Separate three-way ANOVAs were performed for the jitter, shimmer, and signal-to-noise ratio (S/N) ratio values, to examine whether an interaction existed among register and gender, register and vowel type, and gender and vowel type. The results indicated no interaction among these three independent variables (register, gender, and vowel type) with respect to the dependent variables of jitter, shimmer, or S/N ratio. The register main effect for jitter, shimmer and S/N ratio values were all significant [jitter: $F(1,159)=117.7$, $p<0.01$; shimmer: $F(1,159)=104.4$, $p<0.01$; S/N ratio: $F(1,159)=474.7$, $p<0.01$]. Specifically, jitter and shimmer values were significantly greater in vocal fry than in the modal register for both males and females (see Table I). S/N ratio values were significantly greater in modal register than in vocal fry register for both males and females (see Table I). The main effect for vowel type was also significant for S/N ratio [$F(3,76)=14.3$, $p<0.01$]. A Newman–Keuls *post hoc* test indicated that the S/N ratio, in modal register only, was significantly higher for /u/ than /æ/ and /ɑ/, and significantly higher for /i/ than /æ/. A gender main effect was identified with jitter [$F(1,159)=68.0$, $p<0.01$]. Specifically, jitter was significantly higher in the male speakers compared to the female speakers only in the vocal fry productions.

B. Aerodynamic data

1. Airflow

Rate of airflow was measured for the four sustained vowels (/i/, /æ/, /u/, /ɑ/) and for the stop consonant in the syllable /pi/. Four one-way ANOVAs were conducted to evaluate whether differences existed among the four sustained vowels with respect to airflow. Vowel differences were evaluated for each register in both gender groups. No significant differences in flow rate values were noted among the four vowels in either modal or vocal fry productions. Consequently, airflow values were collapsed across the four

TABLE II. Average peak airflow rate values (ml/s) and air pressure values (cm H_2O) for modal and vocal fry registers. Airflow in the sustained condition was averaged across the four vowels. Standard deviations are in parentheses.

	Females		Males	
	Modal register	Vocal fry	Modal register	Vocal fry
Airflow on Sustained vowels	154.6 (38.7)	58.2 (28.2)	213.7 (77.4)	69.7 (35.0)
Airflow on /pi/ Syllables	438.0 (124.2)	175.1 (77.5)	648.9 (123.9)	258.0 (87.8)
Air pressure on /pi/ Syllables	7.56 (1.93)	5.25 (1.56)	7.45 (1.88)	5.51 (3.50)

vowels for each gender and register group. The average airflow rates for the modal and vocal fry registers are reported in Table II.

A two-way ANOVA was performed for the flow rate values collapsed across the sustained vowels to examine whether differences existed between gender and register. The results revealed a significant interaction between gender and register [$F(1,158)=13.6$, $p<0.001$]. A Newman–Keuls *post hoc* test indicated that airflow rates for both males and females were higher in modal register than in the vocal fry register, however males had significantly higher airflow rates than females only in the modal register.

A two-way ANOVA was also performed on the flow rate values for /pi/ to determine if differences existed between gender and register. No interaction was found between gender and register. The gender main effect was significant indicating that males exhibited significantly greater airflow rates for /pi/ than females [$F(1,26)=90.7$, $p<0.0001$]. For both males and females, the register main effect was also significant indicating that airflow rates in modal register production were significantly greater than in vocal fry register [$F(1,26)=18.3$, $p<0.0001$].

2. Air pressure

The average air pressure values for the intervocalic stop in the /pi/ syllable are presented in Table II. A two-way ANOVA was performed which revealed no interaction between the two independent variables of gender and register. Only the main effect for register was significant. For both males and females, air pressure values in the modal productions were significantly higher than those in the vocal fry productions [$F(1,19)=11.8$, $p=0.003$].

C. EGG data

The EGG waveforms were evaluated for qualitative differences between modal register and vocal fry. A visual comparison of EGG waveforms in modal register and singlet vocal fry production is provided in Fig. 1. The EGG waveforms that contained patterns of more than one peak-per-cycle were identified as complex repetitive. Both doublet and triplet cycle patterns were observed in the complex-repetitive waveforms (see Fig. 2). The triplet cycles were always observed in association with doublet cycles, while the doublet cycles did not necessarily accompany triplet cycles.

For the male speakers' vocal fry productions, 99 of the 120 EGG waveforms that were analyzed contained complex-repetitive patterns (83%). For the female speakers' vocal fry productions, 45 of the 120 EGG waveforms contained complex-repetitive patterns (38%). A Mann–Whitney U-test was conducted to assess whether gender differences existed with respect to prevalence of complex-repetitive patterns. Males' vocal fry productions were characterized by a significantly higher prevalence of complex-repetitive patterns than the females' ($U=15.5$, $p=0.007$). Of the 83% of the male productions that contained complex-repetitive patterns, 56% contained only doublet cycles and 44% contained a combination of doublet and triplet cycles. Of the 38% of the female productions that contained complex-repetitive patterns, 87% were characterized by the presence of only doublet cycles and 13% contained both doublet and triplet cycles.

D. Perceptual data

Responses from the 55 listeners were calculated and divided into two groups: scores for the modal productions and scores for the vocal fry productions. A total of 2200 responses were recorded from the listeners (55 listeners$\times$40 tokens). The individual listener scores on the 20 modal productions ranged from 16 to 20 correct responses ($M=19.04$, s.d.$=1.27$). Of the 1100 responses pertaining to the modal productions, 1050 were classified correctly as modal or 95.5% correct. Of the 1100 responses corresponding to the vocal fry production, 100% were correctly identified by the listeners as vocal fry.

Intra-judge reliability was determined by comparing responses for each listener on 10 randomly selected samples that were presented a second time. An intra-judge reliability score of 99.3% was obtained. Agreement was obtained on 546/550 responses.

III. DISCUSSION

The main purpose of this study was to compare acoustic, aerodynamic, EGG, and perceptual properties of vocal fold vibration during modal and vocal fry conditions. Each speaker acted as his/her own control. Comparisons of speech samples produced in the modal and the vocal fry registers were made for each speaker.

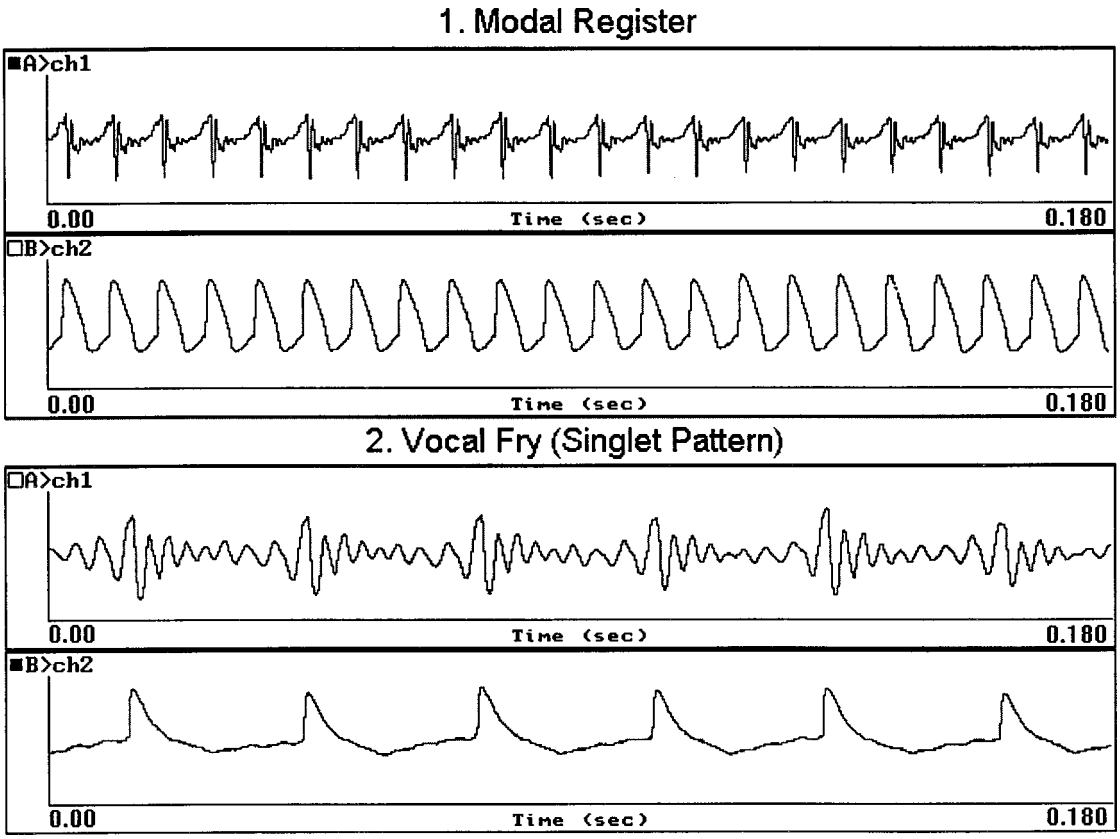

FIG. 1. Illustrations of modal and vocal fry production. Both frame 1 and frame 2 are of the same male speaker producing /ɑ/. Panel A (channel 1) in both the modal and vocal fry frames contain the acoustic signal. Panel B (channel 2) contains the EGG signal. In modal register the speaker's F_0 was 122 Hz while in vocal fry his F_0 was 33 Hz. The illustrated vocal fry production is characteristic of a single pulsing (singlet) pattern.

A. Acoustic measures

1. Fundamental frequency

Considerable differences between modal and vocal fry registers were observed in the present study. Both male and female speakers exhibited significantly reduced F_0 values in vocal fry compared to modal register. These findings agree with the results reported by Hollien and Wendahl (1968), McGlone (1967), and Murry (1971). No intra- or inter-speaker overlap in F_0 between modal and vocal fry was observed. These findings also agree with Hollien's (1974) description of voice register.

The female speakers exhibited significantly higher F_0 values than the male speakers in the modal register. However, the average F_0 values for the female speakers during vocal fry phonation were not significantly different from that of the male speakers. These findings are in agreement with those reported by McGlone (1967) and Hollien and Michel (1968), who suggested a distinct vocal fold vibratory behavior when comparing vocal fry and modal registers.

While general anatomical differences between male and female larynges is often assumed to account for differences in modal F_0, these anatomical differences may not be as relevant when considering vocal fry. For both male and female speakers' vocal fry production, it is possible that vocal fold vibration only occurs over a small portion of the folds. Zemlin (1988) reported that examination of vocal fry with high speed photography revealed ''the folds are approximated tightly, but at the same time they appear flaccid along their free borders, and subglottal air simply bubbles up between them at about the junction of the anterior two-thirds of the glottis'' (p. 166). If vocal fold vibration in vocal fry does indeed occur over a small portion of the total vocal fold length, then the intrinsic longitudinal length of the vocal folds may be less of a mitigating factor in determining the rate of vibration.

Although only part of vocal folds may be vibrating in vocal fry, the intrinsic mass of the vocal folds for male and female speakers may still be inherently different. One might, therefore, still predict gender differences in vocal fry F_0 based on vocal fold mass differences. An alternate ''vocal control'' theory may aid in explaining the absence of gender differences in vocal fry F_0 as found in the present study. Since vocal fry is not typically used by the speakers, gender differences may be obscured. Both the male and female subjects could have adopted the same external standard of a very low fundamental frequency. The similar vocal fry F_0 ranges for males and females may be influenced by the speakers attempt to attain the same task of vocalizating in the sub-60-Hz range.

