Using a Fourier decomposition in a series of the modal shapes of the plate, the pressure jump can be written as

$$\overline{p}(x,y) = \sum_{l=1}^{\infty} \sum_{s=1}^{\infty} p_{ls}\phi_{ls}(x,y). \tag{C4}$$

The plate velocity can be written as

$$v_z^* = \frac{\partial w^*}{\partial t} = -j\omega \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} a_{nm}^* \phi_{nm}(x,y). \tag{C5}$$

This gives the following formula, when the integral on S_p is performed:

$$W = \frac{\omega}{2}\frac{S_p}{4} R_e\left\{ j \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} p_{nm} a_{nm}^* \right\}. \tag{C6}$$

We can now write the p_{nm} coefficients function of the displacement amplitude a_{nm} using the plate equilibrium equation:

$$D\nabla^4 \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} a_{nm}\phi_{nm}(x,y) - m\omega^2 \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} a_{nm}\phi_{nm}(x,y) = \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} F_{nm}\phi_{nm}(x,y) + \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} p_{nm}\phi_{nm}(x,y). \tag{C7}$$

Using the orthogonality relationships between the modal shapes, this gives:

$$m(\omega_{pq}^2 - \omega^2)a_{pq} = F_{pq} + p_{pq}, \tag{C8}$$

and finally introducing (C8) into (C6):

$$W = \frac{\omega S_p}{8} R_e\left\{ j \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} [m(\omega_{nm}^2 - \omega^2)a_{nm} - F_{nm}]a_{nm}^* \right\}. \tag{C9}$$

The structural losses can be introduced by making complex the eigenfrequencies of the modes, by replacing in (C9) ω_{nm}^2 by ω_{nm}^{2*} defined by:

$$\omega_{nm}^{2*} = \omega_{nm}^2(1 + j\eta), \tag{C10}$$

where η denotes the structural damping coefficient.

The normal quadratic volocity is given by

$$\langle v^2 \rangle = \frac{1}{2S_p} \int |v(x,y)|^2 dx\, dy, \tag{C11}$$

where $v(x,y)$ is the local velocity of a point on the plate of the surface S_p. Using an expansion in the series of plate modes for the velocity:

$$v(x,y) = j\omega \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} a_{nm}\phi_{nm}(x,y), \tag{C12}$$

this gives

$$\langle v^2\rangle = \frac{\omega^2}{8}\sum_{n=1}^{\infty}\sum_{m=1}^{\infty}|a_{nm}|^2 \tag{C13}$$

and for the radiation factor

$$\sigma = \frac{W}{\rho_0 c S_p \langle v^2\rangle}, \tag{C14}$$

where W is the radiated power given by (C9).

The velocity, radiated power and radiation factor are presented in dB as follows:

$$\begin{aligned} L_w &= 10\log W, \\ L_v &= 10\log\langle v^2\rangle, \\ L_\sigma &= 10\log\sigma. \end{aligned} \tag{C15}$$

Measurement of the reflection matrix of a discontinuity in a duct

Mohamed Akoum and Jean-Michel Ville
Laboratoire LG2mS, UPRES A CNRS 6066 Département de Génie Mécanique, Université de Technologie de Compiègne, BP 20 529, 60205 Compiègne Cedex, France

(Received 25 September 1996; accepted for publication 30 January 1998)

An original technique of measuring reflection (or transmission) matrices of duct discontinuities is described. The technique is based on measuring the acoustic pressure by microphone pairs in two closed cross sections of a constant area circular duct, which separates incident and reflected modes after a modal decomposition by a Fourier–Lommel transform. Theory, experimental setup, and data treatment are presented. Then experimental reflection and conversion coefficients at an open duct end for plane wave and higher order modes are presented as an application and compared with analytical results. © *1998 Acoustical Society of America.* [S0001-4966(98)02805-7]

LIST OF SYMBOLS

a	duct radius
d	distance between measurement cross sections
r,θ,z	cylindrical coordinates
t	time
$c=340\ \mathrm{m\cdot s^{-1}}$	speed of sound
f	frequency
f^c_{mn}	cut-on frequency of the mode (m,n)
m	azimuthal wave number
n	radial number
$\omega=2\pi f$	pulsation
$k=\omega/c$	total wave number
k_{mn}	axial wave number
λ_{mn}	axial wavelength
p	acoustic pressure
J_m	Bessel function of first kind and order m
χ_{mn}	nth zero of J'_m, first derivative of J_m
A^i_{mn}	amplitude of incident mode (m,n)
A^r_{mn}	amplitude of reflected mode (m,n)
$R_{mn,pq}$	reflection coefficient of incident mode (p,q) over reflected mode (m,n)
$[\ ]$	matrix $N\times N$
$\{\}$	vector

INTRODUCTION

In the studies of mufflers and similar devices, the reflection and transmission properties are of interest. In the general case, with N propagating modes in a duct, these properties have to be described by $[N\times N]$ matrices. Indeed, in a reflection matrix, diagonal terms are the reflection coefficients and other terms are conversion coefficients. Until now, most of the experimental methods provide only the reflection coefficients, because plane wave propagation is assumed.[1] Also, when a spinning mode synthesizer generates one mode at a time,[2] the reflection coefficients of the selected higher order modes are determined.[3] In 1989, Abom, working[4] on a modal decomposition technique based on transfer function measurements between microphone pairs, proposed a method to measure the reflection matrix. However, because of a major problem in the generation of the required number of independent incident fields, experimental results were limited to plane wave propagation.

The method which we are presenting here is similar to that described by Abom.[4] The pressure distribution is measured in two closed cross sections of a constant circular area duct before the discontinuity by a pair of microphones. A specified modal decomposition and an original process of independent incident fields generation are used.

I. THEORY

A. Description of the sound field

Consider acoustic propagation in a semi-infinite hard wall cylindrical duct (Fig. 1) without mean flow. The fluid is assumed to be ideal and linear acoustic theory is valid. Then it is well known that, at time t, the acoustic pressure distribution in the duct can be written in cylindrical coordinates (r,θ,z) as

$$p(r,\theta,z,t)=\sum_{m=-\alpha}^{+\alpha}\sum_{n=0}^{\alpha} C_{mn}(z)p_{mn}(r,\theta)e^{-i\omega t}, \tag{1}$$

with the eigenfunctions

$$p_{mn}(r,\theta)=J_m\left(\frac{\chi_{mn}}{a}\right)e^{im\theta} \tag{2}$$

and the total modal coefficients in the cross section z

$$C_{mn}(z)=[A^i_{mn}e^{ik_{mn}z}+A^r_{mn}e^{-ik_{mn}\cdot z}], \tag{3}$$

where A^i_{mm} and A^r_{mn} are, respectively, the incident and reflected modal coefficients, (m,n) are integer numbers representing azimuthal wave number and radial number, (0,0) corresponds to the plane wave mode, and $k^2_{mn}=k^2-(\chi_{mn}/a)^2$ is the square of the axial wave number.

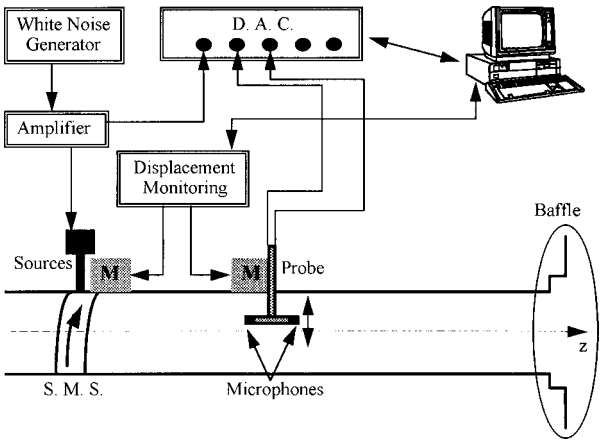

FIG. 1. Duct configuration.

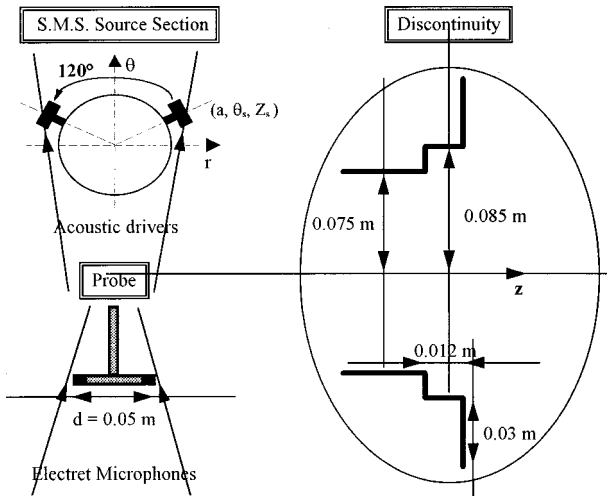

FIG. 2. Test configuration.

B. Determination of incident and reflected modal coefficients A^i_{mn} and A^r_{mn}

In the constant circular area duct, assuming that the sound pressure fields p_1 and p_2 are known in two cross sections located at z_1 and z_2 (Fig. 1), then:

$$p_1(r,\theta,t)=\sum_{m=-u}^{\mu}\sum_{n=0}^{\nu} C^1_{mn}p_{mn}(r,\theta)e^{-i\omega t},$$

$$C^1_{mn}=C_{mn}(z_1), \tag{4}$$

$$p_2(r,\theta,t)=\sum_{m-u}^{\mu}\sum_{n-0}^{\nu} C^2_{mn}p_{mn}(r,\theta)e^{-i\omega t},$$

$$C^2_{mn}=C_{mn}(z_2). \tag{5}$$

In Eqs. (4) and (5), all (u,v) modes, above and below the cutoff, which have significant levels at the z_1 and z_2 measurement positions should be included in the distribution.

A Fourier–Lommel transform[5] is applied to both of the total sound pressure distributions p_1 and p_2 in order to determine the total modal coefficients, $C^1_{mn}(f)$ and $C^2_{mn}(f)$. Incident and reflected modal coefficients, $A^i_{mm}(f)$ and $A^r_{mn}(f)$ are solutions of the following system of equations:

$$\begin{aligned} C^1_{mn}(f)&=A^i_{mn}(f)e^{ik_{mn}z_1}+A^r_{mn}(f)e^{-ik_{mn}z_1},\\ C^2_{mn}(f)&=A^i_{mn}(f)e^{ik_{mn}z_2}+A^r_{mn}(f)e^{-ik_{mn}z_2}. \end{aligned} \tag{6}$$

Equations (6) can also be written in a matrix form as

$$\begin{Bmatrix} A^i_{mn}\\ A^r_{mn}\end{Bmatrix}=M^{-1}_{mn}\begin{Bmatrix} C^1_{mn}\\ C^2_{mn}\end{Bmatrix}, \tag{7}$$

where

$$M_{mn}=\begin{bmatrix} e^{ik_{mn}z_1} & e^{-ik_{mn}z_1}\\ e^{ik_{mn}z_2} & e^{-ik_{mn}z_2}\end{bmatrix}. \tag{8}$$

Equation (7) has solutions if $\det[M_{mn}]\neq 0{:}d\neq q(\lambda_{mn}/2)$, $q=1,2,...$ [$d=z_2-z_1$ is the distance between the cross sections; $\lambda_{mn}=2\pi/k_{mn}$ is the axial wave length of the mode (m,n)]. The influence of errors on the two microphone transfer function technique has already been discussed.[6] The generalization of this technique to a modal propagation results in the following condition on d:

$$\lambda_{mn}/20<d<(2/5)\lambda_{mn}. \tag{9}$$

As the plane axial wavelength is the smallest among all modes, the upper limit in the previous inequality specifies an upper limit $f_{\max}$ to the frequency domain of measurement:

$$f<f_{\max}=\frac{2}{5}\frac{c}{d}. \tag{10}$$

Near mode cut-off frequencies, a large dispersion appears because d is very small compared to an axial wavelength. A frequency domain where error becomes very important is then delimited for each mode, the upper limit of that is deduced from the lower limit of the inequality [Eq. (9)]:

$$\forall(m,n),\ \ f^c_{mn}<f<f^c_{mn}\sqrt{1+\left(\frac{1}{20}\frac{c}{df^c_{mn}}\right)^2}, \tag{11}$$

if $m=0$ and $n=0$, $0<f<c/(20d)$ where f^c_{mn} is the cut–on frequency of the mode (m,n). (In Table II, the associated ka values are calculated with the experimental distance d.)

If the acoustic pressure is distributed over N modes, the overall solution can be written as two vectors A^i and A^r with N components (order is given by cut-off frequency order):

$$A^i=\{A^i_{mn}\} \tag{12}$$

and

$$A^r=\{A^r_{mn}\}. \tag{13}$$

C. Determination of reflection and conversion coefficients

1. Reflection and conversion matrix expression

If the duct can be regarded as a linear, time invariant and passive system in the positive z direction, then there exist a linear relationship between A^i and A^r:

$$\{A^r\}=[R]\cdot\{A^i\}, \tag{14}$$

where $[R]$ is the $[N\times N]$ reflection matrix.

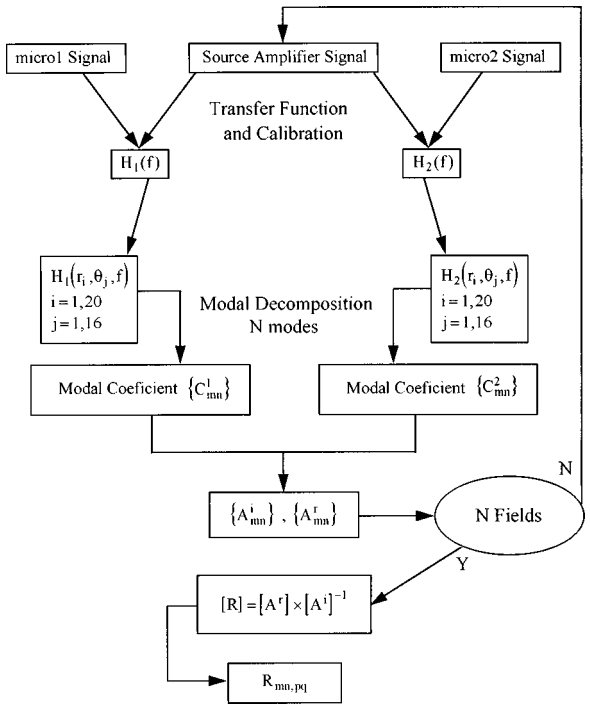

FIG. 3. The data treatment diagram.

Coefficients $R_{pq,mn}$ of matrix $[R]$ are the pressure reflection coefficients: reflection of the incident mode (m,n) on reflected mode (p,q). When $m=p$ and $n=q$ they are called the reflection coefficients of mode (m,n) and when $m\neq p$ or $n\neq q$ they are called the conversion coefficients: the reflection of the incident mode (m,n) to the reflected mode (p,q). As shown by Eq. (15) below, the reflection of the incident mode (m,n) and the conversion of all other incident modes on (m,n) contribute to the amplitude of the reflected mode (m,n):

$$A^r_{mn}=R_{mn,mn}A^i_{mn}+\sum_{mn\neq pq}R_{mn,pq}A^i_{pq}. \tag{15}$$

N independent incident acoustic pressure fields have to be generated in order to calculate N^2 coefficients $R_{pq,mn}$ from the system:

$$[R]=[A^r][A^i]^{-1}. \tag{16}$$

A column j of $[A^i]$ is filled with $A^{i,j}=\{A^{i,j}_{mn}\}$, a vector shown by Eq. (12) but for the jth incident field configuration. The $N\times N$ matrix $[A^i]$ is given by

$$[A^i]=[A^{i,1}_{mn}\quad\cdots\quad A^{i,j}_{mn}\quad\cdots]. \tag{17}$$

The matrix of the reflected pressure fields, $[A^r]$, is also determined and written in the same manner as $[A^i]$.

2. Generation of N independent incident fields

Let $r_s=a$, θ_s, and z_s be cylindrical coordinates of the sth source (Fig. 2) and A_s and φ_s be the amplitude and phase. The modal coefficients A^i_{mn} of the incident acoustic pressure field produced by these N_s point sources in an infinite cylindrical hard wall duct can be written[2] as the product of a coefficient D_{mn} ($D_{mn}=1/2ik_{mn}N_{mn}$, where N_{mn} is the normalization factor) by a function of the location and physical source characteristics:

$$A^i_{mn}=D_{mn}\left(\sum_{s=0}^{N_s-1}A_s e^{i(m\theta_s+k_{mn}z_s+\varphi_s}\right). \tag{18}$$

When N modes propagate, the total incident field is written as a vector:

$$\{A^i\}=\{A^i_{mn}\}=\mathrm{diag}(D_{mn})\left\{\left(\sum_{s=0}^{N_s-1}A_s e^{i(m\theta_s+k_{mn}z_s+\varphi_s)}\right)\right\}. \tag{19}$$

Modification of the source configuration is performed by rotating all sources by an azimuthal angle $j\Delta\theta$ (j is an integer). Then two acoustic incident pressure fields $j=j_1$ and $j=j_2$ are linearly independent if $j_1\neq j_2$ as shown by the following relationship:

$$\{A^{i,j}_{mn}\}=\mathrm{diag}(D_{mn})\left\{\left[\sum_{s=0}^{N_s-1}A_s e^{i(m\theta_s+k_{mn}z_s)}e^{imj\Delta\theta}\right]\right\}. \tag{20}$$

For the case of a pressure field that consists of 4 modes (m_1, 0); (m_2, 0); (m_3, 0); (m_1; 1). Then the rotation is repeated 3 times ($j=1$ to $N-1=3$) and the incident pressure field matrix $[A^i]$ which is based on the 4 configurations ($j=0$ is an initial configuration) is then given by

$$[A^i]=\mathrm{diag}\left(D_{mn}\sum_{s=0}^{N_s-1}A_s e^{i(m\theta_s+k_{mn}z_s+\varphi_s)}\right)\times\begin{bmatrix}1 & e^{im_1\Delta\theta} & e^{im_1 2\Delta\theta} & e^{im_1 3\Delta\theta}\\ 1 & e^{im_2\Delta\theta} & e^{im_2 2\Delta\theta} & e^{im_2 3\Delta\theta}\\ 1 & e^{im_3\Delta\theta} & e^{im_3 2\Delta\theta} & e^{im_3 3\Delta\theta}\\ 1 & e^{im_1\Delta\theta} & e^{im_1 2\Delta\theta} & e^{im_1 3\Delta\theta}\end{bmatrix}. \tag{21}$$

This example points out that, when two modes have the same m but different n, two lines are identical and the matrix $[A^i]$ is not reversible. To avoid this problem, in the fourth field, a source ($\Delta\theta=0$) is translated by Δz from its axial position, as shown below,

$$[A^i]=\mathrm{diag}\left(D_{nm}\sum_{s=0}^{N_s-1}A_s e^{i(m\theta_s+k_{mn}z_s+\varphi_s)}\right)\times\begin{bmatrix}1 & e^{im_1\Delta\theta} & e^{im_1 2\Delta\theta} & e^{ik_{m_1 0}\Delta z}\\ 1 & e^{im_2\Delta\theta} & e^{im_2 2\Delta\theta} & e^{ik_{m_2 0}\Delta z}\\ 1 & e^{im_3\Delta\theta} & e^{im_3 2\Delta\theta} & e^{ik_{m_3 0}\Delta z}\\ 1 & e^{im_1\Delta\theta} & e^{im_1 2\Delta\theta} & e^{ik_{m_1 1}\Delta z}\end{bmatrix}. \tag{22}$$

The N^2 coefficients $R_{pq,mn}$ are determined by solving Eq. (16).

II. THE REFLECTION MATRIX MEASUREMENT TECHNIQUE TEST

A. Experimental setup and procedure

The purpose of the experiment is the measurement of the reflection matrix of an open duct end discontinuity shown on

TABLE I. Source configurations.

Source configuration No.	Source 1 $\theta°$	Source 1 z(m)	Source 2 $\theta°$	Source 2 z(m)	Note
1	0	0	120	0	Experiment
2	15	0	135	0	Simulation
3	30	0	150	0	Simulation
4	40	0	160	0	Simulation
5	50	0	170	0	Simulation
6	0	0	120	0.15	Experiment

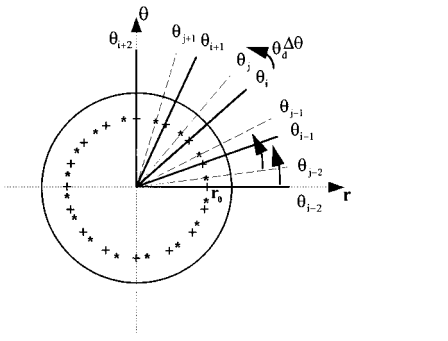
Fig. 2. The duct diameter is 0.15 m. Two acoustic drivers mounted in a duct section which can rotate over 360° are located at the periphery of the wall in the same cross section or at two different axial positions. During an experiment, they are driven in phase with a white noise signal that is band limited to 0–3000 Hz. For this duct radius and frequency range the parameter ka (a is the duct radius) is lower than 4, therefore only 6 modes (0,0); ($\pm$1,0); ($\pm$2,0) and (0,1) are cut-on at 3000 Hz.

Two 0.6-mm-diam electret microphones are mounted back to back on a support which traverses the duct diameter. The axial separation between microphones was set at 5 cm [according to Eq. (10) $f_{\max}=2760$ Hz].

A 320-points discretization of the acoustic pressure field measurement in cross sections z_1 and z_2 (Refs. 7, 8) is achieved by rotating the source section at 16 positions equally space by 22.5° and displacing the probe to 20 radial positions. This allows modal decomposition from $m=-7$ to $+7$ and $n=0$ to 9.

As shown in Fig. 3, transfer function measurements between signals from each microphone and source amplifier are achieved simultaneously in both duct cross sections for each of the 16×20 microphone positions. Then, these transfer functions are Fourier–Lommel transformed[5] for each frequency, yielding the total modal coefficients $C^1_{mn}(f)$ and $C^2_{mn}(f)$ with $-7<m<7$; $n<9$. The incident and reflected modal coefficients vectors $\{^{A^i_{mn}}_{A^r_{mn}}\}$ are then calculated using Eq. (7).

As the measurement section is far from the discontinuity, only the $N=6$ cut-on modes at 3000 Hz will be taken into account to determine the reflection matrix coefficients. Therefore, six source configurations (Table I) which satisfy the conditions explained in Sec. II C2 should be set up.



From 16 Radius (320 mesureament positions) ➡ 16 Interpolated Radius

$\theta_{i+1}-\theta_i=360°/16$ (i = 1, 16) is the experimental azimuthal incrementation

$\theta_{j+1}-\theta_j=360°/16$ (j = 1, 16) is the interpolated azimuthal incrementation

$\Delta\theta=\theta_j-\theta_i$

FIG. 4. Azimuthal interpolation of pressure field.

TABLE II. Cut-on frequency parameter ka.

(m,n)	(0,0)	($\pm$1,0)	($\pm$2,0)	(0,1)	($\pm$3,0)
nondimensional cut-on frequency ka	0	1.84	3.05	3.83	4.2
nondimensional upper frequency limit ka in Eq. (11)	0.47	1.90	3.08	3.86	4.23

To reduce the time for the experimental procedure, the acoustic pressure fields generated by rotation (No. 2, 3, 4, 5) are deduced from the measured field. As the configuration is axisymetric, there is reciprocity between rotating the sources and rotating the probe. In order to simulate the rotation of the sources, a computation of $\Delta\theta$ rotation of the probe is achieved by a B_3 uniform splines function[9] interpolation (Fig. 4) from a measured pressure field.

B. Results

Experimental results are compared with an analytical model based on modal theory of wave propagation in a semi-infinite duct without flow[10] ended by an infinite flange. The radiation impedance condition at the end of the duct are calculated as given by Zorumski.[11] As in the experiment, the duct is ended by a short flange (Figs. 1 and 2), therefore, the theoretical results are expected to slightly overestimate the experimental results.[12]

The modulus and phase of the coefficients are plotted versus ka, for their cut-on frequency to $ka=4$. Results are easier to analyze if the cut-on frequency parameters are followed as indicated in Table II. All results are diverging

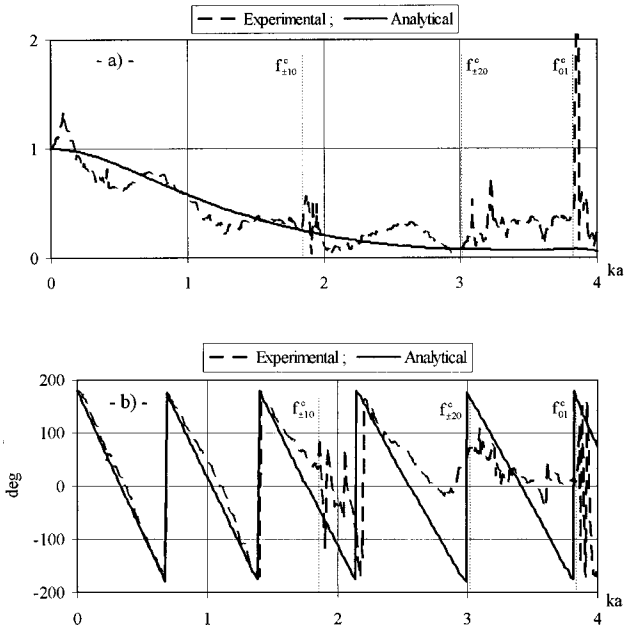


FIG. 5. Reflection coefficient spectrum $R_{00,00}$: (a) modulus; (b) phase.

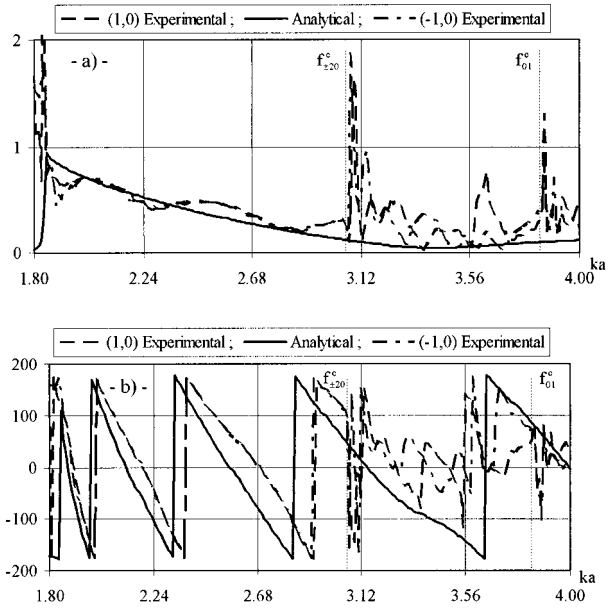

FIG. 6. Reflection coefficient spectrum $R_{\pm 10,\pm 10}$: (a) modulus; (b) phase.

around the cut-off frequencies as pointed out by remarks in Sec. I B.

1. Plane wave reflection coefficient: $R_{00,00}$

The complex coefficient $R_{00,00}$ is plotted (Fig. 5) from $ka=0$ to 4 and compared with theory. Agreement is quite good, but results are diverging around the cut-on frequencies of modes $(\pm 1,0)$, $(\pm 2,0)$, and particularly for (0,1) because its cut-on frequency is higher than $f_{\max}$ [Eq. (10)]. An oscillation is evident which is the characteristic of the diffraction effect[13] by the probe. This oscillation is of the order of the difference between cases with and without the flange. So, one can conclude that our comparison may not give an absolute estimation due to the difference in the cases concerned, i.e., numerical and experimental cases.

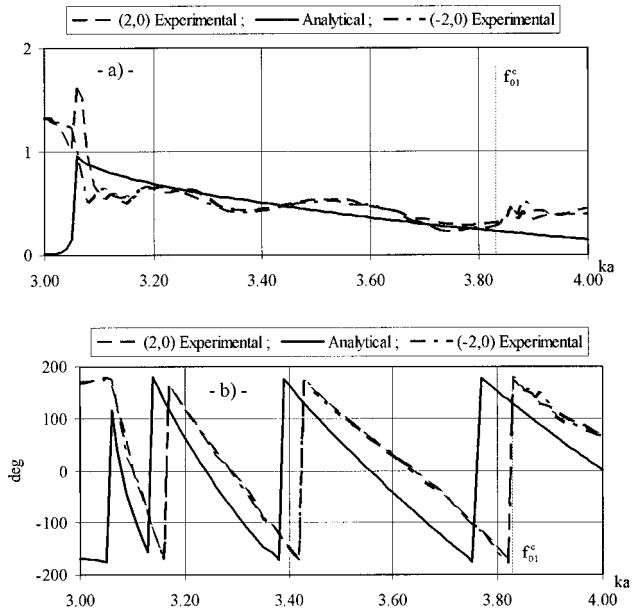

FIG. 7. Reflection coefficient spectrum $R_{\pm 20,\pm 20}$: (a) modulus; (b) phase.

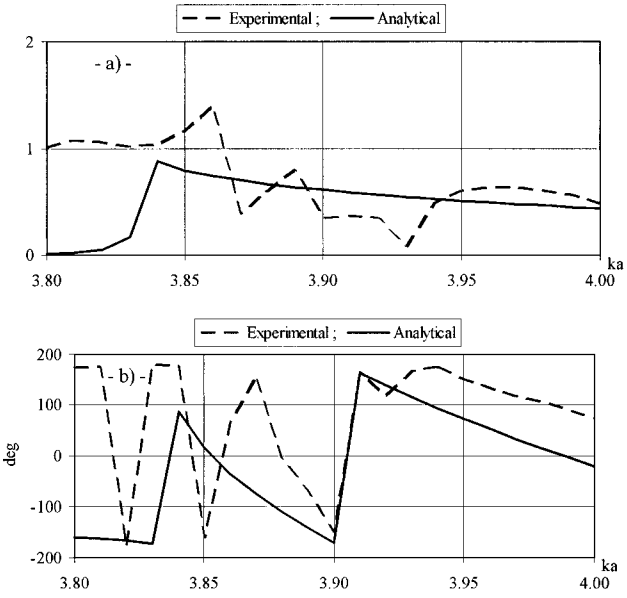

FIG. 8. Reflection coefficient spectrum $R_{01,01}$: (a) modulus; (b) phase.

2. Modes (±1,0) reflection coefficients: $R_{10,10}$ and $R_{10,-10}$

Complex coefficients $R_{10,10}$ and $R_{10,-10}$ are plotted (Fig. 6) from $ka=1.8$ to 4 and compared with theory. The agreement is remarkable except around the cuton frequencies of modes $(\pm 2,0)$, and (0,1).

3. Modes (±2,0) reflection coefficients: $R_{20,20}$ and $R_{20,-20}$

Complex coefficients $R_{20,20}$ and $R_{20,-20}$ are plotted (Fig. 7) from $ka=3$ to 4 and compared with theory. Good agreement is achieved away from the cuton frequency of mode (0,1).

4. Modes (0,1) reflection coefficients: $R_{01,01}$

The complex coefficient $R_{01,01}$ is plotted (Fig. 8) from $ka=3.8$ to 4 and compared with theory. This result is shown over a very short frequency domain around its cuton frequency. Agreement between experiment and theory is not so good as it is for modes with an axial symmetry described previously, because the frequency is higher than $f_{\max}$ [Eq. (10)].

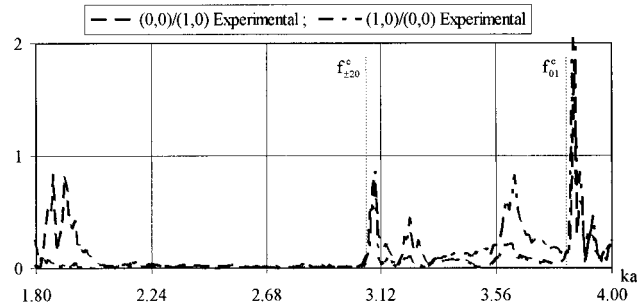

FIG. 9. Conversion coefficient spectra $R_{10,00}$ and $R_{00,10}$: modulus.

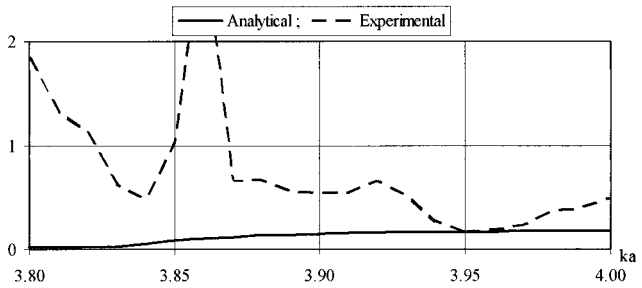

FIG. 10. Conversion coefficient spectra $R_{01,00}$: modulus.

5. Conversion coefficients

As the duct is axisymetric, only conversion between radial modes occurs. In the frequency domain studied, only $R_{00,10}$ and $R_{10,00}$ should then be different from 0. This assumption is experimentally verified on Fig. 9 where $R_{00,10}$ and $R_{10,00}$ are found to be close to zero except around the cut-on frequencies of modes $(\pm 2,0)$ and (0,1). The conversion coefficient $R_{01,00}$ is plotted (Fig. 10) and compared with theory. The agreement is not good with the experimental conversion coefficient being higher than predicted. The lack of agreement can be expected because the analysis is not very reliable since, due to the processing of the experimental data, the frequency range is higher than $f_{\max}$ and around the cut-on frequency of the mode.

III. CONCLUSIONS

A method of measuring pressure reflection coefficient matrices of duct discontinuities has been developed. It can be regarded as an extension of the Chung-Blaser[1] method from plane wave propagation to high order mode propagation and an improvement of the technique suggested by Abom.[4] Indeed, to perform the reflection matrix determination, transfer functions between microphone pairs traversing two duct cross sections are processed in an original way: in addition to a different other modal decomposition technique, a new method of creating linearly incident pressure fields is proposed in order to solve the system.

An experimental test facility has been set up. The experimental design allows the acoustic pressure reflection matrix measurement of an unflanged duct opening to be conducted up to a frequency parameter ka of 4. Experimental data of $R_{pq,mn}$ are presented and compared with theory. A good agreement is found between experiment and theory for reflection coefficients away from cut-on frequencies at which the method is diverging. Also, the conversion coefficients between azimuthal modes with the same radial number are found to be close to zero as expected because of the duct axisymmetry. Results obtained on the radial mode (0,1) are not very reliable because the study is conducted in its cut-on frequency range where the method diverges.

This method will now be used to study other geometrical discontinuities and lined ducts. We also intend to extend it to air flow environments. Improvement on the probe has to be done to avoid the experimental diffraction effects observed and to perform measurements with flow.

Known source detection predictions for higher order correlators

Lisa A. Pflug
Naval Research Laboratory, Code 7173, Stennis Space Center, Mississippi 39529-5004

George E. Ioup and Juliette W. Ioup
Department of Physics, University of New Orleans, New Orleans, Louisiana 70148

(Received 15 January 1996; accepted for publication 21 January 1998)

The problem addressed in this paper is whether higher order correlation detectors can perform better in white noise than the cross correlation detector for the detection of a known transient source signal, if additional receiver information is included in the higher order correlations. While the cross correlation is the optimal linear detector for white noise, additional receiver information in the higher order correlations makes them nonlinear. In this paper, formulas that predict the performance of higher order correlation detectors of energy signals are derived for a known source signal. Given the first through fourth order signal moments and the noise variance, the formulas predict the SNR for which the detectors achieve a probability of detection of 0.5 for any level of false alarm, when noise at each receiver is independent and identically distributed. Results show that the performance of the cross correlation, bicorrelation, and tricorrelation detectors are proportional to the second, fourth, and sixth roots of the sampling interval, respectively, but do not depend on the observation time. Also, the SNR gains of the higher order correlation detectors relative to the cross correlation detector improve with decreasing probability of false alarm. The source signal may be repeated in higher order correlations, and gain formulas are derived for these cases as well. Computer simulations with several test signals are compared to the performance predictions of the formulas. The breakdown of the assumptions for signals with too few sample points is discussed, as are limitations on the design of signals for improved higher order gain. Results indicate that in white noise it is difficult for the higher order correlation detectors in a straightforward application to achieve better performance than the cross correlation. INTRODUCTION

The potential advantages over conventional detection methods that may be obtained using higher order moment and related spectral techniques have received much attention in recent years. Higher order techniques show promise in applications for stationary signals and also for short-time transients where only a single occurrence of a signal may be available for detection (Dwyer, 1984; Hinich, 1990; Hinich and Wilson, 1990; Kletter and Messer, 1990; Sangfelt and Persson, 1993; Delaney, 1994; Tague *et al.*, 1994; Baugh and Hardwicke, 1994; Nuttall, 1994). The latter case, for correlation detectors, has been investigated in previous papers by the authors using both computer simulations (Pflug *et al.*, 1992b, 1994b) and more recently for unknown source detection, using theoretical performance predictions for the case of uncorrelated noise (Pflug *et al.*, 1995b). The theoretical performance predictions are extended in this paper to include predictions for known source detection, of which active detection is the most common application. The formulas can be used to determine under what conditions higher order correlations perform better than the cross correlation detector in uncorrelated noise, if the higher order correlations include more than one hydrophone, or channel, of data. Although the cross correlation is the optimal linear detector in white noise, the inclusion of additional channels of data in the higher order correlations makes them nonlinear detectors, which makes possible improvement over the cross correlation. Preliminary results using these formulas have been included in two abstracts (Pflug *et al.*, 1994a; Ioup *et al.*, 1995) and a proceedings article (Pflug *et al.*, 1995a).

After a background discussion given in Sec. I, the formulas for known source detection are derived in Sec. II. Comparison of the formula predictions with simulations using a set of various test signals is given in Sec. III. Section IV presents a discussion of signal design limitations for higher order gain and the applicability of the prediction formulas. Repeating the source signal in higher order correlation detectors is addressed in Sec. V. Finally, a summary of the findings appears in Sec. VI.

I. DEFINITIONS AND ASSUMPTIONS

The detection criteria used in this paper are based on the second through fourth order moments of a deterministic transient signal $s(t)$, defined by

$$m_p^s = \Delta t \sum_{k=0}^{N_s-1} s^p(t), \tag{1}$$

in which p is the moment order, $t = k\Delta t$, and N_s is the number of points in the source signal. The second through fourth order moments correspond to central ordinate, or zero time lag, values for the cross correlation, bicorrelation, and tricorrelation, respectively. Although the definition of m_p^s includes the factor Δt, changing the sampling rate of a signal results

in a corresponding change in the summation of Eq. (1), leaving the value of m_p^s the same, if the signal is adequately sampled.

The underlying noise process is assumed to be zero-mean stationary, independent, and identically distributed (i.i.d.), and therefore higher order white and uncorrelated. Less restrictive assumptions concerning the noise can be found in Appendices A and B of Pflug *et al.* (1995b). These assumptions can be modified in a straightforward manner to substitute the known source signal for one of the noise sequences. No averaging is used in the detection process, since the transients are nonstationary over their domains. Thus the noise is treated as an energy signal in the process of detecting an energy transient and has moments defined as in Eq. (1).

It is assumed for all but Sec. V that the source signal is simultaneously recorded on each of p-1 spatially separated sensors for the pth order moment. When the source signal is present, the second, third, and fourth order correlation detectors, also called the cross correlation (CC), bicorrelation (BC), and tricorrelation (TC) detectors, have detection statistics

$$\mathrm{CC}=\sum_{k=0}^{N_s-1} s(t)[s(t)+n_1(t)]\Delta t, \tag{2a}$$

$$\mathrm{BC}=\sum_{k=0}^{N_s-1} s(t)[s(t)+n_1(t)][s(t)+n_2(t)]\Delta t, \tag{2b}$$

and

$$\mathrm{TC}=\sum_{k=0}^{N_s-1} s(t)[s(t)+n_1(t)][s(t)+n_2(t)] \times[s(t)+n_3(t)]\Delta t. \tag{2c}$$

In these equations $n_i(t)$ represents the noise at one of the p-1 spatially separated sensors. The first terms in the extended sums of Eqs. (2a), (2b), and (2c) are simply the moments of the signal, as given in Eq. (1). When the source signal is absent, the correlation detectors are given by

$$\mathrm{CC}=\sum_{k=0}^{N_s-1} s(t)n_1(t)\Delta t, \tag{3a}$$

$$\mathrm{BC}=\sum_{k=0}^{N_s-1} s(t)n_1(t)n_2(t)\Delta t, \tag{3b}$$

and

$$\mathrm{TC}=\sum_{k=0}^{N_s-1} s(t)n_1(t)n_2(t)n_3(t)\Delta t. \tag{3c}$$

The amplitude signal-to-noise ratio (SNR) for energy signals is defined by

$$\mathrm{SNR}=\frac{\sigma_s}{\sigma_n}. \tag{4}$$

Conversion of the amplitude SNR in Eq. (4) to power SNR in decibels is accomplished using $20\log_{10}(\sigma_s/\sigma_n)$. The variance of a deterministic signal $s(t)$ is

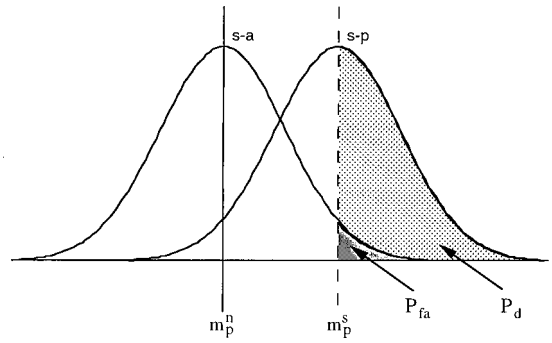

FIG. 1. The signal-absent (s-a) and signal-present (s-p) PDFs that determine the $P_d=0.5$ point of a ROC curve.

$$\sigma_s^2=\frac{\Delta t}{T}\sum_{k=0}^{N_s-1}[s(t)-\bar{s}]^2=\frac{1}{T}\left[m_2^s-\frac{(m_1^s)^2}{T}\right], \tag{5}$$

where the mean is $\bar{s}=m_1^s/T$. For known source detection, the processing window duration, $T=\Delta t N_s$, is by definition equal to the transient signal duration, denoted by T_s. The noise variance, σ_n^2, is defined in the same way as σ_s^2 because the correlations are defined for energy transients. The noise ensemble is ergodic and differences between the sample and population noise means and variances are assumed to be small for comparison of theoretical and simulated results.

II. KNOWN SOURCE DETECTION PREDICTION FORMULAS

Derivations of formulas that predict the SNR at which a passive correlation detector achieves the minimum detectable level (MDL) are given by Pflug *et al.* (1995b). The MDL is the SNR at which a detector achieves a probability of detection (P_d) equal to 0.5 for a selected probability of false alarm (P_{fa}). The derivations are based on the areas beneath the signal-absent (s-a) and signal-present (s-p) probability density functions (PDFs) of the zero lag correlation values that define a receiver operating characteristic (ROC) curve (see Fig. 1). For the pth order correlation, the mean of the s-p PDF is at m_p^s (the pth order signal correlation), and the mean of the s-a PDF is at m_p^n (the pth order noise correlation), which is zero under the assumptions in this paper. The s-a PDF moments are consistent with Gaussian moments, as shown in the Appendix.

Since the s-p PDF is symmetric, the mean is equal to the median of the PDF and the $P_d=0.5$ threshold occurs at the mean, m_p^s (see Fig. 1). For a fixed SNR, this threshold also defines the P_{fa}. The P_{fa}, or area to the right of the threshold, is related to a standardized score, called z_n, by

$$z_n=\frac{m_p^s-m_p^n}{\sqrt{\alpha_p^n}}, \tag{6}$$

where α_p^n represents the variance of the s-a PDF. The standardized score is the abscissa value which defines the tail area for a normalized Gaussian distributed PDF having zero-mean and unit variance. This makes it possible to use one formula or table of areas to find the P_{fa} for any Gaussian distribution, regardless of its defining parameters. A table of these areas can be found in most basic statistics books or

computed numerically. Here, z_n and P_{fa} are inversely related. When α_p^n in Eq. (6) and the corresponding SNR are smaller, z_n is larger, and the two PDFs in Fig. 1 are narrower and have less overlap, resulting in a smaller P_{fa}. For more details on the relationship between z scores and ROC curves, see Egan (1975).

For $P_d=0.5$, Eq. (6) is related to the remaining ROC curve parameters through α_p^n, SNR, and P_{fa}. Since m_p^s and m_p^n are known, if α_p^n can be expressed theoretically as a function of signal and noise parameters, then Eq. (6) can ultimately be used as a prediction formula for detection performance. The derivations of α_p^n for $p=2$, 3, and 4 follow.

The PDF variance, α_2^n, of cross correlation realizations of a finite-length transient signal, $s(t)$, and members of an infinite ensemble of finite-length noise sequences, $n_i(t)$, is given by

$$\alpha_2^n=E\left\{\left[\sum_{k=0}^{N_s-1} s(t)n_{i_1}(t)\Delta t\right]^2\right\} - E^2\left\{\sum_{k=0}^{N_s-1} s(t)n_{i_1}(t)\Delta t\right\}. \tag{7}$$

The expectation operator represents averaging the large number of realizations generated in performing Monte Carlo simulations over the noise ensemble to evaluate detector performance, and is not related to any averaging in the detector itself. Since the signal and noise are approximately uncorrelated across the finite-time interval of interest and the noise is assumed to be zero mean, the second term can be neglected. Then,

$$\alpha_2^n=E\left\{(\Delta t)^2\sum_{k_1=0}^{N_s-1}\sum_{k_2=0}^{N_s-1} s(t_1)s(t_2)n_{i_1}(t_1)n_{i_1}(t_2)\right\} \tag{8a}$$

$$=E\left\{(\Delta t)^2\sum_{k_1=0}^{N_s-1} s^2(t_1)n_{i_1}^2(t_1)\right\} \tag{8b}$$

$$=(\Delta t)m_2^sE\{n_{i_1}^2(t_1)\} \tag{8c}$$

$$=\Delta t m_2^s\sigma_n^2. \tag{8d}$$

The summation over k_2 in the derivation of Eq. (8b) from Eq. (8a) is a result of the assumption that the noise is i.i.d. $E\{n^2(t)\}$ represents the infinite ensemble variance of the noise, which is equivalent to σ_n^2 in Eq. (8d) for an infinite time sum due to the ergodicity of the noise. This derivation also follows from the result given in the Appendix and is based on the assumption that finite-time averages are equal to infinite-time averages, which is approximately true for large enough N_s (see the discussion in Sec. IV for practical restrictions on the signal). For the bicorrelation, noise received from two sensors is used in the s-a PDF variance.

$$\alpha_3^n=E\left\{\left[\sum_{k=0}^{N_s-1} s(t)n_{i_1}(t)n_{i_2}(t)\Delta t\right]^2\right\} - E^2\left\{\sum_{k=0}^{N_s-1} s(t)n_{i_1}(t)n_{i_2}(t)\Delta t\right\} \tag{9a}$$

$$=E\left\{(\Delta t)^2\sum_{k_1=0}^{N_s-1}\sum_{k_2=0}^{N_s-1} s(t_1)s(t_2)n_{i_1}(t_1) \times n_{i_1}(t_2)n_{i_2}(t_1)n_{i_2}(t_2)\right\} \tag{9b}$$

$$=\Delta t m_2^s\sigma_n^4. \tag{9c}$$

Again, N_s must be large. For the tricorrelation, noise received from three sensors is used in the s-a PDF variance.

$$\alpha_4^n=E\left\{\left[\sum_{t=0}^{N_s-1} s(t)n_{i_1}(t)n_{i_2}(t)n_{i_3}(t)\Delta t\right]^2\right\} - E^2\left\{\sum_{t=0}^{N_s-1} s(t)n_{i_1}(t)n_{i_2}(t)n_{i_3}(t)\Delta t\right\} \tag{10a}$$

$$=\Delta t m_2^s\sigma_n^6. \tag{10b}$$

These s-a PDF variances can be substituted in Eq. (6). As mentioned previously, the cross correlation s-p PDF has mean equal to m_2^s, and the expression for z_n becomes

$$z_n=\frac{m_2^s-m_2^n}{\sqrt{\alpha_2^n}}=\frac{\sqrt{m_2^s}}{\sigma_n\sqrt{\Delta t}}. \tag{11}$$

Using Eq. (4) gives

$$\mathrm{SNR}_{\mathrm{CC}}=\frac{\sigma_s z_n\sqrt{\Delta t}}{\sqrt{m_2^s}}. \tag{12}$$

Here, $\mathrm{SNR}_{\mathrm{CC}}$, the MDL for the cross correlation detector, is interpreted as the SNR required to achieve the detection level of $P_d=0.5$ at the P_{fa} corresponding to z_n, the standardized threshold value. Since σ_s is proportional to $\sqrt{m_2^s}$, m_2^s dependence is canceled in the derivation, and $\mathrm{SNR}_{\mathrm{CC}}$ is constant for all signals. This is not to be interpreted as saying that all signals of equal duration and sampling are equally detectable using the cross correlation. The correct interpretation is that the cross correlation detector achieves $P_d=0.5$ for these signals at the same SNR, which requires varying levels of noise for different signals.

The bicorrelation s-p PDF has mean equal to m_3^s, which for simplicity is assumed to be positive. Evaluating the z_n gives

$$z_n=\frac{m_3^s-m_3^n}{\sqrt{\alpha_2^n}}=\frac{m_3^s}{\sigma_n^2\sqrt{\Delta t m_2^s}}. \tag{13}$$

Substituting to obtain the SNR yields the formula

$$\mathrm{SNR}_{\mathrm{BC}}=\sigma_s\sqrt{\frac{z_n^{\mathrm{BC}}\sqrt{\Delta t m_2^s}}{m_3^s}}. \tag{14}$$

A similar analysis for the tricorrelation yields

$$z_n = \frac{m_4^s - m_4^n}{\sqrt{\alpha_2^n}} = \frac{m_4^s}{\sigma_n^3 \sqrt{\Delta t m_2^s}}, \tag{15}$$

and

$$\mathrm{SNR}_{\mathrm{TC}} = \sigma_s \sqrt[3]{\frac{z_n^{\mathrm{TC}} \sqrt{\Delta t m_2^s}}{m_4^s}}. \tag{16}$$

For zero-mean energy signals, the SNR prediction formulas reduce to

$$\mathrm{SNR}_{\mathrm{CC}} = \frac{z_n \sqrt{\Delta t}}{\sqrt{T_s}}, \tag{17}$$

$$\mathrm{SNR}_{\mathrm{BC}} = \sqrt{\frac{(m_2^s)^{3/2} z_n \sqrt{\Delta t}}{m_3^s T_s}}, \tag{18}$$

and

$$\mathrm{SNR}_{\mathrm{TC}} = \sqrt[3]{\frac{(m_2^s)^2 z_n \sqrt{\Delta t}}{m_4^s (T_s)^{3/2}}}. \tag{19}$$

For zero-mean signals, $\mathrm{SNR}_{\mathrm{BC}}$ and $\mathrm{SNR}_{\mathrm{TC}}$ can also be written as functions of signal skewness and kurtosis (Pflug *et al.*, 1995a).

To compare the three detection methods, $\mathrm{SNR}_{\mathrm{CC}}$, $\mathrm{SNR}_{\mathrm{BC}}$, and $\mathrm{SNR}_{\mathrm{TC}}$ should be evaluated at the same P_{fa}. The difference in dB levels is referred to as the SNR gain of the bicorrelation or tricorrelation detector over the cross correlation detector. Using one source signal and p-1 distinct channels of received data, the bicorrelation SNR gain in dB is

$$\mathrm{BCG} = 20 \log_{10} \left[\frac{(m_3^s)^2 z_n^2 \Delta t}{(m_2^s)^3} \right]^{1/4}, \tag{20}$$

and the tricorrelation SNR gain in dB is

$$\mathrm{TCG} = 20 \log_{10} \left[\frac{(m_4^s)^2 z_n^4 (\Delta t)^2}{(m_2^s)^4} \right]^{1/6}. \tag{21}$$

The SNR gain formulas for zero-mean and nonzero-mean signals are the same, since the only dependence on the signal mean in the nonzero mean formulas is through the standard deviation, and the dependence of $\mathrm{SNR}_{\mathrm{CC}}$, $\mathrm{SNR}_{\mathrm{BC}}$, and $\mathrm{SNR}_{\mathrm{TC}}$ on the standard deviation cancels in the gain ratios.

The gain formulas show no functional dependence on T_s. Known source detection, in contrast to unknown source detection (see Pflug *et al.*, 1995a, b) is independent of observation time, T, provided the entire signal is in the processing window. This is because the multiplication of the noise by the signal sets the noise to zero outside the signal window. Known source detection performance does, however, depend on Δt. In particular, for known source detection, $\mathrm{SNR}_{\mathrm{CC}}$, $\mathrm{SNR}_{\mathrm{BC}}$, and $\mathrm{SNR}_{\mathrm{TC}}$ are proportional to the second, fourth, and sixth root of the sampling interval, respectively. Performance improves for all the correlation detectors with decreasing sampling interval. However, as sampling intervals increase, the bicorrelation and tricorrelation detectors degrade less quickly than the cross correlation detector. For a given signal, noise level, and P_{fa}, each of the three detectors is associated with a range of sampling intervals for which it will perform best. For example, if a zero-mean signal has moments $m_2^s = 0.0025$ s, $m_3^s = 0.0022$ s, and $m_4^s = 0.0015$ s, then the bicorrelation and tricorrelation SNR gains versus sampling interval will be as shown in Fig. 2 for $P_{\mathrm{fa}} = 0.001$ ($z_n = 3.09$). For a positive bicorrelation gain, the sampling interval must be 0.000 34 s or larger, and for a positive tricorrelation gain, the sampling interval must be 0.000 44 s or larger.

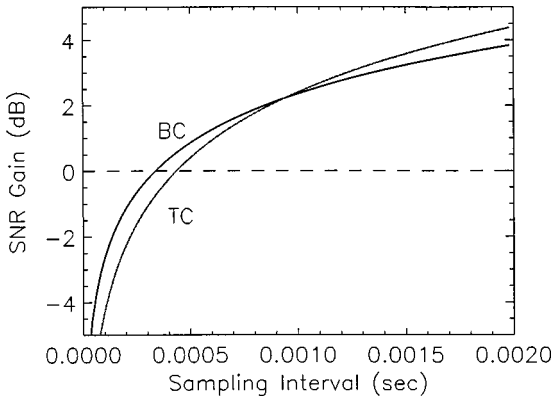

FIG. 2. Bicorrelation and tricorrelation SNR gain versus sampling interval for a zero-mean signal with moments $m_2^s = 0.0025$, $m_3^s = 0.0022$, $m_4^s = 0.0015$, and $P_{\mathrm{fa}} = 0.001$.

Detection performance improves (lower SNR) for the three detectors as z_n decreases, or the tolerance for false alarm increases. However, if the tolerance for false alarm is small, as it often is in practice, the bicorrelation and tricorrelation SNR formulas, which give increasing gain with decreasing P_{fa}, indicate that higher order detectors could outperform the cross correlation.

TABLE I. Moments m_p^s in amplitude units to the pth power times seconds for the eight test signals.

Signal	T_s (s)	m_1^s	m_2^s	m_3^s	m_4^s
Whale transient	1.00	-9.13×10^{-5}	2.78×10^{-1}	1.07×10^{-3}	1.75×10^{-1}

III. COMPARISONS BETWEEN PREDICTIONS AND COMPUTER SIMULATIONS

Pflug *et al.* (1994b) present detection results using hypothesis testing and Monte Carlo simulations with 10 000 Gaussian noise realizations for eight energy signals. Note that the formulas do not require the noise to be Gaussian distributed, but they require the noise ensemble to be i.i.d. The signals are varied in nature, generally of low frequency, and they are described in detail in the above reference. Known source detection simulations are performed with the resulting P_d vs SNR curves interpolated at $P_d=0.5$. These simulations involve only one replica of the source signal in the bicorrelation and tricorrelation. While the focus of the paper by Pflug *et al.* (1994b) is on the advantage of prefiltering in higher order correlations, results for detection simulations with no prefiltering are also given. These results are used to corroborate the known source prediction formulas derived in this paper, which assume there is no signal-specific or situation-specific passband filtering.

Table I lists the signal duration and first through fourth order signal moments used in detection performance prediction for the eight test signals. The test signals include a model 20 Hz finback whale transient, the whale transient shifted to 12 Hz and called the low frequency whale, an amplitude modulated 5 Hz sinusoid, a narrow-time pulse which has a flat magnitude spectrum to approximately 80 Hz and a smooth rolloff to 256 Hz, an amplitude modulated 50 Hz sinusoid, a 49–51 Hz beating sinusoid, an FM linear sweep from 49 to 51 Hz, and a nonlinear FM sweep from 120 to 0 Hz. For the computer simulations, the first four signals are sampled with interval (1/1024) s, the last four with (1/500) s. The low frequency whale transient, 41–59 Hz FM linear sweep, and 120–0 Hz nonlinear FM sweep do not have bicorrelation maximum magnitudes at zero time lag. Also, the whale transient and 50 Hz sinusoid have approximately zero bispectra since the lowest frequency present in the signal is essentially half the highest frequency. This makes the bicorrelation value at zero time-lag inappropriate as a detection criterion (Ioup *et al.*, 1989; Pflug, 1990; Pflug *et al.*, 1992a).

Tables II–IV contain the results of the computer simulations and the theoretical predictions for known source detection at $P_{fa}=0.001$. Excepting the narrow pulse signal, the predictions and simulations agree reasonably well, with the absolute differences between the computer simulations and formula predictions of SNR ranging from 0.10 dB to 0.83 dB for the three detectors. For these seven test signals, the cross correlation detector performs better than the higher order correlation detectors, as shown by the predicted BCG and TCG values in Table V. For the narrow pulse, both the bicorrelation and tricorrelation detectors perform better than the cross correlation. However, the gain achieved in the simulations is significantly lower than predicted with the formulas. The reasons are discussed in detail in the following section.

The difference between the computer simulations and the predictions, which generally fluctuates between 0 and 0.5 dB for the test signals except the narrow pulse, is not removed by finer sampling, which implies that for those signals there is a sufficient number of signal samples for the finite summation to approximate the infinite summation in the formula derivations. For example, in Fig. 3, the computer

TABLE III. Known source detection SNR_{BC} in dB for $P_{fa}=0.001$ calculated from computer simulations and the prediction formulas, and the absolute dB difference between the two methods.

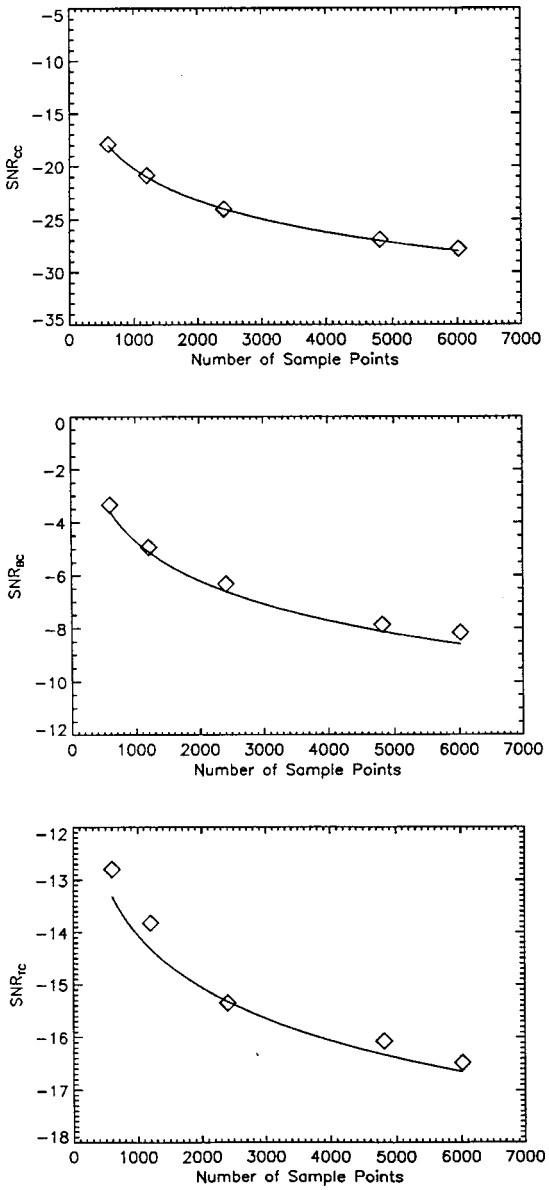

FIG. 3. The minimum detectable level as a function of the number of sample points for the 49–51 Hz sinusoid. The solid curves give the formula predictions and the symbols give the computer calculations.

simulated and predicted SNRs are shown versus number of sample points for the 49–51 Hz sinusoid. The differences fluctuate randomly with increased sampling, but remain less than 0.5 dB for each detector.

Another possible source of error in the computer simulations is that Gaussian noise generators may not perform well when very low levels of noise, corresponding to the tails of the noise distribution, are needed. A potential limitation at low P_{fa} occurs due to the finite number of realizations used in a computer simulation. If 10 000 realizations are used, as in this paper, the minimum nonzero P_{fa} value possible is 1×10^{-4}, or one false alarm out of 10 000 on average. Thus interpolation of the P_d vs P_{fa} curve for a fixed SNR at P_{fa} values lower than 1×10^{-3} is generally not statistically reliable. The number of realizations required to obtain a discrete point on the ROC curve at the desired P_{fa} increases with decreasing P_{fa}. For example, to obtain a P_d vs P_{fa} point at a P_{fa} value of 1×10^{-6}, at least one million realizations would be required.

IV. LIMITATIONS ON THE DESIGN OF SIGNALS FOR POSITIVE HIGHER ORDER GAIN

The physically motivated definition of the signal moments, which includes the time dimension, Δt, in the summation given in Eq. (1), has the intrinsic advantage that the signal moments do not change if the signal is interpolated or decimated in time. Of course, this will only be true if there is sufficient sampling (Pflug *et al.*, 1993), and the interpolation is bandlimited (Bracewell, 1986). The above holds whether or not the moment is normalized by dividing by T_s, and also for the variance, skewness, and kurtosis.

Since the moments do not change with interpolation or decimation, subject to the given restrictions, the entire effect of either of these two operations on the higher order detection gain is contained in the Δt factor of Eqs. (20) and (21). Larger Δt increases the higher order advantage, while smaller Δt does the opposite, favoring the cross correlation detector (matched filter). In fact, in the limit of the continuous-time signal (Δt goes to zero), the gain tends to negative infinity, and the cross correlation is best for any signal if the signal and noise satisfy the necessary assumptions. For a given signal, it is straightforward to determine whether there is any Δt large enough, within the sampling limitations, to give positive higher order gain. It should be noted that experimental conditions may also put limitations on Δt, and these are not considered here.

Another design question which may be asked of the gain formulas is how varying the width of a signal affects the gain. That is, if the signal samples are moved closer together or further apart (Δt is decreased or increased) without changing the signal ordinate values (but changing the moments), how does the gain change? The functions are related by similarity (Bracewell, 1986). As Δt is varied, an upper limit on Δt is determined by the sampling requirement (Pflug *et al.*, 1993). The Similarity Theorem (Bracewell, 1986) describes the effect of varying Δt on the Fourier transform. To analyze the effect of a width change, consider the tricorrelation gain formula

$$\mathrm{TCG}=20\log_{10}\left[\frac{(m_4^s)^2 z_n^4(\Delta t)^2}{(m_2^s)^4}\right]^{1/6}$$
$$=20\log_{10}\left[\frac{z_n^{2/3}(\Sigma_{k=0}^{N-1}s^4(t))^{1/3}}{(\Sigma_{k=0}^{N-1}s^2(t))^{2/3}}\right]. \qquad (22)$$

All the Δt dependence cancels, leading to the conclusion, which agrees with intuition, that as long as the ordinate values of $s(t)$ are unchanged, the gain does not change with a similarity transformation. The same Δt cancellation occurs for the bicorrelation gain.

For many signals, there is a restriction on the use of these formulas for large Δt. First, $N_S=T_S/\Delta t$ must be large enough to ensure that the summation over the product of signal and noise is uncorrelated and that the finite sums approximate the infinite sums. Second, and more specifically, there must be a sufficient number of significant nonzero sig-

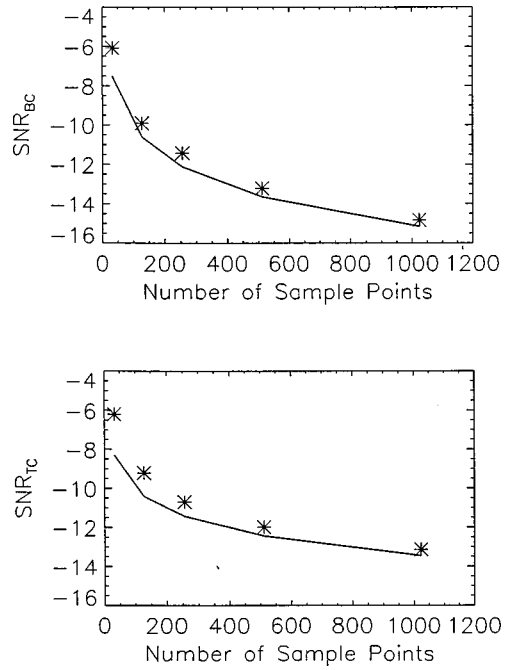

FIG. 4. Formula predictions (continuous curves) and computer simulations (asterisks) of SNR_{BC} and SNR_{TC} for the narrow pulse versus number of sample points within the original signal duration.

nal values, since these determine how many terms contribute significantly to the sums of Eqs. (7), (9a), and (10a). The gain prediction formulas may therefore fail to apply even for a Δt which is small enough to satisfy the sampling requirements.

Consider the case of the narrow pulse. The differences between the predicted SNR and the computer simulated SNR for SNR_{CC}, SNR_{BC}, and SNR_{TC} are 0.03, 1.43, and 2.11 dB, respectively. Differences between the formula predictions and computer simulations grow larger with increasing detector order, and the differences for SNR_{BC} and SNR_{TC} are larger than the differences for the other seven signals in Tables II–IV. Investigation into the source of the difference for the narrow pulse reveals that the bicorrelation and tricorrelation s-a PDFs are noticeably nonGaussian, which violates the assumptions required for the prediction formula derivation. At its original sampling, there are only 32 nonzero signal points in the narrow pulse, causing the breakdown of the assumption that finite-time averages should approximate infinite-time averages, and resulting in a non-Gaussian s-a PDF. Additional computer simulations support this hypothesis. The original 32-point signal is interpolated to contain 128, 256, 512, and 1024 points within in the original 0.03-s signal duration, and the computer simulated values for SNR_{BC} and SNR_{TC} are calculated. The predicted and simulated values become closer as the number of signal samples increases (Fig. 4) and the s-a PDFs become increasingly Gaussian. With 1024 points, the difference between the predicted and simulated SNR values decreases to 0.32 dB for both the bicorrelation and tricorrelation detectors.

For a realistic P_{fa}, the narrow pulse signal does not show a positive SNR gain for the bicorrelation or tricorrelation detectors over the ordinary correlation detector, if Δt is chosen small enough for the prediction formulas to apply. With 128 points within the signal duration, fewer than necessary for the prediction formulas to apply, both the predictions and simulations show that the cross correlation detector performs best. While it is possible to select a large enough Δt to get a positive gain for this signal in simulations, it is simply not possible to predict that gain well with the gain formulas.

V. REPEATED SOURCE REPLICAS IN HIGHER ORDER CORRELATION DETECTION

Repeating the source signal when using bicorrelation and tricorrelation detectors can have beneficial or detrimental effects, depending on the source signal (Pflug *et al.*, 1992b). Derivation of bicorrelation and tricorrelation detector prediction formulas for repeated sources is analogous to the derivations for a single source. If the source is repeated once in the tricorrelation so that signals from only two sensors are used, then the s-p and s-a tricorrelations are

$$\text{s-p:}\quad \text{TC}=\sum_{k=0}^{N_s-1} s^2(t)[s(t)+n_1(t)][s(t)+n_2(t)]\Delta t, \tag{23a}$$

$$\text{s-a:}\quad \text{TC}=\sum_{k=0}^{N_s-1} s^2(t)n_1(t)n_2(t)\Delta t, \tag{23b}$$

and α_4^n, as given by Eq. (A5) in the Appendix, is $\alpha_4^n = \Delta t m_4^s \sigma_n^4$, and the predicted SNR is

$$\text{SNR}_{\text{TC}}^{(2,2)} = \sigma_s \sqrt{\frac{z_n^{\text{TC}}\sqrt{\Delta t}}{\sqrt{m_4^s}}}, \tag{24}$$

where (2,2) denotes the power on the known source in the correlation and the number of channels used in the correlation [see Eq. (23)]. With this notation, all previous formulas would have superscripts of $(1,p-1)$ for the moment of order p. The corresponding SNR gain over the cross correlation detector is

$$\text{TCG}^{(2,2)} = 20\log_{10}\left[\frac{z_n^2 m_4^s \Delta t}{(m_2^s)^2}\right]^{1/4}. \tag{25}$$

This formula shows that for fixed Δt and P_{fa}, the gain depends explicitly on only the signal moments and that the simple calculation of these moments predicts whether repeating the source is advantageous or not.

Improved detection may result from repeating the source signal in the bicorrelation detector. However, at zero lag this higher order repeated source case, with noise from only one sensor, is equivalent to a correlation of a signal filter with one received signal. When only one received signal is used in the detection process, the cross correlation or matched filter is expected to be optimal for detection in white noise (Gardner, 1986). For the bicorrelation with a repeated source, the s-p and s-a bicorrelations are

$$\text{s-p:}\quad \text{BC}=\sum_{k=0}^{N_s-1} s^2(t)[s(t)+n_1(t)]\Delta t, \tag{26a}$$

$$\text{s-a:}\quad \text{BC}=\sum_{k=0}^{N_s-1} s^2(t)n_1(t)\Delta t, \tag{26b}$$

and $\alpha_3^n=\Delta t m_4^s \sigma_n^2$. This leads to

$$\text{SNR}_{\text{BC}}^{(2,1)}=\frac{z_n^{\text{BC}}\sigma_s\sqrt{m_4^s\Delta t}}{m_3^s}, \tag{27}$$

and the corresponding gain over the cross correlation detector which is

$$\text{BCG}^{(2,1)}=20\log_{10}\left[\frac{(m_3^s)^2}{m_2^s m_4^s}\right]^{1/2}. \tag{28}$$

If the source signal is repeated twice in the tricorrelation, then the s-a and s-p tricorrelations are

$$\text{s-p:}\quad \text{TC}=\sum_{k=0}^{N_s-1} s^3(t)[s(t)+n_1(t)]\Delta t, \tag{29a}$$

$$\text{s-a:}\quad \text{TC}=\sum_{k=0}^{N_s-1} s^3(t)n_1(t)\Delta t, \tag{29b}$$

and $\alpha_4^n=\Delta t m_6^s \sigma_n^2$. The predicted SNR is

$$\text{SNR}_{\text{TC}}^{(3,1)}=\frac{z_n^{\text{TC}}\sigma_s\sqrt{m_6^s\Delta t}}{m_4^s}, \tag{30}$$

and the SNR gain for this case is

$$\text{TCG}^{(3,1)}=20\log_{10}\left[\frac{(m_4^s)^2}{m_2^s m_6^s}\right]^{1/2}. \tag{31}$$

The SNR gains for the $\text{SNR}_{\text{BC}}^{(2,1)}$ and $\text{SNR}_{\text{TC}}^{(3,1)}$ are independent of P_{fa} and sampling interval, while the SNR gain for $\text{SNR}_{\text{TC}}^{(2,2)}$ is not. This means that $\text{SNR}_{\text{BC}}^{(2,1)}$ and $\text{SNR}_{\text{TC}}^{(3,1)}$ have the same dependence on the sampling interval and P_{fa} as SNR_{CC}, which is consistent with the fact that these higher order detectors are ordinary filters.

For the seven test signals other than the narrow pulse, the tricorrelation detector with the source repeated once shows a higher SNR gain than the tricorrelation detector without a repeated source for $P_{\text{fa}}=0.001$. Repeating the source twice improves the SNR gain even more. Repeating the source in the bicorrelation detector for these signals results in improvement for some signals, but not others, but the cross correlation still performs best. The predicted bicorrelation gain for the narrow pulse is 1.83 dB without a repeated source, but drops to -0.29 dB with a repeated source. The tricorrelation gain for the narrow pulse is 2.64 dB without a repeated source, drops to 1.98 dB with the source is repeated once, and is -0.60 dB when the source is repeated twice.

VI. CONCLUSIONS

Formulas that predict cross correlation, bicorrelation, and tricorrelation known source detector performance at the minimum detectable level for any probability of false alarm are derived and corroborated with computer simulations. The prediction formulas indicate that there are circumstances under which the higher order correlation detectors could outperform the cross correlation detector for the known source case, and give the relationships to the variables upon which the detection performance depends. They show that the cross correlation, bicorrelation, and tricorrelation detectors are proportional to the second, fourth, and sixth roots of the sampling interval. The SNR gain formulas indicate that the higher order detectors are more likely to exhibit better detection performance than the cross correlation detector when the tolerance for false alarm is low. A simulation result is given in which there is positive SNR gain for the higher order correlations, but the prediction formula assumptions are not satisfied for this case. While it is theoretically possible for the higher order correlation detectors to perform better than the cross correlation detector, only a limited class of signals exists for which they do.

APPENDIX: GAUSSIAN CHARACTER OF CORRELATION CENTRAL ORDINATE PDFS

Following Isserlis (1918) and Gardner (1986), the qth ensemble moments of the pth order correlation central ordinate PDFs are shown to be consistent with a zero-mean Gaussian density where the correlation consists of $(p\text{-}r)$ zero-mean noise sequences correlated with a known signal raised to the rth power. That is, all odd order ensemble moments are zero, and all even order ensemble moments greater than two are appropriately proportional to powers of the second moment, if the assumptions discussed in Sec. I are satisfied.

The qth order ensemble moment of the source signal and $p-r$ sequences drawn from an infinite noise ensemble is

$$\begin{aligned}
M_p^q &= E\left\{\left[\sum_{k=0}^{N_s-1} s^r(t)n_{i_1}(t)n_{i_2}(t)\cdots n_{i_{p-r}}(t)\Delta t\right]^q\right\} \\
&= (\Delta t)^q E\left\{\left[\sum_{k_1=0}^{N_s-1} s^r(t_1)n_{i_1}(t_1)n_{i_2}(t_1)\cdots n_{i_{p-r}}(t_1)\right]\right. \\
&\quad\times\left[\sum_{k_2=0}^{N_s-1} s^r(t_2)n_{i_1}(t_2)n_{i_2}(t_2)\cdots n_{i_{p-r}}(t_2)\right]\cdots \\
&\quad\left.\times\left[\sum_{k_q=0}^{N_s-1} s^r(t_q)n_{i_1}(t_q)n_{i_2}(t_q)\cdots n_{i_{p-r}}(t_q)\right]\right\} \qquad \text{(A1)} \\
&= (\Delta t)^q E\left\{\sum_{k_1=0}^{N_s-1}\sum_{k_2=0}^{N_s-1}\cdots\sum_{k_q=0}^{N_s-1} s^r(t_1)s^r(t_2)\cdots s^r(t_q)\right. \\
&\quad\times n_{i_1}(t_1)n_{i_1}(t_2)\cdots n_{i_1}(t_q)\cdot n_{i_2}(t_1) \\
&\quad\left.\times n_{i_2}(t_2)\cdots n_{i_2}(t_q)\cdots n_{i_{p-r}}(t_1)n_{i_{p-r}}(t_2)\cdots n_{i_{p-r}}(t_q)\right\}, \qquad \text{(A2)}
\end{aligned}$$

with the number of signal points N_s and $t_j=k_j\Delta t$. This expression is zero when q is odd, and whenever all t_j are dis-

tinct. It is only nonzero when q is even and times are equal in pairs. Using delta function notation, the moments are nonzero when

$$M_p^q=(\Delta t)^q E\Bigg\{\sum_{k_1=0}^{N_s-1}\sum_{k_2=0}^{N_s-1}\cdots\sum_{k_q=0}^{N_s-1} s^r(t_1)s^r(t_2)\cdots s^r(t_q)$$
$$\times n_{i_1}(t_1)n_{i_1}(t_2)\cdots n_{i_1}(t_q)n_{i_2}(t_1)n_{i_2}(t_2)\cdots n_{i_2}(t_q)\cdots$$
$$\times n_{i_{p-r}}(t_1)n_{i_{p-r}}(t_2)\cdots n_{i_{p-r}}(t_q)$$
$$\times\Bigg[\sum\ \delta(t_{j_1}-t_{j_2})\cdots\delta(t_{j_{q-1}}-t_{j_q})\Bigg]\Bigg\} \tag{A3}$$

is nonzero, where the summation over the product of delta functions is taken over all possible ways of dividing q integers into $q/2$ combinations of pairs. There are $(1)(3)(5)\cdots(q-3)(q-1)$ terms in the summation. Applying the delta summation, exchanging summations and expectations where appropriate, and using the uncorrelatedness assumptions results in

$$M_p^q=[(1)(3)(5)\cdots(q-3)(q-1)]$$
$$\times(\Delta t)^{q/2}(m_{2r}^s)^{q/2}E\{n_{i_1}^2(t_1)n_{i_1}^2(t_2)\cdots n_{i_1}^2(t_{q/2})\}$$
$$\times E\{n_{i_2}^2(t_1)n_{i_2}^2(t_2)\cdots n_{i_2}^2(t_{q/2})\}\cdots$$
$$\times E\{n_{i_{p-r}}^2(t_1)n_{i_{p-r}}^2(t_2)\cdots n_{i_{p-r}}^2(t_{q/2})\}. \tag{A4}$$

Since the square of the noise is uncorrelated in time, this is equal to

$$M_p^q=[(1)(3)(5)\cdots(q-3)(q-1)]$$
$$\times(\Delta t)^{q/2}(m_{2r}^s)^{q/2}E\{n_{i_1}^2(t_1)\}E\{n_{i_1}^2(t_2)\}\cdots E\{n_{i_1}^2(t_{q/2})\}$$
$$\times E\{n_{i_2}^2(t_1)\}E\{n_{i_2}^2(t_2)\}\cdots E\{n_{i_2}^2(t_{q/2})\}E\{n_{i_{p-r}}^2(t_1)\}$$
$$\times E\{n_{i_{p-r}}^2(t_2)\}\cdots E\{n_{i_{p-r}}^2(t_{q/2})\}$$
$$=[(1)(3)(5)\cdots(q-3)(q-1)]$$
$$\times(\Delta t)^{q/2}(m_{2r}^s)^{q/2}[E\{n^2(t)\}]^{(p-r)q/2}, \tag{A5}$$

which is the even qth order ensemble moment of the correlation of p-r zero-mean noise sequences and the signal raised to the rth power. These moments are consistent with the moment relationships for a Gaussian distributed density.

Reference-beam detection is inherently superior to the knife-edge detection currently in use in scanning laser acoustic microscopy. This new detector makes use of a reference beam, retarded 90 degrees, which is mixed coherently in a photodiode with the acoustically obtained image-modulated beam. The new detector has an isotropic transfer function which is circularly symmetrical around its highest value, namely the zero-frequency point in the spatial spectrum. This property makes it possible to detect spatial frequencies in all directions simultaneously and with equal sensitivity and simplifies the associated electronics. It also makes possible the employment of acoustic evanescent-wave detection so that ultrasound of low temporal frequency can be used and at the same time high spatial frequencies can be detected for obtaining high resolution. Oblique insonification, required for best operation in the knife-edge detector, is thus not preferred in the reference-beam detector and the resultant Doppler shift in the detected frequency of the transmitted zero-order acoustic waves is avoided. © *1998 Acoustical Society of America.* [S0001-4966(98)01905-5]

INTRODUCTION

Scanning laser acoustic microscopy (SLAM) has become a reliable option for obtaining high-quality images on a microscopic scale with good resolution and contrast. It is the only acoustic microscope that produces its images in real time. The conventional technique for image data readout in SLAM is to deflection modulate a laser beam by scanning it over a solid surface containing the acoustic field scattered from the object and then to demodulate the beam by means of a knife-edge detector (KED). The probing beam is reflected from the surface of a mirrored coverslip onto which scattered acoustic waves, transmitted through the object, impinge (see Fig. 1). The image information, is encoded as deflection modulation on the reflected beam and is detected by the KED. As shown, the system consists basically of a knife edge placed in the focal field of a lens with a photodiode positioned behind the knife edge.

The need for higher resolution and more sensitive methods of acoustic data appropriation and image reconstruction of microscopic objects has grown. In the literature a number of systems for detecting scanned laser acoustic images are described.[1–4] Slam and other acoustic microscopes with scanning laser data acquisition are widely used in many applications[5] and are the subject of a strong international research effort. Thus novel techniques for laser-scanned data procurement continue to be researched and developed.[6–10]

This paper gives a brief description of the operation of the KED in SLAM in a more intuitive way than appears in the literature and by means of which a major weakness of the detector is made apparent. We explain precisely how and why the KED is sensitive not only to the spatial frequencies of the sinusoidal components in the object but also to the direction in which the sinusoidal variations take place. We show that the KED transfer function is antisymmetric with zero response at zero spatial frequency and negative response at negative frequencies. Because of the nature of the transfer function, flexibility in choosing the optimum laser spot size is limited. In addition, an obliquely incident insonification at an optimum angle of incidence is ordinarily employed in SLAM, with a resultant Doppler shift in the detected frequency of the transmitted zero-order acoustic beam, along with single side band detection. In spite of the use of these measures, the bandwidth of the spatial frequency spectrum used in reconstructing the image must be restricted so that it does not extend beyond the positive part of the transfer function and avoids and null response at zero frequency. Therefore, the resolution of the reconstructed image is correspondingly limited. Thus while the KED provides acceptable results for imaging when the spatial variations in the object are in the preferred direction and at the preferred frequencies, it is quite unsatisfactory for variations at other spatial frequencies and in other directions and has a severely limited resolution.

Following that we describe and analyze the new reference-beam detector (RBD) and show that its transfer function is symmetric with no negative response anywhere in the spatial frequency spectrum. This function is highest at zero frequency. Thus both side bands can be demodulated so that no signal power is lost. Neither null responses nor negative frequencies have to be avoided and therefore the detected wave field can have a greater bandwidth of the spatial-frequency spectrum than with the KED.

We also show that because of the above characteristics of the transfer function, evanescent-wave detection is possible with the RBD. The maximum spatial frequency for the

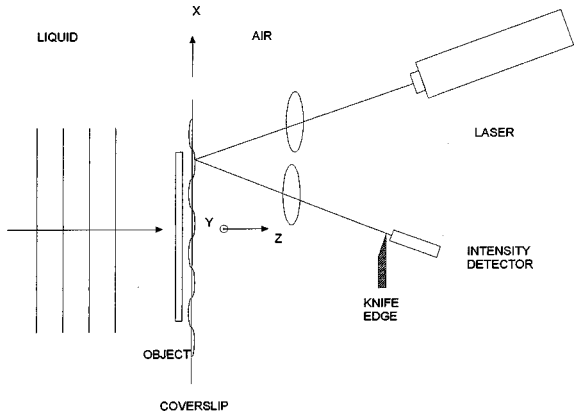

FIG. 1. Basic set up for the knife-edge detector.

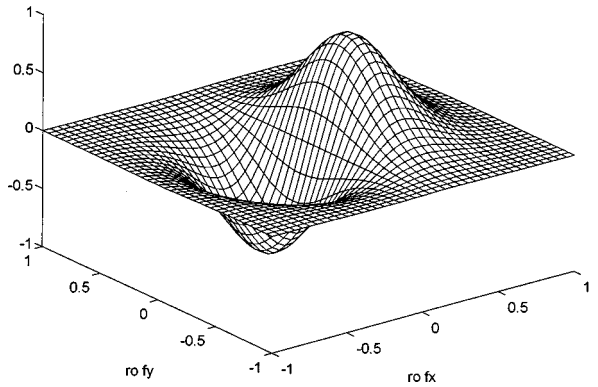

FIG. 2. Normalized transfer function for the knife-edge detector.

detected evanescent waves is limited only by the cross-sectional radius of the scanning laser beam. This frequency can be very high even though the temporal frequency of the sound is low. Thus the propagating acoustic wavelengths can be large, the acoustic temporal frequency (and hence the attenuation in the object) low, and at the same time the fine structure within the object can be highly resolved due to the detection of evanescent waves. Hence, greater sensitivity and higher resolution of the reconstructed image is possible with the RBD and there need be no Doppler shift in the detected frequency of the zero-order waves due to oblique insonification.

I. KNIFE-EDGE DETECTION IN SLAM

As illustrated in Fig. 1, the use of KED in SLAM involves transmitting sonic waves through an object and obtaining a dynamic ripple caused by these waves on a solid mirrorlike surface beyond the object. A scanning laser beam is then employed to probe the ripple and thereby read out the image information concerning the object, this information being contained in the transmitted sonic waves. The motion of the ripple causes the laser beam to be periodically deflected through an angle proportional to the slope of the surface displacement produced by the ripple. In its most sensitive operation, the deflected beam moves perpendicularly with respect to the knife edge causing the light collected by the photodiode behind the knife edge to be intensity modulated. The diode current is substantially proportional to the laser-beam deflection and therefore to the slope of the surface ripple.

Actually the laser beam as it hits the photodiode has been perturbed by two effects: (1) the periodic up-and-down movement of the surface giving rise to phase modulation in the beam and; (2) the periodic tilting of the surface resulting in the deflection modulation. The effect of the up-and-down movement is usually negligible and, as stated before, the magnitude of the signal detected by the photodiode can be taken to be proportional to the slope of the surface displacement in the ripple. This slope, in turn, is proportional to the strength of the sound field transmitted through the object.

As SLAM operates, the laser beam is caused to scan the surface containing the dynamic ripple. The spatial information modulates the beam and is converted to a corresponding temporal signal by means of the scanning and the knife-edge processing.

Based on the above description, the transfer function T_f for the KED using a laser beam with a Gaussian intensity profile is given by[4]

$$T_f = \exp\left(-\frac{\pi^2 r_0^2 (f_x^2 + f_y^2)}{2}\right) \mathrm{erf}\left(\frac{\pi r_0 f_x}{\sqrt{2}}\right), \tag{1}$$

where (f_x, f_y) are the spatial frequencies for sinusoidal variations in the transmittance function of the object along the axes (x,y), and r_0 is the effective beam radius. The knife edge is assumed to be oriented parallel to the x direction; and

$$\mathrm{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x \exp(-t^2)\, dt. \tag{2}$$

A plot with three-dimensional perspective showing normalized T_f as a function of $r_0 f_x$ and $r_0 f_y$ is presented in Fig. 2.

From the plot we can see that insonification at normal incidence, which puts the carrier of the sound transmitted to the coverslip at the zero spatial frequency point, gives the carrier a null response. Obliquely incident insonification must be used to avoid this. As the laser beam moves across the surface to scan out the raster pattern, the waves produced by the sound transmitted through the object move away or toward the detecting beam. Since both are moving, the detected surface waves on the coverslip are Doppler shifted, appearing to have a higher or lower frequency. Thus even the zero-order sound is Doppler shifted, which would not be the case for insonification at normal incidence.

In order to stay away from the null response as much as possible, usually only the upper side band is used in the detection process. In spite of the above measures (oblique incidence and single side band detection) which are employed to widen the useful spatial spectrum, resolution is still not good. The useful spectrum for effective image reconstruction has to be limited to the positive part of the transfer function and must avoid the null at $f_x = 0$. This results in a correspondingly limited resolution in the reconstructed images.

II. REFERENCE-BEAM DETECTION FOR SLAM

The new detector we propose involves a reference beam, retarded or advanced by 90°, which is coherently mixed in a photodiode with the scanning laser beam that has been phase and deflection modulated by the acoustic waves on the coverslip. The transfer function for this reference-beam detector (RBD) will now be derived. In our treatment an object is represented in its most mathematically general form. For simplicity in the derivation we have assumed that the lenses of the system all have the same focal length.

The coverslip surface dynamic ripple can be expressed as

$$z(x,y,t)=\mathrm{Re}\{h(x,y)\exp(-j\omega_s t)\}, \tag{3}$$

where $h(x,y)$ is the complex amplitude distribution function of the surface excursion, (x,y) are the axes coordinates in this plane and $\omega_s=2\pi f_s$, the acoustical temporal frequency.

The coverslip is probed by a laser beam with incident power P and a Gaussian intensity profile centered at the point (x_0,y_0)

$$\Psi(x,y)=\sqrt{\frac{2P}{\pi r_0^2}}\exp\left(-\frac{(x-x_0)^2+(y-y_0)^2}{r_0^2}\right), \tag{4}$$

where Ψ is the complex amplitude distribution function of the beam. In order to simplify the equations, the parameters (x_0,y_0) will be suppressed (that is, assumed to be zero for the time being) and will be appropriately reintroduced in the final result.

The probing beam, after being reflected from the surface of the coverslip is phase and amplitude modulated by the dynamic ripple. Thus the reflected complex amplitude distribution function is given by

$$\Psi_r=\sqrt{\frac{P}{\pi r_0^2}}\exp\left(-\frac{x^2+y^2}{r_0^2}\right)[1+jkh(x,y)\exp(-j\omega_s t) + jkh^*(x,y)\exp(j\omega_s t)], \tag{5}$$

where $k=2\pi/\lambda$ and λ the light wavelength. In Eq. (5) only terms of the first order in $kh(x,y)$ have been retained due to the fact that the value of this product is very small compared with unity.

Lens L1 performs the Fourier transform of Ψ, giving at the plane of the detector

$$\Psi_p=\left(\frac{1}{j\lambda f}\right)\sqrt{\frac{P}{\pi r_0^2}}\left[\pi r_0^2\exp\left(-\frac{\xi^2+\eta^2}{\rho^2}\right) + jk\exp(-j\omega_s t)\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\exp\left(-\frac{x^2+y^2}{r_0^2}\right)h(x,y)\exp\left(-j\frac{2\pi}{\lambda f}(x\xi+y\eta)\right)dx\,dy + jk\exp(j\omega_s t)\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\exp\left(-\frac{x^2+y^2}{r_0^2}\right)h^*(x,y)\exp\left(-j\frac{2\pi}{\lambda f}(x\xi+y\eta)\right)dx\,dy\right], \tag{6}$$

where (ξ,η) are the axial coordinates for this plane.

As seen in Fig. 3, the complex amplitude function Ψ_p is coherently added to the complex amplitude function of the reference beam in the photodiode. This latter function corresponds to the Fourier transform of the complex amplitude function of the incident beam retarded or advanced 90°. Thus the total complex amplitude distribution function Ψ_F for the light at this plane will be

$$\Psi_F=\Psi_P+\left(\frac{1}{j\lambda f}\right)\sqrt{\frac{P}{\pi r_0^2}}\left[j\pi r_0^2\exp\left(-\frac{\xi^2+\eta^2}{\rho^2}\right)\right]. \tag{7}$$

The power received by the photodiode is given by

$$P_s=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\Psi_F\Psi_F^*\,d\xi\,d\eta, \tag{8}$$

the limits of integration in Eq. (8) are chosen from $-\infty$ to ∞ because the photodiode is large compared with the size and excursions of the beams.

Evaluating the above integral we have

$$P_s=P\left[1+\frac{4k}{r_0^2}\mathrm{Re}\left\{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}h(x,y)\times\exp\left(-2\frac{(x-x_0)^2+(y-y_0)^2}{r_0^2}\right)\times\exp(-j\omega_s t)dx\,dy\right\}\right], \tag{9}$$

where the parameters (x_0,y_0) has been reintroduced as indicated before.

The integral in Eq. (9) can be interpreted very simply as the convolution of the impulse response of the system $\mathfrak{T}_s(x_0,y_0)$ with the function $h(x,y)$. Thus we get

$$\mathfrak{T}_s(x_0,y_0)=\frac{4k}{r_0^2}\exp\left(-2\frac{x_0^2+y_0^2}{r_0^2}\right). \tag{10}$$

The transfer function T_s for the RBD is obtained by Fourier transforming $\mathfrak{T}_s(x_0,y_0)$. Thus

$$T_s(f_x,f_y)=2\pi k\exp\left(-\frac{\pi^2 r_0^2}{2}(f_x^2+f_y^2)\right). \tag{11}$$

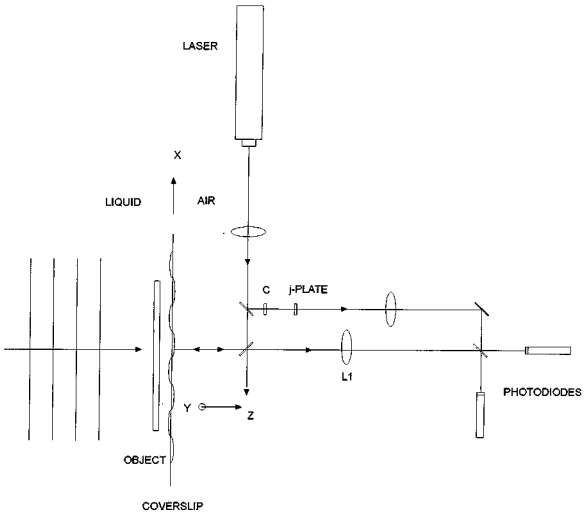

FIG. 3. Basic set up for the reference-beam detector. In the mathematical treatment the lenses are assumed to have the same focal length. C is an element to compensate the optical path of the reference beam. The outputs of both photodiodes are used in the signal processing so that no signal energy is lost.

Equation (11) shows that the transfer function for the reference-beam detector, plotted normalized in Fig. 4, is a Gaussian and therefore isotropic with maximum response at zero spatial frequency. This avoids having to insonify obliquely for best operation and, as we discuss below, permits evanescent-wave detection.

III. DISCUSSION AND CONCLUSIONS

The key component in this new detector is a reference beam advanced or retarded 90° which mixes coherently with the acoustic image-modulated beam and thus eliminates the need for a knife edge. The RBD is inherently superior to the KED used in a conventional SLAM because its transfer function is isotropic and maximum at the origin. These features give rise to high resolution, a reduction in the processing time required to analyze a given object and a simplification in the associated electronics. Furthermore, since the frequency response of the RBD has its maximum at the origin, there is no necessity for the oblique insonification that is

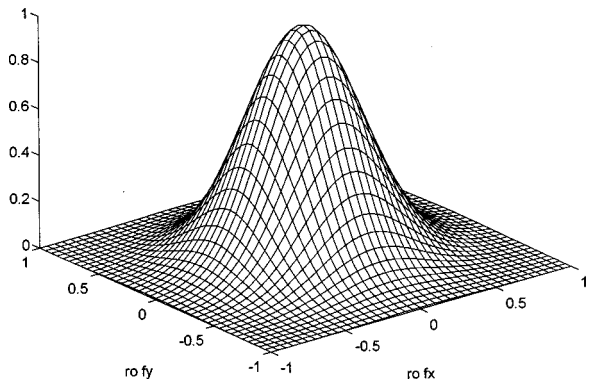

FIG. 4. Normalized transfer function for the reference-beam detector.

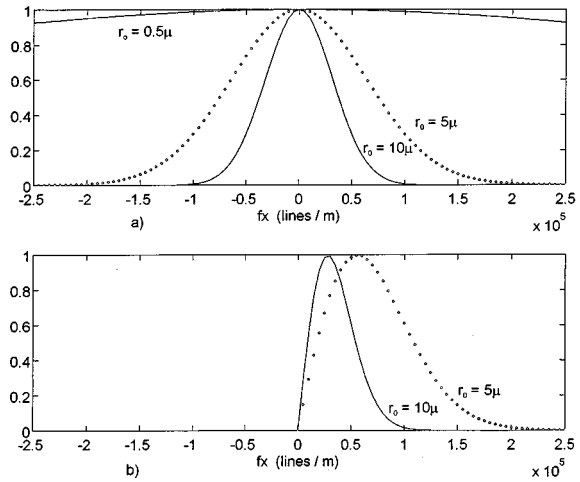

FIG. 5. Normalized one-dimensional transfer function: (a) for the RBD, and (b) for the KED.

required in the KED. This eliminates a Doppler shift in the detected frequency of the transmitted zero-order acoustic waves due to scanning.

We can see from the transfer functions of the two systems (Figs. 2 and 4) and the following arguments that the RBD is capable of much higher resolution than the KED in the direction perpendicular to the knife edge and is always higher in other directions. One reason is that the RBDs transfer function is isotropic and that of the KED is not. Figure 5 displays the normalized one-dimensional transfer functions for the RBD corresponding to three different spot sizes and the useful (that is, positive) part of the transfer functions of the KED for two of these spot sizes. In these plots both detectors appear to be more sensitive to the higher spatial frequencies for the smaller spot size.

However, for the KED (but not the RBD) the maximum response is moved to a higher spatial frequency as the spot size is lowered. The desired frequency for maximum response is that of the transmitted zero-order acoustic waves. Calculations show that when the spot size is cut from 10 μm to 5 μm, the response at the KED maximum drops to 70% of the previous value. Thus the optimal spot size for the KED is set by the angle of insonification needed to achieve the maximum response for the zero-order waves. This spot size is usually around 0.25–0.5 times the acoustical wavelength for the KED.

The RBD does not exhibit this problem. The maximum response remains at zero spatial frequency independent of the acoustic wavelength no matter what the spot size is. The limitation on broadening the spatial-frequency bandwidth is only on how tightly the laser beam can be focused. The smaller the spot size, the higher the spatial frequency that can be detected and the higher the object resolution that can be achieved.

The RBD is capable of detecting evanescent waves, that is, spatial wavelengths shorter than the acoustic wavelength. For example, a helium–neon laser beam can be focused to a radius of about half a micronmeter. If a 100-MHz acoustic frequency is used in water, the acoustic wavelength is 15 μm. However, if the object is mounted in the very near field,

the RBD could detect evanescent acoustic waves 15 times smaller than the acoustic wavelength. This provides a much higher resolution of the object that can be produced by conventional means at this acoustic wavelength. Furthermore, this resolution is independent of the actual acoustic wavelength. With evanescent-waves detection the acoustic wavelengths can be large with corresponding low attenuation in the object and at the same time the object's fine structure can be highly resolved.

(Received 17 January 1996; accepted for publication 23 January 1998)

Auscultation of lung sounds in patient transport vehicles such as an ambulance or aircraft is unachievable because of high ambient noise levels. Aircraft noise levels of 90–100 dB SPL are common, while lung sounds have been measured in the 22–30 dB SPL range in free space and 65–70 dB SPL within a stethoscope coupler. Also, the bandwidth of lung sounds and vehicle noise typically has significant overlap, limiting the utility of traditional band-pass filtering. In this study, a passively shielded stethoscope coupler that contains one microphone to measure the (noise-corrupted) lung sounds and another to measure the ambient noise was constructed. Lung sound measurements were made on a healthy subject in a simulated USAF C-130 aircraft environment within an acoustic chamber at noise levels ranging from 80 to 100 dB SPL. Adaptive filtering schemes using a least-mean-squares (LMS) and a normalized least-mean-squares (NLMS) approach were employed to extract the lung sounds from the noise-corrupted signal. Approximately 15 dB of noise reduction over the 100–600 Hz frequency range was achieved with the LMS algorithm, with the more complex NLMS algorithm providing faster convergence and up to 5 dB of additional noise reduction. These findings indicate that a combination of active and passive noise reduction can be used to measure lung sounds in high noise environments. [S0001-4966(98)02605-8]

INTRODUCTION

Auscultation is the process of listening to sounds emanating from the body. Medical personnel frequently make diagnoses pertaining to the health of the respiratory system using a standard binaural stethoscope. However, this stethoscope is highly prone to interference from ambient noise and thus becomes clinically useless in high ambient noise environments.

In a typical emergency, civil or military, an ambulance or aircraft (helicopter or fixed wing) is used to evacuate critically ill patients. Several sources of noise exist in such vehicles, and their interaction with the interior space or fuselage is complex and time variant due to the wide range of conditions and maneuvers encountered during a typical evacuation. For example, ambient noise levels in the range of 90–100 dB SPL (sound pressure level) exist in the cabin of C-130 aircraft used by the U.S. Air Force (USAF) for aeromedical evacuation. In contrast, normal breath sounds in an healthy adult are roughly 22–30 dB SPL in free space (excluding airflow generated noise radiating from the mouth) and 65–70 dB SPL within a stethoscope coupler (Zenk, 1994). Thus traditional auscultation in such a high noise environment is not feasible due to an inherently poor signal-to-noise ratio (SNR). In fact, even moderate background noise levels such as those found during average conversation are sufficient to hamper auscultation in the clinic. In general, the SNR can be improved either by increasing the signal strength (numerator) or by decreasing the interfering noise (denominator). However, the high noise levels and strong overlap of spectral content of lung sounds and the time-varying vehicle noise impose limitations on the successful employment of conventional passive noise reduction schemes.

Thus in this study, a digital scheme for adaptive noise reduction (ANR) was implemented in addition to passive noise reduction (PNR) at the transducer in an integrated approach. In this manner, the time varying characteristics of the noise are estimated and exploited to effectively extract the desired lung sounds. This manuscript details the design and preliminary testing of a Digital Active Noise Attenuation (DANA) Stethoscope, with a focus on the function of the

adaptive filters. The two algorithms that were implemented are the least-mean-squares (LMS) and normalized least-mean-squares (NLMS).

I. STETHOSCOPE COUPLER

A passively shielded coupler with two omnidirectional electret microphones (Telex ELM-22, Minneapolis, Minnesota) was constructed (Fig. 1). The microphone d is placed in a conical air cavity behind a standard stethoscope diaphragm to detect the lung sounds (Wodicka *et al.*, 1994). Such an arrangement allows significant lung sound energy to reach microphone d, with a frequency response that mimics that of the standard stethoscope. The other microphone, x, measures the noise reference that drives the adaptive filter. These sensors are positioned in the coupler so that microphone x detects very little lung sounds, yet measures sound that is highly correlated to the noise contaminating the lung sounds measured by microphone d. The stethoscope coupler is passively shielded from high frequency ambient noise via a foam surround since the effectiveness of adaptive noise reduction decreases with increasing frequency.

II. ADAPTIVE NOISE CANCELLATION

The conventional method of signal estimation from its noise corrupted version is to pass it through a filter that removes the unwanted noise without significantly affecting the signal. The filter employed can be fixed or self-adjusting, i.e., adaptive. If the signal and noise characteristics are known *a priori* the optimal fixed filter can be designed based on Wiener filter theory. In practice, *a priori* knowledge of noise characteristics is generally not available and hence a filter that adapts to the characteristics of the noise is desired. In the following, we present the basic theory of the adaptive filter algorithms considered in this study.

A. Least-Mean-Squares (LMS) algorithm

The LMS algorithm, developed by Widrow and Hoff in 1959 (Widrow *et al.*, 1985; Haykin *et al.*, 1986), has been studied in great detail and has found a myriad of applications (Widrow *et al.*, 1975; Darlington *et al.*, 1985; Rodriguez *et al.*, 1987; Harrison *et al.*, 1986; Pulsipher *et al.*, 1979; Elliott *et al.*, 1987; Poole *et al.*, 1984). Figure 2(a) depicts the basic construct for noise reduction in a linear system with additive noise. The primary input d consists of signal s and noise n_0 (for convenience the time index j is omitted). The reference input, i.e., the input of the adaptive filter, consists of noise x. The signal s is assumed to be uncorrelated with both n_0 and x, while n_0 and x are assumed to be correlated with each other in some unknown way. n_0 is often referred to as the primary noise and x as the noise reference. In this approach, x is adaptively filtered to produce an output y which is then subtracted from the primary input d to produce the system output e (the recovered signal) where

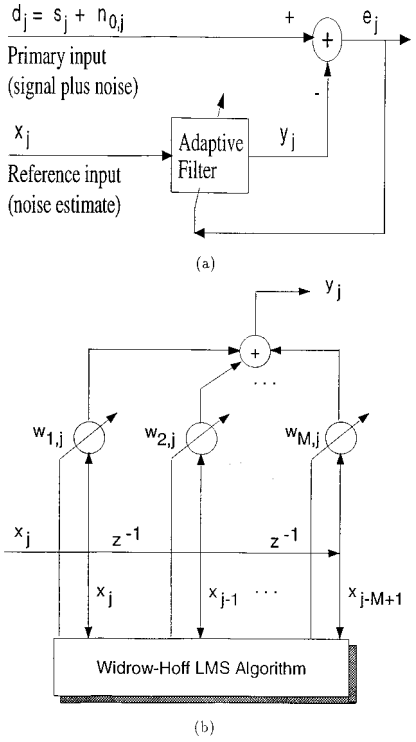

FIG. 2. Adaptive noise canceler: (a) block diagram; (b) tapped delay line.

$$e = s + n_0 - y. \tag{1}$$

From Eq. (1), it is observed that minimization of the mean-square error (MSE) $E[e^2]$ results from the minimization of $E[(n_0-y)^2]$, i.e.,

$$\min E[e^2] = E[s^2] + \min E[(n_0-y)^2] \tag{2}$$

and that smallest possible output power is $E[e^2]=E[s^2]$ when $E[(n_0-y)^2]=0$. In this case, the output y of the adaptive filter is a replica of the noise n_0 in the primary input and thus n_0 is completely eliminated and the output SNR is maximized.

The adaptive filter in Fig. 2(a) typically consists of a tapped delay line as depicted in Fig. 2(b). The output y_j, where j is the time index, is equal to the inner product of noise reference input vector X_j and filter coefficient vector W_j, each of length M, i.e.,

$$y_j = W_j^T X_j \tag{3}$$

and the general expression for the error signal as a function of weight vector is given by

$$e_j = d_j - y_j = d_j - W_j^T X_j \tag{4}$$

In the minimization of the MSE, when the true value of gradient (derivative of $\epsilon_j = E[e_j^2]$ with respect to filter coefficient vector W_j) is equated to zero, the steepest descent method (Widrow *et al.*, 1985) yields the form of the so-called Widrow–Hoff LMS algorithm

$$W_{j+1} = W_j + \mu e_j X_j, \tag{5}$$

where μ is the step size which controls the stability and rate of convergence. The larger the value of μ, the faster the algorithm converges and the more variable is the gradient estimate, and vice versa (Widrow *et al.*, 1976).

The magnitude-squared coherence function

$$\gamma_{pq}^2(e^{j\omega}) = \frac{|S_{pq}(e^{j\omega})|^2}{S_{pp}(e^{j\omega}) S_{qq}(e^{j\omega})} \tag{6}$$

is often used to measure the correlation between two stationary random processes p and q where S_{pq} is the cross-power spectral density of p and q, and S_{pp}, S_{qq} are the respective auto-power spectral densities.

When the filter output signal, e, is orthogonal to the noise reference data, x, the steepest-descent method converges to the optimal Wiener filter coefficients W^* and there are no further updates. On the other hand, in the steady state, the LMS algorithm continues to have updates. These fluctuations, called weight jitters, are about the optimal Wiener filter coefficients W^* and the LMS algorithm does not converge with unity probability. It can be shown that the mean of these updates converges to W^* under the assumption of stationarity of the input to the adaptive filter (Haykin, 1986). However, the MSE, ϵ, converges to a larger value than the optimal minimum mean square error, $\epsilon_{\min}$ (achieved with an optimal Wiener filter).

With the assumptions made in *independence theory* (Haykin, 1986), the necessary and sufficient condition for the convergence of LMS algorithm is that step-size parameter μ satisfies

$$0 < \mu < \frac{2}{\lambda_{\max}}, \tag{7}$$

where $\lambda_{\max}$ is the maximum eigenvalue of the autocorrelation matrix of the input to the filter, R_{MM}. In practice, the calculation of the individual eigenvalues of R_{MM} to find the upper limit of μ given by Eq. (7) is computationally very intensive. Under the stationarity assumption of the input to the filter, and positive definiteness of R_{MM},

$$\lambda_{\max} \leqslant \sum_{i=1}^{M} |\lambda_i| = \text{trace}(R_{MM}) = M\phi_x(0) = MP_x, \tag{8}$$

where P_x is the total power input to the adaptive filter, a generally known quantity. Thus in practice, a tighter bound is placed on the upper limit of μ and Eq. (7) becomes

$$0 < \mu < \frac{2}{MP_x}. \tag{9}$$

B. Normalized LMS (NLMS) algorithm

The LMS algorithm described in the previous section uses a constant step size μ. The stability, speed of convergence, and fluctuation of the adaptation process are governed by the step size μ and the input power to the adaptive filter P_x. The normalized LMS (NLMS) algorithm (Treichler *et al.*, 1987) represents a technique to improve the speed of convergence. This is accomplished while maintaining the steady-state performance independent of the input signal power. This NLMS algorithm uses a time variable convergence factor μ_j,

$$\mu_j = \frac{\alpha}{\xi + P_{x,j}}, \tag{10}$$

where α is the ''normalized'' step size chosen to be between 0 and 2, while ξ is a small positive term included to ensure that the update term does not become excessively large when the input average power at time j, $P_{x,j}$, becomes small. The NLMS algorithm gains its stability by normalizing the weight vector update with an estimate of the signal power. A computationally inexpensive way of obtaining this normalization is via recursive power estimation

$$P_{x,j+1} = (1-\beta)P_{x,j} + M\beta x_j^2, \tag{11}$$

where $0 < \beta \ll 1$ is a smoothing parameter and M is the filter length, with the NLMS algorithm weight vector update equation as

$$W_{j+1} = W_j + \mu_j e_j X_j. \tag{12}$$

C. Criteria for performance measures of adaptive algorithms

A study of the relationship between the speed of adaptation and performance of adaptive systems is complex since different choices of performance measures (often termed misadjustments) yield different ''optimized'' step sizes. To optimize the step size of the LMS algorithm and study its performance, the root-mean-squared (RMS) misadjustment, a performance measure similar to the temporal root-mean-squared MSE was used. This RMS misadjustment is defined as

$$\text{MRMS} = \left[\frac{\langle E[(s_j - e_j)^2] \rangle}{\langle E[s_j^2] \rangle} \right]^{1/2}, \tag{13}$$

where s_j is the lung sounds signal component and e_j is the output of the adaptive system (the recovered lung sounds). MRMS is a normalized root-mean-squared MSE and reflects the degree of the distortion of the desired signal introduced by the adaptive system.

Obviously, the optimal step-size parameter μ_* and the optimal filter length M_* that will yield a minimum MRMS is desired. In general, faster adaptation leads to a more noisy adaptive process. In a stationary environment, enhanced steady-state performance (smaller MRMS) results from a smaller value of the step size μ and thus a slower convergence. In a nonstationary environment however, a compromise has to be made between fast convergence necessary to track the changes in the input signal and slow adaptation needed to reduce the gradient noise (misadjustment). Thus

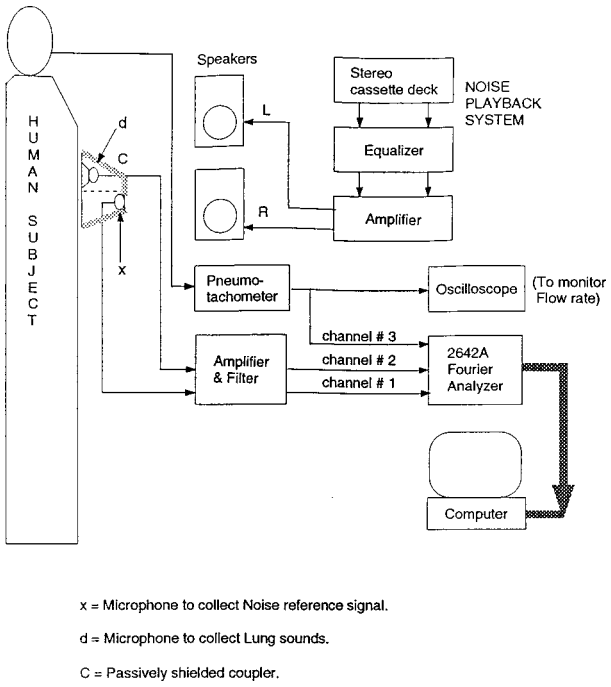

FIG. 3. Experimental apparatus.

the optimal value of μ is a compromise between a fast rate of convergence and a reduced misadjustment. Further, it can be shown that even for a stationary input, the misadjustment due to gradient noise, G, is proportional to μ (Haykin, 1986; Widrow *et al.*, 1976),

$$G = \mu M P_x, \tag{14}$$

and this relationship is used in this study to calculate the value of μ for given values of G, M, and P_x.

A performance measure that reflects the optimization of filter length M also must be chosen. As mentioned previously, the steady-state error signal e (the recovered breath sounds) and the reference data samples x used to obtain the minimum MSE (MMSE) estimate of the desired signal obeys orthogonality for the steepest descent method (and even for the optimal Wiener filter). Expanding upon this relationship, the cross correlation between the output error signal e and the reference noise x should attain some minimum value close to zero for the optimal filter length M_*. To quantitate this relationship, the correlation parameter COR was defined as

$$\mathrm{COR} \doteq \frac{1}{L} \sum_{j=1}^{L} e_j x_j. \tag{15}$$

As M increases, COR should decrease as relatively more and more uncorrelated data samples are taken into the estimation of the desired signal.

III. EXPERIMENTAL APPARATUS AND PROCEDURE

The primary goal of the experimentation was to record and process lung sounds in a simulated USAF C-130 aircraft environment. Figure 3 provides an overview of the experimental apparatus. The protocol was approved by the Purdue University Committee on the Use of Human Subjects. A subject was seated in a soundproof room that contained an audio system which played the recordings of USAF C-130 aircraft fuselage noise to simulate this environment. The subject breathed through a pneumotachograph (Fleisch #2) at target flow rates of 2 L/s. An experimenter held the stethoscope coupler on the subject's right anterior upper chest during the protocol. The signals from both microphones (d and x) were amplified by a factor of 32.5 and high-pass filtered using a fourth-order Butterworth filter at a cutoff frequency of 100 Hz. These signals and the pneumotachograph output were digitized at 5120 samples per second using a Tektronix Fourier Analyzer (2642A, with internal anti-aliasing filters) and stored on an IBM-PC compatible computer. Data segments of 20-s duration were recorded during breathing and apnea at aircraft noise levels of 80, 90, and 100 dB SPL, and also in the quiet room. In addition, noise measurements were made with the coupler placed on the subject's thigh. The stored digital epochs were subsequently processed with the adaptive noise reduction LMS and NLMS algorithms via MATLAB, where a detailed performance analysis was performed.

The signals d and x were also simultaneously input to a ''real-time'' implementation of one version of the LMS algorithm running on a digital signal processing board (AT-DSP2200, National Instruments) with a second IBM-PC compatible computer. The output of this algorithm was fed to an audio amplifier (DRA-345R, Denon) and presented to the experimenter within the chamber via a noise cancellation headset (AH-BG, Bose). Thus the experimenter could monitor the extracted lung sounds (from a specific realization of the algorithm) during the recording process, yet the focus of this study was on the off-line processing of the stored acoustic signals.

IV. RESULTS AND DISCUSSION

A. Characteristics of lung sounds and the interfering noise

Figure 4 depicts representative data collected in the quiet chamber. The pneumotachometer signal [Fig. 4(a)] is positive for inspiration and negative for expiration. Figure 4(b) is the corresponding lung sounds detected at microphone d. For all the plots of microphone measurements, 1 V corresponds to 3.1 Pa. The most clear and audible lung sounds occur for a flow rates above roughly 1 L/s. Figure 4(c) is the time record of the noise reference signal x, where some detection of breathing is observed during expiration due to airborne sounds from the mouth reaching the coupler. Figure 5 provides in the same format a representative data epoch in the presence of the high level noise. Here the measured (unprocessed) lung sounds are overwhelmed by the noise and hence are inaudible. The amplitude of the noise reference is less than that of the lung sounds detected in the presence of noise because the relatively high acoustic impedance of the air cavity in front of microphone d results in greater sound pressure levels measured as compared to microphone x which is essentially open to free space. An estimate of the power spectrum of both inspiratory lung sounds (from the microphone d signal detected during breathing in a quiet chamber) and aircraft noise (from the microphone d

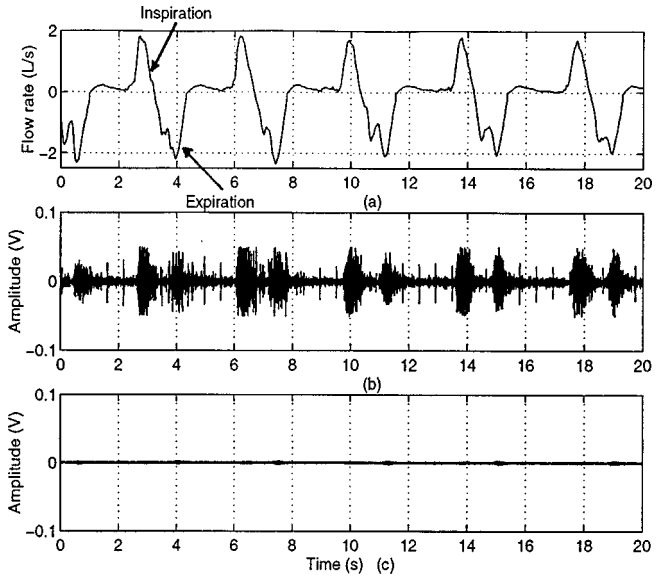

FIG. 4. Time record of (a) pneumotachometer, (b) microphone d (lung sounds), (c) microphone x (noise reference) signals in a quiet chamber.

signal during apnea in presence of 100 dB SPL of aircraft noise) is shown in Fig. 6. The majority of the energy in both signals is concentrated in the 100–600 Hz frequency range. This strong overlap in spectral content makes it particularly difficult to auscultate inside an aircraft. The coherence, as a measure of correlation between the noise reference x and the noise corrupting the lung sounds n_0, is depicted in Fig. 7. The valley in the coherence at just above 800 Hz corresponds to that in the aircraft noise spectra.

B. Performance analysis of the adaptive algorithms

To optimize and preliminary evaluate the processing schemes, the lung sound measurements (microphone d) made in the quiet chamber (signal, s) were first considered the pure desired signal. To this signal, s, the amplitude of the

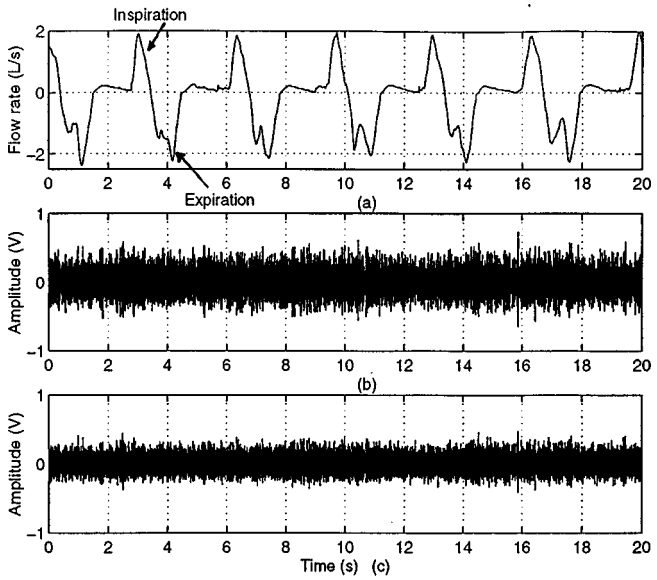

FIG. 5. Time record of (a) pneumotachometer, (b) microphone d (lung sounds), (c) microphone x (noise reference) signals in 100 dB SPL of aircraft noise.

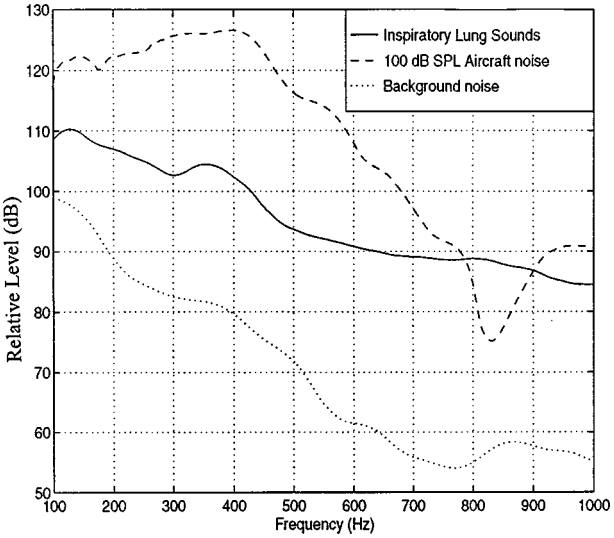

FIG. 6. Relative power spectra of aircraft noise, inspiratory lung sounds, and background noise in a quiet chamber.

aircraft noise detected by microphone d during nonbreathing with the stethoscope coupler on the right thigh was added to obtain a simulation of signal plus noise, $s+n_0$ for each of the respective noise levels. These generated $s+n_0$ data were input as the primary signal to the adaptive filter, with x as the noise reference signal, to analyze and optimize the performance of the algorithm. The resulting algorithms were then used to process actual experimental data. This initial data simulation stage was required since simultaneous recording of pure lung sounds and its corrupted version is not possible.

Some measures that were used to assess the algorithm were:

(1) Optimization of step size μ and filter length M: For the LMS algorithm, the values of μ were calculated using Eq. (14) for various values of gradient misadjustment G ranging from 0.01 to 1.0 and filter lengths M of 10, 20, and 40. With these values of M and the calculated values of μ,

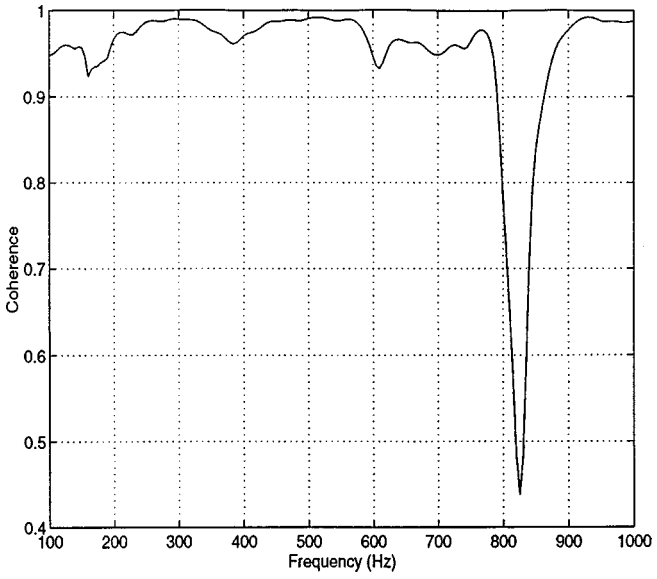

FIG. 7. Coherence estimate between the primary (microphone d) and the noise reference (microphone x) signals at 100 dB SPL of aircraft noise.

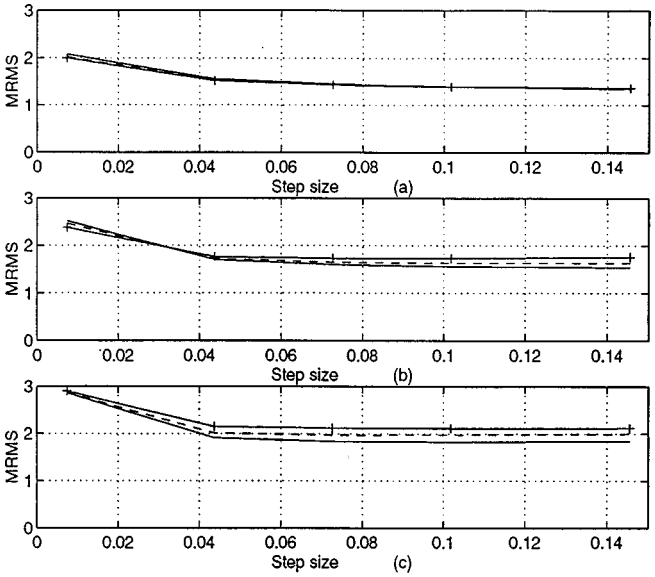

FIG. 8. For the LMS algorithm: Performance measure MRMS versus step size μ for filter length $M=10$ (———), $M=20$ (– – –), and $M=40$ (–+–) in (a) 80, (b) 90, and (c) 100 dB SPL of aircraft noise.

the LMS algorithm was implemented. For each case the performance measures of MRMS and COR were calculated. Figure 8 shows plots of MRMS versus μ for 80, 90, and 100 dB SPL noise levels which are generally consistent with theoretical predictions (Haykin, 1986; Widrow *et al.*, 1976). MRMS for 80 and 90 dB SPL of noise [Fig. 8(a), (b)] was a relatively weak function of μ, with increasing μ slightly increasing the MRMS as a reflection of G. The respective curves for 100 dB SPL of noise [Fig. 8(c)] exhibit the existence of ''optimal'' step-size parameter μ_* for which MRMS is a minimum. In the optimization of filter length M, the COR parameter was also taken into consideration. Plots of COR versus M (Fig. 9) show that in general a filter with a larger number of coefficients has a slightly lower COR.

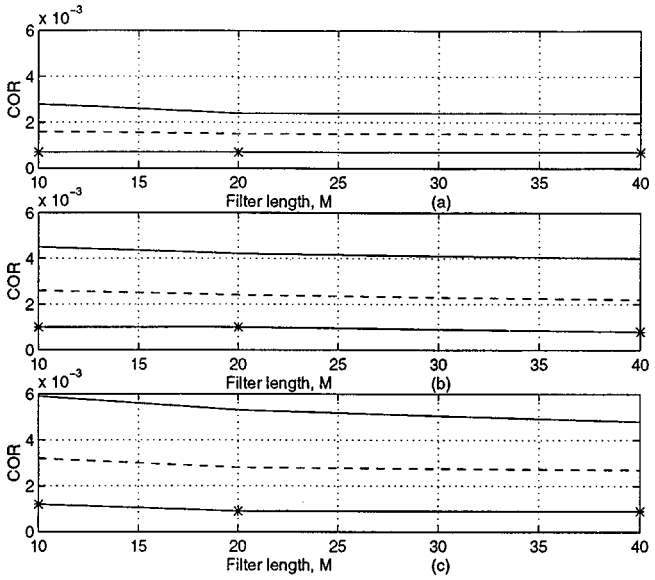

FIG. 9. For the LMS algorithm: Performance measure COR versus filter length M for step size $\mu=0.0073$ (———), $\mu=0.0146$ (– – –), and $\mu=0.0437$ (–*–) in (a) 80, (b) 90, and (c) 100 dB SPL of aircraft noise.

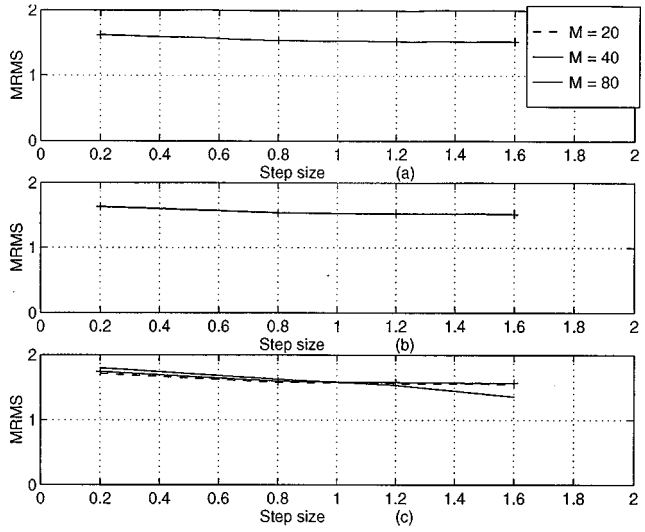

FIG. 10. For the NLMS algorithm: Performance measure MRMS versus step size α for filter length $M=20$ (– – –), $M=40$ (–+–), and $M=80$ (———). (a) 80, (b) 90, and (c) 100 dB SPL of aircraft noise.

When the filter length tends to an ''optimal'' value M_*, the value of COR does not change significantly thereafter. Thus from the perspective of implementation, the lowest value of M whereafter COR remains almost constant could be selected as the ''optimal'' value M_*. A similar evaluation of the NLMS algorithm was carried out for both the simulated and actual data for filter lengths M of 20, 40, and 80 with normalized step sizes α of 0.2, 0.8, 1.2, and 1.6. Plots of the performance measures for this case (Figs. 10 and 11) depict the existence of potentially optimal parameter settings. The MRMS for the NLMS algorithm (Fig. 10) is relatively lower than for the LMS algorithm because the use of a normalized dynamic step size drastically improves the tracking capability of the NLMS algorithm. Further, COR for the NLMS algorithm (Fig. 11) shows $M=40$ as an optimal filter length from an implementation perspective. This observation is similar to that made with the LMS algorithm.

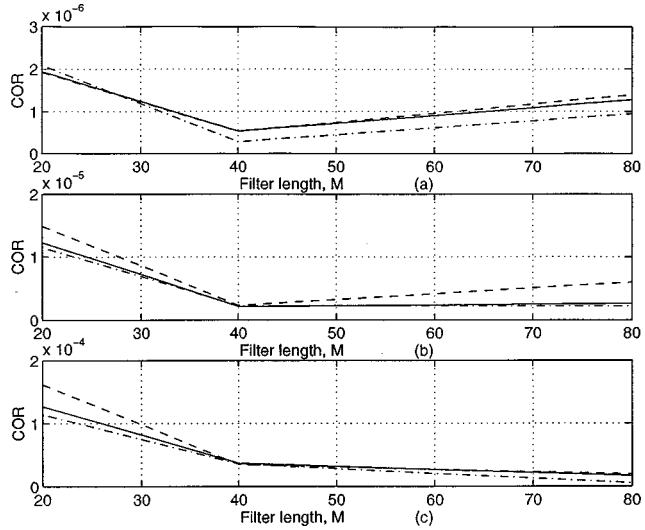

FIG. 11. For the NLMS algorithm: Performance measure COR versus filter length M for step size $\alpha=0.2$ (– – –), $\alpha=0.8$ (———), and $\alpha=1.2$ (–·–·–) *in* (*a*) 80, (*b*) 90, *and* (*c*) 100 *dB SPL of aircraft noise.*

TABLE I. SNR with the LMS algorithm ($M=40$ and $\mu=0.02$), and NLMS algorithm ($M=40$ and $\alpha=1.2$).

90	1.0 : 2.0	2.0 : 1	2.6 : 1
100	1.0 : 7.7	2.1 : 1	2.3 : 1

(2) Signal-to-noise ratio (SNR): In this study, the SNR (in linear form) at the input of the adaptive filter was conservatively defined as the square root of the ratio of variance of the microphone *d* signal when there is no aircraft noise for inspiratory flow rates >1 L/s, to that when the aircraft noise level is present at inspiratory flow rates <1 L/s. The SNR at the output of the adaptive filter was calculated as the square root of the ratio of variances of the recovered signal *e* during inspiratory flow rates >1 L/s to that during inspiratory flow rates <1 L/s. The difference of SNR at the input and output reflects a measure of the noise reduction capability of the configuration. Table I shows that higher SNR values are achieved at the output of the adaptive filter (both for the simulated and actual data) with NLMS algorithm than with the LMS algorithm, for essentially all cases.

C. Detailed performance comparison of LMS and NLMS algorithms

Figure 12(a) presents time records of typical lung sounds detected in a quiet chamber at microphone *d*. The lung sounds detected with microphone *d* and the reference noise detected at microphone *x* in the presence of 100 dB SPL aircraft noise are shown in Fig. 12(b) and (c), respectively. The recovered time series from the NLMS algorithm [Fig. 12(e)] is very similar to that of the pure lung sounds, with the misadjustment less than that of the LMS algorithm [Fig. 12(d)] due to the enhanced tracking ability of the NLMS algorithm. The speed of convergence is also much faster for the NLMS algorithm since it employs a normalized dynamic step size which renders the rate of convergence independent of the input signal power. The spectral features (Fig. 13) of the recovered lung sounds from the algorithms nearly overlap up to approximately 450 Hz, where the NLMS algorithm's recovered lung sounds more closely match the spectra of the pure lung sounds at higher frequencies. It can be inferred from Fig. 13 that roughly 15 dB of noise reduction is attained in 100 dB SPL of aircraft noise in the 100–600 Hz frequency range with LMS algorithm, while the NLMS algorithm provides up to 5 dB of additional noise reduction at frequencies above 450 Hz. The NLMS algorithm therefore affords higher noise reduction over wider bandwidth with a small amount of added computational complexity, and hence it is the algorithm of choice for the reduction of corrupting C-130 aircraft noise.

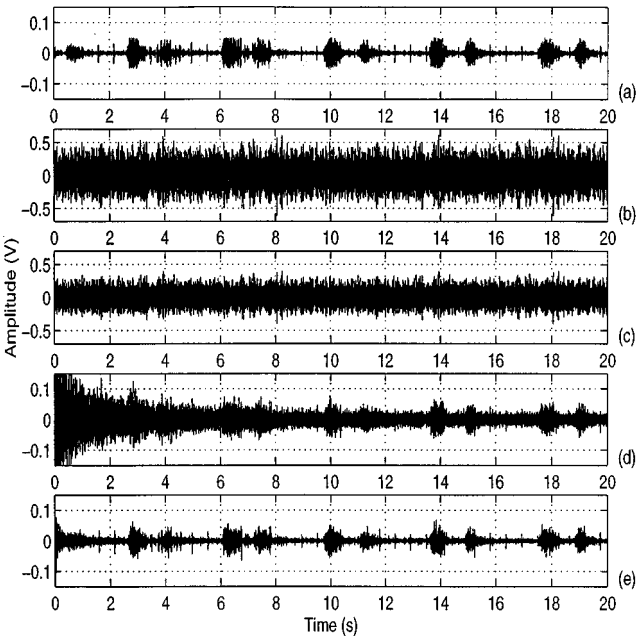

FIG. 12. For simulated data: Time record of (a) typical lung sounds in a quiet chamber, (b) noise corrupted lung sounds (microphone *d*) at 100 dB SPL of aircraft noise, (c) noise reference (microphone *x*) and recovered lung sounds with (d) LMS algorithm ($M=40$ and $\mu=0.02$), and (e) NLMS algorithm ($M=40$ and $\alpha=1.2$) ($1\,V=3.1$ Pa).

The recovered lung sounds for actual data are shown in Figs. 14 and 15, noting that the SNR is lower than that for the simulated case, as expected. This observation highlights the significance of the need for the reference noise (microphone *x*) to be highly correlated with the noise in the primary input (microphone *d*) to enhance the performance of the adaptive noise canceler. For the simulated data, the primary

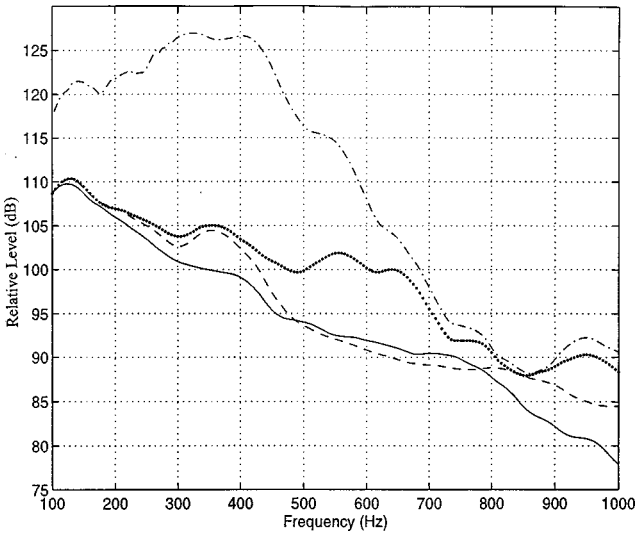

FIG. 13. For simulated data: Estimated relative power spectra of inspiratory lung sounds as measured in a quiet chamber (– – –), noise corrupted lung sounds at 100 dB SPL of aircraft noise (– · – · –), and recovered lung sounds from the LMS algorithm ($M=40$ and $\mu=0.02$) (···), and NLMS algorithm ($M=40$ and $\alpha=1.2$) (———).

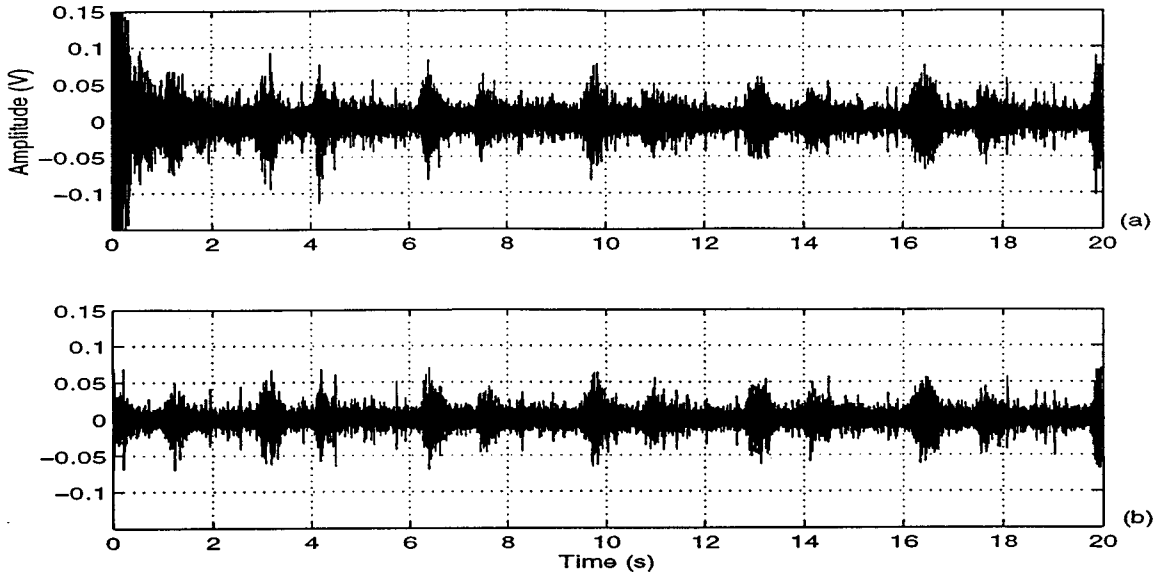

FIG. 14. For actual data: Time record of recovered lung sounds with (a) LMS algorithm ($M=40$ and $\mu=0.02$), (b) NLMS algorithm ($M=40$ and $\alpha=1.2$).

input was composed by adding the microphone d signal during apnea with the coupler placed on the thigh (in presence of the known level of the aircraft noise) to the pure lung sound signal (i.e., microphone d signal during breathing in a quiet chamber). Further, for processing of these simulated data, the same microphone d signal obtained during apnea in presence of the known level of the aircraft noise is used as the reference noise. Hence, for the simulated data, the correlation between the reference noise and the noise in the primary channel is perfect, whereas for the actual data, the primary input (microphone d) and reference noise (microphone x) signals are obtained using two different microphones. Here, the correlation between the primary input and the reference noise is governed by the transfer function between the physical locations of microphones d and x inside the stethoscope coupler. The trade-off in acoustic isolation of these microphones is to collect a reference noise signal that is least ''corrupted'' by the lung sounds and highly correlated with the noise component in the primary input. Thus the adaptive filter algorithm for the simulated data provides a better estimate of the noise in the primary input and hence results in a recovered lung sounds of higher fidelity as compared to those obtained for the actual data.

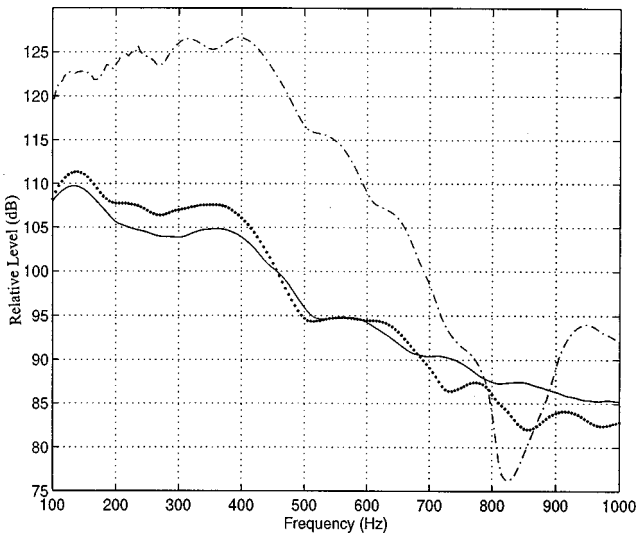

FIG. 15. For actual data: Estimated relative power spectra of noise corrupted lung sounds at 100 dB SPL of aircraft noise (– · – · –), and recovered lung sounds from the LMS algorithm ($M=40$ and $\mu=0.02$) (···), and NLMS algorithm ($M=40$ and $\alpha=1.2$) (———).

V. CONCLUSIONS

In patient transport vehicles, high ambient noise has significant spectral overlap with lung sounds, making lung sounds inaudible through a standard stethoscope and limiting the utility of conventional amplification and filtering techniques. Passive noise reduction techniques such as a coupler housing help to shield the lung sounds from high-frequency noise corruption. An adaptive noise reduction system implemented using a digital adaptive filter employing the LMS or NLMS algorithms significantly reduces the corruptive effects of low frequency noise. The proposed performance criteria of MRMS and COR are useful to determine algorithm parameters, such as convergence factor and filter length for the LMS approach. Approximately 15 dB of noise reduction over a 100–600 Hz frequency range was achieved by the LMS approach, with the somewhat more complex NLMS algorithm yielding faster convergence and up to an additional 5 dB of noise reduction. Further studies on patients during actual medical evacuation are required to refine this technology and determine the scope of its clinical utility under various breathing and noise conditions.

Projection data error estimation and correction for high-resolution tomographic acoustic microscopy

Richard Y. Chiao,[a] Davis Kent, and Hua Lee
Department of Electrical and Computer Engineering, University of California, Santa Barbara, California 93106

(Received 30 June 1995; accepted for publication 15 January 1998)

In scanning tomographic acoustic microscopy (STAM), projection error correction is necessary for high-resolution tomographic reconstruction. In this paper, both phase and alignment errors are examined. These errors arise from several sources, including the quadrature receiver channels, the unknown initial phase term, and any misalignment in the rotational scan. The data acquisition process and the image formation algorithm for the STAM are reviewed, and a description of error estimation and correction is also presented. Experimental results from the STAM are included to demonstrate the capability and effectiveness of the error-removal techniques. © *1998 Acoustical Society of America.* [S0001-4966(98)02005-0]

INTRODUCTION

The scanning tomographic acoustic microscope (STAM) is a scanning laser acoustic microscope (SLAM) enhanced with tomographic reconstruction capability. The SLAM system is a transmission mode acoustic microscope that employs continuous wave insonification.[1] It was developed for high-resolution, real-time imaging in nondestructive testing and biomedical tissue analysis.[2] At an operating frequency of 100 MHz, the SLAM is capable of producing high-resolution images of thin (relative to the acoustic wavelength) specimens. When thick specimens are imaged, resolution is degraded due to diffraction and the overlapping of different depth planes.[3]

In order to achieve high-resolution subsurface imaging for thick objects, the data acquisition system of the SLAM was modified by the addition of a quadrature receiver for the detection of the complex wave field distribution.[4] With the complex wave field, the effects of diffraction can be compensated through numerical holographic reconstruction,[5] and tomographic reconstruction can be performed by coherent superposition of holographic images.[6]

The detection of the phase information, combined with the tomographic summation process, gives the STAM a superior imaging capability as compared with the SLAM. During the tomographic image formation process, data errors occur in various forms at various stages of the operation. In this paper, we study the data errors from the quadrature receiver channels, illumination initial phase variation among projections, and alignment error associated with the rotational scan. Subsequently, we present error estimation and removal techniques for resolution enhancement.

In Sec. I we review the basic data acquisition process of the SLAM and the tomographic reconstruction algorithm. The quadrature data error is examined in Sec. II. The degradation due to the error terms is modeled and observed by experiments, and subsequently an algorithm is developed to estimate and remove the phase error. In Sec. III the illumination phase error is studied. With the phase errors corrected, tomographic reconstruction becomes effective and can be well demonstrated with experimental results of multiple-frequency tomography. In Sec. IV, the projection registration problem in tomographic superposition is discussed and correction schemes are implemented for multiple-angle tomographic reconstruction.

I. STAM DATA ACQUISITION AND RECONSTRUCTION

In this section, the data acquisition process of the SLAM is briefly reviewed and the tomographic image reconstruction algorithm is presented. Figure 1(a) and (b) shows the modified SLAM data acquisition system with the SLAM receiver replaced by the quadrature receiver. The object plane is located at z_0, the incident planar wave field is denoted by $u(x,y,z)$, and the transmitted wave field is $v(x,y,z)$. After being modulated by the specimen, the transmitted wave field causes dynamic surface ripples on the gold-plated coverslip.[7] A laser beam is raster scanned over the reflective surface to detect the wave field information. At each position in the raster scan, the laser beam is angularly deflected by the surface ripples. The instantaneous angular deflection is converted to an intensity signal by a knife-edge detector.[7] At this point the spatial wave field distribution is encoded in a temporal intensity-modulated laser signal. A photodetector placed after the knife edge converts the laser light signal into an electrical signal, which is then fed into the quadrature receiver.[4] The output of the quadrature receiver is digitized for computer processing.

The insonification wave can be written as

$$u(x,y,z)=a_0\ \exp(j2\pi(f_{xi}x+f_{yi}y+f_{zi}z)), \tag{1}$$

where a_0 is the amplitude of the plane wave and f_{xi}, f_{yi}, f_{zi} are the spatial frequencies of the plane wave. The spatial frequencies depend on the insonification angle of the plane wave as well as the acoustic wavelength. At the object plane $z=z_0$, the wave field is modulated by the object transmit-

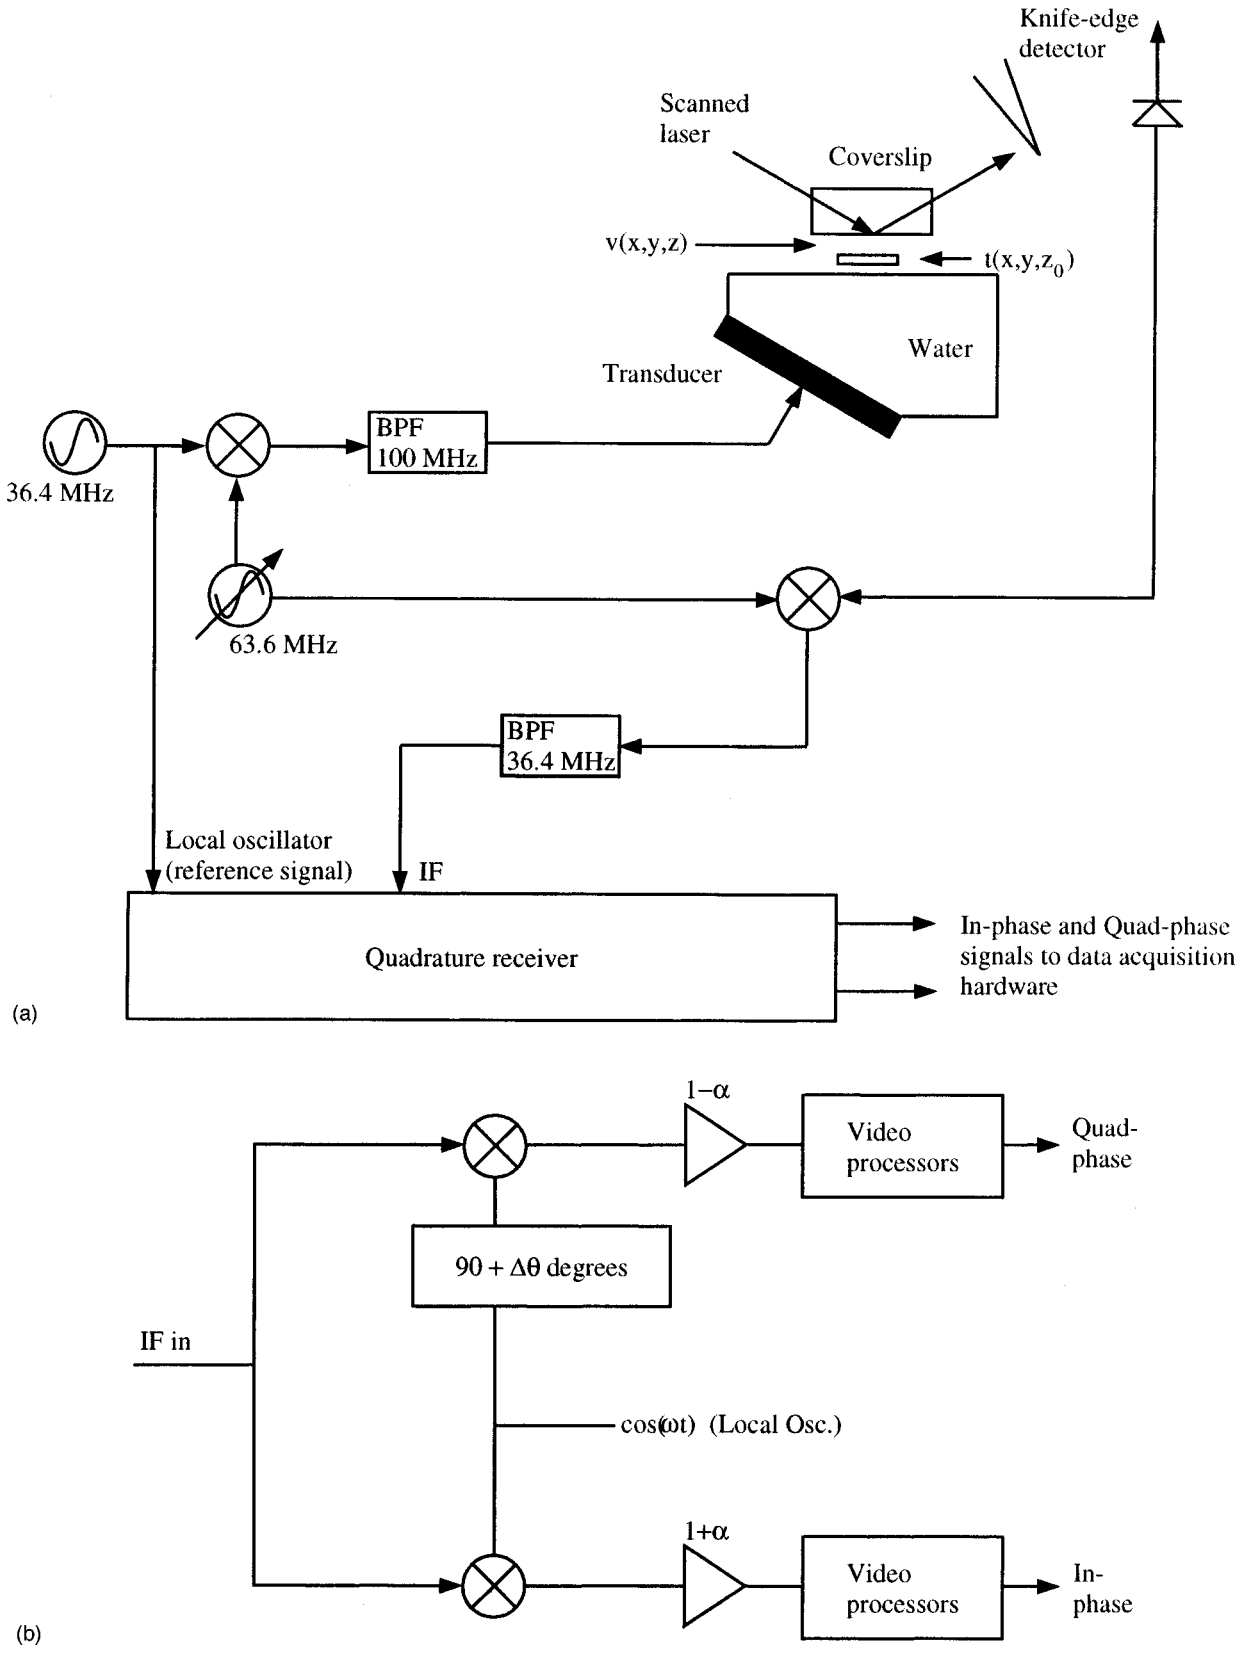

FIG. 1. (a), (b) SLAM data acquisition system.

tance $t(x,y)$, and the transmitted wave field is given by

$$v(x,y,z_0)=u(x,y,z_0)t(x,y). \tag{2}$$

In the Fourier domain Eq. (2) can be written as

$$V(f_x,f_y;z_0)=a_0\ \exp(j2\pi f_{zi}z_0)T(f_x-f_{xi},f_y-f_{yi}). \tag{3}$$

Thus the transmitted wave field is proportional to the object transmittance function modulated by f_{xi} and f_{yi}. The wave

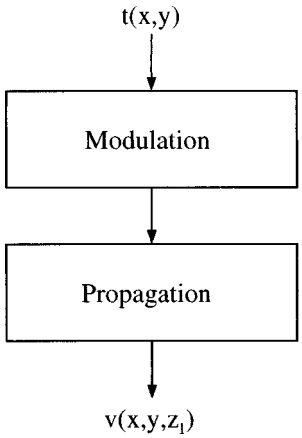

FIG. 2. Block diagram for the data acquisition process.

field $v(x,y,z_1)$ detected at the receiving plane is related to $v(x,y,z_0)$ by

$$V(f_x,f_y;z_1)=V(f_x,f_y;z_0)H(f_x,f_y;z_1-z_0), \tag{4}$$

where $V(f_x,f_y)$ is the Fourier transform of $v(x,y)$, and H is the propagation transfer function given by

$$H(f_x,f_y;z_1-z_0)=\begin{cases}\exp\left[j2\pi(z_1-z_0)\left(\frac{1}{\lambda^2}-f_x^2-f_y^2\right)^{1/2}\right], & f_x^2+f_y^2<\frac{1}{\lambda^2},\\ 0, \quad \text{otherwise,}\end{cases} \tag{5}$$

where λ is the acoustic wavelength. The propagation transfer function is a low-pass function because of the loss of evanescent waves. Figure 2 is the block diagram for the data acquisition process.

In tomographic processing, projections with different insonification angles or acoustic wavelengths are combined to construct the tomographic image. For multiple-angle tomography, f_{xi}, f_{yi}, and f_{zi} vary between projections, and for multiple-frequency tomography, λ varies between projections. Given a set of N projections $v_k(x,y,z_1)$, $k=1,2,...,N$ the subsurface plane $t(x,y)$ can be reconstructed using the backward propagation algorithm. The reconstruction equation for the algorithm is given by

$$\hat{t}(x,y)=\frac{\Sigma_{k=1}^{N}\, u_k^*(x,y,z_0)v_k(x,y,z_0)}{\Sigma_{k=1}^{N}\,|u_k(x,y,z_0)|^2}, \tag{6}$$

which is the least-squares estimate of the object transmittance given the incident wave field and the scattered wave field.[6,8]

To implement Eq. (6), it is necessary to obtain the incident wave field and the transmitted wave field at the plane of interest. One approach is to record the received wave field with and without the specimen. The transmitted wave field at the object plane, $v(x,y,z_0)$, can be estimated by backpropagating the received wave field with the specimen present

$$\hat{V}(f_x,f_y;z_0)=V(f_x,f_y;z_1)H(f_x,f_y;-(z_1-z_0)), \tag{7}$$

and the incident wave field at the object plane can be obtained by backpropagating the received wave field without the specimen. The above method requires two complex wave fields to be recorded for each projection. Alternatively, we can accurately approximate the incident wave field by a plane wave, and obtain

$$\hat{t}(x,y)=\sum_{k=1}^{N}\frac{1}{a_0^{(k)}}\hat{v}_k(x,y,z_0)\exp(-j2\pi(f_{xi}^{(k)}x+f_{yi}^{(k)}y+f_{zi}^{(k)}z_0)), \tag{8}$$

where the k subscripts and superscripts are for different projections. Since the transmitted wave field $\hat{v}(x,y,z_0)$ is modulated by $f_{xi}^{(k)}$, $f_{yi}^{(k)}$, and $f_{zi}^{(k)}$, multiplication by $\exp(-j2\pi(f_{xi}^{(k)}x+f_{yi}^{(k)}y+f_{zi}^{(k)}z_0))$ in Eq. (8) corresponds to demodulation. Consequently, the image formation algorithm can be implemented by superimposing the backpropagated, demodulated, and normalized projections, $w_k(x,y)$, such that

$$\hat{t}(x,y)=\sum_{k=1}^{N}w_k(x,y), \tag{9}$$

where

$$w_k(x,y)=\frac{1}{u_0^{(k)}}\hat{v}_k(x,y,z_0)\exp(-j2\pi(f_{xi}^{(k)}x+f_{yi}^{(k)}y)), \tag{10}$$

and $u_0=a_0\exp(j2\pi f_{zi}z_0)$. Using Eqs. (2), (4), and (7) in Eq. (10), we formulate it as

$$W_k(f_x,f_y)=\begin{cases}T(f_x,f_y), & (f_x+f_{xi}^{(k)})^2+(f_y+f_{yi}^{(k)})^2<1/\lambda_k^2,\\ 0, & \text{otherwise,}\end{cases} \tag{11}$$

which shows that each projection recovers spatial frequencies of the unknown object transmittance within a circular region centered at $(-f_{xi}^{(k)},-f_{yi}^{(k)})$. The superposition of different projections improves the signal-to-noise ratio as well as the resolution by extending the spectral coverage. In practice, there exists significant information redundancy between the projections which can be utilized for error estimation and correction.

II. QUADRATURE PHASE ERROR ESTIMATION AND CORRECTION

In tomographic acoustic microscopy, the first type of phase error occurs during data acquisition, in the quadrature receiver channels. The phase error can be due to either noise fluctuations or crosstalk in the receiver, and it causes significant degradation in the tomographic reconstruction. Here, we first model the phase error as a spatially varying quantity and derive observable effects of the error in a single tomographic projection. Subsequently, an algorithm is developed to estimate the phase error, and the data are then corrected. Finally, we apply the algorithm to experimental data and verify the reduction in phase error and image degradation.

A. Phase error model

From Eq. (4), we denote the received wave field as

$$v(x)=a(x)\exp(j2\pi f_{xi}x), \tag{12}$$

where we remove the y dependence for notational convenience, and $a(x)$ is given by

$$a(x)=F^{-1}\{u_0T(f_x)H(f_x-f_{xi};z_1-z_0)\}, \tag{13}$$

where F^{-1} is the inverse Fourier transform operator. Ideally, the quadrature receiver detects

$$p_r(x)=\text{Real}\{a(x)\exp(j2\pi f_{xi}x)\}$$
$$=|a(x)|\cos(2\pi f_{xi}x+\phi(x)) \tag{14a}$$

and

$$p_i(x)=\text{Im}\{a(x)\exp(j2\pi f_{xi}x)\}$$
$$=|a(x)|\sin(2\pi f_{xi}x+\phi(x)), \tag{14b}$$

where $p_r(x)$ and $p_i(x)$ are the real and imaginary components, respectively, of the wave field present on the coverslip. In practice, a relative phase error, $\Delta\theta(x)$, causes the two output components of the quadrature receiver to become

$$p_r'(x)=|a(x)|\cos(2\pi f_{xi}x+\phi(x)-\Delta\theta(x)/2) \tag{15a}$$

and

$$p_i'(x)=|a(x)|\sin(2\pi f_{xi}x+\phi(x)+\Delta\theta(x)/2). \tag{15b}$$

As a result, the actual recorded wave field is

$$p'(x)=p_r'(x)+jp_i'(x)$$
$$=\cos(\Delta\theta(x)/2)a(x)\exp(j2\pi f_{xi}x)$$
$$+\sin(\Delta\theta(x)/2)a^*(x)\exp(-j2\pi f_{xi}x). \tag{16}$$

Equation (16) shows that the phase error introduces an additional spectral component centered at $-f_{xi}$. The effect of the phase error can be observed by examining the intensity of the recorded wave field

$$|p'(x)|^2=|a(x)|^2+|a(x)|^2\ \sin(\Delta\theta(x))$$
$$\times\sin(4\pi f_{xi}x+2\phi(x)), \tag{17}$$

where the phase error introduces a background fringe pattern with spatial frequency $2f_{xi}$ in the detected wave field.

B. Phase error estimation

To obtain an estimate of the phase error $\Delta\theta(x)$, we first write Eq. (14) as

$$p_r'(x)=\tfrac{1}{2}e^{-j\Delta\theta(x)/2}a(x)\exp(j2\pi f_{xi}x)$$
$$+\tfrac{1}{2}e^{j\Delta\theta(x)/2}a^*(x)\exp(-j2\pi f_{xi}x) \tag{18a}$$

and

$$p_i'(x)=\frac{1}{j2}\,e^{j\Delta\theta(x)/2}a(x)\exp(j2\pi f_{xi}x)$$
$$-\frac{1}{j2}\,e^{-j\Delta\theta(x)/2}a^*(x)\exp(-j2\pi f_{xi}x). \tag{18b}$$

Since a relative phase error cannot be simply estimated from a pair of real numbers, it is not possible to use the outputs of the quadrature receiver to directly estimate the phase error. Instead, we take the single side band of the quadrature receiver outputs. Equation (18) then becomes

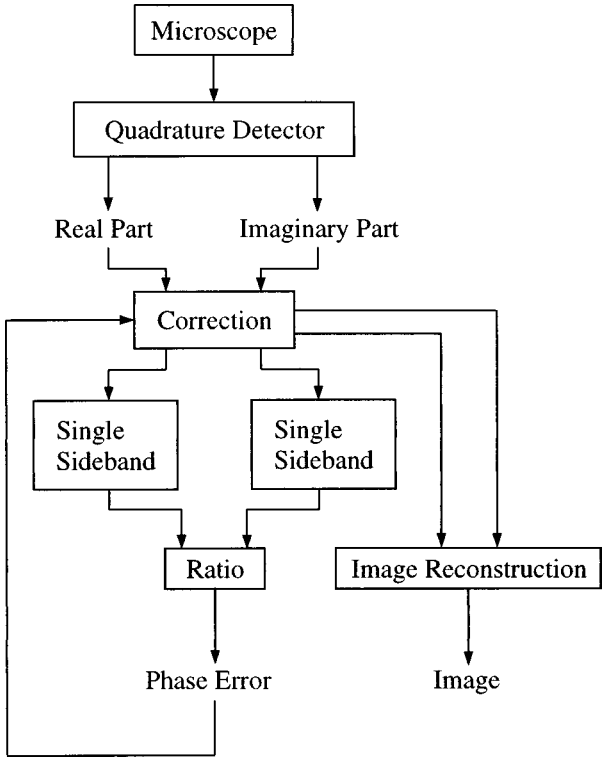

FIG. 3. Block diagram for the recursive quadrature error correction algorithm.

$$p_{r+}'(x)=\tfrac{1}{2}e^{-j\Delta\theta(x)/2}a(x)\exp(j2\pi f_{xi}x) \tag{19a}$$

and

$$p_{i+}'(x)=\frac{1}{j2}\,e^{j\Delta\theta(x)/2}a(x)\exp(j2\pi f_{xi}x), \tag{19b}$$

where the + subscript denotes the positive side band. Subsequently, the phase error can be estimated as

$$e^{j\Delta\theta(x)}=\frac{jp_{i+}'(x)}{p_{r+}'(x)}. \tag{20}$$

Normally, we use only the upper side band to estimate the phase error for better signal-to-noise ratio. In theory, the lower side bands can also be used to improve the phase error estimate.

C. Wave field correction

To derive the correction operation, we first consider the data pair

$$p_r'=A\ \cos(\alpha-\beta),\quad p_i'=A\ \sin(\alpha+\beta), \tag{21}$$

where α and β are constants. We wish to obtain the corrected data in the form of

$$\hat{p}_r=A\ \cos(\alpha),\quad \hat{p}_i=A\ \sin(\alpha). \tag{22}$$

Rearranging Eqs. (21) and (22), we obtain the matrix relationship

$$\begin{bmatrix}p_r'\\ p_i'\end{bmatrix}=\begin{bmatrix}\cos(\beta) & \sin(\beta)\\ \sin(\beta) & \cos(\beta)\end{bmatrix}\begin{bmatrix}\hat{p}_r\\ \hat{p}_i\end{bmatrix}. \tag{23}$$

The correction matrix operation is then in the form of

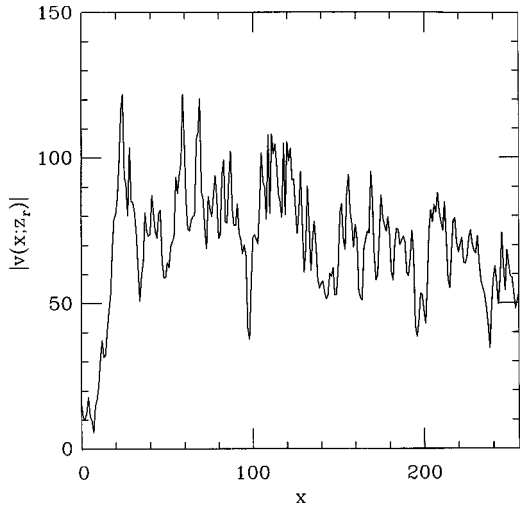

FIG. 4. Magnitude of a complex data sequence from the SLAM.

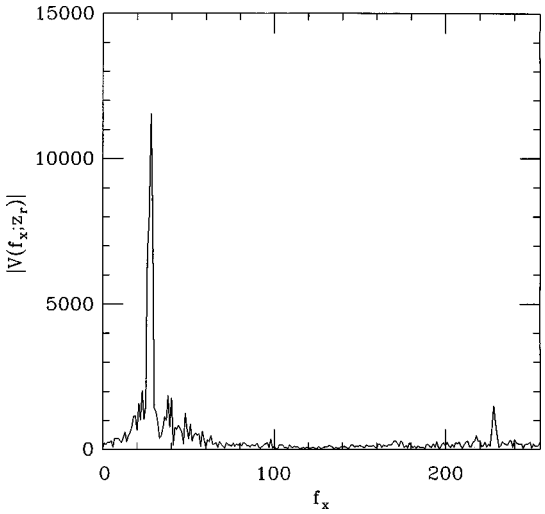

FIG. 5. Magnitude of the spectrum of the complex sequence.

$$\begin{bmatrix}\hat{p}_r\\ \hat{p}_i\end{bmatrix}=\begin{bmatrix}\cos(\beta) & \sin(\beta)\\ \sin(\beta) & \cos(\beta)\end{bmatrix}^{-1}\begin{bmatrix}p_r'\\ p_i'\end{bmatrix}$$
$$=\frac{1}{\cos(2\beta)}\begin{bmatrix}\cos(\beta) & -\sin(\beta)\\ -\sin(\beta) & \cos(\beta)\end{bmatrix}\begin{bmatrix}p_r'\\ p_i'\end{bmatrix}. \tag{24}$$

Letting $\beta=\Delta\theta(x)/2$, we can obtain the corrected signal for each position x

$$\begin{bmatrix}\hat{p}_r(x)\\ \hat{p}_i(x)\end{bmatrix}=\frac{1}{\cos(\Delta\theta(x))}\times\begin{bmatrix}\cos(\Delta\theta(x)/2) & -\sin(\Delta\theta(x)/2)\\ -\sin(\Delta\theta(x)/2) & \cos(\Delta\theta(x)/2)\end{bmatrix}\begin{bmatrix}p_r'(x)\\ p_i'(x)\end{bmatrix}. \tag{25}$$

As previously stated, the accuracy of the error estimate is governed by the variation of the phase error. For phase error variation with significant bandwidth, the error may not be completely removed in a single step. Therefore, for these cases, an iterative process is applied. The phase error is reduced at each iteration, and the algorithm terminates when the error reaches an acceptable level. Figure 3 shows the block diagram of the recursive correction algorithm.

D. General case

To simplify the derivation for the phase error estimator presented in Sec. II B, the amplitudes of the quadrature signals were assumed to be ideal. In practice, the amplitude is also contaminated by error and this will affect the phase error estimation. For the general case where both the magnitude and phase error are present, the signal model corresponding to Eq. (15) becomes

$$p_r'(x)=(|a(x)|\mp|\Delta a(x)/2|)\cos(2\pi f_{xi}x+\phi(x)-\Delta\theta(x)/2), \tag{26a}$$

$$p_i'(x)=(|a(x)|\pm|\Delta a(x)/2|)\sin(2\pi f_{xi}x+\phi(x)+\Delta\theta(x)/2), \tag{26b}$$

where $\Delta a(x)$ is the relative magnitude error between the real and imaginary components. The estimation and correction for the general case is similar to Eq. (25). With slight modification to the ideal magnitude case, the general case correction is

$$\begin{bmatrix}p_r(x)\\ p_i(x)\end{bmatrix}=\frac{1}{\det}\begin{bmatrix}\left(1+\frac{\alpha(x)}{2}\right)\cos(\Delta\theta(x)/2) & -\left(1-\frac{\alpha(x)}{2}\right)\sin(\Delta\theta(x)/2)\\ -\left(1+\frac{\alpha(x)}{2}\right)\sin(\Delta\theta(x)/2) & \left(1-\frac{\alpha(x)}{2}\right)\cos(\Delta\theta(x)/2)\end{bmatrix}\begin{bmatrix}p_r'(x)\\ p_i'(x)\end{bmatrix}, \tag{27}$$

where

$$\det=\left[1-\left(\frac{\alpha(x)}{2}\right)^2\right]\cos(\Delta\theta(x)). \tag{28}$$

E. Experimental results

The algorithm of Sec. D was applied to experimental data from the SLAM. Figures 4 and 5 show the magnitude of a complex data sequence from the SLAM and its corresponding spectrum, respectively. The small peak in the lower side band is due to the phase error, as predicted by Eq. (11). Figure 6 shows the estimate of the phase error distribution of the wave field data sample sequence, while Fig. 7 presents the magnitude of the corrected complex data sequence. Figure 8(a)–(c) shows the phase error after one, three, and five iterations, respectively, to demonstrate the effectiveness of the algorithm.

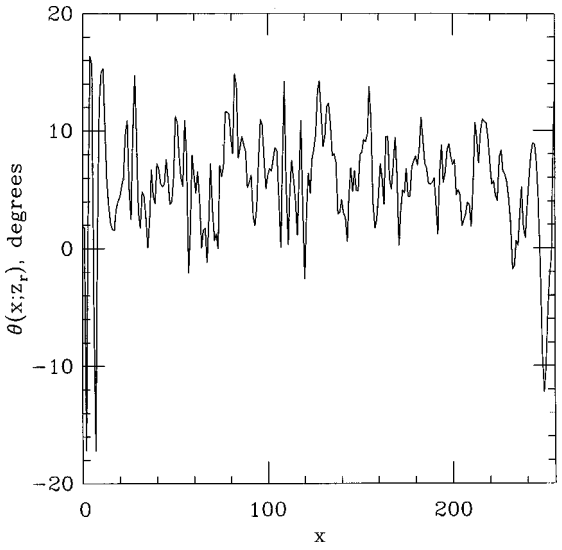

FIG. 6. Estimate of the phase error distribution.

III. INITIAL PHASE CORRECTION

An additional cause of degradation in the tomographic reconstruction is the presence of an unknown phase offset between projections. The phase offset can be due to the initial phase of the illumination wave field of each projection or velocity changes in the water coupler due to temperature fluctuations. In this section, we examine the initial phase error between projections. We first model the phase error in the received wave field, then derive an algorithm to estimate the phase error using the overlapping region of the spectrum of two projections. Finally, we present experimental results to demonstrate the effectiveness of the algorithm.

A. Initial phase model and estimation

To estimate the relative phase offset in tomographic projections, we first rewrite Eq. (11) as follows:

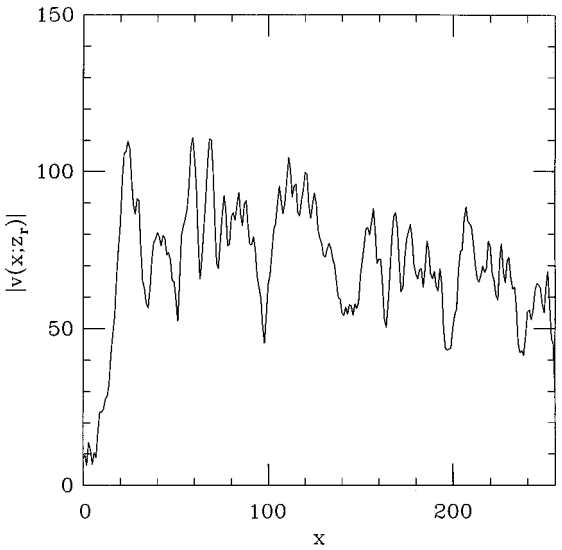

FIG. 7. Magnitude of corrected complex data sequence.

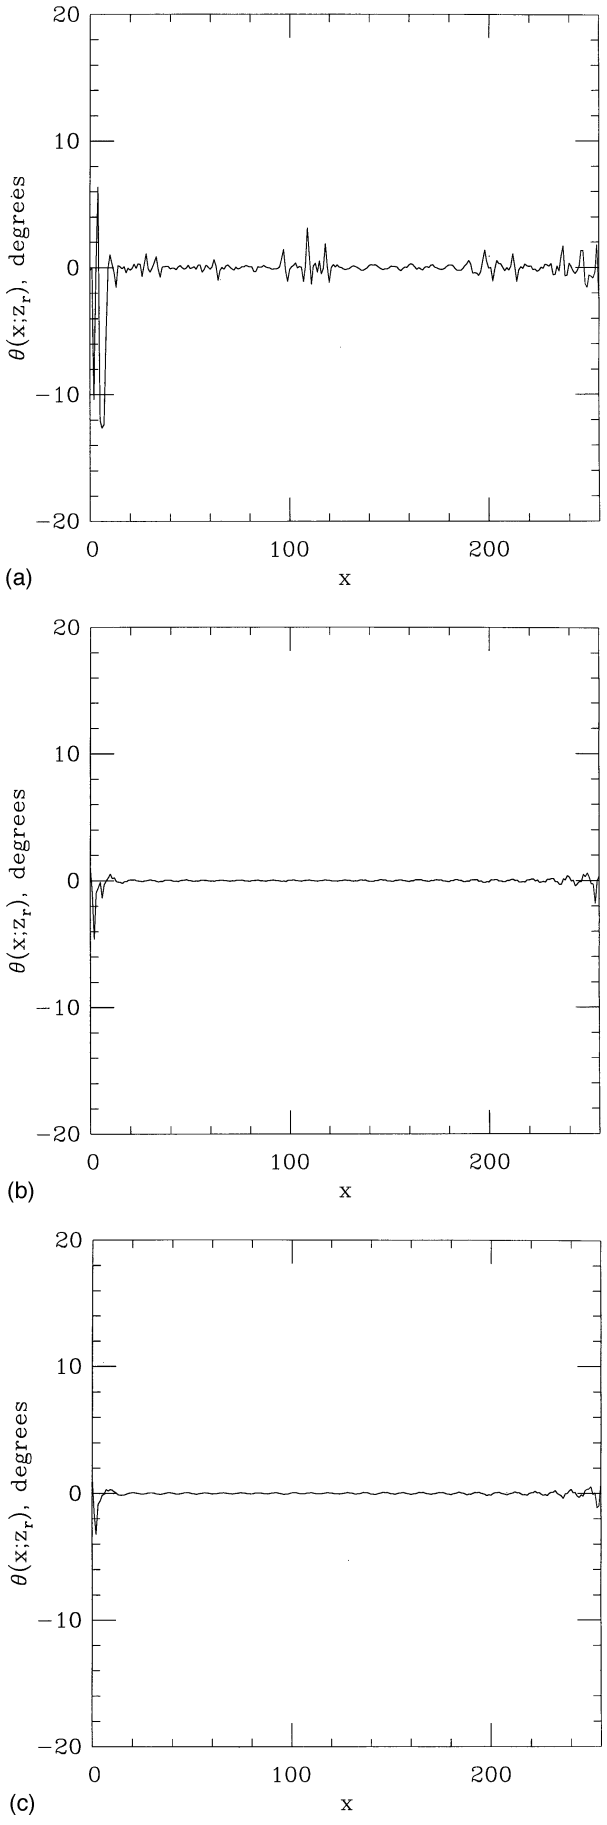

FIG. 8. (a)–(c) Phase error distribution after 1, 3, and 5 iterations.

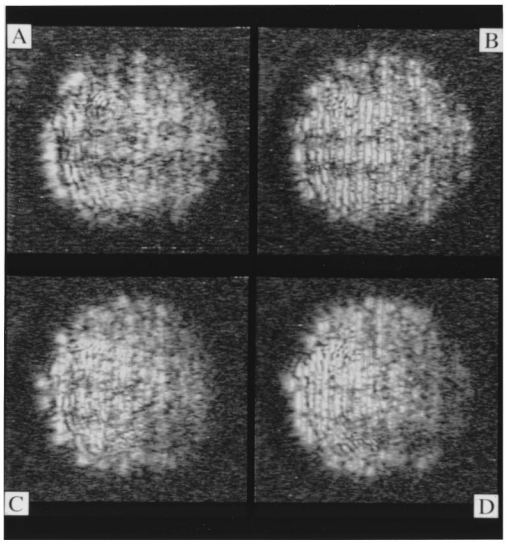

FIG. 9. (A)–(D) Magnitude images of even frequency projections.

$$W_k(f_x,f_y) = \begin{cases} \exp(j\Omega_k)T(f_x,f_y), & (f_x+f_{xi}^{(k)})^2+(f_y+f_{yi}^{(k)})^2<1/\lambda_k^2, \\ 0, \quad \text{otherwise} \end{cases} \tag{29}$$

where Ω_k is the unknown initial phase. Notice that $W(f_x,f_y)$ is nonzero only within a circular passband due to wave propagation, which is different for each projection. For multiple-angle projections, the passbands are centered at different locations, and for multiple-frequency projections, the radii of the passbands also change. The overlapping region of the passbands allows estimation of the phase offset between projections. Using Eq. (29), the phase offset between two projections m and n is expressed as

$$W_m(f_x,f_y)=\exp(j(\Omega_m-\Omega_n))W_n(f_x,f_y) \tag{30}$$

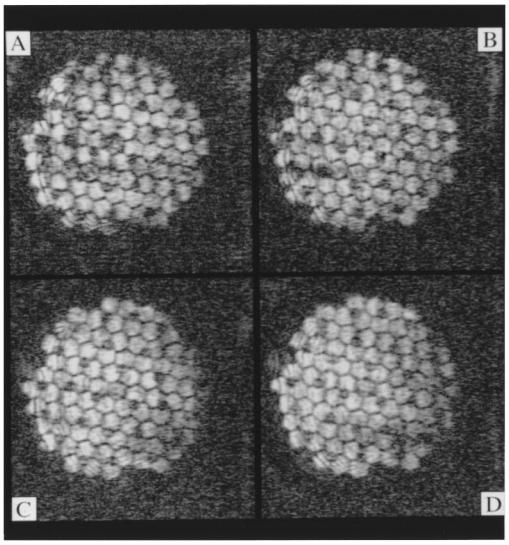

FIG. 10. (A)–(D) Magnitude images of backpropagated and demodulated projections.

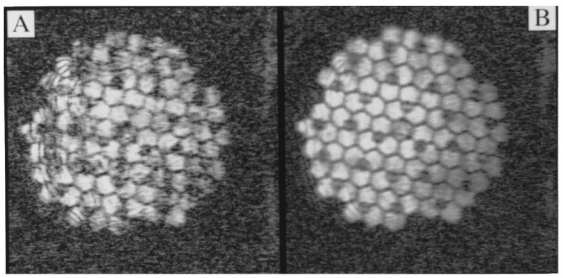

FIG. 11. (A), (B) Multiple-frequency tomographic reconstructions without and with phase correction.

which is valid for f_x and f_y in the overlapping region Γ of the passbands of $W_m(f_x,f_y)$ and $W_n(f_x,f_y)$. The least-squares estimate of $\exp(j(\Omega_m-\Omega_n))$ is computed from Eq. (30) as

$$\exp(j(\Omega_m-\Omega_n))=\frac{\int_\Gamma\int W_n^*(f_x,f_y)W_m(f_x,f_y)df_x\,df_y}{\int_\Gamma\int|W_n(f_x,f_y)|^2df_x\,df_y}. \tag{31}$$

Substituting Eq. (30) in the denominator of Eq. (29) yields as

$$\exp(j(\Omega_m-\Omega_n))=\frac{\int_{-\infty}^{\infty}\int W_n^*(f_x,f_y)W_m(f_x,f_y)df_x\,df_y}{\int_{-\infty}^{\infty}\int|W_n(f_x,f_y)||W_m(f_x,f_y)|df_x\,df_y}. \tag{32}$$

B. Experimental results

The algorithm of Sec. A is applied to four tomographic projections from the SLAM with insonification frequencies of 97 to 103 MHz, with a 2-MHz spacing. Figure 9(A)–(D) shows the magnitude images of the frequency projections. The field of view is 2 mm by 2 mm. The specimen is a honeycomb test grid located 0.5 mm beneath the detection plane ($z_1-z_0=0.5$ mm). Figure 10(A)–(D) shows the magnitude images of the backpropagated and demodulated wave fields. Figure 11(A) and (B) presents the tomographic superposition of the four images of Fig. 10 without and with initial phase correction, respectively.

IV. ALIGNMENT ERROR AND CORRECTION

Multiple-frequency and multiple-angle tomography require correction of the phase errors. Multiple-angle tomography, because of the rotation associated with the scan, requires additional processing to insure correct spatial registration and alignment of the projections. In this section, three alignment tasks are addressed:

(1) Sampling aspect ratio imbalance;
(2) Scanning skew; and
(3) Projection pose identification.

The scan is performed by rotating the specimen instead of the transducer, so estimation and compensation of these items becomes necessary. For multiple-angle tomographic imaging, each projection must be subsequently rotated to a common orientation. Failure to perform accurate compensation prevents a proper spatial alignment and results in degraded reconstructions.

A. Sampling ratio imbalance

The wave field impinging on the coverslip is detected by a laser scanning in a rectangular pattern with sample spacings of Δx and Δy in the x and y directions, respectively. Since the laser scan is not exactly adjusted, the sampling aspect ratio, $\alpha = \Delta x/\Delta y$, is not unity, and consequently the images appear expanded or contracted. If the projections do not involve rotation, this distortion does not seriously degrade the images because each projection is distorted consistently. With the subsequent rotation, the projections are expanded in different directions, preventing proper superposition.

The sampling aspect ratio can be estimated in the spatial domain using corresponding feature points in two projections.[9] Let $\mathbf{q}_i$ and $\mathbf{q}_i'$, $i = 1,2,...,N$ be a set of N corresponding feature points obtained from two projections related by the rotation matrix, $\mathbf{R}$, and the translation vector, $\mathbf{t}$. Then $\mathbf{q}_i$ and $\mathbf{q}_i'$ are related by

$$\mathbf{q}_i' = \mathbf{S}(\mathbf{R}\mathbf{S}^{-1}\mathbf{q}_i + \mathbf{t}), \tag{33}$$

where $\mathbf{S}$ is defined as

$$\mathbf{S} = \begin{bmatrix} \alpha & 0 \\ 0 & 1 \end{bmatrix}. \tag{34}$$

The 2×2 covariance matrix, $\mathbf{Q}$, is defined as

$$\mathbf{Q} = \frac{1}{N}\sum_{i=1}^{N} (\mathbf{q}_i - \boldsymbol{\mu}_q)(\mathbf{q}_i - \boldsymbol{\mu}_q)^T, \tag{35}$$

where $\boldsymbol{\mu}_q$ is the centroid of the feature points of the first image. $\mathbf{Q}'$ is similarly defined. The two covariance matrices are then related by the equation

$$\mathbf{S}^{-1}\mathbf{Q}'\mathbf{S}^{-1} = \mathbf{R}\mathbf{S}^{-1}\mathbf{Q}\mathbf{S}^{-1}\mathbf{R}^T. \tag{36}$$

Equation (36) can be solved[9] for α, yielding

$$\alpha = \sqrt{\frac{q_{11}' - q_{11}}{q_{22} - q_{22}'}}, \tag{37}$$

where q_{ij} and q_{ij}' are the (i,j)th elements of $\mathbf{Q}$ and $\mathbf{Q}'$, respectively. Assuming the scanning system is stable, α remains unchanged and one estimate will suffice. Using this estimate, frequency domain interpolation techniques are employed to correct for the sampling error by expanding or contracting the image in the corresponding direction. After the compensation, the effective sample spacing becomes equal in both directions and numerical rotation can be performed without distortion.

B. Scanning skew

In addition to the sampling aspect ratio inaccuracy, the laser scanning pattern is not perfectly rectangular, as assumed. Instead, the laser scan forms a parallelogram with angles deviating slightly from 90 degrees. As a result, projections will be skewed, again preventing proper superposition after rotation. Several approaches for error estimation and correction are possible. One method matches corresponding feature points in two projections rotated 90 degrees relative to one another, so that simple spatial domain techniques can be used to estimate the error, which indicates the amount of skew. This method requires the use of two projections, accurate rotation of the specimen, and identification of corresponding feature points. A more robust method, which does not require rotation of the specimen or feature point correspondence, is employed instead. This method makes use of the Hough transform, and is described below.

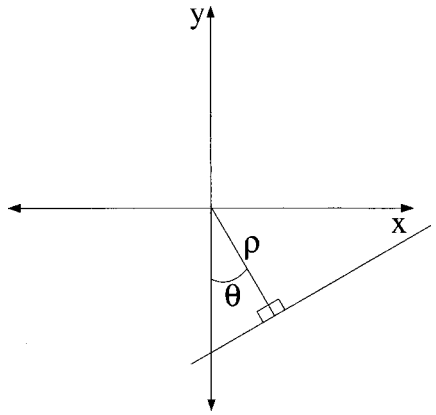

FIG. 12. Illustration of parameters ρ and θ used in the Hough transform for the detection of lines.

The STAM is equipped with an optical sensor that is in perfect registry with the acoustic sensor, permitting estimation of the skew in the acoustic data from the optical image. An optical target consisting of a square pattern is placed on the acoustic stage and illuminated by the laser scan. The optical image of the target is captured and used as the input to a Hough transform[10] which detects the lines corresponding to adjacent sides of the square target. The apparent angle, ϕ, between these lines is calculated. In the presence of a skewed scanning pattern, ϕ will deviate slightly from the correct value of 90 degrees. This angular error needs to be removed for accurate image formation. Since correction of the microscope hardware is complex, all acoustic data are corrected by software interpolation techniques.

The Hough transform may be used to locate any geometrical shape that can be described by an equation of the form

$$g(\mathbf{x},\mathbf{c}) = 0. \tag{38}$$

Here $\mathbf{x} = (x,y)$ are the space indices of the image, and $\mathbf{c}$ is a vector of coefficients or parameters. Since the current application requires detection of lines, the linear expression

$$g(\mathbf{x},\mathbf{c}) = x\,\cos(\theta) + y\,\sin(\theta) - \rho, \tag{39}$$

is used where $\mathbf{c} = (\rho,\theta)$ is defined in Fig. 12. To detect lines in the image, features are first extracted by applying an amplitude threshold. Each pixel greater than the threshold is considered to be a possible member of a line in the image. Since an infinite number of lines may be drawn through each of these pixels, there exist an infinite number of solutions to Eq. (38) for each pixel. The Hough transform represents these solutions in the $\mathbf{c}$-parameter space using an accumulator array, $A(\mathbf{c})$, where the elements of $A(\mathbf{c})$ are referenced by the components of $\mathbf{c}$. The accumulator array is used to form a histogram of the solutions of Eq. (38). After transformation of the image, the array element $A(\mathbf{c}^*)$ contains the

number of pixels in the image that are on the line described by $\mathbf{c}^*$. Pixels which are colinear result in large values, or peaks, in the accumulator array. The values of ρ and θ corresponding to these peaks are used to locate the adjacent sides of the square test target so that the angle between them can be calculated. The angular deviation indicates the amount of skew present in the laser scan.

Searching the accumulator array shows the angle between the horizontal edge and the vertical edge of the square to be $\phi = 92$ degrees, indicating an error of $\phi_e = 2$ degrees. As a result, a horizontal line will appear in the acoustic image with a downward slope of $-\tan(2\pi\phi_e)$. To compensate for the skew, the one-dimensional Fourier transform $V(x, f_y; z_r)$ of the acoustic data is formed in the vertical direction. A phase delay term is multiplied by each column, producing

$$\hat{V}(x, f_y) = \exp(j2\pi f_y x \tan(2\pi\phi_e)) V(x, f_y). \tag{40}$$

The inverse one-dimensional Fourier transform of $\hat{V}(x, f_y)$ is computed to obtain the undistorted image, $\hat{v}(x, y)$. The frequency domain technique is employed because of the automatic interpolation that occurs in the transformation process. In contrast, spatial domain techniques such as simply shifting the data by an integer number of pixels will not be sufficient. Therefore, the frequency domain technique is selected for its superior spectral characteristics.

C. Projection pose identification

Accurate knowledge of the rotation matrix, **R**, and the translation vector, **t**, is essential for high-resolution tomographic superposition. Incorrectly aligned multiple-angle projections can cause significant degradation in the reconstruction. Several methods have been studied for estimation of these imaging parameters. The first method utilizes the redundant information in the overlapping regions of the spatial frequency spectrums of each projection. Instead of extracting feature points in the Fourier domain, an algorithm has been developed to use the continuous distribution of the spectrum.[9] This method has been successfully employed, but some limitations exist. Using this method, the estimation of the parameters relies on the accuracy of the depth of the structures in the specimen. If the depth is incorrectly estimated,[11,12] the estimation of the rotation matrix and translation vector can be erroneous.

An alternative method has been developed for the estimation of the translation vector, or, equivalently, the center of rotation of the specimen using the optical image of the mirrored coverslip. The rotation angle is assumed known as a result of precise control of the rotational hardware.

In a typical configuration, the coverslip placed on the specimen is opaque. Therefore, the optical sensor detects only the image of the mirrored surface of the coverslip, and not the structure of the specimen under investigation. A small identifying mark is placed on this surface such that it is always in the optical sensor's field of view. As the specimen rotates, the mark rotates and optical images are captured at each angle of insonification. After data acquisition is complete, the optical images are superimposed to form one composite optical image. Since the coverslip mark traces out a circular path, the composite image contains a circular shape. Detection of the circular pattern is often complicated by the presence of noise caused by other features on the coverslip and ambient light conditions.

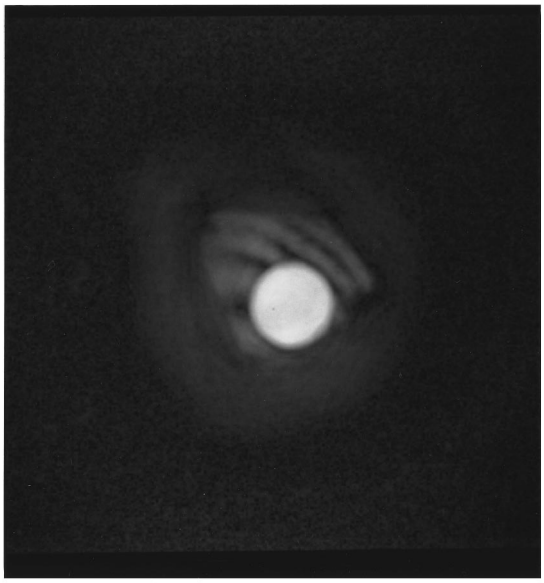

FIG. 13. Reconstruction of circular aperture using 36 multiple angle projections.

A two-step algorithm has been developed that is less sensitive to noise, and accurately detects the circular pattern and estimates the coordinates of the circle's center, which correspond to the center of rotation. The first step employs a Hough transform that detects circular shapes using the function

$$g(\mathbf{x}, \mathbf{c}) = (x - c_1)^2 + (y - c_2)^2 - c_3, \tag{41}$$

where $\mathbf{x} = (x, y)$ are the space indices of the image, c_1 and c_2 are the coordinates of the circle's center, and c_3 is the radius. The algorithm functions similarly to the line detection algorithm described earlier, but is more computationally intensive due to the larger dimension of the parameter space. The algorithm can be made computationally efficient by restricting image analysis to a small area.

After the circular Hough transform of the composite image has been obtained, the location, $\mathbf{c}_m = (c_{1,m}, c_{2,m}, c_{3,m})$, of the maximum value of this array provides an initial estimate of the center of rotation. To improve this estimate, a second step is employed. Using the known width of the circular shape, the values of the accumulator array are summed over the radius parameter, c_3, to form a two-dimensional array,

$$\hat{\mathbf{A}}(c_1, c_2) = \sum_{c_3 = c_{3,m} - W/2}^{c_{3,m} + W/2} A(\mathbf{c}), \tag{42}$$

where W is the expected width of the curve formed by the coverslip mark. The maximum value of $\hat{\mathbf{A}}(c_1, c_2)$ provides an improved estimate of the center of rotation. Without this second step, the estimate of the center may be in error by as much as W pixels, causing significant reconstruction degradation. Experimental results indicate that with this second

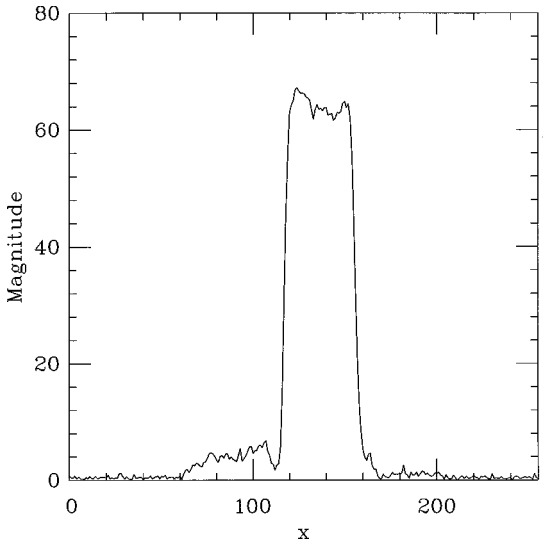

FIG. 14. Cross section through the center of the aperture shown in Fig. 13.

step, the error is reduced to less than one pixel.

To illustrate the effectiveness of this algorithm, a multiple-angle reconstruction is formed of a test specimen consisting of a 380-μm-diam circular aperture in a 3-mm-diameter copper test target. The specimen is placed 640 μm below the coverslip and 36 projections are acquired at 10-degree steps of rotation, using an insonification frequency of 104 MHz. The phase and sampling errors present in the data are first compensated. Using the two-step algorithm, the center of rotation is estimated to be at $x_c = -30$ μm and $y_c = 130$ μm relative to the center of the microscope's field of view. The resulting reconstruction of this specimen is shown in Fig. 13 with the circular aperture in the center of the image. The darker area around the aperture is a result of signal attenuation caused by the epoxy used to secure the specimen to the mounting hardware. Figure 14 shows a cross section taken through the center of the aperture. The sharp cutoff at the edges of the aperture is a result of properly aligned projections. Incorrect alignment would result in a slower transition from the region of the aperture to the surrounding copper material. Measurements taken from Fig. 14 indicate an aperture diameter of 390 μm, representing an error of 10 μm.

V. CONCLUSION

In scanning tomographic acoustic microscopy, projection phase error correction plays a pivotal role in the quality of the final reconstruction. In this paper, two aspects of projection error correction were examined: projection phase errors and projection alignment errors. Phase errors occur in the form of the phase error from the quadrature receiver channels and in the form of the initial phase error between different projections. Both phase errors were modeled and algorithms were developed to estimate and compensate the errors. Experimental results were provided to illustrate the effectiveness of the algorithms.

Three types of alignment errors due to incorrect spatial sampling were discussed: sampling aspect ratio imbalance, scanning skew, and projection pose identification. The error associated with inadequate registration between the projections was also examined. Algorithms for the estimation and correction of these errors were implemented and demonstrated with full-scale experiments.

Because of the successful development of these error estimation and removal techniques, the tomographic acoustic microscope system is now capable of high-resolution three-dimensional imaging at full capacity.

Spectral-ripple representation of steady-state vowels in primary auditory cortex

Huib Versnel[a] and Shihab A. Shamma
Institute for Systems Research and Electrical Engineering Department, University of Maryland, College Park, Maryland 20742

(Received 1 July 1997; revised 8 December 1997; accepted 30 January 1998)

Responses to various steady-state vowels were recorded in single units in the primary auditory cortex (AI) of the barbiturate-anaesthetized ferret. Six vowels were presented (/a/, /ε/, 2 different /i/'s, and 2 different /u/'s) in a natural voiced and a synthetic unvoiced mode. In addition, the responses to broadband stimuli with a sinusoidally shaped spectral envelope (called ripple stimuli) were recorded in each cell, and the response field (RF), which consists of both excitatory and inhibitory regions, was derived from the ripple transfer function. We examined whether the vowel responses could be predicted using a linear ripple analysis method [Shamma *et al.*, Auditory Neurosci. **1**, 233–254 (1995)], i.e., by cross correlating the RF of the single unit, and the smoothed spectral envelope of the vowel. We found that for most AI cells (71%) the relative responses to natural vowels could be predicted on the basis of this method. Responses and prediction results for unvoiced and voiced vowels were very similar, suggesting that the spectral fine structure may not play a significant role in the neuron's response to the vowels. Predictions on the basis of the entire RF were significantly better than based solely on best frequency (BF) (or ''place''). These findings confirm the ripple analysis method as a valid method to characterize AI responses to broadband sounds as we proposed in a previous paper using synthesized spectra [Shamma and Versnel, Auditory Neurosci. **1**, 255–270 (1995)].

INTRODUCTION

Timbre is the aspect of sound which enables us to distinguish the sounds of different musical instruments playing the same tone with the same loudness or to discriminate different vowels spoken with the same fundamental frequency and the same intensity (cf. Plomp, 1976). The spectral envelope is an important physical correlate of timbre: e.g., the more similar the spectra of two vowels the more likely they will be confused. There is growing evidence from recent experiments (Phillips *et al.*, 1985; Schreiner and Mendelson, 1990; Schreiner and Sutter, 1992; Schreiner and Calhoun, 1994; Shamma *et al.*, 1993, 1995; Shamma and Versnel, 1995; Versnel *et al.*, 1995; Kowalski *et al.*, 1996a, b) that the auditory cortex plays an important role in encoding the spectral shape, and thus in encoding of timbre.

Such evidence is found in the organization of the response areas in the primary field (AI): the bandwidth shows topographic organization (Schreiner and Mendelson, 1990; Schreiner and Sutter, 1992; Versnel *et al.*, 1995) and so does the asymmetry of the inhibitory sidebands (Shamma *et al.*, 1993). Secondary fields might widen the range of response areas already available in the primary field as Kowalski *et al.* (1995) found with respect to the bandwidth. The function of the topographic organization is apparent in the tendency of units to respond to spectral features according to their response area: e.g., a unit with a broad response area will preferably respond to a wide-band sound (Phillips *et al.*, 1985; Schreiner and Mendelson, 1990), or units with inhibition below the best frequency (BF) will respond best to sounds with most energy above BF (Shamma *et al.*, 1993). A recent series of experiments in which cortical responses to spectral ripples were examined provided a feasible method for cortical encoding of spectral features. We will refer to this method as ripple analysis (Shamma *et al.*, 1995), where ripple is defined as a sinusoidal modulation of the spectral profile of a broadband sound stimulus.

A. Ripple analysis and encoding of spectral profiles

Units in AI were found to be tuned to different spectral ripples, mostly in bandpass fashion, and the units were topographically segregated with respect to the ripple responses (Versnel *et al.*, 1995). An important consequence of this linear analysis was that responses to an arbitrary spectral profile could be predicted by superposition of responses to the separate ripple components of the stimulus (Shamma and Versnel, 1995). This finding led to the suggestion that cortical cells behave as ripple filters, and accordingly perform a Fourier-like analysis of the auditory spectrum (see for a detailed theoretical background Wang and Shamma, 1995). The ripple analysis appears to be analogous to the spatial frequency analysis in the visual cortex where simple cells are bandpass tuned to spatial frequencies of sinusoidal gratings (De Valois and De Valois, 1990).

In this paper we apply the ripple analysis method and ideas to characterize and predict AI responses to natural broadband stimuli. Steady-state vowels were chosen as natu-

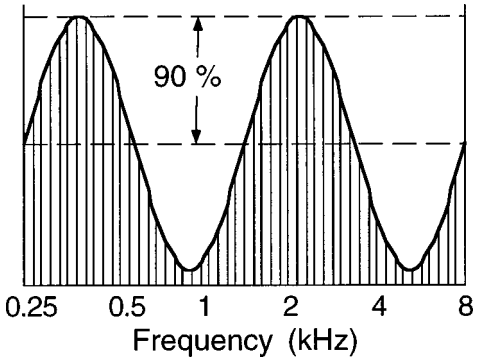

FIG. 1. Schematic of a rippled spectrum stimulus. It is composed of 101 tones equally spaced along the logarithmic frequency axis between 0.25 and 8 kHz. The envelope of the complex is sinusoidally modulated along the logarithmic frequency axis and the amplitude scale is linear. The ripple phase is defined relative to a sine wave starting at the left edge. For the ripple shown, the ripple frequency Ω is 0.4 cycles/octave, the ripple phase ϕ is 0, and the ripple amplitude is 90%.

ral stimuli. We examine whether the relative responses to different vowels can be predicted on the basis of the ripple responses and the spectral envelope of the vowel, analogous to the predictions in Shamma and Versnel (1995). The spectral profiles described in that paper were composed of 2–10 ripple components, and the carrier of this stimulus was the same as that of the rippled stimuli. Here, we use natural voiced vowels which are not artificially composed of ripples and whose carrier is the harmonic series of the natural voicing. Further, we test the ripple analysis on synthesized vowellike stimuli with a carrier as ripples and a spectral envelope as vowels, which can be considered a stage between testing with ripple combinations (Shamma and Versnel, 1995) and natural vowels.

I. METHODS

A. Surgery and animal preparation

The data presented here were collected in 6 young adult male ferrets (*Mustela putorius*) weighing 1.5 to 2.3 kg. A detailed description of the animal preparation is given in Shamma *et al.* (1993). The ferrets were intraperitoneally anesthetized with sodium pentobarbital (40 mg/kg) and atropine sulfate was administered subcutaneously (0.1 mg/kg). An areflexic level of anesthesia was maintained throughout the experiment by continuous intravenous infusion of sodium pentobarbital at a flow rate of about 5 mg/kg/h. The infusion fluids included 5% dextrose in Ringer's solution. The primary auditory cortex on the left hemisphere was exposed by craniotomy and the overlying dura was incised and reflected. The brain was covered in 2% agar in saline to reduce pulsations. The contralateral meatus was exposed, cleaned and partly resected, and subsequently a cone-shaped speculum containing a Sony MDR-E464 miniature speaker was sutured to the meatal stump.

B. Acoustic stimuli

Stimuli were monaurally presented in above described closed-field set up. Calibration of the sound delivery system was performed *in situ* over a range of 0.4–20 kHz using a 3.2-mm (1/8-in.) Bruël & Kjaer probe microphone (type 4170). The microphone was inserted into the ear canal through the wall of the speculum to 5–10 mm of the tympanic membrane. The speculum and microphone setup resembles closely that suggested by Evans (1979). Maximum tone intensities were limited to 85 dB SPL to avoid any distortion.

We presented pure-tone stimuli, complex stimuli with a rippled spectrum (ripple stimuli), natural voiced vowels, and synthetic unvoiced vowels. A Hewlett-Packard 9000/800 series minicomputer controlled stimulus delivery. Pure-tone stimuli of 200-ms duration were generated using a function generator, the vowels were taken from a data base and the other stimuli were computer synthesized. All stimuli were gated to obtain rise and fall times of 7 ms, and then fed

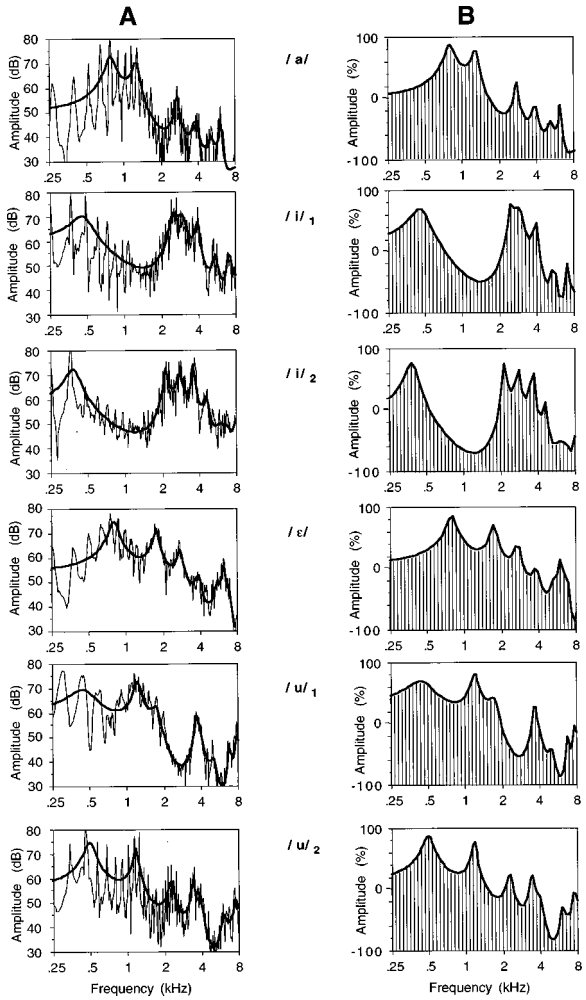

FIG. 2. (A) Frequency spectra of the six natural vowels used in the experiment, /a/, /ε/, 2 different /i/'s, and 2 different /u/'s. The thin line represents the Fourier spectrum and the thick line represents the smoothed spectral envelope which is obtained using linear predictive coding (LPC). (B) Frequency spectra of six unvoiced synthesized vowels. These sounds were composed of 101 logarithmically distributed frequency components between 0.25 and 8 kHz (as used in the ripple stimuli, see Fig. 1). The spectral envelope was derived from the LPC-smoothed spectral envelope of the six natural vowels shown in (A). The envelope was modified such that the maximum peak was at 90% and the minimum trough was at −90% comparable to the amplitude of the ripple stimulus. The vertical lines schematically represent the frequency components, and the thick line represents the envelope.

through an equalizer into the earphone. The interstimulus interval was 1.2 s for the natural vowels, and 1.0 s for the other stimuli.

A schematic of the ripple stimulus is shown in Fig. 1. It consisted of 101 tones that were equally spaced along the logarithmic frequency axis and spanning 5 octaves from 0.25 to 8 kHz. The envelope of the complex was modulated sinusoidally on a linear amplitude scale. The ripple amplitude or depth, ΔA, defined as the maximum percentage change in the component amplitudes, was 90%. The overall level of the ripple stimulus is given by the level of the corresponding flat complex ($\Delta A = 0$). Thus, if the sound pressure level for a flat complex with 101 components is L_1, the level of a single component is $L_1 - 10\log(101) \approx L_1 - 20$ dB. Usually the overall level was set 10–20 dB above the threshold to tones at BF. The ripple frequency (Ω) is measured in units of cycles/octave against the logarithmic frequency axis. The ripple phase (ϕ) is measured in degrees relative to a sine wave starting at the left edge (low-frequency edge) of the complex (Fig. 1). In a single test both Ω and ϕ are randomly varied, Ω from 0 to 1.4 cycles/octave with 0.2 steps, and ϕ over the full 360° cycle in steps of 45°. The duration of the complex stimulus bursts was 50 ms.

Six different vowels were taken from steady-state speech segments in the TIMIT database: /a/, /ɛ/, 2 different /i/'s, and 2 different /u/'s. Subsequently, these vowels were preemphasized (see Rabiner and Juang, 1993; Eq. 3.69, we applied $\tilde{a} = 0.9$) thereby enhancing energy at high frequencies. Figure 2(A) shows the amplitude spectra of the six vowels with their smoothed envelope obtained using linear predictive coding (LPC). The duration of the vowels was 80–140 ms. The vowels were presented at 1–3 levels typically in a range of 47–67 dB SPL.

Unvoiced versions of the natural vowels were synthesized using the smoothed spectral envelope of the natural vowels, and the carrier and other stimulus characteristics of the ripple stimuli [see Fig. 2(B)]. The spectrum was modified such that the maximum peak was at 90% and the minimum trough was at -90% according to the ripple-stimulus amplitude that was used, and the spectral range was 0.25–8 kHz. The transformation to the percentage scale is unlikely to significantly affect the response (Shamma *et al.*, 1995). The duration of the unvoiced vowels was 50 ms. The unvoiced vowels were presented at the level at which the ripple stimulus was presented, and often at one or two more levels in the range 45–65 dB SPL.

C. Recordings

Action potentials were recorded using glass-insulated tungsten microelectrodes with 5–6 MΩ tip impedances. Electrode penetrations were made orthogonal to the cortical surface, and in each penetration, one or two cells were studied. A search stimulus consisted of pure tones manually swept across frequency at various levels. Neural signals were amplified ($\times 10\,000$) and filtered (0.5–5 kHz bandpass) and led through a time-amplitude window discriminator (BAK electronics, model DIS-1). Single-unit spikes were separated and identified on the basis of their waveform and amplitude. During recording the waveform is monitored in order to check the stability of the spike waveform. The time of spike occurrence relative to stimulus delivery was stored using the HP 9000/800 computer. In a single test a type of stimulus (tone, ripple, voiced vowel, or unvoiced vowel) is presented and the stimulus parameters (including sound level) are varied in random order.

D. Data analysis for responses to tonal stimuli

We used the definitions for various response parameters as given by Kowalski *et al.* (1995). The best frequency (BF) is defined as the frequency which elicits the maximum response at a low level (10–20 dB above threshold). After manual assessment of the excitatory region, BF was determined by randomly presenting tones at a low stimulus level with a frequency resolution up to 1/8 octave. The rate-level function at BF was measured over the range of 35–85 dB SPL. The rate-level curve is considered nonmonotonic if the spike count at higher intensities has decreased by more than 25% of the maximum spike count. The best intensity is defined for nonmonotonic curves as the intensity which elicits maximum response, for monotonic curves as the highest level used (85 dB SPL). The threshold is the intensity at which the spike count reached 10% of the maximum. In determining the various parameters, corrections have been made for the cell's spontaneous rate. Spike counts were made over a time window from 10 to 60 ms after onset of the stimulus.

E. Data analysis for responses to ripple stimuli

Figure 3 shows responses of an AI unit to the ripple stimuli and it illustrates the analysis applied. Full details of the analysis are described in Shamma *et al.* (1995). In Fig. 3(A), the raster shows the responses to different phases of the ripple at $\Omega = 0.8$ cycles/octave. Spike counts, obtained from 15 repetitions of each stimulus, were made over a 60-ms time window starting 10 ms after the onset of the stimulus. The spike count curve shown in the inset plot to the right of the raster demonstrates the dependence of the response on the phase of the ripple. In Fig. 3(B), such spike counts from all ripple frequencies are combined in one display. The baseline at each ripple frequency was set equal to the spike count obtained from the flat spectrum ($\Omega = 0$). The best sinusoidal fit to the data (solid line) at each ripple frequency yield amplitude and phase values, and accordingly a transfer function, $AC_1(\Omega)$, is obtained. In order to account for statistical noise and the quality of the sinusoidal fit the amplitude of the transfer function is adjusted as follows. An eight-point Fourier transform is performed on the spike counts at each ripple frequency. The magnitude and phase of the first harmonic, $AC_1(\Omega)$, is extracted and weighted by the rms value of the response as follows (Shamma *et al.*, 1995):

$$T(\Omega) = AC_1(\Omega) \cdot \frac{|AC_1(\Omega)| - |AC_1(0)|}{\sqrt{\Sigma_{i=1}^{4} |AC_i(\Omega)|^2}} \quad \text{if } |AC_1(\Omega| - |AC_1(0)| \geq 0,$$
$$T(\Omega) = 0 \quad \text{if } |AC_1(\Omega| - |AC_1(0)| < 0, \tag{1}$$

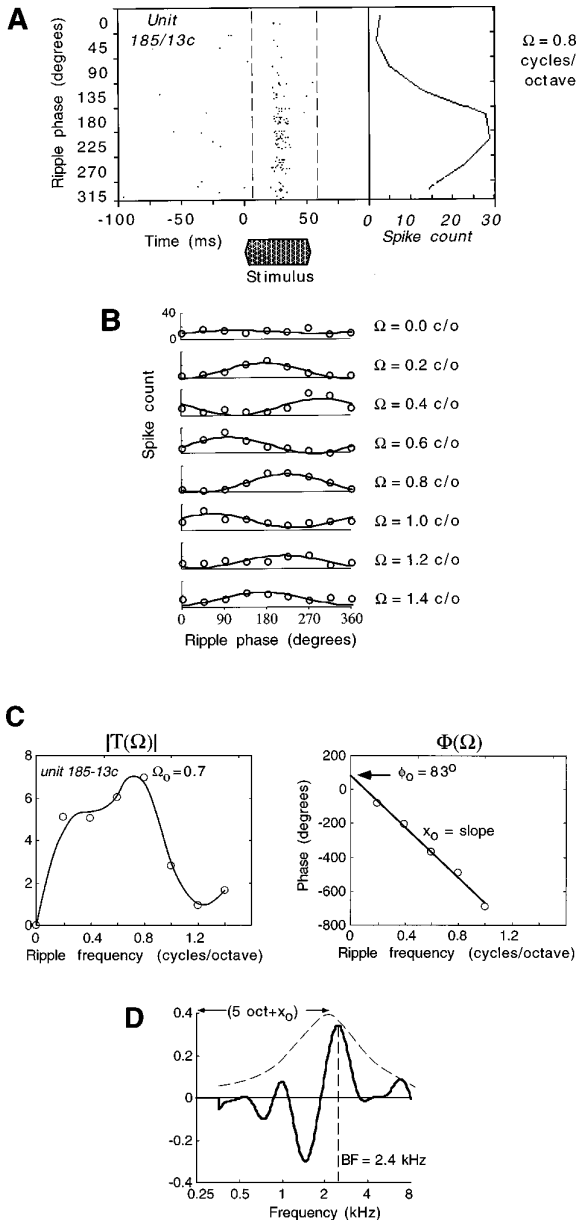

FIG. 3. The analysis of the responses to rippled stimuli. (A) Raster of the responses of an Al cell (185/13*c*; BF of 2.4 kHz) to a rippled spectrum stimulus with a fixed ripple frequency ($\Omega=0.8$ cycles/octave) and various ripple phases (0–315 degrees in steps of 45 degrees). The rise and fall time of the stimulus burst is 7 ms and its duration 50 ms. The stimulus is repeated 20 times for each ripple phase. Spike counts are computed over a time window 10–70 ms after the stimulus onset (indicated by the dashed lines), and are displayed in the inset plot to the right of the raster. (B) Spike counts as a function of ripple phase for various ripple frequencies Ω between 0 and 1.4 cycles/octave. At each Ω, spike counts are indicated by the circles, and the solid line is the best sinusoidal fit to the points (in the sense of mean square error). The baseline at each ripple frequency was set equal to the average spike count to the flat spectrum ($\Omega=0$). (C) The transfer function $T(\Omega)$ is derived from the magnitude and phase of the sinusoidal fitted curve shown in (B). The plot to the left shows the magnitude of the transfer function $|T(\Omega)|$, where the characteristic ripple frequency Ω_0 is the location of the maximum of $|T(\Omega)|$. The right plot shows the phase of the transfer function, $\phi(\Omega)$, where the solid line represents a linear fit to the data with intercept ϕ_0 and slope x_0. (D) The response field (RF) of the cell is derived by an inverse Fourier transform of the transfer function $T(\Omega)$. The dashed curve represents the envelope of the RF. The distance from the left edge of the rippled spectrum to the center of the RF envelope is given by $k2\pi/\Delta+x_0$, where Δ is the step size of the ripple frequencies Ω tested, and k is an integer $\geqslant 1$. The location of the maximum of the RF is defined as $\mathrm{BF}_{\mathrm{RF}}$.

where $|AC_i(\Omega)|$ is the magnitude of the ith Fourier component of the response. In general terms $T(\Omega)$ can be written as follows:

$$T(\Omega)=|T(\Omega|\cdot e^{j\phi(\Omega)}, \tag{2}$$

where $j=\sqrt{-1}$.

Figure 3(C) shows the ripple transfer function $T(\Omega)$: the magnitude $|T(\Omega)|$ (*left*) and the unwrapped phase $\phi(\Omega)$ (*right*). Note that the phase relation is approximately linear. The ripple transfer function can be inverse Fourier transformed to obtain the response field (RF) of the cell which is shown in Fig. 3(D). The RF can be interpreted as an isointensity frequency response curve with the positive peak representing the excitatory portion and the negative peak representing the inhibitory portion.

Several parameters characterize the ripple transfer function and the RF. Figure 4 shows data of three main param-

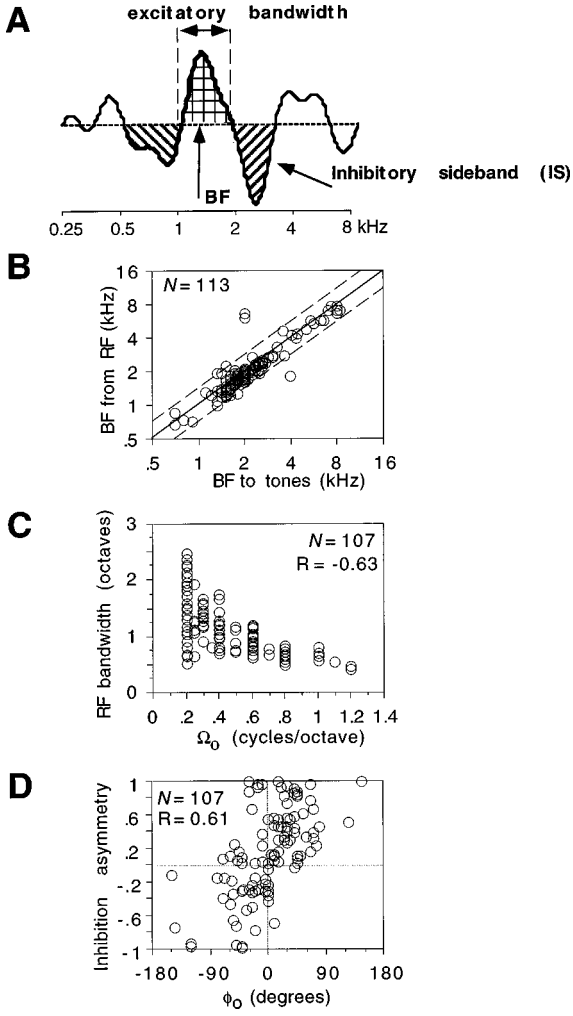

FIG. 4. Interpretation of ripple response parameters. (A) An example of an RF of an AI cell (unit 185/35*a*) illustrating that positive peaks of the RF might be associated to excitation and negative peaks to inhibition. The inhibitory sidebands are indicated with the oblique-line patterns and the excitatory peak with the cross pattern. (B) BF according to RF vs BF found with tones. (C) Excitatory bandwidth of RF vs Ω_0. The bandwidth is defined by the zero crossings below and above BF as illustrated in (A). (D) Asymmetry index of inhibitory sidebands vs ϕ_0. The measure of inhibition asymmetry, M, is defined as $M=(A_{is<\mathrm{BF}}-A_{is>\mathrm{BF}})/(A_{is<\mathrm{BF}}+A_{is>\mathrm{BF}})$, where $A_{is<\mathrm{BF}}$ is the area of the inhibitory sideband below BF and $A_{is>\mathrm{BF}}$ the inhibitory sideband area above BF.

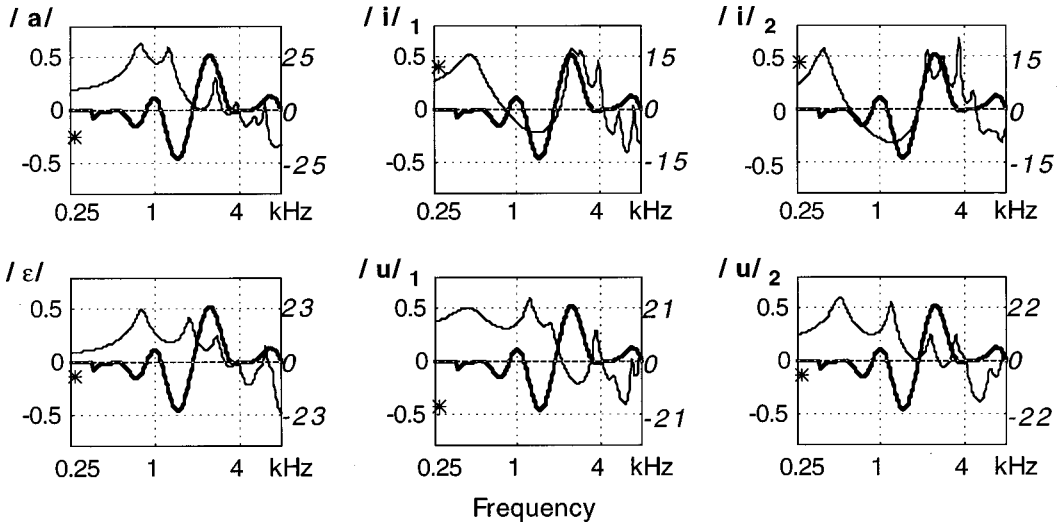

FIG. 5. Example of RF of AI unit (thick line) with vowel's spectral profiles (thin lines). The vowel profiles are scaled and aligned to the RF. The ordinate is given in RF units (spike count). The asterisk reflects the prediction of the response to the vowel which is the cross correlation of the RF and vowel's spectral profile [see Eq. (4)].

eters and illustrates their significance. The most obvious one and easily interpretable is the location of the maximum of the RF along the tonotopic axis. This generally corresponds very well to the tonal BF of the cell [Fig. 4(B)] and will be labeled accordingly as BF_{RF}. The second parameter is the characteristic ripple frequency, Ω_0, which is the ripple frequency where the magnitude, $|T(\Omega)|$, is maximum. Figure 4(C) shows that Ω_0 inversely relates to the width of RF: in general, the higher Ω_0 the narrower RF, and vice versa. Third, the characteristic ripple phase, ϕ_0, is the intercept of the phase function $\phi(\Omega)$. It is derived by fitting a line to the phase function [see Eq. (6), Shamma *et al.*, 1995]:

$$\phi(\Omega)=x_0\Omega+\phi_0, \tag{3}$$

where x_0 is the slope of the line.

The parameter ϕ_0 indicates the asymmetry of the RF about its center [Fig. 4(D)]. For instance, the RF is symmetric for $\phi_0\cong 0$, and strongly asymmetric for $\phi_0\cong -90°$ or $\phi_0\cong 90°$ [as in Fig. 3(D)].

F. Data analysis for responses to vowels

The responses to vowels were obtained from 40 repetitions of each vowel stimulus, and spike counts were made over a 60-ms time window starting 10 ms after the onset of the vowel. The responses were analyzed either across units or across vowels. The former type of analysis provided a population response, in which case the response was normalized by dividing by the maximum response found to BF tones (cf. Sachs and Young, 1979). In the other type of analysis the responses of a cell to the six different vowels are considered relative to each other, i.e., we examine whether the cell responds better to the one than to the other vowel. In this case normalization was not necessary. The relative vowel responses are compared to predictions.

The prediction model basically follows the linear ripple analysis applied in Shamma and Versnel (1995). In that paper the stimuli were profiles shifting along the logarithmic frequency axis, i.e., with a constant ripple frequency content (two or more ripple components) and a varying ripple phase, and the responses were predicted by superposition of the responses to individual components. This superposition can be computed either in the ripple domain by taking the inverse Fourier transform of the product of the cell's ripple transfer function and the stimulus' ripple spectrum or in the logarithmic frequency domain by crosscorrelating the cell's RF with the stimulus' spectral profile. In this paper the stimuli are six profiles which differed in ripple frequency content and ripple phase content. We predicted for each cell the relative responses to the vowels in the logarithmic frequency domain as follows [cf. Eq. (5) in Shamma and Versnel, 1995]:

$$r_p(k)=\frac{\Sigma_x w(x)\cdot p(x;k)}{\sqrt{\Sigma_x w^2(x)\cdot\Sigma_x p^2(x)}}, \tag{4}$$

where integer $k=1,2,...,6$ denotes the vowel, x is the logarithmic frequency axis, $w(x)$ is the RF and $p(x)$ the spectral profile. Strictly speaking, for each vowel k the center element of the cross correlation of $w(x)$ and $p(x)$ is computed whereas Shamma and Versnel computed the entire cross correlation vector in order to predict responses to shifting profiles. The right term of Eq. (4) can be thought of as a match between the profile and RF which is illustrated in Fig. 5. When the vowel's spectral profile matches the RF, e.g., because a formant peak coincides with an excitatory area, then the response is predicted to be large; this is demonstrated for both vowels /i/ in Fig. 5. When the match is poor, e.g., because a formant coincides with an inhibitory area, then the response is predicted to be weak; this is demonstrated for the vowel $/u/_1$. It is obvious from Eq. (4) that an absolute response amplitude or discharge probability is not predicted, instead one predicts whether the response to the one vowel is stronger than to the other. The value of $r_p(k)$ is between -1 and 1. For the prediction the profile $p(x)$ is dB scaled, which gave similar but slightly better results than linear scaling.