2. Jitter, shimmer, and S/N ratio

Gender differences for signal-to-noise (S/N) ratio and shimmer values under both vocal fry and modal register conditions were not significant. However, the male subjects exhibited significantly higher jitter values in vocal fry production compared to the female subjects. Jitter factor values for

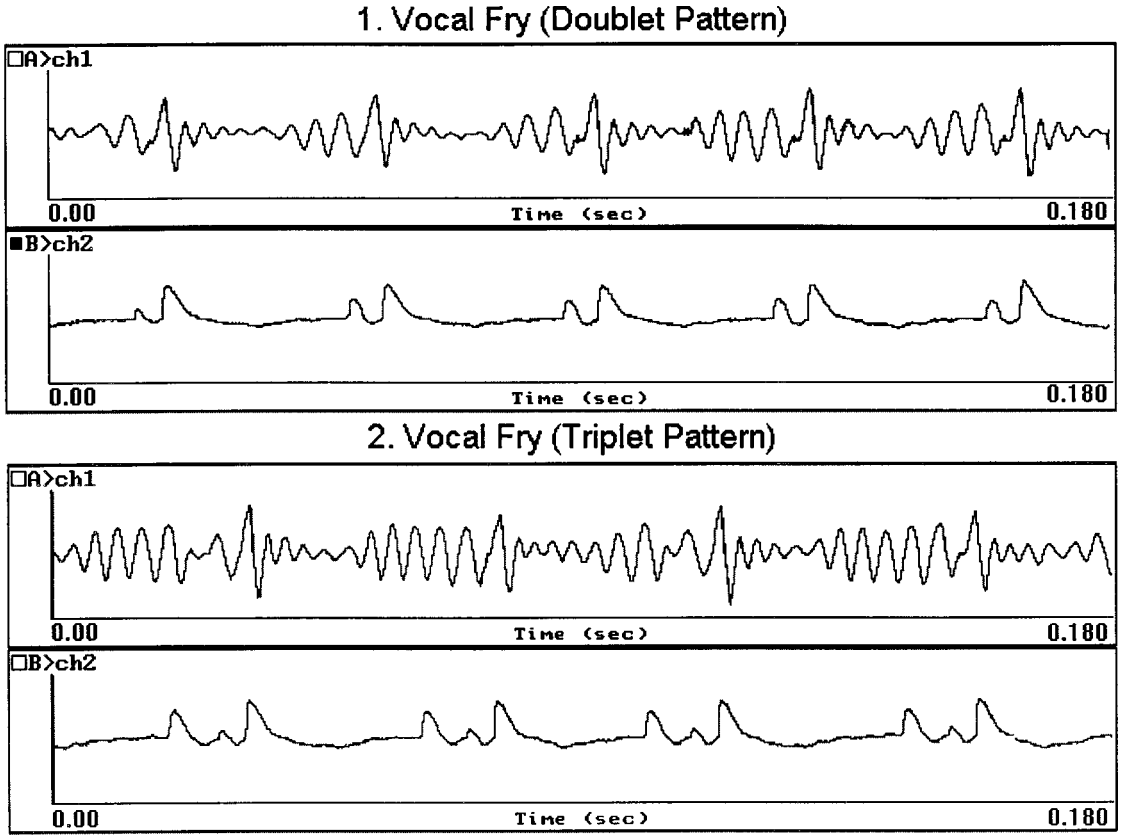

FIG. 2. Illustrations of complex-repetitive vocal fry waveforms. Frame 1 and frame 2 are of two different male speakers producing /ɑ/. Panels A (channel 1) contain the acoustic signal and panels B (channel 2) contain the EGG signal. In the upper frame, double pulsing (doublet) vibratory cycles are displayed at 28 Hz. In the lower frame, triple pulsing (triplet) cycles are displayed at 24 Hz.

modal register production in the present study (*M* males: 1.23%; *M* females: 1.79%) were slightly higher than those reported elsewhere, which are typically slightly less than 1% (Hollien *et al.*, 1973; Murry and Doherty, 1980; Sorensen and Horii, 1983). Shimmer values for modal register production in the present study (*M* males: 0.40 dB; *M* females: 0.38 dB) appeared very similar to previous studies. Horii (1980) reported an average shimmer value across adult males of 0.39 dB and Sorensen and Horii (1983) reported an average shimmer value for adult females of 0.25 dB.

Significant differences in S/N ratio, shimmer, and jitter values were present between the modal and fry registers. When compared to modal register, the vocal fry register was associated with significantly reduced S/N ratio and greater jitter and shimmer values. In vocal fry, higher jitter and shimmer values indicate decreased phonatory stability in the frequency and amplitude domains. Decreased S/N ratio in the vocal fry signal indicates a higher noise energy component relative to the periodic energy component when compared to modal register.

B. Aerodynamic measures

1. Rate of airflow

Rate of airflow was significantly reduced in the vocal fry register when compared to the modal register (see Table II). Rate of airflow in the modal register was reported previously to be 70–200 ml/s (Hirano, 1981). Modal register airflow rates in the present study were slightly higher (*M* males=214 ml/s; *M* females=155 ml/s) than those reported by Hirano (1981). Vocal fry airflow results in the present study (*M* males=70 ml/s; *M* females=58 ml/s) were also higher than values reported by McGlone and Shipp (1971) (*M*=40.4 ml/s).

The present results also indicate that the rate of airflow between male and female speakers was not significantly different in vocal fry. This appears to further support the notion of a similar vocal fold vibratory pattern for both male and female speakers during vocal fry when compared to modal voice production (Hollien *et al.*, 1966).

2. Air pressure

Significantly reduced subglottal pressure values were associated with the vocal fry condition for both males and females (see Table II). The present results are in agreement with the findings of Murry and Brown (1971b), who found lower subglottal pressure values for vocal fry than modal register in connected speech. The present subglottal pressure findings, however, do not support the results reported by Murry (1971). Murry (1971) found that subglottal pressure in sustained vocal fry production was significantly higher than that in modal register. The discrepancy in findings may be due to the different measurement techniques used. Murry (1971) used a tracheal puncture technique to measure subglottal pressure. In the present study, subglottal pressure was estimated for the vowel /i/ by measuring and interpolating the peak intraoral pressure during the stop phase of several

/pi/ syllable repetitions. Although one may argue for the increased validity of the more direct tracheal puncture technique, Murry's five subjects were tested in a nonstandard supine position, compared to a more natural upright speaking position. The absence of gravity on true and ventricular vocal folds in the rostral-caudal (inferior-superior) dimension may influence the vocal fold vibrating pattern.

As described above, vocal fry phonation has been characterized by a condition of closely adducted vocal folds with simultaneously (relatively) flaccid vocal fold margins (Zemlin, 1988). The vocal fold margins are flaccid because of decreased longitudinal tension. It is suggested that less air pressure is required to set the flaccid vocal fold margins into vibration when compared to the taut vocal margins in modal register. In addition, it was observed that the subjects in the present study tended to produce the ''best'' vocal fry phonation when their fry production was perceived to be relaxed with no perception of tension. The present findings of decreased subglottal pressure indirectly supports the notion that reduced vocal fold tension may be required to produce vocal fry.

Glottal resistance can also be used to characterize vocal fry and modal registers. Glottal resistance is calculated by dividing the transglottal pressure differential by glottal airflow ($R=\Delta P/Q$) (Smitheran and Hixon, 1981). In the present study, the average resistance values were 11.5-cm H_2O/l/s for males and 17.5-cm H_2O/l/s for females in modal register. In vocal fry, the average resistance values were 21.4-cm H_2O/l/s for males and 30.0-cm H_2O/l/s for females. The average glottal resistance values were higher in vocal fry than in modal register for both males and females. In order to increase glottal resistance, subglottal pressure increases while flow rate remains constant, or flow rate decreases while subglottal pressure remains constant. In the present study, resistance was increased due to a decrease in both subglottal pressure and flow rate, however, flow rate decreased to a greater extent than subglottal pressure.

C. EGG analysis

The results of the EGG waveform analyses revealed that the vibratory patterns associated with vocal fry may be characterized by single opening and closing, or multiple opening and closing patterns during a single vibratory cycle (doublet and triplet cycles). These findings support previous research indicating that the vocal folds are capable of multiple vibration patterns (Hollien and Wendahl, 1968; Moore and von Leden, 1958; Timcke *et al.*, 1959; Whitehead *et al.*, 1984).

Some researchers have suggested that doublet or triplet vibratory patterns occur as a result of ''mixed'' phonation that contains elements of both vocal fry and modal registers (Hollien *et al.*, 1977; Wendahl *et al.*, 1963). We would tend to argue against this position as the vocal fry productions in the present study were consistently identified by the judges in the perceptual task as vocal fry. In addition, our observed low mean frequencies for vocal fry (below 50 Hz for both males and females) mitigates against classification as a mixed type of phonation.

Vocal fry phonation appears to be associated with closely approximated vocal folds, which is supported by the present findings of lower airflow and increased glottal resistance when compared to modal register. During vocal fry, the arytenoid cartilages may be pressed anteriorly and medially causing the posterior portions of the vocal folds to be held together. The vocal folds become short and thick with only the anterior ligamental portions vibrating. The vocal fold margins, however, remain relatively flaccid because of decreased longitudinal tension (Zemlin, 1988, p. 166). Allen and Hollien (1973) and Hollien (1974) reported that mean vocal fold thickness was greater in vocal fry than in modal register. The thicker and more compact true vocal folds may account for the obtained complex-repetitive pattern in some of the vocal fry EGG waveforms. The doublet or triplet patterns may be representative of double or triple oscillations (per cycle) along the free margin of the vocal folds during vocal fry phonation.

Another explanation for the observed complex-repetitive patterns is based on the x-ray image findings of Allen and Hollien (1973). They found that the inferior surfaces of the ventricular folds may contact the superior surface of the true vocal folds during vocal fry phonation. The subsequent ''thick'' vibrating structure may contribute to the similarity in F_0 between males and females. In addition,the complex vibratory activity of the coupled ventricular and true vocal folds may also contribute to the complex-repetitive patterning.

D. Perceptual identification of vocal fry

In the perceptual study, 55 listeners correctly identified 95.5% of the experimentally classified modal productions of /ɑ/ and 100% of the vocal fry productions. These findings indicate that perceptual differences are discerned between the experimentally classified modal and vocal fry productions. The high agreement between the acoustic, aerodynamic, and EGG distinctions and the perceptual distinction of vocal fry and modal productions appear to add validity to the classification of these distinct registers.

IV. CONCLUSIONS

The findings in the present study attempted to increase present knowledge regarding phonation in vocal fry register. Acoustic findings indicated there was a significant difference in F_0 between males and females in modal register, while gender differences in vocal fry register were not observed. For both males and females, jitter and shimmer values in vocal fry were significantly higher than those in modal register indicating greater frequency and amplitude perturbation in vocal fry. The S/N ratio values in vocal fry register were significantly lower than those in modal register, possibly indicating less efficient valving of the vocal fold mechanism in the vocal fry register. In addition, differences in airflow, air pressure, glottal resistance, and EGG characteristics were identified between modal register and vocal fry register for both males and females.

Vocal fold vibration is the result of a delicate balance of subglottal air pressure driving the folds apart, and the mus-

cular, elastic, and Bernoulli forces that bring them together. In modal register, the vocal folds vibrate in a relatively consistent manner, with the movement of a wave along the vocal margin that propagates superiorly. These movements have been characterized by the two-mass model of vocal fold vibration (Ishizaka and Matsudaira, 1968; Titze, 1981). Vibration of the vocal folds in vocal fry appears to be more complex. While a two-mass model provides a succinct account of phonation in modal register, the complex differences observed in vocal fry phonation will likely require description using a multi-mass model. In order to model the complex vibration patterns in both the anterior/posterior plane and superior/inferior plane of the vocal folds, simultaneous recordings using EGG, acoustic, *and* direct visualization incorporating high-speed filming or stroboscopic techniques appears necessary.

The differences between modal and vocal fry registers with respect to acoustic, aerodynamic, and EGG parameters are believed to be due to two distinct aeromechanical modes of vocal fold vibration. During phonation in the modal register, the vocal folds appear to be tightly adducted along the anterior margins, with the presence of a commonly observed posterior glottal chink (Broad, 1973). In vocal fry, the vocal processes of the arytenoids appear to be pulled inward and forward. The posterior glottal chink may be greatly diminished in vocal fry. The thyroarytenoid muscles tend to shorten, and subsequently thicken the antero-posterior dimension of the vocal folds, allowing the anterior part of the vocal ligaments to vibrate (Allen and Hollien, 1973; Hollien, 1974). As the thyroarytenoid muscle shortens, the vocal fold margins also become more flaccid. The thickening of the vocal folds in combination with decreased vocal ligament stiffness during vocal fry may be two prime factors contributing to the reduced rate of vocal fold vibration, which consequently alter the characteristics of the vibratory cycle.

In the present study, vocal fold vibration in the modal register was maintained by subglottal pressure values of approximately 7.5-cm H_2O, which counteracts the longitudinal tension and medial compression of the thyroarytenoid muscles (Borden *et al.*, 1984). In vocal fry, however, the subglottal pressure values were approximately 5.5-cm H_2O, possibly indicating reduced tension and medial compression. The finding of increased glottal resistance in vocal fry may be explained by the increased vocal fold mass, rather than increased longitudinal tension and medial compression. If, indeed, the vocal folds are less tense in vocal fry than in modal register, then it would appear that less subglottal driving pressure is required to force them apart. We further suggest that reduced subglottal pressure is not just a consequence of vocal fry, but that individuals actively reduce subglottal pressure as an aerodynamic strategy to facilitate achieving fundamental frequencies below 60 Hz.

In conclusion, it was found that vocal fry was distinguishable from modal register production in acoustic, aerodynamic, physiologic, and perceptual measures. Future research regarding the precise degree of vocal fold adduction, degree of vocal fold margin stiffness, and the precise movements of the vocal fold margins and contribution of the ventricular folds will help to further describe the interesting laryngeal phenomenon of vocal fry.