In order to examine whether the entire RF is needed to predict the vowel responses or instead information of the BF

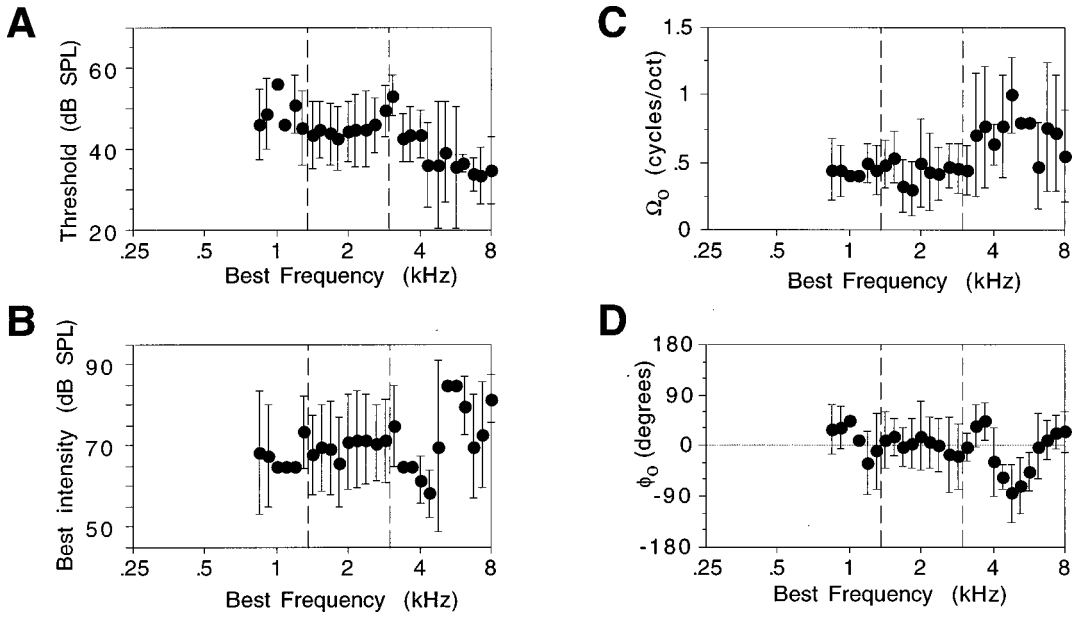

FIG. 6. Average response parameters as a function of BF. The parameter values are averaged over AI cells in 1/4 octave moving segments at 1/8 octave resolution. The BF is estimated from responses to tones. The dashed lines indicate the region where the number of units per segment is 10 or larger; outside this region of the numbers of units are typically between 3 and 5. The bars represent the standard deviation. (A) Threshold for BF tones. (B) Best intensity for BF tones. (C) Characteristic ripple frequency. (D) Characteristic ripple phase.

location alone might be sufficient, we also performed predictions assuming that RF only consists of a sharp excitatory peak at BF. This prediction was as follows:

$$r_p(k) = \frac{w(x = x_{\mathrm{BF}}) \cdot p(x = x_{\mathrm{BF}}; k)}{\sqrt{\Sigma_x w^2(x) \cdot \Sigma_x p^2(x)}}, \tag{5}$$

where x_{BF} is the location of BF along the logarithmic frequency axis.

For each cell a correlation coefficient R is computed using linear regression analysis of the predicted and measured responses, and R^2 is used as a measure of the accuracy of the prediction. For cases where $R<0$, R^2 was made 0 in statistical analyses and data presentation.

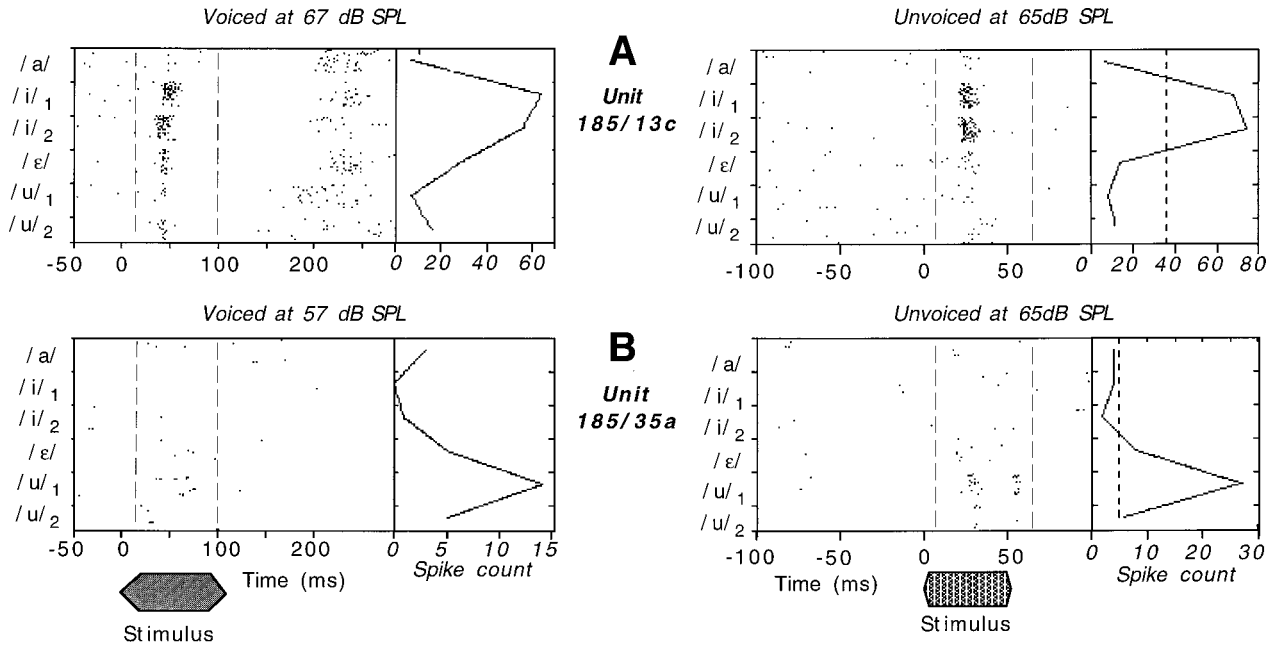

FIG. 7. Rasters of responses of two single units to 6 different vowel stimuli presented in voiced (left) or unvoiced mode (right). Each stimulus is repeated 40 times. Spike counts computed over a time window 10–100 or 10–70 ms after the stimulus onset (indicated by the dashed lines) are displayed in the inset plot on the right. The dashed line in the inset of the responses to unvoiced vowels represent the spike count to a flat spectrum presented at the same sound level. (A) Responses of unit 185/13*c* (BF: 2.4 kHz; $\Omega_0 = 0.7$ cycles/oct; $\phi_0 = 83°$; threshold: 47 dB SPL; best intensity: 65 dB SPL). (B) Responses of unit 185/20*a* (BF: 1.2 kHz; $\Omega_0 = 0.6$ cycles/oct; $\phi_0 = -69°$; threshold: 56 dB SPL; best intensity: 65 dB SPL).

II. RESULTS

We collected data from 113 single units in 6 ferrets. For all units the response to BF tones at the best intensity varied from 0.5 to 4.9 spike per stimulus presentation. The response to the optimal vowel varied from 0.1 to 5.4 spike, and could be twice as large as the response to BF tones at best intensity. A large majority of BFs were between 1.2 and 3 kHz (79%). For 109 units (96%) the BF estimated from the RF differed less than 0.5 octave from BF measured to tones [see Fig. 4(B)]. A BF difference $|BF_{tone} - BF_{RF}|$ can be caused by errors in the RF or tonal BF assessments, and/or by nonlinearities (cf. Shamma *et al.*, 1995). Therefore, BF difference can be used as a rough indicator of RF goodness, and we shall examine whether RF predictions of vowel responses [see Eqs. (4) and (5)], are related to this measure.

A. Basic response characteristics

Figure 6 plots threshold, best intensity, Ω_0, and ϕ_0, as a function of the unit's BF, parameters which characterize the unit's stationary response behavior to a great extent. The data are expressed as averages over 0.25 octave in order to be able to relate them to vowel response profiles which are shown in a later figure (Fig. 8). The parameters have average values expected on the basis of previous reports (Kelly *et al.*, 1986; Kowalski *et al.*, 1995; Shamma *et al.*, 1995). This report, however, covers mostly a lower BF range (below 3 kHz) than our previous reports on ripple responses. Figure 6 shows that in this range the parameters were fairly constant compared to the variations observed at higher BFs (3–8 kHz), partially due to the lower sample sizes.

B. Examples of responses to vowels

Figure 7 shows typical examples of responses of two different AI units to vowel stimuli. The responses are phasic as generally is the case, at least at normal levels of barbiturate anesthesia, for responses to other stationary stimuli such as tones. The two examples in Fig. 7 demonstrate two important response features. First, both units respond selectively, e.g., the unit in Fig. 7(A) responds much stronger to the /i/ vowels than to the other ones, and the unit in Fig. 7(B) prefers the /u/$_1$ vowel. Second, for each unit the responses to the unvoiced and voiced vowels show similar trends.

C. Population response

Figure 8 shows normalized spike counts which are averaged over several units in BF segments of a 1/4 octave as a function of BF, resulting in a population response profile. The response profiles are shown for both voiced and unvoiced vowels and for several levels, and they are compared to the vowel spectrum. Focusing on the BF region covered by the majority of units (1.4–2.8 kHz, indicated by dashed lines) one observes that the response profiles coarsely follow the stimulus spectrum, e.g., the opposite trends of the two vowel spectra are reproduced by the responses, in particular in the 1.4–2 kHz region. However, the responses do not follow the spectral details, e.g., between 2 and 2.8 kHz the response profiles for both vowels are virtually flat while the spectra are sloping. Although the sample size at high BFs is small (about 3 units per data point), the discrepancy between response profiles and vowel spectra, consistent over all sound levels, is striking. The threshold profile [Fig. 6(A)] does not show the variation with BF that might have accounted for this discrepancy.

D. Predictions: RF approach

For each unit we predicted relative responses to vowels on the basis of the RF of the unit and the spectral profile of the vowel [Eq. (4)]. Figure 9 illustrates for three different units how the RF predictions compare to the experimental responses to voiced vowels. In all three examples a response to the one vowel being significantly larger than to the other vowel is predicted well. The good prediction is reflected by the high value of R^2 (greater than 0.7).

Vowel responses vary with level and consequently, the goodness of the prediction as measured by R^2 varies with sound level of the vowel. Figure 10 shows for six different units the responses for three levels of the voiced vowel (A)

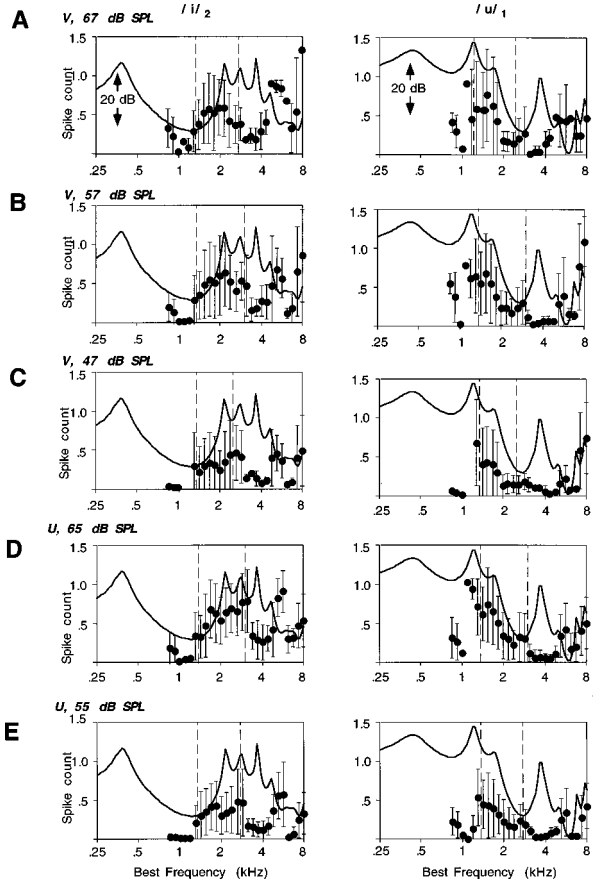

FIG. 8. Average spike count profiles for two different vowels (/i/$_2$ and /u/$_1$). The responses are normalized by dividing over the response to BF tone at best intensity and subsequently averaged over units in 1/4 octave moving segments at 1/8 octave resolution. The BF is estimated from responses to tones. The dashed lines indicate the region where the number of units per segment is 10 or larger; outside this region the numbers of units are typically between 3 and 5. The bars represent the standard deviation. The thick line represents the envelope of the vowel spectrum, which amplitude scale is indicated in the top plots. (A) Response profiles for voiced vowels at 67 dB SPL. (B) Response profiles for voiced vowels at 57 dB SPL. (C) Response profiles for voiced vowels at 47 dB SPL. (D) Response profiles for unvoiced vowels at 65 dB SPL. (E) Response profiles for unvoiced vowels at 55 dB SPL.

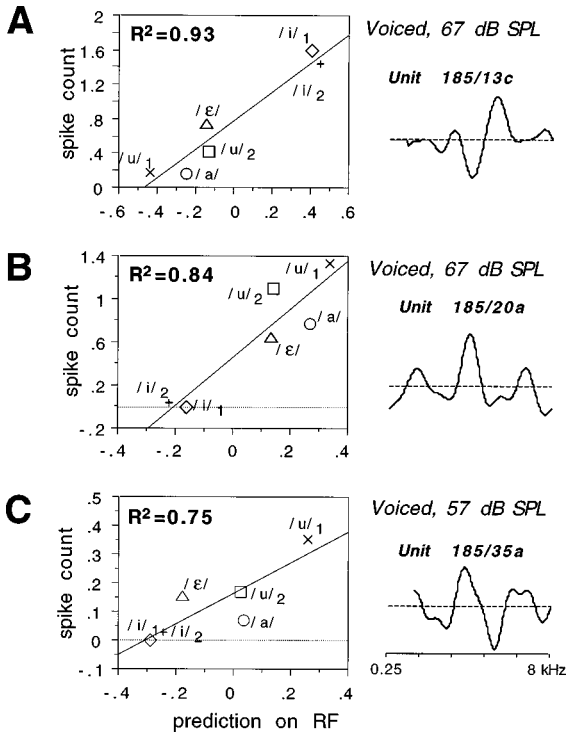

FIG. 9. Examples of spike count (per stimulus presentation) versus predicted response for voiced vowels, for three different AI neurons. The prediction on the basis of RF and spectral envelope [see Eq. (4)] is expressed in relative units. The line reflects the linear regression of the experimental versus predicted response with correlation coefficient R. The index R^2 is used as a measure of the accuracy of the prediction. The unit's RFs are plotted on the right. (A) unit 185/13*c*; (B) unit 185/20*a*; (C) unit 185/35*a*.

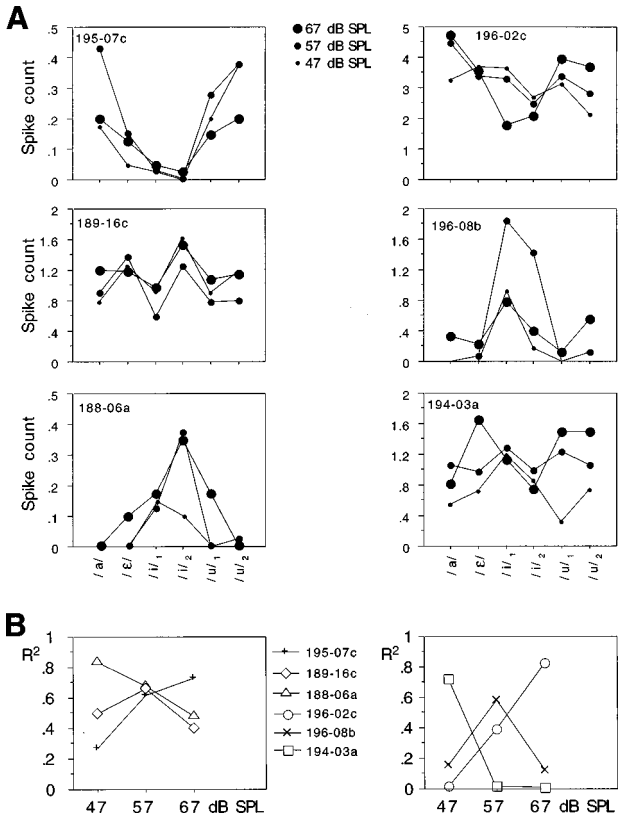

FIG. 10. Level dependence of voiced-vowel responses and their predictions. (A) The response curves at three different levels (47, 57, and 67 dB SPL, represented by different dot sizes) for six different units. The plots on the left show examples where response curves have similar shapes, the plots on the right show examples where the curves change with level. (B) The index $R^2_{\mathrm{RF}v}$ as a function of intensity for the vowel responses shown in (A). The index $R^2_{\max}$, is defined by the maximum. The plot on the left and right correspond to the left- and rightside plots in (A), respectively.

and the corresponding R as a function of level (B). In several cases the level dependence of the relative vowel responses was small which is illustrated by the three plots on the left in Fig. 10(A): all response curves have similar shapes. Consequently, R is stable with level [left plot in Fig. 10(B)]. However, the responses often varied considerably [Fig. 10(A), right-side plots] and consequently the prediction of the vowel responses could be virtually perfect ($R^2>0.7$) at one level and absolutely false ($R^2\approx 0$) at another level [Fig. 10(B), right plot]. In 30% of the units where we found a decrease of R^2 with increase of intensity the drop was more than 0.4 over 10 dB. These findings were similar for voiced and unvoiced vowels. In the following, the maximum correlation coefficient will be referred to as $R_{\max}$.

We examined whether the best-prediction level relates to the best intensity and/or threshold derived from the rate-level function measured for BF tones. If a change in relative vowel responses giving rise to the level dependence of R^2 is related to nonmonotonic response behavior then one would expect a relation to best intensity. However, multiple regression analysis, with threshold and best intensity as independent variables, indicates that the best-prediction level correlates with threshold but not with best intensity. The regression plots in Fig. 11 demonstrate that the intensity of the best prediction correlates well with threshold at BF for the unvoiced vowels ($r=0.63$) but very weakly for the voiced vowels ($r=0.17$).

The histograms in Fig. 12(A), (B) represent the distributions of the maximum squared correlation coefficient, $R^2_{\max,\mathrm{RF}v}$ across units for voiced (A) and $R^2_{\max,\mathrm{RF}u}$ for unvoiced vowels (B). In both histograms the data are split into three groups distinguished by the difference between BF estimates, $|\mathrm{BF_{tone}}-\mathrm{BF_{RF}}|$. In both the voiced and unvoiced case the percentage of units with $R^2>0.4$ is significantly larger for units where the smallest BF difference was found (χ^2 test, $P<0.05$). For voiced vowels [Fig. 12(A)], 44% of the units with $|\mathrm{BF_{tone}}-\mathrm{BF_{RF}}|<0.25$ octave have an $R^2_{\max}$ greater than 0.7 (as the examples in Fig. 8), and 71% of these units have an R^2 greater than 0.4 reflecting a fair to good prediction. For unvoiced vowels [Fig. 12(B)], $R^2_{\max}$ is greater than 0.7 for 51% of the units with $|\mathrm{BF_{tone}}-\mathrm{BF_{RF}}|<0.25$ octave, and greater than 0.4 for 78%. Table I shows the percentages of units with $R^2>0.4$ and the BF difference less than 0.25 octave at the various sound levels. Comparing the prediction results as just described between unvoiced and voiced vowels we see that the results are slightly better for unvoiced vowels, but $R^2_{\max}$ is not significantly larger for unvoiced than for voiced according to a nonparametric test (Wilcoxon test, $p>0.1$).

We examined whether the indices $R^2_{\max}$ vary with any of the characteristic response parameters threshold, best intensity, Ω_0, or ϕ_0. $R^2_{\max}$ was larger for units with a medium Ω_0 (0.4–0.8 cycles/oct) than for high or low Ω_0, which was

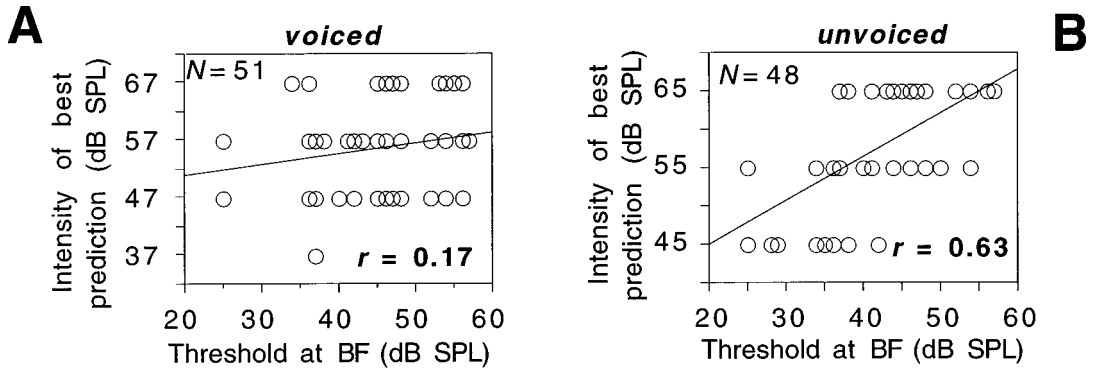

FIG. 11. Intensity of best prediction versus threshold at BF for voiced (A) and unvoiced (B) vowels. The intensity of best prediction is determined if data at three intensity levels are available and $R_{max}>0.4$, or if data at two intensity levels are available and $R_{max}>0.9$. For all AI units $|BF_{tone}-BF_{RF}|<0.5$ octave.

significant for both voiced and unvoiced vowels ($p<0.05$, ANOVA F test). There was no significant relation for other parameters.

The spectral envelope is used as the stimulus descriptor in the prediction [see Eq. (4)]. If indeed the response is determined by the spectral envelope (and not by, e.g., the harmonic fine structure), then the responses to the voiced and unvoiced vowels, which have the same envelope but different carriers (Fig. 2), would be expected to be very similar. Figure 12(C) demonstrates this similarity for a majority of neurons. Figure 12(C) shows the distribution of the index $R^2_{max,vu}$, which is a measure of the match between the responses to voiced and unvoiced for the sound levels with the best match: 61% of the neurons have R^2 greater than 0.7 (as in Fig. 7), and 80% have R^2 greater than 0.4.

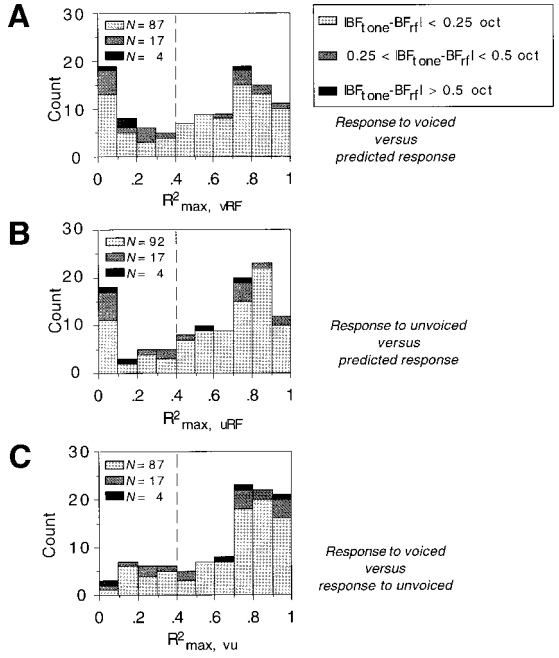

FIG. 12. Distributions of squared correlation coefficients at the level of best correlation, R^2_{max}. The neurons are distinguished on the basis of the difference in tonal and ripple BF, $|BF_{tone}-BF_{RF}|$, which is an indicator for the accuracy of the RF and BF measurement. If $R<0$, R^2 was made 0. (A) Distribution of $R^2_{max,RFv}$ for correlations between responses to voiced vowels and predicted responses. (B) Distribution of $R^2_{max,RFu}$ for responses to unvoiced vowels versus predicted responses. (C) Distribution of $R^2_{max,vu}$ for responses to unvoiced versus responses to voiced vowels.

E. Predictions: BF approach

We wanted to know whether the entire RF is needed to predict the vowel responses or instead information of the BF location alone might be sufficient. Thus, the vowel response was predicted assuming that the RF only consisted of a narrow peak at BF [Eq. (5)]. Figure 13 shows the experimental responses versus these BF-predicted responses for the same three units for which the RF-predicted responses are shown in Fig. 9. The predictions as judged from the correlation coefficients R are fair to good ($R^2>0.4$). However, BF predictions are worse than RF predictions, especially in one case (C) where the decrease in R^2 is considerable.

Focusing on the latter case we see that the responses to /a/, /u/$_1$, and /u/$_2$ are predicted to be similar according to the BF prediction while the response to /u/$_1$ is by far the largest according to the RF prediction [Fig. 9(C)]. The reason for the difference between the predictions is illustrated in Fig. 14 which shows the RF and vowel profiles. All three vowels, /a/, /u/$_1$, and /u/$_2$, have a formant peak around BF giving rise to excitation. However, unlike /u/$_1$, both vowels /a/ and /u/$_2$ have a formant peak at frequencies corresponding to the RF inhibitory sideband above the BF, which gives rise to significant inhibition canceling the excitatory response. In cases A and B the effects of inhibition are more subtle. For instance, examination of the RF of case A (shown in Fig. 5) reveals that both BF and RF predictions should be very similar (large response for the /i/'s, smallest response for /u/$_1$).

The difference between R^2 obtained from the RF prediction and BF prediction for the examples shown in Figs. 9 and 13 were 0.1–0.3. These differences are typical as illustrated in Fig. 15 which shows distributions of these differences, $R^2_{RF}-R^2_{BF}$, across all units for voiced (A) and unvoiced (B)

TABLE I. Percentage of units with $R^2>0.4$, BFdif<0.25 octave.

Vowel type	SPL (dB)	Percentage	N
voiced	67	45	64
voiced	57	51	86
voiced	47	46	70
voiced	best level	71	87
unvoiced	65	55	91
unvoiced	55	60	87
unvoiced	45	47	30
unvoiced	best level	78	92

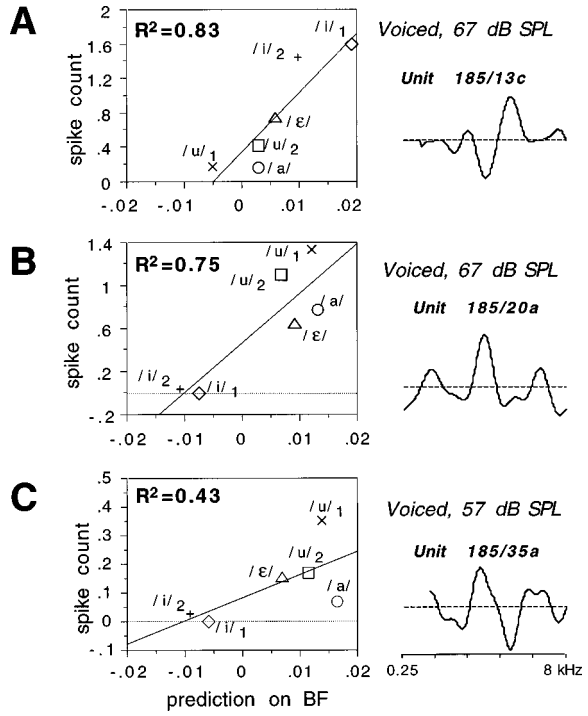

FIG. 13. Examples of spike count (normalized per stimulus presentation) versus responses predicted on the basis of BF and spectral envelope [see Eq. (5)], for voiced vowels, for the three units shown in Fig. 9. See Fig. 9 for further details. (A) unit 185/13*c*; (B) unit 185/20*a*; (C) unit 185/35*a*.

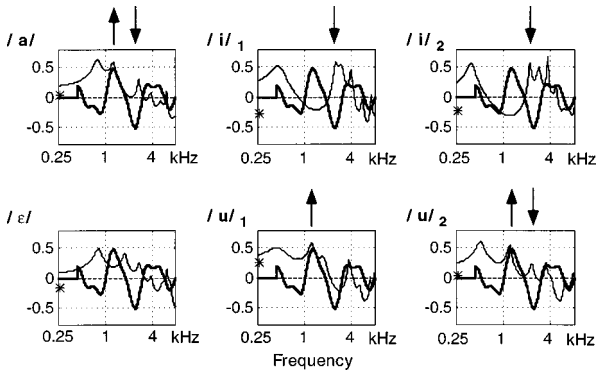

FIG. 14. RF of AI unit 185/35*a* (thick line) with vowel's spectral profiles (thin lines). The vowel profiles are scaled and aligned to the RF. The ordinate is given in RF units (spike count). The upward and downward arrows indicate significant excitatory and inhibitory responses, respectively, as expected from the RF prediction.

vowels. The distribution histograms reveal that for a majority of units the prediction is better, often to a small extent, when based on the entire RF than when based solely on BF. For units with $|\mathrm{BF_{tone}}-\mathrm{BF_{RF}}|<0.25$ octave the R^2 difference is larger than for units with $0.25<|\mathrm{BF_{tone}}-\mathrm{BF_{RF}}|<0.5$ octave, which is statistically significant for voiced vowels at 57 dB SPL [Fig. 15(A)] and for unvoiced vowels at 55 and 65 dB SPL ($p<0.05$, Mann–Whitney test). The results of the statistical analysis of the R^2 difference of units with $|\mathrm{BF_{tone}}-\mathrm{BF_{RF}}|<0.25$ octave are given in Table II and show that the R^2 difference is small but significant for all but one sound level ($p<0.05$, Wilcoxon test).

In Fig. 16 the distributions shown in Fig. 15 are plotted as a function of BF in the same mode as Fig. 8. Two features are evident: between 1.4 and 2.8 kHz where the response and vowel profiles are similar (Fig. 8) the RF prediction is better than the BF prediction, and around 4 kHz where the largest discrepancy between response and vowel profiles was found the RF prediction is worse than the BF prediction.

The difference between R's did not significantly vary with any of the parameters threshold, best intensity, Ω_0, or ϕ_0.

III. DISCUSSION

A. Encoding of vowels at central auditory level

Few data are known on vowel responses at high auditory centers. In contrast, numerous reports have addressed the neural representation of vowel or vowellike sounds in the peripheral auditory system (e.g., Sachs and Young, 1979; Young and Sachs, 1979; Delgutte and Kiang, 1984; Palmer *et al.*, 1986; see overview in Palmer, 1996). The main thread throughout these reports is the question of place and time representation. The auditory nerve and cochlear nucleus have the response properties to use either a rate-place or temporal-place coding scheme to transfer essential information on the vowel to the central system.

The auditory cortex probably plays a role in the processing of natural complex sounds. This role is evident in the bat (Suga, 1984), but not in other mammals in spite of several studies which used in particular animal vocalizations (Newman and Wollberg, 1973; Winter and Funkenstein, 1973; Sovijärvi, 1975). Since those early studies the use of complex stimuli for the study of the cortex in mammals other than the bat has been limited, and more commonly, simple stimuli and semi-complex stimuli as amplitude- and frequency-modulated tones were used. Recently, more use has been made of complex and natural stimuli to characterize cortical responses (Schreiner and Calhoun, 1994; Schreiner and Wong, 1996; Shamma *et al.*, 1995; Wang *et al.*, 1995; Kowalski *et al.*, 1996a; Ohl and Scheich, 1997).

Shamma and Versnel (1995) suggested that for a majority of cells in AI the response to a broadband sound stimulus (expressed in spike count) is based on a linear summation of responses to the ripple components of the spectral envelope of the stimulus. In that paper the sounds used were purposely composed of a few ripple components in order to have a direct test of a ripple superposition. It was still unclear, however, whether this concept, which we refer to as ripple analysis, would in general apply to broadband sounds with any spectral profile. In this paper we addressed this question by examining the responses to vowel sounds in AI in relation-

TABLE II. Difference between goodness of RF and BF prediction for units with BFdif<0.25 octave. The Wilcoxon test is applied for the statistical analysis.

Vowel type	SPL (dB)	R^2rf-R^2bf	P	N
voiced	67	0.01	NS	64
voiced	57	0.08	0.002	86
voiced	47	0.08	0.03	70
unvoiced	65	0.10	0.003	91
unvoiced	55	0.07	0.02	87
unvoiced	45	0.10	NS	30

ship to the ripple responses. The major findings are as follows. First, for most AI cells (71%) the relative responses to natural vowels could be predicted on the basis of the cell's response field (which consists of both excitatory and inhibitory regions) and the smoothed spectral envelope. Second, the responses could be predicted to a fair extent on the basis of the BF (rate-place coding), but predictions on the basis of RF were significantly better. These findings indicate that for most units in AI the ripple analysis applies to natural vowels and to stimuli with natural spectral profiles, thus confirming the ripple analysis as feasible method to characterize Al responses to broadband sounds.

Ohl and Scheich (1997) combined 2DG mapping of responses to synthetic 2-formant vowels with single unit recordings in gerbil AI. Their study demonstrated that spectral profiles are analyzed by features that characterize the entire RF such as bandwidth and inhibitory side bands, thus it supports our findings. Wang *et al.* (1995) found in marmoset AI that the major features of marmoset's vocalization spectra were reflected by the response profiles. This agrees with our finding that the vowels, to some extent, can be encoded on the basis of rate-place information, point-to-point. One might wonder why this straight forward BF coding scheme, although inferior to the ripple coding, holds reasonably well. First, according to the ripple analysis the response to the BF component of the stimulus is included in the total response. Second, when the vowel has a formant peak around BF giving rise to strong excitation, often the troughs of the spectrum lie at the inhibitory regions of the RF giving rise to a weak inhibitory contribution to the total response (e.g., Fig. 5, /i/$_1$), and vice versa, i.e., a weak excitatory component of the vowel response accompanies a strong inhibitory component (e.g., Fig. 5, /u/$_1$). Consequently, the inhibitory effects enhance the contrast between responses to different spectra that already exist due to the excitatory components. Thus it might be a direct consequence of ripple coding that place coding appears to exist.

B. Factors that influence the prediction

There are various factors which influence the prediction of the vowel response on the basis of the ripple model. There might be conditions under which the prediction model [Eq. (4)] is not valid. In testing the model we assume that the RF is well estimated, that the fine structure of the spectrum can be neglected, and that the vowel responses are measured correctly. In the following we discuss assumptions and conditions involved in the prediction.

1. Estimation of the response field

In applying the prediction model formulated in Eq. (4) it is assumed that an Al cell has one unique RF. However, it is not obvious that this is the case. In the primary visual cortex it appears that the receptive field is not static (Gilbert *et al.*, 1996). For instance, the response of a VI cell to stimuli within the receptive field appears to depend on the context in which those stimuli are presented. Thus the RF depends on the stimulus used. Is this also true for AI? We found that RFs measured with tones were generally similar to RFs especially with respect to BF. However, level dependence for the two

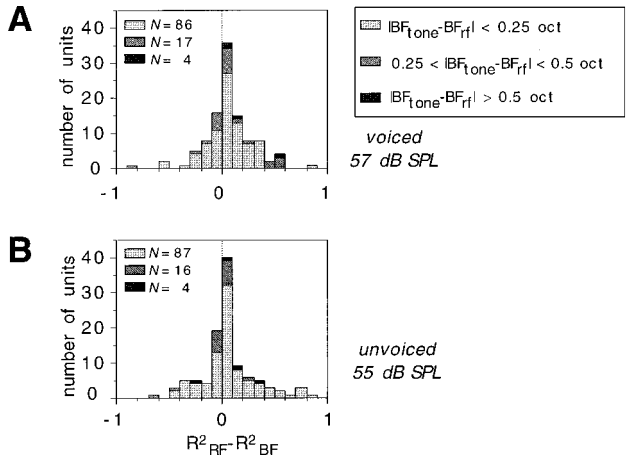

FIG. 15. Distributions of differences between R^2_{RF} reflecting the goodness of the RF prediction and R^2_{BF} reflecting the goodness of the BF prediction. Units are distinguished on the basis of the difference in tonal and ripple BF, $|BF_{tone}-BF_{RF}|$, which is an indicator for the accuracy of the RF and BF measurement. (A) Distribution of $R^2_{RF}-R^2_{BF}$ for voiced vowels at 57 dB SPL. (B) Distribution of $R^2_{RF}-R^2_{BF}$ for unvoiced vowels at 55 dB SPL.

measures is quite different as RFs measured by ripples are quite stable over a 20–30 dB range (Shamma *et al.*, 1995) while tuning to tones can vary dramatically over that same range. We ascribe this discrepancy to nonlinearities that exist along the auditory pathway and are more manifest for narrow band than for broadband stimuli (Shamma and Versnel, 1995). Therefore, it is expected that RFs derived from responses to broadband stimuli would be superior to tonal response measures in order to predict responses. Apart from this principle argument, there are more practical reasons to prefer broadband sounds above narrow-band sounds (see

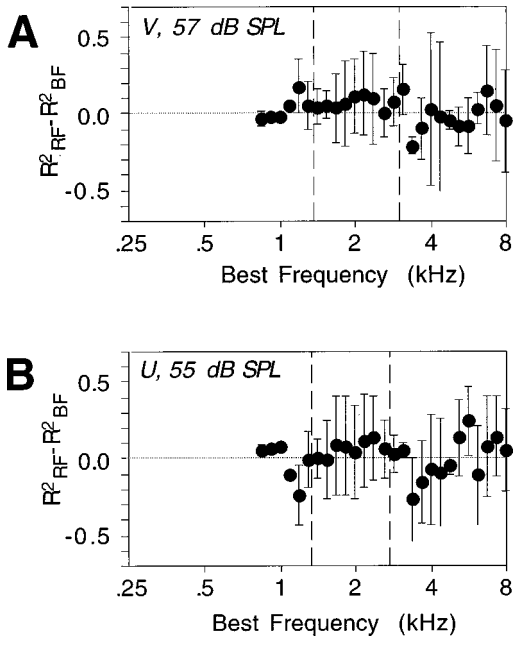

FIG. 16. Average differences between R^2_{RF} and R^2_{BF} vs BF for voiced (A) and unvoiced (B) vowels. The data correspond to those presented in Fig. 15, and all data are included (both units with small and units with large BF differences). The values of $R^2_{RF}-R^2_{BF}$ are averaged over units in 1/4 octave moving segments at 1/8 octave resolution. For further explanation of plots see Figs. 6 and 8.

also Shamma and Versnel, 1995). For instance, the lack of spontaneous activity causes a problem in measuring inhibitory regions using tones.

The ripple responses can be affected by nonlinearities as half-wave rectification and saturation (extensively discussed in Shamma *et al.*, 1995). At low levels the response is affected by rectification, and at high levels by saturation. Although ripple responses are quite robust with level over a 20–30 dB range, other nonlinear effects than half-wave rectification and saturation cannot be ruled out. In this experiment potential errors due to these nonlinearities were largely avoided by using medium levels, which were in the same range of the levels of the vowels.

We assumed that the RF integrates to zero, but it is well possible that either the excitatory or inhibitory regions dominate (which could vary with level, e.g., in nonmonotonic units the inhibitory portion of the RF might be larger at high levels). The dip in the response profile around 4 kHz (Fig. 8) which was unexpected considering the local peak in the vowel spectrum could be caused by inhibitory effects which were stronger than estimated. The relatively low best intensity around 4 kHz [Fig. 6(B)] suggests such strong inhibitory effects. Finally, the RF estimate is affected by statistical noise. A comparison with tonal responses, reflected by the BF difference $|BF_{tone}-BF_{RF}|$ was used as criterion to distinguish RF estimates effected by noise or nonlinearities.

2. Fine spectral structure

The predictions are based on the RF and smoothed spectral envelope, thus neglecting the carrier of the spectrum. A large effect of, e.g., the fine harmonic structure is not expected as this fine structure contains high ripple frequencies (above 2 cycles/octave) which will be filtered by most neurons [highest Ω_0 was 1.2 cycles/octave, Fig. 4(C)]. Similar results obtained for unvoiced and voiced vowels [Fig. 12(C)] confirm that the effect of the carrier is small. The responses to unvoiced vowels can be slightly better predicted [Fig. 12(A), (B); Table I]. This was expected since the carrier is the same as for the rippled stimuli which were used to derive the RF. Yet, the difference is small which underlines that the response is primarily determined by the global spectral structure.

C. Nonlinearities of vowel responses

Half-wave rectification and saturation will affect vowel responses as these nonlinearities affect ripple responses (see above). An example of possible half-wave rectification in vowel responses is the response to $/u/_1$ in Fig. 9(A): this is predicted to be smaller than that to /a/, but the response to /a/ is virtually zero, and consequently the response to $/u/_1$ cannot be smaller. Shamma and Versnel (1995) assessed the subthreshold and supersaturation regions of the responses to multiple-ripple profiles, thus reconstructing the measured response. The correlation between reconstructed and predicted responses was significantly larger than that found between measured and predicted (R increased by 0.11). The biophysical correlate of the reconstructed signal can be thought of as the synaptic potential. The synaptic potential which underlies the neural activity exhibits less saturation and negative responses, and thus is expected to behave more linearly. Jagadeesh *et al.* (1993) experimentally confirmed this by demonstrating that the membrane potential of visual cortical cells evoked by a complex stimulus (moving grating) can be accurately predicted assuming linearity whereas prediction of the corresponding neural response requires nonlinear components (Reid *et al.*, 1991). It would be of great interest to record intracellularly in AI, analogously to Jagadeesh's experiments, to test the ripple analysis without the distorting effects of threshold and saturation.

D. Level dependence of vowel responses

In a majority of the units recorded the relative vowel responses did not vary significantly with absolute level over a 20-dB range [Fig. 10(A)], which is consistent with our findings on multiple-ripple profiles (Shamma and Versnel, 1995). In several cases however, the vowel response often changed with level, sometimes to an extent that within 10 dB a response changed from well predictable to unpredictable [Fig. 10(B)]. These were changes that cannot only be ascribed to saturation or half-wave rectification. We conclude that in general there is an optimal level for which the vowel response can be predicted on the basis of the ripple model and that the linear ripple analysis is restricted to a certain level range. This leaves us with the question how the cortex can apply its ripple analysis to encode profiles over a large range of sound levels. One possibility is that the cortex utilizes the spread of optimal levels across units (Figs. 10 and 11) to encode by means of the ripple analysis at any level. It is likely that optimal levels in mammalian AI in general are represented over a large range given the correlation of optimal level with threshold (Fig. 11) and the large range of thresholds available along isofrequency contours (Schreiner *et al.*, 1992). The ripple analysis model as discussed in previous papers proposes AI to analyze a profile along three dimensions which are spatially organized across AI (BF, ripple frequency, ripple phase). The optimal level could be added as a fourth dimension.

Responses at levels outside the optimal range (not following the ripple analysis) remain puzzling as they seem to distort the ripple encoding of spectral profiles. One might have to assume that at a particular level the responses of units evoked at their optimal level dominate the responses of units responding outside their optimal levels.

IV. CONCLUSIONS

In this paper we have demonstrated that for most units in AI responses to natural vowels can be predicted by cross-correlating the RF and the smoothed spectral envelope of the vowel. In other words, the vowel responses are based on a linear summation of responses to the ripple components of the smoothed spectral envelope of the vowel. This confirms findings in our previous paper with respect to AI responses to synthetic spectra (Shamma and Versnel, 1995). Thus more evidence is provided that AI performs a Fourier-like analysis on the spectral profile of a broadband sound rather than a point-to-point analysis (as a rate-place representation). This

does not mean that for a full description of the responses of the system (which after all integrates several nonlinear processes), a linear model is adequate. For instance, we found that the superposition rule applies to a restricted sound level range, which for some units is quite narrow (less than 20 dB, see Fig. 10). In practical terms our findings imply that given the response field of the AI cell and given the spectral profile of the sound the response magnitude can be predicted relative to the response to other sounds of similar sound level.

Within-channel gap detection using dissimilar markers in cochlear implant listeners

Department of Auditory Implants and Perception, House Ear Institute, 2100 W. Third Street, Los Angeles, California 90057

(Received 25 June 1997; revised 23 October 1997; accepted 15 January 1998)

Temporal gap detection thresholds were measured between perceptually dissimilar electrical markers in cochlear implant listeners. Both markers were presented to the same electrode pair. The amplitude and pulse rate of the first marker were fixed, and gap thresholds were measured as a function of either the pulse rate or the amplitude of the second marker. In either case, U-shaped functions were obtained, with lowest gap thresholds occurring when the two markers were similar in both amplitude and pulse rate. Because the two markers were presented to the same electrode pair, the data cannot be accounted for on the basis of across-channel interactions. It is hypothesized that when different markers are used, the perceptual discontinuity from the first marker to the second is similar to the sensation of a brief gap, and dominates the gap detection process. Thus, gap threshold functions with electrically dissimilar markers serve more as indicators of perceptual distance between the markers and less as measures of temporal resolution. © *1998 Acoustical Society of America.* [S0001-4966(98)01205-3]

INTRODUCTION

In a typical gap detection experiment, the subject is required to detect the presence of a silent temporal gap between two markers. When the two markers are identical, the task can be thought of as a ''within-channel'' task. The detection of the gap in this case will be limited only by the ability of the system to encode the onset of the second marker while it is recovering from the first marker. When the two markers are different in frequency by an amount exceeding a critical bandwidth, the detection of the gap is more difficult. In normal-hearing listeners, one can think of such a task as an ''across-channel'' task because, in this case, the detection of the gap involves the detection of a silent interval between the offset of excitation in one frequency region, and an onset in a distant frequency region. Such a comparison may involve more processing in higher centers of the auditory system than in the ''within-channel'' situation. Another factor likely to influence the detection of a gap is the amplitude scaling performed by the auditory system. For instance, a compressive transformation will reduce the size of the amplitude change signaling the gap. Consequently, although gap threshold has often been considered to be a measure of temporal resolution, researchers have argued that gap detection combines analysis of temporal aspects of the stimulus with analysis of dynamic amplitude changes (Moore and Glasberg, 1988; Moore *et al.*, 1989).

Gap detection thresholds are shortest when the two markers flanking it are identical. When the markers are different, an apparent gap is heard even when there is no actual gap between them. We hypothesize that the primary cue is the system's response to the discontinuity in signal representation, not a discontinuity in time *per se*. Thus, in a two-interval forced choice gap detection task with different markers, both the gap and no-gap intervals would sound as though there is a discontinuity, and gap thresholds would be longer than when the two markers are similar.

In acoustic hearing, the frequency analysis performed by the cochlea, and the broad spread of excitation across different frequency regions, makes it difficult to separate ''within channel'' from ''across channel'' processes. In contrast, in electrically stimulated hearing, one can present two stimuli of different frequency to the same electrode pair, and be reasonably certain that the same neural population is responding to both markers. This makes it possible to explore ''within channel'' mechanisms of perception in a way that would not be possible in acoustic hearing.

The present research stems from work done by Hanekom and Shannon (1997) using ''across-channel'' gap detection as a measure of channel interaction in multielectrode cochlear implant listeners. In that study, the markers flanking the gap were identical signals, but presented to different electrode pairs (the amplitudes were loudness balanced). This created a discontinuity along the location of stimulation in the cochlea (the perceptual correlate of which may be pitch, or timbre, of the sound). Gap detection thresholds were measured as a function of the electrode separation between the first and second markers. When plotted as gap threshold versus electrode number, lowest thresholds were obtained when the two markers were presented to the same electrode, while thresholds rose on either side of this minimum, thus forming a ''tuning'' curve.

In this paper, we describe the results of a study of gap detection using different markers presented to the same electrode pair. It is anticipated that the results will provide an understanding of within-channel gap detection mechanisms, against which we can compare results from across-channel gap detection experiments.

[a]Electronic mail: monita@hei.org

Our experiments were performed with users of the Nucleus 22 multielectrode cochlear implant. Only one electrode pair was stimulated (BP+1 mode). The stimulus comprised a silent gap flanked by markers that were identical (experiment 1), different in amplitude (experiment 2), or different in pulse rate (experiment 3).

I. EXPERIMENTAL DESIGN AND METHODS

All three subjects were adult users of the Nucleus 22 cochlear implant device. They were all postlingually deafened. The subjects were highly trained in various psychophysical experiments.

Three experiments were performed. In experiment 1, the markers were identical in all respects. Gap threshold was measured as a function of marker amplitude, for three pulse rates: 125, 250, and 1000 pulses per second (pps). In experiment 2, both markers were presented at the same rate. The first marker amplitude was fixed at comfortable level, and gap thresholds were measured as a function of the amplitude of the second marker, for two pulse rates (125 and 1000 pps). In experiment 3, both markers were presented at the same subjective loudness. The rate of the first marker was fixed at one of three values (125, 500, or 1000 pps) and gap thresholds were measured as a function of the rate of the second marker. The second marker was always loudness balanced to the first, and both were presented at comfortable level.

The two markers were 100-ms-long, biphasic pulse trains (100 or 200 μs/phase) presented in BP+1 mode to the middle electrode pair (10–12). In this mode of stimulation, the active and indifferent electrodes are separated by one electrode. Thus, current flows from electrode 10 to electrode 12. Subjects N3 and N10 received 100 μs/phase pulse trains. Subject N4, however, required 200 μs/phase pulses to reach comfortable level.

Experiments were software controlled. Stimuli were presented using a custom Nucleus interface (Shannon *et al.*, 1990). The stimuli did not go through the implant processor, but were directly controlled through the interface. All experiments used an adaptive, three-down, one-up paradigm to measure gap thresholds in blocks of two-interval, forced choice trials. Randomly, one of the two intervals in each trial contained a silent gap between the markers. The subject pressed a mouse button to indicate which interval contained the gap. The average of the last 8 out of 12 reversals was computed as the mean gap threshold for each run. The initial (first three reversals) step size was generally twice the final step size, and both were set according to the anticipated threshold for each condition. Visual feedback was provided at the end of each trial. The three-down, one-up paradigm results in convergence at the 79.4% correct point (Levitt, 1971). The mean and standard deviation of two repetitions were calculated for each data point. When the two repetitions yielded widely different results, a third repetition was performed and the mean of all three was calculated.

Stimuli were loudness balanced using a two-up, one-down, 2IFC, double-staircase procedure (Jesteadt, 1980; Zeng and Turner, 1991). The standard was always the 1000-pps signal fixed at comfortable level. The subject heard the standard and a comparison signal in two successive intervals (random order) of a trial and indicated which interval contained the louder signal. The amplitude of the comparison signal was adjusted adaptively to the subject's responses. Each experimental run was composed of two tracks, in which the comparison signal was adjusted until it was heard to be louder 70.7% and 29.3% of the time, respectively. For each track, the last 8 out of 12 reversals were averaged to compute the mean, and the average of the means from the two tracks was computed as the point of subjective equality.

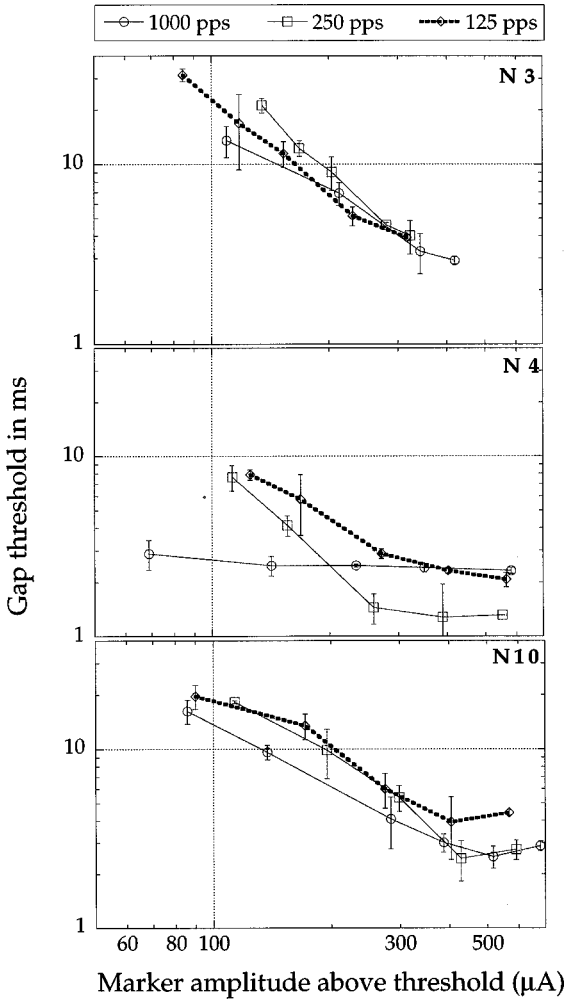

FIG. 1. Gap threshold as a function of marker amplitude in three subjects. The parameter is pulse rate. The two markers were always identical. The horizontal axis represents the level of the markers above threshold in μA.

II. RESULTS

A. Experiment 1: Gap detection as a function of level

The results of experiment 1 are summarized in Fig. 1. In agreement with previous work in acoustic stimulation (Buus and Florentine, 1985; Fitzgibbons, 1983; Plomp, 1964) and electrical stimulation (Shannon, 1986, 1989; Moore and Glasberg, 1988), gap detection thresholds decline with increasing marker level, reaching an asymptote in the range of 1–4 ms above an amplitude corresponding to moderate loudness. Below the asymptote, the function declines as a power function (straight line on a log–log scale). In one subject (N4), the 1000-pps function is quite different from the per-

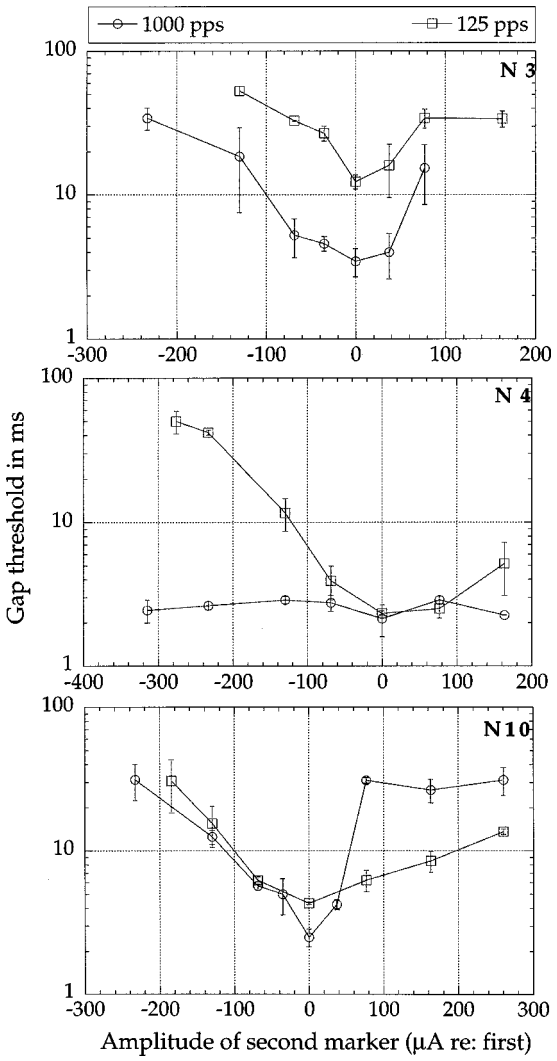

FIG. 2. Gap threshold as a function of the amplitude difference between the second and first markers (second marker−first marker) in μA. The first marker was fixed at comfortable level (zero along the abscissa). The independent variable is the pulse rate, which was identical for both markers.

formance functions for the other two pulse rates: at low current levels, gap thresholds are much lower at 1000 pps, and the slope of the function is much shallower than at 125 or 250 pps. Functions obtained in the other two subjects show little dependence on pulse rate.

B. Experiment 2: Gap detection with markers of unequal amplitudes

Results of experiment 2 are shown in Fig. 2. As in Fig. 1, the parameter is pulse rate (the same for both markers). For each pulse rate, the amplitude of the first marker was fixed at the most comfortable level. The amplitude of the second marker was fixed at different levels, ranging from below to above the level of the first marker. Gap threshold was measured for each level of the second marker.

The gap thresholds in Fig. 2 are plotted on a log axis as a function of the difference in amplitude (in μA) between the first and second markers. In general, gap threshold is minimum at the point where the amplitude of the second marker equals that of the first. Because the pulse rates of the two markers are equal, the markers are identical at the minimum threshold point. Above and below the point of equality, the perceptual discontinuity signaling the change in amplitude is confused with the perceptual discontinuity signaling the gap, and gap thresholds rise with increasing level difference.

It is evident that the shape of the function varies across subjects. The function also varies within subjects, as a function of rate and the level of the first marker. For example, for subject N4, there is little or no dependence on the level of the second marker when the pulse rate is 1000 pps. However, in the same subject and for the same electrode pair, there is considerable dependence on the level of the second marker when the pulse rate is 125 pps. Minimum gap thresholds are typically less than 5 ms, with the exception of subject N3, whose minimum threshold for the 125-pps pulse rate exceeded 10 ms.

C. Experiment 3: Gap detection with markers of unequal pulse rate

In this experiment, the pulse rate of the first marker was kept fixed at 125, 500, or 1000 pps. Gap thresholds were measured as a function of the pulse rate of the second marker, which was fixed at various values ranging from below to above the pulse rate of the first marker. At each point, the amplitude of each marker was loudness balanced to the comfortable level for the 1000-pps marker.

Results from this experiment are shown in Fig. 3. As in experiment 2, the functions show a broad minimum, usually less than or equal to 4 ms. The minimum threshold does not always correspond to the point at which the second marker equals the first in pulse rate. In some cases, the minimum occurs as much as an octave above the pulse rate of the first marker. This may be a reflection of poor pitch judgment among cochlear implant users. As in experiment 2, considerable between- and within-subject variability is observed in the shape of the functions.

III. DISCUSSION

Experiments that would be the direct counterpart in acoustic stimulation do not exist. Presumably, pairs of interrupted or modulated noise markers, presented at different rates or levels before and after the silent gap, would be most comparable to our electrical marker conditions. However, notwithstanding the differences in stimulus and perceptual characteristics, the pattern of our results is in qualitative agreement with similar studies of ''across channel'' gap detection in normal hearing (Formby and Forrest, 1991; Formby *et al.*, 1992; Phillips *et al.*, 1997). Whereas previous work with gap detection has been dominated by time domain analyses, Formby *et al.* (1996) account for their data using concepts of frequency analysis by the auditory system. Based on modeling efforts (Forrest and Formby, 1996; Heinz *et al.*, 1996), they concluded that across-channel gap detection threshold functions can only be accounted for by taking both peripheral filtering and central processing schemes into account.

Gap discrimination experiments of a similar nature performed by Divenyi and Danner (1977) and Divenyi and Sa-

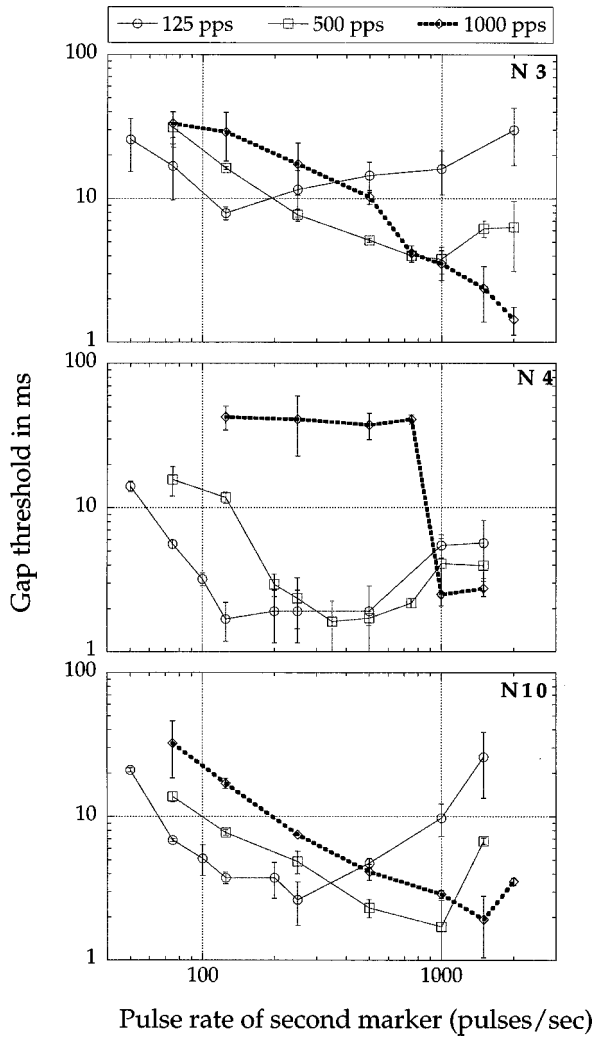

FIG. 3. Gap threshold as a function of the pulse rate of the second marker. The pulse rate of the first marker was kept fixed at 125, 500, or 1000 pps. The amplitudes of the two markers were individually balanced to comfortable level at 1000 pps.

chs (1978) have yielded similar results: the more spectrally similar the two markers, the more discriminable the silent temporal gap.

When experiments involving markers with different frequencies are performed in normal-hearing listeners, the frequency analysis performed by the cochlea maps the markers along the tonotopic axis. When the two markers fall within the same critical band, or ''channel,'' thresholds are lower than when their respective frequencies span more than one critical bandwidth. In experiment 3, the markers, although different in frequency, stimulate the same location in the cochlea. Therefore, we cannot attribute our results to within- versus across-channel mechanisms. The U-shaped functions measured using markers that are different in either frequency or amplitude, in single electrode pair stimulation of cochlear implant patients, indicate that similar functions observed in normal-hearing subjects may be at least partly derived from central mechanisms. However, peripheral capabilities will limit the perceptual distance perceived by the central detector: for example, in cochlear implant listeners, who can only perform temporal analysis on a sound presented to a single electrode, 500 and 1000 pps may sound roughly similar, whereas the normal-hearing listener can discriminate a far wider range of frequencies.

It is evident that gap detection measured with dissimilar marker pairs, which are asymmetric in level or rate, is heavily dependent on the magnitude of the perceptual discontinuity created by the asymmetry. This indicates that the task is not determined solely by peripheral mechanisms, but rather, that gap detection under these conditions is performed at a central stage where rapid changes in stimulus rate and amplitude have already been abstracted. From one perspective, the task of gap detection under these conditions is not a measure of temporal resolution but, rather, a measure of the perceived difference between the first marker and the second. The sharper the slopes of the function relating gap threshold to the difference between markers on either side of the minimum, the greater the subject's sensitivity to the difference. An interesting counterexample to this notion may be found in subject N4's data in Fig. 2: for the 1000-pps marker, his function shows the shallowest slope and the lowest gap thresholds. One may infer that the shallower the slopes of the function (the broader the U), the more the subject is able to attend to the temporal gap in spite of the confounding perceptual change. Thus, overall, the data show considerable differences within subjects under different parametric conditions that cannot be accounted for using either interpretation alone.

These data also emphasize the importance of loudness balancing two different markers in such an experiment as experiment 3. Small changes in perceived loudness will sharpen the slopes on either side of the minimum.

IV. SUMMARY

Gap detection thresholds were measured on a single electrode pair for electrical stimulation of cochlear implant patients, under conditions where the markers flanking the gaps were different in either pulse rate or amplitude. We found that gap detection thresholds increased as a function of the difference between the two markers. The functions generally showed a minimum in the region where the two markers were most similar. We conclude that gap detection under these conditions reflects the perceptual discontinuity between the markers, which presumably involves more than purely temporal processing mechanisms.

(Received 19 August 1997; accepted for publication 9 February 1998)

Traditionally, psychophysical data have been predicted either by constructing models of the peripheral auditory system or by applying signal detection theory (SDT). Frequently, the theoretical detection performance predicted by SDT is greater than that observed experimentally and a nonphysiologically based ''internal noise'' source is often added to the system to compensate for the discrepancy. A more appropriate explanation may be that traditional SDT approaches either incorporate little or no physiology or make simplifying assumptions regarding the density functions describing the physiological data. In the work presented here, an integrated approach, which combines SDT and a physiologically based model of the human auditory system, is proposed as an alternate method of quantifying detection performance. To validate this approach, the predicted detection performance for a simultaneous masking task is compared to predictions obtained from traditional methods and to experimental data. Additionally, the sensitivity of the integrated method is thoroughly investigated. The results suggest that by combining SDT with a physiologically based auditory model, thereby capitalizing on the strengths of each individual method, the previously observed discrepancies can be partially explained as the result of physical processes inherent in the auditory system rather than unspecified ''internal noise'' and more accurate predictions of psychophysical behavior can be obtained.

INTRODUCTION

Data from psychoacoustic experiments have been used to relate physiological mechanisms of the human auditory system to the detection performance of a human listener. In order to gain a greater understanding of the relationship between perception and physiology, substantial research has been devoted to developing methods of predicting human detection performance as well as predicting the neural response of the auditory system to various stimuli. One approach has been to construct models which mimic the physiological mechanisms thought to be operating in the peripheral auditory system (e.g., Carney, 1993; Patterson *et al.*, 1995). Typically, these models simulate the functioning of the cochlea in two stages, one which performs a spectral analysis and one which simulates the neural activity pattern evoked by the stimulus (Yost *et al.*, 1996). A third stage, often added to model the processing performed in the central auditory system, performs temporal integration (Moore *et al.*, 1996). Since these models have been developed to predict peripheral auditory responses (often in terms of neural firing patterns), they have not been used to directly calculate theoretical limits on the discrimination performance achievable by the auditory system. In addition, since the models are in their infancy, their ability to predict the entire range of experimental results has not been fully validated.

Another approach has been to construct models based on the signal processing thought to occur in the peripheral auditory system, for example, an energy detector, an envelope detector, or a leaky integrator (Sherwin *et al.*, 1956; Pfafflin and Mathews, 1962; Jeffress, 1964, 1967, 1968; Green and Swets, 1974). More complex, multiple detector models have also been investigated (e.g., Gilkey and Robinson, 1986). Although some of these models provide a good fit to the general shape of some experimental data, their predictions usually exceed the performance of human subjects and the differences are often attributed to unspecified ''internal'' noise sources in the auditory system or uncertainty in the signal parameters.

Signal detection theory has also been used to generate estimates of the performance bounds by deriving the optimal receiver for a particular task and simulating its performance (Green and Swets, 1974), or by calculating a discriminability statistic, d'. When modeling some experimental tasks, such as detecting a tone in noise, the performance of these receivers far exceeds that of human subjects. Typically, this difference has been compensated for by incorporating an ''internal noise'' process into the receiver system whose variance is adjusted to match experimental data (Pfafflin and Mathews, 1962; Durlach *et al.*, 1986; Dau *et al.*, 1996). While some level of ''internal noise'' has been observed physiologically (Nuttall *et al.*, 1997), the magnitude of the discrepancy is too great to be attributed to ''internal noise'' alone (Green, 1970). Other studies (e.g., Teich and Khanna, 1985; Young and Barta, 1986; Relkin and Pelli, 1987; Viemeister, 1988) have used signal detection precepts to fit ROC curves to neural data. This approach eliminates the need to add ''in-

[a]Electronic mail: lcg@ee.duke.edu
[b]Electronic mail: lcollins@ee.duke.edu

ternal noise'' since it is inherent in the data. The ROCs can then be interpreted in terms of the parameters of an unequal variance Gaussian model. However, comparisons between physiological and psychophysical ROC curves, the former predicting better performance, reveal differences consistent with the idea that the auditory system does not function ideally (Relkin and Pelli, 1987). The second approach, in which a d' statistic is calculated directly from the response data, is based on the assumption that these data follow Gaussian distributions, which may be unrealistic in some cases. These approaches have not consistently modeled experimental data in an accurate manner nor have they provided a physiologically based explanation for the difference between theoretical and experimental results.

Each of the traditional approaches described above has been primarily concerned with either correctly modeling the underlying distributions of the signals or with incorporating the known physiological limitations of the auditory system. The work presented in this paper considers both physical limitations and signal characteristics by integrating a physiologically based auditory model and signal detection precepts. Doing so enables the difference between theoretical performance predictions and the experimental performance of humans to be linked to a physical process in the auditory system rather than attributed to unexplained ''internal noise.'' In order to evaluate the validity of the various approaches, a simple task was chosen for which experimental data and theoretical predictions have historically been mismatched, specifically, the task of detecting a 500-Hz tone in broadband, Gaussian white noise, or simultaneous masking.

In the subsequent sections, an existing model of the peripheral auditory system and the traditional methods of evaluating detection performance, described briefly above, are examined in more detail. It is then shown how the integrated method can be derived from a combination of the peripheral auditory model and signal detection theory. Using this integrated method, the performance of the ideal observer at the output of each stage of Patterson's model of the human auditory system (1995) is evaluated. In addition, the sensitivity of this method to mismatched assumptions is thoroughly investigated. Finally, the detection performance predicted by the integrated method, the energy-detector model, and classical signal detection theory (both the signal-known-exactly and signal-known-statistically cases) are compared to experimental data obtained by Watson and his colleagues (1964). The results suggest that a method combining signal detection theory and a physiologically based auditory model enables previously observed discrepancies between theoretical and experimental results to be partially explained as the result of physical processes inherent in the auditory system, and that more accurate predictions of psychophysical behavior can be obtained.

I. COMPUTATIONAL MODELS OF AUDITORY PROCESSING

Signal processing occurring in the peripheral human auditory system is commonly simulated in two stages. The functional path of the Auditory Image Model (AIM), developed by Patterson and his colleagues (Patterson and Holdsworth, 1994, and references therein) takes this approach and includes a third stage which attempts to link physiology and perception. The first stage, which models the acoustic to mechanical transduction of the basilar membrane, performs a spectral analysis. Experiments have shown that the basilar membrane behaves like a bank of overlapping bandpass filters with sharp high-frequency roll off and shallow low-frequency roll off (von Békésy, 1960). The basilar membrane motion (BMM) module of AIM models this stage of auditory processing as a bank of linear gammatone filters whose impulse response is a good fit to the measured impulse response of cats using the revcor technique (de Boer, 1978). The results from psychological and physiological experiments studying frequency selectivity indicate that the bandwidth of the filters varies with location on the basilar membrane. The gammatone filters have the characteristic of being narrow band at low frequencies with a bandwidth which increases proportionally with the center frequency. Despite some drawbacks (such as the linearity assumption), the gammatone filter was utilized in AIM since it appears to be a good first order approximation to the data, is easy to implement, and is computationally efficient (Patterson and Holdsworth, 1994).

The second stage of AIM encompasses the neural encoding phase of the auditory system in which the filtered output of the basilar membrane is converted into a neural activity pattern (NAP). Data have shown that the signal processing performed by the inner hair cells includes compression, rectification, and low-pass filtering (Patterson *et al.*, 1992). AIM models this stage by rectifying and compressing the output of the first stage (BMM) and applying a two-dimensional time and frequency adaptation, allowing small features to be suppressed in the region of a large feature (Patterson and Holdsworth, 1994).

The final stage of AIM does not directly model any signal processing which takes place in the peripheral auditory system. Rather, it is a purely functional module which attempts to represent an ''auditory image'' of the perceived sound (Patterson and Holdsworth, 1994). Proposed models of the central auditory system based on experimental data suggest that the ear performs temporal integration. One difficulty is that fine-grained temporal information must be retained despite this integration. The mechanism employed by AIM to model this is strobed temporal integration (STI). STI operates on the signal by maintaining an adaptive threshold for each channel. When the output of the NAP exceeds this threshold, the NAP signal is added point for point to the existing auditory image. The threshold then decays exponentially until the next peak is encountered. Thus for a periodic signal, integration will be triggered once in each period, emphasizing periodic information and causing cancelation of aperiodic information introduced by noise. One important feature of STI is that the trigger mechanism is independent across channels, resulting in phase alignment, or equivalently, the loss of phase information (Patterson *et al.*, 1995).

AIM calculates the responses for multiple channels, each of which corresponds to a single filter in the gammatone filterbank. It is reasonable to assume that, for most tasks, all channels will contribute to signal detection, requir-

ing information to be combined in some manner across channels. However, in the past, it has been commonly accepted that, to a first-order approximation, only the information in the channel with the best signal-to-noise ratio is used in detecting a tone in broadband noise (e.g., Dau *et al.*, 1996). Therefore, the following simulations and analyses of a simultaneous masking task utilize only the output of the filter with a center frequency of 500 Hz, the frequency of the tone.

II. TRADITIONAL SIGNAL PROCESSING MODELS OF AUDITORY PROCESSING

Historically, several different methods incorporating signal detection theory have been used to evaluate detection performance for various psychophysical tasks. One common link between these methods is the inability of each to satisfactorily explain the discrepancies between human performance and theoretical results. Although evaluating detection performance using these methods can be efficient and convenient, simplifying assumptions may lead to inaccurate conclusions about performance. The novel approach pursued and evaluated in this paper utilizes a rigorous application of signal detection theory and eliminates the need to make these incorrect assumptions.

The energy-detector model, consisting of a bandpass filter centered at the frequency of the tone followed by a square-law device and an integrator, has been used to model data from several experiments with some success. Pfafflin and Mathews (1962) found that this model accurately predicts the shape of the detection curve of a 1000-Hz sinusoid in noise, however, both internal and external ''noise'' sources were required to explain the discrepancies between the predicted and observed results. Sherwin *et al.* (1956) also added ''internal noise'' to reconcile the differences between human detector and electronic (energy) detector performance on a similar task. Finally, Kidd *et al.* (1989) found that the critical band energy-detector model could predict some, but not all, of the experimental results in a study of the detectability of tones in noise.

Another method commonly used to quantify detection performance in psychophysical experiments involves calculating a discriminability statistic, d', from the response data (Tanner and Birdsall, 1958; Yost, 1996). For the special one-dimensional case where the signal parameters are known exactly and the noise is additive, zero mean, and follows a Gaussian distribution, the theoretical d' can be calculated as

$$d' = \frac{\mu_1 - \mu_0}{\sigma},$$

where μ_1 and μ_0 are the means of the density functions of the signal plus noise and noise alone cases, respectively, and the standard deviation, σ, of both density functions is equal. In the multi-dimensional case, when the received signal is a sampled function of time, and the signal, **s**, is known exactly, then

$$(d')^2 = (\mathbf{\Delta m})^{\mathbf{T}}\mathbf{Q}(\mathbf{\Delta m}), \tag{1}$$

where $\mathbf{\Delta m} = \mathbf{s}$ and $\mathbf{Q}$ is a diagonal matrix for which $Q_{i,i} = [\sigma^2(t_i)]^{-1}$. If the variance is not a function of time, Eq. (1) reduces to

$$(d')^2 = \frac{\mathbf{s}^T\mathbf{s}}{\sigma^2},$$

which is the signal-to-noise ratio. When the statistics of the process are known to be deterministic, but are not known in advance, the statistics of the two density functions can be estimated across realizations and Eq. (1) can be used to calculate d' where $\mathbf{\Delta m} = \hat{\mathbf{s}}$ and $Q_{i,i} = [\hat{\sigma}^2(t_i)]^{-1}$ where $\hat{\mathbf{s}}$ is the estimated time-varying signal and $\hat{\sigma}^2$ is the estimated variance (Van Trees, 1968). In this case, Eq. (1) becomes

$$(d')^2 = \frac{\hat{\mathbf{s}}^T\hat{\mathbf{s}}}{\hat{\sigma}^2}. \tag{2}$$

A more appropriate method which has been used to evaluate the detection performance for a known signal, **s**, embedded in noise using signal detection theory is to generate distributions of the received signal given the following two hypotheses:

H_0: The received signal, **x**, is noise alone.

H_1: The received signal, **x**, is the known signal in noise.

From the density functions of the received data under each of the two hypotheses, $p(\mathbf{x}|H_0)$ and $p(\mathbf{x}|H_1)$, the likelihood ratio, defined as

$$\lambda = \frac{p(\mathbf{x}|H_1)}{p(\mathbf{x}|H_0)}, \tag{3}$$

can be formed. This ratio determines the form of the optimal processor, a monotonic function of the likelihood ratio, which can then be applied to the data in order to derive the Receiver Operating Characteristic (ROC) for a given signal-to-noise ratio (Tanner and Birdsall, 1958). Traditionally, the optimal detector has been derived assuming that signal parameters are known exactly and the distributions under H_0 and H_1 are both uncorrelated, equal-variance Gaussians, the classical Signal-Known-Exactly (SKE) detection problem (Tanner, 1960). Jeffress (1967) suggests that, although this processor does not accurately predict experimental data, it has been widely adopted since it is mathematically tractable. The resulting optimal detector, which will be referred to as the Gaussian–Gaussian processor due to the assumptions made regarding the two density functions, has the form

$$\mathbf{x}^T\mathbf{s} \underset{H_0}{\overset{H_1}{\gtrless}} \beta, \tag{4}$$

where **x** is the received signal, **s** is the known signal, and β is the threshold to which it is being compared (Van Trees, 1968). The performance of this processor is also quantifiable in terms of the d' described in Eq. (2) because the underlying assumptions are met.

Several studies (e.g., Marill, 1956; Egan *et al.*, 1959) have shown that experimental data are better fit when the signal is assumed to be known statistically (SKS) rather than exactly (SKE). In the context of AIM, this uncertainty is justified at the level of the SAI since, due to the strobed temporal integration, information about the phase of the signal is lost and, due to observer uncertainty, the exact frequency of the tone may not be known exactly. This uncertainty can be incorporated into the optimal ''signal-known-

except-for-frequency-and-phase'' (SKEFP) processor by assuming that the *a priori* distribution of the phase is uniform and that the *a priori* distribution of the frequency can be derived from the characteristics of the gammatone filter centered at 500 Hz. This processor, derived using classical signal detection theory methods, can then be applied to the signals outside the ear.

The approach taken in this paper is similar to the standard signal detection theory approach as far as the methodology. However, there are two key differences. First, in contrast to the previously described methods which analyze the signal at the input of the auditory system, this approach allows the analysis of data received after each stage of the model of auditory processing. Second, instead of assuming that the density functions of the data under each hypothesis are uncorrelated Gaussians, the true density functions are simulated at the output of each stage of AIM. This is achieved by generating 9000 realizations of the noise and signal plus noise, propagating them through one, two, or three stages of AIM, and forming histograms of the output signals at each point in time to approximate $p(\mathbf{x}|H_0)$ and $p(\mathbf{x}|H_1)$ and the corresponding statistics (e.g., the mean and variance in the case of Gaussian distributions). Using these density functions, the likelihood ratio is formed [Eq. (3)] and used to determine the corresponding processor. To generate ROCs, 9000 realizations of the signals under each hypothesis are generated and propagated through the model to the desired stage. The output signals are then used as the data upon which the processor operates to generate probability of false alarm and probability of detection values for each threshold. These values are then plotted on normal–normal axes to obtain the corresponding ROC curve. Since this method integrates signal detection theory and a model of the peripheral auditory system, it will be referred to as the integrated approach in the subsequent discussion. The ''optimal'' detector often requires substantial computation time, rendering it impractical for a real-time application. Therefore, the effect of making simplifying assumptions regarding the density functions under each hypothesis has also been investigated.

Each method described above is used to calculate ROC curves which can be used for two purposes. First, these curves allow the comparison of the detection performance of various proposed processors and methods. In addition, the sensitivity of the integrated method can be investigated by computing the ROCs for processors derived under various simplifying assumptions after each stage of the model. In this way, it can be determined which *a priori* assumptions about the received signal have a significant effect on detection performance and processor design. Second, the ROC curves can be used to validate or refute the model. If the results predicted by the model coincide with the experimental data, it can be concluded that the model may accurately represent the signal processing performed by the human auditory system for the given task. It should be noted, however, that this does not mean that the model necessarily specifies the mechanisms which actually exist.

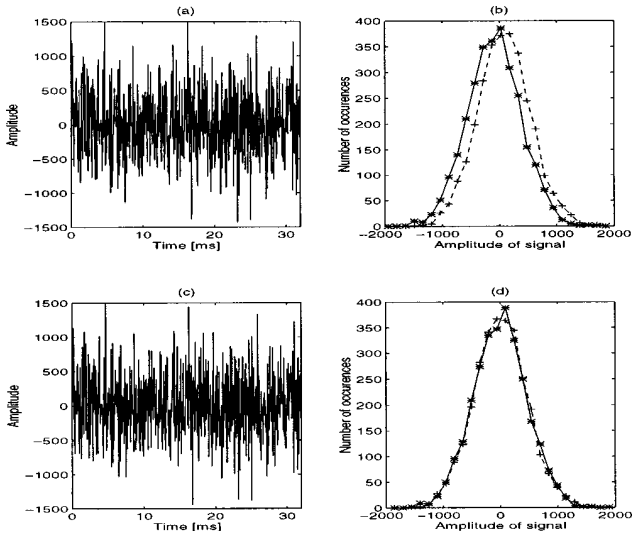

FIG. 1. Outside the ear: (a) Typical realization of 500-Hz tone in broadband, Gaussian noise, $E/N_0=14$; (b) Distribution of responses under H_1 at $t=20.7$ ms (+) and $t=21.7$ ms (∗); (c) Typical realization of broadband, Gaussian noise alone; (d) Distribution of responses under H_0 at $t=20.7$ ms (+) and $t=21.7$ ms (∗).

III. ANALYSIS OF THE INTEGRATED METHOD

A. Detection performance outside the ear

The task of detecting a 500-Hz tone in broadband, Gaussian white noise, known as simultaneous masking, was chosen for this analysis since theoretical and experimental results for this task have historically been mismatched, thereby making it a good test case for the integrated method. Since the integrated method is based on signal detection theory, the derived processor is equivalent to that of the SKE case outside the ear. However, the procedure for determining the optimal processor for the integrated method and simulating its performance was followed and applied to the signals outside the ear to illustrate the approach under a scenario where the correct result was known *a priori*.

In the first step, the density functions of the received data under H_0 and H_1 are determined. Outside the ear, these density functions are specified by the problem parameters for the simultaneous masking task. Namely, under H_0, $x(t_k)$ is a random variable described by a $\mathbf{N}(0,\sigma^2)$ distribution, under H_1, $x(t_k)$ is a random variable described by a $\mathbf{N}(A\sin 2\pi f t_k,\sigma^2)$ distribution, and the signal-to-noise ratio is defined as $KA^2/2\sigma^2$, where K is the total number of time samples. To determine the density functions of the simulated data, many realizations of the noise and signal plus noise were generated and a histogram was formed for each time slice. Figure 1(b) and (d) shows the histograms under H_1 and H_0, respectively, for $t=20.7$ ms, corresponding to the occurrence of a maximum in the input sinusoid, and $t=21.7$ ms, corresponding to the occurrence of a minimum in the input sinusoid. The histograms, and thus the density functions, under H_0 at each point in time are zero mean, uncorrelated, and Gaussian. Likewise, under H_1, at each point in time, the density functions are also uncorrelated and Gaussian, however, the mean of each density function varies sinusoidally in phase with the input tone. These density func-

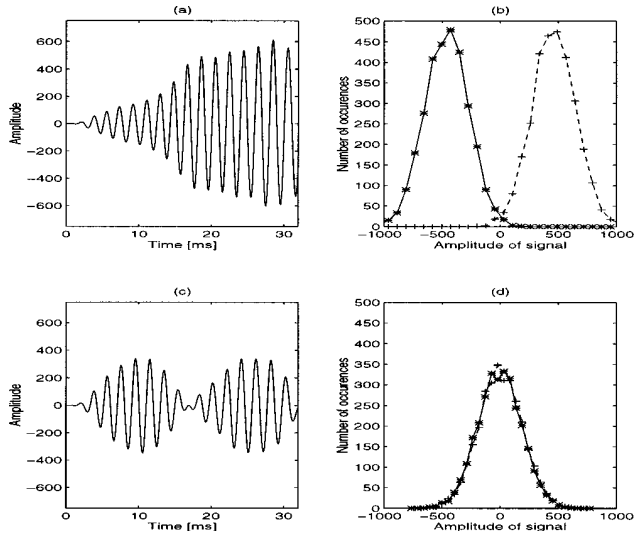

FIG. 2. Post-BMM (a) Typical realization of the received signal under H_1; (b) Distribution of responses under H_1 at $t=20.7$ ms (+) and $t=21.7$ ms (∗); (c) Typical realization of the received signal under H_0; (d) Distribution of responses under H_0 at $t=20.7$ ms (+) and $t=21.7$ ms (∗).

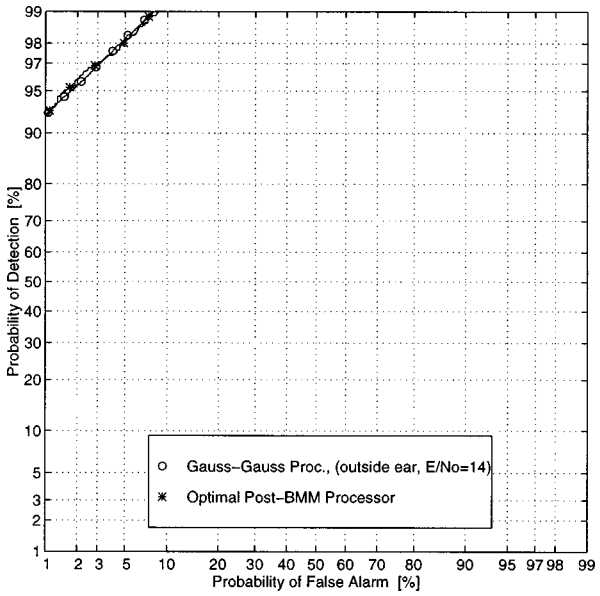

FIG. 3. ROC for the optimal post-BMM processor (∗). The Gaussian–Gaussian processor outside the ear (○) is included as a reference.

tions result in the classical signal-known-exactly (SKE) detection problem and the optimal processor, the Gaussian–Gaussian processor, is given by Eq. (4). Since the assumptions made by classical signal detection theory are met, the predictions made by the two methods are equivalent at this point. The ROC curve for the Gaussian–Gaussian processor corresponding to a value of $E/N_0=14$ outside the ear is included on all the ROC plots in this paper as a reference point to which detection performance of other processors at each stage of AIM can be compared. Since the most complete information about the signal is available outside the ear, and information can only be lost as the signal propagates through the ear, detection performance at successive stages of the model can never be greater than this reference curve for a given signal-to-noise ratio (Taylor and Forbes, 1969).

B. Detection performance post-basilar membrane

To determine the detection performance after the first stage of AIM using the integrated approach, the density functions under H_0 and H_1 were obtained by applying linear systems analysis. When the input to a linear filter is a sinusoid at a particular frequency, the output is a sinusoid at that same frequency whose amplitude and phase may be different. When the input is zero mean, uncorrelated, white Gaussian noise, the output is zero mean, correlated Gaussian noise with an autocorrelation function, $\mathbf{R}_y(\tau)$, equal to $\mathcal{F}^{-1}\{|\mathbf{H}(\mathbf{f})|^2\mathbf{S}_x(\mathbf{f})\}$, where $\mathbf{H}(\mathbf{f})$ is the Fourier transform of $h(t)$, the impulse response of the filter, and $\mathbf{S}_x(\mathbf{f})$ is the power spectral density function of the input signal (Oppenheim and Schafer, 1989). These analytic results were verified by generating multiple realizations of the uncorrelated Gaussian noise and the tone plus noise outside the ear and simulating the output of the first stage of AIM using an analytic form of the gammatone filter. Figure 2(a) and (c) illustrates typical realizations of the received signal under each hypothesis. Histograms were formed from the simulated responses in order to determine the density functions at each time slice. Figure 2(b) and (d) depicts the histograms under H_1 and H_0, respectively, for points in time corresponding to a maximum and a minimum in the sinusoid outside the ear. These two time slices were selected to illustrate the possible variations in the histograms since each is associated with an extreme point in the input. At each point in time, the density functions under H_0 are zero mean and Gaussian, as at the input of the model. However, unlike the input signal, there is a covariance structure inherent in the simulated response. Likewise, under H_1, the density functions are correlated and Gaussian with a time-varying mean.

Given these density functions, the likelihood ratio test can be formed. Simplification results in the optimal post-BMM processor, which incorporates the existing covariance structure,

$$\mathbf{x}^T\mathbf{C}_n^{-1}\mathbf{s} \underset{H_0}{\overset{H_1}{\gtrless}} \beta, \tag{5}$$

where $\mathbf{s}$ is the tone, $\mathbf{x}$ is the received signal, and $\mathbf{C}_n$, the covariance of the noise, is related to the autocorrelation of the output as $\mathbf{C}_n(i,j)=\mathbf{R}_y(i-j)$. To investigate the sensitivity of this method to simplifying assumptions, the Gaussian–Gaussian processor, given in Eq. (4), which ignores the covariance structure inherent in the data, was also applied at the output of the BMM and its performance was determined. Because the covariance matrix closely resembled an identity matrix, the performance for the two processors was essentially the same. A comparison between the ROCs for the optimal post-BMM processor and the Gaussian–Gaussian processor applied outside the ear reveals that the performance of these two processors is essentially the same as well (see Fig. 3). These results suggest that no information has been lost in the first stage of processing which is consistent with the theory of linear filters.

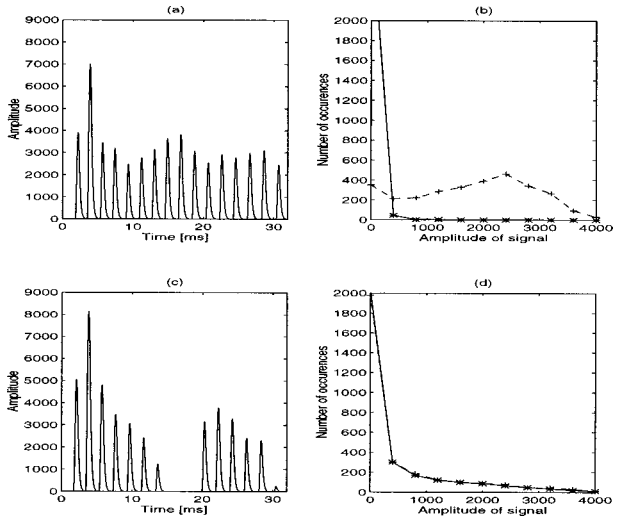

FIG. 4. Post-NAP: (a) Typical realization of the received signal under H_1; (b) Distribution of responses under H_1 at $t=20.7$ ms (+) and $t=21.7$ ms (∗); (c) Typical realization of the received signal under H_0; (d) Distribution of responses under H_0 at $t=20.7$ ms (+) and $t=21.7$ ms (∗).

C. Detection performance post-neural activity pattern

The linearity of the signal processing performed by the first stage of AIM results in a simple relationship between the input and the output signals. The second stage of AIM, however, is nonlinear. Therefore, it is instructive to first consider what form the responses are expected to take given the signal processing that is being modeled by AIM. First, consider the response to the tone alone. Since both the tone and AIM are deterministic, for each point in time the output of AIM will be identical across realizations. One of the functions of the NAP is to rectify the output of the BMM, thus the output of the NAP will be zero when the output of the BMM is negative. Next, consider the response to the noise alone. The noise at the output of the BMM [see Fig. 2(d)] follows a zero-mean Gaussian distribution. Therefore, the probability that the noise has a negative amplitude is equal to one-half. Thus half of the time, the response of the NAP to an input of noise alone will be zero, resulting in a density function that is heavily weighted toward zero and is zero for all negative values. Finally, consider an input of tone plus noise. Whenever the tone's amplitude is negative, the NAP responds as if to noise with a negative mean and, following the argument presented for noise alone, the density function will be even more heavily weighted toward zero than the density function under H_0. When the amplitude of the tone is positive, it will manifest itself as a positive shift in the mean of the density function. These observations suggest that the density functions are not Gaussian and plots of the actual density functions obtained by simulation (see Fig. 4) confirm this hypothesis.

As expected, when many realizations of the noise and tone plus noise are propagated through AIM, the density function under H_0 is identical at all time slices [see typical histograms in Fig. 4(d)] and can be approximated by an exponential density function with a parameter $\boldsymbol{\lambda}$, which can be derived from the data. The density function under H_1 varies across time, as predicted. For time samples when the BMM response to the tone is negative, such as when $t=21.7$ ms, the response of the NAP mimics its response to noise alone, resulting in similar exponential density functions [Fig. 4(b), [∗]]. When the response of the BMM to the tone is positive, such as when $t=20.7$ ms, the resulting NAP density function resembles a truncated Gaussian, however, there is a slight concentration of responses near zero [Fig. 4(b), [+]].

Under the assumptions that the noise follows an uncorrelated exponential distribution with parameter $\boldsymbol{\lambda}$ and the density function for the tone plus noise can be approximated by an uncorrelated Gaussian with mean $\boldsymbol{\mu}_{sn}$ and variance $\boldsymbol{\sigma}_{sn}^2$, the likelihood ratio can be formed. After simplification, the corresponding processor, to be referred to as the Gaussian–Exponential processor, can be expressed as

$$\boldsymbol{\lambda}^T\mathbf{x}-\frac{\mathbf{x}^T\mathbf{x}}{2\boldsymbol{\sigma}_{sn}^2}+\frac{\mathbf{x}^T\boldsymbol{\mu}_{sn}}{\boldsymbol{\sigma}_{sn}^2}\underset{H_0}{\overset{H_1}{\gtrless}}\beta. \tag{6}$$

The assumptions made when formulating the likelihood ratio that resulted in the Gaussian–Exponential processor yield a computationally intense processor. This gives rise to the issue of how sensitive the predicted performance is to the accuracy of the assumptions made regarding the density functions. An additional processor was derived from a likelihood ratio based on the assumptions that the density functions of the received data under H_0 and H_1 were both uncorrelated, equal-variance, nonzero-mean Gaussians. The processor corresponding to these assumptions, referred to as the Gaussian–Gaussian (nonzero-mean) processor, is

$$\mathbf{x}^T\boldsymbol{\mu}_{sn}-\mathbf{x}^T\boldsymbol{\mu}_n\underset{H_0}{\overset{H_1}{\gtrless}}\beta, \tag{7}$$

where $\boldsymbol{\mu}_{sn}$ and $\boldsymbol{\mu}_n$ are the means under H_1 and H_0, respectively. This processor simplifies the computations since it employs a Gaussian instead of an exponential density function. Finally, even the assumption of nonzero-mean noise can be eliminated, resulting in the standard Gaussian–Gaussian processor, given in Eq. (4).

Figure 5 shows the ROCs associated with each processor and indicates that there is some loss in performance predicted by each processor. In addition, these plots illustrate that the decrease in predicted performance is more substantial when simplifying assumptions are made. Thus one can conclude that incorporating more accurate *a priori* information regarding the output density functions increases the predicted performance. If only the results of the simplest processor, the Gaussian–Gaussian processor, were examined, the discrepancy between the theoretical prediction and the experimental data, whose ROC lies closer the the chance diagonal, would be mistakenly assumed to be smaller than that which actually exists and the observed decrease would be attributed to a loss of information in the auditory system rather than to the true cause, an imprecise application of signal detection theory.

As was alluded to above, the Gaussian–Exponential processor was based on a simplifying assumption regarding the density function of the received data under H_1. One final detector, derived by fitting polynomials to the density functions under H_1 at each time sample and assuming an expo-

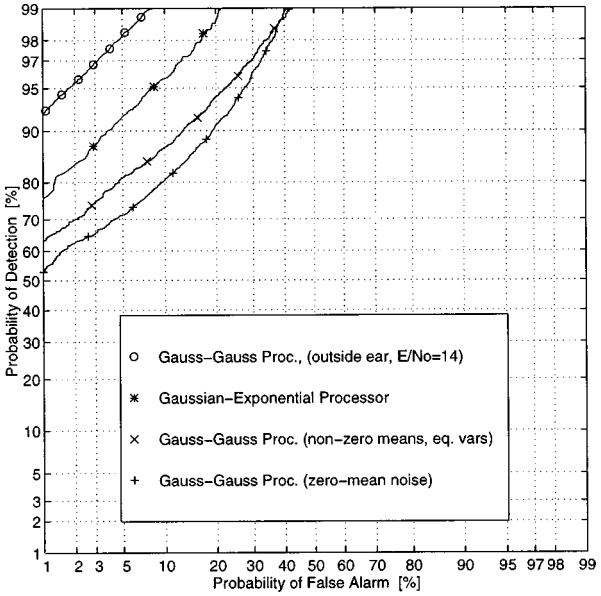

FIG. 5. ROC for the Gaussian-Exponential processor (∗), the nonzero-mean Gaussian–Gaussian processor (×), and the zero-mean noise Gaussian–Gaussian processor (+) applied to the output of the NAP. The Gaussian–Gaussian processor applied outside the ear (○) is included as a reference.

nential distribution for the noise, was evaluated. The performance was not significantly different from the Gaussian–Exponential processor, thus it can be concluded that the additional information contained in a more accurate representation of the density functions does not significantly increase the performance.

Finally, it should be noted that the covariance of the received data was ignored by all of the processors derived above for mathematical tractability. To derive the true ''optimal'' processor, this correlation should be incorporated, however, due to the complexity of the problem and computational constraints, this approach was not pursued. Thus it is possible that the loss in performance predicted by the Gaussian–Exponential processor may be at least partially attributed to this omission.

D. Detection performance post-stabilized auditory image

The purpose of the third stage of AIM is to generate a ''stabilized'' image by performing strobed temporal integration. The density functions under H_0 and H_1 were generated using AIM for a signal with K time samples (Fig. 6). Histograms are shown in Fig. 6(b) and (d), however, at this stage in AIM, they can no longer be considered ''typical'' since the histograms vary widely and unpredictably as a function of time. To obtain the most accurate approximation of $p(x_i|H_1)$ and $p(x_i|H_0)$, polynomials were fit to the density functions at each time slice i. Assuming statistical independence across time, these density functions were then used to calculate a likelihood ratio and corresponding processor of the form,

$$\frac{p(\mathbf{x}|H_1)}{p(\mathbf{x}|H_0)}=\prod_{i=1}^{K}\frac{p(x_i|H_1)}{p(x_i|H_0)}\underset{H_0}{\overset{H_1}{\gtrless}}\beta. \tag{8}$$

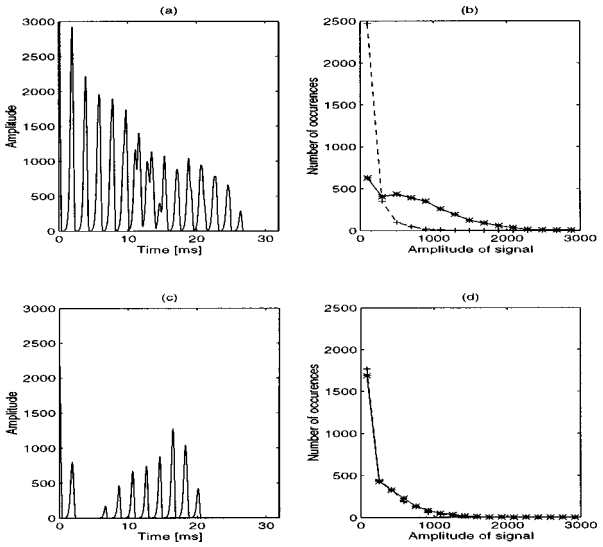

FIG. 6. Post-SAI: (a) Typical realization of the received signal under H_1; (b) Distribution of responses under H_1 at $t=20.7$ ms (+) and $t=21.7$ ms (∗); (c) Typical realization of the received signal under H_0; (d) Distribution of responses under H_0 at $t=20.7$ ms (+) and $t=21.7$ ms (∗).

Again, the sensitivity of this method was investigated by making simplifying assumptions similar to those described for the NAP. The nonzero-mean Gaussian–Gaussian processor, given in Eq. (7), and the classical Gaussian–Gaussian processor, expressed in Eq. (4), were also used to analyze the data. Figure 7 shows the resulting ROCs associated with each processor. Unlike the results after the BMM and the NAP, it appears that making simplifying assumptions does not greatly affect the predicted performance at this stage. However, there is a substantial decrease in performance predicted by all processors. The significance of this result, which is discussed further in the next section, is that white noise was only added to the signal outside the ear before

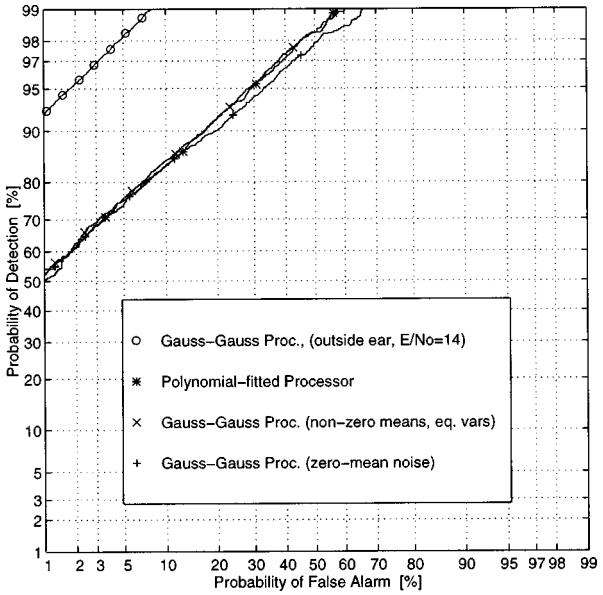

FIG. 7. ROC for the Polynomial-Fitted processor (∗), the nonzero-mean Gaussian–Gaussian processor (×), and the zero-mean noise Gaussian–Gaussian processor (+) applied to the output of the SAI. The Gaussian–Gaussian processor applied outside the ear (○) is included as a reference.

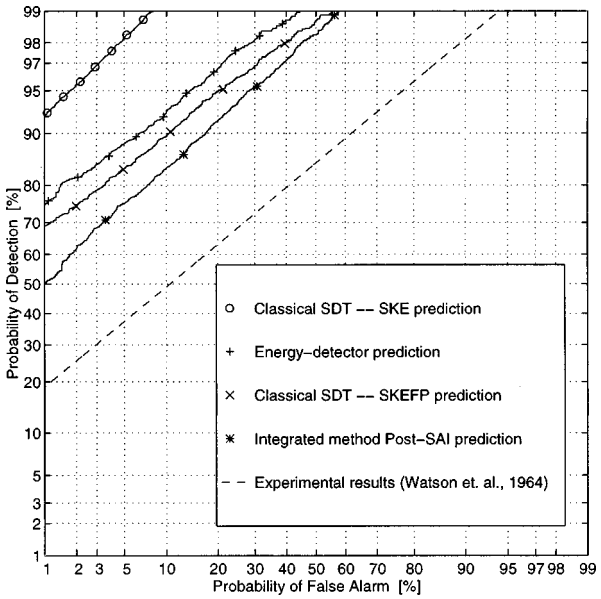

FIG. 8. ROC comparing the performance predicted by various methods, including the classical signal detection theory method (SKE case, ○; SKEFP case, ×), the energy-detector model (+), and the integrated method (*), to experimental results (- -). The experimental ROC was plotted assuming $d_s = 1.13$ and $\sigma_n/\sigma_{sn} = 0.82$, the values derived by Watson *et al.* from their 36-point ROC.

being processed by the auditory model in contrast to some other approaches (e.g., Dau *et al.*, 1996) which add white noise to the data after being processed by a model. As a result, external noise is processed in the exact same manner as the input signal and no assumptions have to be made regarding the internal distribution of the noise.

IV. COMPARISON OF THE PERFORMANCE OF INTEGRATED AND TRADITIONAL METHODS WITH EXPERIMENTAL RESULTS

The results of the integrated approach were compared to the predictions made by several traditional methods of quantifying detection performance and to experimental data obtained by Watson and his colleagues (1964) for a fixed-interval-observation masking experiment (see Fig. 8). In their experiment, the 500-Hz tone, when present, had a duration of 250 ms. The noise was white and the signal intensity was chosen so that $E/N_0 = 14$. Experimental ROCs were determined for three subjects using a 36-point rating method from which the average detectability index, d_s, and the average slope of the line on normal–normal axes were derived. As seen in Fig. 8, the integrated method yields the most accurate prediction of human performance. However, this prediction is still substantially greater than the experimental data. The classical signal detection theory prediction for the ideal observer in the SKE case far exceeds the human performance, yet this result is still useful as it gives an upper bound on performance. The energy-detector model provides an estimate that is closer to experimental data than the SKE case outside the ear, but this prediction exceeds even the integrated method's prediction. The ROC for the classical SDT problem assuming uncertain frequency and phase (SKEFP) yields a more accurate prediction than the SKE processor, however, the integrated method is still a better predictor of human performance. The detection performance predicted by the classical SKS processor (not shown), which only incorporates phase uncertainty, is slightly higher than that of the SKEFP case.

Table I summarizes the ROCs presented throughout this paper in terms of a detectability index, d_s, and a ratio of variances, σ_n/σ_{sn}, measurements suggested by Egan and his colleagues to quantify nonequal-variance ROCs (Egan *et al.*, 1961). Of the traditional methods evaluated outside the ear, the SKEFP processor predicts statistics closest to experimental values. This observation is supported by Marill (1956) and Egan and his colleagues (1959) who found that their experimental data could be best fit assuming the signal was known statistically and that the ratio of variances was less than 1. Regarding the predictions of the integrated method, the general trend is for d_s to become smaller as this method is applied to successive stages of AIM. As would be expected based on the ROCs presented in Fig. 8, the d_s value for the post-SAI integrated method is closer than any of the traditional methods to the experimental value of 1.13.

Examination of the ratio of variances allows additional comparisons to be made. It can be seen clearly that the

TABLE I. Values of the detectability index, d_s, and ratio of variances, σ_n/σ_{sn}, estimated from ROC curves. Experimental values were obtained by averaging the results of three subjects in an experiment conducted by Watson and his colleagues (1964).

Location	Method	Assumptions	d_s	σ_n/σ_{sn}
Outside the ear	Classical SDT	SKE	3.72	1.00
	Classical SDT	SKEFP	2.52	0.81
	Energy-detector		2.80	0.71
Post-BMM	Integrated method	Optimal Proc.	3.71	1.02
Post-NAP	Integrated method	Expon-Gauss. Proc.	3.09	1.02
	Integrated method	Nonzero means, equal variances	2.58	1.01
	Integrated method	Zero-mean noise, equal variances	2.45	1.10
Post-SAI	Integrated method	Poly-fitted Proc.	2.07	0.93
	Integrated method	Nonzero means, equal variances	2.08	0.91
	Integrated method	Zero-mean noise, equal variances	1.99	0.88
Experimental			1.13	0.82

TABLE II. Comparison of d' values calculated using Eq. (2) and actual or experimental values of d'. The post-SAI experimental value was obtained by determining $z(s|H_0)$ when the probability of detection was 0.50.

Location	Actual/experimental d'	Calculated d'
Outside the ear	14.0	14.0
Post-SAI	1.3	371.3

energy-detector method, the SKEFP, and the post-SAI integrated results have $\sigma_n/\sigma_{sn}<1$, similar to experimental data ($\sigma_n/\sigma_{sn}=0.82$). This phenomenon is not observed in the classical SDT results or the predictions made by the integrated method after the BMM or the NAP. This suggests that phase information is important to the ideal observer and leads to the conclusion that uncertainty in this parameter introduced by the auditory system may be one source of information loss partially explaining the deviation of human performance from that of the ideal receiver.

When estimated from the ROCs using Egan's method, d_s and σ_n/σ_{sn} are appropriate psychophysical measures. However, another frequently used method of generating an index of detectability, that of calculating a d' statistic using the raw data (for example, the input and the output data of AIM) and Eq. (2), is not an appropriate statistical measure in this case. Outside the ear, the actual value of d' used in simulations was 14. When Eq. (2) is used to compute d' based on the raw data at this point, the same value of 14 is obtained. Because the distributions of the noise and signal plus noise outside the ear are both uncorrelated Gaussians, the calculation of d' using Eq. (2) is an accurate statistical measure. However, a d' calculated in this manner from the model data (post-SAI) yields a value of 371.3 when the true value is 1.3 (see Table II). The conclusion is that d' is an inappropriate statistical measure, since, as is the case at the output of the model (post-SAI), the assumptions that the data are uncorrelated and Gaussian are not necessarily true.

V. DISCUSSION

The integrated method has been shown to predict psychophysical behavior more accurately than traditional methods and supports previous studies suggesting that phase uncertainty may partially explain why human performance is less than ideal. However, some discrepancy still exists between predictions generated using the integrated method and experimental performance. The success of the integrated method thus far suggests that, rather than default to the ''internal noise'' assumption for an explanation, the assumptions made by the model and the derived processors should be further investigated.

Despite evidence that certain parameters of the auditory system are stochastic (Swets *et al.*, 1961; Kiang, 1984; Teich and Khanna, 1985; Miller *et al.*, 1986), AIM itself is entirely deterministic. Specifically, Teich and Khanna have shown that the interspike time interval for a neural fiber follows a Poisson distribution and Relkin and Pelli (1987) have demonstrated that the pulse number distribution follows a Gaussian distribution. Patterson and Holdsworth (1994) acknowledged that reducing the activity of a fiber to a single number, the average firing rate in the case of AIM, probably results in a somewhat inaccurate representation of the signal at this stage in the auditory system.

In addition to being deterministic, the model does not incorporate certain aspects of the auditory system. For example, only the afferent activity of the auditory nerve has been included in this model. Studies have shown that efferent activity is also a significant factor and has been included in a model developed by Giguère and Woodland (1994). In addition, the filters have been modeled as linear filters, although the auditory system is known to behave in a nonlinear manner producing distortions such as harmonics and difference tones (Smoorenburg, 1972; Hall, 1974; Strube, 1985).

Changes to the model itself may be difficult to implement. However, in some cases, the changes can be effected by modifying the input signal. As discussed previously, a loss of phase information is consistent with experimental data. It has been observed that the incorporation of phase and frequency uncertainty into the SKEFP processor has a significant effect on the predicted performance when used to process the signals outside the ear, making this method better than the classical SKE approach. However, the predictions made by the integrated method are still closer to experimental data. These results suggest that phase and frequency uncertainty should be incorporated into the integrated approach and evaluated at the output of AIM rather than just at the outside of the ear.

VI. SUMMARY AND CONCLUSIONS

Prior to the application of the integrated approach, the difference between the theoretical performance predicted by traditional methods loosely based on signal detection theory and actual experimental performance had often been accounted for by adding internal noise with a level-independent variance after the signal had been processed by the model (e.g., Sherwin *et al.*, 1956; Pfafflin and Mathews, 1962; Dau *et al.*, 1996). While this enables theoretical and experimental results to be matched, there is no complete physiological justification for adding this level of noise. As Green (1970) noted, there are internal noise processes, such as spontaneous neural firings, which contribute to the mismatch, however, such a large discrepancy cannot be attributed to ''internal'' noise alone. Our work has shown that combining signal detection theory with a physiologically based auditory model allows the discrepancies to be partially explained as the result of physical processes inherent in the auditory system, specifically, the loss of phase information. However, there is still a discrepancy between theoretical and experimental results. Rather than add additional internal noise in an *ad hoc* manner, our work suggests that incorporating frequency and phase uncertainty into the integrated approach will likely result in an even closer agreement between theoretical and experimental performance.

Beneficial effects of notched noise on intensity discrimination in the region of the "severe departure"

Christopher J. Plack
Laboratory of Experimental Psychology, University of Sussex, Brighton BN1 9QG, England

(Received 28 October 1997; accepted for publication 22 January 1998)

Intensity discrimination for a 6-kHz sinusoidal pedestal was measured in quiet and in the presence of a noise background. In the first experiment, the level of a 30-ms pedestal was fixed at 45 dB SPL and presented in the temporal and spectral center of a 110-ms notched noise. For a noise spectrum level of between 0 and 15 dB the noise produced a substantial reduction in the Weber fraction, i.e., an improvement in detectability, compared to the condition without the noise. The second experiment showed that, unlike the situation with notched noise, narrow-band noise produced no performance improvement, suggesting that the effect is dependent on noise frequency components outside the critical band of the pedestal. The third experiment showed that the improvement also occurred for a 6-ms pedestal presented in a 10-ms gap between two bursts of notched noise. The experiment rules out an explanation for the effect of the noise in terms of suppression on the basilar membrane. Finally, the effect was shown to decrease as the gap between the noise bursts was increased, in a manner at least broadly consistent with the decay of the temporal excitation pattern. It is suggested that the improvement in intensity discrimination in notched noise is due to an across-frequency comparison mechanism similar to ''profile analysis,'' perhaps operating on a temporally smoothed central representation of the stimulus. © *1998 Acoustical Society of America.* [S0001-4966(98)02505-3]

INTRODUCTION

There are a growing number of examples of situations in which the auditory system can use across-frequency comparisons to aid signal detection. The most well-researched of these are comodulation masking release (Hall *et al.*, 1984) and profile analysis (Green, 1988; Green *et al.*, 1983). Profile analysis refers to the use of spectral changes to detect an intensity increment. In a classic intensity-discrimination task, a listener may be required to detect an intensity difference between sinusoids presented in two observation intervals. Over a series of such trials the standard, or pedestal, intensity is usually kept constant. On each trial the listener is required to choose the interval in which an intensity increment has been added to the pedestal. In a typical profile analysis experiment, however, pedestal intensity is randomized either *between* trials or between observation intervals *within* a trial. The former manipulation ensures that listeners cannot use a long-term memory representation of the standard to aid performance and the latter manipulation ensures that absolute intensity is not a reliable cue. In both cases performance is improved when a background stimulus, containing sinusoidal components with frequencies either side of the pedestal frequency and with intensities equal to the standard intensity, is added to both observation intervals. It appears that listeners can detect the change in spectral shape caused by the addition of the increment. Notice that when the standard intensity is randomized on each presentation, listeners must be basing discrimination on the *relative* difference between the pedestal plus increment and the background.

It has been suggested that measurements of spectral shape are more ''categorical'' and robust than other measures of intensity (Green, 1993). For example, there is very little effect of increasing the delay between the observation intervals when these stimuli are used (Green *et al.*, 1983) suggesting that the coding is highly resistant to memory decay. The idea is similar to the theory of ''context coding'' (Braida *et al.*, 1984; Durlach and Braida, 1969): The context code is assumed to be less susceptible to memory decay than the ''trace code'' that is used in the absence of a reference intensity.

More recently, evidence has been provided that across-frequency comparisons can produce a dramatic improvement in intensity discrimination even in the absence of intensity randomization. Plack and Viemeister (1992a, b) showed that the mid-level elevation in the Weber fraction under forward and backward masking (Plack and Viemeister, 1992b; Zeng *et al.*, 1991) could be reduced by presenting a notched noise with the pedestal. In backward masking, the notched noise caused a very large reduction in the Weber fraction of around 15 dB. The results were taken as evidence against the hypothesis (Zeng and Shannon, 1995; Zeng *et al.*, 1991) that the mid-level elevation in forward masking is due to the selective adaptation of low spontaneous rate (SR) auditory nerve fibers. It was argued that the effects of the notched noise could not be explained by processes at the level of the auditory nerve, although there is still some controversy over this issue (Zeng and Shannon, 1995).

Another situation in which intensity discrimination is poor at mid levels is for short tone bursts at high frequencies (Carlyon and Moore, 1984, 1986; Florentine, 1986). The phenomenon has been termed the ''severe departure'' from Weber's law (Carlyon and Moore, 1984). There have been several explanations for this effect, based on mechanisms at different stages of the auditory system.

(i) Mid-level compression on the basilar membrane (Ruggero, 1992) reduces the effective intensity difference between the pedestal and the pedestal plus increment (Klitzing and Kohlrausch, 1994).

(ii) The rate-level functions of auditory nerve fibers are such that the high-SR fibers are more sensitive to changes in low-level stimuli, whereas the low-SR fibers, with higher thresholds and wider dynamic ranges (Liberman, 1978), are more sensitive to changes in high-level stimuli. At mid levels neither fiber group is within its optimal range and performance is poor (Carlyon and Moore, 1984).

(iii) The increased variability of auditory-nerve firing at mid levels for short tone bursts impairs level discrimination (Oxenham and Moore, 1995; Raab and Taub, 1969).

(iv) At mid levels, the internal intensity reference points (or ''perceptual anchors'') of absolute threshold and discomfort threshold are perceptually distant, so that there is no proximal reference point for representing sound level, and hence coding is inaccurate (Braida *et al.*, 1984; Plack and Carlyon, 1995).

Carlyon and Moore (1984) found that gating a notched noise with the pedestal caused a large increase in the size of the mid-level elevation. However, Oxenham and Moore (1995) argued that this is a manifestation of the ''overshoot'' phenomenon (McFadden, 1989; Zwicker, 1965), whereby the threshold of a short-duration tone is raised near masker onset. It has been shown that overshoot reaches a maximum at mid levels (Bacon, 1990; Oxenham and Moore, 1995). In direct contrast to the results using gated notched noise, Plack and Viemeister (1992a) found that a notched noise with an onset 50 ms before the 30-ms 6-kHz pedestal, caused a substantial *reduction* in the Weber fraction at mid-levels, removing the severe departure completely. So it appears that notched noise can remove mid-level increases in the Weber fraction caused by either forward masking, backward masking, or high frequencies.

Just as the effects of notched noise on intensity discrimination under nonsimultaneous masking have implications for hypotheses regarding the origin of the mid-level elevation in these conditions, the finding that notched noise can remove the mid-level elevation in quiet has implications for explanations of the severe departure. For example, if performance could be improved by a mechanism located centrally to the auditory nerve, then this would raise doubts that discrimination is limited by the information present in the auditory nerve. There are, however, several possible hypotheses for the effect of the notched noise on the severe departure, some peripheral and some more central.

(i) Suppression. The notched noise may suppress the pedestal, thereby reducing the effective level of the pedestal so that it is no longer ''mid level,'' and/or reducing the on-frequency basilar-membrane compression. Palmer and Evans (1982) and Costalupes *et al.* (1984) have shown how notched noise can reduce auditory-nerve firing rate and steepen rate-level functions at mid levels, effects which may be a consequence of both of these processes.

(ii) Adaptation. Adaptation produced by the portion of the notched noise before the onset of the pedestal may reduce the onset response and hence reduce the associated variability (Oxenham and Moore, 1995). This basic argument has been used to explain certain characteristics of the overshoot phenomenon (Bacon, 1990; McFadden and Champlin, 1990). Auditory nerve adaptation is determined by the driven response to the adaptor in the fiber being recorded (Smith, 1979), and depends, therefore, on the adaptor and adaptee falling within the same physiological tuning curve (in psychophysical terms, the same *critical band*).

(iii) Temporal referential coding. Plack *et al.* (1995; Plack, 1996) showed how relative comparisons across time may improve intensity discrimination for tone bursts in the presence of forward or backward masking. These temporal comparisons seem to depend on the pedestal and the comparison tone being within the same critical band (Plack *et al.*, 1995). The same sort of across-time level comparisons, involving components of the noise before or after the pedestal, may improve coding accuracy in the severe departure condition.

(iv) Profile analysis. Similarly, relative comparisons across frequency may also improve discrimination, by providing a reliable level reference (Green, 1993).

Hypotheses (ii) and (iii) suggest that the improvement in discrimination should depend only on the frequency components of the noise within the critical band occupied by the pedestal. On the other hand, hypothesis (iv) suggests that the off-frequency components are more important. Hypothesis (i) suggests that components within the suppression region (Houtgast, 1972), which extends beyond the critical band, may have the most influence. Hypotheses (iii) and (iv) are linked to the context coding explanation of the severe departure, in that the notched noise may provide an intensity reference that is not present in quiet because of the perceptual distance of the internal anchors.

The aim of the experiments described here was to determine the likely mechanism for the effects of notched noise on intensity discrimination for short tone bursts at high frequencies. It was hoped that the data would be relevant both for explanations of the severe departure and for theories of referential intensity coding, such as profile analysis.

I. EXPERIMENT 1: EFFECTS OF NOTCHED NOISE LEVEL

A. Rationale

Experiment 1 was designed first, to replicate the basic finding of Plack and Viemeister (1992a), and second, to determine the optimum level of the notched noise relative to the pedestal. If the improvement in performance is the result of a process akin to profile analysis, it might be expected that the notched noise will be most effective when the excitation produced by the noise is similar to the excitation produced by the pedestal, as the increment would then produce a categorical ''bump'' in the excitation pattern. Theoretically, the accuracy of context coding is assumed to decline as the perceptual distance between the target and the reference is increased (Durlach and Braida, 1969).

B. Stimuli

Intensity discrimination was measured for a 45 dB SPL, 30-ms, 6-kHz pedestal presented either in quiet or in the temporal center of a 110-ms notched noise. Durations included 5-ms, raised-cosine, onset and offset ramps. The

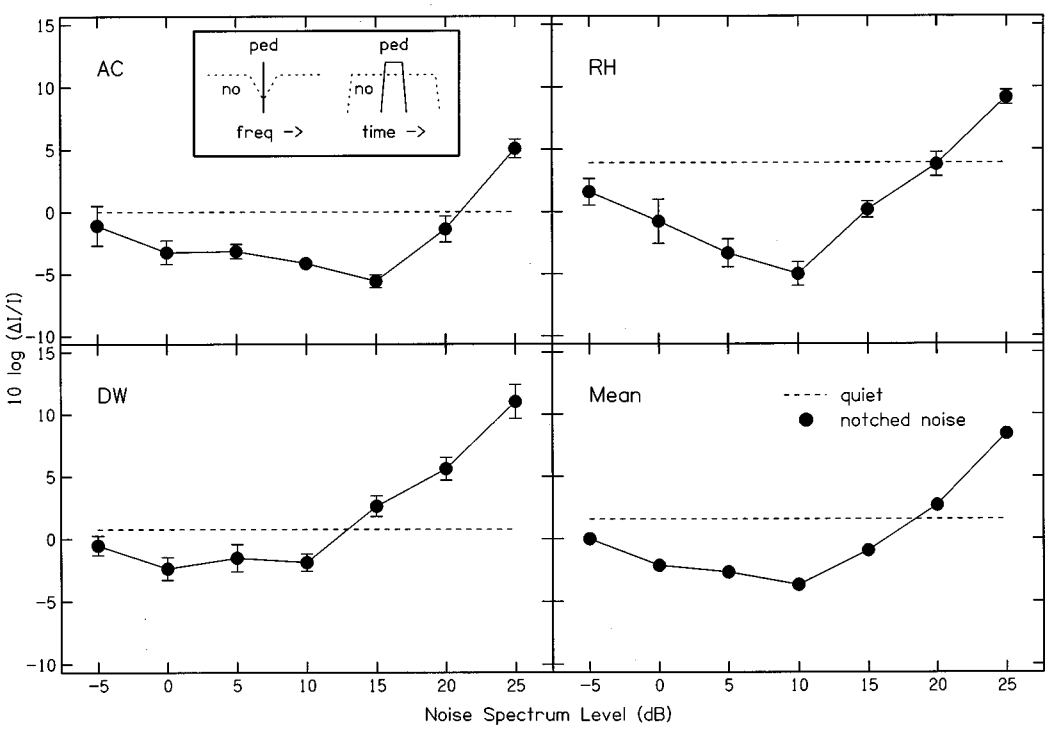

FIG. 1. The results of experiment 1 showing Weber fractions for a 45 dB SPL, 30-ms, 6-kHz pedestal presented in quiet (dashed line) or in the temporal center of a notched noise. The horizontal axis gives the spectrum level of the noise. Error bars are standard errors. A schematic illustration of the spectral and temporal characteristics of the stimuli are provided in the box.

notch had a bandwidth of 1 kHz, centered on 6 kHz. The spectrum level of the noise in the passband was varied between -5 and 25 dB in 5-dB steps.

Stimuli were generated digitally on a Silicon Graphics workstation with a sampling rate of 44.1 kHz. The noise was filtered using a digital FIR filter with a nominal attenuation of 90 dB per octave. Analog waveforms were generated using a built-in 16-bit DAC and were presented through Sennheiser HD414 headphones which were connected directly to the headphone output of the computer.

C. Procedure

A 2I, 2AFC paradigm was adopted throughout. The interstimulus interval was 500 ms. A two-down one-up adaptive tracking rule was used to estimate the 71% correct point on the psychometric function (Levitt, 1971). The level of the pedestal (I) in the standard interval was held constant and the level of the pedestal plus increment ($I+\Delta I$) in the comparison interval was varied adaptively, $10\log(\Delta I/I)$ being increased and decreased by 4 dB for the first four turnpoints, and by 2 dB thereafter. Sixteen turnpoints were recorded in each experimental block and the threshold estimate was taken as the mean of the values of $10\log(\Delta I/I)$ at the last 12 turnpoints. Eight such estimates were made for each listener (one estimate per condition in each experimental session) and the results averaged. Within a session each condition was tested in a random order.

Listeners were tested individually in an IAC single-walled sound-attenuating booth. They made their responses using the numeric keypad on the computer keyboard. ''Lights'' were presented in a graphical display on the computer monitor to delineate the observation intervals, and to provide feedback after each trial.

D. Listeners

Three normally hearing listeners took part. They were paid an hourly wage for their services. Listeners were given at least two hours practice on the task before data collection began.

E. Results and discussion

The results of experiment 1 are presented in Fig. 1. The Weber fraction in dB is plotted against the spectrum level of the notched noise. The horizontal dashed lines show the Weber fraction in the absence of the noise. A consistent pattern is seen across the three listeners. At high spectrum levels, the notched noise masks the pedestal and performance is worse than that in quiet. For noise spectrum levels below about 15 dB the noise produces a considerable improvement in intensity discrimination, confirming the results of Plack and Viemeister (1992a). The optimum spectrum level of the noise appears to be about 10 dB, and performance deteriorates as the noise level is increased or decreased away from this value.

Figure 2 shows the auditory excitation patterns of the notched noise alone (continuous line), the notched noise plus pedestal (dashed line), and the notched noise plus pedestal plus increment (dotted line). The pedestal level was 45 dB and the notched noise spectrum level was 10 dB (the level which produced the largest improvement in performance in experiment). The level of the pedestal plus increment was 48

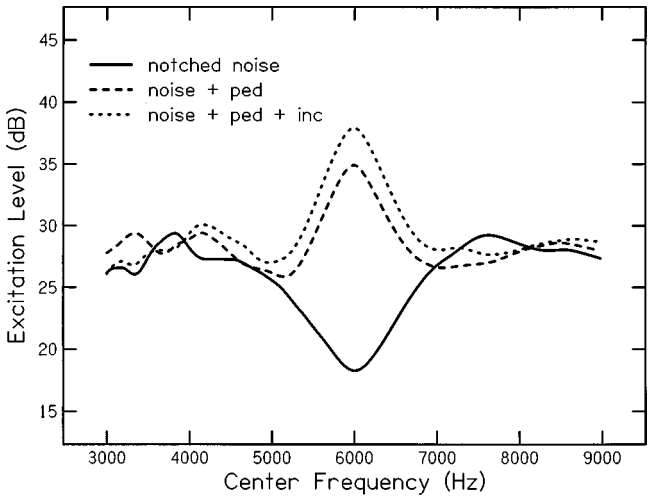

FIG. 2. Auditory excitation patterns for a notched noise with a spectrum level of 10-dB (solid line), a notched noise with a 45-dB, 6-kHz sinusoid (dashed line), and a notched noise with a 48-dB sinusoid (dotted line). Spectra were calculated using a 20-ms sampling window.

dB (Weber fraction=0 dB). The curves were generated from the spectra of actual stimuli used in the experiment, using the equations described by Glasberg and Moore (1990). For the notched noise alone curve, the spectrum was computed over a 20-ms portion of the stimulus before the pedestal onset. For the other two curves, the spectra were computed over the 20-ms portion of the stimulus during which the pedestal was at its steady-state level.

It can be seen from these curves that the excitation level of the noise plus pedestal at 6 kHz is about 8 dB above the level of the ''background'' (i.e., the excitation produced by the noise components away from the pedestal frequency). In a typical profile analysis experiment this would be equivalent to presenting a pedestal about 8 dB higher than the background sinusoids in the complex. This might appear to be inconsistent with the profile analysis/context coding account, since it would be expected from the theory that the noise would be most effective when it produced a flat excitation pattern when added to the pedestal, so that increment could be detected as a distinct ''bump.'' However, in a profile analysis experiment using a wide 20-component background (the configuration most similar to the notched noise used here), Green and Kidd (1983) found that the pedestal level which produced the largest effect was around 6 dB above the background, which is consistent with the results of experiment 1. They further showed that if they removed the adjacent low-frequency components from the background then the optimum relative level was 0 dB. They argued that thresholds might be elevated by the partial masking of the pedestal by these low-frequency components, which counteracts the advantages of a flat profile. The same argument could be applied here, since the 10-dB noise was close to the level at which the noise produced a deterioration, rather than an improvement, in performance. Whether or not this reasoning is valid, it can at least be stated that the effects of noise level are consistent with those seen in profile analysis experiments in which listeners were forced to measure intensity using *relative,* across-frequency, comparisons.

II. EXPERIMENT 2: NOTCHED NOISE VERSUS NARROW-BAND NOISE

A. Rationale

If the effect of the notched noise observed in experiment 1 is due purely to the on-frequency components in the excitation pattern of the noise (see Fig. 2), as implied by the adaptation and temporal referential coding hypotheses, then a narrow-band noise with an excitation level at the pedestal frequency similar to that of the notched noise should be equally effective in improving intensity discrimination. Calculations showed that for the notched noise the excitation level at 6 kHz was about 9 dB below the excitation level in the passband (see Fig. 2). For a narrowband noise with a bandwidth of 1 kHz (centered on 6 kHz) and with the same spectrum level, the excitation level at 6 kHz was about 3 dB less than the excitation level of the notched noise in the passband. In other words, a narrow-band noise with a spectrum level 6 dB below that of the notched noise should produce approximately the same excitation level at the 6-kHz center frequency. In experiment 2, three narrow-band noise spectrum levels were chosen covering a 10-dB range around this value relative to a notched noise spectrum level of 10 dB.

B. Stimuli and procedure

The temporal characteristics of the stimuli, and method of generation, were the same as in experiment 1. The 45-dB pedestal was presented either in quiet, in a notched noise, or in a narrowband noise with a bandwidth of 1 kHz. Notched noise spectrum levels of 10 and 15 dB were tested and narrow-band noise spectrum levels of 0, 5, and 10 dB were tested. The procedure was the same as in experiment 1 and the same three listeners were employed.

C. Results and discussion

The results of experiment 2 are shown in Fig. 3. The 10-dB notched noise once again produced an improvement in performance across all three listeners, although the effect was slightly less than that observed in experiment 1. The narrowband noise had no substantial effect on performance except at a spectrum level of 10 dB, where it produced a slight increase in the Weber fraction. It can be concluded that the on-frequency components of the notched noise are not responsible for the performance improvement. It follows that both the adaptation hypothesis and the temporal referential coding hypothesis should be rejected.

III. EXPERIMENT 3: EFFECTS OF NONSIMULTANEOUS NOTCHED NOISE

A. Rationale

Physiological suppression is a phenomenon believed to be a consequence of nonlinearities on the basilar membrane (Yates, 1995) in which the excitation at one characteristic frequency (CF) acts to reduce the excitation at neighboring CFs. Suppression has a very short time constant (Arthur *et al.*, 1971) which is consistent with the idea that the effect depends on the suppressor and the suppressee interacting on

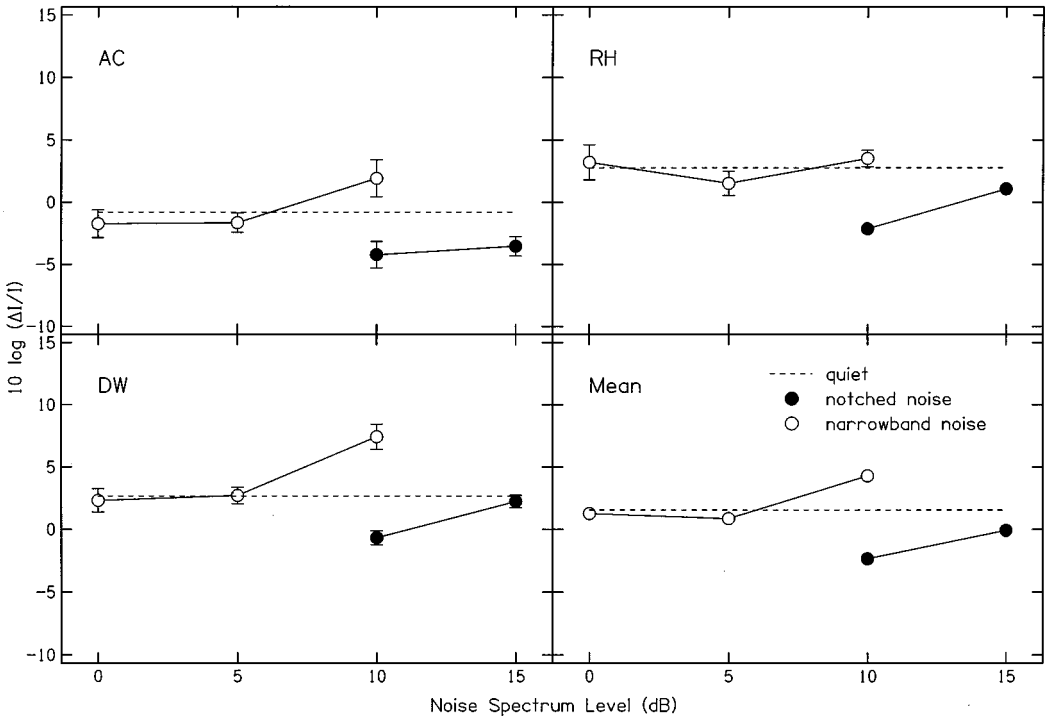

FIG. 3. The results of experiment 2, comparing the effects of a notched noise and a narrow-band noise on intensity discrimination for a 30-ms pedestal. The axes and error bars are as Fig. 1.

the basilar membrane. Following this reasoning, it was decided to determine if it is possible to obtain the beneficial effects of the notched noise without the pedestal and noise overlapping in time. The pedestal was presented in a 10-ms gap between two bursts of noise. At 6 kHz, where the temporal response of the auditory filter is very brief (Kiang *et al.*, 1965), it was reasoned that the gap would be sufficient to avoid significant interaction on the basilar membrane, and therefore to avoid suppression of the pedestal by the notched noise. Plack and Viemeister (1992a) found that a notched noise could reduce the elevation of the Weber fraction under forward masking even when the noise was terminated before the onset of the pedestal. They used this finding as evidence that the effects of the notched noise were not the result of suppression. Similarly, if nonsimultaneous notched noise can reduce the mid-level elevation in quiet, then this will be good evidence that the mechanism underlying this effect is not peripheral suppression.

B. Stimuli and procedure

The sinusoidal pedestal had a steady-state duration of 2 ms with 2-ms raised-cosine onset and offset ramps. The pedestal was presented either in quiet, in the temporal center of a notched noise (no gap), or in the temporal center of a 10-ms silent interval between two bursts of notched noise (gap). The spectral characteristics of the notched noise were the same as in experiment 1. In the no gap condition, the notched noise had a steady-state duration of 200 ms with 2-ms onset and offset ramps. In the gap condition, each noise burst had a steady-state duration of 100 ms with 2-ms onset and offset ramps. The spectrum level of the noise was always 40 dB below the pedestal level. In each of the three conditions, pedestal levels of 30–80 dB SPL were tested in 10-dB steps. The method of stimulus generation and the procedure were the same as in experiment 1.

C. Listeners

Three new listeners took part. They all had normal hearing and were paid an hourly wage for their services. Listeners were given at least two hours practice on the task before data collection began.

D. Results and discussion

The results of experiment 3 are shown in Fig. 4. The basic pattern of results is similar across all three listeners, although the Weber fractions for listener SM are much higher than the others, particularly in quiet. All listeners show a mid-level elevation in the Weber fraction in the absence of the noise (the severe departure). The Weber fraction is maximum for a pedestal level of 50 dB. Consistent with the earlier results, the simultaneous notched noise (no gap) improved discrimination performance at mid levels, removing the severe departure. For pedestal levels below 60 dB, the effects of the nonsimultaneous notched noise (gap) produced performance virtually identical to that observed with the simultaneous noise. For pedestal levels of 60 dB and above, however, the curves diverge. At the highest pedestal level, Weber fractions for the nonsimultaneous noise are substantially higher than those for both the simultaneous noise and quiet conditions.

It is possible that effects of the noise at high levels may be evidence for the beneficial effects of suppression at these levels. It has been shown previously that notched noise can impair performance at high levels, eliminating the ''near

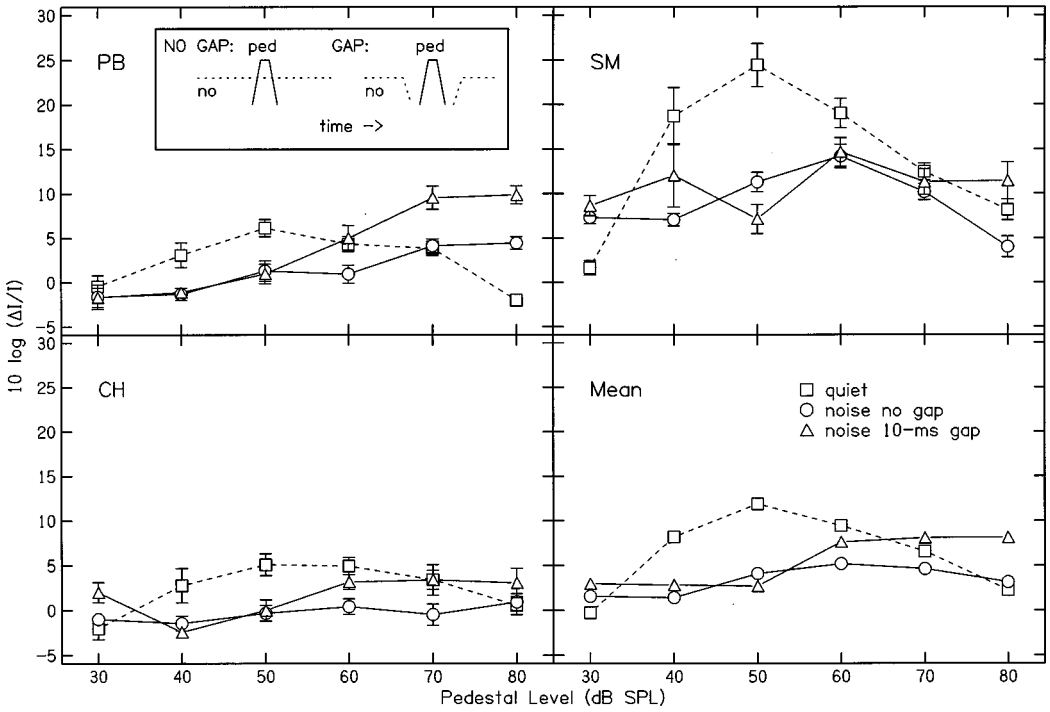

FIG. 4. The results of experiment 3 showing Weber fractions for a 6-ms pedestal presented alone (dashed lines), in the temporal center of a notched noise (circles), or in the temporal center of a 10-ms gap between two bursts of notched noise (triangles). The horizontal axis gives the level of the pedestal. The spectrum level of the noise was 40 dB below the pedestal level. Error bars are standard errors. The temporal characteristics of the stimuli in the region of the pedestal are illustrated in the box.

miss'' to Weber's law (Moore and Raab, 1974). The effect could be attributed to the removal of intensity information from the skirts of the excitation pattern. The present data show that a nonsimultaneous notched noise is even more effective in this regard.

The large dynamic range of hearing has long been a difficult theoretical problem (see Plack and Carlyon, 1995), since the majority of auditory nerve fibers saturate below about 60 dB SPL (Palmer and Evans, 1979). If performance at high levels is dependent on information from the skirts of the excitation pattern (where the neurons are not saturated) then masking the skirts should be very damaging to discrimination. It is conceivable that by suppressing the pedestal to a lower excitation level, where there is richer neural coding at CF, the simultaneous noise may not reveal the true detriment caused by the loss of off-frequency information (Plack and Viemeister, 1993).

Even if suppression by the notched noise is important at high levels, it appears that in the region of the severe departure it has little effect on performance. The results suggest that peripheral suppression is not the cause of the beneficial effects of the notched noise at mid levels.

It might be argued that the data also provide difficulties for the profile analysis account, since the effect has been shown not to rely on across-frequency comparisons between physically simultaneous sounds. However, temporal resolution experiments suggest that the internal representation of a sound stimulus is effectively blurred in time by the action of a central temporal integrator, or ''temporal window,'' with a time constant of about 10 ms (Moore *et al.*, 1988; Oxenham and Moore, 1994). Since the time interval between the end of the first masking burst and the center of the pedestal was only 5 ms in the gap condition, it is conceivable that at some higher stage of the auditory system the noise and the pedestal did in fact overlap in time and a simultaneous comparison might have been possible at this stage. If the argument is valid, then lengthening the gap should cause a reduction in the benefits of the noise, consistent with the decay of the temporal excitation pattern. The final experiment was designed to test this prediction.

IV. EXPERIMENT 4: EFFECTS OF GAP DURATION WITH NONSIMULTANEOUS NOTCHED NOISE

A. Rationale

Assuming that the benefit of the noise is the result of a simultaneous across-frequency comparison after the representation of the stimulus has been smoothed by a temporal window similar to that described by Moore *et al.* (1988), then a gap of around 20 ms should reduce the effective level of the noise at the temporal center of the pedestal by about 10 dB, and a gap of 40 ms should reduce the effective level of the noise by about 20 dB. On the basis of the results of experiment 1, this should be sufficient to substantially reduce the beneficial effects of the noise.

B. Stimuli and procedure

The basic stimuli and procedure were the same as in experiment 3. The level of the pedestal was 50 dB SPL, and the spectrum level of the notched noise was 10 dB. The pedestal was presented either alone or in the temporal center

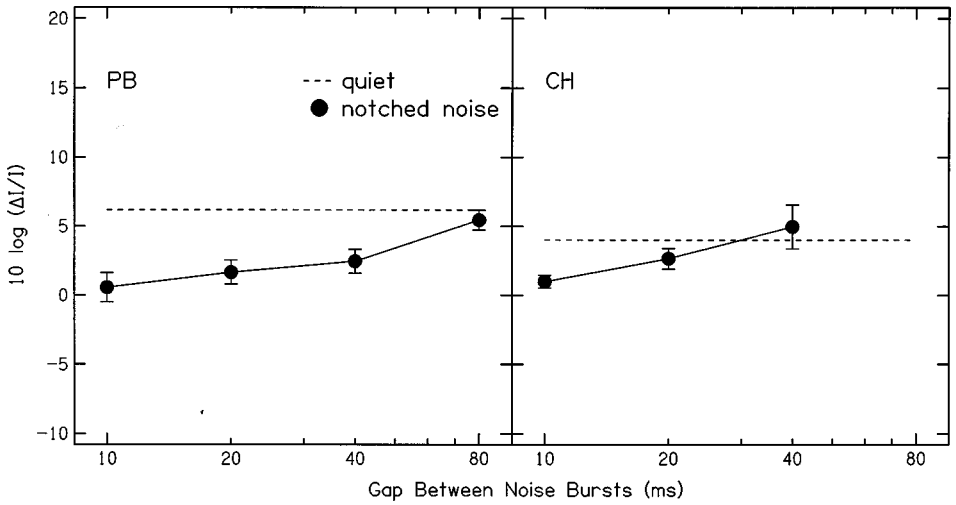

FIG. 5. The results of experiment 3 showing Weber fractions for a 6-ms pedestal presented alone (dashed lines) or in the temporal center of a gap between two bursts of notched noise (circles). The horizontal axis gives the duration of the gap.

of a silent interval between two 100-ms bursts of noise as before. Two of the listeners from experiment 3 were employed here. Gap durations of 10, 20, and 40 ms were tested for both listeners, and a gap duration of 80 ms was added for listener PB.

C. Results and discussion

The results are presented in Fig. 5. Both listeners show a deterioration in performance as the gap between the noise bursts is increased. In other words, the beneficial effects of the notched noise decrease as the gap increases. For listener CH the 40-ms gap eliminated the improvement entirely whereas for listener PB an 80-ms gap was required. In experiment 1, a 15-dB reduction in noise spectrum level almost eliminated the effects of the noise. However, the mean difference in the Weber fraction between noise spectrum levels of -5 and 10 dB in that experiment was 3.7 dB. The mean deterioration between a 10-ms gap and a 40-ms gap (corresponding to roughly a 20-dB attenuation at the output of the temporal window) in experiment 4 was 2.9 dB. If the Weber fraction increases at a steady rate as the noise spectrum level is reduced, then these results are not dramatically different from the predictions of the hypothesis presented in the previous section, that across-frequency comparisons are used after the internal representation of the stimulus has been smoothed by the temporal window.

V. GENERAL DISCUSSION

A. What is the mechanism underlying the effects of the notched noise?

In the introduction, four very different explanations for the performance improvements in notched noise were presented. Two of these, the adaptation and temporal referential coding hypotheses, were eliminated after experiment 2 showed that off-frequency noise energy is required for the effect. The suppression hypothesis appears to be untenable in the face of the results of experiment 3 in which a nonsimultaneous notched noise was shown to have an effect just as great as a simultaneous one. The only explanation which has survived this examination intact is the profile analysis hypothesis, which states that the improvements in intensity discrimination are due to the use of across-frequency, relative level comparisons.

Experiment 1 showed that the level of the notched noise that caused the greatest reduction in the Weber fraction was consistent with the relative level of the background sinusoids that produces the optimum performance in profile analysis experiments (Green and Kidd, 1983). Now, because in the latter case the level of the background is randomized between observation intervals, listeners must base discrimination on some form of across-frequency level comparison. The similarity between the results of the two experiments is further evidence, therefore, that across-frequency comparisons caused the performance improvement in the present experiments. The results of the final experiment raise the possibility that the comparison occurs after the representation of the stimulus has been smoothed in time by the action of a central temporal integrator.

It has been argued that profile analysis involves a ''categorical'' representation of intensity (for example, whether the spectrum is ''bumped'' or ''flat'') that may be simpler to code, less susceptible to memory decay, and hence more reliable than ''absolute'' representations of intensity (Green, 1993). It is suggested here that similar coding strategies may improve performance for intensity discrimination in notched noise.

B. Implications for explanations of the severe departure

Assuming for the moment that a profile analysis mechanism underlies the effects of the noise, it is now possible to consider the implications of this hypothesis for hypotheses relating to the severe departure. If the severe departure is the result of a *peripheral* limitation, then it is not obvious how a *central* mechanism could overcome this limitation. Consider, for example, that the severe departure is a consequence of mid-level basilar membrane compression (Klitzing and Kohlrausch, 1994). The effect of the compression will be to

reduce the level difference between the pedestal plus increment and the pedestal. Whatever happens at later stages will be limited by this process: A reduction in variability caused by a different coding strategy may improve performance overall, but it cannot change the fact that the input is impoverished at mid levels, and it might be expected that the hump should remain. The same basic logic applies to the hypothesis linking the hump to a discontinuity between the rate-level functions of the high-SR and low-SR fibers (Carlyon and Moore, 1984).

There are ways around this argument, although they are not entirely satisfactory. For example, it is conceivable that the across-frequency comparator can only operate effectively at mid levels, so that the peripheral mid-level impairment is followed by a central mid-level facilitation, and the consequence is a flat function. However, this is inconsistent with a study by Green *et al.* (1986) which suggests that profile analysis is not affected by overall level. Alternatively, it could be that there is a very nonlinear ''hard'' central limitation, that does not allow a Weber fraction of less than, say, -5 dB to be detected. The notched noise may only be able to improve performance this far at any level, again producing a flat response. However, this is not consistent with the much lower Weber fractions observed for longer pedestals (Florentine, 1986).

The strong conclusion that the severe departure is not the result of a peripheral mechanism does raise a problem, however. It is clear that the basilar membrane is more the compression remains at high levels (Murugasu and Russell, 1995; Ruggero, 1992; Ruggero *et al.*, 1997; Russell and Nilsen, 1997), and the compression should result in an effective reduction in the level difference at input. On the other hand, analyses of neural firing data suggest that a mid-level limitation is not present in the firing-rate information in the auditory nerve (Delgutte, 1987; Viemeister, 1988), the implication being that the richness of neural coding at mid levels may compensate for the reduction in the level difference.

VI. CONCLUSIONS

(i) For certain noise levels, the addition of notched noise reduced the Weber fraction for a 45-dB, 30-ms, 6-kHz pedestal. The spectrum level that produced the largest improvement in performance was 10 dB. The optimum relative level of the noise and pedestal was similar to the optimum relative level between background and pedestal in profile analysis.

(ii) A narrow-band noise did not produce any improvement in performance. The effect of the notched noise appears to depend on off-frequency components.

(iii) The notched noise was effective at reducing the mid-level elevation even when it was not simultaneous with the pedestal. The finding suggests that peripheral suppression is not involved in the improvement at mid levels, although there is some evidence that it may have an effect at high levels, perhaps improving the dynamic range by suppressing the pedestal to a lower level where there is richer neural coding.

(iv) For a pedestal presented in the gap between two notched noise bursts, the beneficial effect of the noise decreased as the gap was increased.

(v) The results are consistent with an across-frequency comparison mechanism similar to profile analysis. It is possible that this mechanism operates on the temporally smoothed representation of sounds at the output of a central temporal window.

Auditory filter nonlinearity at 2 kHz in normal hearing listeners

Stuart Rosen, Richard J. Baker, and Angela Darling
Department of Phonetics & Linguistics, University College London, 4 Stephenson Way, London NW1 2HE, England

(Received 2 January 1997; revised 29 October 1997; accepted 26 January 1998)

Auditory filters broaden with increasing level. Using a recently developed method of fitting filter shapes to notched-noise masking data that explicitly models the nonlinear changes in filter shape across level, results at 2 kHz from 9 listeners over a wide range of levels and notch widths are reported. Families of roex(p,w,t) filter shapes lead to models which account well for the observed data. The primary effect of level is a broadening in the tails of the filter as level increases. In all cases, models with filter parameters depending on probe level fit the data much better than masker-dependent models. Thus auditory filter shapes appear to be controlled by their output, not by their input. Notched-noise tests, if performed at a single level, should use a fixed probe level. Filter shapes derived in this way, and normalized to have equal tail gain, are highly reminiscent of measurements made directly on the basilar membrane, including the degree of compression evidenced in the input–output function.

INTRODUCTION

A fundamental property of the peripheral auditory system is that it operates as a frequency analyzer. This processing mechanism can be conceptualized as a bank of overlapping bandpass filters, often referred to as *auditory filters*. Some of the applications exploiting the concept of auditory filters (and requiring accurate auditory filter shape characterization) include the design of realistic front ends for automatic speech recognition (Zwicker *et al.*, 1979), modeling the effects of normal and impaired frequency selectivity on the perception of speech or music (Patterson *et al.*, 1982; Rosen and Fourcin, 1986), and modeling loudness perception (e.g., Moore *et al.*, 1997). It has also been suggested that auditory filter shape measurement may be a useful diagnostic tool in the detection of preclinical noise-induced hearing loss (West and Evans, 1990).

The most well developed psychoacoustic technique for measuring auditory filter shapes is the notched-noise simultaneous masking method, supported by an explicit analysis algorithm (for a review, see Patterson and Moore, 1986). Almost always, thresholds are found for a tonal signal at a particular frequency in the presence of fixed-spectrum-level band-stop noises (*notched* noises), with the varying-width notch placed both symmetrically and asymmetrically around the probe frequency (e.g., Dubno and Dirks, 1989; Fidell *et al.*, 1983; Moore *et al.*, 1990; Niemiec and Yost, 1992; Patterson, 1976; Patterson *et al.*, 1982; Weber, 1977; Wright *et al.*, 1997; Shailer *et al.*, 1990, not to mention many others). The dependence of probe threshold on the notch configuration is exploited to estimate the auditory filter shape. The implicit assumption in such studies is that by fixing the spectrum level of the masker, the properties of the auditory filter being measured are also being fixed.

Of course, we could also fix the level of the probe, and vary the masker level for a particular notch. Were auditory filters linear, it would not matter which level was fixed and which was varied. But it is now well known that auditory filters are highly nonlinear, broadening with increasing level. Therefore it is crucial to decide whether to fix probe level or masker level in such experiments. At a more fundamental level, we need to determine what feature of the stimulus configuration controls filter shape. If filter shapes are somehow controlled by probe level, then fixing the masker level will distort considerably the shape of the derived auditory filters, and vice versa.

The question of which, if either of these parameters, actually controls filter shape can also be related to more complete models of auditory filtering. For example, Glasberg and Moore (1990) provide an algorithm for calculating excitation patterns based on the notion that auditory filter shape is determined by the level of the *input* to the filters. Their computations imply that fixing the level of the masker in a notched-noise experiment leads to an approximation of filter shape for a particular level (see below). On the other hand, Carney (1993) has proposed a model in which the output of the filter is rectified and smoothed, then used to control filter shape. With the additional assumption that the efficiency of the post-filtering detection process does not vary with level, such an *output-based* model implies that a fixed *probe* level leads to appropriate filter shapes.

For an *input-based* model it seems unlikely that the spectrum level of the masker *per se* controls the filter shape. Lutfi and Patterson (1984) suggested that the controlling factor is more likely to be the level of the masker in the region of the filter. However, if the ''region of the filter'' is restricted to one *equivalent rectangular bandwidth* (ERB) around the filter's center frequency and, given the above assumption about post-filtering detection, this ''restricted'' input is very closely correlated with filter output.

The excitation pattern model of Glasberg and Moore (1990; and Moore and Glasberg, 1987) implements another *input-based* model in which it is the level of an input com-

ponent integrated over an ERB that controls the amount of attenuation of that particular component by the filter concerned.[1] However, for a broadband signal such as those used in notched-noise masking, the ERB integrated input varies little over the width of the masking noise. For example the ERB is 111 Hz at 800 Hz and 241 Hz at 2 kHz. Accordingly, for a probe frequency of 2 kHz and a fixed masker spectrum level, the ERB integrated input level would vary only by 3.4 dB between masker components at an 800-Hz notch edge and those at the probe frequency in a no-notch condition. On the high-frequency side the filter shape is independent of signal level and so only signal components below and immediately around the probe frequency affect the filter shape in Glasberg and Moore's model. Thus in a notched-noise masking task, fixing the masker spectrum level would be a good approximation to the fixed ERB-integrated-input level that would be required to ensure a constant filter shape under Glasberg and Moore's assumptions.

While there is some debate as to which aspect of the signal controls the filter shape, it is the level of the probe tone or the spectrum level of the masker that are the ones most readily fixed in empirical studies (and in fact the only ones which have been). Given also that there are theoretical proposals to justify both, we focus solely on them.

It is, perhaps, a little surprising that this crucial issue has received relatively little attention until recently. Although two previous studies mentioned above have claimed to come to decisive conclusions (Lutfi and Patterson, 1984; Moore and Glasberg, 1987), we have recently shown that such claims cannot be upheld (Rosen and Baker, 1994). Instead, we have developed quite a different approach, which is to explicitly model the changes in filter parameters as a function of level, and to determine whether a dependence of these parameters on masker level (masker-dependent) or probe level (probe-dependent) better accounts for the data.

To illustrate this idea in a relatively simple case, consider a notched-noise masking experiment performed with symmetric notches only, at a fixed masker level of N_0 dB SPL/Hz. Let us assume the symmetric roex(p,w,t) filter shape to be appropriate (Patterson *et al.*, 1982), so off-place listening can be ignored:

$$(1-w)(1+pg)e^{-pg}+w(1+tg)e^{-tg}$$

where g is normalized frequency ($|f-f_0|/f_0$, f_0=filter center frequency), p and t are parameters determining the sharpness of the filter in the *p*assband and *t*ail, respectively, and w is a *w*eight determining where the tail slopes take over from the passband slopes. For such a shape, the tail slopes can only be shallower than those in the passband. Under certain simplifying assumptions (Rosen, 1989), the power spectrum model of masking (Patterson and Moore, 1986) leads to the level of the probe (P_s dB SPL) being given by

$$P_s = k + N_0 + 10\log(2f_0) + 10\log\left[\frac{(1-w)(2+pg)e^{-pg}}{p} + \frac{w(2+tg)e^{-tg}}{t}\right],$$

where g is now the particular symmetric notch width in question (normalized as above), and k is a measure of the detector efficiency at filter output (signal-to-noise ratio in dB).

Our *Poly*nomial *Fit*ting (PolyFit) procedure[2] might have the analogous equation:

$$P_s = (k_0+k_1N_0)+N_0+10\log(2f_0)+10\times\log\left[\frac{(1-(w_0+w_1N_0))(2+(p_0+p_1N_0)g)e^{-(p_0+p_1N_0)g}}{(p_0+p_1N_0)} + \frac{(w_0+w_1N_0)(2+(t_0+t_1N_0)g)e^{-(t_0+t_1N_0)g}}{(t_0+t_1N_0)}\right],$$

where each estimable parameter has been replaced by a linear function depending on masker level (N_0) with two coefficients to be estimated (the slope and intercept). Note the distinction made here between a *parameter* such as p or k whose single value determines the auditory filter shape, and a *coefficient* whose value is used in an equation to calculate the value of any particular filter parameter. Such an equation would correspond to a family of roex(p,w,t) filters whose shapes would be given by:

$$(1-(w_0+w_1N_0))(1+(p_0+p_1N_0)g)e^{-(p_0+p_1N_0)g} + (w_0+w_1N_0)(1+(t_0+t_1N_0)g)e^{-(t_0+t_1N_0)g}.$$

PolyFit allows the polynomial terms to be of any degree (although terms of a higher order cannot be included in the model without all the terms of lower order), for parameter values to be dependent upon the level of the masker (as above) or of the probe, and for parameters describing the high and low frequency sides of the filter to be specified independently. Thus instead of estimating coefficients for a parameter p, separate sets of coefficients are estimated for a lower p (p_l) and upper p (p_u), and similarly for w and t. The calculations also take into account the possibility of *off-place listening*, where a listener is supposed to attend to the filter which has the greatest signal-to-noise ratio at its output (Patterson and Moore, 1986). More generally, our implementation is a superset of the procedures described by Glasberg and Moore (1990). When analyzing a notched-noise experiment at a single fixed level, it is thus possible to select a model using PolyFit that will give identical fits to theirs.

In this way, it is possible to construct a single model, which, after appropriate coefficients are chosen, can predict thresholds for any combination of notch widths and level. While we have so far concentrated on whether the filter shape varies with N_0 or P_s, there is the separate, and somewhat unrelated, issue of whether P_s should be predicted from N_0 or vice versa when investigating the goodness of fit of a *given model* to the data. We have used the root-mean-square (rms) residual as our measure of goodness of fit. For example, we can take the value of N_0 from a given data point and use the model under investigation to predict P_s and then compare this predicted P_s to the empirical value given by the data point. Or we can, in the same way, predict N_0 given the value of P_s. Because the mathematical formula for predicting thresholds can be written as $P_s = N_0 + (\textit{other terms})$, or conversely as $N_0 = P_s - (\textit{other terms})$, predicting probe thresholds (P_s) from the masker spectrum levels (N_0), as in the first example, or masker levels from tone levels, as in the

TABLE I. Summary data concerning the nine listeners who participated in the study, including the range of conditions over which they participated. Maximum notch widths are shown separately for symmetric and asymmetric notches. Absolute thresholds were obtained using standard pure-tone audiometry.

Listener	Age	Absolute threshold at 2 kHz (dB HL)	Range of levels P_s	Range of levels N_0	Number of notch widths/level	Maximum notch width	Number of conditions	Number of thresholds

WC	20	10	30–70	20–50	16	[0.5, 0.5], [0.4, 0.6]	143	354

second, leads to identical residuals. Therefore it does not matter which way around the prediction is made. In fact, because we use an additive power term to include the effects of absolute threshold (see below), it is intuitively more appealing to predict probe levels, even when the probe level itself is fixed in the experiment.[3]

Fitting the model to the data proceeds in essentially the same way as for the single level case. Instead of searching the space of the parameter values directly for the best-fitting values, the space of the coefficients making up the polynomials is searched.[4] Note that this fitting technique is quite different to the typical procedure used for studies across level, in which filter parameters are estimated separately for each of a number of masker levels, and polynomial fits are made to the values of the estimated parameters as a function of level (as in Moore and Glasberg, 1987). We have, for example, fitted as many as 158 mean data points in a single analysis, instead of doing ten separate analyses (five conditions in which the probe level is fixed, and five in which the masker level is fixed). Thus results from the fixed-probe and fixed-masker experiments can be analyzed together, putting stronger constraints on the way filter parameters can change with level.

A primary advantage of the PolyFit procedure is one of stability of the model fit, because such a large number of conditions can be fit by relatively few free coefficients. For example, in fitting one set of fixed-masker data (involving 13–16 data points) with a roex(p,w,t) filter shape in which p, w, and t are independently estimated on the upper and lower frequency side, seven free parameters must be estimated (including k). To describe the filter shape as a function of level requires multiplying the number of parameters by, for example, five levels of N_0 and five levels of P_s (70 parameters for 160 data points). Using PolyFit to fit the same data with a roex(p,w,t) model in which each of the seven parameters is allowed to take on the form of a linear function of N_0 (or P_s) results in a model with 14 coefficients (7×2) for the same number of data points. This large reduction in the number of free variables allows the stable fitting of complex models such as the roex(p,w,t) shape, something which was not possible using the ''standard'' techniques (Patterson *et al.*, 1982). PolyFit also provides a principled way of comparing results across fixed-masker and fixed-probe conditions. Individual fits leave these results incommensurable.

One further extension to typical roex fitting procedures was implemented. Because absolute thresholds can place a lower limit on masked thresholds in some conditions (for fixed noise maskers at low levels with wide notches), a single estimated parameter corresponding to the absolute threshold of the probe was incorporated. This was done by adding the value of the estimated threshold (in power terms) to the probe level predicted by the model for any particular condition. For probe levels more than 10 and 20 dB above the estimated absolute threshold, this term changes the initially predicted value by less than 0.5 and 0.05 dB, respectively.

Rosen and Baker (1994) report an application of PolyFit using a roex(p,r) shape [equivalent to a roex(p,w,t) shape with $t=0$] to a set of data obtained from two normal-hearing listeners. They showed that models which had filter parameters depending upon the level of the probe were considerably more successful than models in which filter parameters depended upon the level of the masker. They therefore argued that probe level should be fixed for simple measures of auditory filter shape at one level. More importantly, auditory filter shape appeared to be controlled by probe level, or something closely related to it. Here we extend those findings in a number of ways: (1) applying them to measurements made over a considerably wider range of notch widths and stimulus levels; (2) using the more complex roex(p,w,t) shape in place of the roex(p,r); (3) analyzing both group and individual results in a total of nine normally hearing listeners; (4) developing a technique for normalizing filter shapes so as to estimate changes in gain as well as shape across level, thus making our shapes comparable to direct measurements of basilar membrane vibration.

I. METHODS

A. Listeners

Table I presents summary data concerning the nine listeners who participated in the study. All had hearing thresholds within normal limits ($\leqslant$20 dB HL). All testing was

done monaurally, and in a single ear per listener. Mean results averaged over listeners LS and MB have appeared in a previous report (Rosen and Baker, 1994).

B. Threshold estimation

Masked thresholds were determined for sinusoidal probe tones of 2 kHz in the presence of notched-noise maskers with variable notch widths. The notches were placed both symmetrically and asymmetrically about the probe frequency and either the probe level or the noise level could be varied to determine the thresholds. A two-interval, two-alternative forced-choice paradigm with feedback was used to estimate the 79% point on the psychometric function. Listeners responded on a button box, with illuminated buttons indicating presentation intervals and providing feedback. From a starting level at which the probe was clearly audible, the varying sound, either probe or masker, was initially changed in 5 dB steps, with step-size decreasing by 1 dB after each turnaround. Once the step-size reached 2 dB, it remained constant for a further eight turnarounds, the mean of which was taken as the threshold. For each particular combination of notch-width and fixed probe or fixed masker level, two thresholds per listener were typically obtained. Threshold measurements where the standard deviation of the last eight turnarounds exceeded 3 dB were rejected and the measurement repeated. Also, where two measurements of the same condition in the same listener differed by more than 3 dB, a further measurement was taken and the average of all measurements used.

C. Stimulus configurations

The outside edges of the masker noise were fixed at $\pm 0.8 \times f_0$ (400 and 3600 Hz). A maximum of 16 different notch conditions were used, six symmetric and ten asymmetric. The frequencies of the edges of the notch are specified in normalized frequency units relative to the probe frequency (f_0) as given by $(|f - f_0|)/f_0$. In the symmetric conditions, both notch edges were placed at normalized values of 0.0, 0.1, 0.2, 0.3, 0.4, and 0.5. In the asymmetric condition one of the notch edges was set at a normalized value of 0.0, 0.1, 0.2, 0.3, and 0.4, while the other was set to 0.2 normalized units further away (0.2, 0.3, 0.4, 0.5, and 0.6). When the masker level was fixed, a subset of noise-spectrum levels (N_0) was chosen, ranging from 20 to 60 dB re: 10^{-12} W/Hz (the units hereafter referred to as SPL/Hz) in 10-dB steps. When the probe level was fixed, a subset of probe levels (P_s) was chosen, ranging from 30 to 70 dB SPL, again in 10-dB steps. Table I details the experimental conditions for each of the listeners.

D. Stimulus generation

All the stimuli were computer generated at a sampling frequency of 20 kHz. The time waveform of the probe was calculated independently of the masker and consisted of a steady state portion of 360 ms plus 20-ms raised-cosine onsets and offsets. The probe was temporally centered within the masker which consisted of a 460-ms steady-state portion with 20-ms raised-cosine-squared[5] onset and offsets. To generate the masker, the desired frequency spectrum was defined by setting all the spectral components (spaced at intervals of 0.61 Hz) within the appropriate frequency limits to have equal amplitudes while those outside were set to zero. Nonzero components had their phases randomized uniformly in the range of $0-2\pi$ radians. An inverse FFT was then applied to generate the time waveform. At the start of each threshold determination, a 3.2768-s buffer of noise was generated for use during that test. On each trial, a 500-ms portion of the buffer was chosen randomly for each of the two masker intervals within each trial.

The probe and masker were played out through separate channels of a stereo 16-bit D-A converter (PCLX™, Laryngograph Ltd.) and attenuated independently under computer control before being electrically mixed (PA4 and SM3 from Tucker-Davis Technologies). The signal was then sent via a balanced line to a final amplifier in a sound-treated room where it was presented monaurally to the right ear via Etymotic ER2 insert earphones. Calibrations were done using a B&K 4157 ear simulator [conforming to IEC 711 and ANSI S3.25/1979 (ASA 39/179)] with a B&K DB 2012 ear canal extension.

Because the experiments took place over a number of years, two distinct sets of apparatus were used. These differed in detail, but not in essentials. The later experiments (involving listeners AMD, JD, RJB, and WC) were run as described above. The earlier experiments (involving listeners CT, LS, MB, RC, and SK) had the following differences: (1) The 2-kHz sinusoidal probe was hardware generated, and gated by multiplying it with a computer-generated envelope with 10-ms raised-cosine onsets and offsets, and a steady-state portion of 380 ms. The probe was temporally centered within the masker, which consisted of a noise burst with the same gating envelope, but a 480-ms steady state. (2) A 500-ms portion of the buffer was chosen randomly for the masker burst on each trial, but the same masker burst was used for the two intervals of the trial. (3) The masker bursts were output from 12-bit D-A converters, simultaneously with the appropriate gating envelope for the probes. Probe and masker bursts were controlled independently in level by two digitally controlled attenuators (Charybdis), at the output of which they were mixed. We have no reason to suspect that any of these differences affect the results to any significant degree.

E. Analyses

All analyses were performed on means. When averaging over listeners, the contribution of each listener to the mean was kept equal by taking means within a listener before averaging across listeners. If there was no data for a particular condition for any one of the listeners in the mean, that condition was excised. In particular, it was occasionally not possible to present the masker at a sufficiently high level to mask the probe for the widest notch widths and higher probe levels.

Most of the analyses were done individually for each listener. However, in order to simplify the presentation, the first, and most extensive analyses concern the mean of the three listeners who experienced the greatest range of levels

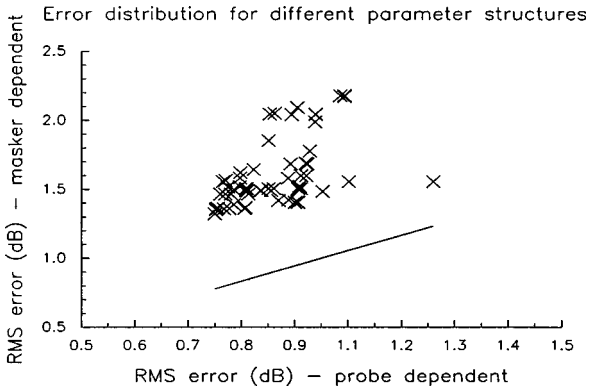

FIG. 1. A comparison of the goodness-of-fit of PolyFit models of identical structure, one of which has filter parameters depending upon probe level (abscissa), and one of which has filter parameters depending upon masker level. The goodness-of-fit measure is the root-mean-square residuals; hence smaller numbers indicate better fits. Only parameter structures resulting in models with a goodness-of-fit less than 2.5 dB are included (a total of 63 comparisons). The solid line indicates equal goodness-of-fit for the two possible dependences.

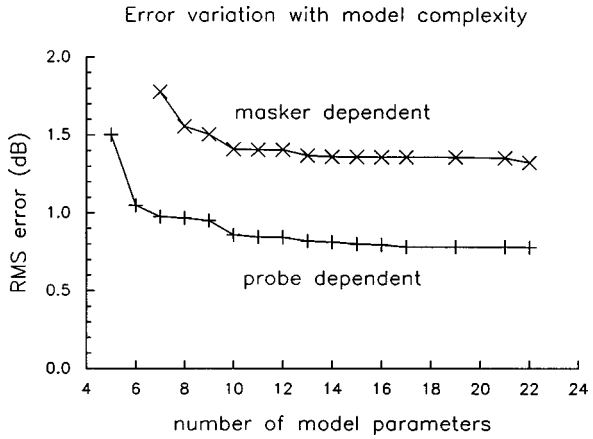

FIG. 2. Summary measures of the goodness-of-fit of PolyFit models which fit the data best with a given number of coefficients, for models in which filter parameters depend upon the level of the probe, and of the masker.

and notch widths (AMD, JD, and RJB). Comparisons are also made with the mean results of LS and MB, as used by Rosen and Baker (1994). Because listeners do vary somewhat in their performance, we only took means across listeners with a common set of conditions. Otherwise, we felt it would have been necessary to implement some kind of weighting to ensure listeners' responses were given equal weight across *all* conditions.

A variety of models were fitted to each data set, using Polyfit. All of the models were variants of the asymmetric roex(p,w,t) model. These included simplified models in which, for example, the upper half of the filter was described with a roex(p) shape whereas the lower half was a complete roex(p,w,t) shape. It is also necessary to estimate k, the signal-to-noise ratio necessary for detection at the output of the filter. All of these parameters can be arbitrary polynomial functions of the level of the masker or the probe, but we have never investigated models with more than a quadratic dependence on level (that is, three coefficients per parameter to be estimated). Finally, we also used Polyfit's ability to estimate an absolute threshold that is never allowed to vary with level (described above).

II. RESULTS AND DISCUSSION

A. Normal listeners: Mean of 3

This data set consists of mean thresholds obtained in 158 distinct conditions (as described above, excluding the [0.6, 0.4] notch at fixed probe levels of 60 and 70 dB SPL), based on a total of 1154 separate thresholds from the three listeners AMD, JD, and RJB.

We fitted 73 models, which differed in parameter structure, assuming filter parameters to vary with probe level or masker level (a total of 146 distinct models). Figure 1 shows that, for models that depend on level, probe-dependent models *always* fit the data better than masker-dependent models. Although the fits obtained from the masker-dependent models might be considered adequate in other circumstances, the rms residual is typically 70% larger than that obtained from the corresponding probe-dependent model (a statistic based on the median ratio of rms residuals).

Another way to demonstrate this is to compare the fits from the best-fitting probe- and masker-dependent models for fixed numbers of coefficients. Figure 2 shows, again, the consistently better fit obtained by making filter parameters depend upon probe rather than masker level.

Although it is quite clear that probe-dependent models give better fits than masker-dependent models, it is much more difficult to choose a particular probe-dependent model out of the many possible. Clearly, for a fixed number of coefficients, one would typically choose the best-fitting model. The difficult issue is the choice of the number of coefficients, and how this trades off against the goodness-of-fit.

To aid us in this task, we have adopted a heuristic approach based on those common in statistical model building (e.g., see Aitkin *et al.*, 1989). Starting off with a model with more coefficients than we think are necessary, we then determine which can be eliminated by looking at changes in the goodness-of-fit as they are excised. Unfortunately, for the type of nonlinear model employed here, there is no statistical theory which can assess the statistical significance of any given numerical change in the rms residual. Often, however, excising some coefficients hardly changes the rms residual, whereas excising others changes the fit of the model dramatically. In our earlier publication (Rosen and Baker, 1994), we had the good fortune for this to be true consistently. Here the results are not as clear cut, but as we shall see, models with similar goodness-of-fit lead to filter shapes that are very similar. Therefore it is not particularly important which model is chosen from the ''better-fitting'' ones. The relatively large number of good-fitting filter shapes is also an indication that the roex(p,w,t) shape may be *too* flexible. There are likely to be other adequate functional forms with fewer controlling parameters (e.g., Irino and Patterson, 1997; Lyon, 1996). For the moment, however, we concentrate solely on the roex family, as they are the only filter shapes which have been shown to be adequate for dealing with a wide variety of results.

First note that a quadratic dependence of all parameters

TABLE II. Goodness-of-fit for the best-fitting model containing 5–22 estimated coefficients. All are probe dependent models. The first seven columns contain the number of polynomial coefficients used for each filter parameter. The last column indicates the % change in the goodness-of-fit measure between the model given by that row, and the model on the row immediately above.

on probe level leads to little improvement on the fits obtainable from a linear dependence. The quadratic model, with 22 coefficients to estimate (three for each of the six filter parameters and k, plus one for absolute threshold) leads to an rms residual of 0.778 dB, whereas the linear model, with 15 parameters, leads to a residual of 0.808 dB. Thus a loss of seven coefficients worsens the goodness-of-fit by only 0.03 dB.

Table II shows the best-fitting models for a particular number of estimated coefficients. Models are generally described by a letter (p or m indicating *p*robe or *m*asker level dependence) followed by a string of seven digits indicating the number of coefficients used for each of the parameters p_l, p_u, k, w_l, w_u, t_l, and t_u, respectively. An ''x'' indicates a parameter that is not needed, for example, when only a roex(p) shape is needed on the high-frequency side of the filter. Thus $p2212x1x$ indicates a model in which both lower and upper p depend upon probe level in a linear way, as does w_l, with a simple roex(p) shape on the high-frequency side. All other parameters are invariant across level. A ''0,'' used only for describing filter parameters for the upper half of the filter, indicates that the filter shape has identical values on its high- and low-frequency sides for that particular parameter. Thus $p1012x1x$ indicates a model with a simple roex(p) shape on its high-frequency side, but symmetric in its passband. Only one filter parameter varies with level (w_l).

Note that it is possible to account reasonably well for the data with as few as 6 coefficients. Of these, two concern absolute threshold and detection efficiency (k), while only four describe filter shape (assuming symmetry in the passband, by setting $p_u=p_l$, did not harm the fit and allowed the loss of one parameter). Only one filter parameter need depend on level (w_l). Also of note is the fact that k can generally be assumed to be invariant across level without affecting the fits obtained. This empirical fact supports a simpler interpretation of our results than would otherwise be the case (see the discussion below).

Figure 3 shows the filter shapes, as a function of level, derived from four of the models described in Table II. Although the goodness-of-fit varies across these four models by about 35%, there is little change evident on the low-frequency sides of the filter. Even the high-frequency sides (which are known to be somewhat difficult to pin down in notched-noise experiments as thresholds are largely determined by the shallower lower side of the filters, Glasberg and Moore, 1990) differ little unless they are not permitted to change with level. So, although there is some uncertainty in choosing a particular model, many of the models which fit the data reasonably well lead to similar conclusions about filter shapes.

We have chosen to focus on $p1312x2x$, as a further reduction in the number of coefficients leads to a relatively large increase (in terms of proportions) in the rms residual, considerably larger than reductions in models with more coefficients. This model appears to be a good compromise between the number of parameters used and the goodness-of-fit, but other choices would lead to conclusions that are little different. The quadratic term for p_u allows the upper slope of the filter to remain relatively constant for low levels, and then to become shallower with increasing level once the probe level reaches about 50 dB SPL. Models in which p_u is constant, or a linear function of level, lead to odd behavior in the upper tails of the filter. In particular, the tail starts just a few dB down from the peak. Clearly, the roex(p,w,t) was not designed with such a possibility in mind, so it seems far preferable to allow a quadratic dependence in one parameter.

That the models do fit the data quite well can be appreciated from Fig. 4, which shows the entire data set, plotted as growth-of-masking functions, along with the predictions from our chosen model. (Note that the ordinate here is signal-to-noise ratio as opposed to the probe level more usu-

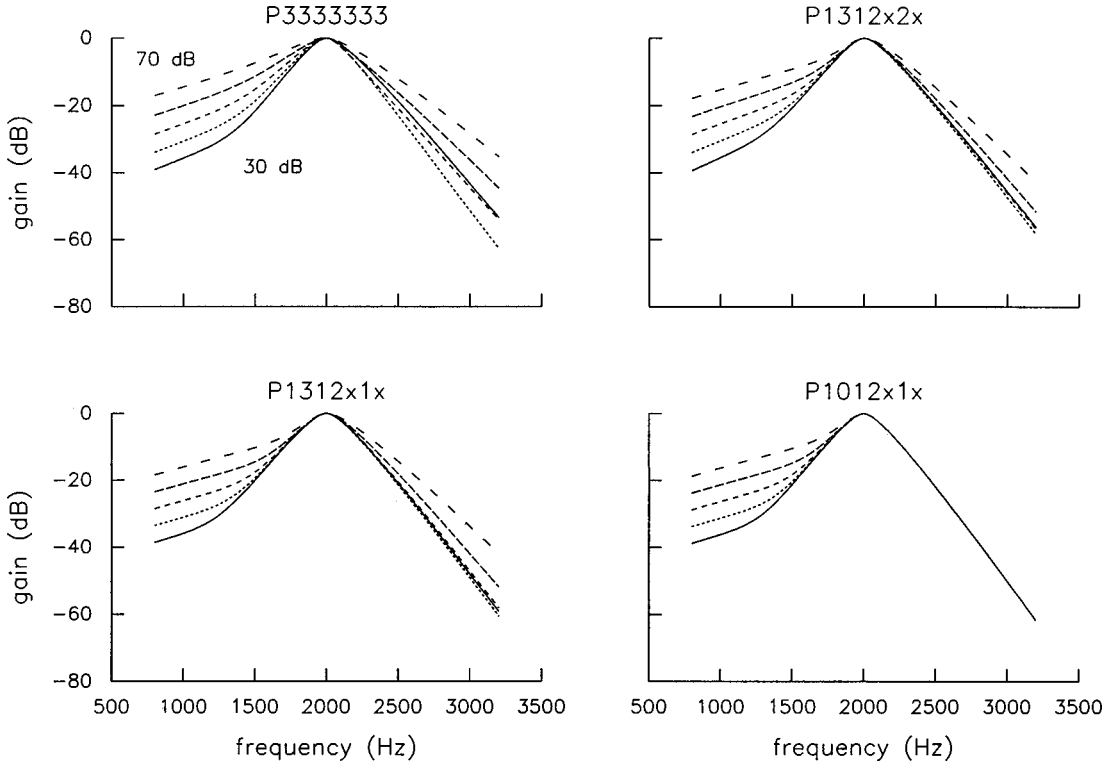

FIG. 3. Filter shapes for four different probe-dependent models. Each plot shows the filter shapes calculated for probe levels of 30–70 dB SPL in 10-dB steps.

ally plotted in such curves. The advantage of this measure is that departures from a linear growth of probe level with masker level, indicated by a horizontal line, are more easily assessed visually.) All predictions are within $-2.8/+2.0$ dB of the obtained data points and the rms residual is only 0.859 dB. Contrast this with the predictions from the best masker-dependent model with the same number of estimated coefficients in Fig. 5 ($m2222x1x$). Although in many situations this would be considered quite a good fit, note the many regions in which the data are consistently predicted poorly. The predictions are only within $-5.7/+3.3$ dB of the obtained data points with the rms residual being 1.41 dB, some 64% worse.

There is another way of plotting filter shapes which also points to probe-dependent models being superior. The filter shapes shown above are all normalized to have unity gain at their peak, as a consequence of the assumptions involved in fitting roex filter shapes. Yet we know from direct measurements of basilar membrane vibration that peak gain varies monotonically with level, being greatest at lowest levels (Ruggero *et al.*, 1992; Ruggero *et al.*, 1997). Such measurements also show basilar membrane response to be linear for frequencies sufficiently below the best frequency of the place on the membrane being investigated, as shown in Fig. 6. While Fig. 6 shows basilar membrane transfer functions for an isointensity stimulus paradigm, the same general properties (variation in peak gain and linearity below CF) can be seen in isoresponse measurements of basilar membrane motion (Ruggero *et al.*, 1997). Note too the compressive response at the peak of the filter, with a change in gain of about 20 dB for a 40 dB input range.

Working on the hypothesis that our behavioral results

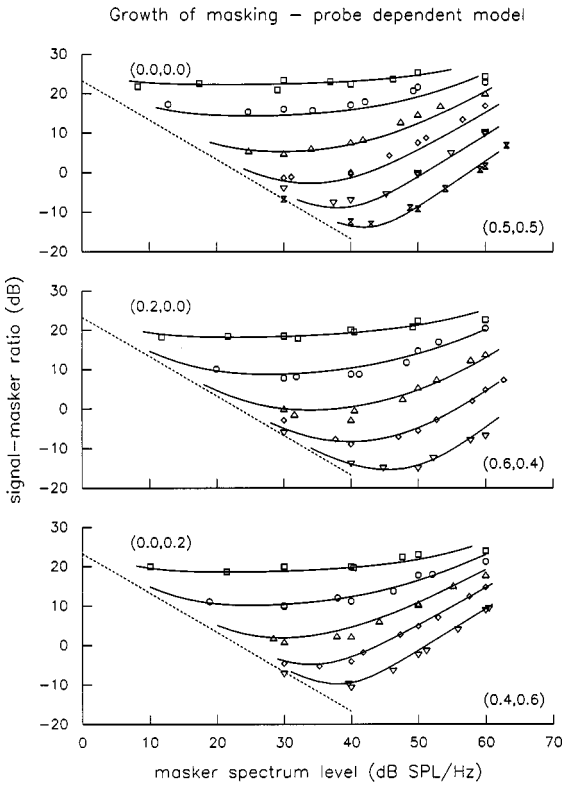

FIG. 4. Masked thresholds expressed as signal-to-noise ratios (probe level in dB SPL minus the masker level in dB SPL/Hz) as a function of masker level. Such curves are known as growth-of-masking functions (although more typically with the level of the probe as the ordinate). The results from symmetric notches and the two types of asymmetric notches are shown in separate graphs. Each symbol indicates a particular pair of notches. The lines are predictions from a model which assumes filter parameters to depend upon probe level. The diagonal line at left indicates absolute threshold.

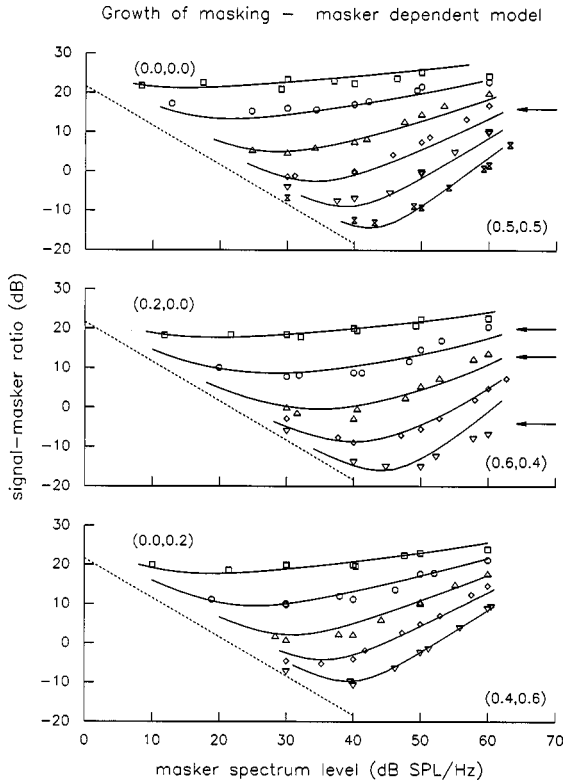

FIG. 5. As for Fig. 4, but with predictions from a masker-level-dependent model. Arrows indicate regions in which the fit of the model is consistently poor.

reflect basilar membrane filtering in a fairly direct manner, we assume that the auditory filter is linear a little more than one octave below its characteristic frequency, thus tacking together the shapes at this point. The resulting curves are highly reminiscent of filtering functions measured on the basilar membrane. In particular the filter sharpness and peak filter gain both increase with decreasing level (Fig. 7), and there is a tendency for the filters to become linear again at frequencies high above CF. The 2:1 compression ratio at the peak is also similar to that evidenced on the basilar membrane, although not too much should be made of this. Other basilar membrane studies indicate greater compression ratios (e.g., Nuttall and Dolan, 1996), but against this must be set the probability that compression ratios vary significantly

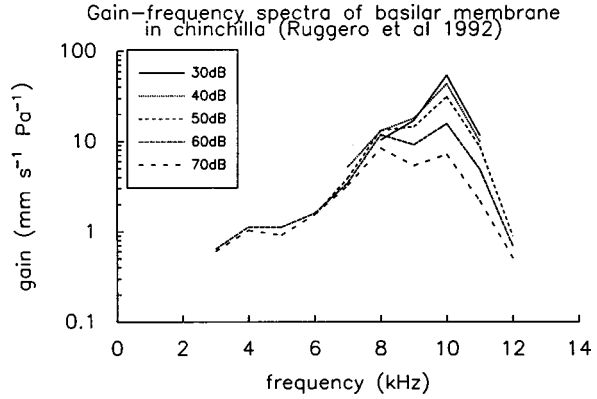

FIG. 6. The frequency response (isointensity) of a single place on the basilar membrane as a function of level (redrawn from Ruggero *et al.*, 1992).

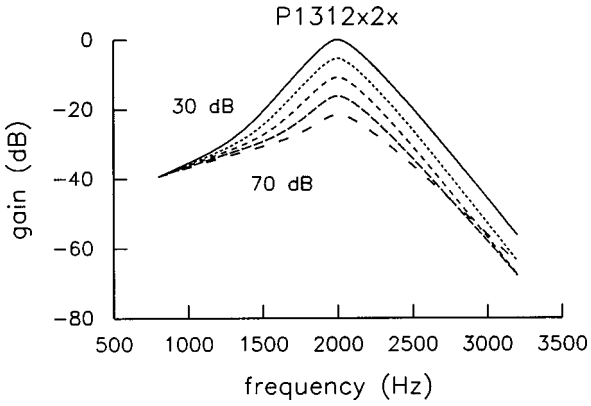

FIG. 7. Filter shapes for a $p1312x2x$ probe-dependent model, calculated for probe levels of 30–70 dB SPL in 10-dB steps, and normalized to have equal gain a little more than one octave below their center frequency.

with frequency, decreasing apically (i.e., at lower frequencies, Cooper and Yates, 1994; Wilson, 1992).

Note too that the filters plotted in Fig. 7 change shape right down to within 15 dB of absolute threshold. This is to say that the nonlinearity extends to levels as low as it is possible for us to measure. There is some controversy about this, with claims that the basilar membrane is linear even at its peak response for stimulus levels as high as 30–40 dB SPL. Recent measurements by Nuttall and Dolan (1996) support our view in showing that the response of the basilar membrane does indeed become linear at low enough levels, but only ‘‘ . . . for basilar membrane velocities below afferent neural thresholds based on discharge rates’’ (p. 1561).

The same manipulation leads to a much less orderly picture for the masker-dependent models. Figure 8 shows the filter shapes normalized in both ways. Although the filter does become shallower with level on its low-frequency side in the passband, the tail sharpness appears to *increase* with increasing level. Also, filter sharpness does not turn out to be linked to peak filter gain in the way suggested by basilar membrane experiments.

We have also found that the filter shapes obtained from masker-dependent models change much more with changes in parameter structure, as can be seen in Fig. 9. In the $m2212222$ model, the change in gain is even greater than the change in input level. Therefore according to this model, output level would *decrease* as input level increases.

In short, there are strong reasons to prefer models of auditory filtering which make filter parameters depend upon probe level rather than masker level: (1) The probe-dependent models predict the data more accurately over the entire stimulus space, with the root-mean-squared residuals 40%–70% larger for masker-dependent models; (2) Probe-dependent models lead to filter shapes much more in keeping with physiological measures. (3) Filter shapes derived from masker-dependent models change greatly with small changes in the parameter structure assumed, while filter shapes derived from probe-dependent models change little even with large changes in the assumed parameter structure.

B. Normal listeners: Mean of 2

Rosen and Baker (1994) reported similar analyses to those above on a set of mean data from two different listen-

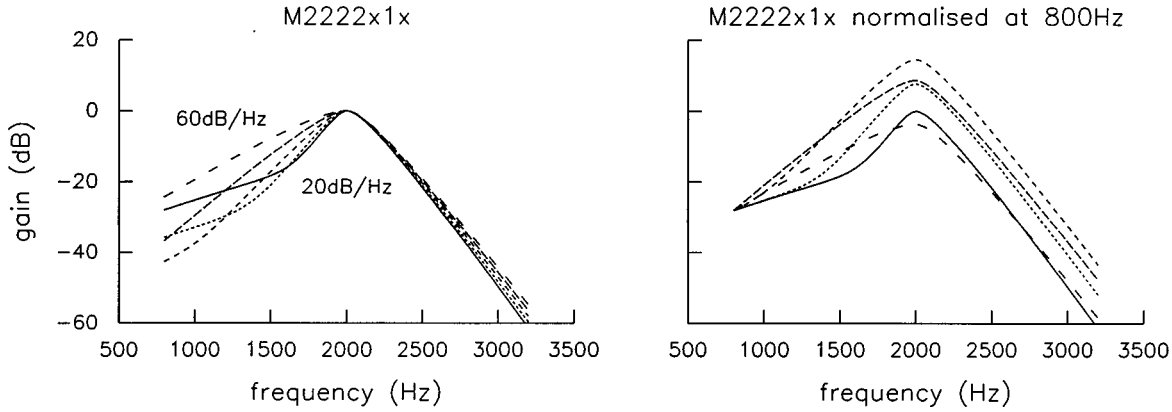

FIG. 8. Filter shapes for a *m*2222*x*1*x* masker-dependent model, calculated for masker levels of 20–60 dB SPL in 10-dB steps, normalized both to have equal gain at their tips, and about an octave below their center frequency.

ers. It is interesting to compare the filter shapes from the two sets of mean data given the differences in listener, apparatus, and particular conditions tested. Figure 10 (corresponding to Fig. 7) shows the filter shapes derived from the same probe-dependent model focused on above. It is clear that the two sets of data lead to highly similar derived filter shapes across level, in spite of all the differences between them.

C. Normal listeners: Individual results

Similar analyses were performed for the individual data sets obtained from each of the listeners. Of some interest is the relationship between the absolute thresholds obtained with standard audiometery (Table I) and the threshold estimated from the fits. Comfortingly, the estimated absolute threshold varied little with the parameter structure of the fitted model (e.g., at most 1.5 dB for the four probe-dependent models specified in Table III). Also, there was typically a close relationship between the two absolute thresholds (within 5.5 dB for six of the nine listeners). Only one listener (SK) had a large discrepancy (>8 dB), with the threshold estimated from the fits about 23 dB greater than her threshold measured audiometrically. Due to the fact that this listener did not participate in the lowest level fixed-masker condition, and that her signal detection efficiency (as measured by k) was the highest of any listener ($+7.5$ dB *re*: the mean level of the other eight normal listeners), no probe level even approached her actual absolute threshold. As it is thus clear

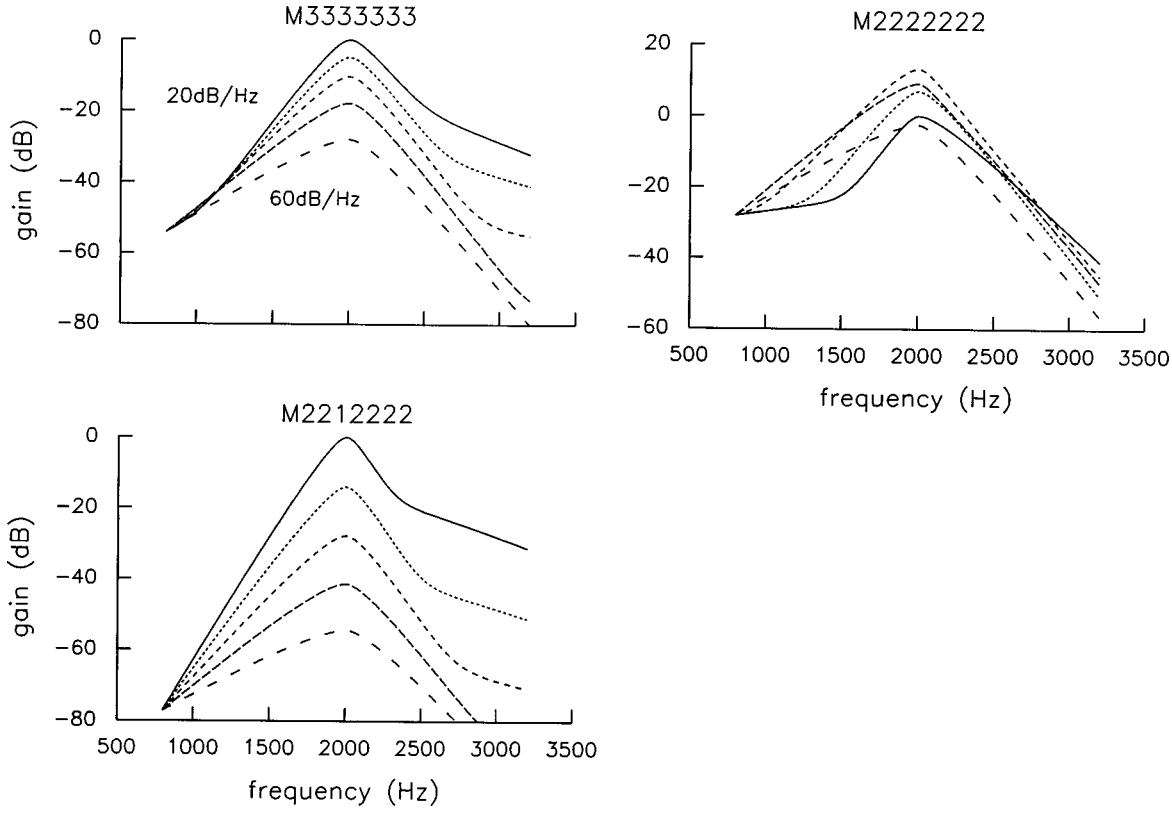

FIG. 9. Normalized filter shapes for three different masker-dependent models. Each plot shows the filter shapes calculated for masker levels of 20–60 dB SPL in 10-dB steps. Note the strong variation in shapes for different parameter structures.

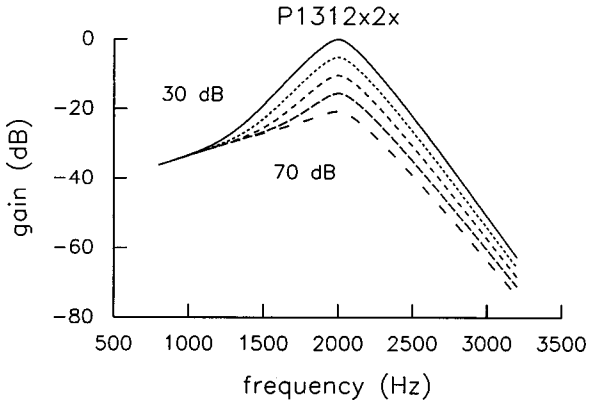

FIG. 10. Filter shapes from the data obtained by two normal listeners in Rosen and Baker (1994). The curves show a $p1312x2x$ probe-dependent model, calculated for probe levels of 30–70 dB SPL in 10-dB steps, and normalized to have equal gain at about one octave below their center frequency. Compare this to Fig. 7.

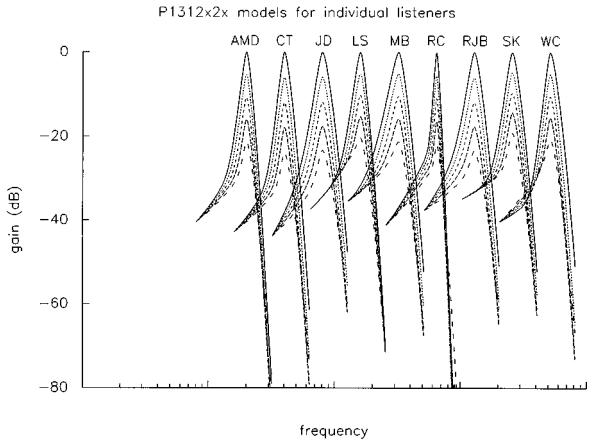

FIG. 11. Filter shapes for nine normal-hearing listeners using a $p1312x2x$ probe-dependent model, calculated for probe levels of 30–70 dB SPL in 10-dB steps, and normalized to have equal gain at just less than one octave below their center frequency. The curves have been shifted along the logarithmic frequency axis for clarity.

that the masked thresholds could not possibly constrain an estimate of her absolute threshold, no fits for SK incorporated an absolute threshold term.

Table III shows the goodness-of-fit measures for a selection of models for each individual data set. These measures vary significantly across listeners for at least two possible reasons. First, listeners differ in their inherent consistency, and we would expect more consistent listeners to have better fits. Second, given that there is some individual variation in filter shape, it may be that the roex(p,w,t) shape just happens to fit some listeners better than others.

Of more interest, in any case, is the pattern of results across conditions within an individual listener. Note first that probe-dependent models always fit the data better than masker-dependent models, again with the rms residual typically more than 50% greater for the masker-dependent models. In fact, we have never found a case in which a masker-dependent model fits the data better than a probe-dependent model of the same structure (in literally hundreds of comparisons). Second, for the probe-dependent model in which all parameters vary linearly with level, there is typically little loss of predictive power in assuming k (signal detector efficiency) to be constant across level.

Figure 11 shows the individual normalized filter shapes arising from the $p1312x2x$ model we used above. Again, however, there are a wide variety of parameter structures which lead to similar filter shapes. Clearly, individual listeners differ in their frequency selectivity, but the essential pattern is strikingly uniform.

In fact, for a number of listeners, there were ten parameter models that led to fits considerably better than the $p1312x2x$ used here. This was investigated further by finding the best ten-parameter model for each listener. If this model led to a goodness-of-fit that was more than 15% better than that from $p1312x2x$ (in terms of the sum of the squared residuals), a new model was chosen for that listener. (All the other listeners had improvements of fit ranging from 0% to 6.5%). One other constraint influenced the selection of the model. No model with a varying k was used, because the evidence from the Mean-of-3 data set so strongly supported the notion of a constant k. In those cases, another model was chosen, either one with fewer parameters, or with one additional parameter, depending upon the goodness of fit in each case. In all the listeners for whom a new model was chosen, the fit was improved by allowing p_l to vary with level, as shown in Table IV. Figure 12 shows the new set of filter shapes derived from the models. As compared to Fig. 11, the main change is seen in listener RC, whose filters were considerably narrower than those of the other listeners. This appears to arise from a poorly fitting model, and indeed, it was

the fit to RC's results that was improved the most by selecting a different model than our standard $p1312x2x$.

Contrast the filter shapes based on probe-dependent models with those that arise from the $m2222x1x$ masker-dependent model discussed above (Fig. 13). These are much more variable from listener to listener, both in the degree of compression (or even expansion) across level, and even in which level leads to the highest gain.

III. SUMMARY AND FINAL REMARKS

We have shown that it is possible to accurately account for the pattern of results across level in a notched-noise masking experiment with filter shape models that explicitly depend upon probe level. Such models have four advantages over models in which filter parameters depend upon the level of the masker: (1) They always fit the data better; (2) Filter shapes change relatively little with changes in the number of coefficients controlling each parameter, and in parameter structure; (3) Different listeners give results that are much more similar; (4) Appropriate normalization of tail gains lead to filter shapes that are highly reminiscent of vibration patterns observed directly on the basilar membrane. Therefore notched-noise measurements that are made only at one level should be performed with a fixed probe level. Fixing the masker level leads to a derived filter shape that is some kind of average of a number of shapes, caused by the change in probe level as notches are varied. In general, such filter shapes will be too narrow, simply because the filter is becoming sharper as the probe level decreases with increasing notch width.

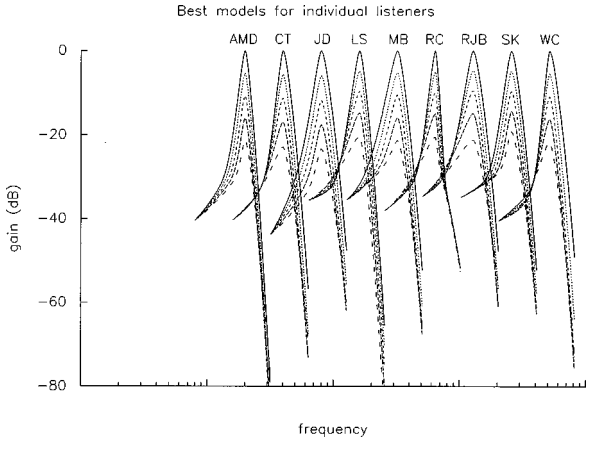

FIG. 12. Same as for Fig. 11, but with different filter shape models for the five listeners specified in Table IV.

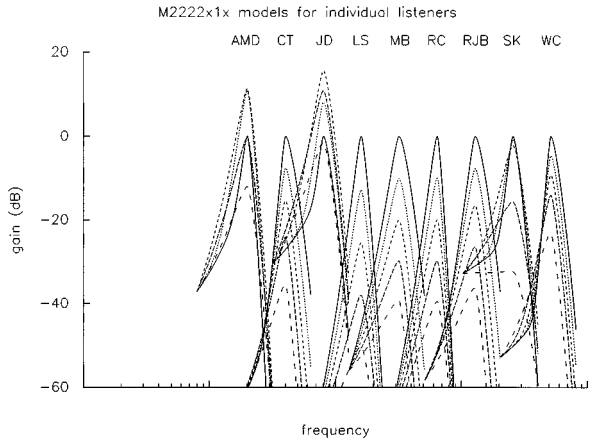

FIG. 13. Filter shapes for nine normal-hearing listeners using an $m2222x1x$ masker-dependent model, calculated for masker levels of 20–60 dB SPL in 10-dB steps, and normalized to have equal gain at just less than one octave below their center frequency (cf. Fig. 11).

Our technique is also likely to clarify the effects of hearing impairment on auditory nonlinearity, especially as it is currently believed that many of the concommitants of sensori-neural hearing loss can be attributed relatively straightforwardly to a loss of nonlinearity [see Moore (1995) for a review]. In particular, damage to the outer hair cells (where the ''motor'' for the nonlinearity is presumed to reside) would be expected to manifest itself in four ways relevant to the discussion here: (1) a loss of absolute sensitivity; (2) smaller or no changes in filter shape across level; (3) degraded selectivity at low levels; and (4) normal selectivity at sufficiently high levels.

Using the PolyFit procedure to analyze notched-noise masking data, we have found evidence for all of these four features in two hearing-impaired listeners with quite minor impairments (Rosen *et al.*, 1996). One had a hearing loss sloping from essentially normal at low frequencies to 35 dB HL at 8 kHz. Although she used hearing aids, her loss at 2 kHz was only 30 dB. Strikingly, her auditory filter shapes did not change at all with level. Filtering on the upper side of the filter was essentially normal, while that on the lower side could only be considered normal at relatively high levels. For low measurement levels, her auditory filter slopes were considerably shallower than normal on the low-frequency side. The other listener, with a subclinical impairment of 20 dB at 2 kHz attributed to frequent exposure to amplified music as a musician, also showed a reduced (but not absent) nonlinearity. Thus at least in these cases, hearing loss appears to consist of a loss of the nonlinear properties of the auditory periphery, most likely arising from damage primarily to the outer hair cells.

On the theoretical (and practical) side, there is still much to be done regarding the computational implementation of nonlinear filters, in order to produce a general-purpose nonlinear auditory filter bank. In terms of the distinction between ''input'' versus ''output'' control of filter shape (Lutfi and Patterson, 1984; Verschuure, 1981), our results clearly support the notion that the filter shape is controlled by its output level. This arises from the finding that k appears to be constant across level, so that fixing the probe level also fixes

the output level of the filter. On the other hand, it may well be that filter structures that are neither directly input- nor output-controlled lead to results consistent with our findings (e.g., the MBPNL model of Goldstein, 1988). Explicit models of auditory filtering will also be necessary for detailed comparisons of basilar membrane data with psychophysical results, preferably obtained in the same species.

ACKNOWLEDGMENTS

This work was supported by the Wellcome Trust (Grant Reference 046823/Z/96) and the Medical Research Council (Grant Reference G9225699N). Thanks to Sarah Kramer and Rosie Casson who collected some of the data reported here, and also to Alberto Recio who provided the data for Fig. 6.

[1]Such a model overcomes the problem associated with narrow- and wide-band maskers if the spectrum level of the masker is taken as the controlling factor. For example, a 1-Hz wide and a 500-Hz wide band of noise may have the same spectrum level, but their masking effect will be very different.

[2]The PolyFit program is available by anonymous ftp from ftp://pitch.phon.ucl.ac.uk/pub/polyfit/.

[3]Were we to make strong statistically based claims about the adequacy of the various models (which we cannot do in such a nonlinear model anyway), we would have to deal more explicitly with the fact that in one-half of the measurements it is the masker level that is fixed (i.e., known without sampling error), whereas in the other half, it is the probe level that is fixed. Here this distinction has little import.

[4]Best parameter values were found using the downhill simplex method (Nelder and Mead, 1965) as implemented by Press *et al.* (1988). In order to avoid the problem of local minima, a variety of strategies were used. First, every optimization actually consisted of two applications of the simplex procedure, in which the second was restarted from the best values found from the first. Second, many different models were fitted, most of which were supersets and/or subsets of other models. The goodness-of-fit was compared across models to ensure that a particular model fit the data at least as well as any model that was a subset of it. Optimizations were started from best fits obtained to supersets and subsets of the model in question, with the appropriate parameters deleted or added, respectively. Finally, the optimization procedure was run until no further improvement in a fit could be made, and with a minimum of ten restarts from the previously found best fit. Although no procedure can preclude local minima, we believe this combination of techniques makes it unlikely that a local minimum was retained.

[5]A 20-ms raised-cosine ramp was accidentally applied twice to the masker in the computer program. This is approximately equivalent to a single application of a 15-ms raised-cosine ramp.

Modeling interaural-delay sensitivity to frequency modulation at high frequencies

Kourosh Saberi[a)]
Massachusetts Institute of Technology, Research Laboratory of Electronics, Cambridge, Massachusetts 02139

(Received 2 December 1996; revised 8 November 1997; accepted 20 January 1998)

Interaural-delay sensitivity to high-frequency ($\geqslant 3$ kHz) sinusoidal-frequency-modulated (SFM) tones is examined for rates from 25 to 800 Hz and depths of -12 to 18 dB. Comparison is made to thresholds obtained for sinusoidal-amplitude-modulated (SAM) tones for the same observers and modulation rates. Both SAM and SFM threshold-by-rate functions are U-shaped with optimum sensitivity to SFM tones occurring at higher rates ($f_m = 200-400$ Hz) compared to those for SAM tones ($f_m = 100-200$ Hz). Effects of modulation depth were examined for rates from 50 to 300 Hz. In all cases thresholds improved considerably with increasing modulation depth. It is also shown that a hybrid dichotic signal composed of an SFM tone presented to one ear and an SAM tone to the other, can perceptually fuse and be lateralized, with the contingency that both stimuli have equal modulation rates but not necessarily equal carrier frequencies. Using bandpass noise to restrict off-frequency listening, it was shown that for this stimulus, observers can use information from filters either below or above the carrier frequency. Consistent with FM-to-AM conversion from cochlear bandpass filtering, several important differences between the SAM- and SFM-tone data can be predicted from a nonstationary stochastic model of binaural interaction whose parameters are uniquely determined from the SAM-tone data.

INTRODUCTION

Sensitivity to interaural delays at high frequencies is documented extensively for amplitude-modulated (AM) sounds. The early studies of AM processing investigated the dependence of sensitivity on a wide range of simple stimulus parameters such as envelope rate, carrier frequency, and modulation type (Leakey *et al.*, 1958; David *et al.*, 1959; Harris, 1960; McFadden and Pasanen, 1974, 1975, 1976; Henning, 1974a, 1980, 1981; Hafter and DeMaio, 1975; Nuetzel and Hafter, 1976, 1981; Yost *et al.*, 1971). Later investigations extended to more complex binaural phenomena such as interference (McFadden and Pasanen, 1976; Zurek, 1985; Trahiotis and Bernstein, 1990; Buell and Trahiotis, 1993; Bernstein and Trahiotis, 1995), summation of interaural information (McFadden and Pasanen, 1976; Hafter *et al.*, 1990; Buell and Trahiotis, 1993; Saberi, 1995), testing models of cross correlation (Colburn and Esquissaud, 1976; Stern *et al.*, 1988a), masking (Henning, 1974b; Bernstein and Trahiotis, 1992; Kohlrausch *et al.*, 1995), motion discrimination (Saberi and Hafter, 1996), adaptation and precedence (Hafter *et al.*, 1988; Blauert and Divenyi, 1988; Saberi, 1996), all at high frequencies.

In contrast, there are only a handful of papers on binaural sensitivity to frequency-modulated (FM) sounds (Henning, 1980; Blauert, 1981; Hukin and Darwin, 1994). The types of FM stimuli to which binaural sensitivity has been shown include phase-jittered tones (Nordmark, 1976; Blauert, 1981), square-wave modulation (Green and Kay, 1975; Green *et al.*, 1976; Kay, 1982), noise-modulated phase (Bielek, 1975), and sinusoidal-frequency-modulated (SFM) tones (Henning, 1980). In spite of their completely flat envelopes, lateralization of high-frequency FM sounds is possible because of an FM-to-AM conversion by cochlear bandpass filtering (Zwicker, 1958; Henning, 1980; Blauert, 1981). The rate, depth, envelope shape, and phase of this AM-like response vary across filters and primarily depend on: (1) the frequency separation between the filter's resonant frequency and the stimulus carrier; (2) stimulus modulation rate, phase and depth; and (3) the impulse response of the filter, including its phase spectrum. The manner in which these factors interact is complex and requires careful and in-depth consideration.

With the exception of Henning (1980), all previous binaural studies on FM at high frequencies have used nonsinusoidal modulation. These stimuli have discontinuities in the slope of the carrier waveform and, therefore, transient byproducts. Sinusoidal modulation however has smoothly varying temporal properties with a power spectrum that is more confined and symmetric about the carrier frequency, and is therefore a useful stimulus for isolating the effects of frequency modulation. The one study that has examined binaural sensitivity to SFM tones at high frequencies was conducted by Henning (1980) who used only a single modulation rate (300 Hz) and carrier frequency (3.9 kHz). Henning reported that thresholds of 80–200 μs for that stimulus were comparable to those observed for quasi–frequency-modulation (QFM) and slightly higher than those for SAM tones with the same rate.

The goal of the present study is to: (1) investigate binaural processing of SFM tones at high frequencies for a wide

[a)]Current address: 216-76 Division of Biology, Caltech, Pasadena, CA 91125, Electronic mail: kourosh@caltech.edu

range of stimulus parameters and in comparison to SAM tones, and (2) evaluate for SFM tones the predictions of a model of binaural interaction whose parameters are uniquely determined from the SAM-tone data. The experiments begin with a measurement of interaural time difference (ΔITD) thresholds for SFM tones at several carrier frequencies and modulation rates. Thresholds are then compared at one carrier frequency to those obtained with SAM tones using the same observers. Data and observations are also reported on a variety of other psychophysical tasks that examine the effects of modulation versus carrier delay, and modulation depth. Finally, binaural interaction between an SFM tone presented to one ear, and an SAM tone to the other ear is examined. We begin with a description of the spectral characteristics of SFM tones.

I. FOURIER SPECTRUM OF SFM TONES

An SFM tone $X(t)=A_c\cos[2\pi f_c t+\beta\cos(2\pi f_m t)]$ has an instantaneous frequency $f_c+\Delta f\sin(2\pi f_m t)$ and a Fourier expansion (Inglis, 1988; Carlson, 1986) expressed as the harmonic series

$$X(t)=A_c\,J_0(\beta)\cos 2\pi f_c t-A_c\sum_{n=0}^{\infty}J_{2n+1}(\beta)\times\{\cos 2\pi[f_c-(2n+1)f_m]t-\cos 2\pi[f_c+(2n+1)f_m]t\}+A_c\sum_{n=0}^{\infty}J_{2n}(\beta)\{\cos 2\pi[f_c-2nf_m]t+\cos 2\pi[f_c+2nf_m]t\}, \quad (1)$$

where $\beta=\Delta f/f_m$, the frequency-modulation index, is the ratio of peak-frequency-deviation to modulation frequency, and

$$J_n(\beta)\triangleq\frac{1}{2\pi}\int_{-\pi}^{\pi}e^{j(\beta\sin\lambda-n\lambda)}\,d\lambda \quad (2)$$

are Bessel functions of the first kind of order n (sideband number) and argument β which define the amplitude coefficients of the line spectra (Fig. 1). Equation (1) shows that the line spectra of SFM tones consist of a carrier frequency f_c and sidebands at $f_c\pm nf_m$ with the *odd*-order lower sidebands inverted in phase relative to the unmodulated carrier.

As β increases, so does the bandwidth of the SFM tone. Usually, the effective bandwidth of this stimulus is approximated from Carson's rule which defines the 98% energy bandwidth as $2(\beta+1)f_m$ (Cooper and McGillem, 1986; Carlson, 1986). While the bandwidth of the SFM tone increases with β, the amplitude A_c of the time waveform and therefore the stimulus power are constant and independent of β. Consequently, changing β must change the stimulus energy at the carrier frequency. For some values ($\beta=2.4$, 5.3) there is no energy at the carrier. This property is very different from that of SAM tones. The carrier of an SFM tone contains part of the modulation information while the carrier of an SAM tone contains no information about the modulation waveform (Couch, 1987; Carlson, 1986).

The amplitude of the sidebands of an SFM tone [Eq. (2)] cannot be expressed in nonintegral form, however, they have been numerically evaluated and tabulated for many values of β (Abramowitz and Stegun, 1972). The lower panel of Fig. 1 shows calculations of sideband attenuation relative to carrier amplitude in decibels for various values of $\beta=0.2$, 0.4, 0.6, 0.8, 1.0, 2.0. Note that these functions are dependent on only one stimulus parameter, β. The amplitude of the sidebands drop rapidly when the sideband number exceeds the value of β for $\beta>1$. For $\beta\leqslant 1$, the stimulus bandwidth from Carson's rule is confined to the frequency region bordered by the second sidebands. For most of the carrier frequencies and modulation rates used in the following experiments, the SFM-tone bandwidth is confined to frequencies considerably above 1.5 kHz. Nonetheless, lowpass noise and highpass filtering are used to eliminate possible low-frequency cues or intermodulation distortions.

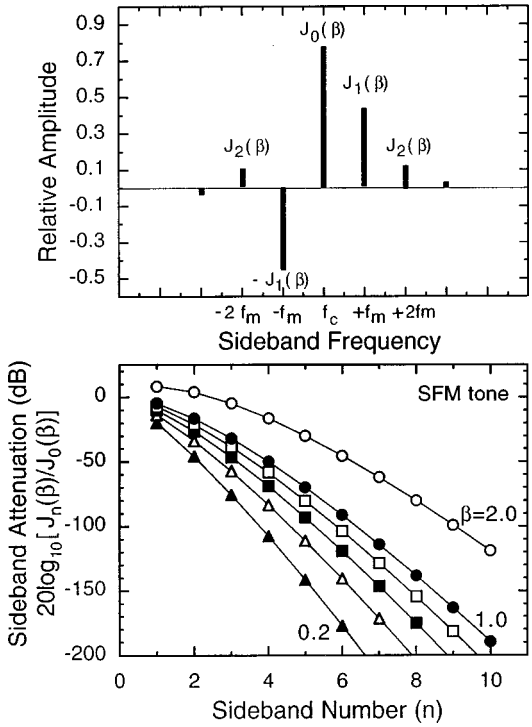

FIG. 1. Top panel shows the amplitude spectrum of an SFM tone with carrier f_c, modulation rate f_m, and a modulation index β of unity. The amplitudes are Bessel functions of the first kind of order n (harmonic number) and argument β. The lower odd harmonics are phase reversed relative to the remaining components [Eq. (1)]. The lower panel shows sideband attenuation in dB *re*: the amplitude of the carrier for $\beta=0.2$, 0.4, 0.6, 0.8, 1.0, and 2.0.

II. MODEL STRUCTURE

In this section a model of binaural interaction is described that is later used to examine the data obtained for both SAM and SFM stimuli. The important feature of the model is that its parameters are determined from the SAM data and predictions are subsequently made for SFM tones. Thus the extent to which the model captures performance reflects the extent to which amplitude envelope cues are used from an FM-to-AM conversion by bandpass filtering. A block diagram of the model structure is shown in Fig. 2. The stimuli are first filtered through a Gammatone filterbank (Holdsworth *et al.*, 1988). The filterbank consists of 30 filters

distributed logarithmically from 2 to 5 kHz. The Hilbert envelopes are then extracted and used to drive a nonstationary fractal point process.[1] The point process, which models the serial correlation of spike patterns from auditory afferents (Teich, 1989; Teich and Lowen, 1994; Lowen and Teich, 1995, 1996) is then subjected to a refractoriness model (Westerman and Smith, 1985; Carney, 1993) with a random dead-time distributed uniformly from $R_A = 0.25 - 0.75$ ms, and a recovery function described by the sum of two exponentials

$$Q(t) = \begin{cases} Q_{\max}\{c_0 \exp[-(t-t_1-R_A)/s_0] \\ \quad + c_1 \exp[-(t-t_1-R_A)/s_1], \quad \text{for } (t-t_1) \geqslant R_A; \\ 0, \quad \text{otherwise,} \end{cases} \tag{3}$$

where $t-t_1$ is the time since the last discharge, and $Q_{\max}$ is the maximum increase in threshold for the recovery function (normalized to unity in the current implementation), $c_0 = 0.55$ and $c_1 = 0.45$ are coefficients for the discharge history effect, and $s_0 = 0.8$ and $s_1 = 25$ ms are time constants. This first stage of the model is used to generate post-stimulus time histograms (PSTH) from 1000 sample waveform presentations; the PSTHs are then low-pass filtered to reconstruct the envelopes of the filtered waveforms. The primary effect of the point process and refractoriness was to enhance the waveform peaks, similar to an expansive nonlinearity used in psychophysical models (Colburn, 1973; Stern *et al.*, 1988a; Shear, 1987) and also reported for physiological recording in the auditory nerve in response to SAM tones (Joris and Yin, 1992). The resultant output of the point process is low-pass filtered at 150 Hz; the slope of the FIR low-pass filter is chosen to fit the SAM-tone data for modulation rates above 150 Hz.

The second stage of the model uses the reconstructed envelopes as inputs to an interaural cross-correlation function

$$\chi(t,\tau,f) = p(\tau) \int_{f_a}^{f_b} \int_{-\infty}^{t} X_l(t,f) X_r(t-\tau,f) \times \{1 + e^{-(t+\mu)/k}\}^{-1} \, dt \, df. \tag{4}$$

The running cross-correlation has a logistic decay with mean $\mu = 20$ ms and slope parameter $k = 0.002$, and a centrality-weighting function $p(\tau)$ that heavily weights τ values near zero and has the form of a sixth-order Butterworth bandpass filter that is maximally flat in the passband and monotonic overall with rolloffs at ± 0.6 ms.[2] The cross-correlation function of Eq. (4) is discretized at a sampling rate of 20 kHz and a deviate $\xi_{\tau,f} \sim \text{normal}(0,\sigma_\xi^2)$ is added, before frequency integration, to each delay-by-frequency sample of the $\tau - f$ plane to model the stochastic nature of the process. The lag (τ) associated with the peak of the cross-correlation output, $\chi_{\max}$, is then used to obtain a lateral position estimate, from which the index of detectability is calculated

$$d' = E[\tau(\chi_{\max}) + \epsilon_p] / (\text{var}[\tau(\chi_{\max})] + \text{var}[\epsilon_p])^{0.5}, \tag{5}$$

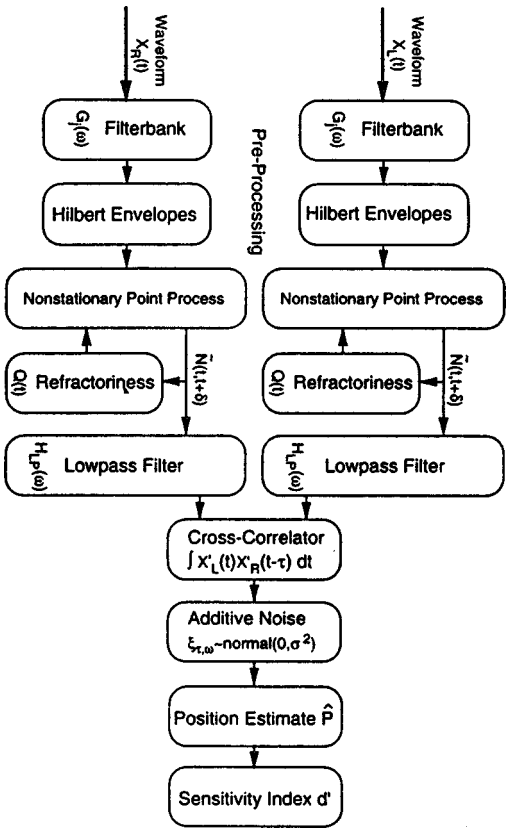

FIG. 2. Schematic diagram of the model structure.

where $\epsilon_p \sim \text{normal}(0,\sigma_p^2)$ is a position noise added to the estimate before calculation of d' to prevent the model from perfect discrimination in those cases where the waveform envelopes have a very high peak factor. Although it is, in principle, useful to maintain this parameter (ϵ), in practice the position noise may be chosen to be substantially smaller than ξ when using high-frequency stimuli, and therefore ϵ may be ignored or set to zero variance. In the model implementation the expected value of d' was estimated from computer simulations of 10 000 trials per each value of interaural delay. Between 2 and 4 values of interaural delay were used to obtain 2–4 values of d' that bracketed 0.78. A least-squares linear fit to log d' vs log ITD was used to obtain the interaural-delay threshold corresponding to 71% correct performance in a 2IFC task ($d' = 0.78$).

There are several reasons for choosing a stochastic approach. First, this approach predicts a reduction of interaural sensitivity at low modulation rates as previously reported for SAM-tone data (Nuetzel and Hafter, 1981). As the rate is reduced, the maximum slope of the envelope diminishes. As the slope of the envelope decreases, the addition of a constant-variance internal noise ξ increases the variance of estimating the peak of the cross-correlation pattern. As the modulation rate is increased, the slope of the envelope increases and the variance of the position estimate is reduced, thus a higher d'. As the rate is still further increased, the sidebands of the complex are increasingly filtered (due to increased component spacing) resulting in a reduced depth of modulation, increased variance of the position estimate, and thereby smaller d'. We next describe experiments that mea-

sure interaural-delay sensitivity to a variety of SFM stimulus conditions and compare performance with that from SAM tones. Model predictions are evaluated for several of these experimental conditions.

III. EXPERIMENT I

A. Lateralization thresholds for SFM tones as a function of modulation rate and carrier frequency

1. Procedure

In each interval of a two-interval, forced-choice (2IFC) task, a 400-ms dichotic SFM tone with a 20-ms cosine-squared rise-decay envelope was presented. The two intervals of the trial were separated by 300 ms. In one interval, the waveform ITD led to the left ear and in the other interval it led to the right ear (except for the gating envelopes which were not interaurally delayed). Waveform delay was achieved by appropriately phase shifting the carrier and modulation waveforms by $\phi_c = 2\pi f_c \mathrm{ITD}$ and $\phi_m = 2\pi f_m \mathrm{ITD}$, respectively. The subject's task was to identify the order of presentation of the tones (i.e., left-leading then right, or, right-leading then left). Each run consisted of 60 trials with visual feedback after each trial. A two-down, one-up procedure (Wetherill and Levitt, 1965; Levitt, 1971) was used to adaptively track the 0.707 probability of a correct response on the observer's psychometric function. The step change in interaural delay was 0.2 log μs up to the fourth reversal and 0.05 log μs for the remaining trials. The starting ΔITD value was 1300 μs (650 μs for each interval of the 2IFC). The first four reversals were discarded and the values of interaural delays at the remaining reversals were averaged to obtain one estimate of threshold.

Each subject completed a minimum of six runs per condition. The carrier frequencies were either 3, 4, or 8 kHz and the modulation rates were 100, 200, 250, 300, 350, 400, 450, 500, 600, and 700 Hz. The modulation index β was equal to unity. Each condition was defined by one value of modulation rate and one value of carrier frequency selected randomly between runs, but fixed within a run. All signals were computed before each trial of the adaptive procedure using an IBM PC and an array processor (Tucker-Davis Technologies TDT AP2). Signals were presented through 16-bit digital-to-analog converters (TDT DA2) at a sampling rate of 40 kHz and were low-pass filtered at 20 kHz. The sound pressure level for a continuous SFM tone was 60 dB SPL. Signals were highpass filtered at 1.5 kHz. In addition, continuous Gaussian noise, low-pass filtered at 1.5 kHz, was presented at a spectrum level of 32 dB to mask low-frequency intermodulation distortions (Henning, 1974a; Henning, 1980; Nuetzel and Hafter, 1981). Delays between left and right channels were checked for accuracy with a Philips dual-channel storage oscilloscope (model PM 3335). Signals were then led to a single-walled sound booth and presented to subjects through Sennheiser (HD-450) headphones.[3] All three subjects (EM, AN, AS) were experienced in lateralization experiments, and each was practiced on various conditions of the experiment until performance seemed to be stable. Two subjects were female and one male (EM) and their ages ranged from 18 to 22. The ear canals of all subjects were examined and cleaned at the University Infirmary. All subjects had normal hearing within 10 dB of ISO standards for frequencies between 125 and 8000 Hz as determined from a Bekesy audiometric test.