Automatic parametrization of differentiated glottal flow: Comparing methods by means of synthetic flow pulses

Helmer Strik[a)]
University of Nijmegen, Department of Language and Speech, P.O. Box 9103, 6500 HD Nijmegen, The Netherlands

(Received 14 July 1997; accepted for publication 14 January 1998)

The automatic parametrization of the first derivative of glottal flow is studied. Representatives of the two types of methods used most often for parametrization were tested and compared. The chosen representatives are all based on the Liljencrants–Fant model. As numerous tests were needed for a detailed comparison of the methods, a novel evaluation procedure is used which consists of the following stages: (1) use the Liljencrants–Fant model to generate synthetic flow pulses; (2) estimate voice source parameters for these synthetic flow pulses; and (3) calculate the errors by comparing the estimated values with the input values of the parameters. This evaluation procedure revealed that in order to reduce the average error in the estimated voice source parameters, the estimation methods should be able to estimate noninteger values of these parameters. The proposed evaluation method was also used to study the influence of low-pass filtering on the estimated voice source parameters. It turned out that low-pass filtering causes an error in all estimated voice source parameters. On average, the smallest errors were found for a parametrization method in which a voice source model is fitted to the flow derivative, and in which the voice source model is low-pass filtered with the same filter as the flow derivative. INTRODUCTION

The technique of inverse filtering has been available for a long time now. This technique, which was first described in Miller (1959), can be used to decompose the speech signal into two components: the voice source and the filter (the vocal tract). In this way an estimate of the glottal volume velocity waveform (U_g) or its first derivative (dU_g) is obtained. For many applications, estimating a voice source signal (either U_g or dU_g) is not enough and the glottal flow signals have to be parametrized. Parametrization of the voice source signals and evaluation of the parametrization methods have received far less attention in the past. That is why we focus on these aspects in this study.

Parametrization of U_g or dU_g can be done in several ways. Often landmarks (like minima, maxima, zero crossings) are detected in the signals (e.g., Sundberg and Gauffin, 1979; Gauffin and Sundberg, 1980, 1989; Alku, 1992; Alku and Vilkman, 1995; Koreman, 1996). Because these landmarks are estimated directly from the voice source signals, these methods will be called direct estimation methods.

Voice source parameters are also calculated by fitting a voice source model to the data (e.g., Ananthapadmanabha, 1984; Schoentgen, 1990; Karlsson, 1992; Strik and Boves, 1992; Fant, 1993; Milenkovic, 1993; Alku *et al.*, 1997). Many different voice source models have been proposed in the literature (see, e.g., Rosenberg, 1971; Fant, 1979; Ananthapadmanabha, 1984; Fant *et al.*, 1985; Fujisaki and Ljungqvist, 1986; Lobo and Ainsworth, 1992; Cummings and Clements, 1995). Because in estimation methods of this kind a model fitting procedure is used, they will be referred to as ''fit estimation'' methods.

Estimation of voice source parameters can be useful for many applications. Although speech synthesis is the application most mentioned, the estimated voice source parameters are also used for fundamental research on speech production (e.g., Ní Chasaide and Gobl, 1993; Strik, 1994; Koreman, 1996). Other applications for which methods to measure voice source behavior could be useful are clinical use, speech analysis, speech coding, automatic speech recognition, and automatic speaker verification and identification. Since most of these applications require that the methods be fully automatic, there is an increasing need for automatic parametrization methods (see, e.g., Fritzell, 1992; Fant, 1993; Ní Chasaide and Gobl, 1993).

The development of an automatic parametrization method constitutes the long term goal of our research. Both direct and fit estimation methods can be made completely automatic. For this reason, and because they are the methods used most often, a representative of the direct estimation method will be compared with a representative of the fit estimation method. The representatives chosen are described in Secs. I E and I F.

The goals of the research reported on in this article are to find out what the pros and cons of each method are, to get a better understanding of the problems involved in estimating voice source parameters, and finally to determine which method performs best. In order to make it easier to compare the two methods, the same voice source model is used in both methods. To this end we use the Liljencrants–Fant (LF) model (Fant *et al.*, 1985). The LF model and the reasons for choosing it are described in Sec. I B. The evaluation method

Glottal flow (U_g) and glottal flow derivative (dU_g) with the parameters of the LF model: time of glottal opening (t_0); time (t_p) and value (U_0) of the maximum of U_g; time (t_e) and absolute value (Ee) of the minimum of dU_g; T_a describes the return phase, it is the length of the time interval between t_e and the projection of the tangent of dU_g in t_e; and the time of glottal closure (t_c).

and material are described in Secs. I C and I D, respectively. Because we want to focus on the parametrization method, we shall not evaluate inverse filtering in the current research. The performance of the parametrization methods is assessed in Secs. II and III. First, in Sec. II, it is studied how well the estimation methods succeed in estimating noninteger values of the parameters, which turned out to be a crucial property. Second, we focus on low-pass filtering in Sec. III. In Sec. IV the findings are discussed and some general conclusions are drawn.

I. GENERAL PROCEDURES

In this article two estimation methods used to parametrize dU_g are tested and compared. Before going on to describe these two methods (in Secs. I E and I F), we shall first give some definitions in Sec. I A, discuss the LF model in Sec. I B, and describe the method and material used for evaluation in Secs. I C and I D, respectively.

A. Definitions

In the current article it will be assumed that dU_g is a digital signal. In order to avoid confusion later on, we shall first define some terms related to sampling and quantization.

For all tests the sampling frequency $F_s=10$ kHz, the number of bits used for quantization $B_c=12$ and the amplitude range is $[-2048,2047]$. Consequently, the sampling time $T_s=1/F_s=1$ ms and the step size $\delta=4096/2^{B_c}=1$. Throughout this article a *time parameter* is said to have an integer value if its value is precisely an integer multiple of T_s. Likewise, an *amplitude parameter* is said to have an integer value if its value is exactly an integer multiple of δ.

B. Liljencrants–Fant model

In the current research the voice source model used is the LF model (see Fig. 1) because the LF model has the following advantages:

(1) In previous research the LF model has often been used to estimate voice source parameters, with manual or (semi-)automatic methods. This research has shown that it is a suitable model for description of the flow derivative (see, e.g., Fujisaki and Ljungqvist, 1986; Karlsson, 1992; Strik and Boves, 1992; Strik *et al.*, 1992, 1993; Childers and Ahn, 1995).

(2) Fujisaki and Ljungqvist (1986) compared several voice source models. Their results showed that the LF model and their own FL-4 model performed best (i.e., had the smallest prediction error).

(3) Previous research has also proven that the LF model is suitable for speech synthesis (see e.g., Carlson *et al.*, 1989).

(4) Due to all research already performed, the model and its behavior are well known.

The parameters shown in Fig. 1, in turn, can be used to derive many other parameters. For instance, the speed quotient is often calculated: $SQ=(t_p-t_0)/(t_c-t_p)$ (e.g., Alku and Vilkman, 1995). However, in our opinion these derived parameters are less suitable for evaluation of the parametrization methods, because whenever there is a change in a derived parameter, it is difficult to determine how this change came about (Strik, 1996). An increase in SQ could be the result of a larger t_p, a smaller t_0, a smaller t_c, or a combination of any of these three changes. On the other hand, whenever a derived parameter remains constant, this does not necessarily imply that the underlying parameters (i.e., the parameters which were used to calculate the derived parameters) remain constant. It is always possible that changes in these underlying parameters cancel each other out. Therefore, we prefer to use the LF parameters specified in Fig. 1 for the evaluation of estimation methods. Since the parameters E_e, t_0, t_p, t_e, and T_a give a complete description of an LF pulse, this set of parameters will be used in this article.

C. Evaluation method

Estimates of voice source parameters can be influenced by a large number of factors. So far, 11 of these factors have been studied: sampling frequency, number of bits used for quantization, position (shift) and amplitude (E_e) of the glottal pulses, t_c, T_0 (length of the fundamental period), signal-to-noise ratio (i.e., the effect of additive noise), phase distortion (which can be caused, e.g., by high-pass filtering), errors in the estimates of formant and bandwidth values during inverse filtering (which will bring about formant ripple in the estimated voice source signals), and low-pass filtering (Strik and Boves, 1994). We have performed over 1000 model fits for each of these 11 factors, making a total of much more than 11 000 model fits. The fact that so many tests had to be performed is the main reason for using the evaluation method described below (other reasons can be found in Strik, 1997).

In our experiments we first synthesize flow pulses (see Sec. I D). As we use the LF model for the fitting procedure, it is obvious that we also used the LF model to synthesize the flow pulses. Subsequently, the parametrization methods are used to estimate the voice source parameters. Finally, the estimated voice source parameters are compared with the correct values (used to synthesize the flow pulses), and the errors are calculated:

TABLE I. Values of t_p, t_e, and T_a (all in ms) for the 11 base pulses.

	Base pulse										
	1	2	3	4	5	6	7	8	9	10	11
t_p	14.0	14.0	16.0	16.0	16.0	16.0	14.0	14.0	15.2	15.2	15.2
t_e	15.2	15.2	17.2	17.2	18.8	18.8	16.0	16.0	17.2	17.2	17.2
T_a	0.4	1.6	0.4	1.6	0.4	0.8	0.4	1.6	0.4	1.0	1.6

$$\mathrm{ERR}(X)=|X_{\mathrm{est}}-X_{\mathrm{inp}}|/X_{\mathrm{inp}}, \quad \text{for } X=E_e$$

$$\mathrm{ERR}(Y)=|Y_{\mathrm{est}}-Y_{\mathrm{inp}}|, \quad \text{for } Y=t_0,\ t_p,\ t_e,\ \text{and } T_a.$$

The experiments were carried out for a number (say N) of test pulses. After calculating the errors in the estimates of the five LF parameters for each test pulse, the errors had to be averaged. This can be done in a number of ways. Generally, averaging was done by taking the median of the absolute values of the errors. Absolute values were taken because otherwise positive and negative errors could cancel each other. The median was taken because (compared to the arithmetic mean) it is less affected by outliers which are occasionally present in the estimates. This method of averaging is the default method in the current article. Whenever another way of averaging was used, this is explicitly mentioned in the text.

In all figures below, the errors are arranged in a similar fashion (see, e.g., Fig. 2). In the upper left corner are the errors for E_e (in%), in the middle row are the errors for t_0 and t_p and in the bottom row are the errors for t_e and T_a. The errors in the time parameters t_0, t_p, t_e, and T_a are expressed in μs.

D. Material

The estimation methods used in this study are pitch synchronous. Among the parameters that have to be estimated are t_0 and t_c. Because these two parameters are not known beforehand, the pitch period cannot be segmented exactly. In practice, we first locate the main excitations (i.e., t_e) and then use a window with a width larger than the length of the longest (expected) pitch period. Generally, the pitch period will be situated between two other pitch periods (except for UV/V and V/UV transitions). Therefore, for each experiment sequences of three equal LF pulses were used. Each time voice source parameters were estimated for the (perturbed) pulse in the middle. Another reason for not using a single glottal pulse for evaluation is that the effects of perturbations cannot always be studied by a single, isolated LF pulse.

Since the effect of a studied factor can depend on the shape of a flow pulse, LF pulses with different shapes were used. These pulses will be called the base pulses. The base pulses were obtained by using the LF model for different values of the LF parameters. The parameters of E_e, T_0, t_0, and t_c were kept constant at 1024, 10 ms, 10 ms, and 20 ms, respectively. The values given for t_0 and t_c are the values for the second of the three pulses. For the first pulse one should subtract 10 ms from the values of t_0 and t_c, and for the last pulse add 10 ms. T_0 and t_c were kept constant because the results of our experiments showed that varying these parameters had very little effect on the estimations. The effects of varying E_e and shift (which is strongly related to t_0) were studied separately (see Sec. II).

For defining the base pulses the values of t_p, t_e, and T_a were varied. Based on the data given in Carlson *et al.* (1989), and the data from previous experiments (Strik and Boves, 1992; Strik *et al.*, 1992, 1993; Strik, 1994) the 11 base pulses shown in Table I were defined.

Subsequently, these 11 base pulses were used to generate the test pulses. For instance, to study the influence of the factor low-pass filtering, the 11 base pulses were filtered with M low-pass filters in order to generate $M\times 11$ test pulses. Calculation of the base pulses and the test pulses was first done in floating point arithmetic. After the test pulses had been created, the sample values were rounded towards the nearest integer (as is done in straightforward A/D conversion).