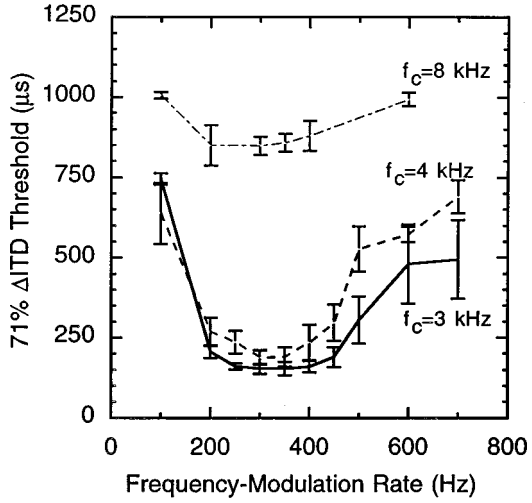

FIG. 3. Interaural-delay difference thresholds for SFM tones as a function of modulation rate. The parameter is carrier frequency. Note that each interval of the 2IFC task carried an interaural delay of ΔITD/2. Data are averaged for three observers and the error bars are one standard error of the mean.

2. Results

Results are shown in Fig. 3. Each line represents the averaged data for one carrier frequency. For the 8-kHz carrier, thresholds are elevated at all rates. At this carrier frequency, the signals are clearly audible and the decline in performance is not due to stimulus detectability. For the 3- and 4-kHz carriers, lowest thresholds are obtained at modulation rates of 200–400 Hz, with the 3-kHz carrier producing slightly better thresholds than the 4-kHz carrier. Best thresholds are on the order of 100–200 μs. One observer (AN) produced low thresholds even at a rate of 700 Hz (thus the large variability). For this one subject, performance degraded to chance as the modulation rate was increased to 1 kHz (not shown). The only previously available related data is from Henning (1980) who used a 300-Hz modulation of a 3.9-kHz carrier. The threshold of 200 μs reported by Henning is similar to the current results. Statistical analysis showed a significant effect of modulation rate for 3- and 4-kHz carriers ($F_{9,20}=2.66$, $p<0.05$; and $F_{9,20}=3.48$, $p<0.05$) but not for the 8-kHz carrier ($F_{5,12}=0.98$, n.s.). Carrier-frequency effects were significantly different between the 3- and 4-kHz conditions [$t(29)=2.36$ $p<0.05$].

B. Effects of carrier versus modulation delay

Studies on lateralization of SAM tones at high frequencies have shown that observers are only sensitive to the interaural delay in the envelope of the stimulus and not the carrier (Henning, 1974a, 1980; Henning and Ashton, 1981; Nuetzel and Hafter, 1976, 1981). If the SFM stimulus is converted into an AM-like response at the auditory periphery, then one may expect a similar dominance of modulation compared to carrier delay. It should be noted however that

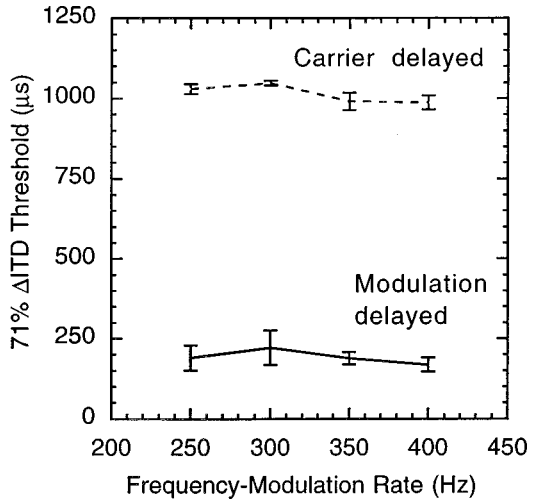

FIG. 4. The dashed line shows interaural-delay difference thresholds measured when the modulation waveforms of an SFM tone remained in phase at the two ears, and the 3-kHz carrier was interaurally phase shifted by $2\pi f_c$ITD. The solid line shows thresholds for the SFM tone when the modulation waveform was interaurally delayed by $2\pi f_m$ITD and the carrier phase was zero at the two ears. The data are averaged for three observers and the error bars are one standard error.

while phase shifting the carrier of an SAM tone produces a constant delay of the carrier, this is not true for SFM tones. A constant carrier phase shift of the SFM tone introduces a dynamic delay in the fine structure. For example, an interaural phase inversion would produce a smaller instantaneous interaural delay in the fine structure when the instantaneous frequency of the waveform is equal to the carrier frequency, compared to when it is at its minimum value $f_c-\Delta f$. While our results below show that these dynamic carrier effects are not important at high frequencies, they should be accounted for when low-frequency carriers are used, especially for large β. All subjects, procedures and stimuli for this experiment were the same as part A with the exception that for the carrier-delayed case the phase of the carrier to one ear was additionally delayed by $\phi_c=2\pi f_c$ITD while $\phi_m=0$ [see Eq. (6b)]. In the modulation-delayed case the modulation waveform was delayed by $\phi_m=2\pi f_m$ITD while $\phi_c=0$. Only one carrier frequency, 3 kHz, and four modulation rates of 250, 300, 350, and 400 Hz for which low thresholds had previously been observed were used ($\beta=1$). Averaged results for the three observers are shown in Fig. 4. The dashed line represents the carrier-delayed condition and the solid line shows the modulation-delayed condition. Error bars are one standard error of the mean. There is no significant carrier-phase effect for the range of parameters examined. Thresholds for the modulation-delayed case (solid line) are comparable to the whole-waveform delayed thresholds shown in Fig. 3.

IV. EXPERIMENT II

A. Comparison of SFM to SAM thresholds

To what extent is the AM induced by bandpass filtering of an SFM tone comparable to that produced by an SAM tone, and to what extent can performance for the SFM stimulus be predicted from data on SAM stimuli? In this section,

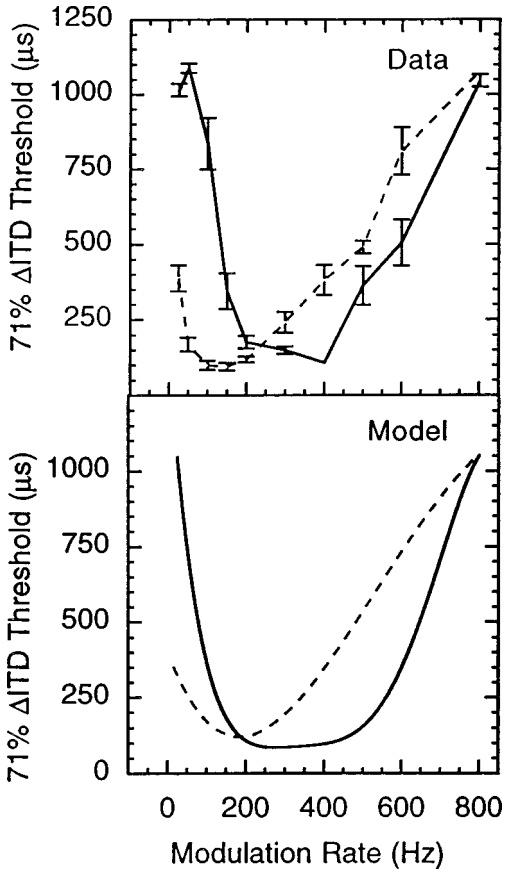

FIG. 5. ΔITD thresholds for SAM tones (dashed line) compared to SFM tones (solid line). The carrier frequency was 3 kHz. Data are averaged across three subjects. Error bars are one standard error of the mean. Lower panel shows model predictions.

ΔITD thresholds are measured for a 3-kHz carrier, either frequency or amplitude modulated at rates from 25 to 800 Hz. This is a slightly larger range of rates than those used in experiment I. The same controls and procedures as before were used in this experiment, except that the amplitude of the SAM tone was adjusted by $m^2/2$ (Viemeister, 1979) to equate the stimulus power with that of the SFM tone for which β was equal to one. Three new subjects were used in this experiment (JA,AW,KS).

1. Results

Top panel of Fig. 5 shows the results averaged for three observers. The bottom panel shows model predictions and will be discussed shortly. The dashed line shows thresholds measured for the SAM tone and the solid line, for the SFM tone. Error bars are one standard error. There is good agreement between the SFM data from experiment I (at 3 kHz) and the current data, in spite of using different observers. It is clear that the SFM data are shifted to the right by about 200 Hz compared to the SAM data. A second observation is that the same observers produced somewhat similar minimum thresholds for SFM and SAM tones, although the minimums occur at different rates (there is a slight edge for SAM thresholds). Previously published data on SAM tones has shown some variability in the minimum of this function, but generally, best sensitivity is observed anywhere from rates of

125–300 Hz (Henning, 1974a, Figs. 7, 8; Nuetzel and Hafter, 1981, Fig. 1). The data reported here show a minimum for the SAM function at a rate of 100–150 Hz for all observers, and a minimum of the SFM function that is centered around 200–400 Hz (Figs. 3, 5). There are statistically significant differences between SAM and SFM functions ($F_{1,40}=21.52$, $p<0.05$), rate effects ($F_{9,40}=23.42$, $p<0.05$), and interaction between condition (FM vs AM) and rate ($F_{9,40}=13.33$, $p<0.05$).

The bottom panel shows model predictions. It is critical to note that the model parameters were determined from the SAM-tone data of experiment II. The following procedure was used to determine these parameters. The noise parameter ξ was adjusted to force the model performance to match that of the single SAM-tone datum at a modulation rate of 150 Hz (average value in Fig. 5). The low-pass FIR filter was then adjusted to best fit the slope of the increasing thresholds as the modulation rate is increased (dashed line in top panel of Fig. 5 from 200 to 800 Hz). No parameter adjustments were made for the low modulation rates below 150 Hz. The model was then presented with the SAM stimuli at all rates (low and high) and with the SFM stimuli. The final output of the model was smoothed with a polynomial function. The following are the important features of the model prediction for experiment II.

(1) An increase in ΔITD threshold with SAM tones is observed as the modulation rate is decreased below 150 Hz. This feature is also observed in the model and is a result of its stochastic nature and the reduction in the slope of the envelopes at the filter outputs as modulation rate is decreased (approaching a dc function as modulation rate approaches zero). Because the cross-correlation function also becomes less peaked, for a constant variance noise ξ, the position estimate becomes less reliable.

(2) At low rates of modulation, thresholds for SFM tones also increase for the same reason, however, thresholds increase much faster than those for SAM tones. This is also observed in the model behavior and is due to the following. For a constant index of frequency modulation ($\beta=\Delta f/f_m=1$) as the modulation rate (f_m) is decreased, the peak frequency deviation must also decrease. Consequently, the instantaneous frequency of the stimulus sweeps through a progressively smaller region of an auditory filter, hence an output which will have a lesser depth of modulation. This is not true of an SAM tone whose amplitude is always fully modulated when $m=1$. Thus thresholds for an SFM tone increase not only because of a decrease in envelope slope (as for SAM tones) but additionally because of a reduction in peak-frequency-deviation and therefore the depth of modulation.

(3) As the modulation rate is increased above 150 Hz, thresholds increase for both SAM and SFM conditions, but they increase more quickly for the SAM stimuli (i.e., for a given modulation rate above 200 Hz, SFM stimuli produce lower thresholds). The model also shows this feature. Here, the reason is similar to that described in the previous point except in the opposite direction. As the rate increases, so does the peak-frequency-deviation. The output of a filter presented with a moderately high rate of frequency modulation (200–500 Hz) is highly peaked since the instantaneous frequency of the stimulus sweeps rapidly through the filter's passband. The highly peaked nature of the outputs of such filters provides a cross-correlation pattern that is also highly peaked. Therefore, the position estimates have a low variance in the SFM case.

(4) The predictions for SFM conditions show a wider region of ''good'' performance at both high and low rates of modulation. This difference is small, but consistent. The width of this region is primarily affected by the slope of the central lowpass filter and the bandwidth of the filterbank model.

(5) Thresholds for both SAM and SFM stimuli converge at the highest rate of modulation (800 Hz), both in the data and in the model predictions. This is not surprising in either case. In the experiments, the adaptive procedure had a ceiling ΔITD of 1300 μs (650 for each interval of the 2IFC task). The procedure produces a maximum threshold estimate of about 1050 μs, even for an undetectable signal, because correct responses are recorded by chance on half the trials (i.e., the probability of two successive chance correct responses is 0.25). For this same reason, we limited the model performance to a high threshold of 1050 μs. Both in the data and predictions, a negative curvature from this feature is observed as the modulation rate approaches 800 Hz.

B. Thresholds as β is varied

Interaural-delay thresholds for SAM tones improve with increasing depth of modulation (Nuetzel and Hafter, 1981). For an SFM tone, as the depth of frequency modulation increases, its instantaneous frequency sweeps through increasingly wider frequency regions and its spectrum widens. As the tone sweeps through wider frequency regions, the AM induced from bandpass filtering may also increase in depth, but not necessarily in all conditions. Because the SFM tone has an infinite number of sidebands and a constant power, increasing the depth of frequency modulation may in fact distribute the spectral energy such that components falling within a filter's passband would produce smaller envelope depths. The widening of the spectrum may also be problematic if leakage through filters with low resonant frequencies is suspected. In the current experiment, the carrier frequency was 3 kHz and three modulation rates of 50, 100, and 300 Hz were used. For the 300-Hz rate, β was restricted to less than 1.5. For the lowest rate of 50 Hz, a maximum value of $\beta=8$ was used (a peak-frequency-deviation of 400 Hz). Note that all signals were additionally highpass filtered at 1.5 kHz and low-pass noise with the same cutoff frequency was continuously presented at $N_0=32$ dB.

Top panel of Fig. 6 shows the averaged data from this experiment for three observers. The error bars are one standard error of the mean. The parameter is modulation rate. Modulation depth is expressed as $20\log(\beta)$ to be consistent with the expression of amplitude modulation depth $20\log(m)$ in decibels. As before, there is an upper bound of $\approx$1050 μs on performance measurement due to the ceiling imposed on the adaptive procedure, thus the negative curvature for the 50-Hz rate. Clearly, a significant monotonic effect of β is observed. It is noteworthy that thresholds at a modulation

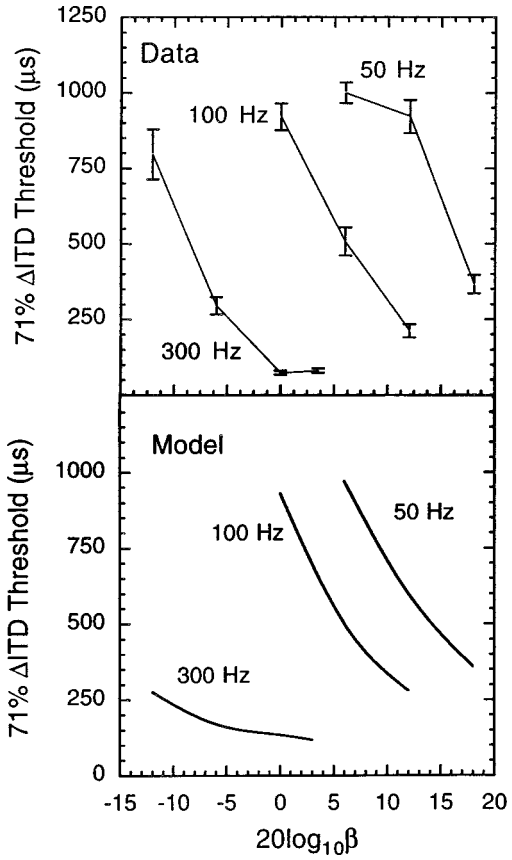

FIG. 6. Top panel shows the effects of changing the frequency-modulation depth on interaural-delay difference thresholds. The stimulus was an SFM tone with a 3-kHz carrier frequency and the parameter is modulation rate. There is an upper bound of $\approx 1050\ \mu$s on performance measurement due to the ceiling imposed on the adaptive procedure. Data are averaged across three observers. Error bars are one standard error of the mean. Lower panel shows model predictions.

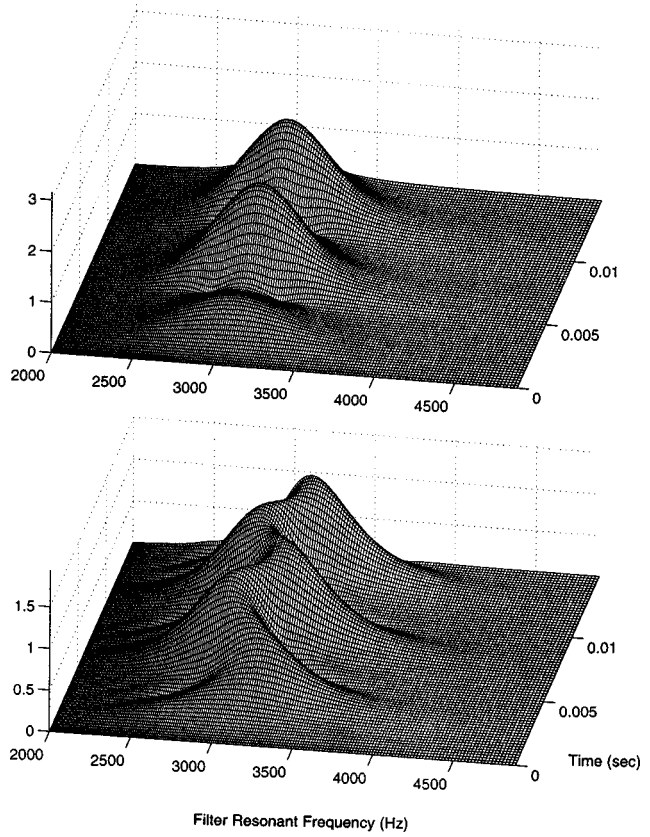

FIG. 7. Output of a Gammatone filterbank in response to an SAM tone (top panel) and an SFM tone (bottom panel). Both stimuli had a carrier frequency of 3 kHz, a modulation rate of 200 Hz, and a rise/fall time of 5 ms.

rate of 50 Hz, where virtually no sensitivity was previously observed, have noticeably improved as β was increased to 8. This indicates that the limiting factor is not rate *per se* but the depth of the induced AM.

The lower panel shows model predictions. Predicted thresholds improve with increasing β because for a constant rate of modulation the peak-frequency-deviation (Δf) increases, producing envelopes at the filter outputs that have a higher peak factor. For $f_m = 300$ Hz the model substantially underestimates the rate of change in threshold as β varies. The reason for this discrepancy is not clear. It should be noted that for these predictions, the noise parameter ξ was adjusted to best match the middle datum at a rate of 100 Hz (0-dB depth). If however, ξ is adjusted individually at each rate to best fit the datum at the middle value of β for that rate, considerably better fits are obtained even at 300 Hz (not shown).[4]

V. EXPERIMENT III

A. Binaural interaction between SFM and SAM tones

It is natural to pose the question that if an FM-to-AM conversion occurs in the auditory periphery, then would an SFM tone presented to one ear, interact with an SAM tone of identical parameters presented to the other ear? Consider a comparison of the outputs of a filterbank model in response to SFM- and SAM-tone stimulation (Fig. 7). The filterbank consisted of 300 Gammatone filters whose resonant frequencies were spaced logarithimically from 2 to 5 kHz. The top panel shows this response to an SAM tone and the bottom panel to an SFM tone, both modulated at 200 Hz and centered at 3 kHz. The SAM tone produces a modulation pattern whose peak amplitude is at the filter centered on the carrier. The rate of modulation is constant and independent of the filter placement. An SFM tone on the other hand produces a somewhat more complicated pattern. Both the depth and rate of modulation vary across filters. The output of the filter centered on the carrier produces a small AM response whose rate is twice that of the stimulus modulation rate. For the filters centered slightly away from the stimulus carrier frequency, the response is an envelope with asymmetrically occurring double-peaks during each cycle of modulation. There is, consequently, substantial spectral energy at the fundamental frequency of modulation at the outputs of even these off-frequency filters (see also Fig. 10). For filters centered further than the first sideband, the filter response is at the modulation rate, however, the response peaks occur at different times for filters centered above and below the carrier frequency. How do the different responses for different filters combine at a later processing stage? One may address some of these questions by examining the interactions that occur when an SFM tone is presented to one ear and an SAM tone to the other. The first part of the data reported here was

presented in summary form in an earlier paper (Saberi and Hafter, 1995). Here individual data are presented in addition to newly collected data and model predictions.

B. Procedure

The left- and right-ear stimuli were SAM and SFM tones, respectively,

$$X_L(t) = A'_C \sin 2\pi f_c t[1 + m \sin 2\pi f_m t], \quad (6a)$$

$$X_R(t) = A_C \sin[2\pi f_c t + \phi_c + \beta \sin(2\pi f_m t + \phi_m)]. \quad (6b)$$

Both modulator waveforms were defined in sine phase, were fully modulated $m = \beta = 1$, had equal modulation rates (250 Hz) and carrier frequencies (3 kHz). The SAM-tone modulation waveform remained in sine phase throughout the experiment and an interaural delay was introduced by shifting the phase of the SFM-tone modulation. Both waveforms had 20-ms cosine-squared ramps that were not interaurally delayed. The task was 2IFC with feedback. In one interval $\phi_m = 0$, and in the other interval $\phi_m = 2\pi f_m$ ITD. As before, observers were instructed to indicate if the auditory image was perceived left–right or right–left. Most observers reported that for the homophasic case, the images were not symmetric about the median plane, but shifted toward the right ear which carried the SAM tone. Because this was the referent condition, the level of the SAM tone was adjusted (A'_c) so that when the modulators were homophasic at the two ears, the intracranial image was centered. All other procedures and apparatus were the same as those described in experiment IA, except that a blocked psychophysical design with fixed stimulus parameters was used instead of the adaptive procedure and the measure of performance was proportion of correct responses in runs of 100 trials, with one run per subject per interaural delay.

C. Results

Subjects reported that a single intracranial image was perceived whose position varied as the interaural modulation phase was varied. Figure 8 shows proportion of correct responses for three observers (filled symbol) as a function of interaural phase disparity. The open symbols are the averaged data and the solid line is model predictions and will be discussed later. When the modulation of the SFM tone was antiphasic relative to the SAM phase (π radians or a 2-ms ITD) discrimination performance was at its maximum. As the phase difference approached a full cycle, performance dropped to chance. One observer reported that for the conditions where $\phi_m > \pi$, the images reversed position and she had to reverse her response pattern (i.e., the correct feedback light became correlated with a reversal of the order of the images). For this case, all observers were instructed to adopt a response strategy to maximize the number of correct responses. Such a reversal of image positions is consistent with the cyclic nature of the modulation waveform.

Figure 9 shows results of a second experiment of this type. As before, an SAM tone with a carrier frequency of 3 kHz and a modulation rate of 250 Hz was presented to the right ear. The left ear, however, received an SFM tone whose

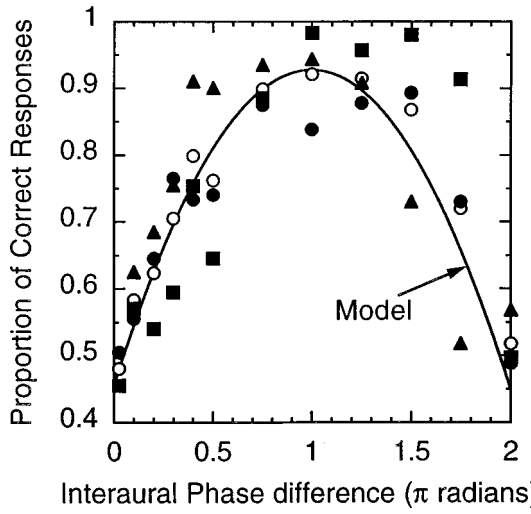

FIG. 8. Results of experiment III. An SFM tone was presented to the right ear and an SAM tone to the left ear. Proportion of correct responses are shown for three subjects (filled symbols). The task was to discriminate homophasic modulation from a delayed-modulation condition (gating envelopes were not delayed). The open symbols are the average for the three subjects and the line shows model prediction.

carrier frequency and modulation rate were parameters of the study. On each run of 100 trials, a single modulation rate and a single carrier frequency were selected for the SFM tone and percent-correct detectability of a 2-ms delay imposed on the SFM-tone modulator relative to the SAM-tone modulator were examined. Two features of these data are important. First, performance is above chance only when the modulation rate of the SFM tone is equal to that of the SAM tone. Other modulation rates do not binaurally interact with the 250-Hz SAM tone.

It is instructive to note a lack of interaction for an SFM-tone rate of 125 Hz with an SAM tone of 250 Hz. An SFM tone with a rate of 125 Hz produces an envelope with a rate of 250 Hz at the output of a filter centered on the carrier. However, this envelope, as observed from Figs. 7 and 10, has a very small depth and its effects are apparently easily overwhelmed by responses from off-frequency filters. Further support for off-frequency listening is provided by Fig. 8. If only the information from the filter centered on the stimulus carrier was used, a bimodal function may be expected with peaks at 0.5 and 1.5 rads.

A second feature of Fig. 9 is that binaural interaction is maintained for a wide range of interaural carrier-frequency disparities, as large as 1 kHz. This result is consistent with that reported for high-frequency SAM tones. Nuetzel and Hafter (1976, 1981) and Henning (1974a) have shown that some observers maintain interaural sensitivity to an SAM tone with interaural carrier-frequency disparity of 0.3–1 kHz. McFadden and Pasanan (1975) have also shown binaural beats with two-tone complexes for relatively large interaural-frequency differences between the complex to the left and right ears (≈ 1 kHz). Naturally, the skirts of cochlear filters extend beyond one critical band. If we consider a Gammatone filter as an approximation, the level of a 3-kHz carrier component of an SAM tone is 30 dB attenuated at the output of a filter centered at 4 kHz, and it is about

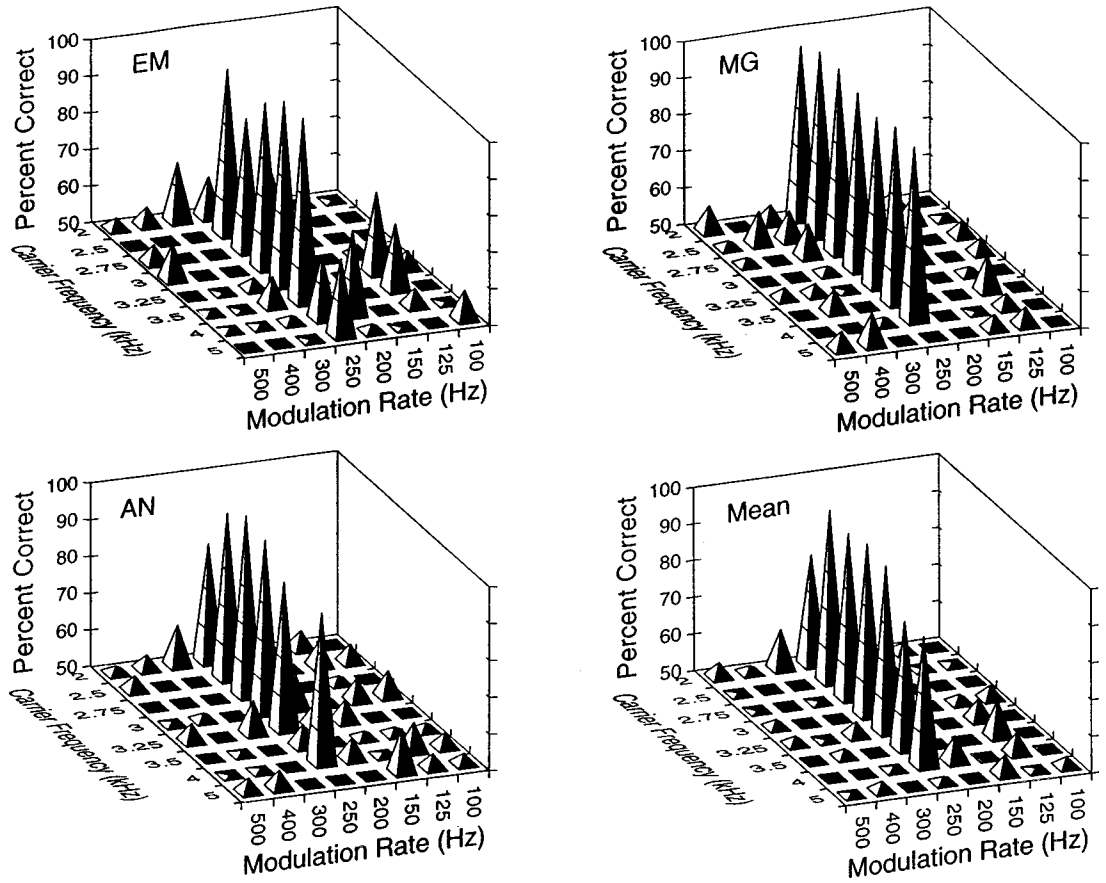

FIG. 9. Interaural-delay sensitivity for unequal carriers and modulation rates. The left ear received an SAM tone with a carrier of 3 kHz and a modulation rate of 250 Hz. The right ear received an SFM tone, the carrier and modulation rate of which were parameters (x and y coordinates). Data were collected for all 64 combinations of carrier versus rate. Each panel shows data from one observer. The lower right panel shows the average data for the three observers.

50 dB attenuated at the output of a filter centered at 2 kHz. These are only moderate attenuations and apparently insufficient to prevent binaural interactions.

Data were also collected at other modulation rates. Some preliminary listening showed that different observers showed best performance at different modulation rates, but generally rates between 100 and 250 Hz were optimal. For one observer, performance was measured at a modulation rate of 100 Hz as β was varied. The number of correct responses out of 100 trials per run were 100 for $\beta=1.0$, 92 for $\beta=0.2$, 88 for $\beta=0.1$, and 72 for $\beta=0.05$. Even at a modulation depth of -25 dB ($\beta=0.05$) where the peak-frequency-deviation is only ± 5 Hz this observer showed above chance performance. The frequency deviation in this case is too small to produce a noticeable modulation depth at the filter centered on the carrier (≈ 0.1 dB if calculated from a Gammatone filter). Listening must therefore occur at more remote filters. We show further data of this type from more observers in the discussion section when considering the off-frequency process underlying this interaction.

For simplicity, the data of experiment III on binaural interaction between an SFM and SAM tone are analyzed by a statistical approach since the data were collected at a fixed modulation rate (the stochastic aspects of the model do not significantly affect this analysis). Figure 11 shows a surface plot of the SFM–SAM cross-correlation function (after bandpass filtering) for the two extreme stimulus phase conditions, that is when the modulation waveforms of the two stimuli were either in-phase (left panels) or out-of-phase (right panels) relative to each other. The surface plots are a top-down view of the τ-f plane; the lighter regions represent the areas of greatest activity. The lower panels are the same as the upper panels except that a logistic frequency-weighting function was used to attenuate the activity above 3 kHz. The upper plots show nearly identical patterns that are mirror images along the frequency axis. It is easy to see that if one were to integrate across frequency, the in-phase and out-of-phase conditions would produce similar outputs and would therefore be the least discriminable conditions.[5] This is opposite to what was observed in the data. However, if observers were to listen off frequency either to auditory filters above or below the carrier (but not both), then these two phase conditions would be maximally discriminable as observed in the data. As the lower panels show, the inclusion of a frequency-weighting function allows discrimination between homophasic and antiphasic conditions because the peak activity is at negative delays for the homophasic conditions and at positive delays for the antiphasic conditions. To evaluate model predictions for this stimulus condition, the cross-correlation function was frequency-weighted prior to frequency integration as shown in Fig. 11. The position estimate ($\hat{p}$) was then calculated as the interaural delay corresponding to the peak cross correlation. Index of detectability ($d'=\hat{p}/\sigma$) was then determined from the position esti-

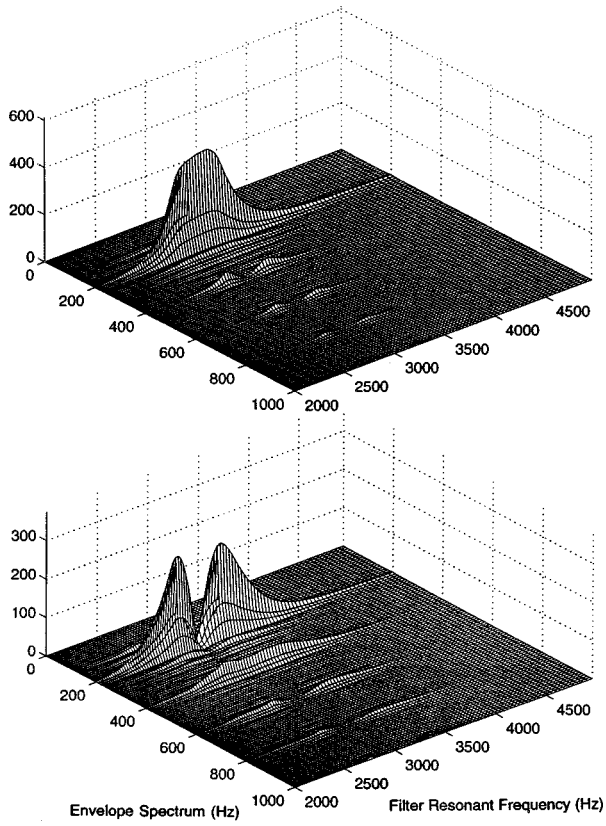

FIG. 10. Spectrum of the envelopes at the output of a Gammatone filterbank for an SAM tone (upper panel) and an SFM tone (lower panel). The stimulus was a 3-kHz carrier modulated at 200 Hz.

mate where σ is the single free parameter of the model. Predictions are plotted in Fig. 8 (solid line) together with the individual data (filled symbols) and averaged data (open symbols) of experiment III. Thus de-emphasizing binaural cross-correlation activity at the higher frequency regions captures the trend of the data.

To further test the validity of this analysis and the off-frequency explanation, an additional control experiment was run in which filtered noise was used to mask either upper, lower, or middle frequency regions of the stimuli. The stimulus conditions and procedures were the same as described for experiment III. The modulation rate and carrier frequency of both stimuli (SFM to one ear and SAM to other) were 250 Hz and 3 kHz, respectively. The task was to discriminate a homophasic from antiphasic condition. The three masking conditions included gated Gaussian noise with a passband of either 2.0–2.9 kHz, 2.8–3.2 kHz, or 3.1–4.0 kHz. No trial-by-trial feedback was provided.

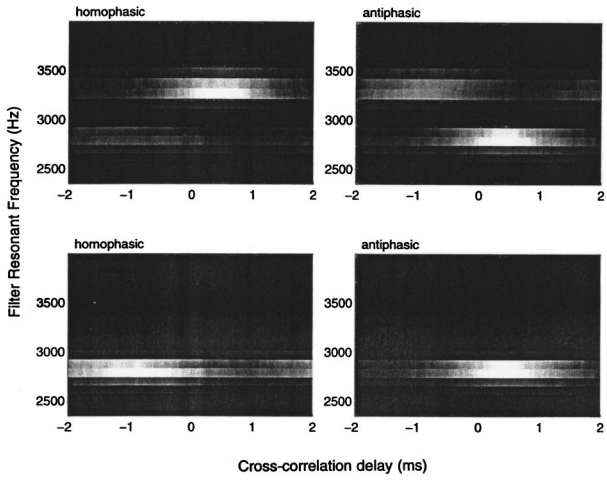

FIG. 11. Surface plots of interaural cross-correlation functions for four conditions (top-down view of the τ-f plane). The lighter regions show the areas of greatest activity. Left panels show the case where the SFM and SAM modulation waveforms were homophasic, and the right panels show antiphasic conditions. The upper panels are unweighted and the lower panels are frequency weighted.

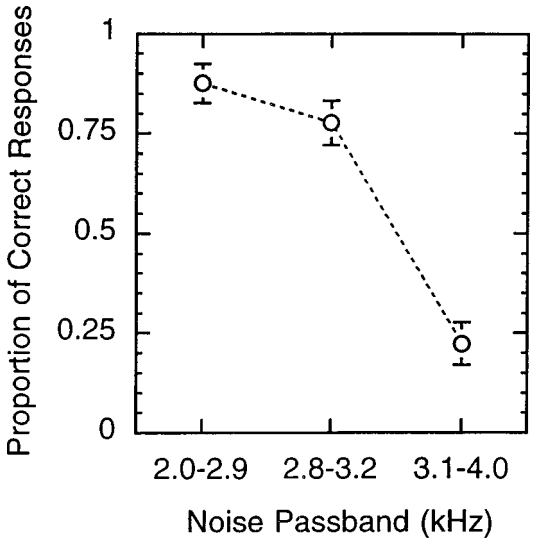

FIG. 12. Proportion of correct responses of detecting a homophasic from antiphasic modulation waveform at the two ears, as a function of masking either lower, upper, or middle frequency regions of the stimuli. Chance performance is 0.5. Left ear received an SAM tone and right ear an SFM tone, both with carriers of 3 kHz and modulation rates of 250 Hz. The subject's task was to respond right if the image orders were left–right and to respond left if the orders were right–left. Correct response was arbitrarily assigned to the homophasic–antiphasic, and incorrect to antiphasic–homophasic order of stimulus presentation in the 2IFC task. Data are averaged for three observers and error bars are one standard error.

Averaged data for three observers are shown in Fig. 12. Correct responses were arbitrarily assigned to one of the two orders of presentation (i.e., homophasic-antiphasic=correct; antiphasic-homophasic=incorrect), although as before, no trial-by-trial feedback was provided to the subjects. A few features of these data are worth emphasizing. First, a reversal of performance is observed when opposite frequency regions of the stimulus are masked, consistent with off-frequency listening and predicted from the cross-correlation analysis discussed above (note that chance performance is 0.5). Second, when the frequency region near the carrier is masked, observers seem to focus on the upper frequency region (i.e., similar performance for 2.0–2.9 and 2.8–3.2 kHz conditions). Third, unmasked performance (Fig. 8) is consistant with the low-frequency masker condition, suggesting that in the unmasked case, observers also attend to the frequency region above the carrier frequency, even though information below the carrier may also be available.[6]

VI. DISCUSSION

We would like to address three issues in this section: (1) Why are threshold-by-rate functions different for SAM and

SFM tones; (2) What are the envelope cues that promote off-frequency listening to SFM tones; and (3) How does the phase response of auditory filters alter the envelope of the AM-like response. The data and predictions both show that interaural-delay thresholds follow U-shaped functions for both SAM and SFM tones as modulation rate is varied (Fig. 5). Why do the minima of these functions occur at different modulation rates? First, consider the stimulus properties that limit interaural-delay sensitivity for SAM tones. At low modulation rates, eventhough the carrier is fully modulated, performance is limited by the inability of the binaural system to track envelope synchrony for tones whose envelopes are changing very slowly (i.e., a dc effect). This is of course not a characteristic of high-frequency fibers *per se* but of envelope slope since highpass filtered clicks are easily lateralized with a precision of better than 100 μs (Hafter *et al.*, 1983, 1988). Performance at low rates may also be affected by a reduction in the number of samples or envelope peaks that the binaural system receives for a fixed stimulus duration (McFadden and Moffitt, 1977). While we do not exclude this factor, it should be noted that the experiment on frequency-modulation depth (Fig. 6) shows that thresholds improve with increasing β, which in turn increases the effective slope of the envelope at a filter's output without changing the number of envelope-peak samples. For the higher modulation rates, SAM thresholds are affected both by cochlear filtering and a possible central low-pass filter (Viemeister, 1979). As the modulation rate is increased, the SAM sidebands are increasingly removed from the carrier and are thereby attenuated by the skirts of the filter centered on the carrier, resulting in a lower envelope depth and, thus, poorer performance (Nuetzel and Hafter, 1981).

What factors limit performance at high and low modulation rates for SFM tones? If the index of modulation is kept constant as the modulation rate is decreased, there is by definition a linear decline in peak-frequency-deviation, Δf. The smaller Δf yields an AM response with a smaller envelope depth. Thus for an SFM tone, not only is performance at low rates degraded by reduced envelope slope (as was the case for SAM tones), but there is an additional reduction of envelope depth due to smaller Δf. Therefore, thresholds degrade more rapidly for SFM tones compared to SAM tones as the modulation rate is reduced. Note that even if Δf for an SFM tone is kept constant as the rate is lowered, there is no reason to believe that the lower end of the rate-by-threshold functions would be identical for SAM and SFM stimuli since the envelope shapes would not be identical (Edwards and Viemeister, 1996). At higher modulation rates of about 300–400 Hz, the SFM tone produces lower thresholds than the SAM tone. One reason for this is an increase in the peak-frequency-deviation with increasing rate and a corresponding increase in depth of the AM-like envelope. At even higher rates (700 Hz) neither stimulus can be lateralized, either because the components are not resolved or because of limitations imposed by a central low-pass filter.

What are the cues that promote off-frequency listening? The data of experiment III suggest that observers do not heavily rely on ITDs from filters on or near the carrier frequency of an SFM tone. If an AM-like cue is the primary information from an SFM tone, then the rate associated with on-frequency listening would be twice the stimulus modulation rate and its depth would be considerably smaller than the response from off-frequency filters. Off-frequency filters produce an envelope rate that either has single peaks at the modulation rate or multi-modal peaks with energy at the fundamental frequency of modulation. The reliance on off-frequency listening is not at a major cost. One can estimate the available cues at different rates of frequency modulation at the outputs of a filterbank model from the Fourier spectrum of their envelopes. Figure 10 shows this output for both an SFM and SAM tone with a 3-kHz carrier and a 200-Hz modulation rate. Clearly, the predominant information is at the fundamental periodicity for both stimuli and the loss in information from neglecting the on-frequency filter is very small for the SFM tone since there is very little envelope-spectral-energy at the output of that filter to begin with. Consistent with these observations, others have provided evidence from monaurally presented stimuli that observers rely on off-frequency filters where the change in excitation pattern in response to frequency modulation is maximal (Moore and Glasberg, 1986; Moore and Sek, 1992; Hartmann and Hnath, 1982).

Finally, a concern throughout this study was how the phase response of auditory filters affect the processing of the FM stimulus. Equation (1) shows that the odd harmonics below the carrier of the SFM tone are inverted in phase relative to the remaining components. The phase characteristic of an auditory filter, of course, would affect the phase relations of this harmonic complex and thereby alter the time envelope at the output of that filter. Unless the filter has a linear phase (i.e., a delay) the envelope of any filtered waveform that contains more than two components within the filter passband will be affected. What then are the phase-by-frequency functions of auditory filters; how do they compare with the phase response of Gammatone filters; and, are changes in envelope from phase effects significant compared to external (stimulus) envelope modulation or that caused by a filter's magnitude response?

Kohlrausch and Sander (1995) suggest that the phase of an auditory filter is consistant with the phase pattern of a negative Schroeder-phase signal. A Schroeder-phase signal is a harmonic complex that has a quadratic phase-by-frequency function

$$\phi_n = \phi_1 - \pi n^2/N, \tag{7}$$

where n is harmonic number, N is the total number of components in the complex, and the sign in front of π defines the sign of the Schroeder phase (Schroeder, 1970). The Gammatone filter used in our analysis has an antisymmetric phase that is increasing in slope below the point of inflection (at the filter's resonant frequency) and decreasing above it. The curvature of this filter's phase (its second derivative) changes signs at the resonant frequency, whereas the curvature of a Schroeder-phase signal is constant. Kohlrausch and Sander suggest that a Gammatone antisymmetric phase would result in similar masking period patterns for negative- and positive-Schroeder-phase maskers, which is not what they have observed in their data (i.e., they suggest that the

TABLE I. Effects of filter phase on modulation depth (dB).

Filter CF (kHz)	Phase: Antisymmetric	+ Schroeder	− Schroeder
2.75	−1.57	−2.22	−2.21
3.00	−19.5	−18.5	−18.4
3.25	−3.3	−4.3	−4.3

Gammatone phase is not the appropriate model for auditory-filter phases). It is not however clear to what extent the filter's amplitude response affects the predicted differences. The models used by Kohlrausch and Sander for comparison were the Gammatone and Strube's (1985, 1986) basilar-membrane (BM) model. The BM model has a phase function with a negative curvature that is constant throughout most of the filter's passband, but has an amplitude response that simulates only the passive properties of the basilar membrane and therefore shows poor frequency selectivity compared to psychophysical and physiological data. The Gammatone on the other hand shows frequency selectivity comparable to psychophysical data, but has the antisymmetric phase response.

Positive- and negative-Schroeder-phase harmonic complexes such as those used by Kohlrausch and Sander may be phase shifted by an allpass filter with an appropriate negative curvature such that one signal would have a high peak factor and the other signal a low peak factor. If these two signals are then filtered with the amplitude response of a Gammatone filter, one observes little difference in the envelopes of the resultant waveforms at the output of the filter (i.e., the Gammatone amplitude response is substantially more significant than its phase response in determining the modulation envelope). Even if the Gammatone filter had a negative quadratic phase, similar predictions would be observed for the positive- and negative-Schroeder-phase maskers.

To observe how these phase-by-frequency functions affect the envelope of an SFM tone, we made comparisons under three conditions: (1) Gammatone antisymmetric phase; (2) negative-Schroeder-phase; (3) positive-Schroeder-phase. All stimuli were defined by summation of 13 primary harmonics of the SFM tone, and then filtered with an allpass filter with the assigned phase condition by phase shifting each component. The stimulus was then filtered with the amplitude response of a Gammatone filter by attenuating each component before summation. Thus, the filtering properties of a hypothetical Gammatone filter with a phase response defined by one of the three conditions was modeled. An SFM tone with a modulation rate of 250 Hz and a carrier of 3 kHz was the stimulus. The filter had a center frequency of 2.75, 3.0, or 3.25 kHz. The Hilbert envelopes of the filtered signals were then used to calculate an amplitude modulation depth in units of $20 \log_{10}[(\max-\min)/(\max+\min)]$.

Results are shown in Table I. The negative- and positive-Schroeder-phase filters produced identical modulation depth, but with slightly asynchronous envelope minima. The difference between the antisymmetric phase and Schroeder phases are generally small, approximately 0.6 dB for filters centered at 2.75 kHz, 1 dB at 3 and 3.25 kHz. The smallest envelope modulation, as expected, occurred at the filter centered on the carrier of the stimulus. Why are the results so similar for the various phase conditions? The primary components of an SFM tone are the carrier, the first and perhaps the second sidebands; further sidebands are not likely to contribute significantly to the envelope of the filtered waveform. As shown in Fig. 1, the first and second sidebands are approximately 5 and 16 dB lower in amplitude than the carrier. For a filter centered on the carrier, the first and second sidebands are further attenuated by 6 and 17 dB, respectively (assuming a Gammatone filter). The first and second sidebands for the modulation rate of 250 Hz are contained within the frequency region of 2.5–3.5 kHz. For components in this region, the filter produces a phase shift that is well modeled by a linear function of frequency for all three phase conditions ($r^2>0.999$). A linear phase shift is of course only a waveform delay, leaving its envelope unaffected; this nearly linear phase also explains the shift in the envelope minima when using filters with negative versus positive Schroeder phases. If we include the effects of the second through fourth sidebands (2.0–4.0 kHz), the deviation from linearity increases, but not substantially (Gammatone: $r^2=0.96$; Schroeder: $r^2=0.98$). For an off-frequency filter centered at 2.75 kHz, the Gammatone-phase curvature becomes more pronounced and the fit to linearity is reduced ($r^2=0.94$ for the 2- to 4-kHz region) while it remains the same for the Schroeder-phase filters ($r^2=0.98$). Although it is difficult to generalize these results (since both the auditory filter phase and amplitude functions are level dependent: Allen, 1983; Ruggero *et al.*, 1992) it seems that the magnitude response of the Gammatone filter and not its phase response is the primary determinant of envelope depth for a filtered SFM tone, at least for the stimulus conditions examined here.

VII. SUMMARY

(1) The binaural system shows optimum interaural-delay sensitivity when SFM tones are modulated at rates of 200–400 Hz, which is somewhat higher than those rates that are optimum for SAM tones (100–200 Hz). Lowest thresholds of about 100–200 μs for SFM tones at $\beta=1$ are not as good as the 80–100 μs lowest thresholds observed for SAM tones.

(2) An SFM tone presented to one ear interacts interaurally with an SAM tone presented to the other ear, but only for equivalent modulation rates. Interaction is maintained, however, for interaural carrier-frequency disparities of up to 1 kHz. Strongest interactions occur for modulation rates between 100 and 250 Hz. Using bandpass masking noise it was shown that observers can use information from auditory filters either above or below the stimulus carrier frequency, although when conflicting information is present, they attend to the high-frequency regions.

(3) SAM-tone data were used to set the parameters of a stochastic interaural cross-correlation model whose predictions were then obtained for SFM tones of various rates and depths. Several differences between the SAM data and SFM data were well predicted by the model whose main features were an FM-to-AM conversion by bandpass filtering, and an

internal-noise limitation on estimating the peak of the cross-correlation function, and thereby, discrimination of lateral position.

Teich for many helpful comments. I also thank members of the Sensory Communication Group and the Research Laboratory of Electronics at MIT.

[1]A fractal renewal process (FRP) is generated from sample times between adjacent events that are independent and selected from the same fractal probability distribution (Lowen and Teich, 1995). The survival function for this renewal process decays as a power law

$$t_i \sim \text{power}\{c/t^D - c/\zeta^D\} \quad \text{for} \quad t < \zeta$$
$$0 \quad \text{otherwise},$$

where t_i are independent samples from a power-law density, D is the fractal dimension set at 0.75 in current implementation (Teich and Lowen, 1994), $\zeta = 0.4$ sec is a cutoff parameter for the waveform duration, and c is a normalization constant that ensures the area under the density integrates to unity. The FRP exhibits fractal behavior over time scales under the value of ζ. The process consists of a set of points on the time axis, but it may be recast as a real-valued Bernoulli process that alternates between two states, for example zero and unity. This alternating function would then start at zero, switch to unity at the time corresponding to the first event, switch back to zero at the second event and so on. A number of identical and independent alternating FRPs may be summed to yield a binomial process with the same fractal dimension as the single alternating FRP (Lowen and Teich, 1995) which may then be scaled by the instantaneous level of the stimulus to be used as the driving function for the Poisson point process

$$\text{Poisson}\{\mu_t = X(t)\Sigma\text{FRP}(t)\} \quad \text{over} \quad [\widetilde{N}(t, t+\delta) = 0,1,2,...],$$

where μ_t is the time-dependent parameter of the nonstationary process, $X(t)$ is the instantaneous pressure waveform, and $\widetilde{N}$ is the number of events within a time specified by the discrete waveform sampling period (δ). The result is a fractal-binomial-noise-driven Poisson point process, a stimulus-level dependent doubly stochastic point process (DSPP) that models fractal spike generation by nerve fibers.

[2]The centrality weighting function, $p(\tau)$ implemented here has the shape of a Butterworth bandpass filter. Previous models have used either a function with a Gaussian density shape (Shackleton *et al.*, 1992; Saberi, 1996), or a hybrid function (Stern *et al.*, 1988b; Saberi, 1995) consisting of a uniformly flat maximum between $\tau = \pm 150$ μs and an exponential rolloff for $|\tau| \geqslant \pm 150$ μs. The Butterworth function was selected because it has the advantage of a relatively flat region near $\tau = 0$, a steep rolloff, but without discontinuities in its derivative at the rolloff transition point (i.e., as does the exponential model at ± 150 μs).

[3]The headphone transfer function, measured with a probe-tube microphone (Etymotic ER-7) inside the ear canal was flat within 0.8 dB from 2750 to 3250 Hz (the frequency region where many of the experiments were focused on). In some experiments additional controls were used to ensure that envelope cues resulting from headphone properties were not significant. For example, in some control cases, inverse digital filtering of the SFM signal inside the observer's ear canal was used to flatten the headphone transfer function. It should also be noted that any cues from the filtering of the SFM tone by the headphone transfer function is not pure AM but rather an FM–AM cue (an envelope modulation of a carrier that is changing in frequency).

[4]It is also worth documenting that attempts were made to measure masking-level differences (MLD) for high-frequency SFM tones in continuous noise. However, as has also be reported for SAM tones, no MLDs were observed for SFM stimuli.

[5]Previous models have used one of two measures of frequency coding. One model uses the straightness (rms error) of peak trajectories (Stern *et al.*, 1988b; Trahiotis and Stern, 1994) and others use frequency integration (Stern and Colburn, 1978; Shackleton *et al.*, 1994; Saberi, 1996). Both measures produce identical results in the analysis described here.

[6]By using a similar masking method, Moore and Sek (1994) have shown that monaural discrimination of SFM from SAM tones, at least at low rates of modulation (10 Hz), is also based on listening to off-frequency filters and that the specific listening region (above or below the carrier) is not critical to the discrimination task.

Forward masked excitation patterns in multielectrode electrical stimulation

Monita Chatterjee[a] and Robert V. Shannon
Department of Auditory Implants and Perception, House Ear Institute, 2100 W. Third Street, Los Angeles, California 90057

(Received 20 June 1997; revised 21 October 1997; accepted 22 January 1998)

Across-channel interactions in multi-electrode cochlear implant patients may be critical to their performance in the natural auditory environment. One measure of channel interaction can be obtained using forward masking. The patterns of threshold shift were obtained as a function of the separation between masker and probe electrode pairs in four Nucleus-implanted patients with varying levels of speech recognition. In the three subjects with better speech recognition (N4, N7, and N13), the masking patterns showed the least parameter dependence. In the subject with the lowest speech scores (N3), the masking patterns showed the greatest dependence on masker level and on probe delay. Masking as a function of masker level also reflected these differences: N3's functions showed the greatest changes for different probe delays. Similar rates of recovery were observed in the three good performers (time constant approximately 70 ms). In contrast, subject N3's recovery function shows a more rapid recovery. These data indicate that channel interaction is individually variable and parameter dependent, both of which may play a role in the perception of dynamic stimuli in the natural auditory environment. © *1998 Acoustical Society of America.* [S0001-4966(98)01105-9]

INTRODUCTION

In acoustic hearing, masking patterns have been used as a measure of the spread of excitation across different neural populations, or frequency channels. Psychophysical masking patterns appear to reflect some basic characteristics of cochlear excitation patterns. Thus, as the level of the masker increases, the pattern of threshold shift broadens in extent across different frequencies. This spread of excitation occurs primarily toward the base (higher frequencies), with a sharp cutoff toward the apex (lower frequencies). In electric hearing, cochlear frequency analysis is replaced by an array of electrodes stimulating afferent auditory neurons at different locations along the cochlea. Stimulation of a particular electrode pair creates an electric potential distribution and a corresponding current path, resulting in stimulation of excitable tissue in the vicinity. As the current strength increases, the potential distribution changes, spreading to more distant locations along the cochlea. The space constant in scala tympani (where electrodes are typically inserted) is relatively long (2–3 mm; Black and Clark, 1980), resulting in considerable current spread. Apart from the current spread, the distribution of surviving neurons in damaged cochleae may be individually variable. Changes in the pattern of excitation created by a stimulus will therefore depend on two factors: (a) cochlear electro-anatomy and (b) the nerve survival pattern.

In multi-electrode cochlear implant patients, channel or electrode interaction is expected to play an important role in auditory perception. Such interaction can occur at various levels of processing. For instance, in the case of simultaneous electrical stimulation of two electrodes, the fields of the two stimuli will interact instantaneously. In nonsimultaneous stimulation, interaction can occur due to charge summation at the capacitive nerve membrane (time scale of the order of microseconds). Another kind of interaction can occur between the response of a neuron to two stimuli presented successively in time: Because the neuron takes time to recover from having responded to the first stimulus, its response to the second stimulus is depressed if it is not given a large enough interstimulus interval. This lowered responsivity is one form of masking. Psychophysical experiments reveal a similar increase in threshold (lowered sensitivity) of a signal (probe) following a prior stimulus, or masker. This effect is known as forward masking.

The amount of threshold shift due to a forward masker is presumed to be related to the degree to which the system responded to the masker, and the temporal course of recovery from the masker. If the masker and the probe activate the same ''channel'' (neural population) in the system, we expect to find a larger threshold shift due to the masker than if the masker and the probe activate different, or independent, channels (neural populations). Assuming this to be true, we can obtain a measure of channel interaction as a function of cochlear distance of the masker electrode pair from the probe electrode pair (Shannon, 1983; Tong and Clark, 1986; Lim *et al.*, 1989). Similar experiments have been performed in acoustic stimulation of normal-hearing listeners in order to estimate the spread of excitation across different frequency regions in the cochlea, in response to a tonal masker (Munson and Gardner, 1950; Zwislocki and Pirodda, 1952; Ehmer and Ehmer, 1969).

The perception of dynamic stimuli such as speech, with parameters changing continuously in time, may be heavily

TABLE I. Duration of implant use and sentence recognition scores for each subject.

Subject	Duration of implant use	Sentence recognition scores (CUNY, sound only)
N3	4 years	68%
N4	4 years	95%
N7	6 years	92%
N13	Single channel: 10 years Multichannel: 7 years	96%

influenced by the way in which the perceptual ''channels,'' and their interaction, change with stimulus parameters. The present study examines the dependence of the measured masking patterns on the masker amplitude and the time interval between the masker and the probe (recovery time).

We present forward masked patterns from four postlingually deafened adult users of the Nucleus-22 cochlear implant. Three of the subjects (N4, N7, and N13) performed well (scoring above 90% correct, sound only) on the CUNY sentence tests (Boothroyd, 1988) whereas the fourth (N3) scored below 70% correct on the same test. Forward masking was measured as a function of cochlear location of the electrode pair, masker level, masker-probe delay, and masker-probe separation.

I. METHODS

A. Subjects

Subjects were adult users of the Nucleus-22 device. All subjects were postlingually deafened. Their sentence recognition scores varied, but overall thresholds in quiet were similar. Sentence recognition scores and duration of implant use are shown in Table I for each subject. Calibration tables for stimulus amplitude for each subject's device were obtained from the manufacturer.

B. Experimental procedure

Stimuli were delivered to the subjects using a custom interface (Shannon *et al.*, 1990). Stimuli were software generated. Both masker and probe were trains of biphasic pulses, 200 μs/phase, presented at 1000 pulses/s. Masker and probe durations were 300 and 20 ms, respectively. The delay between masker offset and probe onset (probe delay) was changed by the experimenter as desired. All stimuli were presented in the bipolar-plus-one (BP+1) mode of stimulation: when electrode (10,12) is selected, current flows from electrode 10, the active electrode, to electrode 12, the indifferent electrode.

In order to measure masking patterns, the masker was presented to a fixed electrode pair, while the probe was presented to different electrode pairs. Threshold shift was plotted as a function of probe location. The masker electrode pair was located in the basal [electrode pair (5,7)], middle [electrode pair (10,12)] or apical [electrode pair (14,16)] regions of the cochlea. Subject N13 was stimulated only on electrode pairs numbered (8,10) and less (basal) in order to avoid uncomfortable/nonauditory sensations.

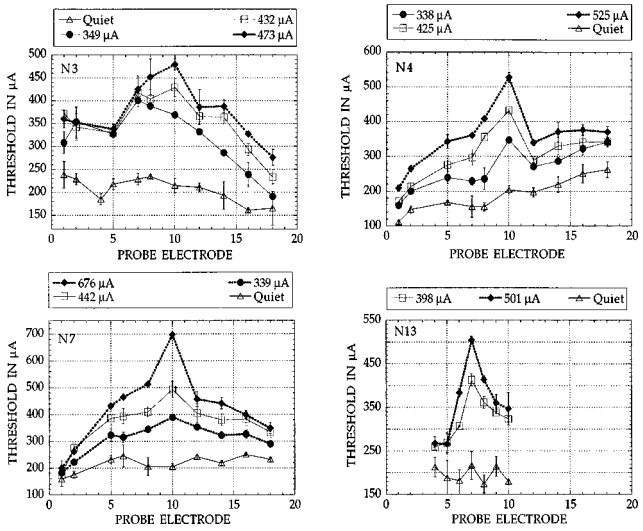

FIG. 1. Examples of masked threshold in μA as a function of probe electrode pair for the four subjects. For subjects N3, N4, and N7, the masker electrode pair was fixed at (10,12). For subject N13, the masker electrode pair was (7,9). The parameter is masker level. The triangles represent probe threshold in quiet for each electrode pair. Solid lines with squares represent the masker amplitude yielding comfortable loudness level for each subject.

Thresholds were measured using a two-interval forced-choice (2IFC), three-down, one-up paradigm. Using this method, the probe level converges at the 79.4% correct point (Levitt, 1971). The mean of the last 8 of a maximum of 13 reversals was calculated as the masked threshold. The step size was 2 dB for the first three reversals, and 0.5 dB for the remaining reversals. Stimuli were presented in two intervals. The intervals were accompanied by visual markers on the computer monitor. The subject heard the masker in both intervals. Randomly, the probe was present in only one of them. The subject indicated which interval contained the probe by pressing the appropriate mouse button. Feedback was provided visually. Threshold shift was measured as (masked threshold - quiet threshold). Generally, an average of two to four repetitions was taken for each data point.

II. RESULTS

A. Dependence on masker amplitude

The effects of masker amplitude (level) on forward masked excitation patterns were studied in individual subjects, for a probe delay of 1 ms. Figure 1 shows examples of raw data obtained in the four subjects. The standard deviations shown are typical. Quiet thresholds were subtracted from the masked thresholds to obtain patterns of threshold shift. Figure 2 shows such patterns obtained in subjects N3, N4, and N7 for maskers located on electrode pair (14,16) (apical location). It is evident that,other than a multiplicative shift, changes in masker amplitude (shown in the legend above each graph) create little or no change in the shape of the pattern for N4 and N7. However, in subject N3, a larger amplitude dependence is observed. This is due to a relatively larger increase in masked threshold around the masker electrode pair at the higher masker amplitude, which results in a more peaked or bandpass masking pattern than at the lower levels.

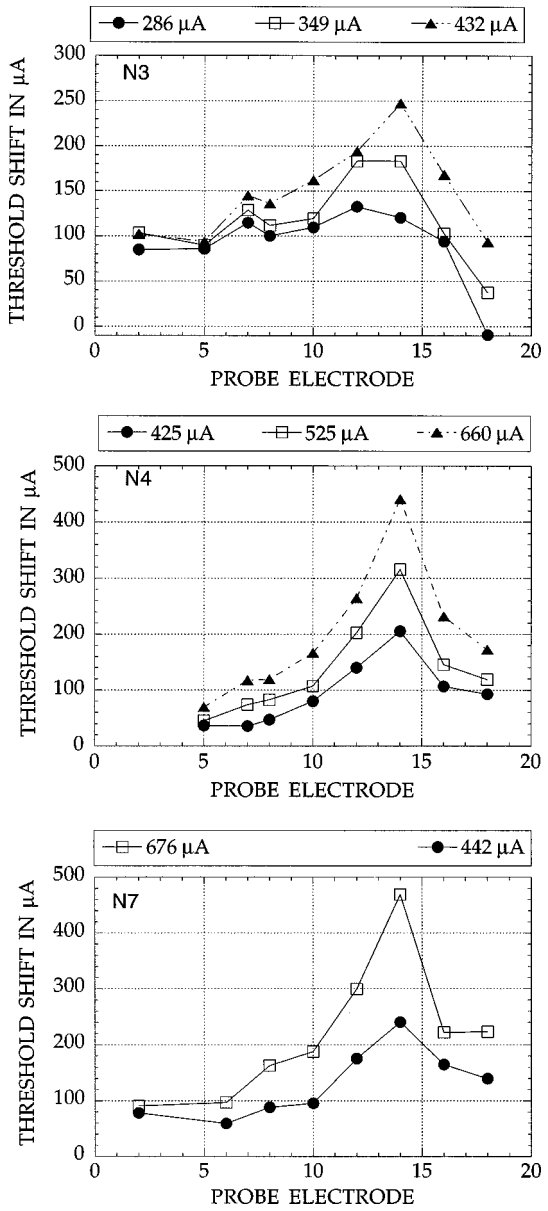

FIG. 2. Threshold shift in μA as a function of probe electrode pair, measured for different masker amplitudes in three subjects. The masker was on electrode pair (14,16) in each case. The open squares represent the masker amplitude yielding comfortable loudness for each subject (subjects N3, N4, and N7).

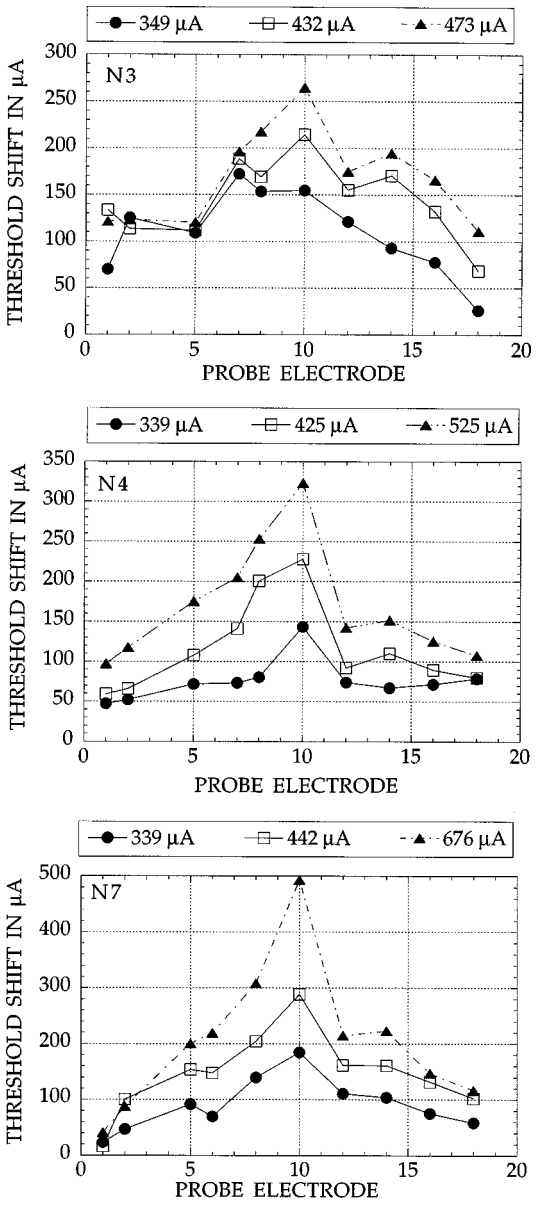

FIG. 3. The same as in Fig. 2: masker on electrode pair (10,12), subjects N3, N4, and N7.

Figures 3 and 4 show further examples of similar patterns obtained with maskers presented to electrode pairs (10,12) (middle location in the cochlea: subjects N3, N4, and N7), and (5,7), (basal location: subjects N3, N4, and N13). Note that the shape of subject N3's patterns show minimal dependence on masker amplitude when the masker is on electrode pair (5,7).

B. Dependence on probe delay

The effect of changing probe delay (Δt) was measured keeping the masker amplitude fixed at a comfortable level for each electrode pair in all subjects. In Fig. 5, patterns of threshold shift are plotted for subjects N4, N7, and N13 for probe delays of 1 and 10 ms. Apart from a multiplicative shift, patterns in these subjects show little change in shape as the probe delay is changed.

Figure 6 shows examples of patterns obtained in subject N3 at probe delays of 1 and 10 ms, at three locations of the masker electrode pair. In this subject, the amount of masking and the shape of the masking pattern both change with probe delay. For the 10-ms probe delay, the masking pattern is relatively flat. For the 1-ms probe delay, the pattern develops a peak around the masker electrode, thus assuming more of a bandpass characteristic. There are also variations with masker electrode location along the cochlea. Thus, note that the change in shape with probe delay is minimal when the masker is on the most basal electrode pair studied [electrode pair (5,7)]. This parallels the minimal change of shape with increasing masker level measured at this electrode pair in this subject (Fig. 4).

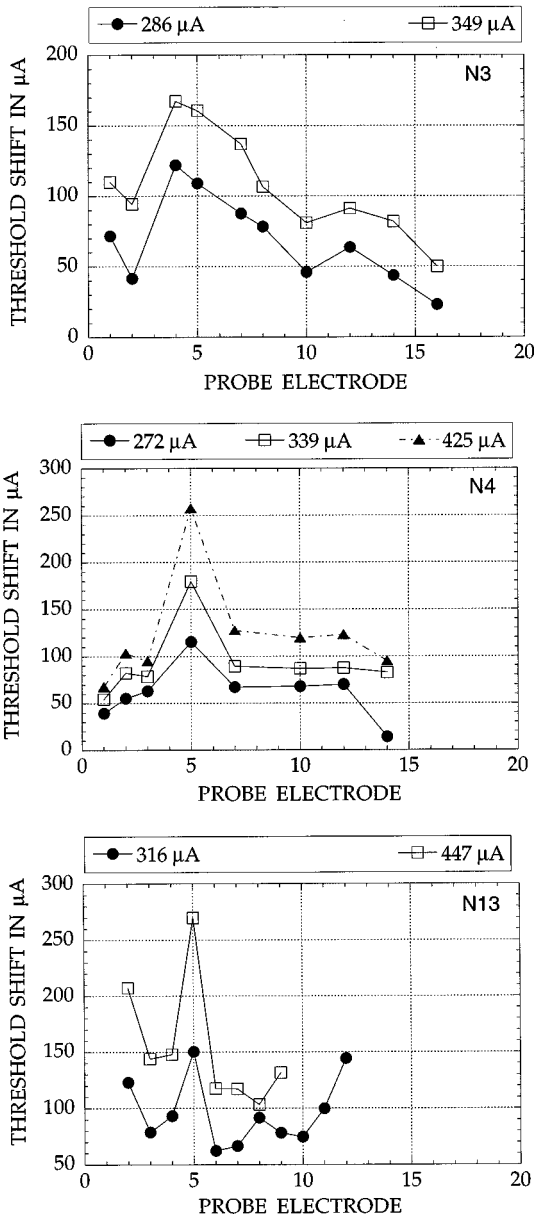

FIG. 4. Same as in Figs. 2 and 3: masker on electrode pair (5,7), subjects N3, N4, and N13.

C. Recovery from forward masking: Dependence on parameters

1. Effects of masker amplitude

Figure 7 shows examples of recovery functions obtained at two different masker amplitudes (corresponding to ''soft'' and ''comfortable'' loudness levels) in subjects N3 and N7. The actual threshold shifts were normalized to the peak in each case, to facilitate comparisons. Masker and probe were on the same electrode pair. It appears that the shape of the recovery function is independent of masker amplitude. Note that N3, the poorer performer, shows complete recovery from masking at less than 200 ms, while N7, who scores well on the sentence recognition test, is still not recovered at 200-ms delay.

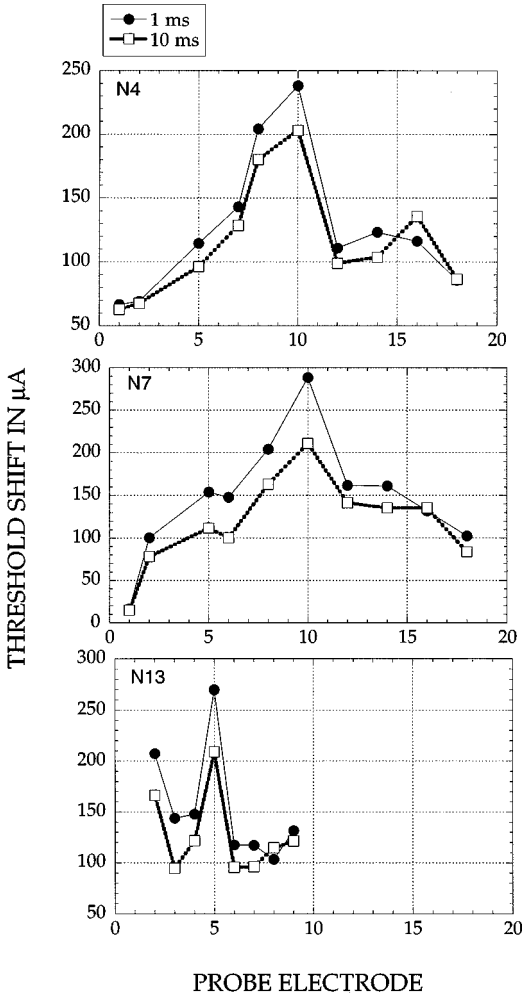

FIG. 5. Threshold shift in μA as a function of probe electrode pair, measured for probe delays 1 and 10 ms. Top: subject N4, masker on electrode pair (10,12). Middle: subject N7, masker on electrode pair (10,12). Bottom: subject N13, masker on electrode pair (5,7). Masker at comfortable level in each case.

2. Effects of probe location

Figure 8 shows recovery functions measured at a comfortable level at two electrode locations in subjects N3 and N7. In each case, masker and probe were presented to the same electrode pair. The threshold shifts have been normalized to the maximum in each case. There is no apparent dependence of the shape of the recovery function on cochlear location.

The shape of the recovery function may, however, change when the masker and the probe are on *different* electrode pairs. Figure 9 shows examples of recovery functions measured in subjects N3 and N7 under such conditions. Each function is normalized to the peak threshold shift to facilitate comparisons. In the case of subject N3 (top), the masker was fixed at electrode pair (14,16) at a comfortable level (432 μA). Normalized recovery functions measured on probe electrode pairs (8,10), (10,12) and (14,16) are shown. For subject N7 (bottom), the masker was fixed at electrode pair (10,12) at comfortable level (442 μA). Normalized recovery functions measured on probe electrode pairs (5,7), (8,10), (10,12), (12,14), and (14,16) are shown. In these two subjects it is evident that the functions change from one probe

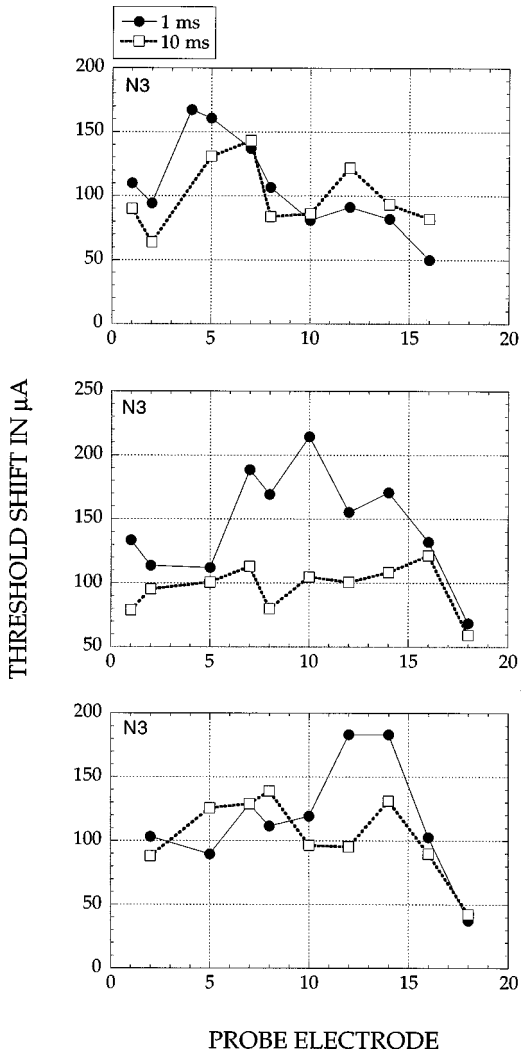

FIG. 6. Same as in Fig. 5: subject N3. Top, middle, and bottom panels: masker on electrode pairs (5,7), (10,12), and (14,16), respectively. Masker at comfortable level in each case.

location to the next. Occasionally, a non-monotonicity, or a bump, is evident in the early part of the recovery function. Such non-monotonicities could be due to the presence of multiple mechanisms in the recovery process.

3. Time constants of recovery: Subject-dependence

Figure 10 shows normalized recovery functions for four subjects. The functions were measured with masker and probe on the same electrode pair in each case. The functions are normalized to the peak threshold shift. The dashed lines represent single exponential curve fits to the normalized data. Time constants calculated from the fits are displayed in the inset in ms. Note that all the subjects, with the exception of subject N3, have very similar recovery functions, with a mean time constant of 72 ms. The time constant obtained for subject N3 is 1.85 times shorter than the mean of subjects N4, N7, and N13. Although the single exponential provides a good fit to the data of N4, N7, and N13, it underestimates the early recovery evident in N3's data.

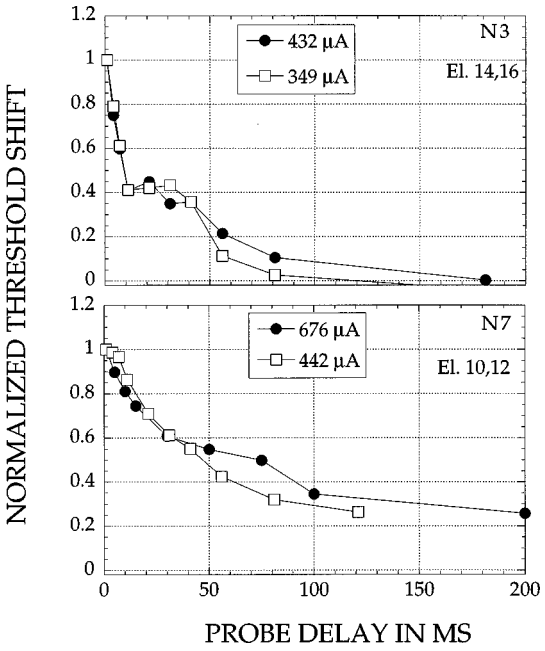

FIG. 7. Recovery from forward masking with masker level as a parameter in two subjects. Masker and probe presented to the same electrode pair in each case. Top: subject N3. Bottom: subject N7.

D. Growth-of-masking functions: Dependence on probe delay

In Fig. 11, growth-of-masking functions are plotted for subjects N3, N4, and N7, at probe delays of 1 and 10 ms. Masker and probe were presented to electrode pair (10,12) in all cases. In subjects N4 and N7, the functions are very similar at the two probe delays, the function for the longer delay being slightly shallower in slope. In these subjects, the

change in the slope of the growth-of-masking function is consistent with the multiplicative shift observed at the two probe delays in Fig. 5. In the case of subject N3, consistent with the changes observed in Fig. 6, the growth-of-masking function changes dramatically when Δt is changed to 10 ms: for $\Delta t = 1$ ms, the function is quite linear, with a slope of about 0.85 (close to the slope obtained in the other subjects); when $\Delta t = 10$ ms, the slope changes to 0.38. It is important to recall that in this subject, the spatial masking patterns change from one masker level to another for a fixed probe delay,indicating that, for a fixed masker location, the slope of the growth-of-masking function changes with probe electrode location. In the other subjects, we can expect the slope differences to be much smaller at different electrode locations, given the relatively unchanging shape of the masking pattern with changes in masker amplitude.

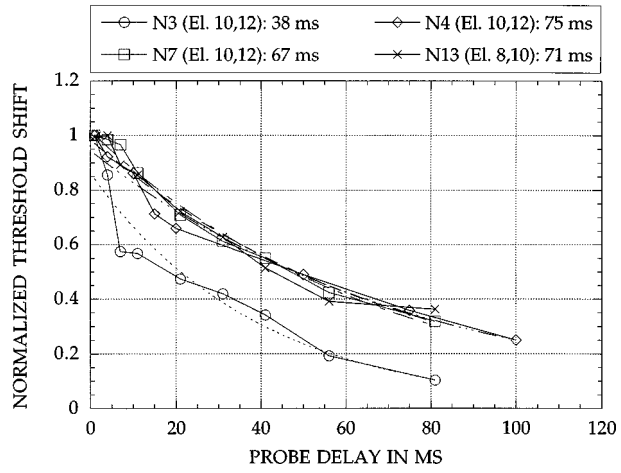

FIG. 10. Recovery from forward masking at most comfortable level in four subjects. The dashed lines show exponential curve fits to the four functions. The inset shows the time constants derived from the curve fits.

III. DISCUSSION

A. Forward masked excitation patterns: General observations

In broad agreement with previous work (Shannon, 1983; Tong and Clark, 1986; Lim *et al.*, 1989) forward masked excitation patterns in all subjects show the following general characteristics:

(1) a spatial band pass characteristic, with a peak in the region of the masker electrode.
(2) Intersubject variability is evident in the actual shape of

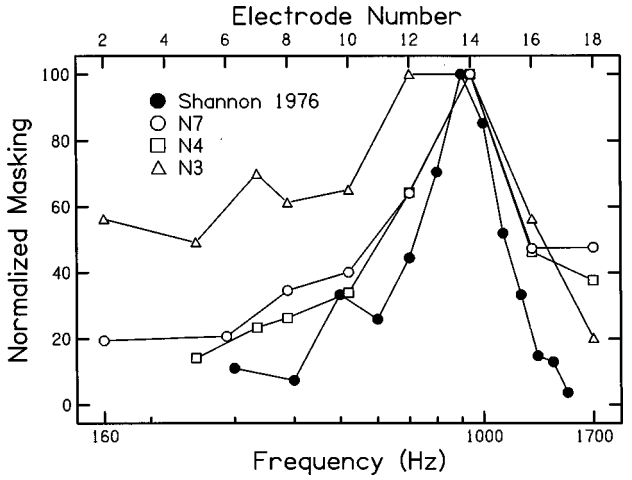

FIG. 12. Masked excitation patterns compared in acoustic and electric stimulation (see text for details).

the pattern. This variability may result from differences in etiology of deafness, nerve survival patterns, electrode insertion depth, etc.

(3) A general shift in symmetry of the excitation pattern is observed when the masker electrode is moved from the basal electrode pair (5,7) to the apical electrode pair (14,16). This is evident in most cases (see Figs. 4–6). For electrode pair (5,7), the pattern is skewed toward the base. For electrode pair (10,12), the pattern is generally somewhat symmetrical, whereas for electrode pair (14,16), there is a skew toward the apex.

B. Comparison with results obtained in normal-hearing listeners

Figure 12 shows a direct comparison of masked patterns obtained in our present study with the forward masking pattern obtained by Shannon (1976) in a normal-hearing listener. All four functions were measured at comfortable loudness levels. The log frequency axis for the normal-hearing listener's data is scaled to correspond to the linear cochlear distance mapped by the electrodes of a Nucleus-22 cochlear implant. The functions are normalized to aid comparisons.

It is evident that, at comfortable loudness, masking patterns in normal acoustic hearing and in electric stimulation are surprisingly comparable in extent as well as in shape. Data from subjects N4 and N7 in particular are very similar to the normal pattern, whereas subject N3's masking pattern is the broadest. It is important to keep in mind when making such comparisons that (a) the dynamic range in normal hearing is large compared with that in electric hearing and (b) that excitation patterns in normal hearing show changes in tuning and shape as the stimulus level is changed. As the compressive nonlinearity present in normal hearing cochleae is absent in electric hearing, phenomena such as the ''upward spread of masking'' are absent.

In agreement with previous work by Shannon (1990), time constants of recovery from masking are comparable with those obtained in normal-hearing listeners. We find a change in the slope of the growth of masking function with a change in probe delay. It may be worthwhile to note that Jesteadt *et al.* (1982, Fig. 1) found a similar trend in normal-hearing listeners.

C. Dependence of masking patterns on stimulus parameters

Results from subjects N4, N7, and N13, who have better sentence recognition scores, show masked thresholds that grow linearly with masker amplitude for all electrodes, with approximately the same slope, resulting in a relatively constant masking pattern. Results from subject N3, who has the poorest sentence score, indicate a growth-of-masking function that has a steeper slope when the probe is on electrodes close to the masker electrode than when the probe is on distant electrodes. This results in a masking pattern that changes from being relatively flat at lower levels of masking to being more peaked around the masker electrode at higher levels. This is in contrast to normal acoustic hearing, where the decay of threshold shift with probe delay is relatively independent of the frequency separation between the masker and the probe.

Similar to the results with changing masker amplitude, patterns obtained in subjects N4, N7, and N13 remained relatively unchanged when probe delay was increased. Subject N3's patterns on the other hand were flat for longer probe delays, but became peaked around the masker electrode for short probe delays. Consistent with these data, subject N3 was found to have a more rapid recovery at and around the masker electrode pair.

Fu (1997) has shown that electrode location plays a significant role in information transfer. Information about electrode location can be conveyed only by the pattern of excitation in the periphery. If the pattern of excitation in the periphery plays a role in coding properties of the stimulus, the shape of the pattern should be robust to changes in stimulus parameters. In the case of N3, information about electrode location, as it is preserved in the neural trace, is lost rapidly, within 10 ms of stimulus offset. This may adversely influence his performance in recognizing features of speech such as formant transitions, which the speech processor translates into electrode transitions. Such tasks would presumably require rapid comparisons between successive patterns in time.

D. Recovery from forward masking

The present data were collected in a small group of subjects, and examined effects of masker amplitude as well as masker-probe distance. We did not find significant changes in recovery functions with masker level, when masker and probe were presented to the same electrode pair. However, when the probe electrode pair was moved to another location, the functions sometimes changed in shape. As we have not found evidence of changes in the shape of the recovery function on the amount of masking (i.e., on the level of the masker), these changes may not be simply due to masked thresholds being lower when the masker and probe are presented to different electrode pairs.

When masker and probe were on the same electrode, recovery functions compared across subjects showed an almost identical shape, with the exception of data obtained from subject N3, which showed a much more rapid recovery. The data were well approximated by an exponential function. Time constants calculated from the curve fits were 75, 67, and 71 ms for subjects N4, N7, and N13, and 38 ms for subject N3. The more rapid recovery in subject N3 is consistent with the large change in the amount of masking at the masker electrode location when Δt was changed from 1 to 10 ms (Fig. 6).

We also found that, when masker and probe were on the same electrode, the slope of the growth-of-masking function decreased with the probe delay, or recovery time, in all three subjects. The change was the greatest in subject N3.

In the normal-hearing system, psychophysical recovery from forward masking has been hypothesized (Smith, 1977, 1979; Harris and Dallos, 1979; Zeng *et al.*, 1991) to be related to peripheral mechanisms of neural adaptation and recovery. Models of single auditory nerve adaptation require a functioning hair cell transducer mechanism at the input stage of a diffusion-limited synaptic transfer (Smith and Brachman, 1982). In electric stimulation, hair cells and synapses can safely be assumed to be nonfunctional. Therefore, the fact that recovery from forward masking follows comparable time courses in electric and acoustic hearing indicates that peripheral synaptic mechanisms are not necessary for psychophysical forward masking (Shannon, 1990). In fact, single-unit recordings in electrically stimulated cats do not show the dramatic adaptation seen in acoustic stimulation (Javel, 1990). On the other hand, Brown and Abbas (1996), in a two-pulse forward masking experiment in patients using the Ineraid device, found similar rates of recovery in the electrically evoked compound action potential and psychophysical forward masked thresholds. We infer from the above that (a) adaptation in the auditory nerve is not related to psychophysical forward masking and (b) other auditory nerve mechanisms of recovery must contribute to forward masking phenomena.

E. Significance of the results

The psychophysical measures studied in this investigation examine perceptual effects of prior stimulation. The relationships of these measures to speech perception are still ambiguous. Subject N3's data are both qualitatively and quantitatively different from the others. However, without further data from a larger subject pool, it is not clear whether the lower sentence recognition scores of subject N3 are in any way related to the greater parameter dependence observed in his forward masked excitation patterns. If similar results are obtained in the future with other subjects, we may hypothesize that robustness to changing stimulus parameters plays a role in speech processing by the electrically stimulated auditory system.

The results presented here serve to underscore the importance of detailed parametric studies of channel interaction. It is clear that in the future, designing stimuli with realistic, time-varying parameters will help further our understanding of the large individual variability in speech recognition by cochlear implant subjects.

ACKNOWLEDGMENTS

Some of the results were presented at the 1997 Midwinter Meeting of the Association for Research in Otolaryngology. We thank the reviewers, particularly Dr. Søren Buus, for helpful comments on the manuscript. Dr. Qian-Jie Fu programmed the software used in these experiments. We thank Dr. Fan Gang Zeng for useful suggestions. Our subjects are thanked for their enthusiastic participation. J. Heller and Cochlear Corporation kindly provided us with the amplitude calibration tables for each subject. Research supported by NIDCD.

(Received 16 November 1996; revised 22 August 1997; accepted 15 January 1998)

In experiment 1 NoSo and NoSπ thresholds for a 500-Hz pure tone were obtained in a low-fluctuation masking noise and a high-fluctuation masking noise for six normal-hearing listeners. The noise bandwidth was 10 Hz. In agreement with previous investigations, the NoSo thresholds were lower in low-fluctuation noise than in high-fluctuation noise. For three listeners, NoSπ thresholds were similar for the two types of noise, while for the other three listeners, NoSπ thresholds were *higher* for low-fluctuation noise than for high-fluctuation noise. In experiment 2, the masker was created by amplitude modulating a 500-Hz pure tone by a 0–10-Hz low-pass noise. The degree of masker fluctuation was controlled by adjusting the average modulation depth (100%, 63%, 40%, and 25%). The signal was a 10-Hz-wide noise centered on 500 Hz. Results were similar to those of experiment 1: for the NoSo conditions, signal detection improved with decreasing degree of fluctuation, and for NoSπ conditions, the results were subject dependent. For three listeners, NoSπ thresholds were again similar in the two types of noise, while for the other three listeners, NoSπ thresholds were again higher in low-fluctuation noise than in high-fluctuation noise. The results showed that a high degree of masker fluctuation sometimes facilitates NoSπ detection. It is possible that the binaural detection mechanism utilizes the relatively good signal-to-noise ratios that occur in the low power or ''dip'' regions of fluctuating masker waveforms. INTRODUCTION

Previous experiments using low-noise (Pumplin, 1985) have investigated the effects of masker amplitude fluctuation on monaural signal detection (Hartmann and Pumplin, 1988). Conditions have contrasted detection in noise having a random phase relation among components (where noise fluctuation is generally high) with detection in noise having components whose phases are selected such that the noise fluctuation is relatively low (low-noise noise). Results (Hartmann and Pumplin, 1988) indicate that monaural signal detection is better for low-noise narrow-band noise than for random-phase narrow-band noise. Similar effects were reported by Margolis and Small (1974) for a low-fluctuation noise produced by frequency modulating a sinewave by a thermal noise. The low-noise noise result is consistent with the notion that random variation in the energy of the masker is detrimental to the detection of the signal (e.g., Bos and de Boer, 1966).

There is reason to believe that studies manipulating noise fluctuation may also be of interest in conditions of binaural unmasking. For example, it is possible that results from low- and high-fluctuation noise conditions may have bearing upon models of the masking-level difference (MLD) (Hirsh, 1948). Specifically, different binaural models may be associated with different predictions concerning the effect of masker fluctuation. In the equalization–cancellation (EC) model of Durlach (1963), the stimulus waveforms at the two ears undergo auditory filtering, level/time equalization, and subtraction. For the sake of simplicity, we will consider only NoSo and NoSπ stimulation. With perfect equalization, the subtraction process would completely eliminate an No masker, and masked signal detection threshold would be similar to that obtained in quiet. However, the model assumes that there is both time and amplitude ''jitter'' in the process, resulting in an No noise being reduced in level rather than eliminated. In contrast, the subtraction process for the Sπ signal essentially results in an in-phase addition of the signal, with a consequent boost in signal level. Thus, for NoSπ detection, the signal-to-noise ratio is effectively increased by the EC process. For an So condition, the subtraction process results in a reduction in signal level. However, because the same jitter parameters hold for both signal and noise, the noise and signal are reduced by similar amounts in the NoSo case. Thus, for NoSo, the signal-to-noise ratio is essentially the same at the EC input and the EC output.

In the EC model, both NoSo and NoSπ detection reduce to the problem of detecting signal energy in noise. If it is supposed that the decision statistic for detection is similar for the NoSo and NoSπ cases, then the effects of low-noise noise should be similar for NoSo and NoSπ detection. Because power fluctuations are relatively minor in low-noise noise, both NoSo and NoSπ thresholds are expected to be relatively lower than in noise with prominent power fluctuations. Because effects of low-noise noise are expected to be similar for NoSo and NoSπ detection, the MLD would then be expected to be similar for low-noise noise and random-phase noise.

In contrast, the MLD is expected to be relatively smaller for low-noise noise conditions from the standpoint of cross-correlation models (Jeffress, 1948; Colburn, 1973; Stern and Colburn, 1978; Stern and Trahiotis, 1992) of the MLD. One

reason for this prediction is related to the fact that, in cross-correlation models, the decision statistic for binaural detection is proposed to be radically different from that associated with monaural, or NoSo, detection. As in the EC model, monaural or NoSo detection is usually hypothesized to be based upon an analysis of stimulus energy. Thus, a relatively low NoSo threshold is predicted for a low-noise noise masker. In contrast, binaural (e.g., NoSπ) detection is assumed to be based upon a cross-correlation process. In the physiological realization of such a process, the decision statistic is presumed to be related to a change in the activity pattern of neurons responding to different degrees of interaural delay. If it is assumed that interaural correlation will be just as high for a random-phase No noise as for a low-noise No noise, there is no reason to expect that the relatively high degree of fluctuation associated with random-phase noise should be deleterious for NoSπ detection. According to this interpretation, the MLD should be smaller in low-noise noise because the NoSo threshold is expected to be lower in low-noise noise than in random-phase noise, but the NoSπ threshold is not expected to be lower in low-noise noise than in random-phase noise.

A second reason that MLDs might be smaller in low-noise noise is directly related to the depth of fluctuation of the masker envelope. Masker dips (where noise power is low for short temporal epochs) are associated with a relatively high signal-to-noise ratio. There is evidence that monaural detection for a signal presented in a band of random noise does not appear to be able to benefit from the good signal-to-noise ratios associated with masker dips (Buus *et al.*, 1996). This may be because it is difficult for the auditory system to determine whether a signal occurring in a masker dip is actually a signal or simply a random fluctuation of the masker. A cross-correlation mechanism offers a potential solution to this problem in that an $S\pi$ signal occurring in an No masker dip will result in interaural correlation quite different from that associated with the masker alone. If such short-duration changes in interaural correlation are effective in cueing detection, $S\pi$ thresholds might actually be better in random-phase noise (where dips are relatively deep) than in low-noise noise (where dips are relatively shallow).

In the course of this investigation, we learned of a similar on-going study of the MLD in low-noise noise maskers, with similar results, by David Eddins and Laura Barber. The manuscripts resulting from his work and the work in our laboratory have therefore been submitted as companion papers.

I. EXPERIMENT 1: MLD IN LOW-NOISE NOISE

A. Method

1. Subjects

Subjects were six listeners with normal hearing, aged between 24 and 44 years. All had previous experience listening in MLD and CMR paradigms.

2. Stimuli

All noise bands were centered on 500 Hz and had a bandwidth of 10 Hz. Each band was composed of 11 equal-amplitude sinusoidal components. For the high-fluctuation noise, the phase relation among the 11 components was random. For the low-noise noise, the phase relations were chosen by the low-fluctuation noise algorithm (Pumplin, 1985). For each type of noise (random-phase or low-noise noise), ten different noise files were generated. One of the ten files was selected randomly from interval to interval in order to reduce possible effects associated with a particular frozen noise sample (Hanna and Robinson, 1985). Each noise file was 4096 samples long, using a sampling rate of 4096 Hz. Noise was delivered via a 12-bit Data Translation D/A converter. The signal was a 400-ms, 500-Hz pure tone, shaped with a 50-ms squared-cosine rise/fall. The masker was gated on (50-ms squared-cosine) 100 ms before the signal was gated on, and was gated off simultaneously with the signal. The masker was always interaurally in phase (No) and the signal was either interaurally in phase (So) or interaurally out of phase (Sπ).

3. Masker statistics

The average kurtosis for the ten low-noise masker waveforms was 1.655 (compared to 3.0 for Gaussian noise). Figure 1 of Hartmann and Pumplin (1988) shows that 1.655 is well outside the expected distribution for kurtosis for random-phase noises. The average crest factor for the ten low-noise noise maskers was 1.710, compared with an expected value of 2.76 for random-phase noises (Hartmann and Pumplin, 1988, Eq. C4). In contrast with the fluctuations in signal power, the low-noise noise maskers showed no special character in their instantaneous phases. Phase variation caused by the center frequency was extracted and the residual phase variation (Hartmann, 1997, Eq. 18.6) was studied. Neither the overall phase variance nor any time-dependent behavior indicated differences between low-noise noise and random-phase maskers. This analysis is relevant because the rate of change in interaural difference cues for an NoSπ stimulus depends upon the changes in the instantaneous phase of the masker. The analysis suggests no obvious differences between low-noise noise and random-noise maskers in this regard.

4. Procedure

Thresholds were determined using a three-alternative forced choice (3AFC) three-down, one-up adaptive procedure, estimating the 79.4% detection threshold (Levitt, 1971). An initial step-size of 8 dB was reduced to 4 dB after two reversals, and further reduced to 2 dB after two more reversals. A threshold run was stopped after 12 reversals, and the average of the last 8 reversals was taken as the threshold for a run. Four threshold runs were averaged to compute the final threshold, unless the range of the runs was greater than 3 dB; in that case, a fifth run was obtained and included in the average. Each trial was preceded by a 300-ms warning light. Each interval was marked by a 400-ms light. The interstimulus interval was 300 ms. Visual feedback was provided after each response. The stimuli were delivered binaurally by means of Sony MDR V6 earphones.

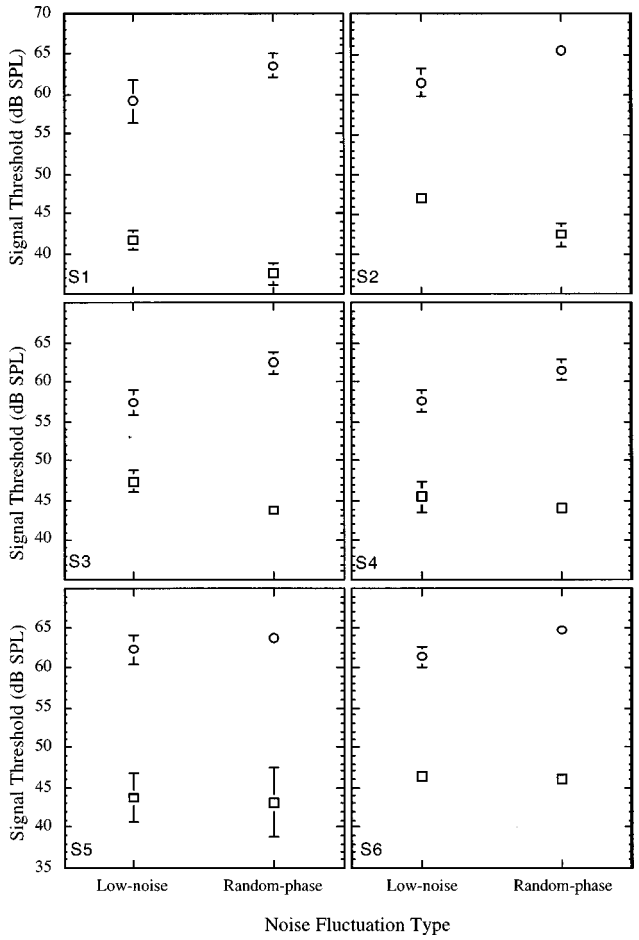

FIG. 1. The NoSo (circles) and NoSπ (squares) thresholds for the six listeners, in low-noise noise (Low) and random noise (High). Error bars show plus and minus one standard deviation. Standard deviations are not shown when they are smaller than the data symbol.

B. Results and discussion

Threshold data for the six subjects are summarized in Fig. 1. Individual rather than average data are shown because there were different patterns of results across subjects. The most consistent finding, of course, was that NoSπ thresholds were lower than NoSo thresholds. A second consistent finding was that, for NoSo conditions, signal thresholds were lower (by about 5 dB) in low-noise noise than in random-phase noise. This result is consistent with that reported by Hartmann and Pumplin (1988). However, results for low-noise noise and random-phase noise were not consistent across subjects for NoSπ detection. In NoSπ conditions, subjects 1, 2, and 3 showed higher thresholds for low-noise noise than for random-phase noise. As can be seen in Table I, these subjects had considerably larger MLDs (by about 9 dB) in random-phase noise than in low-noise noise. For these subjects, MLDs were relatively small in low-noise noise partly because the NoSo thresholds were relatively low in low-noise noise, and partly because the NoSπ thresholds were relatively high in low-noise noise. For subjects 4, 5, and 6, NoSπ thresholds were similar between low-noise noise and random-phase noise (see Fig. 1). For these subjects, MLDs were again smaller in low-noise noise than in random-phase noise, but only by about 2 to 5 dB. In these subjects, the smaller MLD in low-noise noise than in random-phase noise was due primarily to the fact that the NoSo thresholds were lower in low-noise noise than in random-phase noise. Across all subjects, the average MLD for random-phase noise was 20.7 dB, and the average MLD for low-noise noise was 14.5 dB (see Table I).

TABLE I. Individual and mean MLDs (dB) for random phase noise and low-noise masking noise. Data are for experiment 1.

Noise type	S1	S2	S3	S4	S5	S6	Mean
High fluctuation	26.0	23.0	18.7	17.4	20.6	18.7	20.7
Low fluctuation	17.3	14.4	9.8	12.7	18.5	15.1	14.5

The most striking new result of this experiment was the higher NoSπ threshold in low-noise noise than in high-fluctuation noise for three of the six subjects. This result suggests that a cue related to a relatively high degree of masker fluctuation can actually aid binaural signal detection. In order to examine the generality of this result, we performed a second experiment employing a different method for generating maskers with varying degrees of fluctuation.

II. EXPERIMENT 2: MASKING NOISE CREATED BY AMPLITUDE MODULATING A PURE TONE BY A LOW-PASS NOISE

A. Method

1. Subjects

The subjects were the same as those who participated in the first experiment.

2. Stimuli and procedure

The masker was created by multiplying a 500-Hz pure tone by a DC-shifted low-pass noise (0–10 Hz). The masking waveform was defined by

$$A(t)=A_0[1+N(t)]\cos(\Omega_0 t),$$

where t is time, A_0 is the amplitude of the 500-Hz carrier, $N(t)$ is the low-pass noise waveform, and Ω_0 is 2π times the carrier frequency. A similar method was used in a MLD study by Grantham and Robinson (1977). However, in the Grantham and Robinson study, the modulator was a bandpass noise from 43 to 77 Hz, and modulation of the 500-Hz carrier by this bandpass noise resulted in a modulated masker with spectral components extending from approximately 423 to 577 Hz. In the present study, the masker components were restricted to frequencies between approximately 490 and 510 Hz. The degree of fluctuation was adjusted by varying the depth of modulation. Average modulation depths (in terms of percent of modulation) were 100%, 63%, 40%, and 25%, where 100% corresponds to a noise waveform $[N(t)]$ with rms value of approximately 0.707. The level of the masker (carrier plus sidebands) was held constant at approximately 59 dB SPL. The signal was a 10-Hz-wide band of noise centered on 500 Hz. An inverse fast Fourier transform (FFT) incorporating a sampling rate of 11.025 kHz and buffer size of 2^{17} discrete points was used to create the signal. This resulted in a stimulus with approximately 0.08-Hz frequency resolution that, upon cyclical output, had an overall period-

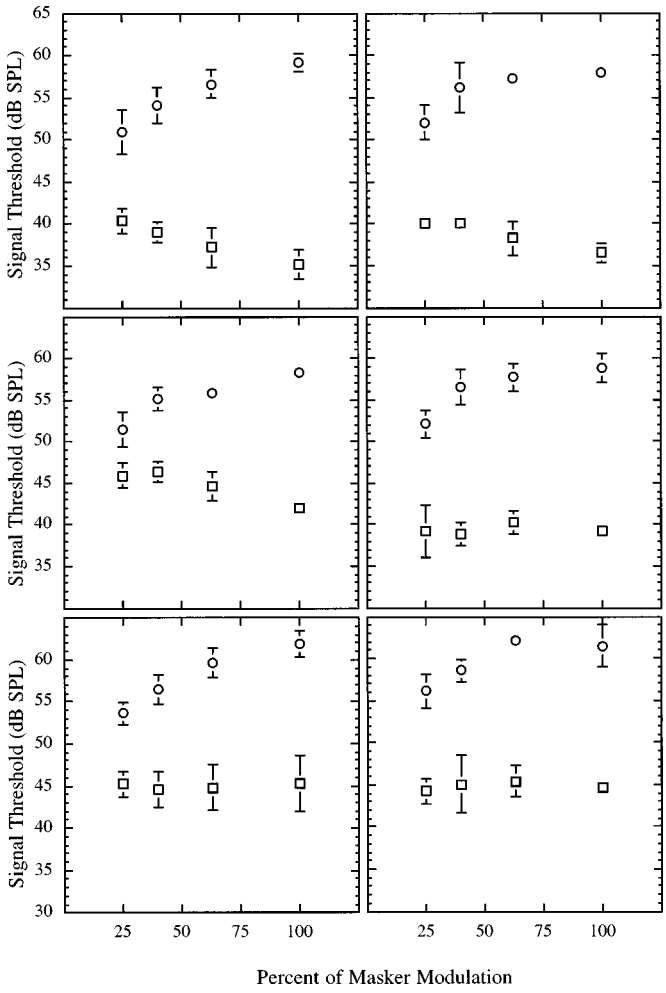

FIG. 2. The NoSo (circles) and NoSπ (squares) thresholds for the six listeners, as a function of the average percent of modulation of the masker. Error bars show plus and minus one standard deviation. Standard deviations are not shown when they are smaller than the data symbol.

icity of approximately 11.89 s. The noise signal was played continuously through a 20-bit digital-to-analog converter and low-pass filtered at 3 kHz, and was gated via a Tucker-Davis SW2 gate. A noiseband was used as a signal, rather than a pure tone, so that the phase between the carrier of the amplitude-modulated masker would be random with respect to the phase of the signal. The signal was 400 ms in duration, and had 50-ms squared-cosine rise/fall. The masker was presented continuously. The masker was always interaurally in phase (No) and the signal was either interaurally in phase (So) or interaurally out of phase (Sπ). The threshold procedure was the same as that used in the first experiment.

B. Results and discussion

Threshold data for the six subjects are summarized in Fig. 2. In several respects, the pattern of results was similar to that obtained in experiment I. As in experiment 1, NoSo thresholds consistently improved as the masker fluctuation decreased. The average NoSo threshold was 59.6 dB for 100% modulation, but improved to 52.7 dB for 25% modulation. As in experiment 1, there were individual differences in the effect of masker fluctuation for NoSπ detection: subjects 1, 2, and 3 again showed higher thresholds with decreases in masker fluctuation, whereas subjects 4, 5, and 6 again showed relatively stable NoSπ thresholds across the different conditions of masker fluctuation. Across all subjects, the average MLDs were 19.1, 16.4, 13.8, and 10.2 dB for 100%, 63%, 40%, and 25% modulation, respectively (see Table II).[1]

TABLE II. Individual and mean MLDs for maskers varying in average percent of modulation. Data are for experiment 2.

Percent modulation	S1	S2	S3	S4	S5	S6	Mean
100	23.9	21.4	16.2	19.7	16.6	16.9	19.1
63	19.4	18.9	11.2	17.4	14.8	16.7	16.4
40	15.0	16.1	8.7	17.7	12.0	13.6	13.8
25	10.5	11.9	5.6	12.9	8.4	11.9	10.2

Again, the most striking finding was that for subjects 1, 2, and 3, NoSπ thresholds increased as a function of decreased masker fluctuation. This result again suggests that a cue related to a relatively high degree of masker fluctuation can aid binaural signal detection. Subjects 4, 5, and 6 again showed little change in the NoSπ threshold with changes in masker modulation depth.

III. GENERAL DISCUSSION

It was pointed out in the Introduction that a straightforward EC model interpretation would predict that NoSo and NoSπ thresholds would depend similarly on masker fluctuation statistics. The findings for the Sπ thresholds did not agree with this prediction. The present findings were in better agreement with a cross-correlation mechanism. For a cross-correlation mechanism, it was predicted that detection for NoSπ would would either not vary as a function of the degree of masker fluctuation, or that Sπ detection might be worse in low-fluctuation noise than in high-fluctuation noise. In three of the listeners tested, Sπ thresholds were similar in low-fluctuation noise and in high-fluctuation noise, and in the three other listeners, NoSπ thresholds were *lower* in high-fluctuation noise than in low-fluctuation noise. The latter result is in direct contrast to the situation for monaural detection, where high noise fluctuation results in relatively poor detection (Bos and de Boer, 1966). It would appear that, at least in some listeners, a high degree of noise fluctuation is favorable for signal detection. It seems likely that this effect is related to low-energy or ''dip'' regions in the masker. In a masker having a relatively low degree of fluctuation, the signal-to-noise ratio is relatively constant over the duration of a signal. However, in a masker having a relatively high degree of fluctuation, the signal-to-noise ratio will be relatively poor in masker peak regions, but will be relatively good in masker dip regions. It is possible that the relatively short but large binaural cues that exist during masker dips are effective in cuing NoSπ detection.

The above interpretation is consistent with Isabelle's (1995) account of NoSπ data in a frozen noise experiment. As in previous experiments by Gilkey and his colleagues (Gilkey *et al.*, 1985; Gilkey and Robinson, 1986), Isabelle attempted to obtain information about the cues accounting for binaural detection by examining performance for particu-

lar digitized samples of noise alone and signal-plus-noise. While Isabelle found that NoSπ performance was not correlated significantly with stimulus energy, modest, albeit significant, correlations were found for some decision statistics based upon variability of the interaural time and/or interaural intensity cues. Interestingly, the highest correlations were found for instantaneous interaural time differences. Isabelle suggested that the auditory system may utilize the infrequent but large interaural time differences occurring near the minima of the masker envelope, noting that ''this strategy may be likened to 'listening in the valleys of the noise.' ''

One feature of binaural analysis that might be seen as in conflict with the notion of relatively fine temporal resolution has been termed ''binaural sluggishness'' (Grantham and Wightman, 1979). This term refers to the fact that listeners are relatively insensitive to dynamic variation in interaural difference cues, in that changes in binaural cues occurring at rates of more than a few Hz are not heard as movement in perceived location, but, instead as a ''blur'' or as diffuseness of location (Blauert, 1972; Grantham and Wightman, 1978). Grantham and Wightman (1979) reported data consistent with an interpretation that binaural sluggishness may be associated with small MLDs. They investigated the detectability of a brief Sπ tone burst presented in a noise masker whose interaural phase varied sinusoidally between 1.0 and -1.0. When the short signal was presented at a time when the masker had interaural correlation near 1.0, a MLD occurred, provided that the sinusoidal modulation of interaural masker phase was very slow (e.g., 0.5 Hz). However, essentially no MLD occurred when the modulation rate was raised to only 4 Hz. This result is consistent with an interpretation that binaural sluggishness prevented the auditory system from taking advantage of the short temporal epochs when the stimulus was in NoSπ configuration. However, it reasonable to assume that the use of binaural signal detection information during short temporal epochs is poor only when both the masker and signal-plus-masker contain dynamically varying interaural cues (as was the case in the Grantham and Wightman study). When the masker has a stable interaural phase, it is likely that the binaural system can take advantage of binaural detection information in short temporal epochs. Indeed, the robust MLDs that occur for short Sπ signals in stable No maskers (Blodgett *et al.*, 1958; Green, 1966; Robinson and Trahiotis, 1972; Grantham and Wightman, 1979) provide strong evidence that the binaural system can make good use of binaural detection information occurring in a short temporal epoch. We therefore do not view binaural sluggishness as incompatible with a detection process involving relatively fast sampling of interaural correlation.

ACKNOWLEDGMENTS

Constantine Trahiotis and Huanping Dai made several helpful suggestions concerning the interpretation of the results. We thank Steve Colburn for helpful suggestions and for bringing Scott Isabelle's dissertation to out attention. Raymond Dye and two anonymous reviewers made helpful suggestions on a previous version of this manuscript. We appreciate technical assistance provided by Saju Joy. This research was supported by grants from NIH (NIDCD R01 DC00397 and NIDCD R01 DC00181) and AFOSR.

[1]It should be mentioned that during the review process for this manuscript Kohlrausch *et al.* (1997) published results comparing MLD data for random-phase and low-fluctuation noise. They used a 1000-Hz center frequency and examined masking bandwidths from 5 to 100 Hz. For the NoSo conditions, their average data (four subjects) indicated lower thresholds for low-fluctuation noise, and for the NoSπ conditions, their average data indicated similar thresholds between random-phase and low-fluctuation noise (similar to our data for subjects 4, 5, and 6).

The influence of stimulus envelope and fine structure on the binaural masking level difference[a)]

David A. Eddins and Laura E. Barber
Psychoacoustics Laboratory, Department of Speech and Hearing Sciences, Indiana University, Bloomington, Indiana 47405

(Received 16 November 1996; revised 10 September 1997; accepted 15 January 1998)

A masking level difference (MLD) paradigm was used to investigate the influence of stimulus envelope and stimulus fine-structure characteristics on monaural and binaural hearing. The degree of masker envelope fluctuation was manipulated by selecting narrow-band noises (50 Hz) on a continuum of values of the normalized fourth moment of the envelope. The noises were specified as low-noise noise (LNN), medium-noise noise (MNN), and high-noise noise (HNN). Fine-structure cues were studied by measuring thresholds at 500 and 4000 Hz, regions in which the availability of such cues to the auditory system differ substantially. In addition, thresholds were measured for Gaussian noise maskers (GN) and for maskers having a flat magnitude spectrum, termed equal-magnitude noise (EMN) maskers. The results indicated lower NoSo thresholds for LNN than for the other four masker types. Furthermore, there were no differences in threshold for maskers having moderate and high degrees of envelope fluctuation (MNN and HNN). The NoSπ thresholds were not significantly different across masker type and were characterized by large individual differences among the seven listeners. The results are considered in relation to models of monaural and binaural processing. Consistent with previous reports, the results indicate that binaural detection depends on interaural differences in the stimulus envelope and fine structure at low frequencies and changes in the envelope at high frequencies. INTRODUCTION

Since the duplex theory of sound localization was first suggested by Lord Rayleigh (1907), it has become abundantly clear that binaural auditory processing relies on interaural time and level differences to differing degrees across stimulus frequency. Consistent with this theory, results obtained in binaural masking level difference (MLD) paradigms using broadband masking noise indicate that the masking release is maximal at low signal frequencies and diminishes with increased frequency. Likewise, the lateralization of sinusoids and clicks based on interaural timing differences is limited to low stimulus frequencies (e.g., Klumpp and Eady, 1956; Yost *et al.*, 1971). These results are often explained in terms of the reduced accuracy in temporal coding at high frequencies due to the degradation in neural phase locking to the temporal fine structure with increasing stimulus frequency (e.g., Durlach, 1964).

It is clear, however, that interaural disparities conveyed by slowly fluctuating temporal envelopes can contribute to binaural processing at high stimulus frequencies in binaural detection and lateralization tasks (e.g., Klumpp and Eady, 1956; McFadden and Pasanen, 1976, 1978; Zurek and Durlach, 1987; Bernstein and Trahiotis, 1992a, 1992b). Thus, while phase locking to stimulus fine structure may provide binaural cues at low frequencies, interaural differences in temporal envelope may provide interaural cues at both low and high stimulus frequencies (Bernstein and Trahiotis, 1985a, 1985b). The present experiment was designed to explore the contributions of stimulus envelope and stimulus fine-structure cues to monaural and binaural detection using a MLD paradigm.

In the classic MLD paradigm, masked signal detection measured under homophasic (NoSo) conditions is compared to detection under antiphasic (NoSπ) conditions. For homophasic conditions, like monaural detection, thresholds are similar at low and high signal frequencies. Thus stimulus fine structure likely plays little role in these conditions. Changes in the masker envelope fluctuation, however, may have a substantial influence on detection in homophasic conditions (e.g., Hartmann and Pumplin, 1988). For antiphasic conditions, masked signal detection may be influenced by both changes in stimulus fine structure and envelope fluctuations, as noted above. One means of assessing the role of stimulus fine structure in antiphasic detection is to make measurements at relatively low (e.g., 500 Hz) and high (e.g., 4000 Hz) frequencies, where the availability of fine-structure information differs widely. To gain insight into the importance of the stimulus envelope in antiphasic detection, as well as homophasic detection, the present experiments employed masker types that differed in degree of envelope fluctuations. The first masker type was narrow-band, Gaussian noise, which is characterized by pronounced envelope fluctuations. The second type of masker was characterized by *minimal* envelope fluctuations.

To minimize envelope fluctuations, low-noise noise maskers were used, the details of which have been described

[a)]Portions of this research were presented at the 129th meeting of the Acoustical Society of America, Indianapolis, Indiana, May 1996 [J. Acoust. Soc. Am. **99** 2471(A) (1996)].

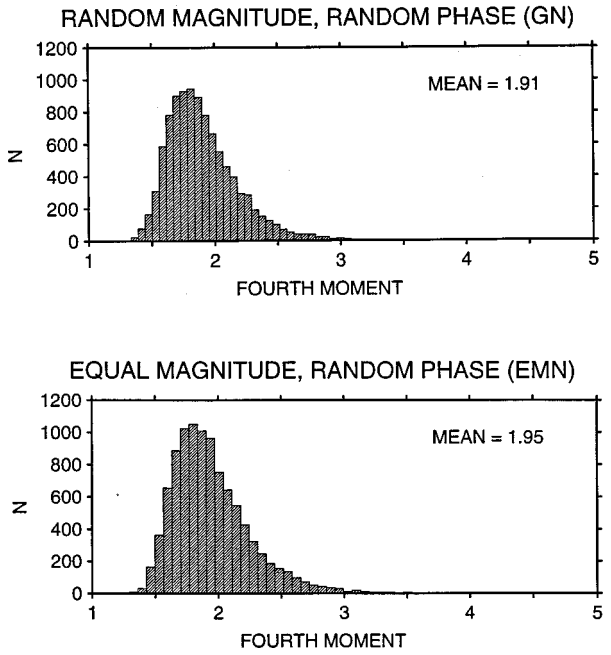

FIG. 1. Distribution of normalized envelope fourth moments obtained in 10 000 random samples of Gaussian noise (upper panel) and equal-magnitude noise (lower panel).

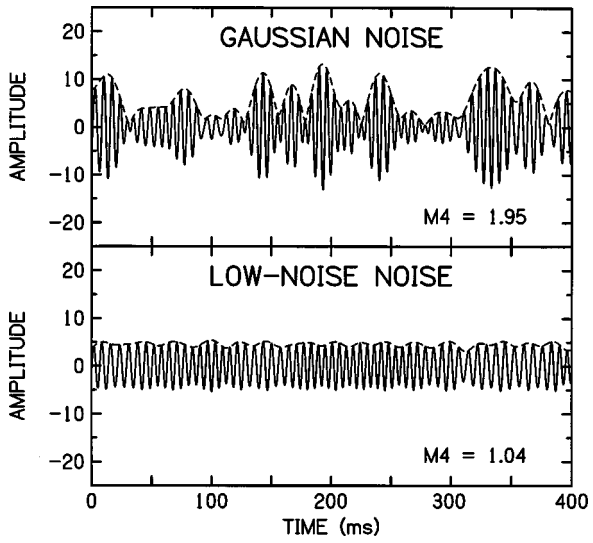

FIG. 2. The upper panel shows a sample of Gaussian noise having a normalized envelope fourth moment approximately equal to the mean of the distribution of fourth moments (see Fig. 1). The lower panel shows the sample of low-noise noise used in the present experiment. The waveforms are shown by the solid curves and the stimulus envelope by the dashed curves. The noise bandwidth is 50 Hz. The fourth moment of the envelope is denoted M4.

by Pumplin and Hartmann in a series of papers (Pumplin, 1985; Hartmann, 1987; Hartmann and Pumplin, 1988, 1991a). Briefly, a sample of low-noise is obtained by minimizing the fluctuations in the power of the waveform. Beginning with a magnitude spectrum, a directed search of the multidimensional space of possible component phases results in the set of phases that produces minimal variance in the power of the waveform. In practice, however, use of the algorithm becomes increasingly computationally intensive with increases in the number of spectral components comprising the stimulus. Fortunately, Hartmann and Pumplin (1991b) published a series of tables providing the phase spectra necessary to generate a number of different low-noise noises. As noted by Hartmann (1987), for psychoacoustic consideration, it may be more appropriate to consider the normalized fourth moment of the *envelope* rather than the fourth moment of the *waveform*, as the power fluctuations of the waveform contain frequencies too high to be perceptually relevant. For narrow-band noise, however, the normalized fourth moment of the waveform, W, and envelope, Y, are related in a simple way, $Y=2/3W$ (Hartmann and Pumplin, 1988). The term fourth moment will be used hereafter to refer to the normalized fourth moment of the envelope, $Y=\langle E\rangle^4/(\langle E^2\rangle)^2$, where E is the stimulus envelope.[1]

To facilitate the comparison of thresholds obtained with Gaussian noise (GN) and low-noise noise (LNN) maskers, it is helpful to understand the range of possible fourth moments under consideration. The upper panel of Fig. 1 illustrates the distribution of fourth moments obtained in 10 000 random samples of narrow-band (50 Hz) GN composed of 21 sinusoidal components with component magnitudes selected from a Rayleigh distribution and phases selected from a uniform distribution (0 to 2π). Note that the distribution of fourth moments is skewed toward the upper edge (range $=1.31$ to 4.35, mean$=1.91$, median$=1.86$, s.d.$=0.29$). A sample of noise having a fourth moment close to the mean of this distribution is shown in the upper panel of Fig. 2 (solid curve). The envelope of this waveform is shown by the dashed curve and has a fourth moment of 1.95.

Because the phase search necessary to generate low-noise noises was prohibitively long for 21-component stimuli, we chose to use a sample of noise taken from the tables of Hartmann and Pumplin (1991b). In this sample, each component of the magnitude spectrum had the same value and component phases were chosen to minimize the fourth moment. As Hartmann (1987) has shown, the distribution of waveform sample values for equal-magnitude noises (EMN) differs from noises composed of Rayleigh-distributed magnitudes for a very small number of components (<10), but is nearly indistinguishable for larger numbers of components. The same is true for the distribution of fourth moments for EMN (Fig. 1, lower panel). Note that this distribution is nearly identical to the distribution for Gaussian noise shown in the upper panel (range$=1.29$ to 4.62; mean$=1.95$; median$=1.89$; s.d.$=0.32$). The LNN waveform (solid curve) and envelope (dashed curve) are shown in the lower panel of Fig. 2. The fourth moment of the LNN sample used here, 1.04, is not likely to occur in random sampling from this distribution.

By manipulating the nature and availability of stimulus envelope and fine-structure cues to the auditory system, a better understanding of the dependence of masked threshold on various monaural and binaural cues can be achieved. Eddins (1994, 1996) has demonstrated the usefulness of LNN in identifying stimulus envelope contributions to complex detection tasks such as profile analysis and comodulation masking release (CMR). In those experiments, the choice of reference threshold was shown to have a strong influence on the estimated masking release. In the present experiment the

homophasic (NoSo) threshold will serve as the reference when computing the MLD. Since lower thresholds are typically observed with LNN than with GN maskers (e.g., Hartmann and Pumplin, 1988), it appears likely that any differences in MLD magnitude obtained with these two masker types will reflect, at least in part, changes in the NoSo (reference) condition. Specifically, with respect to homophasic detection, and by inference, monaural detection, changes in the stimulus fine structure are not expected to yield substantial differences in masked threshold; however, minimizing the degree of envelope fluctuation should result in lower masked thresholds.

It is not entirely clear how NoSπ thresholds might differ with the two maskers. While the addition of a sinusoidal signal to either GN or LNN will produce changes in the envelope relative to the masker-alone stimulus, there are two important differences in these masker conditions. First, the amount of fluctuation in the maskers themselves differs, providing very different standard or reference stimuli. Second, the envelope fluctuations will change in opposite directions with the addition of a sinusoidal signal to the two noise types. The degree of envelope fluctuation will decrease for GN maskers and will increase for LNN maskers. How will such changes, and the resulting interaural differences, influence masked threshold in the NoSπ condition?

To obtain some insight into this question, we considered the model described by Bernstein (1996) and Bernstein and Trahiotis (1996), based simply on a cross correlation of the stimuli at the two ears after processing by a half-wave rectifier and low-pass filter. This model is similar, in many respects, to most models of binaural interaction, which center around a binaural comparator based on the cross correlation, or the coincidence, of input from the two ears. Excellent reviews of such models are provided by Colburn and Durlach (1978), Durlach and Colburn (1978), Hafter and Trahiotis (1994), and Stern and Trahiotis (1995). Bernstein and Trahiotis (1996) have shown that such a model provides a reasonable account of the detection of interaural time differences as well as masked signal detection under antiphasic conditions over a wide range of stimulus frequencies. Furthermore, the change in correlation resulting from the addition of an antiphasic signal at threshold is comparable to direct measures of binaural correlation discrimination, leading to the interpretation that binaural detection relies on a constant change in interaural correlation of the stimuli following peripheral processing. It should be noted that the interaural correlations computed here are *normalized correlations* and not *normalized covariances* (i.e., Pearson product-moment correlation).[2]

If detection thresholds are mediated by changes in the interaural correlation produced by an antiphasic signal, then an examination of the output of such a model should predict the influence of the opposing cues obtained with GN and LNN maskers. In order to account for differences in listener performance across stimulus frequency, Bernstein and Trahiotis (1996) included half-wave rectification and low-pass filtering prior to the correlation computation. The low-pass filter stage, in essence, serves to limit the availability of interaural differences in the stimulus fine structure as stimulus frequency increases, and is based, in theory, on physiological processes in the auditory periphery (cf. Weiss and Rose, 1988). Model predictions were obtained by computing interaural correlations resulting from NoSπ conditions using either GN or LNN maskers following half-wave rectification and low-pass filtering. The model details are presented in the Appendix. The model simulations indicated a *larger* change in interaural correlation when the signal was added to LNN than when added to GN. Thus, assuming that a listener requires a *fixed criterion change in interaural correlation* to detect the presence of a signal, the model predicts that thresholds should be 3 to 5 dB *lower* for the LNN than the GN masker in the NoSπ condition. Combining the above assumption and model predictions with the report by Hartmann and Pumplin (1988) for the detection of a tone in LNN and GN, one may formulate general predictions for the present experiment. For homophasic conditions, masked thresholds should be lower for LNN than for GN and should be similar at 500 and 4000 Hz. For antiphasic conditions, thresholds should also be lower for LNN than GN, and should be higher for both masker types at 4000 Hz than at 500 Hz, the latter due to the loss of fine-structure coding.

The purpose of the present investigation was to explore the contributions of stimulus envelope and fine structure to monaural and binaural processing using a MLD paradigm. Characteristics of the masker envelope were manipulated by using noises differing in the normalized fourth moment of the envelope while the fine structure was manipulated by varying the stimulus frequency. The results will be considered in terms of current models of monaural and binaural processing. The reader should note that the authors became aware of an independent, ongoing investigation of the MLD using LNN maskers by Hall *et al.* (1998) during the course of this study. Discussions between the authors revealed that, although substantial differences in experimental method were employed, the results obtained seemed wholly compatible. Thus, the authors decided to submit the works as companion papers.

I. GENERAL PROCEDURES

A. Conditions

Masked pure-tone thresholds were obtained at 500 and 4000 Hz for homophasic (NoSo) and antiphasic (NoSπ) stimulus configurations using five masker types. The maskers of primary interest were Gaussian noise (GN) and low-noise noise (LNN). New samples of Gaussian noise were generated on each observation interval as the sum of sinusoidal components having Rayleigh-distributed magnitudes and uniformly distributed phases (0 to 2π). The LNN masker was composed of a single set of sinusoidal components having equal magnitudes and phases chosen such that the fourth moment of the waveform was minimized.[3] The same noise sample was presented in every observation interval of a given psychophysical trial and thus can be considered frozen noise in a statistical sense. Any differences in masked thresholds obtained with these two noise types might be attributed to three factors: (1) magnitude spectrum (contoured versus flat), (2) waveform regularity (random versus

frozen), or (3) temporal envelopes (fluctuating versus flat). Additional masking conditions were included to control for the first two possibilities.

To control for differences in the spectral shape or contour, masked thresholds were obtained with random samples of EMN. Any differences between GN and LNN attributable to differences in spectral shape might arise as differences in threshold between the GN and EMN maskers. Based on the statistical attributes of the two noise types, substantial differences in thresholds with these two maskers were not expected. To control for the random versus frozen difference, a sample of EMN having a fourth moment equal to the mean of the distribution of fourth moments (1.95) was chosen. This masker, termed medium-noise noise (MNN), is similar to the LNN masker in spectral shape (equal magnitudes) and regularity (same noise presented in every observation interval). On the basis of envelope fluctuation alone, thresholds obtained with EMN and MNN should be similar, since on average they will have the same fourth moment. However, if the frozen nature of the MNN influences detection, then the obtained thresholds should differ.

It is important to note that, for all frozen-noise maskers used in this study, the envelope starting phase was randomized across intervals in an attempt to reduce the possibility of improved detection resulting from the memorization of various aspects of the frozen maskers through repeated presentation. This was accomplished by the addition of a phase shift to each sinusoidal component proportional to the component frequency. The amount of phase shift was random from interval to interval. This operation resulted in a new starting point for the waveform presented in each interval and had no influence on the fourth moment of the envelope.

Finally, for completeness a high-noise noise (HNN) masker was included. It was reasoned that if thresholds were highly dependent on the magnitude of the fourth moment, then perhaps there would be a systematic change in threshold along the continuum of fourth moment values (e.g., LNN, MNN, and HNN). The HNN was arbitrarily defined as the sample of EMN which was the same distance from the mean of the EMN distribution as the LNN sample (0.91 units). Thus, the HNN had a fourth moment of 2.88.

B. Stimulus generation

All stimuli were generated using a digital array processor (TDT AP2) and two 16-bit D/A converters with a sampling period of 24.4 μs (40 984 Hz). Noise bands were generated in the frequency domain by filling portions of two 16 384-point buffers with the appropriate component magnitudes or phases. The magnitudes were scaled so that each noise sample had the same overall energy and a random, frequency-proportional phase shift was added to each component. A subsequent inverse FFT on the complex buffer pair yielded the desired noise waveform having a bandwidth of 50 Hz and a pressure spectrum level of 50 dB SPL. Pure-tone signals were generated in the time domain and were random with respect to the masker. The masker and signal were shaped by 10-ms $\cos^2$ onset and offset ramps and output simultaneously (400 ms) via separate D/A converters, and routed through two dual-channel adders (TDT SM1). One channel was equipped with a phase-inverter which, when engaged, introduced a phase shift of π radians.

C. Procedures

An adaptive, two-interval, two-alternative forced-choice method with a three-down, one-up tracking algorithm was used to estimate the signal level corresponding to 79.4% correct detection (Levitt, 1971). The step size in the adaptive procedure was 2 dB. Threshold was estimated by averaging the signal level at each of the last even number of reversals, excluding the first three reversals. The final threshold for a condition was taken as the average threshold across six 60-trial blocks. Three additional runs were included if the standard deviation across the six runs exceeded 2.3 dB. Each trial, consisting of two 400-ms observation intervals separated by 400 ms and marked by LEDs, was followed by visual feedback. Stimuli were presented via ER-2 (Etymotic) insert earphones and testing was conducted in a sound-attenuating chamber.

D. Listeners

Seven listeners participated, ranging in age from 22–30 years. All had pure-tone thresholds of 15 dB HL or better at octave frequencies from 250 to 8000 Hz and normal middle-ear function based on a screening tympanogram (Y, 226 Hz). Only one of the listeners had previous experience in psychoacoustic listening tasks. Excluding the two authors, listeners were paid an hourly wage and received a 10% bonus upon completion of the study.

The possible effects of practice on listener performance were examined and found to be minimal. Subjects who initially showed small MLDs at 500 Hz were given additional practice (approximately 1200 trials) prior to data collection with no substantial improvement. Upon the completion of data collection, thresholds for several conditions were re-estimated and no substantial differences (<2 dB) were found for any listener.

II. RESULTS

The mean data are shown in Fig. 3, with the upper two panels displaying masked thresholds (in dB SPL) and the lower two panels displaying the corresponding MLDs (in dB). The five masker conditions are listed on the abscissa. Data for the 500- and 4000-Hz frequencies are shown in the left and right columns, respectively.

A. Homophasic detection

In the homophasic condition (filled squares), the GN, EMN, MNN, and HNN maskers produced roughly the same amount of masking, with thresholds ranging from 60–65 dB SPL (mean$=62.9$, s.e.$=0.5$). The LNN produced about 5.5 dB less masking than the other four masker types, the average threshold being 57.4 dB SPL. This difference is consistent with previous comparisons of masked thresholds in GN and LNN for frozen noise maskers (Hall *et al.*, 1996; Hart-

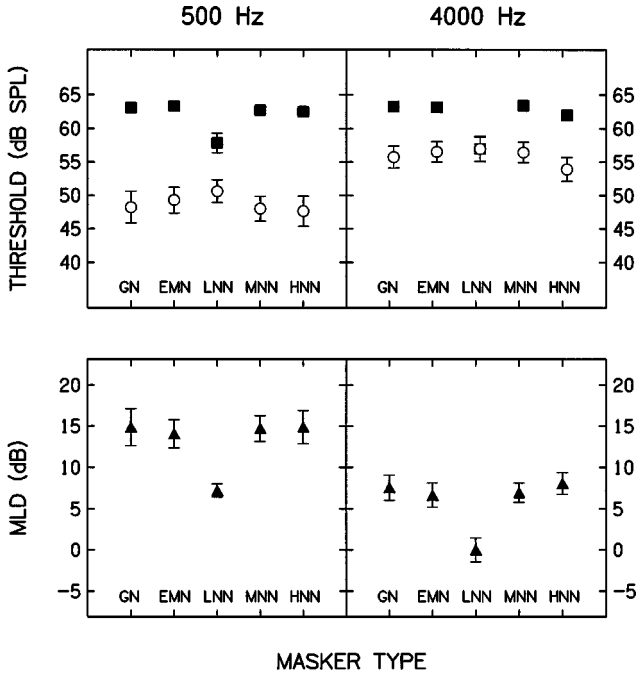

FIG. 3. Mean thresholds in dB SPL (upper panel) and corresponding masking level differences in dB (lower panel). The results are shown for 500 Hz on the left and 4000 Hz on the right. The five masker types are shown on the abscissa. Symbols represent the NoSo (filled circles) and NoSπ (open squares) conditions.

mann and Pumplin, 1988; Kohlrausch, 1996) and for random noise maskers (Kohlrausch, 1996). One of the listeners, however, showed no threshold difference between the LNN and the other masker types at either 500 or 4000 Hz. This listener generally had the highest NoSo and NoSπ thresholds and the smallest MLDs of the seven listeners. Interestingly, one of the six listeners in the Hartmann and Pumplin (1988) investigation showed equivalent homophasic thresholds in their LNN and GN conditions. That listener also had the highest thresholds across conditions among their six listeners.

Differences among thresholds obtained with the GN and LNN maskers can be better understood by first considering the relatively small differences in NoSo thresholds obtained with GN, EMN, MNN, and HNN. The lack of a threshold difference for the GN and the EMN maskers indicates that the shape of the short-term magnitude spectrum had little influence on tone detection in narrow-band noise, as expected. Further, thresholds were not strongly influenced by the use of frozen noise samples, as demonstrated by threshold comparisons between the MNN and EMN maskers. This result is contrary to many previous studies comparing masked thresholds in frozen and random narrow-band noise (e.g., Isabelle and Colburn, 1991; Kidd *et al.*, 1993). Evidence from those studies and from this laboratory (Eddins, 1996) indicate that listeners often are able to ''learn'' the pattern of envelope fluctuations of a frozen noise, facilitating detection and discrimination. The ''frozen'' stimuli used here, however, were randomized with respect to time, and thus were somewhat ''thawed,'' a process that apparently was successful in limiting listener's abilities to learn specific masker characteristics. Finally, although the fourth moments associated with the LNN, MNN, and HNN maskers increased progressively (1.04, 1.95, and 2.88), thresholds in these conditions did not reflect this systematic change. The NoSo thresholds were clearly lowest with the LNN masker, but there was essentially no difference between thresholds in the MNN and HNN conditions. Thresholds do not appear to be highly dependent on the magnitude of the fourth moment over the entire range of possible values. Given these results, it is reasonable to assume that the difference between masked thresholds in the GN and LNN conditions are the result of temporal differences between the two maskers.

B. Antiphasic condition

Thresholds for the antiphasic condition (open circles) were similar across all five masker types. Thus, the advantage gained for NoSo detection in LNN did not extend to NoSπ detection. In fact, for each listener, the NoSπ threshold was slightly worse for LNN than for GN. In addition, there were marked differences across frequency, with thresholds averaging 7.2 dB higher at 4000 Hz than at 500 Hz. A repeated-measures analysis of variance revealed significant main effects of frequency [$F(1,24)=7.20$, $p=0.01$], interaural condition [$F(1,24)=52.53$, $p<0.01$], and masker type [$F(4,96)=8.59$, $p<0.01$] as well as significant interactions of frequency and interaural condition [$F(1,24)=60.00$, $p=0.01$] and interaural condition and masker type [$F(4,96)=3.37$, $p<0.01$]. *Post hoc* analyses (Tukey-HSD) of the interaural condition–frequency interaction confirmed that while NoSo thresholds did not differ across frequency, the NoSπ thresholds differed from each other at 500 and 4000 Hz and from the NoSo thresholds at either frequency. Similar analyses of the interaural condition–masker type interaction revealed three significant differences: (1) lower NoSo thresholds for the LNN masker than the other four maskers, (2) higher NoSo than NoSπ thresholds for all masker types, and (3) higher NoSπ thresholds for the LNN masker than for the HNN masker.

The lower two panels of Fig. 3 show corresponding MLDs at 500 (left) and 4000 Hz (right). The MLDs were similar in magnitude for the GN, EMN, MNN, and HNN maskers, averaging 14.6 dB at 500 Hz and 7.3 dB at 4000 Hz. Most interesting are the very small MLDs obtained with LNN maskers, averaging 7.2 and 0.0 dB at 500 and 4000 Hz, respectively. A repeated-measures analysis of variance on the MLDs revealed significant main effects of masker type [$F(4,48)=61.70$, $p<0.01$] and signal frequency [$F(1,12)=6.51$, $p<0.01$] but no masker-frequency interaction. *Post hoc* analyses (Tukey-HSD) revealed that the MLDs obtained with the GN, EMN, MNN, and HNN maskers were not significantly different from each other but were all significantly higher than the MLDs for the LNN maskers. Thus, MLDs were smaller for LNN maskers than for maskers with higher fourth moment values and were smaller at 4000 than 500 Hz.

C. Individual differences among subjects

Despite having only a 5-dB range of thresholds across listeners in the NoSo conditions, large individual differences in the NoSπ thresholds were obtained. These are reflected in the error bars about the open symbols of Fig. 3. As an ex-

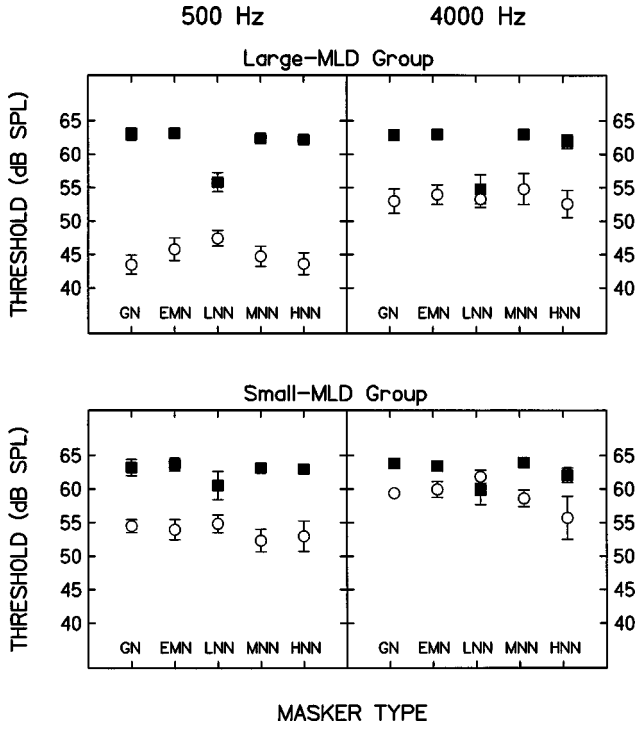

FIG. 4. Thresholds in dB SPL for the large-MLD group (upper panel) and the small-MLD group (lower panel). The results are shown for 500 Hz on the left and 4000 Hz on the right. The five masker types are shown on the abscissa. Symbols represent the NoSo (filled circles) and NoSπ (open squares) conditions.

ample, consider the GN masker at 500 Hz. Four of seven listeners had MLDs exceeding 17 dB, while the three remaining listeners had MLDs less than 10 dB, almost entirely due to differences in the NoSπ conditions. As a result, the mean MLDs for the GN masker, as shown in Fig. 3, are somewhat smaller than those typically reported for very narrow masker bandwidths (Bernstein and Trahiotis, 1992b; Hall and Harvey, 1984; Kohlrausch *et al.*, 1995; McFadden and Pasanan, 1978; Metz *et al.*, 1968; Staffel *et al.*, 1990; Zurek and Durlach, 1987). To better appreciate the rather large individual differences here, as well as the large differences among stimulus conditions obtained for some listeners, the data are considered below for a large-MLD group (four listeners) and a small-MLD group (three listeners), separated on the basis of their MLDs in the 500-Hz, GN masker condition. The results for these two groups are plotted in the upper and lower panels of Fig. 4 as a function of masker type. The data for the 500- and 4000-Hz conditions are shown in the left and right columns, respectively.

Considering first the thresholds for the NoSo conditions (filled squares), it is clear that the GN, EMN, MNN, and HNN maskers produced roughly the same amount of masking for each subgroup. Thus, differences in performance across the groups would not appear to result from a general deficit in masked signal detection. Substantial differences between the two groups were obtained for the LNN conditions. The LNN produced about 8 dB less masking than GN for the large-MLD group at both test frequencies, whereas the difference was only about 3.5 dB for the small-MLD group.

The NoSπ thresholds (open circles) revealed a pattern of results that were similar at 500 and 4000 Hz and generally similar across subject groups. While both subject groups demonstrated higher NoSπ thresholds at 4000 Hz than at 500 Hz, performance for the small-MLD group averaged 7.1 dB worse than the large-MLD group. The average MLDs for the GN, EMN, MNN, and HNN maskers were 18.3 dB at 500 Hz and 9.1 dB at 4000 Hz for the large-MLD group, as compared to 9.8 (500 Hz) and 4.9 dB (4000 Hz) for the small-MLD group. The results for the large-MLD group are consistent with many previous studies with Gaussian, narrow-band noise maskers in terms of the magnitude of the masking release and the difference across frequency (Bernstein and Trahiotis, 1992b; Hall and Harvey, 1984; Kohlrausch *et al.*, 1995; McFadden and Pasanan, 1978; Metz *et al.*, 1968; Staffel *et al.*, 1990; Zurek and Durlach, 1987). For LNN, however, the MLDs were relatively small with substantial between-group differences. The LNN MLDs at 500 and 4000 Hz were 8.4 and 1.5 dB for the large-MLD group and 5.7 and -2.0 dB for the small-MLD group, respectively, which reflected a decrease in NoSo threshold combined with a slight increase in NoSπ threshold. Despite their differences, the groups demonstrated a similar pattern of thresholds and MLDs across masker type and frequency, suggesting that their binaural processing was not fundamentally different. Relative to the small-MLD group, however, the large MLD group consistently showed better detection in all of the antiphasic conditions *and* in the NoSo LNN conditions. These differences may reflect basic differences in encoding, processing, and/or attention to the rather subtle cues (monaural and binaural) carried by the temporal envelope.

III. DISCUSSION

A. Individual differences

The large individual differences reported here for the NoSπ conditions are not uncommon in the MLD literature, although the most substantial individual differences typically occur with narrow-band maskers at high-signal frequencies. At frequencies of 1000 Hz and below, threshold differences among listeners as large as 5 to 9 dB have been reported (Hall and Grose, 1995; Hall and Harvey, 1984; Jain *et al.*, 1991; Staffel *et al.*, 1990). Several factors may account for the very large differences (>16 dB) at 500 Hz among our seven listeners. First, general deficits in binaural processing cannot be ruled out. Unfortunately, no other tests of binaural hearing were conducted with the three listeners in the small-MLD group to either confirm or refute this possibility. Second, large individual differences in masked thresholds, particularly in masking release paradigms, have been associated with ''burst'' masking paradigms, in which the signal and masker are gated on and off synchronously (e.g., Fantini *et al.*, 1993; McFadden and Wright, 1992; Hatch *et al.*, 1995), although this is not a universal finding (e.g., Hall and Grose, 1990; Kohlrausch, 1986). Although a comprehensive evaluation of the burst-continuous continuum was not pursued, an informal test using several masker-fringe conditions was conducted for one listener (who had the highest thresh-

olds in NoSπ and in LNN conditions) with no substantial change in threshold for any condition.

In addition to the observation of rather large individual differences, several important results related to both monaural and binaural hearing emerge from these data. The following discussion addresses first the results obtained in the NoSo conditions, along with relevant models of monaural processing, followed by a discussion of the NoSπ conditions and models of binaural processing.

B. Homophasic detection

Implicit here is that the diotic condition, NoSo, primarily reflects monaural auditory processing as this condition does not introduce interaural differences, *per se*. This assumption is supported, in part, by the common result that thresholds are equivalent in the NmSm and NoSo stimulus configurations (e.g., Blodgett *et al.*, 1958).[4] The three most notable results obtained in NoSo detection are: (1) improved detection in LNN relative to the other maskers, (2) the lack of a systematic change in threshold with changes in the fourth moments of the maskers (LNN, MNN, and HNN), and (3) the similarity among thresholds at 500 and 4000 Hz. Any comprehensive explanation should address these three findings. The results of several recent investigations of monaural perception of tones masked by frozen and random narrow-band noise suggest that the masker envelope may have considerable influence on signal threshold, although the exact way in which listeners use such cues remains unclear (e.g., Kidd *et al.*, 1993; Kohlrausch, 1996; Richards, 1992). Indeed, the 6-dB difference between thresholds obtained with the GN and LNN maskers (8 dB for the large-MLD group; 3 dB for the small-MLD group) likely reflects differences in the masker envelope. The magnitude of this threshold difference is in good agreement with previous reports on the detection of tones in GN and LNN. For example, Hartmann and Pumplin (1988) reported a 5-dB difference in thresholds for frozen maskers using GN and LNN, whereas Kohlrausch (1996) reported differences of 8 dB in a frozen noise condition and 5 dB in a random-noise condition. Though minor, the differences among the three studies might well reflect differences in the stimulus bandwidth (100 Hz for Hartmann and Pumplin and Kohlrausch versus 50 Hz here), individual differences among listener performance (as noted here and by Hartmann and Pumplin), differences in the specific noise samples, and/or differences in the random nature of the noises (e.g., Kohlrausch).

Since the GN and LNN maskers were equal in overall energy, an explanation based on a simple energy detector model appears inconsistent with the large difference in thresholds reported, a conclusion common to several recent investigations using narrow-band maskers (Hartmann and Pumplin, 1988; Kidd *et al.*, 1993; Richards *et al.*, 1991; Richards, 1992).[5] In addition, the fact that thresholds did not differ across frequency suggests that the fine structure of the stimulus was not an important determinant of threshold in the NoSo conditions. Thus it seems that the present results favor an explanation for these differences based on changes in the temporal envelope of the signal-plus-masker stimulus.

In four of the five masker types employed here (GN, EMN, MNN, and HNN), the masker itself had salient fluctuations and the addition of a signal tended to reduce those fluctuations. A reasonable decision rule for signal detection, therefore, would be ''choose the interval containing the stimulus with the 'smoother' temporal envelope.'' For the LNN masker, however, the detection strategy might be quite different. In this case, the noise masker alone has a very smooth temporal envelope, with minimal fluctuations and the addition of a tonal signal *increases* the amount of envelope fluctuation. Thus, an appropriate decision rule would be the inverse of the rule stated above.

A variety of models and/or decision statistics have been suggested to account for the detection of a tonal signal masked by a narrow-band noise. In an attempt to illuminate potential cues related to signal detection in the present experiment, a series of computer simulations was conducted employing several common models of signal processing based upon an analysis of the stimulus envelope (e.g., Green *et al.*, 1992; Forrest and Green, 1987; Hartmann and Pumplin, 1988; Richards, 1992; Viemeister, 1979). As none of the models employed here are new, only a brief description will be provided. The interested reader is referred to the original papers for additional detail.

Due to the narrow bandwidth of the stimuli used in the present experiment, the effect of peripheral filtering on stimulus processing was judged to be relatively minor, and no attempt was made to incorporate such filtering in the simulations. For each of the six models, the stimulus envelope was extracted from the digital signal[1] prior to computing a particular decision statistic. In the first model examined (power spectrum of the envelope), psychometric functions were generated for each masker type, based on 1000 stimuli per level. From these functions, the signal level corresponding to 79.4% correct was estimated and taken as threshold. In the remaining five models, threshold estimates were based upon the same adaptive tracking procedure described in Sec. I C. In each case, 20 threshold estimates were obtained for each of the 10 stimulus conditions (2 frequencies by 5 masker types). Unless otherwise noted, the predictions of each model were essentially the same for the 500- and 4000-Hz stimuli and are only reported for the 500-Hz stimuli. While three of the models yielded predicted thresholds that were markedly different from those obtained behaviorally, the other three provided predictions that closely mimicked the pattern of behavioral thresholds obtained.

The power spectrum of the envelope model (PSEN) is a modification of the quasi-optimum detector of changes in the shape of envelope power spectrum proposed by Green *et al.* (1992). In this model, it is assumed that the auditory system extracts the waveform envelope and bases subsequent decisions upon changes in the shape of the power spectrum of that envelope resulting from the addition of a signal. Green *et al.* showed that (1) the powers of various envelope components are nearly exponentially distributed, and (2) an optimum decision statistic would be the cross correlation of the normalized envelope power spectrum and the weights $(\eta - \tau)$, where η is the exponential parameter representing the masker and τ is the exponential parameter for the signal plus

TABLE I. Behavioral thresholds for the large-MLD group and corresponding predictions for ten models of monaural perception for each of the five masker types listed on the left. Differences between predicted and obtained thresholds are shown in parentheses. Stimulus conditions are identical to those described in the Methods section. See text for descriptions of the various models.

	THD LG MLD	PSEN	EMS ENV	NUM MAX	$M4$	σ/μ ENV	Mx/Mn ENV
GN	63.00	63.00 (0.00)	60.43 (2.57)	62.82 (0.18)	63.85 (−0.85)	64.08 (−1.08)	65.34 (−2.34)
LNN	55.80	53.90 (1.90)	55.56 (0.24)	53.9 (2.71)	28.65 (27.15)	31.39 (24.41)	43.12 (12.68)
EMN	63.10	63.00 (0.10)	60.41 (2.69)	63.04 (0.06)	64.14 (−1.04)	63.75 (−0.65)	64.45 (−1.35)
MNN	62.40	59.40 (3.00)	60.43 (1.97)	60.85 (1.55)	63.55 (−1.15)	62.97 (−0.57)	52.30 (10.10)
HNN	62.20	56.10 (6.10)	58.12 (4.08)	59.61 (2.59)	58.52 (3.68)	54.78 (7.42)	62.22 (−0.02)

masker. Following Green *et al.*, the fixed set of component weights ($\eta_i - \tau_i$) was obtained separately for each masker type by subtracting the normalized envelope power for a signal added to the noise at an E/No of 10 dB from the normalized envelope power for the masker alone. Next, it was assumed that the estimation of optimal weights and the extraction of the stimulus envelope by human observers would be imperfect. Thus, internal noises were introduced at both of these stages, modeled as independent additive Gaussian processes. The model predictions obtained for a 500-Hz signal frequency are shown in column 2 of Table I (labeled PSEN) along with the mean thresholds obtained for the large-MLD group in column 1 (labeled THD).[6] The difference between predicted and obtained thresholds are listed below each model prediction. On average, the model predictions were slightly better than the behavioral thresholds (2.2 dB), however, there was a substantial discrepancy for the HNN masker (6.1 dB). Because the pattern of predicted and obtained results differs somewhat, several additional models are considered below.

In the second model, employed successfully by Richards (1992) and Bernstein and Trahiotis (1994), detection is based on the ratio of the envelope mean slope of the signal-plus-masker and masker-alone waveforms. The envelope slope was estimated as follows: the envelope was extracted, normalized, and the absolute values of the differences between successive points in the digital representation of the envelope were averaged. Again it was assumed that this process would be influenced by internal noise associated with coding the envelope slope. Thus, an internal (Gaussian) noise was added to this process. For GN, EMN, MNN, and HNN, the decision rule was to choose the waveform having the smaller mean difference (''smoother'' envelope) as the signal-plus-noise waveform. For LNN, an opposite rule was used. The thresholds obtained from simulations employing an adaptive threshold tracking procedure are shown in column 3 of Table I (labeled EMS). The predicted thresholds are similar to those obtained behaviorally, and similar in pattern to those obtained with the PSEN model. The greatest discrepancy between predicted and obtained thresholds again occurred for the HNN masker (4.08 dB).

Despite the close agreement between behavioral thresholds and those estimated from the models above, a model based simply on a count of the number of envelope maxima provided the most accurate threshold predictions of all. As before, the model included additive internal noise and the decision rule was to choose as the signal the stimulus containing the fewer envelope maxima. The results of this simulation are shown in column 4 of Table I (NUM MAX). In this case, the predicted thresholds were on average 1.4 dB better than behavioral thresholds, with the greatest discrepancy occurring for the LNN (2.7 dB).

As seen in columns 5–7, the threshold predictions obtained with the next three models were, in general, *higher* than behavioral thresholds for the GN, EMN, and MNN maskers, and substantially *lower* than behavioral thresholds for the HNN and LNN conditions. In order of presentation, these models based decisions on the normalized fourth moment of the envelope (column 5, $M4$), the standard deviation of the normalized envelope (column 6, σ/μ), or the ratio of the maximum to minimum value of the normalized envelope (column 7, Mx/Mn ENV). Of the six models evaluated, the first three models provide a much more accurate description of the data than the latter three. The model which counts the number of envelope maxima is perhaps most appealing, because of the accuracy achieved, its simplicity, and the fact that it is physiologically tractable. It is not difficult to imagine a mechanism that reduces the envelope information to a simple sum of envelope peaks. To be successful over a modest range of stimulus bandwidths, the task would require accurate coding of approximately 5–125 events per second (representing bandwidths of about 10–200 Hz).

C. Antiphasic conditions

Several features of the dichotic results merit further discussion, including the small increase in $\mathrm{NoS}\pi$ thresholds for the LNN masker relative to the remaining maskers and the change in $\mathrm{NoS}\pi$ thresholds across frequency. Although $\mathrm{NoS}\pi$ thresholds were not significantly different across the five masker types, the large MLD group exhibited thresholds that were, on average, 4 dB worse for the LNN than for the

GN condition. It should be noted that Hall *et al.* (1996) reported that about half of their six listeners had poorer NoSπ thresholds with LNN than GN maskers, although the remaining half performed equally as well in the two conditions. Also note that the signal used in that experiment was narrow-band noise rather than a sinusoid.

Clearly the present results are not in accord with the predictions of the interaural envelope correlation model described in the Introduction. Recall that the predicted NoSπ thresholds were some 3–5 dB lower for LNN than GN, whereas the obtained thresholds are in the opposite direction. The work of Bernstein (1996) and Bernstein and Trahiotis (1996) indicated that binaural detection/discrimination could be explained on the basis of a constant-criterion change in the normalized correlation. The model estimates of interaural normalized correlations produced by a signal at threshold ranged from 0.91–0.99 across the five masker types at 500 Hz. This range is consistent with previous direct measures of the jnd for interaural correlation (Bernstein and Trahiotis, 1996; Koehnke *et al.*, 1986) and the range of correlations produced by threshold ITD values measured by McFadden and Pasanen (1976) and Nuetzel and Hafter (1981),[7] although the present interaural correlations tend toward the lower end of performance in those studies. At 4000 Hz, the large range of interaural normalized correlations (0.72–0.91) suggests that performance in the different masker conditions did not depend on a single-valued change in correlation, as predicted by Bernstein and Trahiotis. In a more general analysis, the low-pass filtering introduced by Bernstein and Trahiotis was omitted, and, as shown in the bottom panel of Fig. A1, the interaural normalized correlations are still larger for GN than LNN. Thus, a simple examination of interaural cross correlation does not help to explain the data reported here. Perhaps more detailed modeling, taking into account the cross-correlation space across time and frequency, would be more informative (e.g., Stern *et al.*, 1988; Stern and Shear, 1996).

Several recent models of binaural processing have emphasized, among other parameters, the relative importance of interaural time or phase differences of relatively *small* magnitude (e.g., ITDs$<$200 μs), a concept known as ''centrality'' (e.g., Jeffress, 1972; Stern and Trahiotis, 1992). This weighting of small interaural differences is based on physiological evidence that there are more neurons that are sensitive to small interaural delays than to large interaural delays (Kuwada *et al.*, 1987). An examination of the distributions of interaural differences as a function of signal-to-masker ratios (SMR) for GN waveforms indicates increasing standard deviations of IPDs and IIDs (about a mean of zero), and a shift in the maxima or modes of the probability density functions for IPDs and IIDs away from zero with increasing signal level (Zurek, 1991). Thus the *variability* and *magnitude* of interaural disparities increase with SMR (at least over a 20-dB range about threshold). Similar analyses for the five masker types used here reveal that, for a fixed signal level, the standard deviation of IPDs and IIDs increases sharply with increasing masker fourth moment (i.e., from LNN to HNN). This change is consistent with improved detectability with increasing masker fourth moment, similar to the present results. Based upon these interaural disparities, however, the predicted difference in detection among the five maskers is some 8–10 dB rather than the 3–5 dB observed. Conversely, the maxima or modes of the probability density functions shift away from mean zero as the masker fourth moment *decreases*. Taken together, these distributions indicate that IPDs and IIDs tend to be *larger* (higher modal values) and *more regular* as the masker fourth moment decreases (i.e., from HNN to LNN). These properties favor detection in LNN over GN or HNN maskers, however, the concept of centrality suggests that the *shorter* IPDs (i.e., higher fourth moment maskers) are given relatively greater weight. Thus, one possible explanation of the present results is that the change in the magnitude of interaural disparities with masker type, mediated by centrality, results in the pattern of detection thresholds reported here.

Differences in NoSπ detection at 500 and 4000 Hz are consistent with differences between the distributions of interaural phase and intensity based upon the stimulus waveform and those based upon the stimulus envelope. In particular, as suggested by Bernstein and Trahiotis (1985a, 1985b, 1986), at low signal frequencies, interaural differences may be conveyed by both the stimulus fine structure and stimulus envelope, whereas at high signal frequencies, only the envelope-based cues would be available. While the distribution of envelope-based IPDs and IIDs paralleled those based upon the waveform (see above), the standard deviation and maxima of the distributions were uniformly smaller for envelope-than waveform-based interaural differences. This is consistent with the finding of higher NoSπ thresholds at 4000 than at 500 Hz.

IV. SUMMARY AND CONCLUSIONS

The present study investigated the influence of masker envelope and fine structure on NoSo and NoSπ detection commonly measured in a masking level difference paradigm. The fourth moment of the envelope was the metric used to quantify the masker envelope fluctuations, and was systematically varied from low to high values using a low-noise noise masker as defined by Pumplin (1985) and medium- and high-noise noise maskers defined on the basis of the distribution of fourth moments obtained from a large sample of random noises. The fine structure was not manipulated *per se*, but the availability of fine-structure cues to the auditory system was varied by manipulating the stimulus frequency.

In general, NoSo thresholds were lower in the LNN masker than any of the other four masker types. The threshold values were nearly the same at 500 and 4000 Hz. Similar NoSo thresholds in the GN, EMN, MNN, and HNN maskers revealed a negligible influence of (1) the random nature of the magnitude spectrum of the narrow-band noises (Rayleigh distributed versus equal magnitude), (2) the constraints on the particular noise sample (random versus frozen), and (3) rather substantial variation in the masker envelope fluctuations over the range of moderate to high fourth moment values. Detection thresholds in the NoSo condition were best described by a model that was based on the number of envelope maxima in the masker alone or masker-plus-signal.

The NoSo thresholds were similar across the seven normal-hearing subjects; however, substantial individual differences in NoSπ thresholds were obtained. On the basis of the size of the MLD obtained for GN at 500 Hz, the listeners were separated into two groups, a large-MLD group and a small-MLD group, for the purpose of summary and discussion. Listeners in the large-MLD group had MLDs exceeding 17 dB while listeners in the small-MLD group had MLDs less than 10 dB in this condition.

Mean NoSπ thresholds were about 4 dB worse in the LNN masker than the GN masker at 500 Hz for the large-MLD group. This pattern of results is similar to recent results obtained by Hall *et al.* (1996) and Kohlrausch (1996). Over both frequencies, however, differences in NoSπ thresholds among the five masker types failed to reach significance for either listener group. This pattern of thresholds is inconsistent with the predictions of a simple interaural-cross-correlation model based on normalized correlation subsequent to half-wave rectification and low-pass filtering. Such a model, which has been highly successful in accounting for detection and discrimination results in the NoSπ conditions of previous investigations, predicts *better* performance ($\approx$5 dB) in the LNN masker than the GN masker. The observed pattern of binaural (antiphasic) thresholds may be understood by consideration of the distributions of interaural disparities. In general, the results are consistent with the use of changes in both envelope- and fine-structure-based interaural cues at 500 Hz, but only envelope-based cues at 4000 Hz.

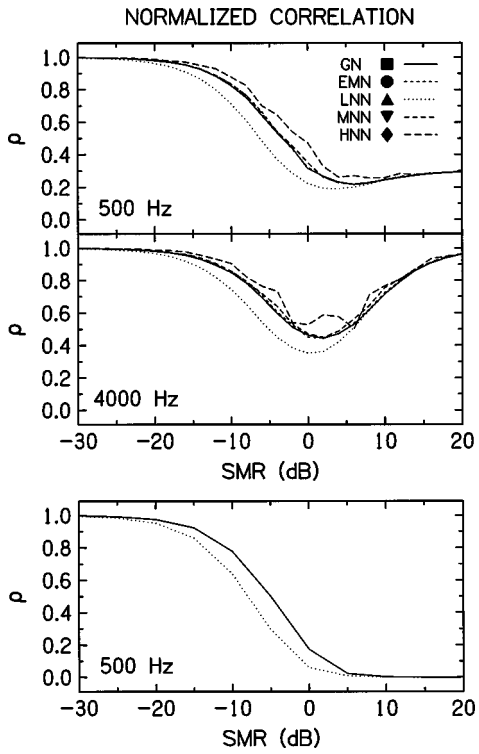

FIG. A1. Interaural normalized correlations at the output of the cross-correlation model described in the text. The curves in each panel represent different masker types. Obtained predictions from the Bernstein and Trahiotis (1996) model for the 500-Hz (upper panel) and 4000-Hz (center panel) signal frequencies and obtained predictions based upon half-wave rectified waveforms for the 500-Hz signal frequency (lower panel).

ACKNOWLEDGMENTS

The authors would like to thank Dr. Ann Clock Eddins, Dr. Larry Humes, and two anonymous reviewers for helpful comments on previous versions of this manuscript. We also thank Dr. Les Bernstein for helpful discussions concerning the cross-correlation model and Dr. Joseph W. Hall III, Dr. John H. Grose, and Dr. Armin Kohlrausch for interesting discussions of masking by LNN.

APPENDIX: NORMALIZED CROSS-CORRELATION ANALYSES

This Appendix provides a description of the interaural normalized cross-correlation model presented in the Introduction and a description of model predictions for the conditions of the present experiment. The model was first described by Bernstein (1996) and Bernstein and Trahiotis (1996) to explain NoSπ detection and is based simply on the normalized cross correlation of the stimuli at the two ears after processing by a half-wave rectifier and low-pass filter. Stimulus generation followed the methods described in Sec. I B. Interaural correlations were based on 100 trials per level and were computed over a 50-dB range of signal-to-masker ratios (SMR) in 2-dB steps.

The results of the computer simulations are shown as the curves in Fig. A1 for the 500-Hz (upper panel) and 4000-Hz (middle panel) frequencies. The lower panel will be described below. The different line types correspond to each of the five masker types of the present experiment as described in Sec. I A [Gaussian noise, GN; equal-magnitude noise, EMN; low-noise noise, LNN; medium-noise noise, MNN; and high-noise noise, HNN]. A comparison of the general form of the functions in the two panels illustrates the differences imposed by low-pass filtering. Note that for a given SMR, smaller interaural correlations correspond to better detection. The work of Bernstein (1996) and Bernstein and Trahiotis (1996) indicated that binaural detection/discrimination could be explained on the basis of a constant-criterion change in the normalized correlation. Under such an assumption, the model predicts that detection would be best for LNN, followed by GN, EMN, HNN, and MNN (see Method section for descriptions of EMN, MNN, and HNN). Over the range of behaviorally relevant correlation values (e.g., >0.90), the curves predict some 3–5 dB better performance for the LNN than the GN condition. Threshold in these conditions corresponded to SMRs from -16 to -19 dB. At 4000 Hz, the simulations yielded the same pattern of results for small SMRs. Here, the SMRs at threshold ranged from -8 to -11 over the five masker types.

The lower panel of Fig. A1 shows interaural correlations for GN and LNN without the low-pass filter stage of the Bernstein and Trahiotis model, and thus represents a more general analysis of interaural normalized correlation. Again note that the correlations are smaller for LNN than GN, implying that the predictions reported above are not specific to the Bernstein and Trahiotis implementation of the interaural cross-correlation model.

[1]The envelope was taken as the root-mean square of the real and imaginary parts of the analytic signal derived via Hilbert transform.

[2]Important distinctions between the *normalized correlation* and the *normalized covariance* (i.e., Pearson product-moment correlation) have been detailed in recent papers by van de Par and Kohlrausch (1995), Kohlrausch *et al.* (1995), and Bernstein and Trahiotis (1996). Briefly, the two measures are equivalent if the two arguments of the correlation have a mean of zero (e.g., stimulus waveforms) but differ if their means are not equal to zero (e.g., stimulus envelopes). These studies have shown that the normalized correlation provides a better index of performance in binaural tasks than does the normalized covariance.

[3]The reader is referred to Hartmann and Pumplin (1991b), table IV B, for a list of the appropriate phases used to generate the low-noise noise.

[4]Langhans and Kohlrausch (1992) reported substantial differences in NoSo and NmSm thresholds using a frozen wideband noise and short duration tone bursts. They also reported lower NoSo thresholds for frozen noise than for running noise. In addition to duration and bandwidth differences between that study and the present experiment, no differences were seen between our running (EMN) and frozen (MNN) conditions. Thus, the randomization of the time axis in the present experiment seems to have eliminated many of the effects of ''frozen'' noise typically reported. Despite the results of Langhans and Kohlrausch, we maintain that the NoSo thresholds here primarily reflect monaural detection.

[5]Hartmann and Pumplin (1988) have suggested that an energy detector combining multiple, brief observations spanning the duration of the signal might account for the reduced masking of LNN. They did not provide a detailed description of or analysis with such a model. Perhaps a decision statistic based on the variance of those multiple observations would be able to account for the present results as well as recent results obtained with of tone-in-noise detection. It is not obvious that such a model would yield predictions that differ from the envelope-based models presented below.

[6]Any suitable model would have to account for the results of all listeners rather than the ''average'' listener or any subset of listeners. Since there were substantial differences in masked threshold across the subjects, we chose the conservative approach of gauging model performance by the thresholds obtained for the large-MLD group. In the case of each model considered, the shortcomings would also hold for the small-MLD group or the average performance across all listeners.

[7]This statement is based on the transformations of Bernstein and Trahiotis (1996) in which the threshold ITDs reported by McFadden and Pasanen (1976), and Nuetzel and Hafter (1981) were converted to corresponding normalized correlations. The reader should note that Koehnke *et al.* (1986) measured the jnd for the normalized covariance (Pearson Product Moment Correlation) rather than the normalized correlation, and for comparison the values reported in that paper should be converted to normalized correlations.

Masker fluctuation and the masking-level difference

John H. Grose and Joseph W. Hall III
The Division of Otolaryngology Head & Neck Surgery, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599-7070

(Received 22 December 1996; revised 27 July 1997; accepted 15 January 1998)

Previous work suggests that, for some listeners, masker fluctuation may be advantageous for NoSπ detection. This study tested the hypothesis that the benefit of masker fluctuation to binaural analysis is based on the ability to take advantage of epochs of low masker energy in the fluctuating masker where the cues underlying binaural signal detection are more salient. The hypothesis was evaluated using the time-domain version of COSS analysis derived by Buus *et al.* [J. Acoust. Soc. Am. **99**, 2288–2297 (1996)] which measures the perceptual weight applied by a listener within a relatively brief time window as a function of the masker level during the window. The results indicated a dependency of signal detection on short-term masker level in the NoSπ condition but not in the NoSo condition. This finding supports a new perspective indicating that binaural signal detection depends upon the envelope of a masker in a way that is fundamentally different from that typically associated with monaural detection. © *1998 Acoustical Society of America.*

INTRODUCTION

In its most common form, the masking-level difference (MLD) represents the difference in threshold levels between a signal presented interaurally in phase (So) and the same signal presented interaurally out of phase (Sπ) when both signals are masked by a noise which is presented interaurally in phase (No) (Hirsh, 1948). The magnitude of the MLD is greater at low frequencies than at high frequencies, consistent with interpretations based on the dominant role of stimulus temporal fine structure (Durlach, 1963; Hirsh, 1948; Rabiner *et al.*, 1966; Webster, 1951). However, the role of envelope cues in the binaural analysis of high-frequency stimuli has received considerable attention (Bernstein and Trahiotis, 1992; McFadden and Pasanen, 1978; Zurek and Durlach, 1987). Several recent studies have also examined the role of masker envelope, or fluctuation, in the binaural analysis of low-frequency signals (Eddins, 1996; Hall *et al.*, 1998).

The study by Hall *et al.* (1998) compared MLD performance in random-noise maskers and ''low-fluctuation noise'' maskers for a low-frequency signal. In the low-fluctuation noise condition, the degree of masker fluctuation was minimized either by selecting component phases which resulted in a low fourth moment of the waveform or by modulating a pure tone with an attenuated dc-shifted low-pass noise. The intent of the study was to test predictions arising from two classes of model of the MLD: cross-correlation models (Colburn, 1973; Jeffress, 1948; Stern and Colburn, 1978; Stern and Trahiotis, 1992) and the Equalization/Cancellation model (Durlach, 1963). For NoSo detection, it was expected that thresholds would be lower for low-fluctuation noise maskers than for random-noise maskers because, by extension from monaural conditions (Hartmann and Pumplin, 1988), tonal signals are more readily extracted from maskers whose energy fluctuations are minimal. For NoSπ detection, the two classes of model differ in their predictions. Because an Equalization/Cancellation model reduces to an energy-based mechanism for detecting signals in noise, it can be argued that such a model would predict a correspondingly lower NoSπ threshold in low-fluctuation noise than in random noise. The net result would be a constancy of MLD magnitude measured in the two masker types. A cross-correlation model on the other hand, being based on the pattern of interaural correlation, might predict no change in NoSπ threshold between the two masker types since the pattern of correlation is not expected to be a function of envelope fluctuation. Such a model would therefore predict a smaller MLD in low-fluctuation noise than in random noise. The results of the Hall *et al.* (1998) study showed partial support for the cross-correlation model in that half of the subjects showed the predicted pattern of reduced NoSo thresholds in low-fluctuation noise relative to random noise with no corresponding change in NoSπ thresholds. However, the unpredicted result was that half of the subjects showed a *decrease* in NoSπ threshold (better performance) in the random noise masker. This result suggested that, for some listeners, there is an advantage of masker fluctuation for NoSπ detection. The results of Eddins (1996) also support this interpretation.

The purpose of this study was to directly test the hypothesis that masker fluctuation is advantageous for NoSπ detection. The hypothesis is based on the premise that cues underlying binaural signal detection are more salient during epochs of low masker energy in a fluctuating masker than during epochs of high masker energy. One interpretation of the heightened cue saliency during masker ''dips'' is that the auditory system attributes greater weight to stimulus epochs where masker energy is low and where the signal-to-masker ratio is correspondingly high. This strategy amounts to ''listening in the dips,'' a strategy proposed to underlie comodulation masking release (CMR) (Buus, 1985; Buus *et al.*, 1996). Buus *et al.* (1996) tested the dip-listening hypothesis

of CMR by modifying a quantitative method known as COSS analysis (Berg, 1989) to apply to the time domain. The time-domain version of COSS analysis put forward by Buus *et al.* (1996) measures the weight attributed to a relatively brief ''listening window'' as a function of the masker level during the window. A dip-listening strategy is suggested by the result that the signal weights applied by the listener are high during epochs where the short-term masker level is low (during the envelope dips), and that weights are low when the short-term masker level is high (during the envelope peaks). In the present context, it is hypothesized that if masker fluctuation is advantageous to NoSπ detection, and if this advantage is due to a dip-listening strategy, then a time-domain COSS analysis should indicate relatively high listener weights during minima in the masker envelope and correspondingly low weights during envelope maxima. For NoSo detection, where no benefit of masker fluctuation is expected, it is predicted that listener weights should be independent of short-term masker level.

I. METHOD

A. Time-domain COSS analysis

In its original form, COSS analysis (Berg, 1989) derives the perceptual weights applied by a listener to the individual spectral components within a complex signal by measuring the sensitivity of the listener to random perturbations placed independently on each component during a signal detection task [specifically, Profile Analysis (Berg and Green, 1990)]. Buus *et al.* (1996) modified the technique to apply to a single-component signal. Rather than perturbing the individual (simultaneous) components of a spectrally complex signal, individual (nonsimultaneous) segments of a single-tone signal were perturbed. This was achieved by employing a train of iso-frequency tone bursts as the signal, where the amplitude of each tone burst was independently varied. By measuring the sensitivity of the listener to perturbations in the amplitude of individual tone bursts as a function of the short-term masker levels in which each tone burst occurred, the ability of the listener to independently weight temporal epochs of the masker could be assessed. The complete quantitative derivation of the time-domain COSS analysis is provided in Buus *et al.* (1996); key elements in the procedure are described at the appropriate junctures below.

B. Subjects

Four listeners with normal hearing participated in the experiment. Each listener had audiometric thresholds better than 20 dB HL across the octave frequencies 250–8000 Hz. All listeners were highly experienced in psychoacoustic tasks.

C. Stimuli

The signal to be detected was a train of 500-Hz tone bursts masked by a narrow band of noise centered at 500 Hz. The masking noise was obtained by digitizing a 50-Hz-wide band of Gaussian noise centered at 500 Hz. This noise was generated by passing a broadband, constant spectrum level noise through a digital filter (IHR Universal). The sampling rate of the filter was 5000 Hz and the output was lowpass filtered at 2000 Hz (VBF8 90 dB/oct). The 50-Hz-wide band of noise was then adjusted in level to optimize the dynamic range of the ADC (TDT DD1). Next, 100 segments of the noise, each segment 600 ms in duration, were digitized at a sampling rate of 5000 Hz. Following digitization, each segment was shaped with a 20-ms cosine-squared rise/fall time and stored on disk. For each observation interval of a two-alternative forced choice (2AFC) trial, one of the 100 noise segments was randomly selected for presentation, the only limitation being that the same segment could not be selected for presentation in both intervals of the same trial.

The signal consisted of a train of six tone bursts, each 50 ms in duration, centered at 500 Hz, and digitally generated at a sampling rate of 5000 Hz. Each tone burst was shaped with a 15-ms rise/fall time, where the duration of the rise/fall refers to the interval between the 10% amplitude and the 90% amplitude points. This rise/fall time was selected as being the maximum duration that would allow the peak amplitude of the tone burst to remain approximately equivalent to the peak amplitude of an unshaped 500-Hz pure tone. The level of the tone burst was then expressed in terms of the sound pressure level of the continuous unshaped pure tone. In the first stage of the experiment, the amplitude of the tone bursts was held constant. In the second stage of the experiment, the amplitude of each individual tone burst was randomly perturbed, with the perturbation being drawn from a normal distribution having a mean of 0 and a standard deviation of 3 dB. (The perturbation was limited to ± 2 standard deviations.) When presented together, the masker onset preceded the signal onset by 200 ms; the masker offset therefore lagged the signal offset by 100 ms. In each interval of a 2AFC trial, the selected masker waveform and (if the target interval) the signal waveform were output through separate DAC channels (TDT DD1) at a rate of 5000 Hz. Following low-pass filtering at 2000 Hz (VBF8 90 dB/oct), the masker waveform was presented diotically at an overall level of 80 dB SPL and the signal was presented either diotically (to yield NoSo) or was inverted at one ear (to yield NoSπ). Stimuli were delivered over Sony MDR-V6 headphones to the listener seated in a double-walled sound-treated booth.

D. Procedure

In the first stage of the experiment, masked thresholds were obtained for NoSo detection and NoSπ detection. As noted above, the amplitudes of the six tone bursts in the tone-burst train were equal for this stage of the experiment. A 2AFC procedure was employed which incorporated a three-down, one-up stepping rule to converge upon the 79.4% detection level. The initial step size was 8 dB and this was reduced to 4 dB after two reversals in level direction; after a further two reversals the step size was reduced to its final level of 2 dB. A run was terminated after 12 reversals and the mean of the final 8 reversal levels was accepted as the threshold estimate for that run, provided that the standard deviation of those 8 reversal levels did not exceed 3 dB in which case the run was rejected and another one undertaken. For each signal phase condition, five threshold estimates

were collected and the mean of these five was taken as the threshold signal level. The MLD was calculated as the difference between level of the NoSo threshold and the level of the NoSπ threshold.

In the second stage of the experiment, a 2AFC procedure continued to be used but now the signal level was not varied *adaptively*. Instead, for each listener, the signal level which elicited 79.4% correct detection for each condition was targeted. However, in each trial of a 50-trial block, the level of each tone burst in the burst train was independently perturbed as described above. Each listener undertook 5000 trials and, since each trial contained six independent epochs of signal level, a total of 30 000 signal+masker combinations were collected for each listener and condition. For each listener and condition, a record was kept of every trial, including the masker waveform presented during the signal interval and the amplitudes of the six tone bursts presented in that interval.

E. Data analysis

In a preliminary step, the masker levels within 20-ms rectangular windows centered on the peaks of the signal tone-burst occurrences were computed for each of the 100 masker waveforms. These 600 levels (6 epochs $\times$100 waveforms) were divided into 10 bins of 60 levels each. Thus the bin at one extreme contained masker ''peaks'' and the bin at the other extreme contained masker ''dips.'' A look-up table was constructed in which, for each masker waveform, the sequence of six bins (i.e., the sequence of six short-term masker levels) contained within that waveform was tabulated.

After the 5000 trials for a listener and condition had been collected, the 30 000 random amplitude perturbations were also divided into 10 bins, with approximately the same number of amplitude values per bin. A 10×10 matrix was then constructed which tabulated the 10 masker level bins against the 10 signal level bins. Within each cell of the matrix, the results of the trial which included that signal level/masker level combination were accumulated. Each cell contained approximately 300 observations. For the roughly 300 observations per cell, the percent correct score was computed and converted to d' units using the tables of Green (cf. Green and Dai, 1991).

II. RESULTS

The first phase of the experiment involved the measurement of a standard MLD for the tone-burst train signal where the level of each tone burst was equal. The mean NoSo threshold level for the four listeners was 83.1 dB SPL (standard deviation=1.4 dB) and the mean NoSπ threshold level was 59.4 dB SPL (standard deviation=3.3 dB). The mean MLD was therefore 23.7 dB, which is in line with other studies using similar masker bandwidths and signal frequencies (Grose *et al.*, 1997, 1995; Zurek and Durlach, 1987).

The second phase of the experiment involved the derivation of perceptual weights for each listener and condition. The key premise in this step is that, for a given short-term masker level, the function relating d' to the energy of a signal segment (i.e., a single tone burst) should be a straight line whose slope is proportional to the perceptual weight applied to that signal segment (cf. Buus *et al.*, 1996, equation 6).[1] Accordingly, for each listener, signal phase condition, and short-term masker level, a plot was generated of d' as a function of signal intensity (i.e., the tone-burst intensity centered in each of the ten signal level bins). Figure 1 shows the results of this analysis for each of the four listeners for the two extremes of short-term masker level: the masker peaks and the masker dips. Each panel in the upper row shows the results for one listener for the NoSo condition; the lower row of panels shows the corresponding NoSπ results. In each panel, the squares indicate data for masker peaks and triangles indicate data for masker dips. Notice that the dependency of d' on signal intensity appears more marked for masker dips than for masker peaks in the NoSπ condition in comparison to the NoSo condition.[2]

In order to extract the perceptual weights, a linear regression was undertaken for each plot and the slope of the line taken as an indicator of weight for that combination of signal phase (So or Sπ) and short-term masker level. These slopes were then normalized for each listener and condition according to the equation

$$\text{normalized weight}_k = \frac{10b_k}{6\sum_{i=1}^{10} b_i}, \tag{1}$$

where the normalized weight applied to the signal during the kth range of short-term masker level is equal to the slope, b, of the regression line for that kth masker level range scaled by a value proportional to the sum of all the slopes for that condition. This normalization procedure results in a weight of 0.167 for the situation where equal weights are applied to the signal across all ranges of short-term masker level. The normalized weights computed for the individual listeners were then averaged for each signal phase condition and the results are shown in Fig. 2. Mean normalized weights are plotted against short-term masker level for both the NoSo condition (squares) and NoSπ condition (triangles). The solid line indicates the result expected if perceptual weights were uniform across short-term masker level. These data were submitted to a regression analysis which indicated that the perceptual weights for the NoSo condition did not depend upon short-term masker level [$F(1,8)=1.37$; $p=0.28$]. However, the weights for the NoSπ condition did depend upon short-term masker level [$F(1,8)=162.58$; $p<0.0001$], with greater weight being given to the signal during low masker levels.

III. DISCUSSION

The finding that listeners placed greater weight on the signal during epochs of low masker energy in the NoSπ condition but not in the NoSo condition supports the hypothesis that masker fluctuation is advantageous to NoSπ detection and that this advantage is associated with the masker minima. This is consistent with the findings of Isabelle (1995) who observed that the largest interaural differences (in terms of both phase and level) brought about by the addition of an antiphasic signal to a diotic masker occurred at

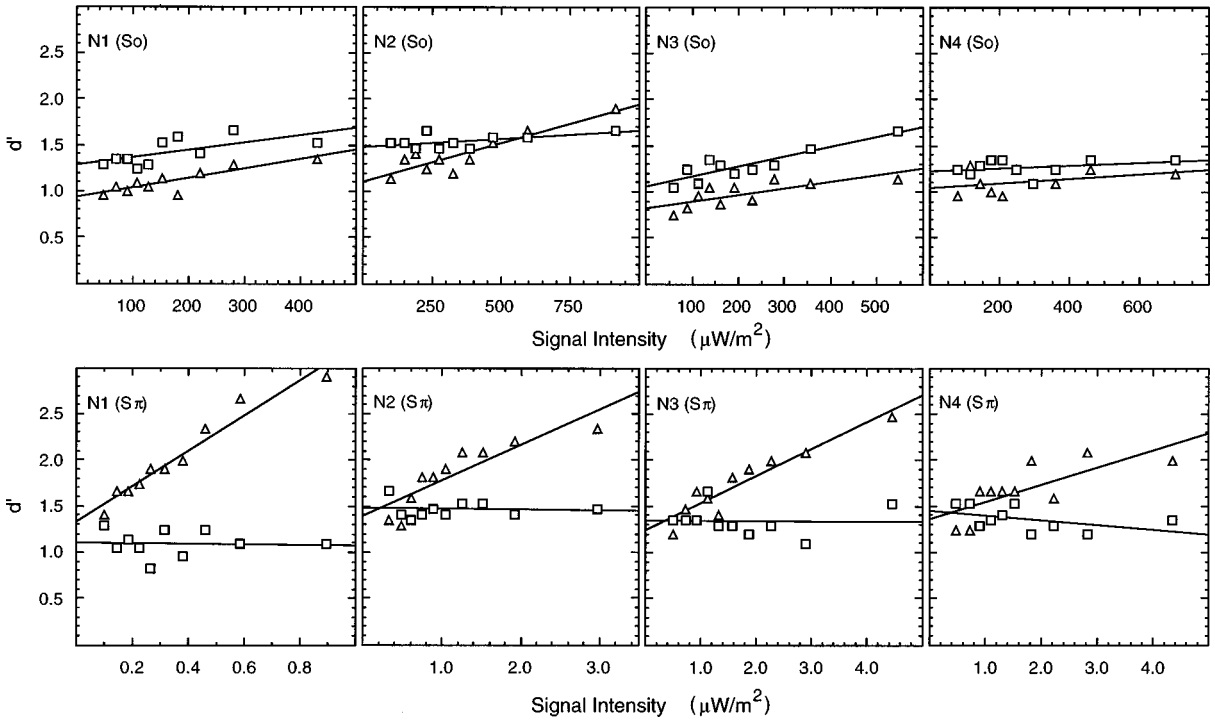

FIG. 1. Individual data for the two extremes of short-term masker level: masker peaks (squares) and masker dips (triangles). Each panel plots d' as a function of signal intensity (the tone-burst intensity centered in the range of each of the ten signal level bins). The upper row of panels show results for the NoSo condition; the lower row of panels shows the corresponding NoSπ results. Each column of panels represents an individual listener. The solid lines are best-fitting linear regressions.

minima in the masker envelope. This resulted in a significant correlation of NoSπ performance with instantaneous interaural time differences in some subjects. However, before interpreting the present finding as supporting a dip-listening strategy, some clarification of terminology is necessary. The strategy of ''listening in the dips,'' or ''dip listening,'' is associated with the phenomenon of CMR and connotes a mechanism whereby the extracted envelope of a masker remote from the signal is used to weight the contribution of stimulus epochs at the target frequency to the signal detection process. In a sense, the degree to which information at the target frequency is attended to is determined by the status of some reference envelope. In the present case of NoSπ detection, it is less parsimonious to invoke the existence of a reference envelope to control the distribution of weights. Rather, a simple monitoring of interaural differences (with uniform weight across time) would yield the same result since the influence of the signal on momentary interaural differences is relatively greater during masker minima. Thus the weights attributed to the signal in the present case of binaural detection should probably be considered a metric of cue effectiveness.

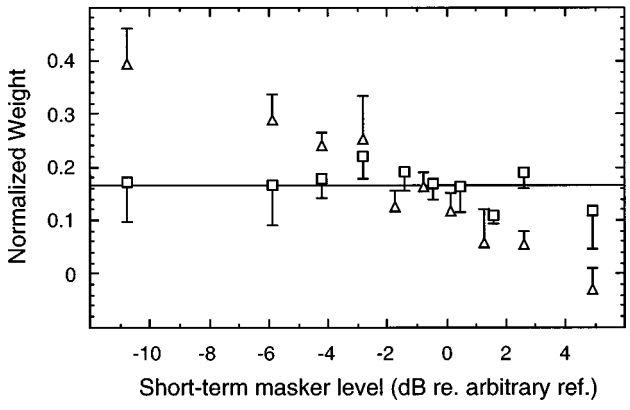

FIG. 2. Mean normalized weights as a function of short-term masker level for both the NoSo condition (squares) and NoSπ condition (triangles). Error bars are one standard deviation. The solid line indicates the result expected if perceptual weights were uniform across short-term masker level.

In conclusion, the results of this study provide new, direct evidence indicating that binaural detection differs fundamentally from monaural detection for signals in random noise in terms of the particular temporal stimulus epochs that determine signal detection. Specifically, information in the masker dips is relatively more effective in NoSπ detection than NoSo detection. It is interesting that a similar dependency of threshold on masker dip information is seen in the special monaural case of CMR. Whether the processes accounting for the masker dip phenomena in monaural CMR experiments and the present MLD experiment are related remains to be determined. The hypothesis that masker fluctuation is advantageous to NoSπ detection because of the implementation of a dip-listening strategy can be further tested. First, the hypothesis predicts that perceptual weights should be more uniform across short-term masker levels for NoSπ detection in low-fluctuation noise maskers. Second, the benefit of masker fluctuation for NoSπ detection should be evident in higher frequency regions. Evaluation of these predictions should shed further light on the role of masker fluctuation in binaural analysis.

[1]The decision variable in a 2AFC task is normally computed as the difference between the observations in the signal and standard intervals. In the present application, as equations 2–4 of Buus *et al.* (1996) show, this reduces to the weighted sum of the signal energies because (a) the masker is assumed to be independent of the signal in the signal interval and (b) the difference between the sums of the weighted masker energies in the two intervals is expected to be zero.

[2]The NoSo data (upper panels of Fig. 1) provide the impression that a signal of any given intensity is more detectable when presented in the peaks of the masker than in the dips. This counterintuitive trend is also evident in the analogous Single Band data of Buus *et al.* (1996) [see their Fig. 1]. Interpretation of this trend awaits further investigation.

Spontaneous classification of complex tones at high and ultrasonic frequencies in the bat, *Megaderma lyra*

Annemarie Preisler and Sabine Schmidt
Zoologisches Institut der Universität, Luisenstrasse 14, 80333 München, Germany

(Received 13 January 1997; accepted for publication 20 January 1998)

Megaderma lyra, a bat species using harmonically structured calls for echolocation, exploits the spectral content of its echoes for texture discrimination. It is the aim of the present study to test according to which sensory qualities harmonic complex tones are spontaneously classified by this bat. The applied experimental paradigm is especially adapted to the preference of *M. lyra* to use absolute pitch cues. Three animals were trained in a 2-AFC procedure to classify three-component stimuli as low or high, with all their harmonics below or above a pure tone reference of 33 kHz, respectively. Later, the original tones were interspersed with ''incomplete'' test stimuli, with their fundamentals (and lower harmonics) missing. These were ambiguous in that their possible virtual, i.e., collective pitches were below the reference whereas their pure tone pitches were above it. Bat 1 classified 22 of 23 test stimuli with missing fundamentals between 5.3 and 28.3 kHz according to their collective pitches, whereas bat 2 judged all presented ambiguous tones on the basis of their pure tone pitches. Bat 3 failed the pitch control criterion which is why in this case results cannot be interpreted unequivocally. The implications of these findings are discussed with respect to the bats' behavioral context, as well as to psychoacoustical models of the formation of the pitch of complex tones. © *1998 Acoustical Society of America.* [S0001-4966(98)00405-6]

INTRODUCTION

Echolocating bats predominantly perceive their environment by acoustical cues extracted from echoes of their sonar calls (Schnitzler and Henson, 1980). Recent studies on texture perception in bats with a broadband echolocation system have shown that the animals use the spectral characteristics of their echoes to discriminate between targets (Schmidt, 1992; Mogdans *et al.*, 1993). However, the sensory qualities extracted from the broadband spectral information are still unknown.

The present study was designed to test the significance of different sensory qualities, as already established for human perception, in *Megaderma lyra*, a bat species using harmonically structured sonar calls.

Human listeners are able to classify complex tones with respect to the pitches of the most prominent spectral components or to the pitch of the fundamental, and to timbre. Although pitch sensations evoked by single spectral components are likely to reflect the most elementary stage of neural processing (Whitfield, 1980), analytical listening requires training and seems to be the exception rather than the rule (Lichte, 1941; Hartmann, 1988).

In 1843, Seebeck made the unexpected observation that the perceived fundamental pitch is not affected when the first harmonic is removed from a spectrum. Later psychoacoustic experiments revealed that the case of the *missing fundamental* is just a special aspect of complex pitch perception. Terhardt *et al.* (1982) report that ''complete'' complex tones with a first harmonic below 800 Hz elicit fundamental pitch sensations that are more strongly determined by upper harmonics than by the fundamental frequency itself. For tones with fundamentals at higher frequencies, pitch sensations evoked by single spectral components become predominant. In the literature, for the latter type of sensations the term *spectral pitch* has been adopted. But as ''spectral'' refers to the physical domain and ''pitch'' to the subjective perceptual domain, we prefer the expression *pure tone pitch*. Low-frequency pitch sensations, not directly evoked by corresponding spectral components, have been termed *residue pitch* (Schouten, 1940a, b; De Boer, 1956, 1976; Ritsma, 1967; Patterson, 1973), *periodicity pitch* (Licklider, 1954; Walliser, 1969), and *virtual pitch* (Terhardt, 1974). Unfortunately, all these expressions still imply assumptions about the underlying mechanisms and thus are counterproductive for an unbiased discussion. We therefore, when referring to the pitch of complex tones, in the following confine ourselves to speak of *collective pitch* sensations. For the sake of conformity, the expression is also applied to models and data from literature, where originally a different terminology was used.

While collective pitch sensations do not depend on the presence/absence of single partials, i.e., on the exact spectral composition of a complex tone (Patterson, 1973; Terhardt, 1974; Preisler, 1993), timbre depends primarily on the frequency spectrum, although it also depends on the sound pressure and the temporal characteristics of the sound (ANSI S1.1-1994, 12.09). In other words, a complex tones' timbre is characterized by its specific spectral composition irrespective of its collective pitch. Thus, according to this definition, collective pitch and timbre represent complementary higher-order perceptual qualities.

Smoorenburg (1970) developed a two-alternative forced choice (2-AFC) test in order to test the predominance of pure tone versus collective pitch sensations. The method involves sequences of ''incomplete'' tones that are ambiguous in that their missing fundamentals rise whereas their present har-

monics fall in pitch (or vice versa). Smoorenburg (1970) reports that for two-tone stimuli less than half of the tested subjects spontaneously classified most of the sequences according to their collective pitches. However, subsequent experiments revealed that the proportion of ''collective pitch perceivers'' increases with the number of presented harmonics and strongly depends on the energy distribution of the entire spectrum (Preisler, unpublished data). Moreover, a low signal-to-noise ratio increases the percentage of decisions in favor of collective pitch (Hall and Peters, 1981).

For comparative psychoacoustical studies in higher vertebrates, modified versions of the Smoorenburg test, making use of operant conditioning methods, were applied. Results indicate that starlings (Cynx and Shapiro, 1986) and cats (Heffner and Whitfield, 1976) predominantly categorize complex tones according to the pitch of their missing fundamentals. Using a different paradigm, Tomlinson and Schwartz (1988) showed that rhesus monkeys are able to match tones with their fundamentals missing with comparison harmonic complexes having the same pitch.

It has to be emphasized that 2-AFC procedures, allowing a stimulus classification in terms of a dichotomous criterion (e.g., pure tone versus collective pitches), only indicate which characteristic is predominantly perceived by the tested subjects. Obtained preferences, however, do not reveal whether the alternative aspect of information, in principle, is available to these subjects.

Since *M. lyra*, like starlings (Hulse and Cynx, 1985), cebus monkeys, and rats (D'Amato, 1988), has been found to rely mainly on absolute pitch (Schmidt *et al.*, 1994; Preisler and Schmidt, 1995), Sedlmeier (1992a, b) applied a testing procedure especially adapted to this preference. In his experiments, five bats were trained by operant conditioning to classify the collective pitches of complex tones, consisting of the first four harmonics, as higher or lower than a fixed pure tone reference. When the first harmonic was gradually attenuated to a sound-pressure level of 0 dB and masked by bandpass noise in addition, while maintaining positive reinforcement, the animals' classification behavior remained unchanged. Sedlmeier (1992a, b) interpreted this result an evidence for collective pitch sensations in bats. However, in view of the applied experimental paradigm, the possibility of the bats simply having learned the responses by stepwise generalization cannot be ruled out. So, the bats may have memorized each of the tested spectra on the basis of the absolute pitches of their higher harmonics and reacted to them consistently on the basis of positive reinforcement.

The aim of the present study was to find out by which criteria bats spontaneously classify complex tone stimuli and thus to evaluate the significance of different sensory qualities for the animals' natural behavioral context. Therefore, in contrast to Sedlmeier's study, all responses to critical test and control stimuli were rewarded in order to avoid biased operant conditioning.

I. METHODS

A. Experimental setup

The experiments were carried out in a sound-attenuated chamber (2.5 m×3 m×2.2 m). The bats' starting position was placed 20 cm from the middle of the wall opposite to the entrance. The loudspeaker was positioned at a distance of 1.9 m, 40° below the starting position, and directly aligned with the bats' head. Two feeding dishes were mounted symmetrically to the left and right of the loudspeaker. The experimenter, seated behind the speaker, triggered the start of a trial by pressing a button. A schematic top view of the experimental setup is given in Fig. 1.

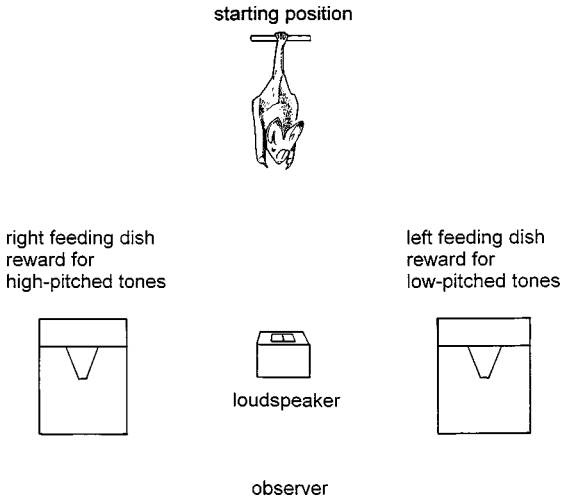

FIG. 1. Experimental chamber (for further explanations, see text).

Stimulus selection, control of external devices, and data collection were performed by a 486 personal computer. Acoustical stimuli were generated using a four-channel-synthesizer (HP 8904). They were fed into a custom-made envelope shaper, followed by an attenuator (Leader LAT-45), a buffer amplifier (chip: Burr Brown, 3553 AM), and a loudspeaker (Technics EAS-10TH800C).

B. Stimuli

1. Time pattern

The time pattern of the stimulus presentation is shown in Fig. 2. The trapezoidally shaped tone pulses had a duration of 400 ms, with rise and decay times of 1 ms. During training, a sequence of at most ten pulse pairs (which in case of reaction was interrupted by the bat's return to the perch) consisting of a reference tone followed by a comparison tone was presented [Fig. 2(a)]. The intertone interval was 400 ms and the interpair interval was 1200 ms. In the testing ses-

sions, the reference was omitted and a series of at most ten comparison tones was presented with an intertone interval of 2000 ms [Fig. 2(b)].

2. Intensity and spectral composition

The experiments were carried out at two different intensity levels (conditions 1 and 2). Standard stimuli were the same for both conditions, whereas test and control stimuli differed in order to prevent learning transfer.

Overall sound-pressure levels, as measured at the position of the bats' perch, and spectral compositions of all complex tones are listed in Tables I–III. The sound-pressure levels were balanced for standard, test, and control stimuli in order to prevent their discrimination on the basis of level cues.

For all complex tones, the relative intensities of the present harmonics decreased by 6 dB per octave. This decay was chosen as a compromise between the requirements to present test tones having a timbre similar to the bats' own calls (Schmidt, 1992) and to guarantee that all included spectral components lie above the auditory threshold of *M. lyra* (Schmidt *et al.*, 1983).

a. Reference tone. As a reference stimulus, a pure tone pulse with a frequency of 33 kHz was presented (Fig. 3, dashed line).

b. Standard stimuli. We used 24 complex tones, consisting of the first three harmonics, as standard stimuli (Table I). As indicated by the range bars in Fig. 3, the fundamentals (f_0) of the 12 low standards [Fig. 3(a)] varied between 9 and 10.5 kHz, those of the 12 high standards [Fig. 3(b)] between 34 and 39.8 kHz. For both types of standards, the fundamental frequencies were varied in steps of 25 cents ($\frac{1}{8}$ of a whole tone), a distance expected to roughly represent the bat's fre-

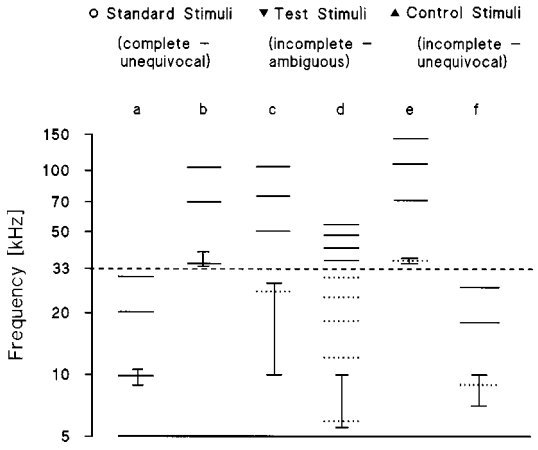

FIG. 3. Examples, indicating the spectral composition of the stimuli [dashed line: pure tone reference at 33 kHz, solid lines: presented harmonics, dotted lines: omitted harmonics, range bars: regions of the present or missing fundamentals (f_0) of all applied complex tones]: (a) low standard stimuli, (b) high standard stimuli, (c) test stimuli for bats 1–3, (d) additional test stimuli for bat 1, (e) control stimuli for bat 1, and (f) control stimuli for bats 2 and 3.

quency resolution for successively presented tones (Sedlmeier, 1992a). Since all single and collective pitches that may be elicited by a given tone are either below or above the reference, these stimuli do not discriminate between both sensory qualities and are unequivocal in this respect. Standard stimuli were presented at a sound-pressure level of 65.8 ± 1.6 dB in condition 1 and of 47.8 ± 1.6 dB in condition 2.

c. Test stimuli. Test stimuli were ''incomplete'' complex tones in which all spectral components below 33 kHz were omitted [Fig. 3(c) and (d)]. These tones are ambiguous in that their spectral components are above the reference, whereas their missing fundamentals are below it.

(i) Bats 1–3. For condition 1, five test tones with missing fundamentals between 10.6 and 26.7 kHz were presented at a sound-pressure level of 47.8 ± 2.8 dB [Table II; Fig. 3(c)]; for condition 2, ten test tones with missing fundamentals between 10 and 28.3 kHz were presented at a sound-pressure level of 65.6 ± 2.4 dB [Table III; Fig. 3(c)].

(ii) Bat 1. In addition, bat 1 was presented with three test tones with very low missing fundamentals between 5.3 and 8.4 kHz (sound-pressure level: 46.7 ± 0.6 dB) for condition 1 [Table II; Fig. 3(d)] and five test tones with very low missing fundamentals between 5.6 and 8.9 kHz (sound-pressure level: 65.4 ± 1.6 dB) for condition 2 [Table III; Fig. 3(d)].

The frequencies of the missing fundamentals were chosen in steps of 400 cents in condition 1 and 200 cents in condition 2.

d. Control stimuli.

(i) High control stimuli [Fig. 3(e)]. For animals classifying the ambiguous test tones as low, four incomplete tones, which are unequivocal in that both their possible collective and pure tone pitches are above the reference, were employed as control stimuli. Their missing fundamentals were set to 36 and 37 kHz (condition 1; Table II) and to 34 and 35 kHz (condition 2; Table III). Since the spectra of both the controls and the highest test tones consist of the second to fourth harmonic, the frequency of the missing fundamentals provides the only cue for correctly discriminating these stimulus types by means of the 33-kHz reference [cf. Fig. 3(c) and (e)]. Thus, an identification of the control stimuli as high indicates collective pitch formation. If test and control stimuli are not discriminated, the bats' behavior has to be accounted for by a characteristic both types have in common, i.e., the specific timbre of complex tones without a fundamental.

(ii) Low control stimuli [Fig. 3(f)]. For animals classifying the ambiguous test tones as high, incomplete tones, which were unequivocal in that both their possible collective and pure tone pitches were below the reference, were chosen as control stimuli. In condition 1, the frequencies of the missing fundamentals were 7 and 8 kHz (Table II); in condition 2, they were 9 and 10 kHz (Table III).

If the controls were categorized as low, the classification of the test tones is to be attributed to pure tone pitch perception. Otherwise the test tones and the controls may have been classified according to some other quality than pitch, e.g., timbre [cf. Fig. 3(c) and (f)].

3. Calibrations

The frequency response of the speaker and the spectral composition of the tone pulses were checked using a B&K measuring amplifier (2610) with a $\frac{1}{4}$-in. microphone (4135), positioned at the bats starting position and connected to a spectrum analyzer (HP3590A). Between 9 and 100 kHz, the sensitivity of the speaker dropped almost linearly by about 10 dB with local deviations of less than ± 1.5 dB.

Inspection of all incomplete tone spectra [Fig. 3(c)–(f)] revealed that nonlinear distortions were at least 60 dB down (see Fig. 4).

C. Experimental animals

Megaderma lyra (Megadermatidae; Geoffroy 1810), a gleaning bat preying on insects and small vertebrates, emits broadband (20–120 kHz) sonar pulses that comprise the first five harmonics. The sound-pressure levels of these calls vary between 75 and 80 dB (determined for hand-held animals at a distance of 10 cm to the microphone), which is relatively low as compared to other bat species that achieve sound-pressure levels of up to 120 dB (Neuweiler, 1990). The relative intensities of the spectral components show a considerable variability in the course of one call and between the individuals. Relative to the frequency region with the most prominent energy, ranging from the second to fourth harmonic, the fundamental is significantly attenuated by 20–35 dB and may have sound-pressure levels between 40 and 60 dB (Schmidt, 1992). In the course of a typical call, having a duration of 0.5 ms, the frequency of the first harmonic sweeps downward from about 26 to 19 kHz. *M. lyra*

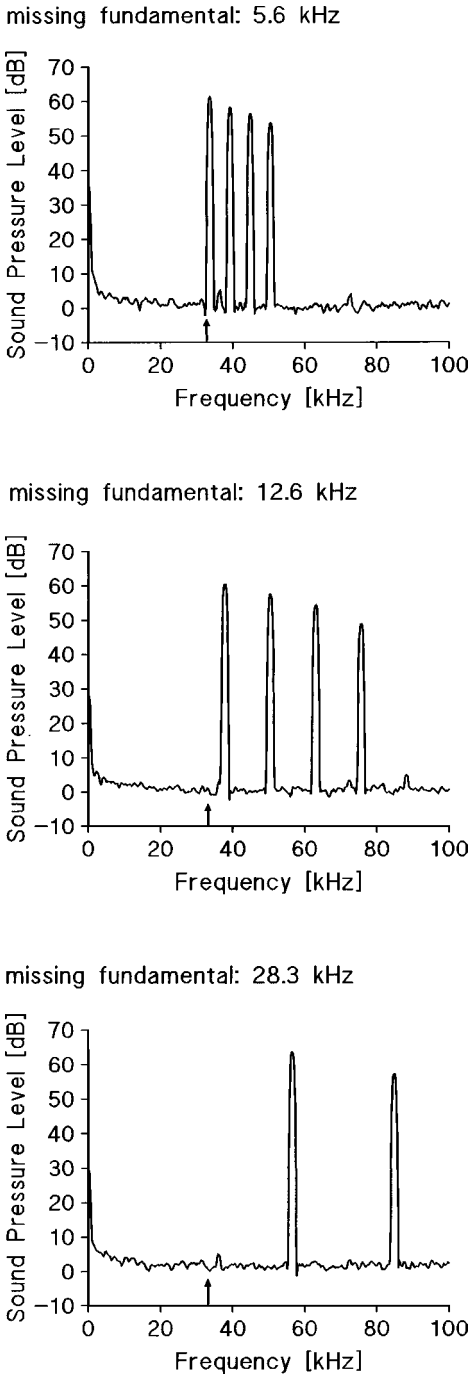

FIG. 4. Spectra of three test tones with missing fundamentals in the low-, middle-, and high-frequency region, measured at a sound-pressure level of 75 dB; S/N ratio: 60 dB (spectrum analyzer HP 3590 A). Harmonics above 100 kHz are outside the analysis range of the analyzer. The arrow at 33 kHz indicates the frequency of the pure tone reference. Please note that no nonlinear distortions are seen below the reference.

has a nearly flat audiogram with low hearing thresholds below a sound-pressure level of 0 dB in the range between 16 and 85 kHz (Schmidt *et al.*, 1983).

Three individuals (bat 1: male, 1 year old; bat 2: female, 4 years old; bat 3: female, unknown age) were used. Bats 1 and 2 were born in captivity as descendants of animals from Tirunelveli (South India). Bats 1 and 3 had already participated in psychoacoustic tests earlier.

The animals were fed mealworms exclusively during the experimental sessions. In addition, a house mouse was supplied every two weeks. The weight of the animals was monitored daily and kept at the normal individual preexperimental weight between 30 and 40 g. The bats were kept in a weakly illuminated flight room at 28 °C with free access to water.

D. Training procedure

The bats were first trained to compare the pitch of the standard stimuli to the fixed pure tone reference with a frequency of 33 kHz. They were rewarded for selecting the left or right feeding dish for standard stimuli below or above the reference tone, respectively. For every trial, a stimulus was selected randomly from a set of 24 standard tones. A correct response was rewarded by opening the chosen feeding dish, allowing the bat to take out some mealworms. Stimulus presentation stopped automatically when the animals returned to the starting position. Trials in which the bats did not select one of the feeding dishes during the ten presentations of the stimulus pair (i.e., within 24 s) were discarded. After four weeks, all three animals had learned the training tasks with a hit rate of more than 90%.

E. Testing procedure and data analysis

Since in previous studies (Sedlmeier, 1992a, b; Schmidt *et al.*, 1994) *M. lyra* has been found to have an excellent memory for absolute pitch, the reference was omitted after the training procedure without affecting the bats' discrimination performance. In the trials of each experimental session, up to 34 different stimuli were presented in random order. The standard tones were interspersed with the ambiguous test stimuli with a probability of about 25%. After the first sessions, in addition, the standard and test stimuli were interspersed with adequate control stimuli [Fig. 3(e) and (f)] in order to test whether the categorization of incomplete tones was due to perceived pitch or to any other cues.

On average, 30 trials per day were obtained from each individual. The data were collected in a period of seven months. Data points were calculated for each individual as the percentage of high categorizations for a given stimulus; each data point represents at least 30 classifications.

To evaluate the significance of the bats' decision behavior, one-dimensional χ^2 tests were performed on the obtained frequencies of left/right decisions for each stimulus. For samples of $N=30$, 75% choices to one side indicate a preference, statistically significant at $p<0.01$. For comparison of two frequency distributions, four-field χ^2 tests were calculated.

The average response latencies for different types of stimuli were compared using a t test for dependent samples. In contrast to simply recording the preferred type of reaction, latency analyses determine subtle behavioral differences that have to be attributed to underlying perceptual differentiation. When two types of stimuli are classified by means of the same predominant criterion (e.g., choice of the right feeding dish because of perceived high pitch), response latencies provide information whether these stimuli might be discerned on the basis of subdominant cues as well. In case the nature

TABLE IV. Results of bat 1 for conditions 1 and 2. The percentage of correct trials refers to their absolute number. The significance of the bat's preference for one side is evaluated by a one-dimensional χ^2 test. The average latencies are given separately for all, correct, and incorrect responses. For the ambiguous test stimuli, latencies refer to trials categorized as low or high, respectively.

Stimulus type	No. of trials	% of trials	χ^2	p	Average latency (ms)		
Standards-low		Correct			Overall	Correct	Incorrect
Condition 1	449	95.6	373	<0.001	1226	1322	3643
Condition 2	700	99.3	680	<0.001	469	446	3601
Standards-high		Correct			Overall	Correct	Incorrect
Condition 1	393	92.6	286	<0.001	4750	4980	1859

Condition 2	70	7.1	51	<0.001	3952	4121	1761

of such secondary characteristics is not directly evident from the experimental situation, it has to be subject to further considerations.

II. RESULTS

The classification behavior of the bats for different types of stimuli is summarized in Tables IV–VI. Reactions to each single task are shown in Figs. 5–7.

All bats discerned the standard stimuli as low or high with an error rate of less than 6% (Figs. 5–7; open squares). The test stimuli (Figs. 5–7; filled downward triangles) were classified differently by each bat. Nevertheless, in each individual the decision behavior was highly stable over time.

A. Animal 1

The reaction behavior for both intensity conditions is shown in Table IV and Fig. 5. The animal significantly categorized 22 of the 23 test stimuli as low [condition 1: $\chi^2_{\text{test}}=179$, $N=259$, $p<0.001$; condition 2: $\chi^2_{\text{test}}=328$, $N=478$, $p<0.001$], whereas it classified each of the four control stimuli as high [condition 1: $\chi^2_{\text{control}}=56$, $N=60$, $p<0.001$; condition 2: $\chi^2_{\text{control}}=51$, $N=70$, $p<0.001$]. This bat therefore based its final decisions on the pitches of the missing fundamentals.

Average response latencies (ARLs) for correctly classified high standard [Fig. 3(b)] and control stimuli [Fig. 3(e)], both having present or missing fundamentals between 34 and 37 kHz, differ significantly (condition 1: $\text{ARL}_{\text{control high correct}}$: 5827 ms, $\text{ARL}_{\text{standard high correct}}$: 4980 ms, $t=19.6$, df$=421$, $p<0.001$; condition 2: $\text{ARL}_{\text{control high correct}}$: 4121 ms, $\text{ARL}_{\text{standard high correct}}$: 5404 ms, $t=26$, df$=694$, $p<0.001$). As the overall intensities of both types of stimuli were balanced (cf. Tables I–III), this result cannot be accounted for by perceived level differences. Thus, it must be concluded that, despite the predominance of collective pitch sensations, the spectral composition, i.e., the timbre, of the tones was available to the animal as a subdominant cue, as well.

B. Animal 2

Results are summarized in Table V and displayed in Fig. 6. Bat 2 categorized all test stimuli as high (condition 1: $\chi^2_{\text{test}}=61$, $N=155$, $p<0.001$; condition 2: $\chi^2_{\text{test}}=193$, N

TABLE V. Results of bat 2 for conditions 1 and 2. For further explanations, see Table IV.

Condition 2	67	82.1	170	<0.001	8487	8377	8993

TABLE VI. Results of bat 3 for conditions 1 and 2. For further explanations, see Table IV.

Stimulus type	No. of trials	% of trials	χ^2	p	Average latency (ms)		
Standards-low		Correct			Overall	Correct	Incorrect
Condition 1	361	92.8	264.5	<0.001	3091	2953	4871
Condition 2	709	94.5	562	<0.001	1529	1467	2595
Standards-high		Correct			Overall	Correct	
Condition 1	311	92	219	<0.001	4313	4255	4979
Condition 2	576	94.3	543	<0.001	4743	4740	4784
Test stimuli		Low			Overall	Low	High
Condition 1	156	7.7	112	<0.001	4626	5634	4543
Condition 2	312	6.4	237	<0.001	5065	3189.5	5193
Controls (low)		Low			Overall	Low	
Condition 1	74	51.4	0.05	n.s.	4454	4841	4045
Condition 2	72	0	72	<0.001	9264	···	9264

$=304$, $p<0.001$). The animal met the control criterion by correctly classifying all four unequivocal incomplete complex tones [Fig. 3(f)] as having a low pitch (condition 1: $\chi^2_{\text{control}}=57$, $N=61$, $p<0.001$; condition 2: $\chi^2_{\text{control}}=170$, $N=67$, $p<0.001$). This bat thus focused its attention on the pure tone pitches of the present harmonics.

When presented with the ambiguous test stimuli [Fig. 3(c)], the animal decided for the low side to a somewhat higher extent than when presented with the unequivocal high standards [Fig. 3(b)]: condition 1: test tones: 18.7%, high standard tones: 6.8%, $\chi^2=15.1$, $N=463$, $p<0.001$; condition 2: test tones: 10.2%, high standard tones: 5.9%, $\chi^2=5$, $N=797$, $p=0.02$. This result may indicate that the bat based some of its decisions on the collective pitch of the test stimuli. Alternatively, it may reflect an uncertainty of the animal due to the unfamiliar timbre of the test tones.

A comparison of the average response latencies for correctly classified high standard stimuli [Fig. 3(b)] with those for test tones [Fig. 3(c)] categorized as high reveals that the animal left its starting position more quickly when presented with the latter type of stimulus (condition 1: $\text{ARL}_{\text{standard high correct}}$: 2860 ms, $\text{ARL}_{\text{test high}}$: 2798 ms, $t=16.8$, df$=411$, $p<0.001$; condition 2: $\text{ARL}_{\text{standard high correct}}$; 2626 ms, $\text{ARL}_{\text{test high}}$: 1706 ms, $t=23.9$, df$=735$, $p<0.001$). This result reveals that although both types of tones were predominantly classified according to their pure tone pitches, they were discernible on the basis of subdominant cues as well. Again, it cannot be decided from the present data whether collective pitch or timbre sensations are responsible for the observed differences. Moreover, the response latencies for correctly classified low standard [Fig. 3(a)] and low control stimuli [Fig. 3(f)] differ significantly (condition 1: $\text{ARL}_{\text{standard low correct}}$: 1697 ms, $\text{ARL}_{\text{control low correct}}$: 3434 ms; $t=11.6$, df$=342$, $p<0.001$; condition 2: $\text{ARL}_{\text{standard low correct}}$: 962 ms, $\text{ARL}_{\text{control low correct}}$: 8487 ms; $t=11.12$, df$=578$, $p<0.001$). This result can only be explained on the basis of perceived differences in timbre.

C. Animal 3

Results are summarized in Table VI and displayed in Fig. 7. Bat 3 classified all test stimuli as high (condition 1: $\chi^2_{\text{test}}=112$, $N=156$, $p<0.001$; condition 2: $\chi^2_{\text{test}}=237$,

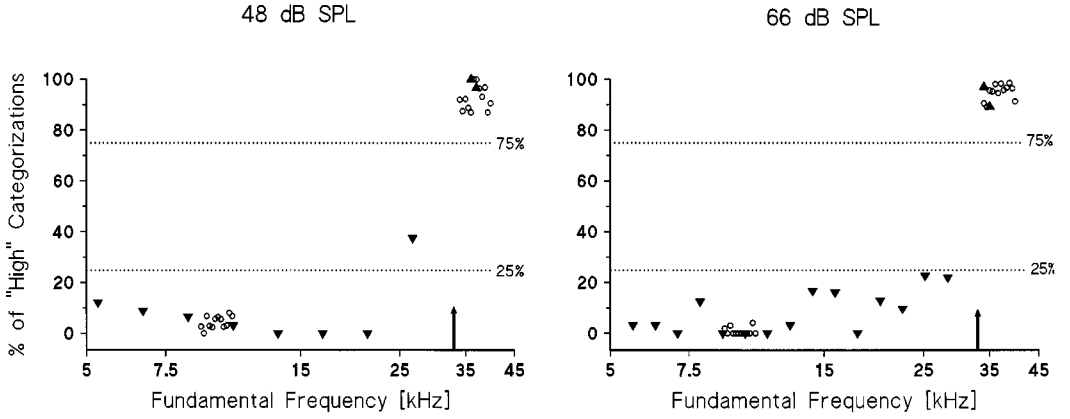

FIG. 5. Pitch classifications by bat 1 for the low-level stimuli (sound-pressure level: ~48 dB; condition 1) and the higher-level stimuli (sound-pressure level: ~66 dB; condition 2). The abscissa represents the frequency of the present or missing fundamentals of the complex tones. The arrow at 33 kHz marks the reference. On the ordinate, the percentage of choices to the side associated with a high pitch is plotted. For all stimuli, at least 30 trials were obtained per data point, corresponding to a significance level of $p<0.01$ for 75% of the choices to one side (dotted lines) for a one-dimensional χ^2-test. Small open circles (○) represent the classification behavior for the standard stimuli, filled downward triangles (▼) for the ambiguous test tones, and filled upward triangles (▲) for the control tasks.

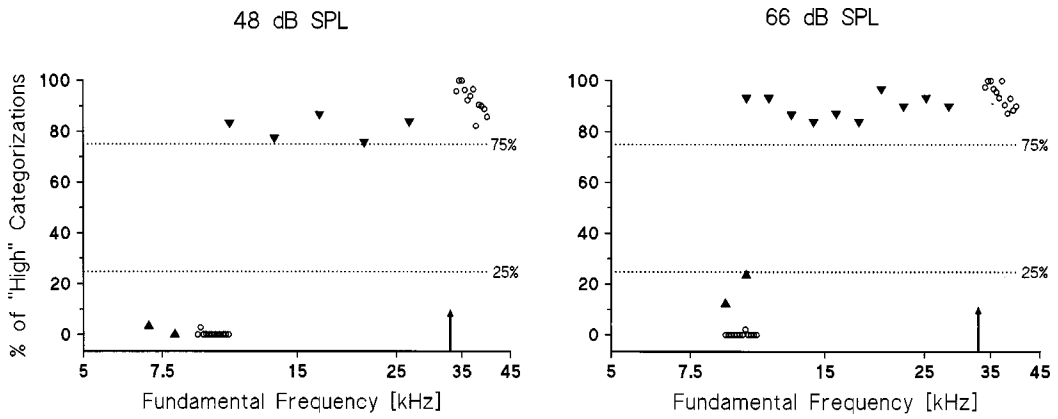

FIG. 6. Pitch classifications by bat 2 for conditions 1 (sound-pressure level: ~48 dB) and 2 (sound-pressure level: ~66 dB). For further details, see Fig. 5.

$N=312$, $p<0.001$). In contrast to bat 2, three of the four control tasks [Fig. 3(f)] were categorized in the same way as the test stimuli, i.e., the bat preferred the feeding dish associated with a high pitch (condition 1: $\chi^2_{\text{control}}=0.05$, $N=74$, n.s.; condition 2: $\chi^2_{\text{control}}=72$, $N=72$, $p<0.001$). This result is incompatible with the assumption that this bat used either collective or pure tone pitches as the decisive cue. We hypothesize that bat 3 preferably paid attention to the similar timbre of all incomplete tones and arbitrarily associated this characteristic with the right feeding dish.

III. DISCUSSION

The present results show that *M. lyra* is not restricted to a single criterion when classifying complex tone stimuli, but rather is able to extract different features from a given spectrum. The predominant classification criterion was found to vary between individuals and to persist over a long period of time in each individual.

This finding is in good agreement with results obtained from human listeners. Although a human subject is normally able to concentrate on each of the three qualities ''pure tone pitch,'' ''collective pitch,'' and ''timbre,'' attention is focused on maximally two of these aspects simultaneously, namely on timbre and on spectral or collective pitch (Smoorenburg, 1970; Houtsma and Goldstein, 1972). For a given ambiguous stimulus, the sensational predominance of one aspect of pitch over the other has been found to be a quite stable individual characteristic (Albrecht, 1972; Deutsch and Steeger, 1978). However, a complex tone's spectral composition (Preisler, unpublished data), its context (Houtgast, 1976), and the actual S/N ratio (Houtgast, 1976) highly determine the probability with which one perceptual mode will predominate the other.

In all three bats, the average response latencies differed significantly for tones including their fundamentals from tones with their fundamentals missing. Hence, it can be concluded that each animal was able to discern the stimuli on the basis of their spectral composition, i.e., their timbre. However, only in bat 3 choices in favor of one feeding dish were determined by that criterion. In contrast, bats 1 and 2 based their decisions solely on pitch criteria, namely on perceived collective and pure tone pitch, respectively. In these animals, the spectral composition of the tones did not directly affect the classification behavior and thus seems to have been of lesser importance.

Subsequently, the following questions will be dealt with:

(a) Can the behavior of bat 1 be explained by any effects other than collective pitch formation, such as a detection of difference tones or focused attention on specific spectral characteristics of the stimulus components?

(b) What are the implications of collective pitch formation at high and ultrasonic frequencies for current models of pitch perception?

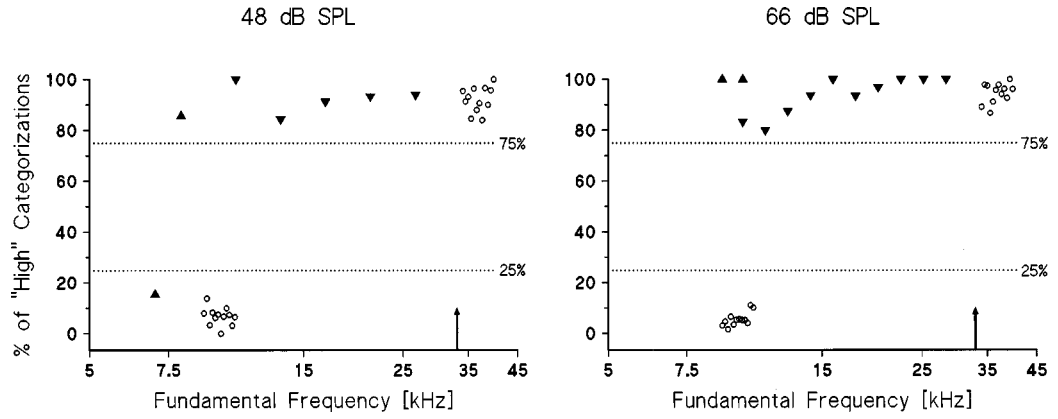

FIG. 7. Pitch classifications by bat 3 for conditions 1 (sound-pressure level: ~48 dB) and 2 (sound-pressure level: ~66 dB). For further details, see Fig. 5.

(c) What is the significance of the observed differences in classification behavior for *M. lyra*?

A. Alternative hypotheses to explain the behavior of bat 1

Collective pitch sensations at ultrasonic frequencies are an interesting phenomenon for two reasons. On the one hand, they bear on theories of how the mammalian auditory system extracts pitch from complex tones. On the other hand, they provide insight of how bats might cope with the problem of the rapidly fluctuating echo spectra in their natural environment.

Therefore, alternative hypotheses to explain why bat 1 consistently classified test tones with missing fundamentals between 5.3 and 28.3 kHz as low have to be tested conscientiously before drawing any further conclusions from this result. In the following, we discuss whether nonlinear distortions originating from the experimental apparatus or the cochlea, or specific characteristics of the incomplete complex tones, may have provided alternative decision cues to this bat.