E. Direct estimation method

In direct estimation methods, voice source parameters are calculated directly from dU_g or U_g by means of simple arithmetic operators like min, max, argmin, and argmax. These arithmetic operators are used to detect landmarks in the signals. Some examples of estimations used quite often are: $U_0=\max(U_g)$, $t_p=\mathrm{argmax}(U_g)$, $E_e=-\min(dU_g)$, and $t_e=\mathrm{argmin}(dU_g)$ (see, e.g., Sundberg and Gauffin, 1979; Ananthapadmanabha, 1984; Gauffin and Sundberg, 1980, 1989; Alku, 1992; Alku and Vilkman, 1995; Koreman, 1996). Except for the value and the place of a maximum or minimum, the place of a zero crossing is also used to estimate parameters. For instance, in this way t_0 and t_c can be estimated (see Fig. 1).

One of the aims of the research reported in this article is to compare the performance of a typical direct estimation method with that of a fit estimation method. To this end we chose the direct estimation method described in Alku and Vilkman (1995), primarily because these authors provide a fairly detailed description of their method (see especially page 765 of their article), and because with this method it was possible to estimate the LF parameters E_e, t_0, t_p, and t_e (for which they use the terms $A_{\min}$, t_0, t_m, and t_{dm}, respectively).

In their method Alku and Vilkman (1995) do not estimate T_a. They use the parameter t_{ret} to describe the return phase. Since T_a cannot be derived from t_{ret} and an LF model is not complete without T_a, another method had to be used to estimate T_a. For the current research all estimates were made in the time domain. Because it is very difficult to estimate T_a in the time domain with a direct estimation method, estimates of T_a were obtained by fitting the LF model to the

glottal pulse. More precisely, for given values of E_e, t_0, t_p, and t_e (made with the direct estimation method) the optimal value of T_a was estimated by fitting the LF model to the data. Therefore, strictly speaking, only E_e, t_0, t_p, and t_e can be said to be the result of the direct estimation method, while T_a is subsequently estimated with a fitting procedure. However, it is important to notice that the estimate of T_a does depend to a large extent on the estimates of E_e, t_0, t_p, and t_e made before with the direct estimation method. Furthermore, estimating one parameter (here T_a) with a fitting procedure, is a relatively simple operation. Consequently, the results showed that the error in the estimates of T_a is mainly the result of the errors in the estimates of E_e, t_0, t_p, and t_e made with the direct estimation method. For instance, if estimates of E_e and/or t_e are too large, the resulting estimates of T_a will generally be too small.

F. Fit estimation methods

In our fit estimation method five LF parameters (E_e, t_0, t_p, t_e, and T_a) are estimated for each pitch period. The method consists of three stages:

(1) initial estimate;
(2) simplex search algorithm;
(3) Levenberg–Marquardt algorithm (Marquardt, 1963).

The goal of the fit estimation method is to determine a model fit which resembles the glottal pulse as much as possible. This resemblance is quantified by means of an error function, which is calculated in the following way. The optimization procedure provides a set of LF parameters. These LF parameters and the analytical expression of the LF model are used to calculate a continuous LF pulse. The LF pulse is then sampled and zeros are added before t_0 and after t_c (until the length of the fitted signal is equal to that of the glottal pulse). These samples of the fitted signal together with the samples of the glottal pulse constitute the input to the error function that provides a measure of the difference between these samples. The fitting procedure tries to minimize this error.

We have experimented with several error functions which were defined either in the time domain, the frequency domain, or in both domains simultaneously. Defining a suitable error function in the frequency domain, for this automatic fitting procedure, turned out to be problematic. Probably the main reason is that the spectrum contains some details (e.g., the harmonics structure, the high-frequency noise) which need not be fitted exactly. With simple error measures, like, e.g., the root-mean-square (rms) error, we did not succeed in obtaining a reasonable model fit. More sophisticated error functions are needed for this task. A suitable error function should abstract away from the details which are not important, and emphasize the important aspects (e.g., the slope of the spectrum).

In the time domain it is much easier to obtain a fairly good model fit of dU_g. Here a simple rms error does yield plausible results. Still, also in the time domain some aspects of dU_g could be more important than others. It is likely that more sophisticated error functions could be defined which emphasize the relevant (e.g., perceptual) aspects. However, what is relevant depends on the application. In the current research we did not have a specific application in mind. The goal of this research was to develop a method for which the error in the estimated voice source parameters is small. Therefore, an important property of the error function is that it should decrease when the errors in the voice source parameters become smaller (this may sound trivial, but it is not). The rms error (defined in the time domain) did have this property and thus was suitable for this task, as our experiments revealed.

For the fitting procedure different nonlinear optimization techniques were tested: several gradient algorithms and some versions of a nongradient algorithm, i.e., the simplex search algorithm of Nelder and Mead (1964). Of the algorithms tested the simplex search algorithms usually came closer to the global minimum than the gradient algorithms. Owing to discontinuities in the error function, gradient algorithms are more likely to get stuck in local minima than simplex search algorithms are. Therefore the best version of the simplex search algorithm is used in the second stage of the fit estimation method. However, in the neighborhood of a minimum, the simplex algorithm may do worse (see Nelder and Mead, 1964). As a final optimization, the Levenberg–Marquardt algorithm (a gradient algorithm) is therefore used in the third stage (Marquardt, 1963).

In order to start the simplex search algorithm of stage 2 an initial estimate is required, which is made in the first stage. In principle, the best available direct estimation method should be used to provide the initial estimate. In this case the rms error for the fit estimation method can never be larger, and will almost always be smaller than the rms error for the direct estimation method used (because in stage 2 and 3 of our fit estimation method the rms error can never increase, and usually decreases gradually). Consequently, the errors in the voice source parameters estimated with the fit estimation method would almost always be smaller than those estimated with the direct estimation method used for initial estimation. Therefore, if we had used the direct estimation method described in the section above for initial estimation, the performance of this direct estimation method would probably have been worse than that of the fit estimation method. Because we considered this to be an unfair starting point, we decided to apply for initial estimation the routine used in our previous research (Strik *et al.*, 1993).

In Sec. III we will introduce a second version of this fit estimation method. This second version differs only slightly from the version described here. Together with the direct estimation method described in Sec. I E, the number of methods studied amounts to three.

Above we already mentioned that so far 11 different factors have been studied. In this article we shall confine ourselves to the most important results, namely those concerning the factors position (shift) and amplitude (E_e) (Sec. II) and those of low-pass filtering (Sec. III).

II. EXPERIMENT 1:SHIFT AND AMPLITUDE

A. Introduction

Direct estimation methods try to locate (important) events in the voice source signals. Thus the resulting esti-

mates are generally limited to the place or amplitude of samples in the discrete signals, i.e., they are integers. Our intention was to develop a fit estimation method that would make it possible to estimate noninteger values too. Here we shall test how well the fit estimation method succeeds in estimating noninteger values of the voice source parameters, and what the resulting errors are for the two estimation methods for different values of shift and amplitude.

B. Material

The definition of the 11 base pulses is such that all time parameters have an integer value (see Sec. I D). In order to create test pulses in which the time parameters did not have integer values, the 11 base pulses were shifted in steps of 0.01 ms, from 0.0 up to 0.1 ms (11 values). This variable will be called *shift*. For only two of the chosen 11 values of shift (i.e., shift=0.0 and 0.1), the time parameters will have an integer value, while for the other 9 values of shift all time parameters will have noninteger values.

In order to create test pulses in which the amplitude (E_e) does not have integer values the amplitude E_e was varied from 1023 to 1025 in steps of 0.2 (11 values). This makes a total of 1331 test pulses (11 base pulses$\times$11 shift values$\times$11 E_e values). Next, the direct estimation method and the fit estimation method were used to estimate the voice source parameters for these 1331 test pulses. The errors in these estimations were then calculated.

C. Results of the direct estimation method

First, the results of the direct estimation method are presented in Figs. 2 and 3. Each error in Fig. 2 is the median of 121 errors (11 base pulses$\times$11 E_e values), while each error in Fig. 3 is the median of another set of 121 errors (11 base pulses$\times$11 shift values).

Let us first look at the errors in Fig. 2. To estimate t_0 a threshold function is used in the direct estimation method. The consequence is that the estimate of t_0 is always much too large (on average about 820 μs; see Fig. 3). For a shift of 0.03 ms the average error in t_0 is minimal, while for a shift of 0.04 ms it suddenly becomes maximal. The reason is that this extra shift of 0.01 ms causes the threshold to be exceeded one sample later in many test pulses, and thus the average error in t_0 suddenly increases. The average errors of the other parameters all behave as expected: the average errors are zero for a shift of 0.0 and 0.1 ms and larger in between.

The errors in the estimates for different values of E_e are shown in Fig. 3. The errors in the time parameters t_0, t_p, and t_e obviously do not depend on the value of E_e. Therefore, the errors for these time parameters are constant. If a large number of moments is randomly distributed, the average error (both the arithmetic mean and the median) due to rounding toward the nearest sample would be $T_s/4=25$ μs. The average errors of t_p, t_e, and T_a do not deviate much from this theoretical average. The reason why the error in t_0 is much larger was already explained above.

The average errors in the estimates of E_e behave as was expected: the average errors are minimal for integer values of E_e, and are larger in between. The median error in E_e is never zero, because it is obtained by averaging over different values of shift, and for most values of shift the error in E_e is larger than zero. The estimate of T_a depends on the estimates of E_e and t_e, and thus is not constant as a function of E_e.

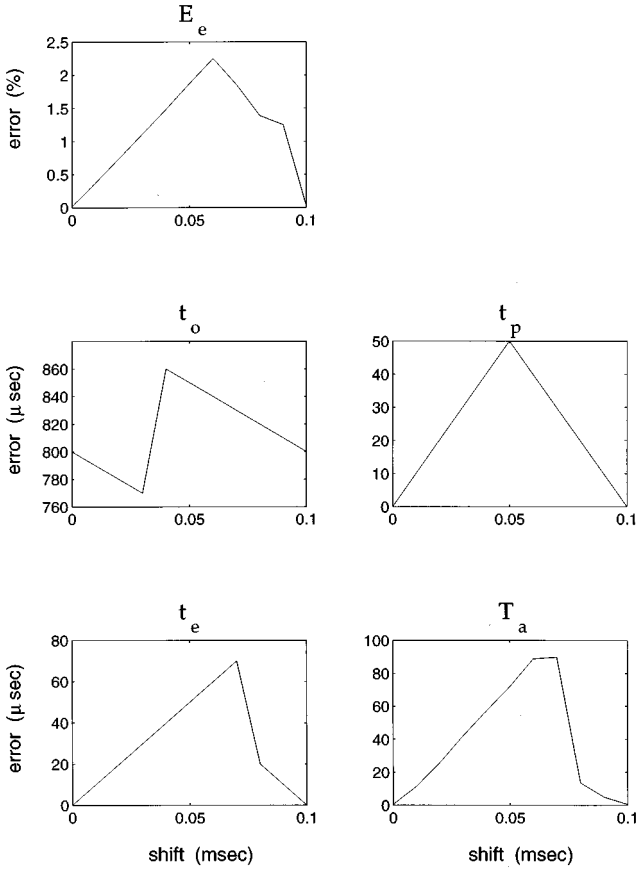

FIG. 2. Results of the direct estimation method: median error for the estimated parameters for different values of shift.

D. Results of the fit estimation method

The resulting average errors for the fit estimation method are shown in Figs. 4 and 5. In this case the errors were averaged by taking the mean value. This was done for two reasons: (1) since there are no outliers, median and mean values do not differ much; (2) by taking the mean it is also possible to calculate standard deviations. In turn, this makes it possible to test whether there is a significant difference between two mean values.

In this case for each value of shift the mean and standard deviation of 121 errors (11 base pulses$\times$11 E_e values) were calculated. The results are shown in Fig. 4. Likewise, for each value of E_e the mean and standard deviation of 121 errors (11 base pulses$\times$11 shift values) were calculated. The results are shown in Fig. 5.