With our equipment, difference tones from the apparatus were not measurable. As the noise floor in our experiments was 60 dB down (cf. Fig. 4), the sound-pressure levels of possible distortions were at least below -13 dB in condition 1, i.e., below the behavioral auditory threshold of *M. lyra* (Schmidt *et al.*, 1983).

Cubic difference tones (CDTs) are the most prominent cochlear distortions, also arising at low sound-pressure levels (Zwicker, 1990; Kössl, 1992). Subsequently, only the first lower sideband CDT at a frequency of $2f_1-f_2$ will be dealt with. We estimated at what intensities CDTs were to be expected below the 33-kHz reference. For test tones with missing fundamentals between 16.5 and 33 kHz (cf. Table II, tasks 30–32; Table III, tasks 47–51), the frequency ratio of the primary tones f_2/f_1 (3rd/2nd harmonic) is 1.5 and the frequency of a possible CDT matches that of the missing fundamental. The CDTs arising from higher adjacent harmonics (e.g., 4rd/3th, 5th/4th harmonic) can be neglected, since they coincide with the low harmonics of the stimulus. For test tones with a collective pitch below 16.5 kHz (cf. Table II, tasks 25–29; Table III, tasks 37–46), as a consequence of the omission of more than one harmonic, ratios of adjacent primaries are smaller than 1.5. The CDTs arising from the two lowest present harmonics have frequencies below the reference, but do not coincide with the missing fundamentals.

Kössl (1992) measured the intensities of low side CDTs in *M. lyra* as a function of the sound-pressure levels and frequency ratios of the primary tones. As the levels of the CDTs were found to systematically drop for primary ratios exceeding 1.2, larger ratios, like the one of 1.5 which is relevant for the present stimuli, were not especially considered in this study.

In case the lower primary tone had a sound-pressure level between 40 and 50 dB, as relevant for our experiments in condition 1 (average sound-pressure level: 45.4 dB), a CDT having a sound-pressure level between -20 and 0 dB was obtained at the largest tested frequency ratios.

In a later study (Kössl, personal communication), CDTs were measured for different primary tone levels at a constant frequency ratio of 1.5. According to these data, a CDT having a sound-pressure level of less than -13 dB is predicted for a lower primary at a sound-pressure level of 45 dB. For test tones with missing fundamentals above 16.5 kHz, the distortion product thus remains well below the behavioral auditory threshold of *M. lyra* (Schmidt *et al.*, 1983) at least in condition 1.

For test tones with a lower collective pitch, the distances between the remaining adjacent primaries get increasingly smaller (frequency ratios: 1.33–1.17) and higher CDT levels are to be expected (Kössl, 1992). However, CDTs with frequencies below the reference but above the missing fundamentals still remain below the auditory threshold in condition 1.

Moreover, paying attention to local cues, like the prominence of single harmonics or spectral regions, could not have provided useful cues for consistent classifications since 23 different test stimuli of varying overall intensity (± 2 dB) and frequency composition (f_0: 5.3–28.3 kHz) were presented in random order.

B. Implications for current models of the perception of the pitch of complex tones

Since Seebeck's (1843) discovery of the phenomenon of the missing fundamental several attempts were made to explain this ''auditory illusion.'' Different theories attribute collective pitch sensations to an analysis of the acoustical signal either within the time domain, the frequency domain, or both (for review, see De Boer, 1976; Preisler, 1993).

In an early model, Schouten (1938, 1940a, b) regarded collective pitch as an inevitable by-product of the restricted frequency resolution of the basilar membrane. When a cochlear filter is activated simultaneously by more than one harmonic, the period of the superimposed signal is the reciprocal of the highest common divisor of the included frequencies. Hence, in the harmonic case the period of the envelope matches the reciprocal of the frequency of the present or missing fundamental. The model later received physiological support from the observation that neural discharge patterns tend to synchronize to the frequency of single components (Javel, 1986) as well as to the compound signal envelope of spectrally unresolved components (Rose, 1970). To account for the present results by Schouten's theory, one would have to claim phase coupling to modulation frequencies between 5.3 and 28.3 kHz.

In a more recent model, Langner (1981, 1983, 1984, 1988) postulates that information about the missing fundamental is derived from a cross-correlation of the neural spike patterns, driven by the carrier and the modulation frequency of the spectrally unresolved signal. Therefore, to elicit collective pitch sensations at 28 kHz, a carrier at 84 kHz (center frequency of a three-component stimulus, consisting of harmonics 2–4) needs to be coded in the time domain.

Other theories (Moore, 1982; Lazzaro and Mead, 1989; Meddis and Hewitt, 1991; Delgutte and Cariani, 1992) claim that for each cochlear filter channel first an autocorrelation of interspike intervals is performed. At a higher stage of neural

processing, a summation autocorrelogram, including the outputs of all channels, is supposed to account for the final pitch sensation. Again, such models require temporal coding of either the compound signal envelope or of at least the two lowest spectrally resolved components.

In mammals, phase locking has not been reported for frequencies above 5 kHz (Hind *et al.*, 1967; Javel, 1986; Joris and Yin, 1992). This upper frequency limit (3–4 kHz) was confirmed by Fourier analyses of the period histograms, as obtained from the discharge patterns of auditory nerve fibers in cats (Horst *et al.*, 1986), and may thus reflect an intrinsic property of the ascending auditory pathway. It has been suggested that synchronization breaks down at higher frequencies because the ac responses of the hair cells become small in comparison with the dc responses (Russell and Sellick, 1978), the temporal jitter in the initiation of nerve impulses limits synchronous firing (Fay, 1984), and the synapses between hair cells and auditory nerve fibers have low-pass transfer characteristics (Weiss and Rose, 1988).

In bats, neural synchronization to steady-state signals has been found for frequencies up to 3 kHz at the level of the cochlear nucleus (Suga *et al.*, 1975; Vater, 1982), and only up to 350 Hz in the inferior colliculus of the auditory midbrain (Schuller, 1979). Hence, in this respect the bats' temporal resolution is comparable to that of other mammals and does not show specific adaptations for the use of ultrasound.

Thus, neither the original theory of Schouten (1938, 1940a, b), nor later models, regarding phase locking as an essential supposition for collective pitch formation (Langner, 1981, 1983, 1984, 1988; Moore, 1982; Lazzaro and Mead, 1989; Meddis and Hewitt, 1991; Delgutte and Cariani, 1992), are able to account for the present result.

On the other hand, collective pitch sensations at high and ultrasonic frequencies could well be explained on the basis of spectral pattern recognition models (Goldstein, 1973; Wightman, 1973; Terhardt, 1974, 1976; Cohen *et al.*, 1995). The only requirement that has to be met is that, on the basis of a place mechanism, the included partials are sufficiently resolved by the auditory system.

Terhardt (1974, 1976) conjectured that collective pitch formation is a by-product of speech acquisition. The model, which has been critically reviewed and not generally shared by the experts within the last two decades, starts from the assumption that the harmonic structure of voiced sounds of speech (Stoll, 1980) is learned unconsciously in an early period of life as an acoustical reference pattern. Later, stimulation by a single pure tone should be sufficient to produce pitch cues corresponding to its subharmonics. Accordingly, a collective pitch sensation should correspond to the frequency at which most of the subharmonics of a complex tone's spectrally resolved components coincide. However, it is misleading to suppose that pure tones, *per se*, evoke imaginations of their possible subharmonics. Rather, stimulation of a collective pitch by a single pure tone is possible only if the missing information can be inferred from context and can be considered masked by distracting sound (Houtgast, 1976).

If ''speech'' is replaced by the more general term ''acoustical communication,'' Terhardt's concept may be applied to all species whose calls comprise harmonic portions, whose auditory system guarantees spectral resolution, and who possess sufficient learning capabilities. Many birds and mammals meet these requirements.

The widths (Sedlmeier and Schmidt, 1989) and shapes (Schmidt *et al.*, 1994) of auditory filters in *M. lyra* allow the spectral resolution of most of the applied stimuli's single components. A detailed examination of the spectra reveals that this holds for each of the 23 test stimuli.

In view of the available physiological data it is unlikely that collective pitch sensations at high and ultrasonic frequencies originate from an analysis of neural interspike-interval patterns. On the other hand, several psychoacoustical and physiological findings in humans reveal the temporal encoding of pitch information, namely the pure tone pitch sensations evoked by repetitive electrical stimulation of the auditory nerve (Eddington, 1980; Townshend *et al.*, 1987; McKay *et al.*, 1994; Pijl and Schwartz, 1995) and the faint collective pitch sensations elicited by dichotically delayed wideband noise (Bilsen and Goldstein, 1974), sinusoidally modulated or pulsed white noise (Miller and Taylor, 1948; Small, 1955; Harris, 1963; Rosenberg, 1965; Burns and Viemeister, 1976, 1981), and spectrally unresolved frequency components (Houtsma and Smurzynski, 1990). De Boer (1956) suggested that collective pitch sensations are due to two different mechanisms, a phase-sensitive mechanism for harmonics that are too close to be aurally resolved and a phase-insensitive mechanism for widely spaced components. Subsequent studies revealed that perceived collective pitch is predominantly determined by the low resolved components (Ritsma, 1967; Plomp, 1967; Preisler, 1993; Clarkson and Rogers, 1995). Shackleton and Carlyon (1994) and Carlyon and Shackleton (1994) report that the pitch of stimuli consisting of unresolved harmonics increases by an octave when the harmonics are presented in alternating sine–cosine phase, but not in sine phase. This is not the case for complex tones only comprising spectrally resolved components. Moreover, the authors report that when listeners were required to compare the collective pitches of two simultaneously presented complexes, performance was better when the two complexes consisted of the same ''type'' than when one complex consisted of resolved harmonics and one consisted of unresolved harmonics. Based on these results, Carlyon and Shackleton (1994) favor the idea that collective pitch sensations, in contrast to the basic assumptions of autocorrelation models (Moore, 1982; Lazzaro and Mead, 1989; Meddis and Hewitt, 1991; Delgutte and Cariani, 1992), are elicited by two different mechanisms. Meanwhile, this view has been further corroborated by Plack and Carlyon (1995).

In principle, the following alternative conclusions may be drawn from studies supporting a dual hypothesis of collective pitch formation:

(1) There are two distinct mechanisms, both operating on periodicity detection.
(2) For high, unresolved harmonics the periodicity of the composite waveform is coded by neural phase locking, whereas low, resolved harmonics give rise to collective pitch impressions on the basis of spectral pattern recognition, mediated by

(a) a pure place code (Wightman, 1973; Terhardt, 1974, 1976) and
(b) a combination of place and time code (Goldstein, 1973; Srulovicz and Goldstein, 1983; Cohen *et al.*, 1995).

Since harmonics, far extending over the ultrasonic region, are spectrally but not temporally resolvable by the peripheral auditory system of *M. lyra*, our results are only compatible with interpretation (2)(a). We thus infer that spectral pattern recognition, based on a pure place code, is in principle sufficient to elicit collective pitch sensations in mammals. However, in view of the highly reliable results of cochlear implant research (Eddington, 1980; Townshend *et al.*, 1987; McKay *et al.*, 1994; Pijl and Schwartz, 1995; Nelson *et al.*, 1995), interpretation (2)(b) is likely to be valid for species hearing in the normal frequency range.

C. The significance of different modes of complex tone classification for *M. lyra*

According to a stimulus-related definition, the timbre of a steady-state signal is determined by the relative intensities and ratios of the perceptible partials. The absolute pitches of the spectral components play a negligible role, since they affect the sensation only in case the entire spectrum is shifted over a frequency range wide enough to allow an influence of varying auditory thresholds. Collective pitch is an abstract category complementary to timbre, since it depends on the employed spectral frequencies, but does not necessarily vanish with the cancellation of single partials. Thus, collective pitch assignment makes melodic information highly robust in the presence of spectral variations due to selective filtering and masking.

In *M. lyra*, paying attention to single components analytically may increase the animals' ability to detect spectral irregularities within the echoes which provide cues about the position and texture of reflecting objects (Schmidt, 1992; Neuweiler, 1993).

However, the bats may derive such information in a holistic way from variations of timbre, as well. Moreover, like many other higher vertebrates, bats are likely to exploit characteristics of timbre for the recognition and classification of different environmental sounds.

The results of comparative studies in different mammalian species (Heffner and Whitfield, 1976; Tomlinson and Schwartz, 1988) and birds (Cynx, 1986) provide evidence that collective pitch formation is widespread and thus seems to be an essential characteristic of vertebrate auditory systems.

In bats, the horizontal angle between the alignment of the outer ear and the position of the reflecting object determines frequency specific interference patterns within the ear, which are the basis for further neural encoding (Neuweiler, 1993). In species emitting broadband signals, the gain/attenuation of specific frequencies depends on the elevation (vertical angle) between the object and the ear, as well. Hence, the spectral composition of an echo is highly sensitive to spatial changes of the bat, the target, or both. Moreover, echoes originating from structured objects comprise spectral notches and gains which are directly related to the grain size of the texture (Schmidt, 1992). Thus, collective pitch, which is unaffected by single spectral notches and gains, may be employed as an invariant reference within the rapidly fluctuating spectral content of the echoes.

In view of the facts that in *M. lyra* the sound pressure level of the echolocation calls' fundamental frequency may vary between 40 and 60 dB (Schmidt, 1992) and that the hearing thresholds are below a sound-pressure level of 0 dB in the relevant frequency region (Schmidt *et al.*, 1983), these bats should be easily able to perceive the fundamentals of their emitted calls. In case a bat emits a sonar signal at a range of 30 kHz, which is slightly above the fundamental frequency of the echolocation calls of *M. lyra*, towards a small, spherical target at a distance of 3 m, the echo is attenuated by about 65 dB because of geometrical spreading loss and atmospheric attenuation. If the reflecting object is a large, planar surface, the 30-kHz component may be maximally perceived up to a target distance of 12 m due to an attenuation of 65 dB (Lawrence and Simmons, 1980). To account for the energy scattered elsewhere or absorbed by the target's shape during echo formation, further attenuation must be added. Moreover, masking by environmental noise may deteriorate the S/N ratio and so further reduce the distance of perceptibility. Thus, it has to be inferred that the first harmonic is only occasionally perceptible within the reflected echo spectra. It might hence be advantageous for *M. lyra* to replace the faint or missing fundamentals of its echoes by corresponding collective pitch sensations.

In human listeners it has been shown that low signal-to-noise ratios induce a shift of attention from the analytical to the more reliable comprehensive aspect of pitch (Houtgast, 1976; Hall and Peters, 1981). We hypothesize that bats benefit from collective pitch sensations, when listening to their own echoes or to other complex signals in noisy surroundings, in a comparable way.

Since the extensive exploitation of different sound characteristics bears numerous advantages, it has to be assumed that during evolution of the vertebrate auditory system there was a selective pressure to utilize all available cues for signal identification and interpretation. From this point of view, the different classification criteria, as employed by the tested bats, are an interesting but not unexpected finding.

The pitch of a mistuned harmonic: Evidence for a template model

Jian-Yu Lin and William M. Hartmann
Department of Physics and Astronomy, Michigan State University, East Lansing, Michigan 48824

(Received 18 July 1996; accepted for publication 15 January 1998)

A harmonic of a periodic complex tone can be heard out as a separate entity if the harmonic is slightly mistuned from its correct frequency. Pitch matching experiments show that the pitch of such a mistuned harmonic differs systematically from its frequency. The shift in pitch is found to be an exaggeration of the frequency mistuning. This article considers two classes of model for the pitch shift. In the first class are tonotopically local interaction models which attribute the pitch shift to interactions between the mistuned harmonic and neighboring harmonics, where the neighborhood is established by peripheral filtering. The second class of model attributes the pitch shift to a contrast between the mistuned harmonic and a broadband harmonic template. This article describes six pitch matching experiments using complex tones having spectral gaps, strategically chosen to compare local interaction and template models. The results show that when a competition is set up between local interactions and a template, the template proves to be dominant. A parallel between the pitch shifts of mistuned harmonics and periodicity pitch, also attributed to a harmonic template, is seen as the frequency range of the mistuned harmonic is changed. Tonotopically local influences are evident in several experiments, but they are of secondary importance. © *1998 Acoustical Society of America.* [S0001-4966(98)00305-1]

INTRODUCTION

A complex periodic tone with many harmonics is normally perceived as a single entity with a pitch approximately equal to the fundamental frequency of the tone. The individual harmonics are not heard separately. However, if a harmonic is mistuned from its correct frequency, it may be detected as a separate entity (Moore *et al.*, 1986; Hartmann, 1988). The mistuned harmonic sounds like a sine tone against the background of the low-frequency complex tone. The background, with a complex timbre, has a pitch close to the fundamental, though this pitch can be shifted as a result of the mistuning (Moore *et al.*, 1985; Darwin *et al.*, 1994). The mistuned harmonic appears as a pure tone, and its pitch is also shifted. Matching it with a (nonsimultaneous) sine tone gives a matching frequency that systematically disagrees with the mistuned harmonic frequency (Hartmann *et al.*, 1990).

The pitch shift of the mistuned harmonic can be described succinctly as an exaggeration of the frequency mistuning. For example, the third harmonic of a 200-Hz tone is normally at 600 Hz. If the harmonic is mistuned by 8%, its frequency becomes 648 Hz. Typically its pitch would increase to 655 Hz, corresponding to a pitch shift of 1% $[(655-648)/648=0.01]$. If the harmonic is mistuned by -8%, its frequency decreases to 552 Hz, but its pitch would typically decrease to 546 Hz, corresponding to a pitch shift of -1% $[(546-552)/552=-0.01]$. The reader will notice that pitch shifts are computed with respect to the mistuned harmonic frequency. The present article is a study of the pitch shifts of mistuned harmonics.

To find a model for the pitches of mistuned harmonics, it is natural to begin with previous work, which has been on the pitches of correctly tuned harmonics. In 1979, Terhardt presented a semi-empirical algorithm to calculate the pitches of the harmonic components of complex tones. These then became the *spectral pitches* that were combined to form a virtual pitch for the tone as a whole (see also Terhardt *et al.*, 1982b). According to the algorithm, the pitches of individual harmonics are shifted due to partial masking caused by the excitation patterns of neighboring harmonics.

The algorithm is based on experimental data showing that when a sine tone is partially masked by a sound having a lower frequency than the sine itself, the pitch of the sine is shifted upward. Similarly, masking by a sound having a higher frequency than the sine tone tends to shift the sine tone pitch downward.[1] Terhardt extended these sine tone masking ideas to the pitches of components in a complex tone. A harmonic, somewhere in the middle of the spectrum, tends to be shifted upward by neighboring harmonics having lower frequencies, and it tends to be shifted downward by neighboring harmonics having higher frequencies. Because of the asymmetry of auditory filters there is an upward spread of masking, and the usual net result is that the pitch of a harmonic is shifted upward. An exception occurs for the fundamental component, where there is no lower frequency excitation. Then the model predicts that the pitch shift is downward.

Because Terhardt's model is a place-based excitation pattern model, it can also be used to predict pitch shifts for inharmonic components. For example, Terhardt *et al.* (1982a) used the model to predict the pitches of church-bell tones. However, when the model was applied to mistuned harmonics it predicted positive pitch shifts no matter whether the mistuning was positive or negative. Although it correctly predicted the pitches found experimentally for positive frequency mistuning, it failed to predict the negative shifts for negative mistuning (Hartmann *et al.*, 1990; Hartmann and Doty, 1996).

To try to explain the observed pitch shifts for mistuned harmonics, Hartmann and Doty developed an alternative model based on neural timing. The model began with the idea that pitch should be determined by the peaks of the interspike interval (ISI) histogram, as suggested by Goldstein and Srulovicz (1977). According to the model, the pitch of a component is shifted when excitation from neighboring harmonics appears in the same auditory filter, leading to a complicated temporal pattern. In general, the effect of such interaction on the ISI histogram is to cause a harmonic to be attracted in pitch to its nearest neighbors. Therefore the higher neighbor tends to make a positive pitch shift, and the lower neighbor tends to make a negative pitch shift, an ''attraction'' effect which is opposite to Terhardt's ''repulsion'' effect. Decreasing the spacing in frequency between the harmonic and a neighbor by mistuning the harmonic results in an increased attraction.

The timing model was capable of producing the positive and negative pitch shifts that occur for positive and negative mistunings. With appropriate model parameters, calculated pitch shifts could be brought into agreement with experimental results for mistuned harmonics 2, 3, 4, 5, 7, 9, and 11 [Doty (Smith), 1989; Hartmann and Doty, 1996]. However, there was one glaring exception, namely the mistuned fundamental. The model said that the pitch shifts should be unusually small and opposite in sign to the mistuning. In contrast, experiment showed unambiguously that the mistuned fundamental behaves just like any other mistuned harmonic—pitch shifts are substantial and in the same direction as the frequency shift.

This difficulty led us to consider an alternative paradigm. Terhardt's excitation pattern model and the timing model of Hartmann and Doty are local interaction models is the sense that the pitch shifts depend mainly on neighboring harmonics. The two nearest neighbors are especially important. A limitation of such local interaction models is that they give no recognition to the role of the entire spectrum in integrating a correctly tuned harmonic into a complex tone, or to the role that a broadband harmonic template might play when the harmonic is segregated by mistuning. A harmonic template is an internalized pattern for the components of a periodic tone. Current models of complex tone pitch perception (Goldstein, 1973; Terhardt, 1974) say that the pitch is the fundamental frequency, or harmonic spacing, of the best fitting template. Further, the ''pitch meter'' studied by Duifhuis *et al.* (1982) and Scheffers (1983) uses a self-consistent harmonic template to determine whether each resolved spectral component of the physical tone should be integrated into a complex tone percept or should be segregated. The experiments of this article were designed to search for a role for a broadband template and to establish a contrast between template models and local interaction models in the pitch of mistuned harmonics.

I. EXPERIMENTS

A. Method

Experiments were performed to measure a quantity defined as the *pitch shift gradient*. The gradient concept originated in the observation that pitch shifts for mistuned harmonics are in the same direction as the frequency mistuning. Therefore, if one takes the difference between the pitch shifts observed for positive and negative mistunings, the result should be larger and more robust than either pitch shift alone. An example is shown in Fig. 1; part (a) plots pitch, and part (b) plots pitch shift. The pitch shift observed for a mistuning of $+8\%$ is $\Delta p_+ = 1.1\%$. The pitch shift observed for a mistuning of -8% is $\Delta p_- = -1.3\%$. The pitch shift gradient is $\Delta p_+ - \Delta p_- = 2.4\%$, and there is an average pitch shift of $(\Delta p_+ + \Delta p_-)/2 = -0.1\%$.

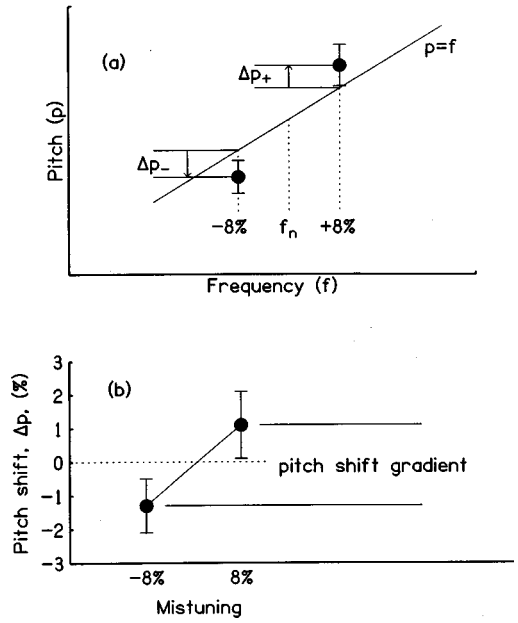

FIG. 1. Pitch shift gradient. A positive pitch shift gradient occurs when pitch changes more rapidly than frequency. Part (a) shows the mean and standard deviation of pitch matching data for a positively mistuned harmonic ($+8\%$) and a negatively mistuned harmonic (-8%). In the absence of a gradient, the pitch shifts Δp_+ and Δp_- would be the same. In fact, however, these shifts even have different signs. Part (b) plots the values of Δp_+ and Δp_- to show the pitch shift gradient. This gradient would be called *large* because the error bars for matching positive and negative mistunings do not overlap. The error bars are two standard deviations in overall length. All the data presented in this article are represented by graphs like part (b). To measure a pitch shift gradient does not necessarily require positive and negative mistuning of a harmonic. A gradient can be measured using any two frequencies that are not greatly different.

A pitch shift gradient is a perturbation in the smooth functional relationship between pitch and frequency. It occurs when, over a small range in frequency, the pitch changes differently from the frequency itself. Therefore, a pitch shift gradient can be measured by measuring the percentage pitch shifts for any two frequencies that are rather close together and taking the difference. If the measured pitch shifts turn out to be a constant percentage of the frequencies, then the pitch shift gradient is zero. The experiments below all used mistunings of plus and minus 8% to measure the gradients. Doty's data indicate that pitch shifts grow with increasing mistuning up to mistunings of about $\pm 4\%$ and remain flat, or decrease slightly out to $\pm 8\%$. Therefore, $\pm 8\%$ is a reasonable standard. The results would likely have been the same had the mistunings been as small as $\pm 4\%$.[2]

1. General procedure

The listener was seated in a sound-treated enclosure, holding a response box that controlled the events of an experimental trial. The listener pressed a yellow button to hear a complex tone with one of its harmonics mistuned. The listener pressed an orange button to hear a matching sine tone with a frequency that the listener could adjust by means of a ten-turn potentiometer on the box. Each tone was preceded by a 300-ms silent interval to minimize interactions between intervals. The listener could call up the complex tone or the matching tone in any sequence, with no time limit. When satisfied with the match, the listener pressed the green button to finish the trial. The stimulus and matching frequencies were recorded, and then the next trial began, with a different complex tone. There was no feedback to the listener.

The experiments used a wide variety of tones with as few as three and as many as six different complex spectra in a run. Each experimental run included at least one presentation of each spectrum with a mistuned harmonic mistuned by $+8\%$ and -8%. Therefore, a run included from 6–12 trials. It took from 10–20 min for a listener to finish a run. After a run was completed, the listener could come out to rest. Runs continued until each listener had done at least 12 runs in each experiment. Every data point shown in the figures that follow was based on the final 12 matches.

2. Stimuli

The complex tones with mistuned harmonics contained from 8–16 partials of equal amplitude. The fundamental frequencies varied from 150–800 Hz. Complex tones were generated by sound files, which were specific as to the fundamental frequency, the harmonic content, the mistuned harmonic number, and the percentage of mistuning—either plus or minus 8%. For a given trial, the appropriate sound file was loaded into a digital buffer 16k (16 384) samples long and was converted by a 16-bit DAC at a nominal sample rate of 16k/s. To prevent the listener from using pitch memory in the task, the sample rate was actually different on every trial. It was randomized over a range of $+10\%$ to -10%, with a rectangular distribution. Because of this randomization, all the numerical values of frequencies given in this article are nominal values.

The output of the DAC was low-pass filtered at 7 kHz, -115 dB/oct, and then shaped by a computer-controlled amplifier to give it an envelope with a 10-ms raised-cosine onset and offset, and a full-on duration of 1 s. The signal was presented to the listener via Sennheiser HD480 headphones such that each component had a level of 58 dB SPL. Therefore, a 16-component complex tone had a level of 70 dB SPL.

The matching tone was generated by repeatedly cycling a buffer using fractional-addressing technology. One cycle of a sine wave was loaded into a 16k buffer and sampled at the rate of 32k/s. The fractional address increment was determined by the potentiometer on the control box, as read by a 12-bit ADC. An exponential frequency control law was applied in software, leading to a frequency resolution of 0.06%.

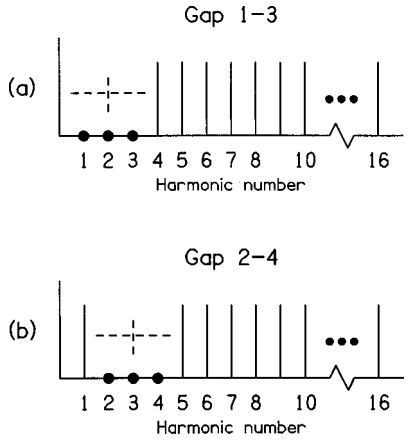

FIG. 2. Spectra for experiment 1. (a) Gap 1–3. A single mistuned harmonic (number 1, 2, or 3) added to harmonics 4–16. Vertical solid lines represent perfectly tuned harmonics. A vertical dashed line represents a mistuned harmonic. A dot is put on the horizontal axis where a harmonic is omitted. (b) Gap 2–4.

The matching tone was filtered and enveloped like the complex tone. The matching tone level was 55 dB SPL, 3 dB lower than a component of the complex tone, causing the matching tone to be approximately as loud as the mistuned harmonic. It was expected that equal loudness would make the pitch matching task easier.

3. Listeners

There were four listeners, three males, B, J, T, and one female, C. Their ages ranged from 19–55. All the listeners had negative otological histories and had some training as performers of musical instruments. They could perform accurate sine–sine pitch matching in the range 150–1000 Hz. Listeners J and B were the authors.

B. Experiment 1

1. Spectra of the complex tones

The spectra of the two complex tones in experiment 1 are shown in Fig. 2. The stimulus in Fig. 2(a) was made by starting with a periodic complex tone with a nominal fundamental frequency of 200 Hz and harmonics 4–16. Then one (and only one) of the omitted harmonics (1, 2, or 3) was reinserted as a mistuned harmonic, mistuned by either $+8\%$ or -8%. There were, therefore, six different stimuli in this experiment. This experiment is called ''gap 1–3.''

The stimulus in Fig. 2(b) was made in the same way except that harmonics 2, 3, and 4 were initially omitted. Then one of those harmonics was reinserted as a mistuned harmonic, mistuned by either $+8\%$ or -8%. This experiment also had six different stimuli, and it is called ''gap 2–4.''

2. Results—The zigzag effect

Figure 3 shows the results for gap 1–3 and gap 2–4 experiments, one panel for each subject. There are several observations to be made: First, there is a large pitch shift gradient for each plus–minus mistuned pair. Second, there are average shifts for some of the pairs, though these differ in size from subject to subject. Finally, although the magni-

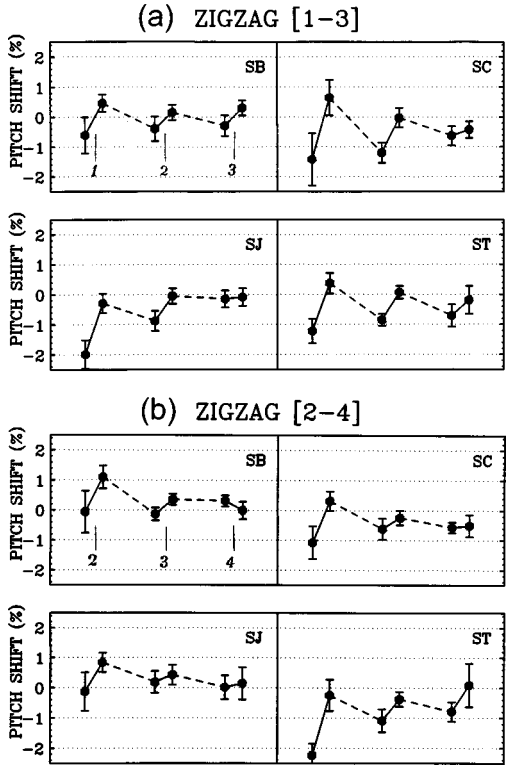

FIG. 3. Results of experiment 1. There are four panels (a) for the gap 1–3 experiment, and four panels (b) for the gap 2–4 experiment. In each panel there are three pairs of data points representing the ±8% mistuned pairs for three mistuned harmonics. Members of a pair are connected with a solid line so that one can compare the gradients of different pairs. A dashed line connects pairs to illustrate the ragged dependence of the pitch shift on the mistuned harmonic frequency, indicating the *zigzag effect*. The horizontal axis is monotonic (but not linear) with mistuned harmonic frequency.

tudes of the gradients are different for different listeners, there is a common tendency for low mistuned harmonics to have larger gradients. This low-frequency tendency will be seen in other experiments too.

Experiment 1 shows that the pitch shifts do not vary smoothly with mistuned harmonic frequency. The patterns shown in Fig. 3(a) and (b) are zigzags. These zigzag functions are evidence against an important class of models in which pitch shifts are mediated by local interaction. The gap 1–3 experiment is critical. The stimuli for gap 1–3 can be regarded as six target sine tones, increasing in frequency from harmonic 1 mistuned by −8% to harmonic 3 mistuned by +8%. As its frequency increases, the target tone gets closer to the rest of the spectrum (harmonics 4–16), which is responsible for the pitch shifts. Local interaction models based on the interaction of excitation patterns logically require that a shift varies smoothly with the separation between the target and the rest of the spectrum because the interaction decreases monotonically with increasing separation in local models. This prediction is contrary to the zigzag pattern observed experimentally. Local interaction models based on timing, like Hartmann–Doty, do not necessarily predict a smooth behavior for the gap 1–3 experiment, but the peripheral filtering in these models causes them to predict that gradients should increase in magnitude as the mistuned harmonic number increases from 1 to 3. In fact, the zigzag pattern does the reverse. It is largest for mistuned harmonic

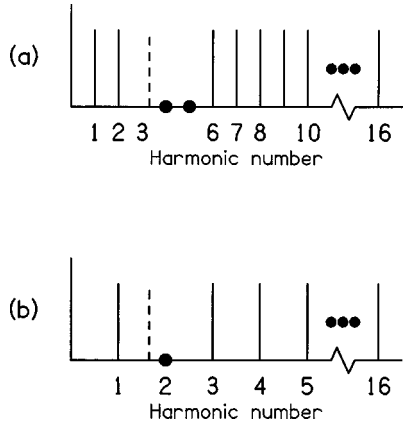

FIG. 4. Spectra for experiment 2. Part (a) shows mistuned harmonic number 3. Part (b) shows mistuned harmonic number 1.5. A dot appears on the horizontal axis where a harmonic is omitted.

number 1 and smallest for number 3. The zigzag pattern seen for gap 1–3 occurs also for the gap 2–4, except that the gradients are somewhat smaller in gap 2–4.[3]

The results of experiment 1 suggest that local interaction models are not appropriate models for the pitches of mistuned harmonics. Instead, it suggests that there is something special about the integer harmonic numbers, even when they are in a gap. A large pitch shift gradient occurs when the pair straddles a special frequency where a harmonic is supposed to be. This, in turn, is evidence that the complex tone forms a harmonic template within the auditory system, signalling the location of harmonics.

C. Experiment 2

1. Spectra of the complex tones

The purpose of experiment 2 was to make a direct comparison between two stimuli: (a) in which the target tone was a mistuned harmonic, and (b) in which it was not. If a harmonic template is the dominant influence on the pitch shifts of mistuned harmonics, as suggested by experiment 1, then shifts should be evident for the mistuned harmonic in (a) but not for the target in (b). The key to experiment 2 was that the local spectral structure around the target was similar for both stimuli. Therefore, local interaction models predict similar pitch shifts for both (a) and (b).

The spectra for the tones of experiment 2 are shown in Fig. 4(a) and (b). For stimulus (a), the fundamental frequency was 200 Hz. Harmonics 4 and 5 were omitted, and the third harmonic was mistuned, either by +8% or −8%, i.e., it was nominally either 648 or 552 Hz. For stimulus (b), the fundamental frequency was 400 Hz, and the second harmonic was omitted to make a gap. A target, having the same frequency as the target in stimulus (a), was inserted in the gap. Figure 4(b) shows that the target, with frequency of 648 or 552 Hz, looks like a mistuned component with harmonic number 1.5. Therefore, stimulus (b) makes an adequate test: the harmonics neighboring the target have the same frequencies as in stimulus (a) [the spectral differences between (a) and (b) are six (Cambridge) critical bandwidths away from the target region], but 1.5 is not a legitimate harmonic number.

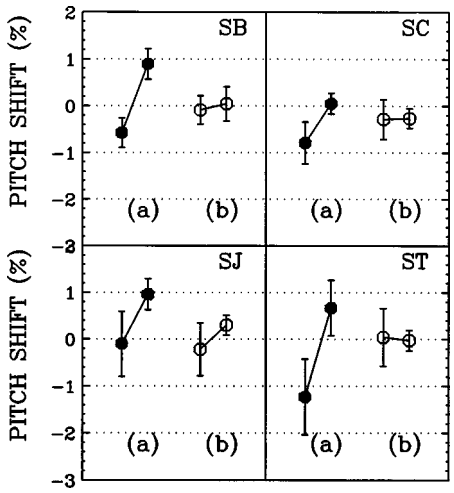

FIG. 5. Results of experiment 2. There are four subjects. Letters (a) and (b) refer to spectra in Fig. 4. The gradient is seen to be smaller in case (b), mistuned harmonic number 1.5, indicating the *integer effect*.

2. Results—The integer effect

The results of experiment 2 are shown in Fig. 5, one panel per subject. For all the subjects there are substantial shift gradients for stimulus (a), where the frequencies of the pair straddle harmonic 3, but there are no similar gradients for stimulus (b), where the frequencies of the pair are not close to an integer harmonic. The effect is significant $[F(1,3)=16, p<0.03]$. The result of experiment 2 is called the ''integer effect,'' meaning that large pitch shift gradients occur when the frequencies of the pair straddle integer harmonic frequencies. The integer effect suggests that a harmonic template plays an important role in the shifts.

For local interaction models, one expects pitch shifts to be mainly determined by the closest frequency components. Therefore, local interaction models tend to predict approximately the same pitch shifts for stimuli (a) and (b). Specific calculations with the tonotopic model of Terhardt *et al.* (1982a, 1982b) and the timing model of Hartmann and Doty both predict that (a) and (b) should have the same pitch shifts to five significant figures. These predictions are contrary to the large difference between (a) and (b) shown in Fig. 5.

D. Experiment 3

1. Spectra of the complex tones

The main purpose of experiment 3 was to see whether spectrally distant harmonics contribute to the pitch shift of a mistuned harmonic. The experiment used five complex tones, all with a period of 1/200 s. All had a mistuned fundamental. The spectra are shown in Fig. 6: Tone (a) was a 16-component complex tone. Tones (b)–(d) were the same as tone (a) but with increasing number of omitted harmonics. Tone (e) had only harmonics 1, 2, and 3.

2. Results—The proximity effect

The results of experiment 3 are shown in Fig. 7. Because listener SB did not complete this experiment, data are shown for only three listeners; the results are essentially the same for all three. As the neighboring harmonics 2, 3, and 4 were

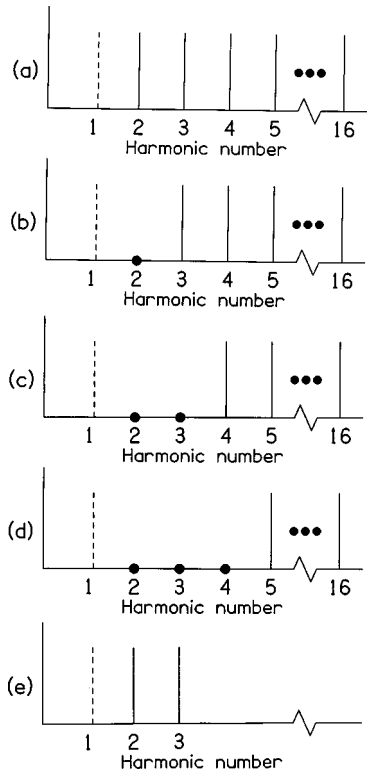

FIG. 6. Spectra for experiment 3. Tones (a)–(e) have a mistuned fundamental. Harmonic spectral blocks run from proximate (a) to remote (d). Tone (e) had only three harmonics. Dots on the horizontal axis mark the positions of omitted harmonics.

omitted one by one, the pitch shift gradient became smaller, but some gradient was always present. In only one case, tone (d) for SJ, was the gradient less than the error bars.

The results of the experiment show that distant harmonics are capable of generating a pitch shift gradient. Because the distant harmonics were well outside the critical band containing the target, the pitch shifts cannot be understood from a model that treats only a single peripheral channel. Specific calculations using Terhardt's model show negligible pitch shift ($<0.1\%$) for a mistuned fundamental when harmonic 2

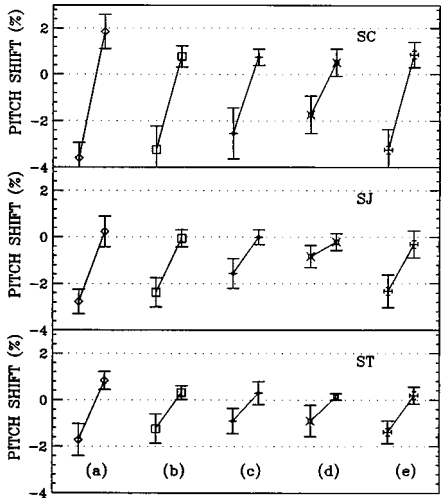

FIG. 7. Results of experiment 3. There are three subjects. Letters (a)–(e) refer to spectra in Fig. 6. Pitch shift gradients decrease in order (a) through (d), indicating the *proximity effect*.

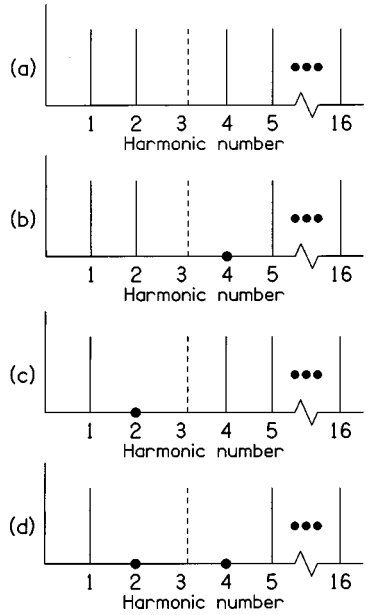

FIG. 8. Spectra for experiment 4. A mistuned third harmonic in symmetrical [(a) and (d)] and asymmetrical [(b) and (c)] harmonic environments. Dots on the horizontal line indicate omitted harmonics.

is omitted and even smaller shifts for other omitted-harmonic stimuli. The Hartmann–Doty model underpredicts the pitch shift for the mistuned fundamental, as always.

The fact that appreciable pitch shift gradients were caused by distant harmonics suggests that pitch shifts originate at a higher level, where the outputs of tuned channels are combined. This result is consistent with a template model for the shifts.

A second result of experiment 3 is that the shift gradients were smaller when the target was farther from the harmonics of the complex tone. This result is a ''proximity effect,'' which might be regarded as evidence for the importance of a local interaction such as partial masking. However, the large size of the shifts themselves in Fig. 7 seems out of proportion to the small weight that local interaction plays in other experiments, such as experiment 2. It seems more likely that the proximity effect represents increasing influence for a harmonic template when the components that establish the template become closer to the target.

E. Experiment 4

1. Spectra of the complex tones

Experiment 4 created spectral asymmetries for the mistuned harmonic target by selectively eliminating nearest-neighboring harmonics. The motivation for this experiment was that both the Terhardt place model and the Hartmann–Doty timing model are sensitive to local spectral structure. The former is particularly sensitive to the removal of a lower harmonic; the latter is sensitive to both lower and upper neighbors of the mistuned harmonic. Experiment 4 looked for the expected large changes in average shifts.

The target was a mistuned third harmonic, mistuned by $+8\%$ or -8%. The fundamental was 200 Hz. The spectral contexts are shown in Fig. 8: In tone (a) all harmonics were present. In tone (b) the fourth harmonic was omitted. In tone (c) the second harmonic was omitted. In tone (d) both the second and the fourth harmonics were omitted. The Terhardt model predicts that eliminating the second harmonic changes the average shift from 1.9% to 0.5%. The Hartmann–Doty model predicts that all shifts, regardless of mistuning, are positive for an omitted second harmonic, and all shifts are negative for an omitted fourth harmonic.

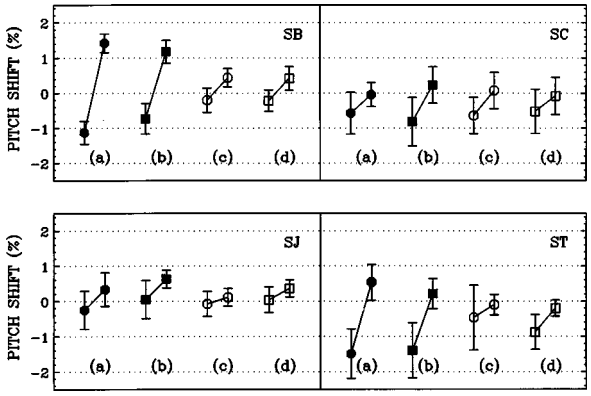

FIG. 9. Results of experiment 4. There are four subjects. Letters (a)–(d) refer to spectra in Fig. 8. Larger gradients occur for tones (a) and (b) where the second harmonic is present, indicating a *local asymmetry effect*.

2. Results—The local asymmetry effect

The data from experiment 4 are shown in Fig. 9, one panel for each subject. The first observation to be made is that the large changes in average shifts (average over positive and negative mistunings) predicted by local interaction models for asymmetrical spectra (b) and (c) did not materialize. The changes in average shifts are small, and the directions of the changes are different for different listeners. This result is evidence against local interaction models. The largest effect seen in this experiment was a reduction in gradient caused by removing the second harmonic (spectra c and d), whether or not the fourth was removed. For SB and ST the change was dramatic. Overall, the reduction in pitch shift upon removal of the second harmonic was significant $[F(1,7)=11.3,\ p<0.02]$. The special importance of the second harmonic in producing the gradient, in comparison with the fourth, is a *local asymmetry*. Generalized from this experience with a mistuned third harmonic, a statement of the local asymmetry effect says that the harmonics below the target are more important than the harmonics above the target in making a pitch shift gradient. Like the proximity effect, the local asymmetry effect has some of the character of a local interaction model. The upward spread of excitation might be expected to result in just this kind of asymmetry. However, local interaction models have the problem that an interaction large enough to generate a large change in gradients (e.g., SB and ST) also tends to generate a large shift in average pitch, which is not seen experimentally.

F. Experiment 5

1. Spectra of the complex tones

Experiment 5 was done to see the how pitch shift gradients for the mistuned fundamental depend on the period of the complex tone. There were three complex tones with eight

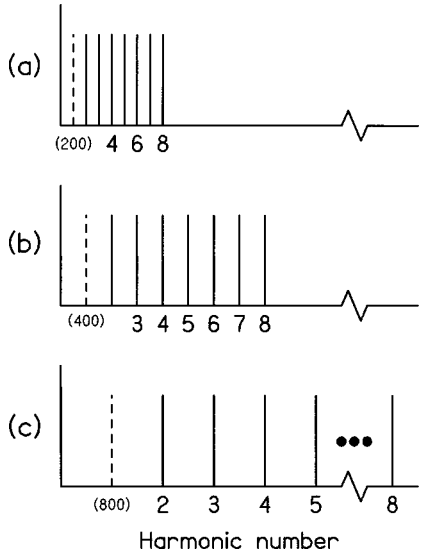

FIG. 10. Spectra for experiment 5. The three complex tones are scaled so that nominal fundamental frequencies are 200, 400, and 800 Hz. The fundamentals are mistuned.

components and mistuned fundamentals. The only difference among the tones was the nominal fundamental frequency: (a) 200 Hz, (b) 400 Hz, and (c) 800 Hz, as shown in Fig. 10.

2. Results—The frequency effect

The results of Experiment 5 are shown in Fig. 11. The results clearly show that the pitch shift gradient decreases with increasing fundamental frequency. Whereas the gradients at 200 Hz are large, greater than 2% for all listeners, the gradients at 800 Hz are almost zero. This is the frequency effect. The gradient is larger for 200 Hz than for 400 Hz [$F(1,3)=53$, $p<0.01$], and it is larger for 400 Hz than for 800 Hz [$F(1,3)=24$, $p<0.05$].

The Terhardt model predicts the frequency effect, largely because of the increased sensitivity to SPL excess as the frequency decreases. It also predicts the dominance of negative pitch shifts seen experimentally. However, the predicted pitch shift gradient has the wrong sign, and, therefore, the model fails. The Hartmann–Doty model fails for a mistuned fundamental, as usual, because it predicts that the gradient is too small to be observed, whatever the fundamental frequency.

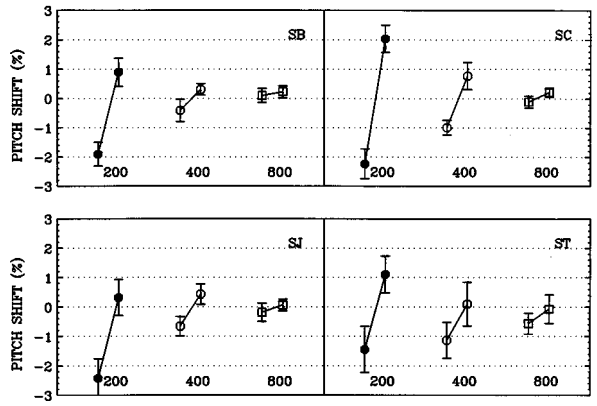

FIG. 11. Results of experiment 5. There are four subjects and three fundamental frequencies with spectra given in Fig. 10. The gradients are seen to be smaller for higher fundamental frequencies, indicating a *frequency effect*.

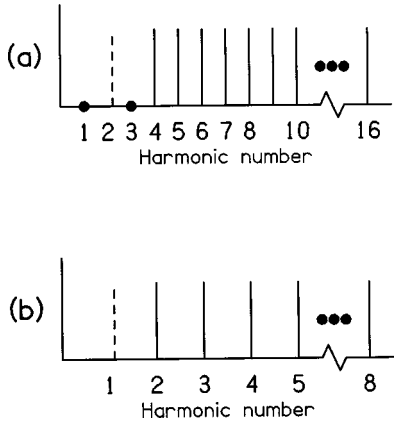

FIG. 12. Spectra for experiment 6. A mistuned ''400-Hz'' component serves as a mistuned second harmonic (a), or as a mistuned fundamental (b).

The small gradients seen at 800 Hz might have been predicted from a harmonic template model because periodicity pitch is weak at 800 Hz. Modern pitch perception models suggest that periodicity pitch, as seen in tones with missing fundamentals, is the result of a central harmonic template. The DWS pitch meter is an example (Scheffers, 1983). According to Ritsma's 1962 amplitude modulation experiments, 800 Hz is the upper limit for the existence of periodicity pitch. It seems natural to attribute this limit to a weakness in template influence for fundamental frequencies as high as 800 Hz. An ineffective template, in turn, would produce small pitch shift gradients, as observed in experiment 5. A possible further interpretation for the results of experiment 5 is that templates with low fundamental frequencies or long periods (e.g., 1/200 s are more effective than templates with short periods (e.g., 1/800 s). This interpretation was tested in experiment 6.

G. Experiment 6

1. Spectra of the complex tones

Experiment 6 had two goals. The first was to test the template period conjecture from experiment 5, the second was to explore the dependence of pitch shift gradients on harmonic number. The idea was to create a similar local spectral environment for mistuned harmonics, subject to two different overall periodicities. The spectra are shown in Fig. 12. In tone (a) the second harmonic of the complex tone was mistuned and its neighbors (the fundamental and the third harmonic) were omitted. The fundamental frequency was 200 Hz. In tone (b) the stimulus was a 400-Hz complex tone with its fundamental mistuned. The local spectral structures for the mistuned harmonic were similar for both (a) and (b), but the harmonic number in (a) was 1 (the fundamental), and the harmonic number in (b) was 2 (the second harmonic). Both stimuli had the same power. According to local interaction models both should have the same pitch shift (less than 0.2% in Terhardt's model).

2. Results

The results of experiment 6 are shown in Fig. 13. For all the subjects, the lower harmonic number (the fundamental)

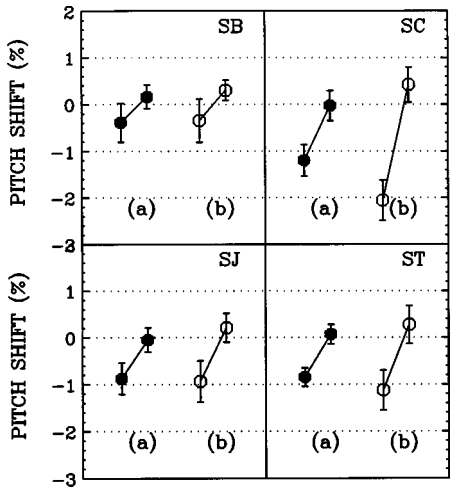

FIG. 13. Results of experiment 6. There are four subjects. Letters (a) and (b) refer to spectra in Fig. 12. The gradients for (b) tones are slightly larger, indicating a *harmonic number effect*.

suffered the larger gradient. This is a harmonic number effect. The effect is not significant according to our usual test $[F(1,3)=4.4]$ because the size of the difference varies among subjects leading to a large variance. It is important, however, that the reverse effect did not occur.

The results of experiment 6 affect our interpretation of experiment 5. If long-period templates are more effective than short, as conjectured in the discussion of experiment 5, then experiment 6 should find a larger pitch shift gradient in case (a) (200-Hz complex tone) than in case (b) (400-Hz complex tone). In fact, this did not occur. Instead, the larger gradient occurred for the 400-Hz complex tone. Therefore, our interpretation of the frequency effect in experiment 5 is that templates are less effective in shifting the pitches of higher-frequency fundamentals.

II. DISCUSSION AND CONCLUSION

A. Outcomes and interpretations

The pitch matching experiments of this article confirmed that the pitch of a mistuned harmonic differs from its frequency and that the shift in pitch exaggerates the frequency difference caused by mistuning. The experiments used computer-generated complex tones with specially tailored spectra. The principal goal was to distinguish between two classes of models for the pitch shifts, one based on tonotopically local interactions, the other based on a broadband template.

In a local interaction model, either place based or timing based, the pitch shifts are attributed to the effect of neighboring harmonics. The effects of distant harmonics are imagined to be attenuated by peripheral auditory filters. It is reasonable to try to apply local interaction models to mistuned harmonic pitch because these models have provided a qualitative account of many other pitch shift effects that occur for sine tones when noise or other tones are added to the signal (Webster and Muerdter, 1965; Terhardt, 1971; Rakowski and Hirsh, 1980; Burns and Osterle, 1980; Houtsma, 1981; Hartmann, 1996, 1997).

In a template model, by contrast, it is hypothesized that pitch shifts result from the influence of a broadband framework established by all the harmonics of the complex tone. Because the template model is more central than local interaction models, it is less clear how one should proceed to make it quantitative. The fact that pitch shifts are almost always found to be exaggerations of the frequency mistuning means that the template acts in such a way as to enhance contrasts. The enhancement favors the segregation of the mistuned harmonic as an independent entity.

Important evidence in favor of the template model came from the *zigzag* effect in experiment 1, where the presence of upper harmonics led to a ragged pitch shift pattern for mistuned lower harmonics. We found it helpful to think about this experiment in the following physical terms: In experiment 1 (gap 1–3), there is an empty spectral region where harmonics 1–3 have been omitted. Above this region there is spectral strength in harmonics 4–16. Experiment 1 consisted of placing a sine tone probe somewhere in the empty spectral region and observing ''forces'' on it caused by harmonics 4–16. The imagined forces are the influences that shift the pitch of the sine tone. The zigzag effect indicated an apparent force whereby pitches are ''repelled'' from sites where harmonics ought to be. The gap 2–4 variation of experiment 1 could be analyzed similarly.

The *integer* effect, found in experiment 2, gave additional evidence for the influence of a harmonic template because no significant pitch-shifting forces were found for sine tones half way between harmonic sites. By contrast, a large pitch shift gradient appeared, for the same local spectrum, when the sine tone was near a harmonic site.

Experiments 3 and 4 led to the *proximity* and *local asymmetry* effects, which indicated a role for local interaction. These effects are strong enough that any complete model for pitch shifts must take them into account. These effects essentially showed that spectral components near the mistuned harmonic target are more important in shifting the pitch of the target than are remote components. This result suggests a role for peripheral filtering of the kind that is always observed in masking experiments, but it is not clear that the effects actually resemble masking. Masking models, or other local interaction models consistent with the proximity effect, also tend to predict large average pitch shifts for asymmetrical spectra, and these were not observed. Instead, the proximity and local asymmetry effects may indicate a restricted ''range of interaction'' for a template.

Experiment 5 studied mistuned fundamentals for three tones with spectra that were identical except for octave scaling factors. This experiment found that a low-frequency mistuned fundamental was shifted considerably more than a high-frequency mistuned fundamental. We interpreted this observation as a *frequency* effect, which says that a template is more effective at a low frequency, such as 200 Hz, than at a higher frequency, such as 800 Hz. Such a frequency effect is well known in experiments that study the strength of periodicity pitch, which has often been attributed to template matching, and it was gratifying to find it in our experiment. An alternative interpretation for experiment 5 would be that templates with long periods are more effective than tem-

plates with short periods. However, evidence contrary to the latter interpretation was found in experiment 6, which systematically changed the period of the template. In general, experiments 3–5 exhibited larger pitch shift gradients for lower frequencies.

B. Caveats and conjectures

The experiments reported in this article measured pitch shifts, defined as the difference between the frequency of a mistuned harmonic and the frequency of a matching sine tone. A measured shift is, therefore, the change in the pitch of a sine tone when it is embedded in an otherwise periodic complex, with the period chosen in such a way that the sine tone becomes a mistuned harmonic. To avoid misinterpretation, it is important to note that our experiments did not measure the change in the pitch of a harmonic as the harmonic frequency changes from correctly tuned to mistuned. Therefore, our measured shifts can be interpreted as the pitch shifts caused by mistuning a harmonic only if it is assumed that the pitch of a correctly tuned harmonic is equal to the frequency of the harmonic. The preponderance of evidence suggests that this this assumption may be valid. In 1971 and 1979 Terhardt reported that the pitches of harmonics of a complex tone differed from their frequencies. However, extensive experiments by Peters *et al.* (1983) failed to confirm that result. Further, when the zero-frequency-shift data were extracted from the pitch measurements made by Doty (1989), it was found that harmonic pitches were statistically the same as harmonic frequencies, in agreement with Peters *et al*. Therefore, it is likely that our measurements actually do reflect the change in pitch as a spectral component becomes inharmonic, even though that is not what we measured. Our focus on pitch shift gradient made it unnecessary to measure the pitch shift caused by mistuning *per se*.

The focus on pitch shift gradient has another advantage, especially when comparing data to theory. There are pitch shifts with signal level, even for the sine-wave matching tone, and these effects are included in models such as Terhardt's. However, these level effects cancel in the measured gradient. Therefore, they do not confound the spectral context effects of interest here.

As noted in the Introduction, mistuning a harmonic in a complex tone leads to a shift in the low pitch (virtual pitch) of the tone overall as well as a shift in the pitch of the harmonic. Possibly these two shifts are related. Specifically, it might be imagined that pitch of the mistuned harmonic is shifted in order to agree with a harmonic of the shifted virtual pitch. This conjecture, however, does not square with the facts. According to the measurements of Moore *et al.* (1985), changing the frequency of a harmonic by a certain percentage leads to a change in virtual pitch that is always a considerably smaller percentage. By contrast, changing the frequency of a harmonic leads to a *larger* percentage change in the pitch of that harmonic.

It seems evident that the pitch shift observed for a component that has been perceptually segregated from a complex tone is likely to be closely associated with the process that segregates the component in the first place. It is the pitch, after all, that identifies a perceptually segregated component in a mistuned harmonic experiment. Recently, de Cheveigné (1997) has proposed a statistical decision theory model that successfully predicts the pitch shift of a mistuned harmonic as a function of the mistuning as measured by Doty. The model begins by assuming that a component of a complex tone can be represented by a distribution of pitch cues on an internal tonotopic coordinate. Pitch cues that are close to a harmonic place are perceptually integrated with the rest of the complex tone. Pitch cues that are more remote lead to a segregated tone. Precisely because they are more remote, these pitch cues lead to a pitch shift for the segregated tone. Although the model in its present version cannot account for both the pitch shifts and the high hit rates for mistuned harmonic identification found by Hartmann and Doty, this model does appear to be consistent with the pitch shift effects reported in the present article.

III. CONCLUSION

When a harmonic of a complex tone is mistuned, the harmonic can be heard out as a separate entity, distinct from the complex tone background. Pitch matching experiments show that the pitch of the mistuned harmonic does not agree with its frequency. The shift in pitch is, very reliably, found to be an exaggeration of the physical mistuning.

This article considered two possible kinds of model to account for the pitch shift. A tonotopically local model attributes the shift to the influence of neighboring harmonics. The influence may be the result of partial masking of firing rate excitation patterns (Terhardt) or it may stem from alterations in neural spike timing, as appear in the interspike interval histogram (Hartmann–Doty). In either case the effects are restricted by peripheral filtering. A second class of model attributes the pitch shift to a contrast between the mistuned harmonic and a spectral pattern in the mind of the listener that serves as a template against which tones are compared.

To try to distinguish between the two models, pitch matching experiments were done using special spectra. By changing the spectrum near the mistuned harmonic while maintaining the best fitting template (experiment 1) or by changing the template while maintaining the local spectrum (experiment 2) we were able to show a dominant role for a template. Scaling the frequency range of the matching experiment showed that pitch shifts tend to vanish for mistuned fundamentals near 800 Hz, similar to the limit for virtual pitch formation (experiment 5). This agreement is expected if both the pitch shift and virtual pitch are derived from a template.

Further experiments that maintained the best-fitting template while changing the spectrum near the mistuned harmonic (experiments 3 and 4) indicated a role for the local spectrum, which altered the details of the pitch shifts but did not upset the basic pattern established by the template comparison process. In the end, the dominance of the template is overwhelming.

[1]Terhardt's semiempirical model is unspecific concerning a physiological mechanism for the pitch shift, but in the low-frequency range the model is consistent in spirit with the idea that pitch is determined by a moment (e.g., centroid) of a neural excitation pattern along the tonotopic axis, and that the effect of masking is to erode the excitation pattern caused by the target component, thereby reducing the statistical weight of target excitation closest to the place of the masker. All the mistuned harmonics in the present paper are in this low-frequency range.

[2]Mathematically, a ''gradient'' is a slope, calculated as the ratio of rise-to-run on a graph. Our measure of the ''pitch shift gradient'' would have been more consistent with this definition had we divided our data by the 16% change in mistuned harmonic frequency $[+8\%-(-8\%)=16\%]$. Doing so, however, would have been misleading because the pitch shift saturates as a function of frequency shift. Doty's 1989 measurements show that pitch shifts measured at $\pm 8\%$ hardly differ from pitch shifts measured at $\pm 4\%$. Nevertheless, we use the term ''pitch shift gradient'' because the frequency change (the putative denominator) was always constant in our experiments, and because this term conveys the idea of a wrinkle in the pitch continuum that causes the pitch shift not to be a constant.

[3]Specific calculations using Terhardt's model show negligible pitch shift gradients for gap 1–3 and pitch shifts that are always positive and decreasing with increasing target frequency for gap 2–4. That occurs because this model gives great weight to low frequency partials. Predicted pitch shift gradients for gaps 2–4 have the wrong sign as usual.

Monaural phase discrimination by macaque monkeys: Use of multiple cues

David B. Moody, Colleen G. Le Prell, and Andrew J. Niemiec[a)]
Kresge Hearing Research Institute, University of Michigan Medical School, Ann Arbor, Michigan 48109-0506

(Received 14 May 1996; revised 27 May 1997; accepted 15 January 1998)

Research examining the discrimination of monaural phase change has suggested that temporal envelope shape, which varies with phase, may be an important cue. Much of that research employed stimuli consisting of three components, a center frequency (F_c), which is varied in phase, and an upper and lower sideband separated from the carrier by some frequency (ΔF). As the phase of the center component is varied, both temporal envelope and temporal fine structure change. The present research explored the salience of both envelope and fine structure as cues in a phase discrimination task. Monkeys were trained to report detection of a change from a three-tone complex with 90° starting phase for the center component to one in which the starting phase was smaller. In general, for the values of F_c tested, thresholds for phase change decreased as ΔF increased. When tested with comparison stimuli that had a temporal envelope closely matched to that of the standard, but 0° starting phase, subjects had difficulty discriminating these stimuli from the standard for smaller ΔF, but readily discriminated them at larger ΔF values. These findings suggest that temporal envelope is a critical cue in discrimination of three-tone complexes on the basis of the starting phase of the center component at small values of ΔF, but that other cues are used at larger ΔF values.

INTRODUCTION

Under appropriate conditions, changes in the phase of a monaurally presented auditory stimulus can be detected. The principal conditions required for such detection to occur are that the stimulus consists of two or more components, and that the component varied in phase is close enough in frequency to at least one of the other components so that it cannot be separately resolved by the auditory system. The resulting perceptual differences are described as changes in ''roughness'' or ''timbre'' (Mathes and Miller, 1947; Goldstein, 1967; Patterson, 1988) or in pitch (Buunen *et al.*, 1974; Moore, 1977; Moore and Glasberg, 1988). In general, the results of these studies suggest that the shape of the temporal envelope, which varies with change in component phase, produces the resulting perceptual differences.

The stimulus configuration most commonly employed in these experiments consists of three sinusoidal components: a carrier (F_c) and two half-amplitude sidebands separated from the carrier by some frequency (ΔF). The stimulus complex thus consists of $F_c-\Delta F$, F_c, and $F_c+\Delta F$. When the starting phase of the carrier and sidebands are all 0°, these components produce a sinusoidally amplitude-modulated (SAM) tone at F_c with a modulation frequency equal to ΔF. When the starting phase of the carrier is 90° relative to the sidebands, the stimulus is referred to as a quasi-frequency-modulated (QFM) condition. Although the long-term power spectra of these two signals are identical, the shape of the temporal envelope and the temporal fine structure differ significantly. In the SAM signal, the envelope of the waveform reaches zero amplitude at periods of $T=1/\Delta F$ and the waveform crosses zero at periods of $T=1/F_c$. In the QFM signal, the envelope does not reach zero, with the waveforms being much less modulated and the envelope reaching minima at periods of $T=1/2\Delta F$. In addition, the times between zero crossings do not occur at the same period but vary during the modulation cycle, thus resembling a frequency-modulated stimulus. As phase is varied between 0° and 90°, there is a gradual transition in the features of the stimulus between being SAM and QFM. Examples are given in Sec. I.

Mathes and Miller (1947) were among the first to demonstrate the role of limited auditory frequency resolution in the perception of monaural phase effects. von Helmholtz, a century earlier (as reprinted in 1954), had suggested on theoretical bases that phase relations of closely spaced tones had important implications for auditory theory. However, his empirical observations led to what is known as Ohm's acoustic law or Helmholtz's phase rule, which essentially states that the ear is phase deaf. Using both SAM and QFM stimuli, Mathes and Miller (1947), and later Goldstein (1967), clearly demonstrated that the two types of stimuli are discriminable only when the components are within a limited frequency region. Both studies showed that the size of that frequency region was level dependent, with estimates ranging from 15% of F_c at 20 dB SL to 40% of F_c at 60 dB SL (Mathes and Miller, 1947). These results indicate that the critical bandwidth for phase effects differs from the critical bandwidth observed with other auditory phenomena in that it is wider as well as being more level dependent.

Nelson (1994) defined the critical bandwidth for phase

[a)]Current address: Department of Psychology, Kenyon College, Gambier, OH 43022-9623.

(CB_{phs}) as the ΔF at which subjects could no longer distinguish QFM from SAM waveforms. He showed that the level-dependent behavior of CB_{phs} could be inferred from the filter slopes derived from forward-masking psychophysical tuning curves. Since the ability to discriminate phase changes is tied to the failure to resolve the frequency components of the complex stimulus, it might be assumed that poor frequency resolution, such as might occur in certain types of hearing impairment, would yield good phase discrimination. Indeed, Rosen (1984, 1986, 1987) has shown wider CB_{phs} values for hearing-impaired listeners; that is, they could detect the difference between SAM and QFM signals over a wider range of frequencies at equivalent sound pressure levels. Using a task similar to that of the present study, Rosen and Smith (1988) showed greater sensitivity to phase change for impaired listeners relative to that of normal-hearing subjects, a result consistent with wider CB_{phs}. Results indicating wider CB_{phs} were also shown by Moore and Glasberg (1988, 1989) using different phase discrimination tasks. Nelson and Schroder (1995), on the other hand, showed narrower or equivalent CB_{phs} values in hearing-impaired listeners at equivalent SPLs.

When the individual components of a signal cannot be separately resolved by the auditory system, it is assumed that discrimination is based on temporal changes in the stimulus, most notably on the temporal envelope which is strongly affected by phase changes. In other words, the output of the auditory filter that is stimulated presents a time-varying output to the nervous system resulting from the interaction of the stimulus components contained within its passband. Based on the demonstrations of de Boer (1961) that only phase changes which affect the envelope of a signal give rise to subjective differences, Buunen (1975) concluded that the only signal parameter needed to describe time-structure detection was the envelope of the signal. However, changes in temporal fine structure might also be detected. Buunen (1975) and Nelson (1994) considered cues that might be provided by an ''internal spectrum'' produced by the phase-dependent interaction of nonlinear distortion products with each other and with the acoustic components. Both authors suggest that these two explanations are not mutually exclusive, and may simultaneously contribute to phase discrimination.

We know of no studies of monaural phase discrimination in nonhuman subjects. The present experiment extends the study of phase discrimination to the macaque monkey, which shows frequency selectivity (Serafin *et al.*, 1982) and critical band functions (Gourevitch, 1970) similar to those from humans, but somewhat poorer frequency discrimination (Prosen *et al.*, 1990). The intent of the study was not to determine the range of ΔF within which phase could be discriminated as has been done in previous research with human listeners, but rather to explore the conditions under which temporal envelope appears to be the cue that is used to make such a discrimination. We believe such data will help to identify those features of complex auditory signals which may be most salient to these animals in the discrimination of complex signals such as are used in communication.

I. METHOD

A. Subjects

Four male macaque monkeys served as subjects in this experiment. One of the subjects, M141, was a *Macaca nemestrina*; the remaining three subjects, M161, M172, and M174, were *Macaca fuscata*. At the start of testing, the ages of the subjects were as follows: M141, >13 yr; M161, 13 yr; M172, 8 yr; and M174, 8 yr. All subjects had previous experience in psychoacoustic experiments, having served in studies of pure-tone frequency discrimination (M141, M161, and M174), discrimination of frequency modulation (M141 and M172) and discrimination of amplitude modulation (M141 and M161).

The subjects were individually housed and were maintained on a restricted food regimen in which they received a daily allotment of whole-diet, banana-flavored reward pellets (Bio-Serve, 190 mg) and Purina high-protein monkey chow. The amount of food given was sufficient to maintain steady weight gains throughout the experiment. Fresh fruit was provided three times per week. Water was freely available in the home cage at all times. Environmental enrichment in the form of toys and foraging puzzles was provided in the home cages. The animal facilities were AAALAC accredited and animal husbandry met or exceeded applicable standards, including the NIH Guide for the Use and Care of Laboratory Animals.

B. Apparatus

Prior to each testing session, the animals were placed in primate restraining chairs (Moody *et al.*, 1970) and transported from the animal quarters to the laboratory. Once in the laboratory, they were placed in double-walled sound rooms (Industrial Acoustics). Their heads were restrained, earphones (TDH-39P), mounted in universal joints, were placed over each ear, and a food-delivery chute was mounted on the chair. When required by the experimental procedure, the banana-flavored reward pellets could be automatically delivered down the chute such that the monkey could pick them up with his tongue. Mounted in front of the chair at the monkey's eye level was a cue light surrounded by a metal cylinder. Contact with the cylinder served as the behavioral response, and was sensed by a circuit that detected a minute electrical current that passed from the restraint chair through the monkey.

An Intel-based computer system controlled all aspects of the experiment, including generation and presentation of stimuli, implementation of experimental contingencies, and recording of data.

C. Stimuli

The stimuli were digitally synthesized using additive synthesis techniques and a 20-kHz clock rate. Each of the three sinusoidal components was separately generated and all three were then added together. The starting phase of the center component was varied as required to produce the test stimulus sets; sidebands both started at 0° and had amplitudes half that of the center component. Thus, the power

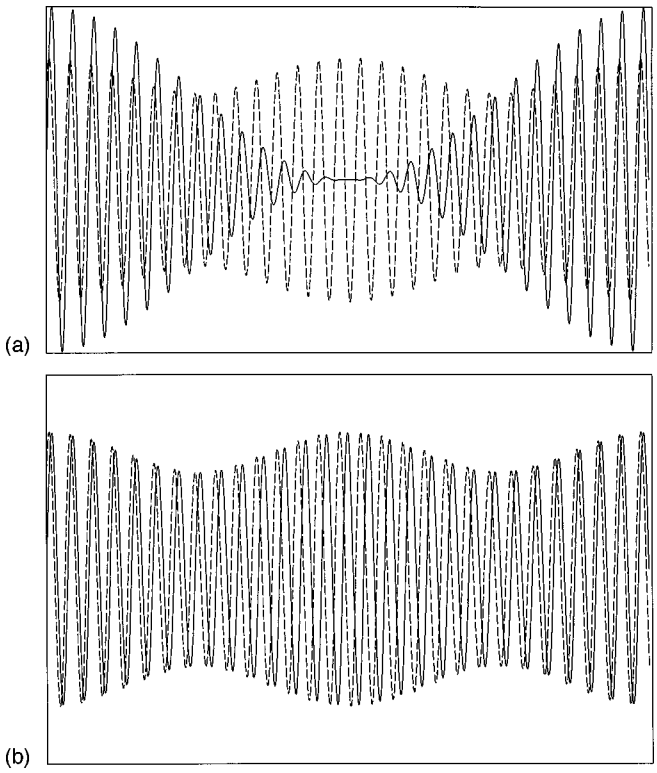

FIG. 1. (a) Examples of three-component stimuli having identical power spectra but with 0° (solid line) or 90° (dashed line) starting phases for the center component. The 0° condition results in a sinusoidally amplitude-modulated (SAM) signal at the frequency of the center component. The 90° condition results in a quasi-frequency-modulated (QFM) signal. (b) Examples of three-component stimuli having closely matched temporal envelopes but different starting phase, sideband spacing, and sideband envelopes. The dashed line is identical to that in panel (a); the solid line is a signal with 0° starting phase for the center component, but with sidebands spaced at twice the frequency of those of the SAM signal in panel (a) and with amplitudes of 0.079 that of the center component.

spectra of all stimuli for a particular combination of F_c and ΔF were identical. Schematic examples of stimuli with 0° and 90° center components are shown in Fig. 1(a).

The test stimuli were 250 ms in duration and were generated with 20-ms rise/fall times using a cumulative normal distribution function as the gating waveform. The digitized stimuli were presented through a 12-bit digital–analog converter and were low-pass filtered with an 8-kHz cutoff. All stimuli were presented at a level of 74 dB SPL. The response of the earphones was flat (± 1 dB) within the range of frequencies in the test stimuli.

Three values of F_c (0.5, 1, and 2 kHz) and four values of ΔF (25, 50, 100, and 200 Hz) were employed in the experiment, although not all values of ΔF were tested with each F_c. In addition, special stimuli were generated that had temporal envelopes that were closely matched to each of the 90°-phase (QFM) conditions, but with different sideband structures and with 0° starting phase for the center component. The sidebands for these stimuli were located at $2\Delta F$ of the corresponding QFM stimulus, but their amplitudes were set to 0.079 of the amplitude of the center frequency resulting in a SAM stimulus with a modulation index of 0.158. The overall gain of this stimulus was also adjusted to compensate for the reduction in sideband level. The QFM and envelope-matched stimuli generated using these parameters are depicted in Fig. 1(b). Although these stimuli did not, in fact, have mathematically identical envelopes,[1] we will use the term ''equal envelope'' to refer to the SAM stimuli having envelopes modeled after the QFM stimuli.

D. Procedure

The behavioral procedure was based on one that was originally devised for determining frequency and intensity difference thresholds (Moody *et al.*, 1976). Briefly, the subject was required to wait until the onset of a flashing cue light, and then to make contact with the response cylinder. Once contact was made, and for as long as it was maintained, the cue light remained steady and an auditory stimulus (the standard) was repeatedly presented through the right earphone. Stimuli were on for 250 ms and off for 250 ms. From 1 to 9 s after onset of the first standard stimulus, a test trial was initiated during which a comparison stimulus alternated three times with the standard. If the subject responded to the comparison stimulus presentation during the 2.8-s trial by releasing contact with the cylinder (a hit), a food pellet reward was delivered and the cue light and auditory stimuli were terminated. The flashing cue light was presented again as soon as 3 s passed without a response. Also included in the procedure were catch trials during which no comparison stimulus was presented, but cylinder releases were recorded to provide an estimate of the frequency with which the subject was responding in the absence of an appropriate stimulus (false alarms). Data from sessions during which responses occurred on more than 20% of the catch trials were discarded. Any responses that occurred at any other time than during test trials, or failure to respond to a test trial, resulted in a brief time-out from the experiment. During this 5-s interval, the cue light and stimulus presentation were discontinued and the subject was required to refrain from touching the response cylinder. These contingencies were effective in reducing the frequency of inappropriate responses.

For these experiments, the standard stimulus was the 90°-phase condition (QFM), and the comparison stimuli consisted of three-tone complexes in which the starting phase of the center component was less than 90°. During a given session, eight different comparison stimuli were presented according to the method of constant stimuli, and a threshold was determined as that starting phase that was detected on 50% of the test trials. The eight comparison stimuli were selected such that at least one, but no more than two, of the stimuli were detected on fewer than 50% of the test trials.

Testing was continued on each combination of F_c and ΔF until stability was achieved, as defined by the criterion that the thresholds measured on four of five consecutive days had to be within $\pm 10\%$ or $\pm 1°$ (whichever was greater) of the median threshold for those five days. The median was then taken as the estimate of threshold.

Following determination of each threshold estimate, an additional condition was run in which the most difficult stimulus in the test set (the one closest in phase to the 90° standard) was replaced with one, as described earlier in Sec. I C, having a temporal envelope closely matched to that of the QFM standard. All other experimental conditions re-

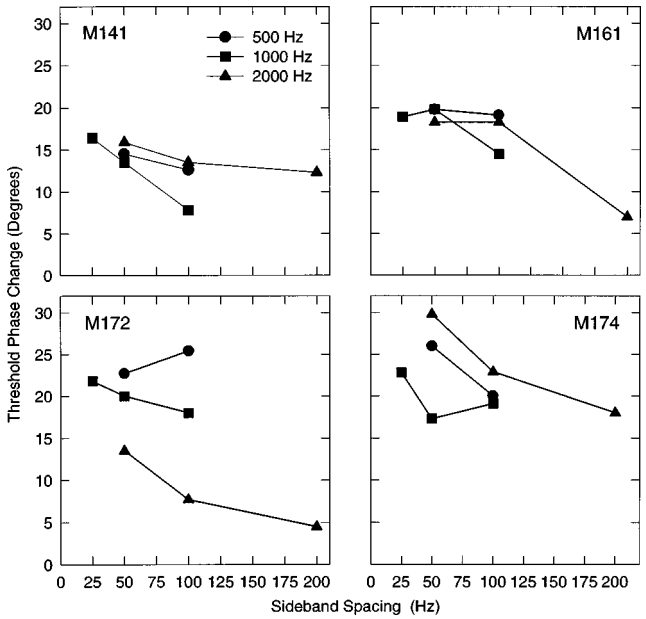

FIG. 2. Thresholds from each of the four subjects for detecting a change in phase of the center component of a three-component complex. The standard stimulus had a 90° starting phase. The ordinate values represent the decrement in starting phase required for the subject to detect the phase difference on 50% of the presentations. The symbols represent different values of the center frequency (F_c).

mained unchanged. Because this stimulus had a temporal envelope like that of the QFM standard stimulus, but was actually a SAM stimulus having lower-amplitude sidebands spaced at twice the frequency of the standard, it provided an indication of the extent to which the phase discrimination was based on the temporal envelope of the waveforms rather than on difference in temporal fine structure or sideband configuration. In order to reduce the likelihood that subjects would learn to ignore the temporal envelope which, in these stimuli, was no longer a reliable cue for discriminating comparisons from the standard, generally no more than three sessions were run before switching to another phase-discrimination condition. For one subject, M174, up to nine sessions with equal-envelope stimuli were carried out to determine if any progressive improvement occurred. During the equal-envelope testing sessions, percent hits to the envelope-matched stimulus were taken as indicators of the salience of the temporal envelope cue. If subjects failed to discriminate the equal-envelope stimulus from the standard, then envelope was assumed to be the cue being used in the phase discrimination. If subjects readily discriminated the equal-envelope from the standard, then it was assumed that cues other than envelope were available.

II. RESULTS AND DISCUSSION

Average threshold values required for each of the four subjects to discriminate a change in phase from the 90° standard are shown in Fig. 2. All subjects were able to discriminate the change in the starting phase of the center component of the three-component complex, in some cases showing remarkable sensitivity. For most subjects, thresholds were in the 10°–20° range, similar to those reported for normal and impaired humans by Rosen and Smith (1988) on a similar task but with quite different stimulus values. Discrimination of all stimulus combinations was expected in this study since all values of ΔF were much less than 40% of F_c, which, based on human data (Mathes and Miller, 1947), would be expected to be within the CB_{phs}. The values of ΔF were also less than the values of the conventionally defined critical band for macaque monkeys (Gourevitch, 1970). Since phase change could be readily discriminated within the range tested, the objective was to determine which features of the stimulus were used by the subjects in making the discrimination.

Although there are a few exceptions, the general tendency is for phase change to become more discriminable as ΔF increases. Since a decrease in center-component phase results in an increase in modulation depth, comparison of these data with those derived from temporal modulation transfer functions (TMTFs) is relevant. Based on TMTFs determined for macaque monkeys (including M141 and M161 from the present experiment; Moody, 1994), the expectation would be that, if anything, temporal envelope shape would become less discriminable at ΔF values of 100 and 200 Hz. Because the modulation rate of the envelope of the QFM standard stimulus is $2\Delta F$, the present data from ΔF values of 100 and 200 Hz are most appropriately compared with TMTF results obtained at modulation frequencies near 200 and 400 Hz, respectively. In the Moody (1994) data, sensitivity to modulation drops dramatically above 160 Hz. These TMTF observations call into question the notion that it is change in the temporal envelope of the waveform that provides the most salient discriminative cue to the subject, at least for the higher values of ΔF.

Comparisons with TMTF results must be carefully qualified, however. The Moody (1994) TMTF data were obtained with sinusoidally amplitude-modulated noise carriers, not pure tones as in the present study. The TMTF data are not normally obtained using sinusoidal carriers because it would be difficult to differentiate between the detection of modulation and the detection of spectral changes in sideband amplitude as modulation is varied. Viemeister (1979) presents TMTF data in which restricted spectral regions are stimulated by bandpass filtering broadband modulated noise. Those data suggest reduced sensitivity at lower values of F_c, but show the same decrease in sensitivity with increases in modulation frequency (ΔF) seen in the broadband data. Thus, those data provide additional evidence that if envelope is the cue being used to make the discriminations in the present study, sensitivity should decrease rather than increase as ΔF increases.

A second important difference is that the TMTF animals in the Moody (1994) study were discriminating an amplitude-modulated stimulus from an unmodulated standard, rather than a modulated stimulus from another modulated stimulus. It seems unlikely, however, that this difference could result in greater sensitivity to envelope change at higher modulation frequencies.

If temporal envelope is not the relevant discriminative cue, then an alternative cue is detection of changes in the temporal fine structure of the QFM standard as the phase of the center component is reduced toward the SAM condition.

Since the amount of change in the temporal fine structure is related to the value of ΔF, there would be greater changes at larger ΔF values, which would be expected to be more easily discriminable. However, certain aspects of the data are not compatible with that interpretation. If one assumes that the ability to discriminate changes in temporal fine structure resulting from changes in phase is related to frequency discrimination ability, then one would conclude that phase discrimination acuity should be related in an orderly way to F_c for a given value of ΔF. That is, the fine-structure changes produced by a given phase change for a given ΔF should be most easily discriminated with the 500-Hz F_c, and least easily discriminated when the F_c is 2000 Hz. The data do not provide strong evidence of such a difference, and for one subject, M172, the reverse ordering of thresholds as a function of F_c was observed.

Thus, two observations suggest that multiple mechanisms might be contributing to the observed results. The first observation is the inference from the TMTF data that discrimination based on envelope changes seems unlikely at higher values of ΔF. The second observation is that discrimination based on fine structure change also seems unable to explain all aspects of the data. The suggestion of multiple mechanisms was evaluated by presenting subjects with stimuli that had envelope structures closely matched to those of the standard QFM stimuli, but that had different sideband spacing, sideband amplitudes, and 0° carrier phase. The extent to which subjects failed to respond to such stimuli during initial exposures was used as an indication of the extent to which envelope was the dominant cue for the phase discrimination.

The results of the equal-envelope tests are presented in Fig. 3, which shows the percent of time the subject detected the equal-envelope stimulus for each of the conditions. The lines connecting the solid symbols indicate the average results from all sessions. The smaller open symbols indicate the hit rate for the first session in which a particular equal-envelope stimulus was presented.

The low hit rate for the smaller values of ΔF clearly indicates that the subjects had difficulty discriminating a QFM stimulus from a stimulus that had a closely matched envelope but that differed in spectral content and phase. This observation strongly suggests that envelope was the cue being used to make the discrimination at low ΔF values. Additionally, for most of the lower values of ΔF, there was no indication of improvement with additional testing, even though responses to the equal-envelope stimuli were reinforced. Even in M172, the animal that was tested nine times with the $F_c = 2$ kHz and $\Delta F = 50$ Hz, no indication of improvement was seen. This lack of improvement with explicit training suggests that, although other cues were present in the stimuli, they were not readily available to the subjects.

At higher values of ΔF, subjects more readily discriminated the equal-envelope stimuli from the QFM standards, even on the first equal-envelope test session. This observation suggests that the subjects might be using nonenvelope cues, possibly temporal fine-structure changes, to discriminate phase change. The general relationship seen in Fig. 3 between F_c and discriminability supports use of a fine-structure cue. At low values of F_c, nonenvelope cues become salient at lower values of ΔF, suggesting a Weber's law type of discriminability. Those suggestions must be further qualified, however, because the discrimination could also have been based on spectral resolution of the wider sidebands in the equal-envelope stimuli. Since this cue was unavailable in the phase-discrimination condition, the discrimination of fine structure, i.e., changes in instantaneous frequency, at larger ΔF values is more parsimonious in the sense of explaining both sets of data. One remaining possibility is that the envelopes were not equated after peripheral filtering, and therefore that discrimination of postfiltering envelope differences may have occurred. Although we believe this explanation to be less likely, we have no direct tests to rule out the possibility. It is likely that different mechanisms are used for discrimination at high versus low values of ΔF.

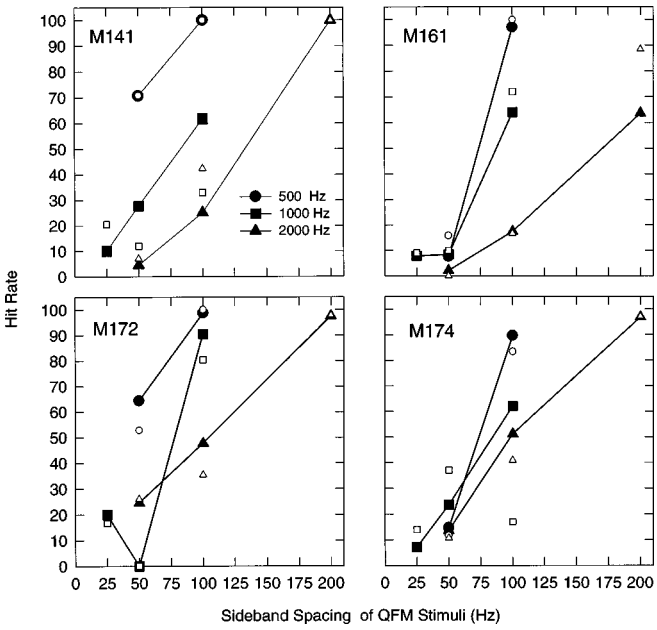

FIG. 3. Percent of time each of the four subjects responded to presentations of a stimulus having a temporal envelope closely matched to that of the 90° standard, but that differed in starting phase, sideband spacing, and sideband amplitude. The filled symbols represent the average of all presentations; the smaller open symbols represent data obtained on the first session of each condition. Low hit rates at narrow sideband spacings on this task suggest that temporal envelope was the most probable cue being used in the discrimination task to detect phase differences. In almost every case, hit rates and false alarm rates were similar when the hit rate was below 20%, suggesting that detection of the equal-envelope stimuli was truly at chance levels.

III. CONCLUSIONS

Within the range of F_c and ΔF values that were tested in this study, macaque monkeys were able, in a psychophysical task, to detect when the starting phase of the center component of a three-component complex was decreased from 90°. In general, phase discrimination thresholds decreased as sideband spacing was increased. Based on TMTF data, this observation suggested that a cue other than temporal envelope was being used to make the discrimination, at least at higher sideband spacing. When tested with a stimulus that had a temporal envelope closely matched to that of the QFM

standard, but that differed in center component phase, sideband spacing, and sideband amplitude, the subjects had difficulty in making the discrimination for narrower sideband spacing, but readily discriminated stimuli with wider spacing. Together these findings suggested that temporal envelope was the cue being used for narrower sideband spacing, but that some other cue was used as sideband spacing increased. It is likely that the cue was temporal fine structure, but the present data do not eliminate other possibilities. Thus, monaural phase discrimination can be based not just on temporal envelope changes, but also on other differences that are available as component phase is varied.

ACKNOWLEDGMENTS

This research was supported by Program Project Grant No. 2 P01 DC00078 from the National Institute on Deafness and Other Communication Disorders. The authors wish to express their appreciation and thanks to Catherine Thompson who had the primary responsibility for the daily testing of the subjects in this experiment, and also to thank the two reviewers who provided many useful suggestions on improving the manuscript and insights into the mathematical relationships involved in describing the envelopes of SAM and QFM stimuli.

[1]For these experiments, the sideband level required to produce closely matching temporal envelopes was determined empirically by adjusting sideband amplitude and overall gain until the two waveforms appeared to match, determined by visual inspection, as shown in Fig. 1(b). Subsequent mathematical determinations, using the equations provided by Rosen and Smith (1988), have indicated that the sideband amplitude required to produce a modulation depth equivalent to that of the QFM stimulus should have been 0.086 of the carrier (SAM index of modulation=0.172). In addition, even when the modulation depth is matched, the envelope of the QFM stimulus slightly departs from being strictly sinusoidal. Neither the mismatch of modulation depth nor the mismatch of envelope shape would be expected to modify the conclusions of the present study.

(Received 24 January 1996; revised 10 October 1997; accepted 5 December 1997)

Lateralization and just-noticeable difference (jnd) measurements relative to the center were tested in a large group of patients with pontine lesions caused either by stroke or multiple sclerosis. Stimuli included binaural clicks, and low- and high-frequency narrow-band noise bursts. Two major types of abnormalities were revealed in the lateralization performances: perception of all stimuli, regardless of interaural differences (time and/or level) in the *center* of head (center-oriented), or lateralization of all stimuli to one side or the other of the head (side-oriented). The only significant correlation between jnd and lateralization performances was that an elevated jnd was always manifested in abnormal lateralization, while abnormality in lateralization did not necessarily indicate an abnormal jnd. Center-oriented lateralization was observed either for both interaural differences or only for one of them, and was found in both MS and stroke patients. All side-oriented stroke patients were similarly unable to center binaural stimuli for both time and level cues, whereas only one MS patient had this abnormality for interaural time differences, while his level performance was normal. More abnormalities were detected in the narrow band stimuli tests, although in some cases performance was more degraded for click stimuli. Lateralization tasks with high-frequency stimuli were more sensitive detectors of abnormality than jnd for any kind of stimulus, or lateralization tasks with low-frequency stimuli or clicks. INTRODUCTION

The perception of auditory stimuli presented simultaneously to both ears has been investigated for several decades, yet the processes and structures responsible for binaural interaction are far from being fully understood. Considerable evidence indicates that this analysis is performed in the brainstem and that the cues used to perceive the sources of stimuli in auditory space consist of the differences between the stimuli reaching the two ears—either interaural time differences (ITD) or interaural level differences (ILD). Psychophysical experiments, concentrating in general upon people with normal hearing, have been among the most commonly employed for testing interaural faculties in humans (Tobias and Zerlin, 1959; Domnitz, 1973; Domnitz and Colburn, 1977; Durlach and Colburn, 1978; Wightman *et al.*, 1987; Algom *et al.*, 1988). Since the 1980's, interest has increased in the performance of multiple sclerosis (MS) patients in response to binaural stimuli (Hausler and Levine, 1980; Jenkins and Masterton, 1982; Hausler *et al.*, 1983; Hendler *et al.*, 1990; Furst *et al.*, 1990, 1992, 1995; Levine *et al.*, 1993a, b). These experiments were either discrimination tests, measuring just-noticeable differences (jnd) for ITD and ILD (Hausler and Levine, 1980; Levine *et al.*, 1993a); masking level difference (MLD) tests (Hendler *et al.*, 1990; Levine *et al.*, 1994), or lateralization tests using a click stimulus (Furst *et al.*, 1990, 1992, 1995; Furst and Algom, 1995).

It is difficult to arrive at firm conclusions from these studies, as they employed different stimuli and different experimental methods. Yet the following points may be suggested: (a) Abnormal performance in jnd tests is more likely to occur when high-frequency stimuli are presented, while low-frequency and broadband stimuli may still result in good discrimination ability. (b) Inability to perform interaural time discrimination can coexist with normal interaural level discrimination. (c) Some patients cannot discriminate small interaural differences. Of such patients some lateralize all click stimuli to one or the other side of their heads. Other patients never lateralize the clicks but refer the clicks only to the middle of their heads, for all interaural differences of time or level.

[a)]This study has been carried out in accordance with the principles of the Helsinki Declaration.
[b)]Electronic mail: mira@eng.tau.ac.il

These observations do not enable us to answer questions about the relationship between discrimination and lateralization, or the relationship between perception of transients and longer stimuli.

The purpose of the present study was to examine these relationships. We examined both stroke and MS patients with pontine lesions, and compared the performances obtained with clicks, high-frequency narrow-band noise, and low-frequency narrow-band noise. Each patient was tested in both discrimination and lateralization tasks.

I. EXPERIMENTAL METHODS

Eleven young healthy subjects and 22 patients went through the experimental procedure. The healthy subjects were students ranging in age from 20 to 30 years. All had normal audiograms and served as a control group. The patients who participated in the study were 9 multiple sclerosis (MS) patients and 13 stroke patients with pontine lesions, as indicated by clinical symptoms and routine MRI analysis. The MS patients were 27 to 43 years old and the stroke patients ranged in age from 57 to 82. All the patients had normal audiograms according to the standard of their age group.

Preliminary results from a complementary investigation of healthy elderly subjects indicate that there is no significant difference between young and elderly controls with regard to the psychophysical tests of this study (Babkoff *et al.*, 1996).

The test procedures included measurements of lateralization and discrimination ability. All the tests were performed during the same session for each subject. Each test was repeated for three stimulus types: clicks, and two $\frac{1}{3}$-octave noise bursts. Stimuli duration were 0.1 ms for the click and 250 ms for the noise bursts. The high-frequency narrow-band noise (HNB) was centered around 4 kHz and the low-frequency narrow-band noise (LNB) around 0.5 kHz. All stimuli were computer generated by an Ariel board 16+, based on a TI TMS320-C25 DSP chip, and using a 44-kHz sampling rate. The clicks were computer generated rarefaction clicks 40 s long. The narrow-band (NB) noises were generated by MATLAB, as a sum of sinusoidal components whose amplitudes and phases were uniformly distributed. To smooth the generated waveform, a Hanning filter was used.

All the tests took place in a sound-proof chamber, and the stimuli were delivered through calibrated Yamaha HP-2 earphones. Each subject's threshold for pure tones at frequencies from 250 Hz to 8 kHz and for the test stimuli was measured prior to the binaural tests. The stimuli were presented at a level 50 dB above the subject's threshold.

The procedure for the lateralization tests was similar to that described by Furst *et al.* (1995). Interaural time and intensity differences of stimuli were presented to a subject through earphones. In each trial, two successive short bursts were introduced, separated by an interval of 500 s. The first presented diotic stimuli to the two ears, whereas in the second, either the arrival time of the stimulus to one of the earphones was delayed (ITD trials), or the level was increased at one ear and decreased at the other ear by the same amount (ILD trials). Interaural time differences were varied from -900 to 900 s in 225-s steps (negative values indicate delays to the right ear). Interaural level differences ranged between -10 and 10 dB, in steps of 2.5 dB, where negative values indicate a higher intensity to the left ear. Thus both types of trials had a nine-level scale. After listening to both intervals, the subject's task was to indicate the position of the auditory image of the second burst by pushing one of nine equally spaced buttons on a rectangular keyboard. Button Number 1 on the subject's left signified sound to the left side; Button Number 9 signified the right side. Button 5 was considered analogous to the middle of the head with four numbers on each side of the center.

Prior to the lateralization testing each subject underwent a training session, to ensure that the instructions were fully understood. The training lasted a few minutes. The subject pushed the nine different buttons and listened to the ITD and ILD corresponding to each button. Each subject then decided when he/she felt ready to start the lateralization tests. At that point, the experimenter instructed the subject to close his/her eyes. As the experimenter pushed one of the buttons randomly, the subject was asked (1) to point to the position on his/her scalp which most closely corresponded to where the sound was perceived and (2) to relate this position to one of the nine button numbers.

Immediately following this training session the lateralization experiment was begun. Interaural level or time differences were presented randomly for one of the three types of stimuli (click, LNB, or HNB). The run was completed when each of the 17 different interaural differences had been presented at least 4 times for this stimulus. The same procedure was then repeated for the other two types of stimuli.

For all three types of stimuli, just-noticeable differences (jnd) of interaural time and level were measured with respect to the stimulus presented diotically. An adaptive 2-interval 2-alternative forced choice procedure was used (Levitt, 1971). The stimuli and interaural differences were similar to the ones used in the lateralization tests; here, however, time and level jnds were measured separately. The subject listened to successive intervals (300 ms each) with a 300-ms pause between them. His/her task was to press one of two buttons to indicate whether the signal in the second interval was perceived to the right (right button pressed) or left (left button pressed) of the signal in the first interval. Each of four successive presentations had the same interaural difference; the order of the two intervals was randomized for the four presentations. Performance on the four presentations determined the next interaural difference, as follows. All four correct resulted in a smaller interaural difference with the next four presentations. Three correct resulted in a repetition of the same interaural difference with the next four presentations. When only were one or two were correct, or when two successive sets of four presentations yielded one error in each, a larger interaural difference was introduced. The test ended when six reversals had occurred. The jnd was defined as the mean of the six reversals.

II. LATERALIZATION DATA REPRESENTATION

Typical lateralization performance results are shown in the histograms in Fig. 1, obtained from a subject in the con-

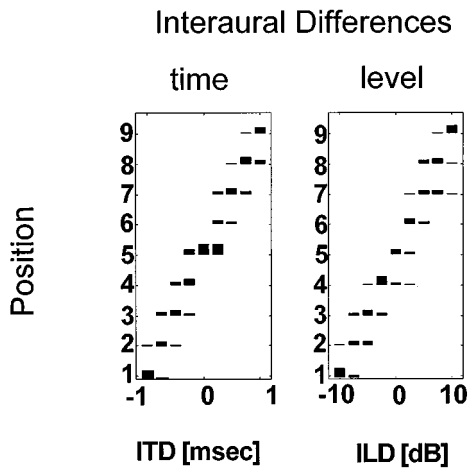

FIG. 1. Estimated joint probability functions, pdf(POS, ITD) and pdf(POS,ILD), represented by histograms, provided by the performance of a normal subject in the lateralization experiment for click stimuli. The histograms were obtained by counting the number of times the subject reported perceiving a certain position in response to dichotic stimuli with different ITDs and ILDs.

trol group. The left panel represents the subject's performance for clicks stimuli with ITDs and the right panel, the response to click stimuli with ILD. In both panels, the y-axis represents the nine positions defined by the test procedure, and the x-axis the interaural difference. Each bin in the histograms in Fig. 1 is defined as $h(\text{pos,ITD})$ or $h(\text{pos,ILD})$, which is equal to the relative number of times the subject indicated a certain position (pos) for a given interaural difference, ITD or ILD. The height of each bin represents the value of $h(\text{pos,ITD})$ or $h(\text{pos,ILD})$. Thus

$$\sum_{\text{pos}}\sum_{\text{ITD}} h(\text{pos,ITD})=1, \quad \text{and} \quad \sum_{\text{pos}}\sum_{\text{ILD}} h(\text{pos,ILD})=1. \tag{1}$$

There is a high correlation between the indicated positions and the interaural differences, as shown in Fig. 1. It is possible to calculate this correlation by fitting linear lines (regression lines):

$$\text{POS}=a^t\cdot \text{ITD}_{\text{pos}}+b^t \tag{2}$$

$$\text{POS}=a^l\cdot \text{ILD}_{\text{pos}}+b^l, \tag{3}$$

when POS$=1,2,...,9$ are the positions perceived, $\text{ITD}_{\text{POS}}=1,2,...,9$ are the introduced positions for ITD$=-900$, -675, -450, -225, 0, 225, 450, 675, 900 μs, respectively, and $\text{ILD}_{\text{POS}}=1,2,...,9$ for ILD$=-10$, -7.5, -5, -2.5, 0, 2.5, 5, 7.5, 10 dB, respectively. The coefficients a^t, b^t, a^l, and b^l in Eqs. (2) and (3) are derived by means of minimum-squared error fitting to the data. For the normal subject whose performance with click stimuli is presented in Fig. 1, the coefficients derived were: $a^t=a^l=0.95$, $b^t=0.27$, and $b^l=0.19$. For all the subjects in the normal control group and for all the stimulus types (click, LNB, and HNB), the regression line fit yielded the following coefficients: $0.84<a^t$, $a^l<1$ and $b^t,b^l<0.7$. The normal means and standard deviations are presented in Table I.

Representative patients' performances in the lateralization experiment are presented in Fig. 2. The performance of three stroke patients for clicks is presented in a histogram similar to that in Fig. 1. Comparison of the performance of the three patients to normal performance (presented in Fig. 1) indicates that Pt35's performance (top panels in Fig. 2) is the closest to normal. The values from his regression line fit [Eqs. (2) and (3)] are $a^t=0.93$, $b^t=0.26$, $a^l=0.87$, and b^l

TABLE I. Mean and standard deviation (s.d.) of the six lateralization indices, the four regression line parameters and the jnds, for ITD and ILD, obtained by the control group for clicks.

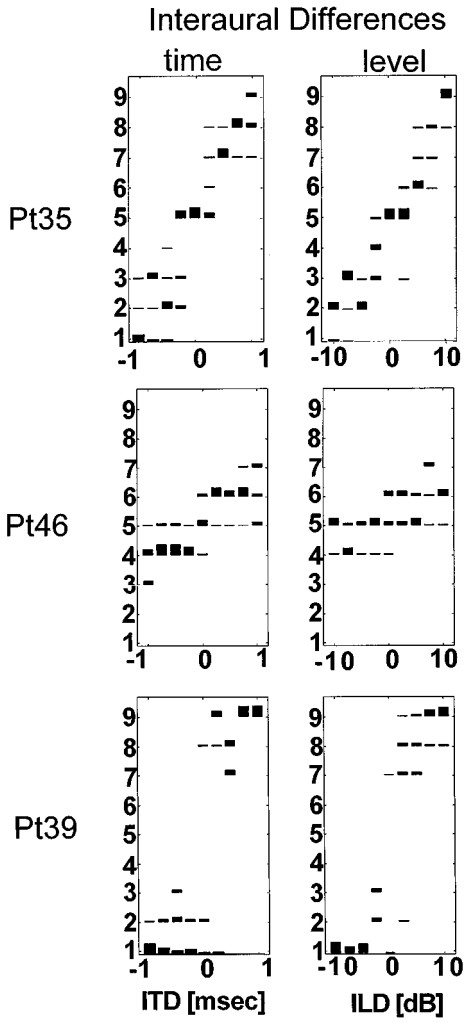

FIG. 2. Histograms of the estimated joint probability functions, pdf(POS, ITD) and pdf(POS, ILD), for clicks for patients: Pt35, Pt46, and Pt39.

TABLE II. Mean and standard deviation (s.d.) of P_{ITD} (pos) obtained by the control group for clicks.

Position:	1	2	3	4	5	6	7	8	9
Mean	0.113	0.105	0.110	0.099	0.122	0.103	0.109	0.112	0.116
s.d.	0.082	0.072	0.044	0.036	0.055	0.039	0.047	0.076	0.072

$=0.42$. Those values are all in the normal range, thus we can consider this patient's performance as normal for click lateralization.

Pt46 (Fig. 2, middle row) perceived most binaural stimuli near the center (positions 4, 5, and 6), resulting in the following regression line coefficients: $a^t=0.44$, $b^t=2.78$, $a^l=0.23$, and $b^l=4.11$ are all significantly different from those of the control group. On the other hand, the performance of Pt39 (Fig. 2, bottom row) is abnormal but in a different way than Pt46. This patient perceived the binaural stimuli only at the sides (positions 1, 2, 3 or 7, 8, 9) and never in the center (positions 4, 5, 6). The regression line slopes were $a^t=1.15$, $a^l=1.21$, and y intercepts ($b^t=-0.97$, $b^l=-1.21$) were significantly abnormal (more than 3 standard deviations from the mean). Although these slopes are well outside the normal range (Table I) from inspection of Pt39's data, it is clear that the regression line statistics do not capture the full external of the abnormality. For this reason another measure was developed to complement the regression line. In order to provide a measure of a listener's tendency to report sounds at some locations and not others, the number of times that each perceived position was selected during an experiment was counted. We then defined the probability of perceiving a given position as

$$P_{\mathrm{ITD}}(\mathrm{pos})=\sum_{\mathrm{ITD}} h(\mathrm{pos},\mathrm{ITD}), \tag{4}$$

and

$$P_{\mathrm{ILD}}(\mathrm{pos})=\sum_{\mathrm{ILD}} h(\mathrm{pos},\mathrm{ILD}), \tag{5}$$

when pos$=1,2...,9$. The performance of all subjects in the control group yields $P_{\mathrm{ILD}}(\mathrm{pos})\approx P_{\mathrm{ITD}}(\mathrm{pos})\approx 0.11$ for every stimulus and every pos$=1,...,9$. In Table II are the mean and standard deviation (s.d.) of $P_{\mathrm{ITD}}(\mathrm{pos})$ obtained for clicks from the normal control group.

We have chosen to further collapse our data for two reasons. First, with 9 positions and 2 types of interaural differences, 18 measures for each stimulus type become unwieldly. Second, if the mean ± 2.5 s.d. were used to define the normal range, then note (Table II) that for almost every position the lower boundary of the normal range is negative. Other stimuli and ILD experiments yielded similar values. Thus if a subject ignores any position [i.e., $P_{\mathrm{ITD}}(\mathrm{pos})=0$ or $P_{\mathrm{ILD}}(\mathrm{pos})=0$] the performance would still be considered normal, and therefore this measure is meaningless. Therefore, we have chosen to characterize lateralization performance by using only three principal positions: left, center, and right. In terms of the lateralization experiment, positions 1, 2, and 3 constitute ''left;'' positions 4, 5, and 6 ''center;'' and positions 7, 8, and 9 ''right.'' Thus instead of considering the probability for perceiving a given position, we now consider the probability for perceiving left, right or center. From reviewing all our data we conclude that the principle features of subject performance are preserved using this collapsing method.

Formally, we then define a lateralization index, Θ_α^β, where the superscript β stands for the interaural difference presented (t for time, l for level) and the subscript α stands for the principal position (C for the center, L for the left, and R for right). Thus

$$\Theta_L^t=\sum_{\mathrm{pos}=1}^{3} P_{\mathrm{ITD}}(\mathrm{pos}), \tag{6}$$

$$\Theta_C^t=\sum_{\mathrm{pos}=4}^{6} P_{\mathrm{ITD}}(\mathrm{pos}), \tag{7}$$

$$\Theta_R^t=\sum_{\mathrm{pos}=7}^{9} P_{\mathrm{ITD}}(\mathrm{pos}). \tag{8}$$

The control subjects displayed little or no difference between the left and right lateralization indices, none of the right–left differences reached a level of statistical significance according to Student's t test ($p<0.01$). Thus side lateralization indices, Θ_S^t and Θ_S^l, were defined the algebraic means of left and right indices for the respective interaural differences. The mean normal values and their standard deviations are given in Table I. As can be seen from this table, with this procedure for collapsing the data the mean $-2.5\cdot$s.d. is now meaningful (>0).

Now if we examine the lateralization indices for the patients of Fig. 2, we find that Pt35, whose performance we consider as normal, also had normal indices ($\Theta_L^t=0.41$, $\Theta_C^t=0.29$ and $\Theta_R^t=0.30$). For Pt39, who ignored the center positions, $\Theta_L^t=0.30$, $\Theta_C^t=0.0$, and $\Theta_R^t=0.70$, only Θ_L^t is in the normal range, while Θ_C^t is much smaller than the normal range and Θ_R^t is much higher. The low value of Θ_C^t indicates that the center positions are ignored. For Pt46, who ignored the side positions $\Theta_L^t=0.05$, $\Theta_C^t=0.89$, and $\Theta_R^t=0.06$. His Θ_C^t is much higher than normal, and his side indices were much lower than the normal range.

If we label the normal range of each lateralization index as $\underline{\Theta}_\alpha^\beta$, we can define side-oriented performance as having $\Theta_C^\beta<\underline{\Theta}_C^\beta$ and $\max\{\Theta_R^\beta,\Theta_L^\beta\}>\overline{\Theta}_S^\beta$, and analogously we can define center-oriented performance when $\Theta_C^\beta>\overline{\Theta}_C^\beta$ and $\min\{\Theta_R^\beta,\Theta_L^\beta\}<\underline{\Theta}_S^\beta$. With these definitions, Pt39's performance is side-oriented for click lateralization, and Pt46 is center oriented.

Both measures, the regression line fit and the lateralization indices, will be used to characterize lateralization performance. The regression line reveals to what extent left and right can be distinguished, whereas the lateralization indices reveal to what extent regions are ignored. Not surprisingly, the values of the regression line parameters and the lateral-

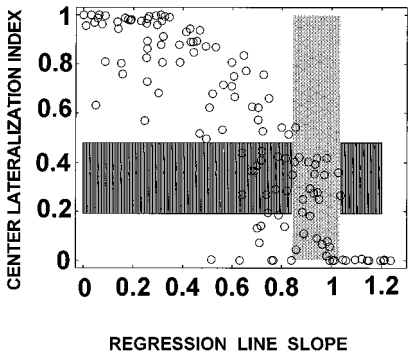

FIG. 3. Regression line slope as a function of the center lateralization index derived by all patients in the different lateralization experiment. The shadowed areas are the normal range of performance.

ization indices are highly correlated. In Fig. 3 the center lateralization index [Eq. (7)] is plotted against the corresponding regression line slope [a^t or a^l, in Eqs. (2) and (3)] for all six lateralization experiments of every patient. As can be seen in Fig. 3, there is a high correlation between the two measures ($r=0.93$). Similar correlation was found between the center lateralization index and the y intercepts of the regression line.

With this approach, a subject's performance for each stimulus can be characterized by the values of 12 parameters. Namely, the six lateralization indices (Θ^t_L Θ^t_C Θ^t_R Θ^l_L Θ^l_C and Θ^l_R) the regression line parameters (a^t, a^l, b^t, and b^l) and the jnd for ITD and ILD (δ^t and δ^l).

III. RESULTS

For the control group, the difference in the means and s.d.'s of Θ^t_C, Θ^l_C, a^t, and a^l as obtained for the different stimuli (click, LNB, and HNB) was not statistically significant ($p<0.01$ according to Student's t test). Thus the normal ranges plotted in Fig. 3 (shadowed areas) reveal the mean $\pm 2.5\cdot$s.d. obtained by the control group for all stimulus types.

Performance characterized as center oriented always had regression line slopes below the normal range. For those experiments in which all stimuli appeared to be heard very close to the center (Θ^t_C, $\Theta^l_C>0.9$), regression line slopes varied widely, ranging between 0 and about 0.4. In other words, some patients (a^t, $a^l=0$) were unable to differentiate at all the position of any of the stimuli on the basis of their interaural differences, while other patients were able to do so (a^t, $a^l>0$) appropriately to some extent. No subjects differentiated position inappropriately (a^t, $a^l<0$).

Performances characterized as side oriented had regression lines whose slopes ranged from beyond the normal range to about 0.5. In some cases the regression line slope was within the normal range. In other words (as typified by Pt39 of Fig. 2), all subjects with side-oriented performances, even if unable to hear stimuli as coming from the center, lateralized the stimuli with interaural differences to the correct side.

For the three stimulus types, means and standard deviations (s.d.) were calculated for each psychophysical parameter from the control group's data, and they are presented in Table I. The jnd values were similar to those reported previously (Levine, 1994; Furst and Algom, 1995).