In Figs. 4 and 5 one can observe that the mean errors do not differ significantly from each other. Furthermore, no trend can be observed in the errors. Put otherwise, the magnitude of the error in all estimated parameters does not depend on the value of the factors shift and E_e. Furthermore, all errors are very small, in general much smaller than the

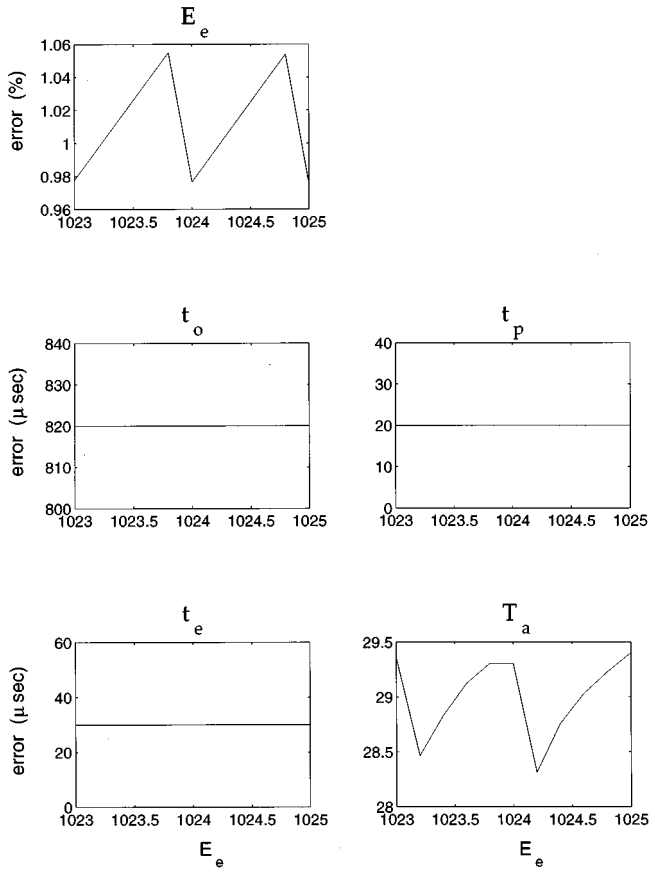

FIG. 3. Results of the direct estimation method: median error for the estimated parameters for different values of E_e.

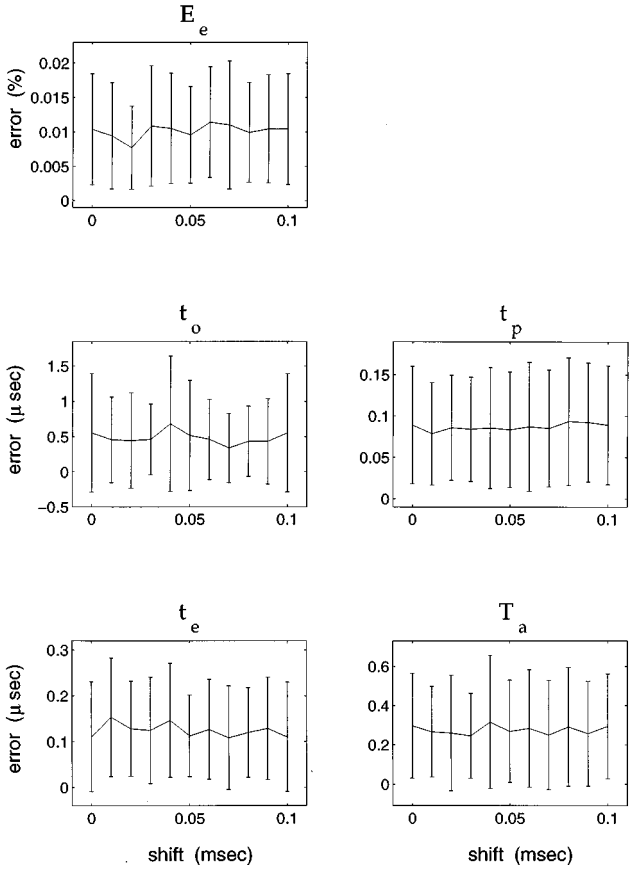

FIG. 4. Results of the fit estimation method: mean and standard deviation of the errors in the estimated parameters for different values of shift.

errors for the direct estimation method. Except of course for the cases in which all the LF parameters have an integer value. In the latter case the errors for the direct estimation method are zero, which is smaller still than the tiny errors found for the fit estimation method. However, it is clear that in practice the voice source parameters will seldom have exactly an integer value.

E. Conclusions

The conclusions that can be drawn from these tests are the following. The errors obtained with the fit estimation method are very small, in general much smaller than those for the direct estimation method. With the fit estimation method noninteger values can be estimated as accurately as integer values. Therefore, the quality of the model fit does not depend on the exact value of E_e and the position of the pulse (which is determined here by the variable shift). This explains why t_0 and E_e could be kept constant in the definition of the base pulses (see Sec. I D).

For the direct estimation method the average errors in t_0 are always larger than for the fit estimation method, because in the former a threshold function is used to estimate t_0. In fact, the error in t_0 can be substantially reduced, simply by subtracting a constant from its estimate. For the other parameters the estimation errors for the direct estimation method are zero if the parameters have exactly an integer value. Since in practice parameters rarely have an integer value, the estimates of the parameters will almost always contain an error due to this fact alone. These errors will be called the intrinsic errors, because they are intrinsic to the estimation methods. They will always be present, even if the glottal pulses are perfectly clean glottal pulses, as was the case in these tests. The results presented in this section make it possible to estimate what the average intrinsic errors are. For the direct estimation method the average error in the time parameters (except t_0) is about $T_s/4=25$ μs, which is the theoretical average for randomly distributed values, while for E_e it is about 1% (see Fig. 3). For the fit estimation method the average error in the time parameters is less than 0.5 μs, while the average error for E_e is about 0.01% (see Figs. 4 and 5).

III. EXPERIMENT 2: LOW-PASS FILTERING

A. Introduction

Before the glottal flow signals are parametrized, they are low-pass filtered at least once in all methods, viz., before A/D conversion. Often, they are low-pass filtered again after A/D conversion, usually to cancel the effects of formants that were not inverse filtered or to attenuate the noise component. The latter operation seems very sensible for direct estimation methods, because in these methods high-frequency disturbances can influence the estimated parameters to a large extent. Although parametrization of inverse filtered signals has been done in many studies for almost 40 years now (i.e.,

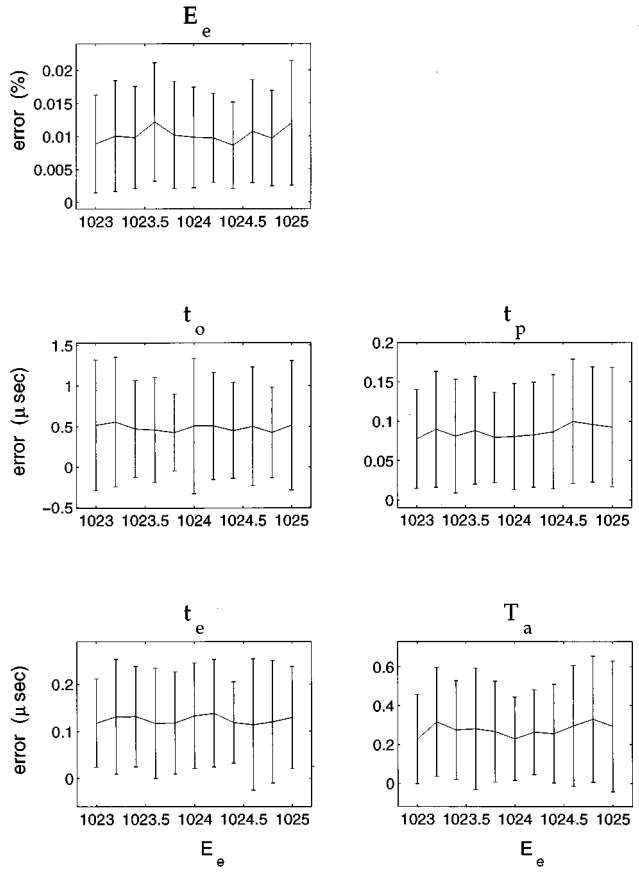

FIG. 5. Results of the fit estimation method: mean and standard deviation of the errors in the estimated parameters for different values of E_e.

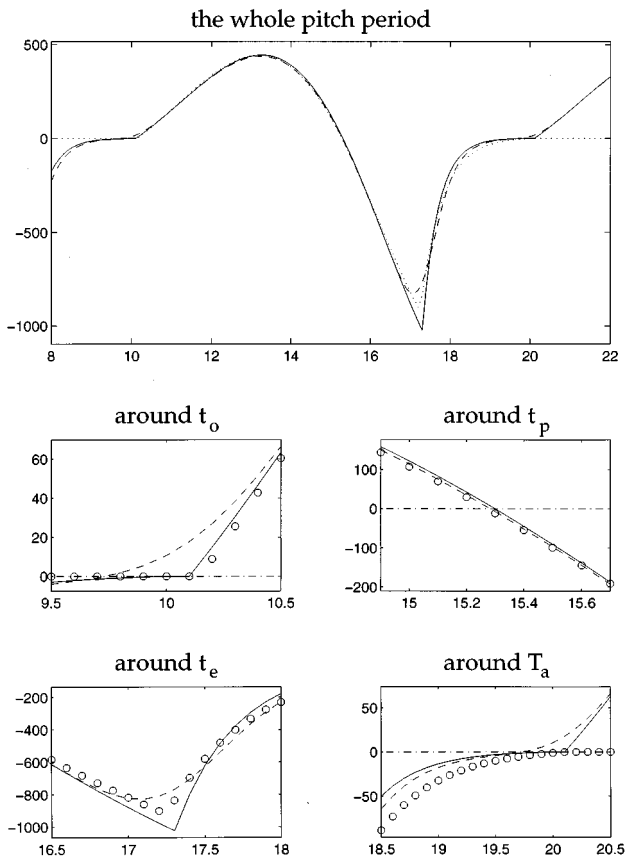

FIG. 6. An example of a differentiated flow pulse before (solid) and after (dashed) low-pass filtering, and a fit on the low-pass filtered pulse (dots in the top panel, open circles in the lower four panels). Shown are the whole pitch period, and some details around important events. For clarity, the zero line (dashed-dotted) has been omitted in the top panel.

since Miller, 1959), it has only recently been noted that low-pass filtering can influence the estimated voice source parameters (Strik *et al.*, 1992, 1993; Perkell *et al.*, 1994; Alku and Vilkman, 1995; Strik, 1996; Koreman, 1996). Thus it becomes very important to study what the effect of low-pass filtering exactly is. This will be done in the present section.

An example of the distortion of a differentiated flow pulse caused by low-pass filtering is given in Fig. 6. For low-pass filtering a convolution with a 19-point Blackman window was used. Shown are a base pulse before (solid) and after (dashed) low-pass filtering, and a model fit on the low-pass filtered pulse (dotted). Besides a picture of the three signals for the whole pitch period, some details around important events are also provided.

One can see in Fig. 6 that low-pass filtering does influence the shape of the pulse. From this figure one can deduce that the change in shape can have a large impact on the estimates obtained by means of a direct estimation method. This is most clear for the estimate of E_e, which will generally be too small, but the estimates of the other parameters will also be affected.

Low-pass filtering will also affect the estimates of a fit estimation method. After low-pass filtering the shape of the pulse is changed. The fitting procedure will try to find an LF pulse that resembles the filtered pulse as closely as possible. This is done by minimizing the rms error, which is a measure of the difference between the test pulse and the fitted LF pulse. The result is a fitted LF pulse that deviates from the original base pulse (see Fig. 6).

The distortion of the differentiated glottal flow signals depends on a number of factors, like, e.g., the type and the bandwidth of the low-pass filter, the frequency contents of the differentiated glottal flow signals, and the parametrization method used. We will study the effect of low-pass filtering for two parametrization methods (i.e., the direct estimation and the fit estimation method), for glottal pulses with different frequency contents (i.e., the 11 base pulses), and for different values of the bandwidth of the low-pass filter.

Low-pass filtering is done by means of a convolution with a Blackman window.[1] The bandwidth of this low-pass filter is varied by changing the length of the Blackman window (the longer the window, the smaller the bandwidth). This type of low-pass filtering was chosen because preliminary tests had shown that the error in the estimates induced by this filter was smaller than that of other tested filters. In part this can be explained by the fact that this low-pass filter does not have a ripple in its impulse response, while a ripple is present for many other low-pass filters. Therefore, for most other low-pass filters (including the generally used standard FIR filters) the estimation errors will be (much) larger than the errors presented below (Strik, 1996).

In the example provided in Fig. 6 the test signal is low-pass filtered. An LF model is then fitted to the low-pass

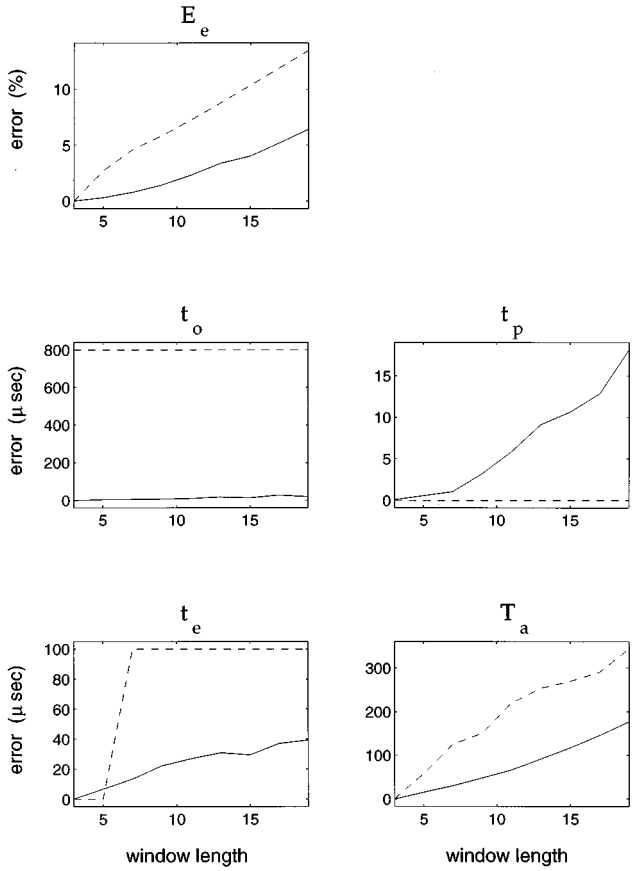

FIG. 7. Median errors in the estimated voice source parameters due to low-pass filtering by means of a convolution with a Blackman window. The length of the Blackman window varies from 3 to 19 in steps of 2. Shown are the errors for the direct estimation method (dashed) and for the first version of the fit estimation method (solid).

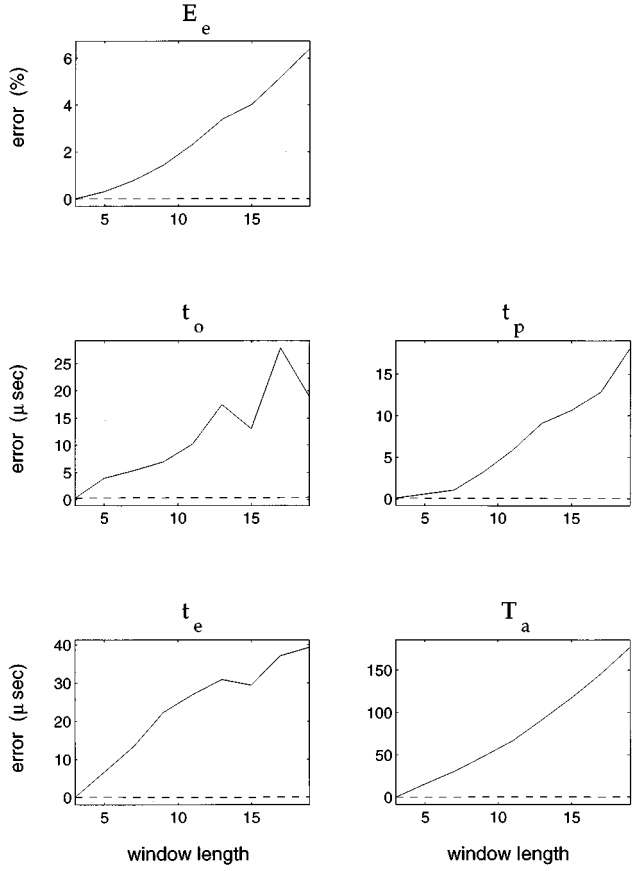

FIG. 8. Median errors in the estimated voice source parameters due to low-pass filtering by means of a convolution with a Blackman window. The length of the Blackman window varies from 3 to 19 in steps of 2. Shown are the errors for the first (solid) and the second (dashed) version of the fit estimation method. Note that the vertical scales are different from those in Fig. 7.

filtered test pulse. This seems the most obvious way to apply the fit estimation method, and will be called the first version of the fit estimation method. However, there is an alternative (which will be called the second version of the fit estimation method): apart from the test pulse one could also low-pass filter the fitted LF pulse. In this case, the test pulse and fitted LF pulse are altered in a similar fashion. In this way we hope to achieve that the error in the estimated parameters (which is due to low-pass filtering) will be smaller than when only the test pulses are low-pass filtered. It is obvious that the same procedure cannot be used in a direct estimation method, because in this case the parameters are calculated directly from the (low-pass filtered) signal.

B. Material

The 11 base pulses were low-pass filtered by means of a convolution with a Blackman window. The length of the window was varied from 3 to 19 samples in steps of 2 samples (9 lengths). For the resulting 99 test pulses (11 base pulses$\times$9 window lengths) the parameters were estimated with the direct estimation method and the fit estimation method. For each length of the Blackman window the results of the 11 base pulses were pooled and the median values of the absolute errors were calculated. These median values are shown in Figs. 7 and 8.

C. Results of the direct estimation method

In Fig. 6 one can see that low-pass filtering has most effect on the amplitude of the signal (E_e) and the shape of the return phase. Low-pass filtering causes the excitation peak to be smoother, and thus the estimate of E_e will be too small. Low-pass filtering also makes the return phase less steep, and therefore the estimate in T_a too large. These effects are enhanced if the length of the Blackman window increases (i.e., if the bandwidth of the low-pass filter is reduced). Therefore, the median errors of E_e and T_a increase with increasing window length.

Low-pass filtering does not have much influence on t_p (=the position of the zero crossing in dU_g; see Fig. 6). Therefore, in the majority of the cases the error in the estimates remains within half a sample, and the median of the errors is zero.

Usually, low-pass filtering causes the estimates of t_e to be too small (see Fig. 6). If the window length is 3 or 5, most of the errors in t_e remain within half a sample, and thus the median error is zero. However, for larger window lengths the errors in t_e become larger. As a result the median error increases too.

Finally, the error in t_0 remains constant, at the value of 820 μs (see also Fig. 3). This can be explained with the help

of Fig. 6. In this figure one can see that low-pass filtering has a large effect on the signal in the direct neighborhood of t_0, and that this effect diminishes away from t_0. If the threshold chosen is high enough (which is the case for the direct estimation method used in the current research), low-pass filtering will not have much influence on this estimate of t_0.

D. Results of the fit estimation method

In Fig. 7 not only the errors of the direct estimation method are presented, but also those of the first version of the fit estimation method (i.e., the version in which only the test pulses were low-pass filtered). If the median errors of the fit estimation method are compared with those of the direct estimation method, the following observations can be made:

(i) The median errors are larger for t_p for all window lengths, and for t_e for windows with a length of 3 or 5.

(ii) In all other cases the errors of the first version of the fit estimation method are smaller than those of the direct estimation method.

The fact that in certain cases the error of the direct estimation method is smaller than the error of the fit estimation method can be explained quite easily. If the effect of a studied phenomenon (here low-pass filtering) on an event (here t_p or t_e) is such that the event is shifted by less than half a sample, the error with the direct estimation method is zero, while that of the fit estimation method is larger than zero. However, one should keep in mind that this is only the case for pulses in which all events coincide exactly with a sample position, as is the case with the test pulses. Only in this case does rounding towards the nearest sample position mean rounding towards the correct value.

In Fig. 8 the results of the two versions of the fit estimation method are compared, i.e., the first version, in which only the test pulses are low-pass filtered (solid lines), and the second version, in which both test pulses and fitted LF pulses are low-pass filtered (dashed lines). Clearly, the errors for the second version are much smaller. The errors are not zero, as may seem to be the case from Fig. 8, but they are extremely small. The largest error observed in the time parameters is 1 μs, and the errors in E_e are always smaller than 0.03%.

E. Conclusions

From our research we can conclude that low-pass filtering changes the shape of the flow pulses, and thus affects the estimates of all voice source parameters. The error due to low-pass filtering does depend on a lot of factors, e.g., the shape of the flow derivative, the low-pass filter and the estimation method used. So even for a given low-pass filter and estimation method (i.e., within one experiment) the error is not constant, because the shape of the glottal pulses is generally not constant. Furthermore, for a low-pass filter with a ripple in its impulse response (like the often used standard FIR filters) the average errors will be larger than for the low-pass filter used in this study, i.e., a convolution with a Blackman window (Strik, 1996).

Generally, the errors for the direct estimation method are larger than those of the first version of the fit estimation method. In turn, these errors are larger than the errors of the second version of the fit estimation method. Therefore, the conclusion is that the second version of the fit estimation method is superior. Low-pass filtering both the test pulse and the fitted voice source model seems to be a very good way to reduce the error caused by low-pass filtering. Of course, it cannot be used in a direct estimation method (as was already noted above).

IV. DISCUSSION AND GENERAL CONCLUSIONS

Before we draw our conclusions regarding the comparison of the three estimation methods, we first discuss some aspects of the fit estimation methods used in this study. The first aspect is the voice source model used in the fit estimation method, in our case the LF model. In the literature several voice source models have been described (see, e.g., Rosenberg, 1971; Fant, 1979; Ananthapadmanabha, 1984; Fant *et al.*, 1985; Fujisaki and Ljungqvist, 1986; Lobo and Ainsworth, 1992; Cummings and Clements, 1995). All voice source models for which an analytical expression exists can be used with the proposed fit estimation method to parametrize either U_g or dU_g. In our program there is a subroutine which calculates the fitted signal. The model fit is now calculated with the LF model, but this part can easily be replaced by the analytical expression of any voice source model. Furthermore, any number of voice source parameters can be used for parametrization. However, increasing the number of parameters makes the optimization problem (i.e., the error space) more complex, thus increasing the probability that the fitting procedure gets stuck in a local minimum.

Using a voice source model for parametrization has some advantages, one of them being the possibility that the estimated voice source parameters can subsequently be used for speech synthesis. Of course, for fit estimation methods a voice source model is mandatory. However, probably the most important disadvantage of a voice source model used for this purpose is that it cannot describe all the observed glottal pulses. Although the LF model is capable of describing many different glottal pulse shapes, it cannot describe all details. Whether a voice source model is suitable for a certain type of research depends on the goals of this research. Above we explained that with our fit estimation method it is possible to use many voice source models. The reasons for choosing the LF model in this study are given in Sec. I B.

The second aspect of the fit estimation method we want to discuss concerns the properties of the LF routine, which is the routine used to calculate the LF pulses. The way in which the LF routine is implemented turned out to be extremely important. The first version of our LF routine was taken from Lin (1990). Since in this version all input parameters are rounded toward the nearest integer, the shapes of the resulting LF pulses do not change gradually but abruptly. The consequence is that also the calculated rms error jumps from one value to the next. Thus the error function has the shape of a staircase, which is problematic for many optimization algorithms: they often get stuck in a local minimum. This is especially the case for gradient algorithms, because the gradient is zero for each stair.

In the second version of the LF routine, oversampling was used within the LF routine. For instance, we tried over-

sampling by a factor 10. Thus not only integer values can be estimated, but also nine values between these integers. However, the error function still has the shape of a staircase. Since the stairs are ten times smaller (compared to the first version of the LF routine), the resulting estimates were better. Still, the optimization often did not come close to the global minimum.

Our conclusion is that oversampling can reduce the width of the stairs in the error function, and thus improve the estimates, but it can never take away the fundamental problem for optimization, i.e., that the error function is a staircase. That is why we tried to find an implementation of the LF routine for which the error function changes smoothly. This property will be called the ''smooth property.'' The third version of the LF routine, which is described in Sec. I F, did have this property. In this version the analytical expression of the LF model is used to calculate a continuous LF pulse, which is then sampled. An enormous improvement in the fit estimation method was observed when the third version of the LF routine was used (compared to the first and second version). The reason is that a smooth error function is an enormous advantage for both simplex search and gradient algorithms. All results presented in this article are obtained with the third version of the LF routine.

The third aspect of the fit estimation method which will be discussed is that no anti-aliasing low-pass filter is used. In the LF routine a continuous LF pulse is first calculated and is then sampled with the same sampling frequency (F_s) as the flow derivative which has to be parametrized (here, 10 kHz). We did not use an anti-alias low-pass filter here, because we wanted to be able to study each factor in isolation. If we had used an anti-alias low-pass filter, this factor (and its effect on the estimated voice source parameters) would always have been present, thus making it impossible to study it independently of other factors.

If no anti-aliasing low-pass filter is used, aliasing effects can be present in the digital signals. Careful inspection showed that this was not the case for the LF pulses used in this study. The dU_g signals on average have a slope of -6 dB/oct. The first fundamental is at 100 Hz, so at 5 kHz the attenuation is usually more than 30 dB. Using a F_s of 10 kHz made it possible to study the effect of the factor low-pass filtering independently of other factors (like, e.g., shift and E_e).

If aliasing is a problem (e.g., because F_s is smaller than 10 kHz), an anti-alias low-pass filter has to be used. The most straightforward way to do this is to sample the continuous LF signal first with a sampling frequency F_s, and next use a digital low-pass filter with a bandwidth smaller than $F_s/2$. However, in that case the smooth property is lost, and the error function (which quantifies the difference between the LF signal and the flow derivative) becomes a staircase. The result is that the average error in the estimated voice source parameters becomes larger, as mentioned above. A somewhat better solution is to oversample the LF signal before digital low-pass filtering. By oversampling noninteger values can also be estimated. Furthermore, the stairs of the staircase become smaller. Consequently, the average error in the estimated voice source parameters also becomes smaller. Probably the best solution would be to use the analytic anti-alias low-pass filter proposed by Milenkovic (1993), which can be applied in continuous time. In this way the smooth property is preserved, and the error function remains a function that changes smoothly (instead of being a staircase).