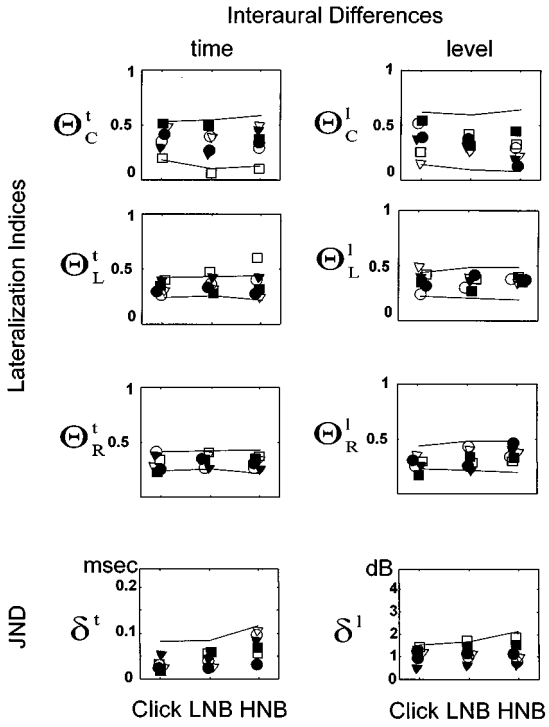

FIG. 4. Lateralization and jnd performances for patients in group A. Stroke patients: Pt23—open circle; Pt25—open triangle; Pt36—open square. MS patients: Pt35—filled triangle; Pt50—filled circle; Pt52—filled square.

Patients were grouped according to their click ITD lateralization. Each group performance is described in a separate figure (see Figs. 4, 6, 8, and 9). For each patient his/her lateralization indices and jnds can be found corresponding to a unique symbol (open=MS, filled=stroke) in one of these four figures. Each figure consists of eight panels, distributed in four rows and two columns. The lateralization indices for center, right, and left are in the top three rows, respectively, and the jnd's, δ^t and δ^l are in the bottom row. ITDs are in the left column and ILDs are in the right column. The three stimulus types, Click, LNB, and HNB form the horizontal axis of each panel. The normal range (mean $\pm 2.5\cdot$s.d. of the control group), is marked by solid lines on each panel. Only the upper limits are indicated for the jnd's. Because the regression line data and the lateralization indices are highly correlated (Fig. 3), the regression line coefficients are not included in these figures, but will be discussed.

Patients were always able to perform the lateralization procedure, but some were not always able to perform the jnd task for some stimuli (for the largest interaural differences our system allows). Thus if a symbol is missing from a panel, it means that the patient was unable to perform that particular jnd.

A. Patients with normal click lateralization

Three patients with MS and three with stroke had normal click lateralization indices and are shown in Fig. 4. Five of these six patients had normal jnd and lateralization indices

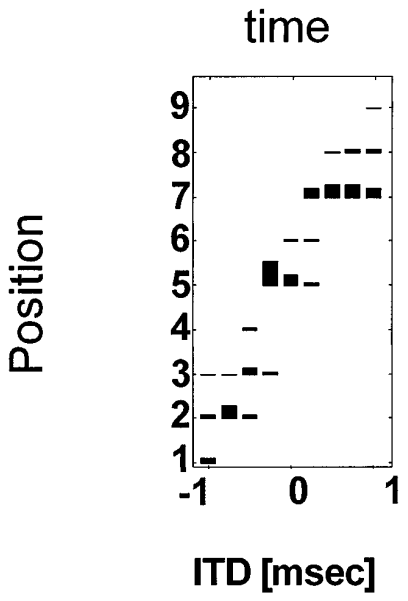

FIG. 5. Histogram of the estimated joint probability function pdf(POS, ILD) for LNB for patient Pt25.

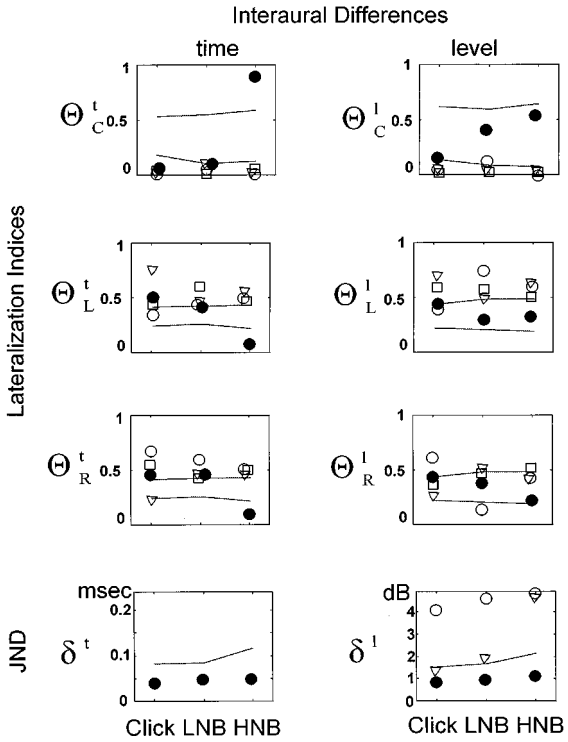

FIG. 6. Lateralization and jnd performances for patients in group B. Stroke patients: Pt39—open circle; Pt43—open triangle; Pt44—open square. An MS patient: Pt40—filled circle.

for all other stimuli as well. Only stroke patient Pt36 (open square) had any abnormalities. His ITD lateralization was left oriented for both LNB and HNB (but was normal for ILDs). The center ITD indices were very low for both types of narrow-band noise ($\Theta_C^t = 0.02$ for LNB, and 0.07 for HNB). The left indices were abnormally high and the right indices were within the normal range. All his regression lines were normal.

The regression lines were not uniformly normal for these subjects. In about a third of the conditions (11 out of 36) the regression-line slopes were too shallow, i.e., below the normal range (between 0.6 and 0.8). The abnormality was never because the slope was too steep. Figure 5 is an example of lateralization performance with an abnormally shallow regression line. Shown is Pt25's lateralization for LNB with ILDs. The regression line slope is 0.72, which reflects in part the fact that the most extreme positions (1 and 9) were infrequently selected.

B. Patients with side-oriented click lateralization

Four patients, three with strokes and one with MS, had side-oriented performance for clicks (Fig. 6). All three stroke patients lateralized symmetrically for click, ITD, and ILD. They all had a very low Θ_C^t and Θ_C^l and at least one abnormally high side index for both time and level differences. The side indices clearly show asymmetry between left and right for these three patients. Each one of them had a very high left or right index for time and level, while the other side's two indices were almost normal. Insight into this asymmetry can be obtained by referring back to Fig. 2 and examining the actual distribution of responses for Pt39 (open circle in Fig. 6). It is obvious that the patients did not confuse left stimuli with right, but perceived most of the center stimuli to the left and a few right stimuli to the left.

In this group an MS patient, Pt40, indicated by filled circles in Fig. 6, presented a different pattern of behavior. The left and right side indices of this patient were symmetrical for both time and level tests.

Like the data for clicks, the performance for NB noise of all three stroke patients was side oriented for ITD and ILD. However, Pt43 (open triangle in Fig. 6) had similar left and right indices for LNB stimuli with both ITD and ILD, while his HNB lateralization was biased to the left as it was for clicks. Pt44 (open square in Fig. 6) displayed symmetry between left and right for HNB and LNB with both ITD and ILD. Pt39 (open circle) had a remarkable preference for the right side for clicks (for both ITD and ILD), but a preference for the left for both LNB and HNB ILDs. On the other hand, for both LNB and HNB this subject's ITD performance was abnormal, but similar to left and right sides.

For the one MS patient, Pt40, the NB tests were normal for ILD, but yielded highly irregular performance for ITD; for LNB, performance had a tendency toward side orientation while for HNB stimuli performance was strongly center oriented: high Θ_C^t and low Θ_L^t and Θ_R^t indices. With both narrow-band stimuli as with clicks, Pt40 perceived stimuli at the left and right positions symmetrically, for both interaural differences.

As shown in Fig. 3, most side-oriented subjects had abnormal high regression line slopes (see also Pt39 of Fig. 2). However, in some of the performances categorized as side oriented, the slope of the regression line fit was either within or even below normal limits. The lateralization performance of Pt43 for click ITDs is such an example (Fig. 7). The regression line yielded a slope of 0.76 (below the normal

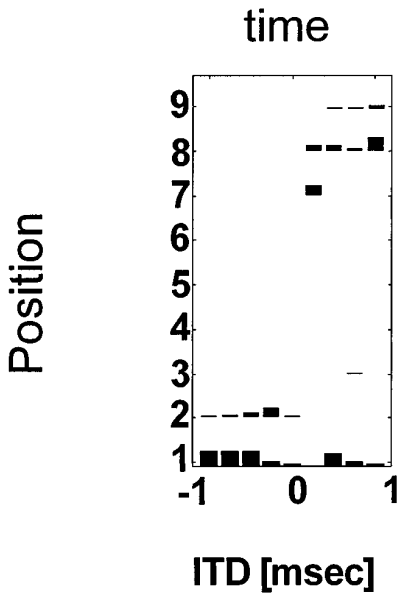

FIG. 7. Histogram of the estimated joint probability function pdf(POS, ITD) for clicks for patient Pt43.

range). This low value was due to the fact that the patient selected left of center positions for some of the right ear leading ITDs. Nonetheless, it is clear that generally Pt43 made correct right–left distinctions.

The single MS patient in this group, Pt40, had normal jnd's for all stimuli. But all the three stroke patients were unable to perform time jnd, and Pt44 (open square) could not perform level jnd as well. Another stroke patient (Pt39, open circle) had abnormally high δ^l values for all stimuli. Pt43 (open triangle) had normal level jnd for click and LNB, and abnormally high jnd for HNB.

C. Patients with center-oriented click lateralization

Center-oriented performance for click lateralization occurred in the other 12 patients. Seven were center oriented for both ITD and ILD click lateralization, three were center oriented for ITD click lateralization only, one was clearly center oriented for ILD clicks but borderline for ITD clicks, and one was borderline for both ITD and ILD.

In Fig. 8 are the data from the seven patients who had similar abnormalities in ITD and ILD click lateralization. Five were stroke patients and two MS patients. One stroke patient (Pt32, open hexagon) never perceived the stimulus as coming from the right ($\Theta^t_R = 0.0$) but did have a normal Θ^t_L. All other patients had abnormally small side lateralization indices, but similar ones on both sides.

All but one of the patients of Fig. 8 had similar results for NB lateralization as for click lateralization. The one exception was a stroke patient Pt29 (open triangle), whose HNB lateralization was center oriented, but his LNB lateralization was not. For LNB, his Θ^t_C was normal, Θ^t_L was low and Θ^t_R was high. For ILD, all his LNB lateralization indices were normal.

Four of the stroke patients and one MS patient whose performances are shown in Fig. 8 had normal or near normal jnd's. Two of the patients presented in Fig. 8, one stroke

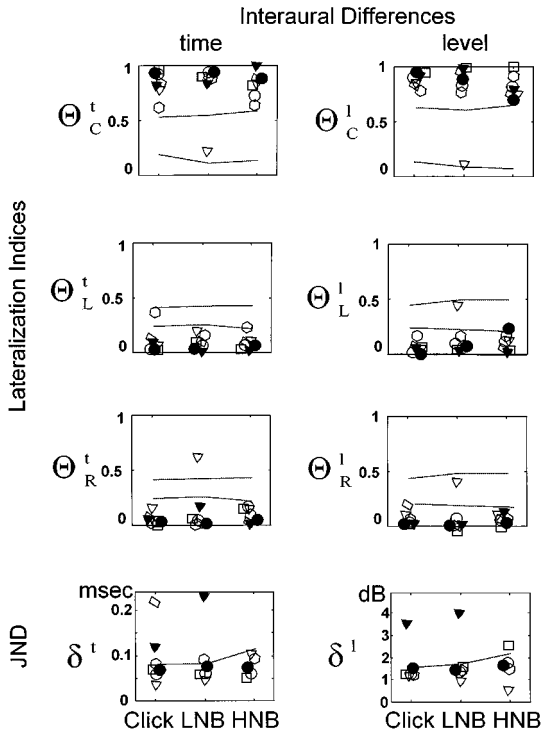

FIG. 8. Lateralization and jnd performances for patients in group C. Stroke patients: Pt29—open triangle; Pt30—open rectangle; Pt32—open hexagon; Pt37—open circle; Pt47—open square. MS patients: Pt46—filled triangle; Pt49—filled circle.

(open rectangle) and one MS (solid triangle), had very high jnd's for both ITD and ILD. In fact, the MS patient could not perform any of the HNB jnd's and the stroke patient was unable to perform any of the jnd's, with the exception of ITD clicks (for which his jnd was highly abnormal).

In Fig. 9 are the data from another five patients whose performance is also classified as center oriented for ITD clicks. All had normal or near normal time and level jnd's, and all were center oriented for HNB ITD. Otherwise they were a heterogeneous group. Three (two stroke patients and one MS patient) performed abnormally for click time lateralization, but normally for click level lateralization. Two of these three were also center oriented for LNB ITDs.

Another two MS patients had near normal performance for click ITD lateralization, but had center-oriented performance for click ILD lateralization. MS patient Pt38 (filled square) was at most slightly center oriented for LNB time lateralization. This patient's ILD lateralization revealed a center orientation in LNB stimuli, but normal HNB performance. The lateralization of MS patient Pt42 (filled circle) was actually side oriented for LNB with ITD, normal for LNB with ILD and center oriented for both HNBs.

Of the three who had normal lateralization for ILD clicks, the lateralization of stroke patient Pt54 (open circle) was highly center oriented for both LNB and HNB with ILD as well as ITD. The MS patient, Pt48 (filled triangle), had high center indices for all ITD but normal center indices for all ILD. The only right–left asymmetry in his lateralization indices occurred for LNB with ITD. For this one stimulus condition his left index was normal, while his right index

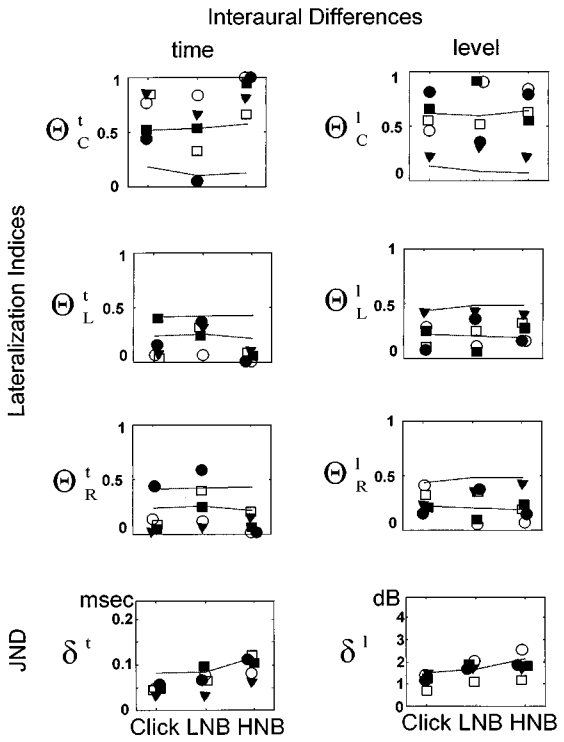

FIG. 9. Lateralization and jnd performances for patients in group C. Stroke patients: Pt31—open square; Pt54—open circle; MS patients: Pt38—filled square; Pt42—filled circle; Pt48—filled triangle.

was very low. Aside from click and HNB ITD, stroke patient Pt31 (open square) had normal lateralization.

IV. DISCUSSION

Many new features were observed in the present study as compared to previous reports on the psychophysical performance of patients with pontine lesions (Furst *et al.*, 1992; Levine *et al.*, 1993a, b; Furst *et al.*, 1995). While previous studies have dealt only with MS patients, the present study includes stroke patients whose ischemic lesions, unlike MS, are pathologically similar to the destructive lesions that have been studied in experimental animals (Masterton *et al.*, 1992).

In the present report we have also studied nine MS patients, which is comparable to the seven MS patients of our previous study (Furst *et al.*, 1995). In Table III patients from both studies are combined together for a total of 29 patients. Subjects are grouped together according to their underlying disease (MS or stroke) and their lateralization performance for clicks. It is clear from Table III that similar center- and

TABLE III. Number of MS and stroke patients according to their lateralization performance. The MS patients group includes also those who were tested in our previous study (Furst *et al.*, 1995). The number of patients in the previous study is indicated in parenthesis.

Lateralization performance:	Normal	Center oriented	Side oriented
MS	5 (2)	7 (2)	4 (3)
Stroke	3	7	3

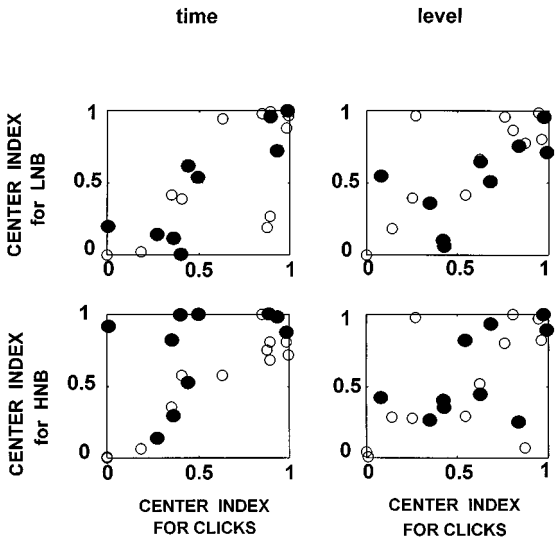

FIG. 10. Center lateralization index for narrow-band noise bursts (LNB and HNB) as a function of the center lateralization index for clicks, of all patients. MS patients are indicated by filled circles and stroke patients by open circles.

side-oriented behaviors were detected for both stroke and MS patients, despite their very different pathologies.

If the lesions responsible for these results were shown to be in the same location then this would imply that abnormal lateralization performance is independent of pathology. A second possible scenario is that there is an interaction between lesion type and lesion location; the type of abnormal lateralization may depend upon both factors. The reason only two types of abnormal lateralization has emerged from our studies is because a disturbance of the pontine binaural processing system can only manifest itself (for our lateralization paradigm) in these two basic abnormal patterns. Whatever the case, these two patterns of abnormal lateralization performance are revealing something fundamental about the neurology of the binaural system. Future studies will further clarify the nature of this processing.

As an elaboration upon previous lateralization procedures (Furst *et al.*, 1992, 1995), where only click stimuli were used, this study also included narrow-band noises, at high and low frequencies. Comparison with the results for click lateralization tests indicated the same abnormal performance types reported by Furst *et al.* (1995). When performance was abnormal, interaural differences of either type (ITD or ILD) were for the most part perceived either to the sides or only at the center of head. Of the parameters we analyzed the center lateralization index was the parameter that best characterized the lateralization abnormality. Center-oriented performance yields a high value of center lateralization index (approaching 1), while side oriented yielded a very low value (close to 0).

Comparison between patients' performance in the lateralization experiment for clicks and their performance for narrow-band noise bursts is shown in Fig. 10. The center lateralization index obtained by each patient for HNB and LNB is plotted as a function of his/her center lateralization index for clicks. For both ITD and ILD stimuli there is a very

high correlation between the performance for clicks and both NB stimuli. For HNB $r=0.70$ for ITD and 0.77 for ILD. Similarly, the correlation between the response to clicks and LNB yielded $r=0.86$ for ITD, and $r=0.70$ for ILD.

Not surprisingly, this correlation is not perfect. For example, as can be seen in Fig. 10, of the subjects that were highly center oriented (very high center indices) for ITD HNB, three had normal ITD click lateralization and one was highly side oriented for ITD click lateralization (very low center index). Similar examples of ''out-liers'' can be found for the three other plots of Fig. 10. The fact that lateralization performance can be so different in some subjects for these two different stimuli implies that lateralization not only depends upon the location of lesions, but also on the characteristics of the stimulus. Because a click is a broadband stimulus, more spectral cues are available for judging lateralization of a click than for either of the narrow-band noise bursts. On the other hand temporally the noise bursts are of much longer duration than the click. Since in general psychophysical performance degrades with shortening of stimulus duration (Tobias and Zerlin, 1959), all the other things being equal, psychophysical performance for the noise bursts should have an advantage over psychophysical performance for clicks.

Previous studies of MS subjects (e.g., Levine *et al.*, 1993a) measured jnds for high- and low-frequency noise and found that tasks with high-frequency stimuli were more sensitive detectors of abnormality than were tasks with low-frequency stimuli. Our results are consistent with this observation, since from review of Figs. 4, 6, 8, and 9 it is clear that the HNB jnd for ITD were always abnormal whenever any other jnd was abnormal. On the other hand, our results show that jnd can be normal while lateralization is distinctly abnormal (Fig. 8). Furthermore our results also indicate that, if any jnd or lateralization task is abnormal, then lateralization for HNB with ITD will always be abnormal. We can extend then the original observation of Levine *et al.* and state that lateralization tasks with high-frequency stimuli are more sensitive detectors of abnormality than (1) jnd for any kind of stimulus and (2) lateralization tasks with low-frequency stimuli or clicks.

The similarity between ITD and ILD abnormalities in lateralization, previously reported by Furst *et al.* (1995) and Furst and Algom (1995) for MS patients, was further explored in the present study. In most cases, for both MS and stroke patients, similar ITD and ILD behaviors were found for all types of performance, for all stimulus types, and for both types of patients, stroke and MS. These results make it clear that binaural processing in the brainstem involves both interaural time and level analysis, perhaps using the same mechanisms and depending on the same anatomical structures, and ITD tasks are more sensitive to disruption.

Furst and Algom (1995) tested both lateralization and discrimination tasks during the same session, and showed that in most cases abnormal lateralization coincided with abnormal jnds with but two exceptions. In the present study, we have found many subjects with normal jnd but markedly abnormal lateralization. In Fig. 11, time jnds are plotted against center lateralization index for the same stimulus (for all patients and all stimuli). The normal ranges for both jnd and the center lateralization index are shaded. For patients who could not perform the jnd task, their jnd was arbitrarily assigned the value 1. It is clear from this data that patients who performed normally in jnd tests varied in their lateralization performance, presenting normal, center-oriented, or side-oriented click lateralization. On the other hand, patients who had abnormal jnds for ITD and/or ILD had extremely abnormal lateralization performance; their center lateralization index could be zero (side oriented), or close to one (center oriented). As in Levine *et al.* (1993a), in most patients abnormality in the jnd task was for high frequencies.

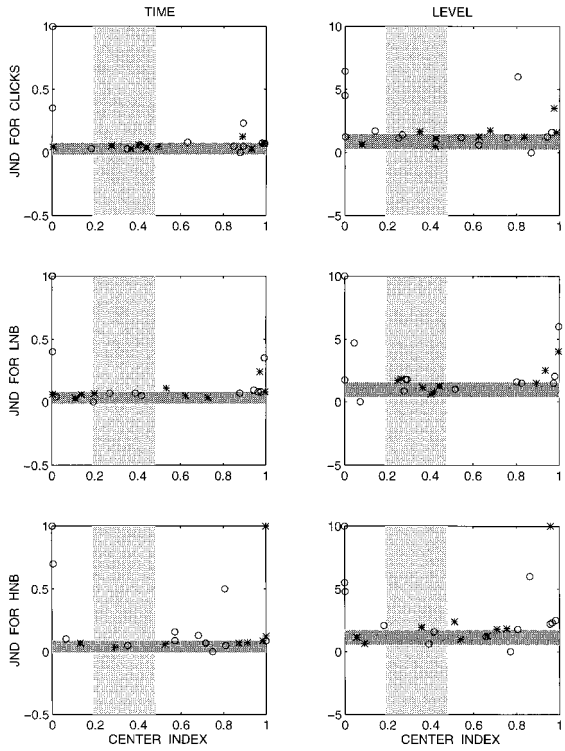

FIG. 11. Time and level jnds as a function of the center lateralization index, for clicks, LNB and HNB stimuli, of all patients. MS patients are indicated by crosses and stroke patients by open circles. The shadowed areas indicate the normal range.

The fact that some patients could have normal jnd and poor lateralization but not vice versa suggests that while performing jnd tasks, subjects use many different cues. The lateralized position, as we have measured it, is only one of the possible cues. It would at first glance appear to be the most natural one and it might be sufficient; however the results of the present study make it clear that lateralized position is not a necessary cue for discrimination (jnd).

For side-oriented lateralization, a subject generally can make right–left distinctions correctly (regression line slope >0.5, see Fig. 3). Hence this right–left cue is probably available for the jnd task, and could explain normal jnd performance when lateralization is side oriented. However, this clue is not available for many subjects with center-oriented lateralization since their regression line slope is zero. Thus the fact that such subjects with regression line slopes can have normal jnd makes it clear that lateralized position is not a necessary cue for interaural discrimination (jnd).

One possible explanation is that the brainstem binaural processing analyzes right–left position in two ways; (a) on a ''gross'' basis that is responsible for our large scale right–left analysis, such as involved in our lateralization task; (b) on a ''micro'' basis that is responsible for detecting tiny right–left changes such as in a jnd task. Furthermore it could be that the ''gross'' right–left detector operates well throughout auditory space, whereas, the ''micro'' right–left detector operates optimally near center space where jnds are smallest.

The results seem to hint that several independent mechanisms participate in the process of binaural time and level perception. The brainstem auditory pathway, where most of this processing probably takes place, contains several levels at which an estimate for either ITD or ILD could occur. Future work will examine the relationship between (a) lesion location (from MRI scan data) and (b) both abnormalities in binaural psychophysical performance and abnormalities in electrophysiology (from binaural auditory evoked potentials). With such an approach it might be possible to develop a qualitative and *quantitative* model for the structure and function of the nuclei and tracts of the brainstem that take part in binaural processing.

Spectro-temporal factors in two-dimensional human sound localization

(Received 6 June 1997; revised 5 December 1997; accepted 29 January 1998)

This paper describes the effect of spectro-temporal factors on human sound localization performance in two dimensions (2D). Subjects responded with saccadic eye movements to acoustic stimuli presented in the frontal hemisphere. Both the horizontal (azimuth) and vertical (elevation) stimulus location were varied randomly. Three types of stimuli were used, having different spectro-temporal patterns, but identically shaped broadband averaged power spectra: noise bursts, frequency-modulated tones, and trains of short noise bursts. In all subjects, the elevation components of the saccadic responses varied systematically with the different temporal parameters, whereas the azimuth response components remained equally accurate for all stimulus conditions. The data show that the auditory system does not calculate a final elevation estimate from a long-term (order 100 ms) integration of sensory input. Instead, the results suggest that the auditory system may apply a ''multiple-look'' strategy in which the final estimate is calculated from consecutive short-term (order few ms) estimates. These findings are incorporated in a conceptual model that accounts for the data and proposes a scheme for the temporal processing of spectral sensory information into a dynamic estimate of sound elevation. © *1998 Acoustical Society of America.* [S0001-4966(98)03005-7]

INTRODUCTION

Human auditory localization depends on implicit binaural and monaural acoustic cues. Binaural cues arise through interaural differences in sound level (ILD) and timing (ITD) that relate in a simple way to the horizontal component of sound direction relative to the head. The auditory system, however, cannot distinguish, from these cues, between all source positions with the same horizontal component that lie on the so-called ''cone of confusion.'' Due to the front–back symmetry of the ITD and ILD cues, a sound azimuth (α) estimate provided by these binaural cues is therefore ambiguous (e.g., Blauert, 1996; Wightman and Kistler, 1992).

Monaural cues consist of direction-dependent linear spectral filtering caused by the torso, head, and pinnae. Incident waveforms are reflected and diffracted in a complex and direction-dependent way, which typically gives rise to strong enhancement and attenuation at particular frequency bands (Hebrank and Wright, 1974; Shaw, 1974; Mehrgardt and Mellert, 1977; Middlebrooks *et al.*, 1989; Lopez-Poveda and Meddis, 1996). These cues are essential for elevation (ϵ) localization and in resolving front–back ambiguities (e.g., Batteau, 1967; Musicant and Butler, 1984; Blauert, 1996).

The relation between the pinna geometry and the direction-dependent filtering has been shown in both experimental and theoretical studies (Batteau, 1967; Teranishi and Shaw, 1968; Han, 1994; Lopez-Poveda and Meddis, 1996). The actual importance of the filtering in two-dimensional localization has been underlined by various behavioral experiments. In some of these studies, the geometrical structure of the pinna was altered artificially, resulting in a degraded localization performance (Gardner and Gardner, 1973; Oldfield and Parker, 1984b). In other studies, manipulation of the sound spectra and the resulting effects on elevation localization could be related to spectral features in the pinna filters (e.g., Middlebrooks, 1992; Butler and Musicant, 1993).

The features in the spectral pinna filter, or head-related transfer function (HRTF), are believed to carry the information about sound location (Kistler and Wightman, 1992). Yet, a fundamental problem arises in the processing of these features into estimates of sound location (Zakarouskas and Cynader, 1993; Hofman and Van Opstal, 1997). At the level of the eardrums, the available spectrum, $y(\omega;\mathbf{r}_S)$, associated with the source position, $\mathbf{r}_S=(\alpha_S,\epsilon_S)$, results from the source spectrum, $x(\omega)$, filtered by the particular direction-dependent HRTF, $h(\omega;\mathbf{r}_S)$:

$$y(\omega;\mathbf{r}_S)=h(\omega;\mathbf{r}_S)\cdot x(\omega) \tag{1}$$

with ω the frequency in octaves. In principle, the auditory system has no knowledge about the relative contributions of neither $h(\omega;\mathbf{r}_S)$ nor $x(\omega)$. Yet, it is necessary to minimize the source influences in order to recognize $h(\omega;\mathbf{r}_S)$ and thus determine the position, $\mathbf{r}_S$ (mainly elevation and front–back angle, as left–right angle is determined predominantly from binaural cues).

So far, only a few computational models have been proposed, which suggest how this could be done. A possible solution to this problem would be to make a priori assumptions about the sound source spectrum. It would enable the auditory system to directly compare the incoming spectrum to the (stored) HRTFs (e.g., Neti *et al.*, 1992; Zakarouskas

[a]Electronic mail: paul@mbfys.kun.nl

and Cynader, 1993; Middlebrooks, 1992). Neti *et al.* (1992) showed that a feed-forward neural network could be trained to accurately extract the location of broadband noise on the basis of the spectral filter properties of the cat's pinna. Since the model was only trained with white noise, however, it is not clear how it withstands spectral variations.

Zakarouskas and Cynader (1993) proposed a model in which the comparison between the cochlear spectrum and the HRTFs is based on spectral derivatives of first and second order (i.e., $dy/d\omega$, $d^2y/d\omega^2$). For a sound source spectrum that is locally constant, or has a locally constant slope, the model was shown to recognize essential spectral features of the underlying HRTF (specifically relevant peaks and notches), and thus correctly extract the direction of the sound.

In an alternative model, proposed by Middlebrooks (1992), the sensory spectrum is compared with the HRTFs by computing a spectral correlation coefficient. This scheme suggested that localization is accurate if the source spectrum is broadband and sufficiently flat, such that the sensory input maintains maximal correlation with the underlying HRTF of the associated source position.

In the latter two models, accurate localization relies on specific spectral constraints on the source spectrum. This assumption is supported by recent experimental results. On one hand, the auditory system appears to tolerate random variations within the broadband sound spectrum (e.g., Wightman and Kistler, 1989). On the other hand, if relative variations in the source spectrum become too large, localization can be disturbed dramatically (e.g., Middlebrooks, 1992). It therefore remains unclear what the actual spectral constraints are.

So far, the majority of localization studies have applied stimuli with stationary spectral properties. Yet, natural sounds possess a high degree of nonstationarity. Although it is commonly accepted that spectral shape cues play an essential role in elevation detection, it is as yet unknown how the auditory system applies the spectral analysis to nonstationary sensory information. In addition, due to the fundamental relation between the temporal and spectral domains, a sufficiently high spectral resolution requires a minimal time window over which the spectral estimation is integrated: $\Delta f \cdot \Delta T = \text{constant}$. The temporal and spectral resolutions needed for adequate sound localization, however, are not well known.

One possibility is that the sensory information is integrated over a time scale of order, say, 100 ms to obtain an average spectrum on which a spectral (shape) analysis can be applied. If true, sounds with the same average power spectrum on that time scale would be localized equally well: It would allow a considerable amount of freedom for the phase spectrum on that time scale.

An alternative possibility could be that the auditory system applies a ''multiple-look'' strategy, in which elevation estimation is based on multiple, consecutive short-term (say, of order a few ms) spectral analyses of the ongoing sensory information. This latter scheme would imply that the spectral-temporal behavior of the stimulus on that short time scale is also important.

In the present study, we specifically focused on these spectro-temporal aspects for sound localization in two dimensions. To our knowledge, such data are not available in the current literature. In two experiments, the sensitivity of the localization process to short-term spectro-temporal variations was of interest. Localization to frequency-modulated tones (''FM sweeps'') and trains of short-duration broadband bursts was measured. These stimuli had similar broadband average power spectra, but fundamentally different spectro-temporal behaviors. In a third experiment, we estimated the minimal time needed by the localization process to complete elevation estimation. To that means, localization to broadband noise of various durations (3–80 ms) was measured. In a recent pilot study by Frens and Van Opstal (1995), it was shown that localization performance systematically deteriorates in elevation, but not in azimuth, when stimulus duration of broadband noise bursts is shorter than 10 ms.

Saccadic eye movements were used to quantify the response accuracy. It enabled accurate measurements (within 1 deg) of a very early spatial percept (below 200 ms) for stimuli presented within the oculomotor range (35-deg eccentricity range in all directions). Subjects were tested under entirely open-loop conditions, i.e., neither acoustic, nor visual or verbal feedback was provided.

The results of our experiments show a consistent and systematic influence of spectro-temporal factors of the stimulus on the elevation component of the localization response in all subjects tested. These findings will be discussed in terms of a conceptual spectro-temporal model of human auditory localization in two dimensions.

I. METHODS

A. Subjects

Seven male subjects participated in the localization experiments. Their ages ranged from 23 to 39 years. Subjects were employees and students of the department. Three of the subjects (PH, JO, and JG) were experienced in sound localization experiments, whereas the other subjects had no such previous experience and were kept naive as to the purpose of this investigation. Inexperienced subjects were given one or two practice sessions to get acquainted with the setup and localization paradigm and to gain stable performance. All subjects reported to have no hearing problems of any kind.

B. Apparatus

Experiments were conducted in a completely dark and sound-attenuated room with dimensions $3\times3\times3$ m. The walls, floor, and ceiling were covered with acoustic foam, that effectively absorbed reflections above 500 Hz. The room had an A-weighted ambient background noise level of 30 dB SPL.

The orientation of the subject's right eye was measured with the scleral search coil technique (Collewijn *et al.*, 1975; Frens and Van Opstal, 1995). The oscillating magnetic fields that are needed by this method were generated by two orthogonal pairs of square 3×3 m coils, attached to the room's edges: one pair of coils on the left and right walls generated a horizontal magnetic field (30 kHz) and a second pair on the ceiling and floor created a vertical magnetic field (40 kHz).

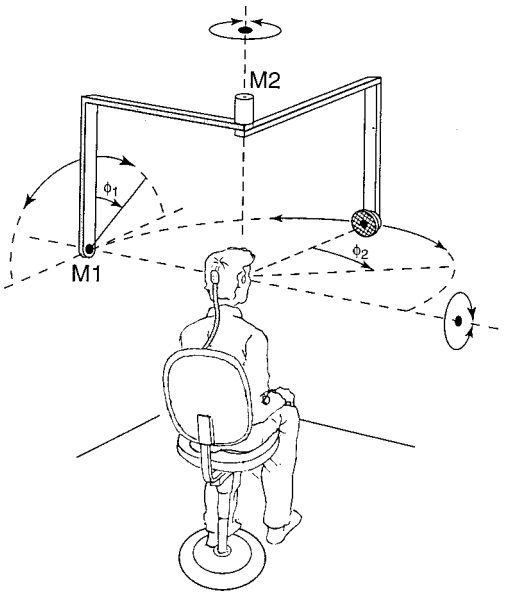

FIG. 1. Experimental setup for delivering acoustic stimuli at various spatial locations. Two stepping motors, M1 and M2, independently control the rotation angles ϕ_1 and ϕ_2, respectively. This construction ensures a fixed distance from the speaker to the center of the subject's eyes (0.9 m) for any stimulus direction (ϕ_1, ϕ_2).

An acoustically transparent frontal hemisphere (consisting of a thin wire framework, covered with black silk cloth) with 85 red light-emitting diodes (LEDs) was used for calibration of the eye-coil measurements and for providing a fixation light at the start of each localization trial. LED coordinates are defined in a two-dimensional polar coordinate system with the origin at the straight-ahead gaze direction. Target eccentricity, $R \in [0,35]$ deg, is measured as the gaze angle with respect to the straight-ahead fixation position, whereas target direction, $\phi \in [0,360]$ deg, is measured in relation to the horizontal meridian. For example, $R=0$ (for any ϕ) corresponds to ''straight ahead,'' and $\phi=0$, 90, 180, and 270 deg (for $R>0$) correspond to ''right,'' ''up,'' ''left,'' and ''down'' positions, respectively. LEDs were mounted at a distance of 85 cm from the subject's eye, at directions $\phi=0,30,60,...,330$ deg and at eccentricities $R=0,2,5,9,14,20,27,35$ deg.

Sound stimuli were delivered through a broad-range lightweight speaker (Philips AD-44725) mounted on a two-link robot (see Fig. 1). The robot consisted of a base with two nested L-shaped arms, each arm driven by a separate stepping motor (Berger Lahr VRDM5) with an angular resolution of 0.4 deg. It enabled rapid (within 2 s) and accurate positioning of the speaker at practically any point on a frontal hemisphere with a radius of 90 cm, the center of which was aligned with the LED hemisphere's center. To prevent spurious echoes, the robot was entirely coated with acoustic foam.

The robot's stepping engines produced some sound while moving which, at first sight, might be suspected to provide additional cues with regard to the speaker position. However, the first engine (M1) always remained in place, at the left of the subject. The sound of the second engine (M2), that moved in the midsaggital plane above the subject, appeared to provide no localizable stimulus cues. This was experimentally verified with two subjects in a previous study (Frens and van Opstal, 1995).

A second potential source for response biases was the speaker displacement between consecutive trials. Especially if a new stimulus position is close to the position of the previous trial, the subject might conclude a small displacement of the speaker from the short duration of motor movements. This potential problem was effectively resolved by incorporating a random movement with a minimal displacement of 20° for each engine and prior to each trial.

Two PCs controlled the experiment: a PC-386 and PC-486 that acted as a master and slave computer, respectively. The master PC was equipped with hardware for data acquisition, stimulus timing and control of the LED hemisphere: eye position signals were sampled with an AD-board (Metrabyte DAS16) at a sampling rate of 500 Hz, stimulus timing was controlled by a digital IO board (Data Translation DT2817) and the LEDs were controlled through a second digital IO board (Philips I2C).

The slave PC controlled the robot and generated the auditory stimuli. It received commands from the master PC through its parallel port. Stimulus generation was done by storing a stimulus in the slave's RAM before a trial and, after receiving a trigger from the timing board in the master PC, passing it through a DA converter (Data Translation DT2821) at a sampling output rate of 50 kHz. The output of the board was fed into a band pass filter (Krohn–Hite 3343) with a pass band between 0.2 kHz and 20 kHz, amplified (Luxman A-331), and passed to the speaker.

C. Sound stimuli

Gaussian white noise (GWN), recorded from a function generator (Hewlett–Packard HO1-3722A) and passed through a band pass filter (Krohn–Hite KH 3343 with pass band 0.2–20 kHz flat within 1 dB) was used as a basis for the noise stimuli. The speaker characteristic was flat within 12 dB between 2 and 15 kHz and was not corrected for. In all experiments (also in each session), the same broadband noise burst with a duration of 500 ms was included as the control stimulus. All stimuli had 1-ms sine-squared onset–offset ramps.

In experiment I (subjects BB, JO, PH), the test stimulus set consisted of broadband noise of various durations, $D=3$, 5, 10, 20, 40, and 80 ms [see Fig. 2(a)]. Each stimulus that was presented within one session was drawn randomly from the recorded noise.

In experiment II (subjects JG, JR, PH), the test stimuli were trains of 3-ms bursts with various duty cycles, $\Delta T=3$, 10, 20, 40, 80 ms [see Fig. 2(b)]. A duty cycle of ΔT ms means that the onsets of consecutive bursts were ΔT ms apart. Each 3-ms burst of the train had been drawn randomly from the recorded noise. A single 3-ms burst stimulus (i.e., same as in experiment I with $D=3$ ms) was included as the limit case $\Delta T=\infty$. The total duration of each burst train was about 500 ms.

In experiment III (subjects KH, PH, VC), the test stimulus set consisted of sweeps of various periods [see Fig. 2(c)]. Inverse Fourier transforms ($N=64,128,...,2048$ points) were

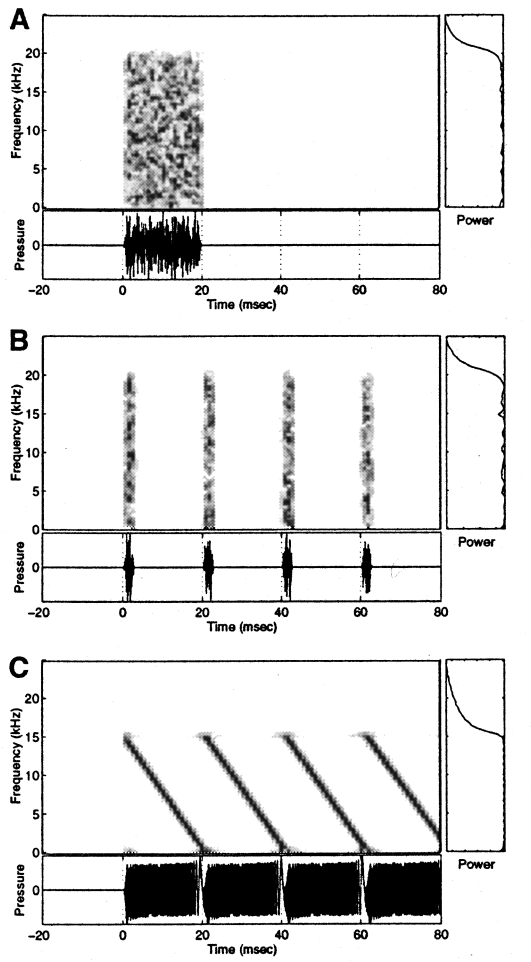

FIG. 2. Examples of the three stimulus types used in the localization experiments: a noise burst with $D=20$ ms (a), a pulse train with $\Delta T=20$ ms (b) and an FM sweep with $T=20$ ms (c). The graphs show the stimuli from 20 ms before stimulus onset until 80 ms after stimulus onset. The large panels show the sonograms, which describe the spectro-temporal behavior of the power spectrum; spectral power is coded by the gray scale, where bright corresponds to low power, dark to high power. The panels on the right contain the time-integrated power spectra (all on the same scale). Finally, the lower panels show the stimulus waveforms.

used to transform an amplitude spectrum, that was flat up to 16 kHz with a corresponding phase spectrum calculated according to Schröder's algorithm, in to the time domain (Schröder, 1970; Wightman and Kistler, 1989). This procedure yields FM sweeps with fixed periods $T=1.28$, 2.56, 5.12, 10.24, 20.48, or 40.96 ms. The instantaneous characteristics of this stimulus are narrow band with a center frequency that (repetitively) traverses the entire frequency range downwards with a constant velocity of $16/T$ kHz/s. The total stimulus duration was 500 ms.

Examples of the spectograms of synthesized stimuli that were used in the experiments (before being passed through the speaker) are shown in Fig. 2: a noise burst with duration $D=20$ ms, a burst train with duty cycle $\Delta T=20$ ms, and a sweep with period $T=20$ ms. As can be seen, the noise burst contains spectral power over the entire frequency range and over the entire stimulus duration. In a burst train, the total stimulus duration is long and the stimulus is broadband, but power is only present during short 3-ms intervals. Like the noise burst, the sweep contains no silence periods throughout the whole stimulus duration. The sweep can be considered ''broadband'' if one regards a whole period, yet narrow band on smaller time scales. Thus all stimuli have flat, broadband time-averaged power spectra, whereas the spectro-temporal behavior is fundamentally different for the three stimulus types.

The control stimulus and all test stimuli had equal rms values. For the burst trains this rms value refers to the non-silence periods. The A-weighted sound level at which the stimuli were delivered was 70 dB, measured at the subject's head position (measuring amplifier Brüel & Kjær BK2610 and microphone Brüel & Kjær BK4144).

D. Stimulus positions

In this paper, the coordinates of both the oculomotor response and the sound source position are described in a double-pole coordinate system, in which the origin coincides with the center of the head. The horizontal component, azimuth α, is defined by the stimulus direction relative to the vertical median plane, whereas the vertical component, elevation ϵ, is defined by the stimulus direction relative to the horizontal plane.

The stimulus positions were confined to 25 ''boxes'' centered at azimuths $\alpha=0,\pm 13,\pm 26$ deg, and elevations $\epsilon=0,\pm 13,\pm 26$ deg [see, e.g., Fig. 5(a)]. The dimensions of each box were 8 deg$\times$8 deg, limiting the total stimulus range in both azimuth and elevation to $[-30,30]$ deg. Sets of 25 stimulus positions were composed by randomly selecting a position within each box. Already for one set, this selection procedure ensured a high degree of uncertainty in the stimulus position while maintaining a homogeneous distribution over the oculomotor range. Importantly, the number of stimulus positions could thus be limited for each stimulus condition, which was highly desirable as each experiment had seven different conditions.

E. Paradigm

The eye position in a head-fixed reference frame was used as an indicator of the perceived sound location (see also Frens and Van Opstal, 1995). In order to calibrate the eye coil, each session started with a run in which all 84 peripheral LEDs on the hemisphere were presented in a random order. Subjects were instructed to generate an accurate saccade from the central fixation LED at 0-deg eccentricity to the peripheral target, and to maintain fixation as long as the target was visible. After calibration, the eye position was known with an absolute accuracy of 3% or better over the full oculomotor range.

In the subsequent runs, sound stimuli were presented. A trial always started with the central visual fixation stimulus. Then, after a random period of 0.4–0.8 s, the LED was switched off and the sound was presented at some peripheral location. The subject's task was to direct the eyes as fast and as accurately as possible toward the apparent sound location without moving the head. A firm head rest enabled the subject to stabilize his head position throughout the session.

A typical run with sound stimuli consisted of the control stimulus and six other sound stimulus conditions. During the 175 consecutive trials, each stimulus was presented once at a set of 25 pseudo-randomly drawn positions (see above). The order of stimulus conditions and positions throughout a session was randomized.

Each subject participated in four sessions on four different days. Hence, each subject traversed a total number of 700 localization trials. Each of the seven temporally defined stimuli was presented 100 times in total four times within each of the 25 stimulus boxes. Subject PH participated in all three experiments (2100 trials).

F. Data analysis

Eye positions were calibrated on the basis of responses to 85 visual stimuli in the first run of the session. From this run, sets of raw eye position signals (AD values of the horizontal and vertical position channel) and the corresponding LED positions (in azimuth and elevation) were obtained. LED azimuth, α, and elevation, ϵ, were calculated from the polar coordinates, (R, ϕ), of the LEDs by:

$$\alpha = \arcsin(\sin R \cos \phi),$$
$$\epsilon = \arcsin(\sin R \sin \phi). \tag{2}$$

These data were used to train a three-layer backpropagation neural network that mapped the raw data signals to calibrated eye position signals. In addition, the network also corrected for small inhomogeneities of the magnetic fields and a slight crosstalk between the horizontal and vertical channels.

A custom-made PC program was applied to identify saccades in the calibrated eye-position signals on the basis of preset velocity criteria for saccade onset and offset, respectively. The program enabled interactive correction of the detection markings. The endpoint of the first saccade after stimulus onset was defined as the response position (see also Sec. II). If saccade latency re. stimulus onset was less than 80 ms or exceeded 500 ms, the saccade was discarded from further analysis. Earlier or later stimulus-evoked responses are highly unlikely for a normal, attentive subject, although the precise values of the boundaries are somewhat arbitrary. Earlier responses are generally assumed to be predictive and are very inaccurate, even for visually evoked saccades. Later responses are considered to be caused by inattention (see also Sec. II).

Response positions versus stimulus positions were fitted for the respective components with a linear fit procedure that minimizes the summed absolute deviation (Press *et al.*, 1992). This method is less sensitive to outliers than the more common least-squares method. For the same reason, the correlation between response- and stimulus positions was quantified by the nonparametric rank correlation coefficient, rather than by Pearson's linear correlation coefficient.

Confidence levels for both the linear fit parameters and the correlation coefficients were obtained through the bootstrap method (Press *et al.*, 1992), since explicit expressions for the confidence levels in the methods described above are not available. In the bootstrap method, one creates N synthetic data sets by randomly selecting, with return, data points from the original set (N typically about 100). A synthetic set has the same size as the original set, so that a given data point from the original set can occur more than once in the synthetic set. The parameter of interest is then computed for each synthetic data set and the variance in the resulting N parameter values is taken as the confidence level.

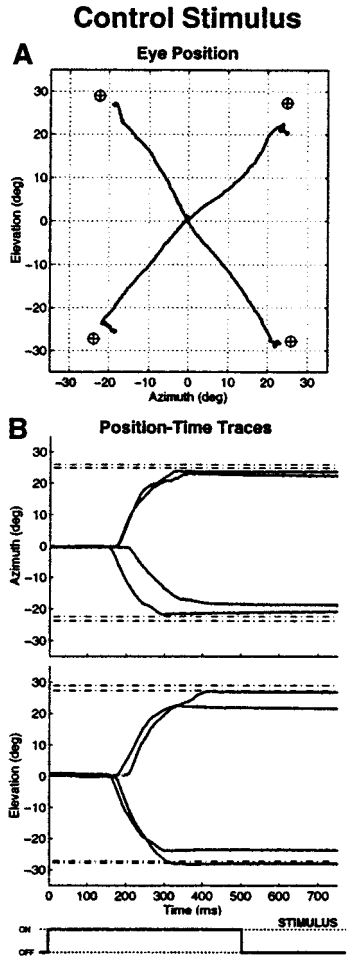

FIG. 3. Typical saccadic eye movement responses towards the control stimulus (GWN, $D = 500$ ms) at four different eccentric positions. (a): Eye-position trajectories during the full duration of the trial. (b): Corresponding position-time traces for both azimuth and elevation during the first 750 ms after stimulus onset. Stimulus positions are indicated by the visor symbols (a) and by the dot-dashed lines (b). Stimulus timing is indicated at the bottom. Data from naive subject BB.

II. RESULTS

A. Control condition

Characteristics of typical responses to four eccentric stimulus positions in the control condition are plotted in Fig. 3. It shows the eye-position trajectory in space and the separate eye-position components (i.e., azimuth and elevation) versus time. One can see that the offset position of the eye (i.e., the response position) corresponds closely to the stimulus position. The response is accurate for both azimuth and elevation components.

It can be seen from Fig. 3(b) that the responses follow shortly after stimulus onset. In these examples, primary sac-

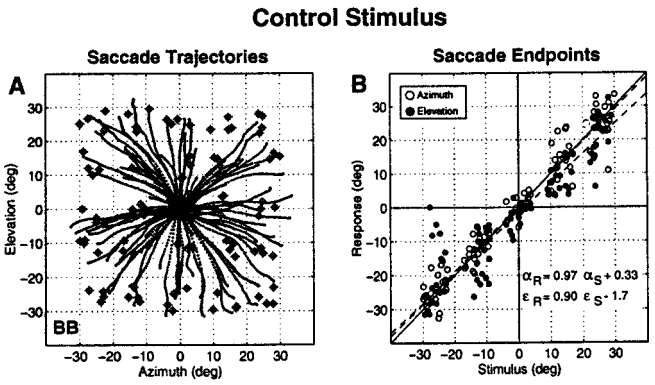

FIG. 4. Saccadic responses to the control stimulus. (a) Trajectories of primary saccades (thick dotted lines, sampled at 2-ms intervals) to control stimuli presented throughout the entire stimulus range. Stimulus positions are indicated by the visor symbols. (b) Endpoint positions of the same primary saccades as in (a) versus stimulus positions for both azimuth (○) and elevation (●). Also the linear-fit results for response positions versus stimulus position are provided (azimuth: α_S vs α_R; elevation: ϵ_S vs ϵ_R). Note large slopes (0.97 and 0.90, respectively; $N=98$) and small offsets (within 2 deg). Subject BB.

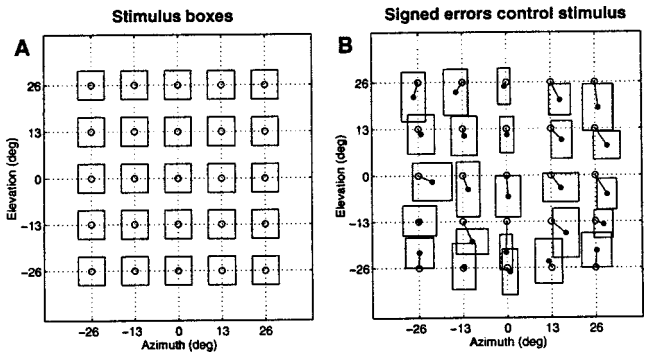

FIG. 5. (a) Stimulus positions were presented within the square boxes, with dimensions 8×8 deg. Sets of 25 stimulus positions were composed by selecting a position at random within each box. (b) The lines from the open symbols to the closed symbols correspond to local mean signed errors. For each stimulus box, the mean signed error is computed by averaging the individual mean signed errors of all seven subjects. The width and height of a box correspond to twice the standard deviation in the signed errors for azimuth and elevation, respectively. The center of each stimulus box is indicated by the open circle [in both (a) and (b)]. Note the clear separation of almost all response boxes, and the larger response scatter in the elevation components as compared to the azimuth components.

cades are initiated with a latency of approximately 200 ms, and are completed within 400 ms after stimulus onset (i.e., before stimulus offset time).

All subjects in this study made accurate localization responses to the control stimulus (500-ms GWN) in all directions (azimuth and elevation). Figure 4 shows all saccade trajectories [Fig. 4(a)] and saccade endpoints [Fig. 4(b)] for all four sessions of one of the subjects (BB). Note how both the stimulus positions and saccade trajectories are distributed over the entire stimulus range. Note also, that the accuracy of response elevation is both quantitatively and qualitatively similar to azimuth localization. A summary of the results for all subjects is listed in Table I.

Figure 5(b) gives an overall impression of the local localization accuracy by showing the averaged signed errors of the saccadic responses for each stimulus box. For each subject and each stimulus box, the mean signed error was computed for all responses to stimuli presented within that box (typically 4–8 responses for each box and each subject). Then, a final mean signed error for each stimulus box was obtained by averaging the subject-mean signed errors over all 7 subjects.

Note that, for the majority of the error boxes in Fig. 5(b), the height is larger than the width. Thus the scatter in the responses is somewhat larger for elevation than for azimuth. These scatter properties underline the fact that azimuth and elevation localization are dissociated processes (see the Introduction). They clearly contrast with the scatter properties of visually evoked saccadic responses, that betray the polar organization of the visuomotor system (e.g., Van Opstal and Van Gisbergen, 1989).

One may observe that the highest accuracy for azimuth localization is reached near the median plane, whereas elevation accuracy is approximately homogeneous over the entire oculomotor field. The largest signed errors were found for

TABLE I. Parameters of the azimuth (α) and elevation (ϵ) response components to the control stimulus (500-ms white noise) for each subject. Columns 2–3: rank correlation coefficient ρ between response position and stimulus position. Note that correlation coefficients $\rho_\epsilon > 0.90$ for elevation and $\rho_\alpha > 0.95$ for azimuth. Columns 4–5: slope, or gain, G, of a straight-line fit for response versus stimulus position. Columns 6–7: standard deviation Δ_{FIT} of the difference between the actual response and the response predicted by the fit (in degrees). Columns 8–9: average absolute localization error Δ_{RESP} (in degrees). Column 10: median response latency (in ms). The two bottom rows present, for each column, the mean and standard deviation, respectively, pooled for all subjects.

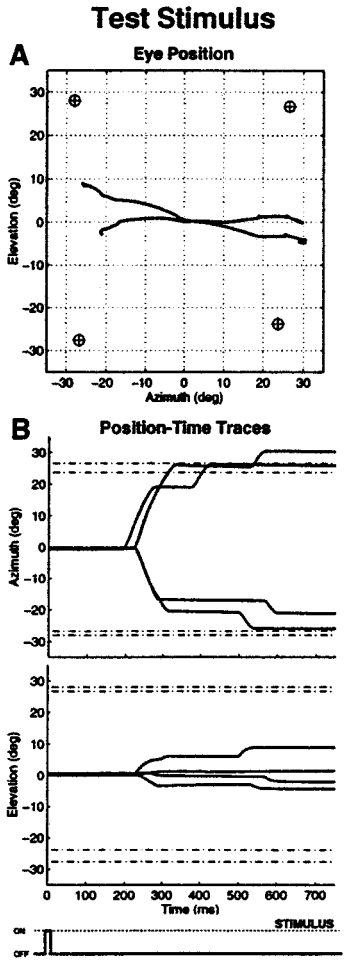

FIG. 6. Typical responses toward short-duration noise bursts ($D=3$ ms) at four different eccentric positions. Note marked undershoot of the elevation components, whereas the azimuth components remain accurate (cf. Fig. 3). Note further that also small secondary saccades are made after approximately 400 ms. See legend of Fig. 3 for further details.

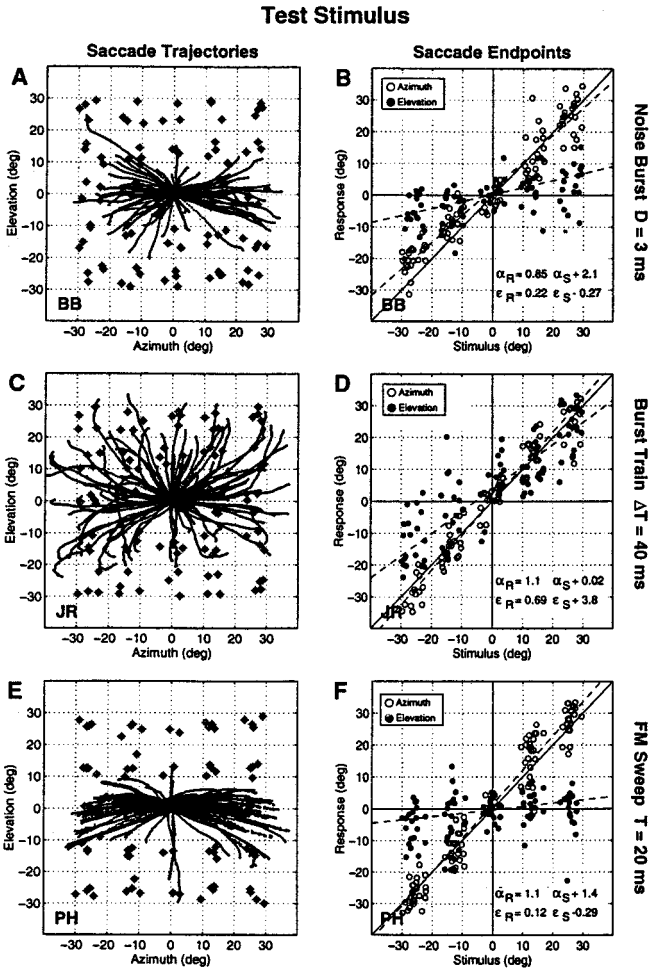

FIG. 7. Saccadic responses to test stimuli. (a) and (b) responses of subject BB to noise bursts of duration $D=3$ ms (correlations for azimuth and elevation: $\rho_\alpha=0.97$, $\rho_\epsilon=0.69$; $N=95$). (c) and (d) responses of subject JR to pulse trains with duty cycle $\Delta T=40$ ms ($\rho_\alpha=0.97$, $\rho_\epsilon=0.86$; $N=97$). (e) and (f) responses of subject PH to FM sweeps with period $T=20$ ms ($\rho_\alpha=0.96$, $\rho_\epsilon=0.38$; $N=143$). Correlations for response position versus stimulus position are listed in Tables II, III, and IV. See legend of Fig. 4 for further details.

stimulus positions within the box at $(\alpha,\epsilon)=(0,-13)$ deg, where response elevations were, on average, about 8 ± 5 deg lower than the actual stimulus elevations.

B. Test conditions

Typical responses to four eccentric stimulus positions in one of the test conditions (noise burst, duration $D=3$ ms) are plotted in Fig. 6. It is clear that azimuth localization is accurate. However, in contrast to the control condition, where elevation detection was also accurate, the responses now exhibit large undershoots in elevation.

Typical responses for the three different stimulus types employed in this study are shown in Fig. 7 (data from subjects BB, JR, and PH, respectively). The most obvious feature of these data, obtained for all three test conditions, is that the saccade trajectories cover only part of the vertical stimulus range [compare Fig. 7(a) with Fig. 4(a)]. Compared to the control condition (see Fig. 4), localization accuracy has clearly deteriorated for elevation, whereas it has remained the same for azimuth [Fig. 7(b), open symbols]. However, although elevation accuracy has deteriorated in these test conditions, the correlation between stimulus elevation and response elevation is still highly significant. This can also be seen in Tables II, III, and IV, which summarize the regression results for all subjects and the test conditions.

In summary, we found for all spectro-temporal stimuli that, although response elevation could be incorrect, it was quite consistent and correlated highly with the real stimulus elevation: $\rho_\epsilon \geqslant 0.4$ for all conditions. This is also expressed by the difference, Δ_{FIT}, between the responses and the straight line fits (dashed lines in Fig. 4 and Fig. 7): Δ_{FIT} remained within 4–8 deg for elevation and within 3–6 deg for azimuth for all stimulus conditions and subjects. Hence, the variance in the responses did not increase substantially with respect to the control condition (compare with Table I).

C. Response gain

Next, we compared the responses for each subject for the different temporal parameters D, ΔT, and T with the results from the control stimulus ($D=500$ ms). The straight

TABLE II. Parameters of the responses to noise-burst stimuli with various durations D (in ms) for three subjects. Note that elevation gain increases systematically with increasing D, but that the variability in the data (Δ_{FIT}) is independent of D. Azimuth gain, however, is not affected by D. Note also, that the median latencies tend to decrease as D increases. See Table I for further explanation of the columns.

line appeared to yield a reasonable description of the relation between response versus stimulus position, and the slope of the line turned out to be a characteristic parameter for the responses in a given condition. One can immediately see from Fig. 8 that the response gains for elevation varied systematically with all three temporal parameters (bottom panels). The azimuth component of the saccades was unaffected by the stimulus parameters (top panels).

For the noise burst, the same systematic variation with D is observed for all three subjects: the response elevation gain increases gradually with stimulus duration D, from $D=3$ ms up to $D=80$ ms. Although there is some intersubject variability as to the absolute values of these gains, all subjects followed a similar trend. Note that similar quantitative inter-subject differences were also obtained for the control stimuli. Furthermore, as the control stimulus is a noise burst with $D=500$ ms, the results suggest that for broadband noise bursts responses stabilize at roughly $D=80$ ms. Note that the

TABLE III. Parameters of the responses to the burst-train stimuli with various duty cycles ΔT (in ms). Elevation gain, but not azimuth gain, depends systematically on ΔT. $\Delta T=\infty$ refers to the single 3-ms burst stimulus. Median latencies tend to decrease with ΔT for all three subjects. See Table I for explanation of the columns.

short bursts already account for relatively large gains: for example, the gains at $D=10$ ms are already about 40%–80% of the final gains obtained for $D=80$ ms.

For the burst-train stimulus, response gain decreases monotonously with the duty cycle ΔT for subjects PH and JR. The response gain of subject JG, although displaying a similar overall trend, does not vary significantly for the intermediate values of $\Delta T=10,20,40,80$ ms. In this experiment, the intersubject variability for the gains is small for both the burst trains and the control condition. For the shortest duty cycles applied ($\Delta T=3$ ms), the gain is similar as for the control condition (indicated by C). In addition, for subject PH who also participated in experiment I, the gain for $\Delta T=80$ ms is very similar to the gain observed for the single noise burst at $D=3$ ms (condition $D3$ in Fig. 8). This result could be expected: the latency of this subject's response lies around 150 ms (see Table III), so that only the first burst (i.e., at $t=0$ ms) and maybe the second one (at $t=80$ ms) could actually have been processed by the auditory system for generating the first saccade.

For the sweeps, the elevation gain decreases when the period T increases. In contrast to the noise burst and the burst train, the change with the temporal parameter is more sudden. Approximately $T=5$ ms seems to be a critical value, where the response elevation changes most rapidly with T. From $T=10$ ms (subject KH) or $T=20$ ms (subjects PH and VC) there is little change in the gain which lies between 0.1 and 0.2. Although the gains for $T\geqslant 10$ ms are relatively low, correlations for the sweep data were still 0.38 or higher.

D. Response latency

The latencies of primary saccades are typically well below 300 ms. Figure 9(a) shows a latency distribution for saccades to the control stimulus (subject PH). One can see that latencies peak near 170 ms and remain within the [100,300]-ms interval. This interval was typical for all subjects, which can be further appreciated from the cumulative latency distributions in Fig. 9(b). Data from three different subjects for the control condition are presented: latencies that were relatively short (subject JR), long (VC), and intermediate (PH). Note that, also for subject VC, more than 90% of the latencies remained below 300 ms.

It may be observed that in Fig. 9(b) the curves are nearly linear and roughly parallel to each other (see Sec. III). This is most obvious for the distributions of subjects PH and VC, which are well-defined, since they consist of a relatively high number of saccades. For other subjects, fewer saccades were available for each condition, but the distributions exhibited roughly similar characteristics [e.g., subject JR, Fig. 9(b)].

For subject PH, also cumulative distributions are shown that resulted from the several short-noise burst experiments. One can see that latencies systematically increase as the duration of the noise burst decreases. The same trend was observed for the other subjects (BB, JO) who participated in this experiment (see Table II). Also in the other experiments, a systematic shift of the (reciprocal) latency distribution as function of the temporal stimulus parameter was observed as well (except for subjects VC and KH in response to FM sweeps). Median latencies also show this trend (see Tables II, III, and IV). For different stimulus conditions, the reciprocal latency distributions differed in their offset, but retained their shape.

E. Primary and secondary saccades

The endpoint of the primary saccade was accepted as a valid response when its onset latency fell in the interval [80,500] ms. For the average subject, a valid response was measured in $97\%\pm 2\%$ of the trials. In the same time inter-

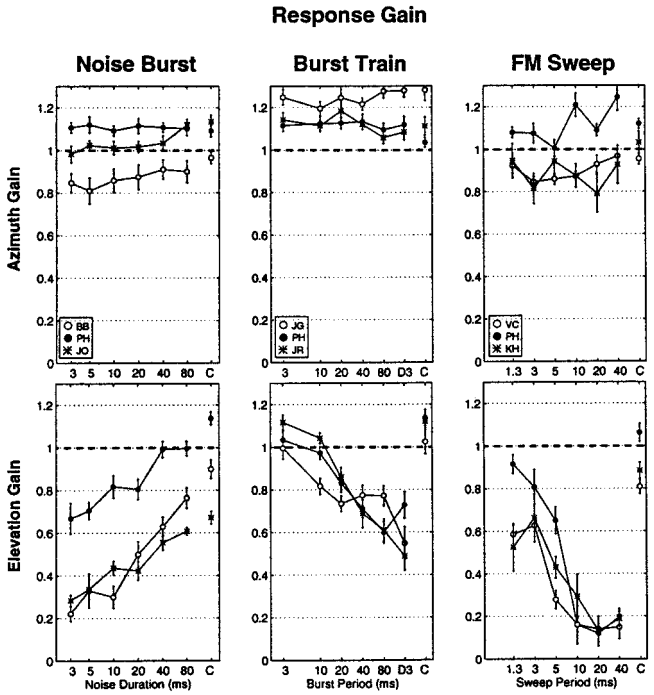

FIG. 8. Response gains for all subjects and all conditions. The gain is defined as the slope of the straight line fitted through response component versus stimulus component (see also Fig. 4 and Fig. 7). Top panels: azimuth gains. Lower panels: elevation gains. Gains are plotted as function of the temporal stimulus parameters D, ΔT, and T. The control condition is indicated by C. The single-burst condition in the burst-train experiments is labeled by D3. Optimal agreement of response and stimulus position is associated with gain 1.0 (dashed lines). Lowest correlations ρ_ϵ obtained for noise bursts, burst trains and sweeps were 0.58, 0.83, and 0.38, respectively, but still highly significant (see Tables II, III, and IV).

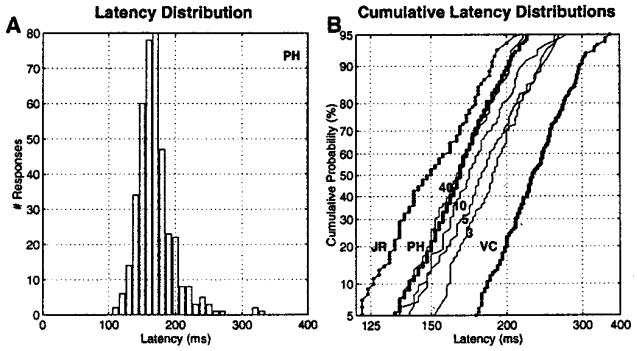

FIG. 9. (a) Response latency distribution for the control condition. Subject PH. (b) Cumulative response latency distributions. The latency axis has a reciprocal scale, whereas the abscissa is on probit scale. In this format, a Gaussian distribution of reciprocal latency results in a straight line. The thick dotted lines refer to the control conditions for subject JR, VC, and PH; the distributions consist of 99, 219, and 398 saccades, respectively. The thin lines show the cumulative distributions of responses to short noise bursts with $D=3$, 5, 10, 40 ms (subject PH). For each condition D, about 116 saccades are included.

val, a secondary saccade was observed in $23\% \pm 9\%$ of the trials, and a third saccade in less than 4% of the trials.

To test whether the secondary saccade was corrective (which is known to be the case for visually evoked saccades), the unsigned errors after the primary saccade, and after the secondary saccade were compared for each subject. This was done for saccade azimuth α, elevation ϵ, amplitude R and direction ϕ. The analyses revealed that incorporating the second saccade did not significantly change (i.e. neither improve nor deteriorate) response accuracy (data not shown).

To further check for a possible relation of the secondary saccade with the stimulus position, an additional analysis was performed by comparing the directions of the primary saccade, the secondary saccade and the stimulus. First, the difference in direction, $\Delta\phi_{12}$ between the primary and the secondary saccade was computed. For all subjects pooled, it was found that $\Delta\phi_{12}=4\pm48$ deg. The individual results for each subject were similar. Thus the secondary saccade generally proceeds in the same direction as the primary saccade. Next, $\Delta\phi_{12}$ was compared to the difference in direction, $\Delta\phi_{01}$, between the primary saccade and the stimulus position (i.e., the direction error). No significant correlation between $\Delta\phi_{12}$ and $\Delta\phi_{01}$ was found. Thus the secondary saccade does not correct for a residual direction error after the primary saccade either.

III. DISCUSSION

A. General findings

In the present study, human localization experiments were performed using a wide range of acoustic stimuli. The time-averaged power spectra of the stimuli were always broadband and identical in shape, but the spectro-temporal behavior on a millisecond time scale was fundamentally different. Localization performance varied systematically with the experimental parameters T, ΔT, and D. Whereas elevation detection appeared to be very sensitive to the spectro-temporal stimulus behavior, azimuth localization remained unaffected and was equally accurate for all conditions.

Our findings provide new insights into the spectro-temporal processing of acoustic sensory information. The data suggest specific temporal constraints for accurate acoustic localization of stimulus elevation. Moreover, these results underline the presence of separate dynamical processes underlying the analysis of the different acoustic cues for the detection of azimuth (ITD, IID) and elevation (spectral shape cues).

B. Saccadic eye movements

1. Orienting to sounds through saccadic eye movements

Saccadic eye movements were used to measure the perceived sound direction. The results show that this method yields a highly reproducible and accurate measure of the acoustic localization percept for stimuli presented within the oculomotor range (approximately 35 deg in all directions). Correlations for both the horizontal and vertical components of responses to control stimuli exceeded 0.9 in experienced as well as in naive subjects. The oculomotor response forms an important part of the natural repertoire of stimulus-evoked orienting (including head and body movements) and does not require any specific training of the subjects. Moreover, the response is fast (latencies remain well below 300 ms; see also Frens and Van Opstal, 1995).

In previous localization studies with human subjects, different response methods have also been used to quantify the localization percept: arm pointing (e.g., Oldfield and Parker, 1984a), the naming of learned coordinates (e.g., Wightman and Kistler, 1989), and head pointing (e.g., Makous and Middlebrooks, 1990). The first two methods are substantially slower than the eye-movement method and may thus be assumed to measure a later acoustic percept, possibly also incorporating cognitive aspects. The head-pointing method is potentially faster. Although latencies of head movements can be similar to eye movement latencies, head-movements dynamically alter the acoustic input for long-duration stimuli, which was deemed to be an undesirable factor for the purpose of this study.

2. Potential artefacts

We are confident that our main results cannot be ascribed to peculiar properties of the oculomotor system. First, the sound stimuli were presented well within the oculomotor range and stimulus types and stimulus positions were always presented in a randomized order. Therefore, the results cannot be due to a (conscious or subconscious) strategy adopted by the subjects.

A second argument for believing that the results reflect properties of the auditory system, rather than of the visuomotor system, is that quite different behaviors were obtained for the azimuth components of the responses, than for the elevation components. Such a behavior is never encountered in visually evoked eye movements toward stimuli at similar locations.

We also believe that the auditory stimuli were always presented well above the detection threshold, since similar temporal-dependent response behaviors were obtained for all three acoustic stimulus types. The finding that the azimuth components of the responses remained unaffected by the stimulus parameters, indicates that the stimuli were well-perceived by the auditory system, despite the fact that the overall acoustic energy of the stimuli varied greatly. This is also supported by the fact that the standard deviations of the latency distributions were hardly affected [see Fig. 9(b), and below].

Finally, also the result that response variability did not change systematically with the temporal stimulus parameters (Tables II, IV, and III) argues against the possibility that the auditory stimuli may have been close to the detection threshold for the shortest stimulus durations D or longest duty cycles ΔT.

3. Latency characteristics

There are some interesting aspects regarding the auditory-evoked saccadic latency distributions. First, the cumulative latency probabilities in Fig. 9(b) are plotted on a so-called probit scale, which is the inverse of the Error function. If the cumulative distribution on probit scale yields a straight line, the variable follows a Gaussian distribution. This linear feature of reciprocal latency distributions has been shown to be characteristic for visually evoked saccades (Carpenter, 1995). In the present study, straight lines were also obtained for auditory saccades, despite the different origin and encoding format of acoustic sensory information.

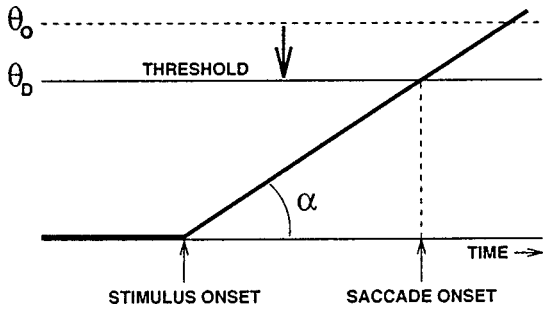

FIG. 10. A simple model that accounts for the observed characteristics of the latency distribution (see also Carpenter, 1995). At stimulus onset, a decision signal rises with a constant rate, α, and upon exceeding a fixed threshold, at θ_D, a saccade is initiated. In each trial, the increase rate, α, is drawn from a gaussian distribution. In order to incorporate the condition-dependent modulations on the latency in this study, it is proposed that the threshold is not constant, but instead decreases during stimulus presentation, from the initial value θ_0 to the final value θ_D.

Carpenter (1995) proposed a simple model for visual saccade initiation that accounts for this characteristic property (Fig. 10). The model assumes that a decision signal starts to increase after stimulus onset and, subsequently, initiates the saccade upon exceeding a fixed threshold (θ_0). Consequently, the time-to-threshold (i.e., the saccade latency) is inversely proportional to the increase rate of the decision signal. The increase rate (slope α) is assumed to vary from trial to trial, but remains constant during a trial. If this rate is distributed as a gaussian over trials, then the reciprocal latency is necessarily distributed likewise. Our data suggest that a similar mechanism could underlie the initiation of auditory-evoked saccades.

Yet, the question remains how stimulus-related shifts in the distributions could arise. For example, Fig. 9(b) shows that latencies become larger for shorter stimulus durations. The simple model described above has only a few parameters that can cause a shift in the distribution: the initial level of the decision signal, its mean increase rate, and the threshold level. The first two parameters have preset values and are assumed to depend on expectation about the stimulus. Since the different stimuli were presented in random order, expectation is not likely to play a role in the present situation. The shift in the median latencies is qualitatively explained, however, if it is assumed that the threshold decreases as more sensory information comes in (θ_D). For short burst durations, the threshold would then remain systematically higher (yielding longer latencies) than for longer stimulus durations (see also Fig. 10).

4. Secondary saccades

The typical response pattern of an auditory orienting trial usually consists of a large primary saccade followed by a smaller secondary (and occasionally a tertiary) saccade. A similar pattern is also typical for visually elicited responses. The primary saccade carries the eye over roughly 90% of the required trajectory (undershoot), whereas the secondary saccade corrects for the remaining retinal error. It has been proposed (Harris, 1995) that such a motor strategy minimizes

(in a statistical sense) the time needed to fixate the target, by taking into account both the effects of a longer duration needed to complete larger saccades, and the additional time needed to program a corrective saccade in the opposite direction (due to an overshoot). Here, the question was what the underlying strategy for secondary saccades could be in the case of a sound stimulus.

Analysis of the auditory responses indicated that the secondary saccades were not corrective. Note that, in contrast to visual stimulus conditions, the oculomotor system is not provided with any feedback concerning its performance after completing the primary auditory saccade. Notwithstanding, the occurrence of a small secondary saccade in roughly the same direction as the primary saccade was quite typical in all subjects tested. We propose that this phenomenon reflects a property of the programming mechanisms underlying the oculomotor response, rather than auditory processing. The data suggest that the secondary saccade is a pre-programmed movement that in this case, however, does not (cannot) correct for a residual error.

C. Temporal aspects of sound localization

1. Effect of stimulus duration

It should be realized, that the programming of an auditory-evoked saccade consists of at least two main stages: a target localization stage, in which the acoustic information is transformed into an estimate of target location, and a response initiation stage in which the estimated target coordinates are transformed into the appropriate motor commands. We believe that the data obtained from the noise-burst experiments may be interpreted in the light of these two, partly separate, stages.

First, it was found that the response elevation gain increases systematically as function of stimulus duration, and that it reaches a plateau for stimulus durations exceeding 80 ms (Fig. 8). From these data we infer that the auditory localization system needs roughly 80 ms of Gaussian broadband input to reach a stable estimate of target elevation.

Second, the latency data [Fig. 9(b) and Table II] may provide further insights into the processing time of the response initiation stage. Although it takes less time for the short-duration bursts to complete, the associated latencies were about 20 ms longer than for the longest stimuli (see Table II). This suggests that the movement initiation stage takes, at least, about 20 ms longer to initiate a saccade toward the shortest burst. We have no simple explanation for this apparent, yet consistent, discrepancy.

In contrast to sound elevation, sound azimuth can apparently be determined accurately on the basis of only a few milliseconds of sensory information. Even for the shortest stimuli ($D=3$ ms), the accuracy was about the same as for the control condition ($D=500$ ms). In this sense, azimuth localization can be considered as a much ''faster'' process than elevation localization. From our data it is not possible to conclude whether this property is due to mechanisms processing either the interaural phase or intensity differences, since the broadband bursts provided both cues simultaneously.

2. Effect of nonstationarity of the short-term spectrum

The results obtained from the FM sweeps provide some further interesting suggestions regarding the temporal processing of sensory information in sound localization. In contrast to the noise bursts, the duration of the sweeps was kept constant (at 500 ms), but the spectro-temporal behavior was varied by means of the cycle variable T. Response characteristics were similar as in the case of the noise bursts. Although elevation localization accuracy varied with T, responses remained consistent: high correlation coefficients of response versus stimulus position were obtained for all conditions. Because elevation localization performance was most accurate for $T<5$ ms and relatively inaccurate for $T>5$ ms, it is suggested that the auditory localization system discriminates spectro-temporal patterns at a temporal resolution down to about 5 ms.

A possible explanation for this ability is that the auditory system applies a so-called *multiple-look* strategy (e.g., Viemeister and Wakefield, 1991). In such a mechanism, the input spectrum is measured over consecutive short time windows, each lasting only a few milliseconds. Each short-term spectrum is processed into a position estimate, which, at a higher level, is integrated with the earlier estimates into a final estimate (see below, Fig. 12). This explanation is also in line with the interpretation of the burst-duration experiments (see above).

As an example, consider the computation of a short-term spectrum over a 5-ms time window somewhere in the cycle of an FM sweep with a long period, e.g., $T=20$ ms. The outcome will vary substantially for different window positions within the cycle. Elevation updates computed from consecutive (but very different) short-term spectra would then be inconsistent throughout the cycle and prevent the dynamic elevation estimate to stabilize at the actual target elevation. Note, that such a 5-ms time-averaged spectrum in a fast sweep ($T<5$ ms) would be broadband, whereas it would be narrow band for very slow sweeps ($T\gg 5$ ms).

3. Effect of silence gaps in the stimulus

The data obtained from the burst-train stimuli suggest further constraints on the dynamics of the spectral analysis in the localization process. For the shortest burst intervals, ΔT, near-optimal localization performance was obtained, although each burst was only 3 ms long.

Interestingly, the elevation gain was observed to decrease significantly when the individual bursts of the train were all chosen to be identical, rather than randomly drawn as in the experiments presented here, even for $\Delta T=3$ ms (data from subject PH only, not shown). Thus acoustic input presented at later times indeed contributes to the improvement of the final elevation estimate.

The low gains at long intervals are not explained by the fact that, within the latency period of roughly 180 ms, only two to four 3-ms bursts may have contributed to the programming of the first saccade, because the final estimate of the oculomotor responses (even after 500 ms) was not systematically better than the estimate recorded after the primary saccade. Rather, the decrease of elevation gain with

increasing ΔT indicates that the subsequent elevation estimates, based on each 3-ms sound burst, are not kept in acoustic memory forever. Possibly, the integrative mechanism that combines subsequent elevation estimates (see above) is leaky. If so, the data suggest a time constant for this integrator in the order of a few tens of ms.

D. Toward a spectro-temporal model of sound localization

In this section we study the properties of a monaural localization model that relies on spectral correlations in order to estimate sound elevation, ϵ_S (see also Middlebrooks, 1992). In addition, a biologically plausible mechanism for the dynamic implementation of these correlations, based on our data, will be briefly described.

1. Spectral correlations

In the proposed spectral correlation approach, it is assumed that the auditory system bases its comparison between the sensory signal and the HRTF on the log power of these spectral functions. In addition, a logarithmic scaling of the frequency domain, reminiscent to the tonotopic neural representation of sound frequency throughout the auditory system, is applied. By applying the logarithm to the power of the sensory signal measured at the eardrum, Eq. (1) can be rewritten as:

$$Y(\omega;\epsilon_S)=H(\omega;\epsilon_S)+X(\omega), \tag{3}$$

where ω is in octaves, and ϵ_S is the source elevation. The capitals indicate the logarithmic power spectra [e.g., $X(\omega) \equiv \log|x(\omega)|$]. Note, that elevation, ϵ_S, rather than position, $\mathbf{r}_S$, is used in Eq. (3), as it is assumed that azimuth, α_S, is already extracted from binaural cues.

A quantitative scalar measure of similarity for two spectral functions can be given by the spectral correlation coefficient. Therefore, the mean, $\overline{F}$, and variance, σ_F^2, for an arbitrary spectral function, $F(\omega)$, are first introduced:

$$\begin{aligned}\overline{F}&=\langle F(\omega)\rangle\equiv\int_0^\infty d\omega\ p(\omega)F(\omega),\\ \sigma_F^2&=\langle(F(\omega)-\overline{F})^2\rangle,\end{aligned} \tag{4}$$

with $p(\omega)$ a normalized weighting function that is nonzero in the (broad) frequency band of interest. Here $p(\omega)$ was chosen to be uniform in the [2, 16] kHz range, and zero elsewhere. The spectral correlation, $\mathsf{C}(F(\omega),G(\omega))$, between two functions, $F(\omega)$, and, $G(\omega)$, is then defined as

$$\mathsf{C}(F(\omega),G(\omega))\equiv\left\langle\left(\frac{F(\omega)-\overline{F}}{\sigma_F}\right)\left(\frac{G(\omega)-\overline{G}}{\sigma_G}\right)\right\rangle. \tag{5}$$

The outcome varies in $[-1,1]$, where $\mathsf{C}(\cdot)=1$ corresponds to ''maximal similarity,'' and $\mathsf{C}(\cdot)\leqslant 0$ means ''no similarity.''

In the present discussion, the spectral correlation compares the sensory signal, $Y(\omega;\epsilon_S)$, with (neurally stored) HRTFs, $H(\omega;\epsilon)$, for all sound elevations ϵ. By using Eq. (3) and by taking the mean (where $\overline{Y}=\overline{H_S}+\overline{X}$), this comparison reads:

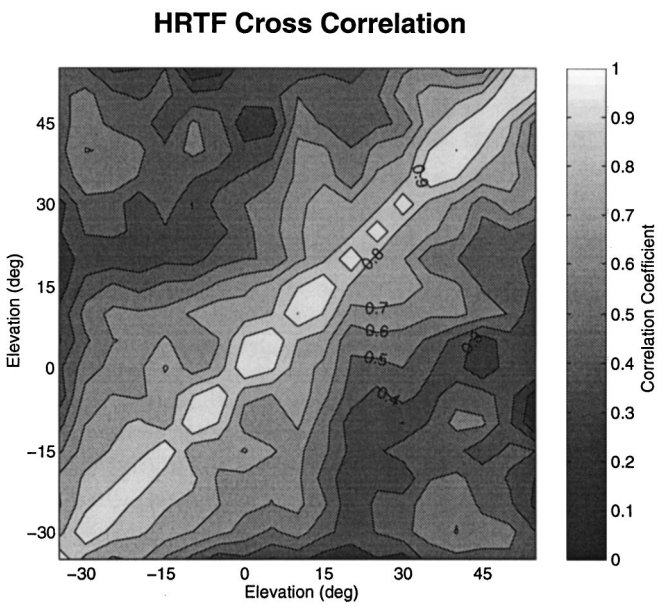

FIG. 11. Spectral correlations of human HRTFs, measured in the midsaggital plane at elevations $\{-35,-30,...,+50,+55\}$ deg. Subject PH. The strength of the correlation is coded by brightness. Markers label the contours at different values. Note that HRTFs correlate strongest with themselves and with HRTFs at neighboring elevations. Correlations were computed in the frequency range [2,16] kHz and HRTFs were sampled at 1/20 octave intervals.

$$\begin{aligned}C_Y(\epsilon;\epsilon_S)&\equiv\mathsf{C}(Y(\omega;\epsilon_S),H(\omega;\epsilon))\\ &=\left(\frac{\sigma_{H_S}}{\sigma_Y}\right)\mathsf{C}(H(\omega;\epsilon_S),H(\omega;\epsilon))\\ &\quad+\left(\frac{\sigma_X}{\sigma_Y}\right)\mathsf{C}(X(\omega),H(\omega;\epsilon))\\ &\equiv\left(\frac{\sigma_{H_S}}{\sigma_Y}\right)C_H(\epsilon;\epsilon_S)+\left(\frac{\sigma_X}{\sigma_Y}\right)C_X(\epsilon),\end{aligned} \tag{6}$$

with σ_Y, σ_{H_S}, σ_X the standard deviations of the respective quantities in Eq. (3). Thus Eq. (6) quantifies the spectral correlation of each stored HRTF (associated with sound elevation, ϵ) with the measured spectrum at the eardrum (resulting from a sound source at elevation, ϵ_S). It proposed that the perception of sound elevation essentially consists of selecting the unique position $\epsilon=\epsilon_P$ at which the global maximum, $C_Y(\epsilon_P;\epsilon_S)$, is attained.

In its decomposed form, Eq. (6) can be readily interpreted. The first term on the right-hand side, $C_H(\epsilon;\epsilon_S)$, is the spectral correlation between the HRTFs $H(\omega;\epsilon)$ and $H(\omega;\epsilon_S)$. Under the assumption that HRTFs are unique with respect to position, $C_H(\epsilon;\epsilon_S)$ reaches a maximum in the neighborhood of ϵ_S, i.e., at $\epsilon\approx\epsilon_S$.

Figure 11 shows that this is indeed a reasonable assumption. In this figure, measured HRTF functions in the median plane of one of our subjects have been correlated with each other. Note that only along the principal diagonal a high correlation is obtained, indicating that, indeed, HRTFs only resemble themselves. Therefore, these functions contain unique information about target elevation, when all frequency bands are allowed to contribute to the computational

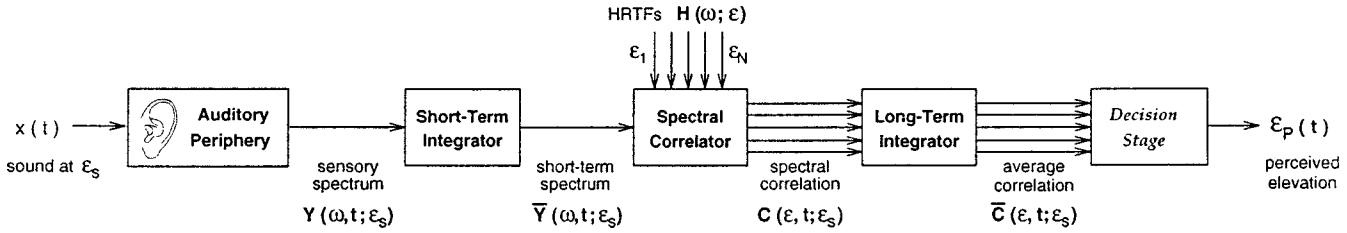

FIG. 12. Conceptual spectro-temporal correlation model of human sound localization. The first stage represents the auditory periphery, where a sound, $x(t)$, at elevation, ϵ_S, is processed from the external ear up to the cochlea. In the second stage, a short-term (order a few ms) averaged spectrum, $\bar{Y}(\omega,t;\epsilon_S)$, is determined around the current time, t, from the ongoing sensory spectrum, $Y(\omega,t;\epsilon_S)$. Then, $\bar{Y}(\omega,t;\epsilon_S)$ is correlated with the neurally stored HRTF representations, $H(\omega;\epsilon)$, for all possible elevations ϵ, i.e., $\epsilon_1,\ldots,\epsilon_N$, yielding short-term correlations $C(\epsilon,t;\epsilon_S)$. Next, integration is done over a longer time span (order several tens of ms), resulting in a long-term correlation up to current time t, $\bar{C}(\epsilon,t;\epsilon_S)$. This integration process may be leaky. In the decision stage, the average correlation at time t yields a perceived elevation, $\epsilon_P(t)$. It is proposed that this decision depends on the maximum of the average correlation, but also on the consistency of that average and on the initial elevation percept.

process. We have verified that this conclusion also holds for the entire elevation domain ($\epsilon \in [-60,90]$ deg, front and back), although the region of maximum correlation broadens appreciably close to zenith positions ($\epsilon \approx +90$ deg; data not shown). It is therefore expected, that stimuli presented within that range are not well localized and discriminated.

The second term in Eq. (6), $C_X(\epsilon)$, expresses the resemblance of the source spectrum $X(\omega)$ with each particular HRTF $H(\omega;\epsilon)$. If the source spectrum does not correlate significantly with any of the stored HRTFs, then $C_X(\epsilon) \approx 0$ for all ϵ [for example, this would be true if $X(\omega)$ is flat and broadband]. In that case, the maximum correlation $C_Y(\epsilon_P;\epsilon_S)$ will be reached at $\epsilon_P = \epsilon_S$, thus the sound would be accurately localized. It is expected that there will be a broad range of naturally occurring acoustic stimuli for which there is little or no resemblance with the stored HRTFs, i.e., $C_X(\epsilon) \approx 0$.

However, the second term does come into play, if the source spectrum $X(\omega)$ does correlate well with a given HRTF, say $H(\omega;\epsilon_*)$. This occurs if $X(\omega)$ contains prominent features that are characteristic for $H(\omega;\epsilon_*)$. Then, $C_X(\epsilon_*) \gg 0$, meaning that $C_Y(\epsilon;\epsilon_S)$ contains a second local maximum at $\epsilon = \epsilon_*$. This could even be the global maximum in which case the perceived position, ϵ_P, would be, ϵ_*, rather than the actual position, ϵ_S, thus $\epsilon_P = \epsilon_* \neq \epsilon_S$. This might occur, for example, when $X(\omega)$ is narrow band (i.e., peaked) with its center frequency at a characteristic peak of $H(\omega;\epsilon_*)$. In the study of Middlebrooks (1992), consistent mislocalizations were attributed to such spurious correlations between the narrow-band source spectrum and one of the HRTFs.

2. Conceptual spectro-temporal model

The data presented in this study clearly indicate that the spectral estimation performed by the auditory localization system is also a temporal process. Therefore, if the auditory system bases its spatial estimation on spectral correlations, the underlying computational mechanisms have to be incorporated within a temporal scheme. Figure 12 provides a conceptual model of the successive stages in this spectral-temporal process (see legend for specific details). The model accounts for the different aspects that have been derived from the data for each of the spectro-temporal stimulus patterns (see above, Sec. III C).

(1) The sweep data suggest that the elevation localization system first measures spectra on a short time scale of about 5 ms (''multiple looks''). Accurate localization requires a broadband, short-term spectrum (fast sweeps, noise bursts). Inaccurate localization results if the short-term spectrum is narrow band (slow sweep).
(2) The noise-burst data suggest that acoustic information needs to be delivered over a (longer) time scale of roughly 80 ms. If short-term estimates are consistent over time (fast sweeps, noise) averaging will enhance the final estimate. Yet, if the estimates vary strongly (e.g., for slow sweeps) the estimates may cancel each other on average.
(3) The burst-train data suggest a power-dependent gating mechanism and leakiness of the long-term integration process. Estimates at different time windows (e.g., in burst trains with a long duty cycle) are not heavily suppressed by the intervening silence periods, thus gating is plausible. Leakiness is inferred from the finding that the elevation gain drops as the silence period increases.

In this scheme, the current estimate, $\epsilon_P(t)$, of target position, ϵ_S, smoothly develops over time as more acoustic information enters the system.

The experimental data further suggest that, in the absence of sufficient spectral processing the auditory localization system stays close to its default initial estimate of elevation, typically near the horizontal plane. An interesting question that remains to be investigated, is whether the system's default elevation estimate depends on the initial gaze direction, or on head orientation. In the present study, initial eye position, the horizontal plane of the head, and the earth-fixed horizon always coincided. This problem could be studied by systematically changing these different frames of reference with respect to each other under similar stimulus conditions as applied in this study.

ACKNOWLEDGMENTS

The authors are indebted to Jeroen Goossens and Jos Van Riswick for their participation in the experiments. We thank Hans Kleijnen and Ton Van Dreumel for valuable technical assistance. BB, KH, and VC are acknowledged for volunteering as experimental subjects. The authors also thank both referees for their useful and constructive com-

ments. This research was supported by the Netherlands Foundation of the Life Sciences (SLW; PH) and the University of Nijmegen (AJVO).

(Received 15 September 1997; accepted for publication 3 February 1998)

The purpose of the study was to examine the acoustic, aerodynamic, physiologic, and perceptual characteristics of modal and vocal fry production. Twenty normal speakers (10 males, 10 females) participated in the study. Speech material included four sustained vowels (/i/, /ɑ/, /æ/, /u/), and syllable strings of /pi/ repetitions produced in both modal and vocal fry registers. Acoustic data (fundamental frequency, jitter, shimmer, and signal-to-noise ratio), aerodynamic data (airflow and air pressure), and electroglottographic (EGG) data were obtained simultaneously. Results demonstrated considerable differences across voice parameters for the modal and vocal fry registers. Fundamental frequency was significantly lower in vocal fry than in modal register for both males and females, however, significant gender differences existed only in modal register. For both males and females, measurements of jitter and shimmer were significantly higher and signal to noise ratio was significantly lower in vocal fry. In addition, airflow rate in modal register was almost three times as high as the airflow rate in vocal fry register during sustained vowel production. During syllable string production, subglottal air pressure values in modal register were approximately 1.5 times higher than that in the vocal fry register. In general, these data emphasize that the aeromechanical mechanisms of vocal fold vibratory behavior are substantially different between modal and vocal fry registers. A model of vocal fry phonation is presented to account for the present results. [S0001-4966(98)04005-3]

INTRODUCTION

According to Hollien (1974) there are three vocal registers. Although variously labeled over the past 40 years, common designations have included (a) falsetto or loft register for the highest of the human vocal frequencies, (b) modal or chest register for the ''normal'' speaking or singing voice, and (c) vocal fry, glottal fry, creak, or pulse register for the phonation produced at the lowest end of the human vocal frequency range. Hollien stated that a vocal register is a series or range of consecutively phonated frequencies that can be produced with nearly identical vocal quality and with little or no overlap in fundamental frequencies (F_0) between adjacent registers. He suggested that a voice register can be operationally defined according to the following parameters: (1) perceptual; (2) acoustic; (3) physiologic; and (4) aerodynamic. In addition, Daniloff *et al.* (1980) reported that ''the complex physiological structure of the larynx can vibrate in three (or more) relatively different ways, giving rise to airflow modulation that yields acoustically and perceptually distinct vocal quality'' (p. 209). The present study explored the acoustic, aerodynamic, physiologic, and perceptual characteristics of two of the three normal voice registers; specifically, modal and vocal fry registers.

Modal register refers to the range of F_0 used in the ''normal mode'' of speaking and singing (Hollien, 1974). Vocal fry is a voice register approximately one octave below the frequencies noted for the normal male modal register. Vocal fry consists of a train of discrete, low-frequency, glottal pulses produced by the larynx (Hollien and Wendahl, 1968). McGlone (1967) indicated that vocal fry exists as a physiologically normal mode of laryngeal vibration which results in a distinctive acoustic signal.

A. Acoustic properties of vocal fry

The F_0 ranges in modal register are characterized by values of approximately 100–140 Hz for males (Hollien and Jackson, 1973; Krook, 1988), and 175–240 for females (Stoicheff, 1981; Krook, 1988). In contrast, vocal fry is associated with a very low F_0. The F_0 of vocal fry samples obtained by Hollien and Wendahl (1968) ranged from 31.6 to 69.1 Hz. McGlone (1967) found values ranging from 10.9 to 52.1 Hz. Murry (1971) obtained values of 22–92 Hz for vocal fry, and 73–98 Hz for the low modal register range. McGlone and Shipp (1971) obtained values of 18–65 Hz for vocal fry. Average frequencies of vocal fry vibration, extrapolated from the literature, range from approximately 20 to 70 Hz with a mean of approximately 50 Hz.

Women usually have a broader F_0 range than men in modal register. In vocal fry register, a negligible difference in F_0 range between males and females has been reported by McGlone (1967). McGlone found that the F_0 range in vocal fry was from 10.9 to 51.0 Hz for males, and from 15.5 to

48.8 Hz for females. Hollien and Wendahl (1968) obtained similar findings for males (24–52 Hz), and females (18–46 Hz). Acoustic parameters of pitch perturbation, shimmer, and signal-to-noise ratio do not appear to have been thoroughly investigated for vocal fry phonation.

B. Aerodynamic properties of vocal fry

1. Airflow

According to McGlone (1967), vocal fry is produced with an average airflow ranging from 2.0 to 71.9 ml/s. McGlone also found that, unlike modal register, airflow rate in vocal fry did not increase as vocal fry frequencies increased. Murry (1971) reported that when vocal fry is sustained, the airflow rate is significantly reduced compared to modal register; about 10–100 ml/s in vocal fry, and 70–180 ml/s in modal register.

2. Subglottal air pressure

Murry (1971) reported subglottal air pressure (Ps) data during vocal fry of 8.0–11.0 cm H_2O. The values were significantly greater than those produced in the modal register (5.0–6.0 cm H_2O). He concluded that Ps increased during the long closing phase to force apart the large vocal fold mass. However, McGlone and Shipp (1971) found that the Ps ranged from 2.5 to 7.6 cm H_2O for vocal fry, and from 2.8 to 7.0 cm H_2O for modal register. Differences between the two vocal registers were not significant. It is clear that the findings of Murry (1971) and McGlone and Shipp (1971) differ and additional research is warranted to further evaluate the vocal fold driving pressures in modal and vocal fry registers.

C. Physiological properties of vocal fry

Vocal fry is characterized by a glottal area function that has sharp, short pulses followed by a long closed glottal interval (Childers and Lee, 1991). There is a very short open period and a very long period where the vocal folds are completely adducted. Due to the short open period in fry phonation, the open quotient (OQ) of vocal fry is less than other registers. Childers and Lee (1991) examined four voice types using electroglottography (EGG): modal, vocal fry, falsetto, and breathy. They found that the glottal pulse widths were smaller (25%–45%) in vocal fry phonation compared to modal register, due to the shorter open phase. Murry (1971) suggested that the low airflow rate in vocal fry was related to the long closed phase of the vocal fold vibratory cycle.

Moore and von Leden (1958), using high-speed laryngeal cinematography, found that during vocal fry the vocal folds opened and closed twice in rapid succession. However, Hollien *et al.* (1977) argued that Moore and von Leden (1958) used a rough type of phonation, and consequently obtained a ''mixed'' phonation which was not indicative of true vocal fry. Later, Whitehead *et al.* (1984) using high-speed laryngeal photography found that the vocal fold vibratory patterns in vocal fry can be associated with single, double, or triple opening and closing gestures followed by a lengthy closed period. The findings by Whitehead *et al.* (1984) appear to support the conclusions of Moore and von Leden (1958), however further research seems warranted to verify the extent and characteristics of multiple opening and closing gestures in vocal fry.

D. Perceptual properties of vocal fry

Vocal fry has been described as sounding similar to the ''popping of corn,'' the imitated sound of a ''motor boat engine,'' or a ''creaky voice.'' In essence, the vocal folds tend to vibrate so slowly that individual vibrations can be perceived (Colton and Casper, 1996). Hollien and Wendahl (1968) reported that the F_0 of their vocal fry samples was very low, and the perceptual regularity of vocal fry provided evidence against classifying it as a voice pathology. Vocal fry may also be regarded as a lower extension of the normal pitch range as brief vocal fry production is common at the very end of sentences when pitch and vocal intensity are beginning to decay (Zemlin, 1988, p. 167).

E. Summary

As vocal fry register is a portion of the full capability of the human vocal range, it appeared that further study should enhance our knowledge of the complex process of phonation. Attempts have been made to understand the phonational properties of vocal fry using a variety of measurement techniques (Childers and Lee, 1991; Hollien and Michel, 1968; McGlone and Shipp, 1971; Murry and Brown, 1971a; Whitehead *et al.*, 1984). Results from these studies vary considerably. To date no studies have measured simultaneously the acoustic, aerodynamic, physiologic, and perceptual characteristics of vocal fry. The purpose of this research is to integrate simultaneous measurement of vocal fry and modal phonational registers to better understand the aeromechanical mechanisms involved with vocal fry production.

I. METHOD

A. Subjects

Twenty normal nonsmoking adult speakers (10 males and 10 females) with ages ranging from 22 to 65 years participated in the present study. Potential subjects were screened for their ability to produce and sustain vocal fry phonation. Each subject's ability to produce vocal fry was judged by two of the experimenters. In order to be considered for inclusion in the present study, speakers were required to produce approximately four seconds of vocal fry in two vowels (/ɑ/ and /i/). Approximately 35 speakers were screened. A total of 24 subjects were selected for recording based on the screening task. Four subjects were subsequently excluded from the study due to their inability to maintain vocal fry in all of the experimental tasks. Subjects were all native speakers of American English, and did not report or exhibit any voice, speech, language, or hearing problems.

B. Speech material

Four vowels (/i/, /ɑ/, /æ/, /u/) were produced by the 20 speakers in both modal and vocal fry registers. The vowels were randomized for each subject. For each register, the vowels were sustained for approximately 6 s and were pro-

duced three times at a normal conversational loudness level. Each speaker also produced a string of seven contiguous /pi/ syllables (/pipi...pi/) three times at normal loudness level in both the modal and vocal fry registers. The speakers were instructed to take a full breath and produce the seven consecutive /pi/ syllables on one breath.

C. Recording procedure

Voice recordings were conducted in a single-wall, sound-isolated booth using an 8-channel PCM data recorder (TEAC, RD-111T). All recordings were digitized, thus avoiding low-frequency distortion inherent in traditional audiotape. Airflow, air pressure, EGG, and acoustic signals were recorded simultaneously on high quality digital tapes. The acoustic signal was acquired via a dynamic microphone (Shure, 515SP) and recorded on one channel of the digital data recorder. A mouth-to-microphone distance of 20 cm was maintained. The EGG signal was obtained using a laryngograph (Kay Laryngograph Ltd.) and recorded on a second channel of the digital data recorder. The EGG signal was sensed by two electrodes, which were placed directly over each subject's thyroid lamina. The electrodes were fixed on a Velcro strip that was then placed around each speaker's neck. The airflow signal was obtained via a pneumotachograph mask that was held securely against each subject's face by one of the researchers to avoid air leakage during the experiment. Air pressure was measured via a 6.0-cm-long polyethylene tube with an internal diameter of 2.5 mm. The tube was passed through the pneumotachograph mask with one end placed in the speaker's mouth, and the other end attached to an air pressure transducer. The airflow and air pressure signals were transduced by using a standard aerodynamic system (Rothenberg, 1973) and were amplified (Glottal Enterprise, MS100-A2) before being recorded. The amplified airflow and air pressure signals were recorded on two separate channels of the data recorder.

The airflow and air pressure signals were calibrated after each recording. During the calibration, two different levels of airflow (0.5 l/s, 1 l/s) and three levels of air pressure (0-cm H_2O, 5-cm H_2O, 10-cm H_2O) were generated by using the Mask Calibration Unit (Glottal Enterprise, MCU-3). All calibration signals were recorded on the PCM data recorder.

D. Analysis

The four signals (airflow, air pressure, EGG, and acoustic) were fed from the data recorder into a computer (80586, CPU) and analyzed by using an integrated computer hardware/software package (Kay Elemetrics, CSL-4300B). The four signals were simultaneously displayed on four separate windows on the computer monitor. For the sustained vowel productions, only airflow and the acoustic signals were analyzed.

The sustained vowel airflow values were obtained by superimposing two markers on the digital flow waveform to delineate a 400-ms segment to be analyzed. The demarcated segment of the flow waveform was then expanded to clearly display the individual peaks corresponding to the individual glottal pulses. The peak airflow of five glottal pulses was measured for each vowel repetition. Thus averaged airflow measures from each subject (in each vowel and in each register) were calculated from 15 peak airflow measures (5 measures per repetition$\times 3$ repetitions). For the /pi/ syllable productions, peak airflow was calculated on the middle five of the seven /pi/ repetitions. Peak airflow in the /pi/ syllable repetition task was measured from the baseline to the maximum point of excursion on the flow waveform following the release of the stop phase of the /p/.

The acoustic analysis was performed on a 1500-ms steady-state segment from the center portion of each sustained vowel production. Vowel samples were digitized using CSL at 20 000 Hz and converted to a waveform file. Waveform analysis (F_0, jitter, shimmer, and signal-to-noise ratio) was conducted with PC-AUDED software (Boston University). Since the vocal fry acoustic waveform was characterized by relatively high variability, the automatic pitch period detection method was not used. Instead, pitch period markers were inserted manually at positive-going zero crossings. The PC-AUDED program allows for a straightforward method of inserting pitch period markers. PC-AUDED scans the signal and automatically imposes the pitch period marker at the exact zero crossing point closest to the manually placed impulse marker. Once the pitch period segments were marked, PC-AUDED computed F_0, jitter, shimmer, and signal-to-noise ratio. Jitter was calculated as a percentage of frequency perturbation (*jitter factor*), which is the mean of the absolute difference between sequential vocal F_0s (in Hz) divided by the mean F_0. This proportion is then multiplied by 100 to attain the percentage score. Shimmer was calculated as the *mean shimmer in decibels* which is the sum of the absolute values of the differences between the current and the previous sample divided by the number of periods minus one. Signal-to-noise ratio was calculated as the difference in dB of the average signal amplitude and the noise signal amplitude. Average signal amplitude and noise signal amplitude were first calculated as rms (root mean square). Then, the average signal amplitude (rms) and the noise signal amplitude (rms) were converted to dB using the following formula: $\mathrm{dB}=20\log_{10}(\mathrm{rms})$.

Subglottal pressure was estimated for the vowel /i/ by measuring and interpolating the peak intraoral pressure during the stop phase of five /pi/ syllable repetitions (Lofqvist *et al.*, 1982; Rothenberg, 1982; Smitheran and Hixon, 1981). The technique is based on the assumption that the vocal folds are fully abducted before the release of the burst during the production of /p/. At that instant, the intraoral pressure is equivalent to the subglottal pressure. For the /pi/ string, only the middle five syllable productions in the vocal fry and modal registers were analyzed. Peak airflow and peak air pressure values were recorded for the middle five productions of /pi/. All airflow and air pressure values were obtained by using a linear regression function calculated from the calibration signals.

The EGG signals were displayed using CSL. Each signal produced in vocal fry register was compared to the EGG signal in modal register. Qualitative visual comparisons were made and deviations in the EGG waveform between the two

TABLE I. Average fundamental frequency (Hz) and standard deviations in semitones (ST), jitter factor (%), mean shimmer (dB), and S/N ratio (dB) for the modal and vocal fry registers. Standard deviations are in parentheses.

	Males		Females	
	Modal register	Vocal fry	Modal register	Vocal fry
F_0 (ST)	117.5 (2.3)	49.14 (3.7)	211.0 (2.0)	48.1 (3.5)
Jitter (%)	1.23 (.83)	14.9 (7.1)	1.79 (.53)	8.8 (4.4)
Shimmer (dB)	0.40 (.21)	1.41 (.66)	0.38 (.20)	1.38 (.82)
S/N ratio (dB)	13.27 (3.87)	0.67 (2.55)	12.84 (3.75)	1.29 (2.74)

registers were noted. Specifically, the number of peaks per cycle were identified. In the present study, an EGG pattern with one opening/closing pattern per vibratory cycle was identified as a *singlet*. The EGG waveforms that contained patterns of more than one peak-per-cycle were identified as *complex repetitive*. Complex-repetitive patterns could include both double peaks (*doublet* cycles) and triple peaks (*triplet* cycles).

E. Perceptual identification of glottal fry

A perceptual task was conducted to determine if listeners were able to differentiate between the modal and glottal fry registers. Forty recordings of the sustained vowel /ɑ/ (one modal and one glottal fry production from each of the 20 subjects) were randomized and presented to a group of 55 listeners. Samples were presented in a sound field via eight overhead speakers. Listener-to-speaker distance ranged from 2 m to 5 m. Several samples of modal and vocal fry production were presented to the listeners for practice before the experimental task. An additional 10 samples were randomly selected from the original samples to serve as an intra-judge reliability test. The listeners were undergraduate and graduate students in the Communication Disorders program at the University of Connecticut. The undergraduate students had no course-work in the area of voice, while the graduate students had a course in voice and some experience listening to voice samples. In a forced-choice format, each listener was asked to rate the 50 samples as either modal or vocal fry register.

II. RESULTS

A. Acoustic data

The F_0 data for the male and female speakers in the modal and vocal fry registers are presented in Table I. A three-way analysis of variance (ANOVA), with gender, vowel type, and register as independent variables, and F_0 as the dependent variable, was performed to determine if significant differences existed among the three independent variables. The analysis indicated no interaction between register and vowel type, or between gender and vowel type with respect to F_0. There was a significant interaction between register and gender [$F(1,159)=372.5$, $p<0.01$]. A one-way ANOVA was performed within in each gender group to examine whether significant differences existed between vocal fry and modal register. The findings indicated that a significant difference existed between vocal fry and modal register for both males and females with respect to F_0 [male: $F(1,79)=341.6$, $p<0.01$; female: $F(1,79)=1355.1$, $p<0.01$]. For the female speakers, the average modal register F_0 was 211 Hz with a range of 175–266 Hz, and the average vocal fry register F_0 was 48 Hz with a range of 24–77 Hz. For the male speakers, the average modal F_0 was 117 Hz with a range of 86–170 Hz, and the vocal fry F_0 was 49 Hz with a range of 24–72 Hz. There was a significant difference between female and male speakers in the modal register [$F(1,79)=342.4$, $p<0.01$] but not in the fry register. The female speakers had a higher mean F_0 than the male speakers only in the modal register.