In the current study two factors were studied in detail. As parameters rarely have an integer value, we first estimated what the resulting intrinsic errors are for the two methods. For the direct estimation method they turned out to be much larger than for the fit estimation method.

Next, the effect of the factor low-pass filtering was studied independently, i.e., with all input parameters having an integer value. For low-pass filtering we found that the errors of the direct estimation method are sometimes smaller than those of the fit estimation method. However, if the important events had been positioned randomly, the errors of the fit estimation method would have been slightly larger while those of the direct estimation method would have been substantially larger. For a realistic comparison of the two methods the intrinsic errors should be added to the errors found for low-pass filtering alone. If this is done the average errors of the direct estimation method are always larger than those of the first version of the fit estimation method, and these in turn are larger than the average errors of the second version of the fit estimation method.

The conclusion which can be drawn on the basis of the tests presented in this article is that the second version of the fit estimation method is superior. However, the effect of more single factors and factors in combination should be studied to get a more thorough understanding of the intricacies of the various parametrization methods.

In order to test and compare the parametrization methods we have used a novel evaluation method in which synthetic test material is generated by a production model. Subsequently, the same production model is used to re-estimate the synthesis parameters. This evaluation method turned out to be useful for our research, e.g., it helped us find the importance of the properties of the implementation of the LF routine and the effects of the factor low-pass filtering. We are convinced that with other evaluation methods this would have been much more difficult or even impossible (see also Strik, 1996).

Since in the present research we want to focus on the estimation of voice source parameters from the flow derivative, without being distracted by the problems of inverse filtering, we use a voice source model (the LF model) as the production model. For other purposes a vocal tract model or a complete synthesizer could be used.

A similar method was used by McGowan (1994) to evaluate the estimation of vocal tract parameters. In our research, just as in McGowan's work (1994), all details of the generating procedure are explicitly known. We therefore agree with him that these kinds of studies should be regarded as best case studies which can be used to study the limitations of estimation procedures and to optimize these estimation procedures. There are two other reasons why the present study is a best case study. First of all, because the test signals are clean LF pulses, and besides the influence of low-pass filtering contain none of the other disturbances that are gen-

erally present in natural speech. And second, because for a standard FIR filter, which is used most often as a low-pass filter, the resulting average errors are larger than for the low-pass filter used in this study. Consequently, when estimation methods are used to parametrize inverse filtered natural speech signals, the errors in the resulting parameters will generally be (much) larger.

The final topic we want to discuss is how the proposed estimation methods can be used to estimate voice source parameters for natural speech. The answer is straightforward: first use inverse filtering to obtain estimates of the glottal flow signals, and then apply the estimation methods. In Strik and Boves (1992) and Strik *et al.* (1992) we showed that this is possible for previous versions of the fit estimation method. We only have to exchange the previous version of the fit estimation method with the new improved version. The best solution would be to take the second version of the fit estimation method, and in the error routine use the same low-pass filter as used during the inverse filter procedure.

ACKNOWLEDGMENTS

The research of Dr. H. Strik has been made possible by a fellowship of the Royal Netherlands Academy of Arts and Sciences. I would like to thank Loe Boves, Bert Cranen, and Jacques Koreman for fruitful discussions. Furthermore, I am grateful to Paavo Alku, Anders Löfqvist, and an anonymous reviewer for their useful comments on a previous version of this paper.

(Received 6 June 1997; revised 17 November 1997; accepted 19 December 1997)

This study examined the effect of sentence context and local acoustic structure on phoneme categorization. Target stimuli from a 10-step GOAT–COAT continuum, differing only on a temporal cue for voice onset time (VOT), were embedded in carrier sentences that biased interpretation toward either ''goat'' or ''coat.'' While subjects listened to the sentences they also responded as quickly as possible to a visual probe by indicating whether the probe matched the target stimulus they heard. Results showed that the interaction of VOT and sentence context significantly affected both identification and RT for stimuli near the perceptual boundary; the identification function showed a boundary shift in favor of the biased context and peak response times for each context reflected the shifted identification boundaries. In addition, response times were faster for identification of stimuli near the category boundary when responses were congruent, rather than incongruent with the sentence context. The response time differences for congruent versus incongruent responses in the boundary region are interpreted as depending on the results of initial phonological analysis; potentially ambiguous categorizations may be subject to additional evaluation in which a context-congruent response is both preferred and available earlier. © *1998 Acoustical Society of America.* [S0001-4966(98)02405-9]

INTRODUCTION

The perception of speech sounds is an important part of understanding spoken language. A speaker's message must be recovered by the listener, even though the continuously changing acoustic signal that comprises the speech stream does not stand in one-to-one correspondence with the words and meanings of an utterance. Instead, perception flexibly adjusts to changing contexts so that different acoustic signals can yield equivalent categorizations and identical acoustic signals may be categorized differently (Liberman *et al.*, 1967, 1957). Experimental studies of nonlinguistic contextual influences on phoneme identification abound (see Repp and Liberman, 1990 for a good review), but less is known about the specific role of other linguistic information in phoneme identification.

Linguistic context alone can guide identification when acoustic information is absent, as in the phoneme restoration effect (Warren, 1970). When part of an utterance is replaced by noise, such as a cough, listeners automatically and unconsciously fill in the missing segment. In normal conversation, however, both the acoustic object and its context are usually available to the listener. The relative contribution of these two factors has been investigated by presenting speech sounds in varying signal-to-noise ratios under different context conditions and to different populations. For young adults, the presence of lexical, syntactic, and semantic constraints increases the probability of recognizing degraded speech sounds; more highly constrained (more predictable) contexts produce greater effects (Boothroyd and Nittrouer, 1988). Although children and older adults do not recognize speech in noise as accurately as do young adults, and they differ in the effectiveness of semantic and lexical constraints, all three groups improve when contextual constraints are available (Nittrouer and Boothroyd, 1990).

The demonstration of faster detection of a target phoneme in words than in nonwords (Rubin *et al.*, 1976) provided early evidence that linguistic context influences phoneme recognition even when the signal is not degraded. Phoneme categorization is also facilitated when the phoneme appears as part of a word. For example, in continua in which the endpoint stimuli begin with voiced or voiceless stop consonants, but only one forms a word (e.g., DASH–TASH, DASK–TASK), identifications of boundary stimuli show a strong word bias in that the same acoustic stimulus elicits a greater probability of identification as a word than a nonword (Ganong, 1980). Although average response times are faster to endpoint stimuli than to those at the boundary, response times to boundary stimuli are faster when the identifications result in words rather than nonwords (Connine and Clifton, 1987).

One possibility is that the effect of lexical status on phonemic processing actually reflects a general attentional effect, not a specifically linguistic one. Connine and Clifton (1987) examined identification and response times to nonword stimulus continua (e.g., DICEL–TICEL), but biased the voiced or voiceless response by a monetary payoff scheme. In the voiced-biased condition, for example, voiced responses were rewarded and voiceless responses were penalized. There was also a small penalty for responses that were ''acoustically incorrect'' according to the individual subjects' identifications on an unbiased pre-test of the same stimuli. The results were a shift in the identification boundary in favor of the biased response (i.e., the point on the voicing continuum that would correspond to a 50% identification of either percept is shifted away from the biased endpoint). However, unlike the effects of lexical bias, response times for monetary biased responses were faster than nonbiased ones only for endpoint stimuli that could be reliably categorized on the basis of acoustic information alone.

We assume that processes that theoretically require more ''processing resources'' or are more difficult to complete will be associated with longer response times; this assumption is well grounded in the experimental literature even for the same kinds of effects being investigated here (Clifton *et al.*, 1984; Fodor *et al.*, 1996; Shapiro *et al.*, 1993). Thus at the unambiguous endpoints, a phonological decision may be produced quickly on the basis of the acoustic signal alone, but at the potentially ambiguous boundary, lexical information influences phonological processing. Unlike the effects of lexical status, the influence of monetary payoff seems to be post-perceptual.

The most obvious difference between lexical bias and monetary payoff is that only the former is in the linguistic domain, as is phonological processing. Hence, one might expect the effects of other linguistic information, such as sentence context to resemble those of lexical status more than monetary payoff. Connine (1987) constructed word–word continua (e.g., GOLD–COLD) and embedded the stimuli in sentences biased toward one or the other interpretation. For example,

(1a) She told the client to sell all the [GOLD/COLD].
(1b) She closed the window to keep out the [GOLD/COLD].

Subjects were asked to identify the beginning sound of the last word in sentences like (1a) and (1b), then circle whether the word was ''sensible'' or ''anomalous'' in the given sentence frame. The identification functions showed the same boundary shift in favor of the biased response that had been observed with lexical status and monetary payoff. But when response times for sentence-congruent versus sentence-incongruent responses were compared, the congruency advantage appeared only at the endpoints, not near the category boundary. It was not the case that categorizations that ''make sense'' are simply faster because anomalous responses at the endpoints were faster than sensible responses near the boundary. Connine concluded that the similar response time patterns for monetary payoff and sentence bias were produced by similar post-perceptual processing that was different from the interactive processing of lexical bias.

Taken together, the results for biasing by lexical status, monetary payoff and sentence context present something of a puzzle. If it were the case that linguistic information is more available during the process of phoneme identification than nonlinguistic information, why would semantic sentence context be treated more like the nonlinguistic monetary payoff than like lexical status? The answer to that may lie in the degree of autonomy of different linguistic domains, but such an account would require the unlikely combination of a semi-autonomous phonological level that is both interactive with a word recognition system and impenetrable by semantic sentence context. An alternative explanation for the surprising difference between the results of biasing by lexical status and sentence context might lie in the methodology of the Connine (1987) experiment. First, seven different voicing continua were used, each with a different VOT range (e.g., 14–60 ms for DENT–TENT and 68–115 ms for DRIP–TRIP); there was, in fact a significant effect of continuum (''item'') in both the boundary and endpoint analyses as well as several interactions with item. These differences, as well as significant individual differences among subjects, required extensive adjustments in the analyses that may have muddied the results. Second, the critical acoustic target for identification was always the last word in the sentence, but context integration has been shown to occur at pauses or interruptions, even for tasks and stimuli for which context effects were not otherwise demonstrated (Nicol and Swinney, 1989; Nicol *et al.*, 1997). A third potential problem in the Connine experiment was the use of each sentence frame for every VOT value (14 unique sentence frames for seven voicing series×two contexts); recall of a prior response to an apparently identical sentence might affect a current identification.

The present experiment sought to clarify whether semantic sentence context influences phoneme categorization during the processing of an ongoing sentence and whether the congruency of a response has a similar effect for sentence context and lexical status. To this end, we examined the effects of acoustic parameter value and sentence context using (a) a single stimulus continuum, (b) a cross-modal ''word-matching'' task that requires identification judgments during the course of a sentence, and (c) a unique sentence frame for every trial. The critical tests for a context effect are a shift in the identification function in favor of the biased context and the presence of an interaction between the acoustic parameter value and the sentence bias. If the congruency of a response with a real word and with the meaning of a sentence have similar effects on response times, the boundary stimuli, rather than endpoint stimuli, should be preferentially influenced by sentence context.

I. METHOD

A. Subjects

Thirty-three undergraduates participated in this experiment in return for research credit in their introductory psychology class. They identified themselves as monolingual

TABLE I. GOAT-biased sentence components.[a]

	Sentence position				
	A	B	C	Target	D
1	The busy	dairyman	hurried to milk the	[GOAT/COAT]	in the kitchen garden
2	The handsome	farmer	forgot to feed the	[GOAT/COAT]	in the drafty barn
3	The laughing	children	loved to tease the	[GOAT/COAT]	in the grassy field
4	The fussy	zoo-keeper	wanted to cage the	[GOAT/COAT]	in the crowded pen
5	The lively	toddler	ran to chase the	[GOAT/COAT]	in the quiet pasture

[a]Sentence example: [The laughing]$_{A3}$ [farmer]$_{B2}$ [hurried to milk the]$_{C1}$ [GOAT/COAT]$_{Target}$ [in the crowded pen]$_{D4}$.

TABLE II. COAT-biased sentence components.[a]

	Sentence position				
	A	B	C	Target	D
1	The elderly	grandma	stopped to button the	[GOAT/COAT]	in the corner closet
2	The careful	laundress	had to dry-clean the	[GOAT/COAT]	in the back bedroom
3	The expert	seamstress	tried to shorten the	[GOAT/COAT]	in the tiny cloakroom
4	The cheerful	tailor	hurried to press the	[GOAT/COAT]	in the dusty storeroom
5	The foolish	cleaner	liked to wear the	[GOAT/COAT]	in the cluttered attic

[a]Sentence example: [The careful]$_{A2}$ [tailor]$_{B4}$ [had to dry-clean the]$_{C2}$ [GOAT/COAT]$_{Target}$ [in the dusty storeroom]$_{D4}$.

native speakers of American English with normal hearing, normal or corrected to normal vision with no known speech or language impairments.

B. Stimuli

1. Original sentences

Sentence meanings were biased toward either ''goat'' or ''coat'' as in (2a) and (2b).

(2a) GOAT-biased: The laughing dairyman hurried to milk the [GOAT/COAT] in the drafty barn.

(2b) COAT-biased: The expert tailor tried to shorten the [GOAT/COAT] in the cluttered attic.

Each of the sentences in each biasing condition contained a different, unique arrangement of the same set of components. The sentence components are listed in Table I (GOAT-biased) and Table II (COAT-biased). Twenty-one subjects participated in a paper and pencil ''fill-in-the-blank'' test in which they judged whether (a) only ''goat,'' (b) only ''coat,'' or (c) either ''goat'' or ''coat'' could complete 25 randomly selected sentences of each type, as well as 50 unbiased sentences. Results confirmed the sentence biases: 99.6% of GOAT-biased sentences and 99.5% of COAT-biased sentences were completed with the appropriate item (21 subjects each). The original sentences were recorded in a quiet room using a high fidelity table top microphone and a Marantz stereo cassette tape recorder (model PMC 420). The sentences were then digitized onto computer from the tape using a 16 bit audio card and a sampling rate of 22 050 Hz. The original sentences included the context appropriate word, ''goat'' or ''coat,'' although the original items were later replaced by the manipulated target stimuli described below.

2. Target words

A stimulus continuum was constructed by manipulating the recorded natural speech of the sentence reader, using a waveform editor. The sentence fragment ''the coat in the'' that contained a ''good'' /kot/ was excised from one of the COAT-biased sentences. This unmanipulated sentence fragment in which the aperiodic initial segment of /kot/ was 64 ms (measured from the beginning of the stop release burst to the onset of periodicity) was used as the longest VOT stimulus. The other tokens in the continuum were constructed by subtracting incremental segments (in 6-ms steps) from the midpoint of the initial aperiodicity of the original /k/ in /kot/ in order to preserve the natural variability in the energy associated with the consonant burst as well as the natural transitions between the different states. For example, the 58-ms stimulus value consisted of the first 29 ms of the original 64-ms stimulus, then the interval from 35 ms to 64 ms (see Fig. 1). In the continuum, the shortest VOT value corresponded to that measured in the natural ''goat'' (10 ms); the longest VOT value was equivalent to /k/ in the natural ''coat'' (64 ms). The ten resulting VOT values were: 10, 16, 22, 28, 34, 40, 46, 52, 58, and 64 ms.

3. Manipulated sentences

In each sentence, the fragment ''the goat/coat in the'' was replaced with one from the stimulus continuum using a waveform editor. The splices were placed at zero crossings

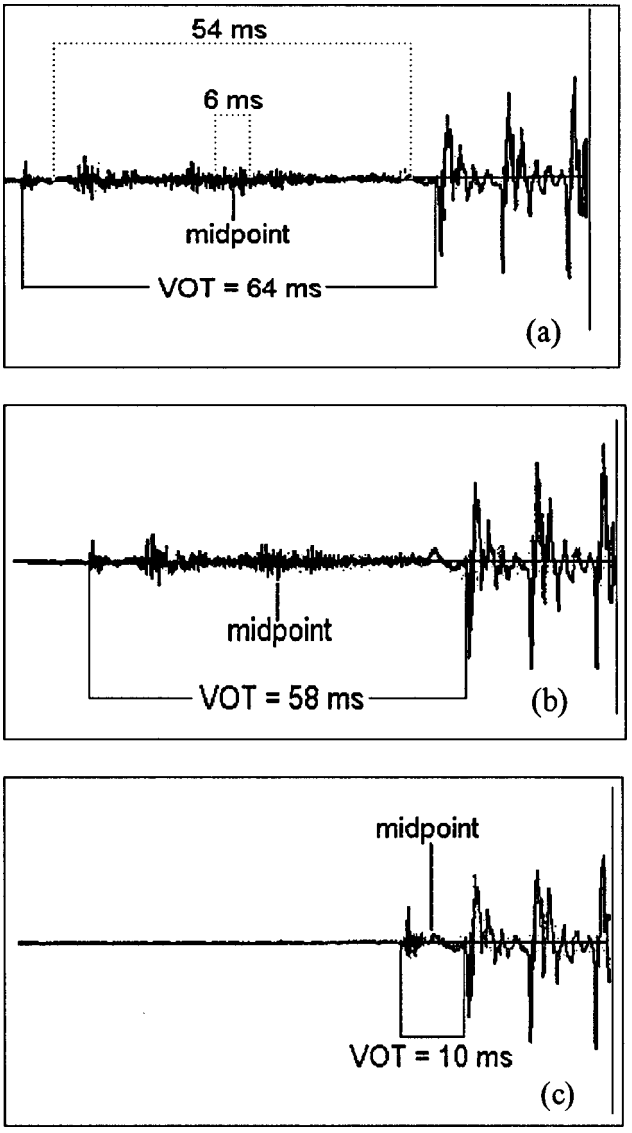

FIG. 1. The acoustic manipulation of the target GOAT/COAT stimuli by deleting segments from the midpoint of the 64-ms aperiodic portion of a ''natural'' /kot/. (a) VOT=64 ms: the voiceless endpoint stimulus that was the unaltered ''natural'' /kot/. The 6-ms and 54-ms segments that were deleted to produce VOT=58 ms and VOT=10 ms, respectively, are also indicated. (b) VOT=58 ms: The result of the 6-ms deletion shown above. The remainder of the stimuli were created by incrementing the value of the deleted segment in 6-ms steps until the result was (c) VOT=10 ms: The voiced endpoint where the deleted segment equaled 54 ms.

in the waveform to avoid acoustic discontinuities; also, any unnatural acoustic effects introduced by the manipulation would not be near the target word. Ten GOAT-biased sentences and ten COAT-biased sentences were constructed for each of the ten VOT values for a total of 200 sentences. A 1000-Hz tone inserted at the offset of the target stimulus was used to trigger the visual probe. This tone was placed on a second audio channel and was inaudible to the subjects. The manipulated sentences were then recorded back onto tape.

4. Visual probes

The visual probes consisted of the word ''goat'' or the word ''coat'' that appeared on the CRT at the offset of the target word in each sentence. The probes were balanced within each VOT×Context combination.

C. Procedure

Subjects, tested individually, were seated directly in front of a CRT in a quiet room. The sentences were presented binaurally over headphones. Subjects were instructed to look at the CRT while listening carefully to each sentence, paying attention to both sound and meaning. Comprehension was encouraged and assessed by testing recall for 20% of randomly selected trials. Subjects were instructed that when the word ''goat'' or ''coat'' appeared on the CRT, they should press, as quickly as possible, the button labeled YES (the word on the screen is the word they heard) or NO (the word on the screen is not the one they heard); the auditory sentence continued uninterrupted. Because the probes were balanced within each VOT×Context combination, a subject making, for example, the same ''goat'' identification response for every presentation of the same target stimulus would do so by responding ''yes'' to GOAT on one-half of the trials, and ''no'' to COAT on the other half. This strategy balanced any ''yes'' or ''no'' response biases and also prevented subjects from responding prior to the presentation of the embedded target word. The computer recorded both the responses and the response times, measured from the onset of the visual probe (at the offset of the target word) to the button press. The experiment consisted of a 20 sentence practice session and two 100 sentence blocks, with sentence order randomized, separated by a rest period. The criterion for including a subject in the data analysis was correct recall for 95% of the sentences.

II. RESULTS

The two dependent measures were the probability of a ''coat'' versus ''goat'' identification for each VOT×Context condition, and the response time for the decision task. If context influences phoneme categorization during sentence processing, a VOT×Context interaction for identification and a shift of the identification boundary in favor of the biased context should be observed. Similarly, response times should show a VOT×Context interaction and peak response time should shift with the identification function. If the congruency of a response with the sentence context acts like congruency with a real word (Connine and Clifton, 1987), the congruency advantage should be observed only for intermediate VOTs. In contrast, if the results confirm those of Connine (1987), the congruency advantage should be restricted to extreme VOTs.

Data from 30 subjects were included in all analyses (three subjects were excluded for failure to meet the sentence recall requirement). The effect of identification by a ''yes'' or by a ''no'' response was not significant ($p>0.8$), nor were there any significant interactions of ''yes'' or ''no'' responses with VOT or context. Therefore, subjects' ''yes'' and ''no'' responses will be referred to in terms of the stimulus identification.

For all 30 subjects, identification was near 100 percent ''goat'' at the shortest VOT and near 100 percent ''coat'' at the longest VOT. A shift of the identification boundary in favor of the biased context was observed for every subject as well as for the mean. The results of a 10×2 repeated-

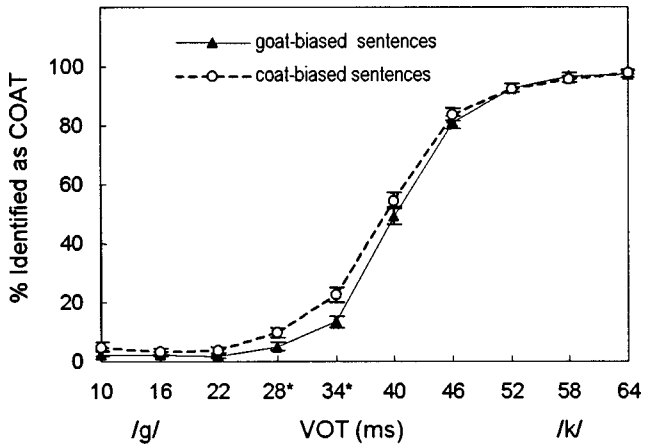

FIG. 2. The mean identification function by acoustic parameter and sentence context. Error bars indicate one standard error above and below the mean.

measures ANOVA, with VOT and biasing context as main effects were significant for VOT [$F(9,261)=388.79$, $p<0.01$], context [$F(1,29)=11.41$, $p<0.02$], and their interaction [$F(9,261)=2.37$, $p<0.01$].[1] The simple effect of context at each VOT was significant only for VOT=28 ms [$F(1,29)=4.12$, $p<0.05$] and VOT=34 ms [$F(1,29)=14.61$, $p<0.01$]. For both stimuli, a greater percentage of ''coat'' identifications were made in the COAT-biased context than in the GOAT-biased context (Fig. 2).

The response times for identification were then examined. ''Yes'' responses were faster overall [$F(1,29)=36.04$, $p<0.01$] but there were no ''yes'' vs ''no'' interactions with any other factors. Mean response times were greater for mid-range VOT and, like the identification functions, the peak response time for each biased context was shifted away from the biased endpoint. This pattern is shown in Fig. 3.

A 10×2 repeated measures ANOVA determined that VOT [$F(9,261)=15.32$, $p<0.01$], context [$F(1,29)=14.46$, $p<0.01$], and the VOT×Context interaction [$F(9,261)=2.03$, $p<0.03$] all influenced response times. The simple effect of context at each VOT was significant for VOT=10 ms [$F(1,29)=7.33$, $p<0.01$], VOT=16 ms [$F(1,29)=15.77$, $p<0.01$], and VOT=28 ms [$F(1,29)$

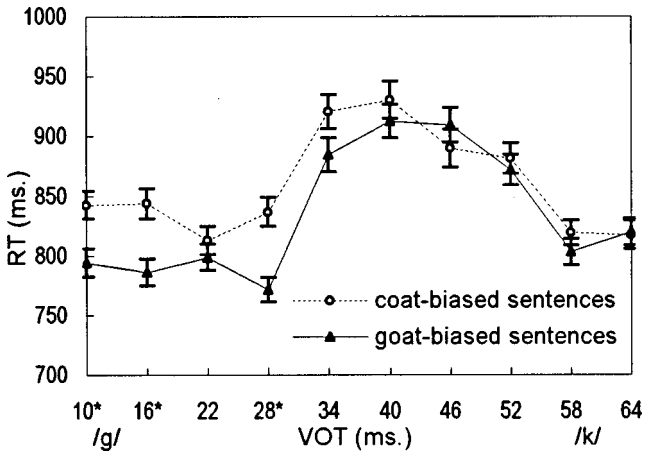

FIG. 3. Mean response time by acoustic parameter value and biasing context. Error bars indicate one standard error above and below the mean.

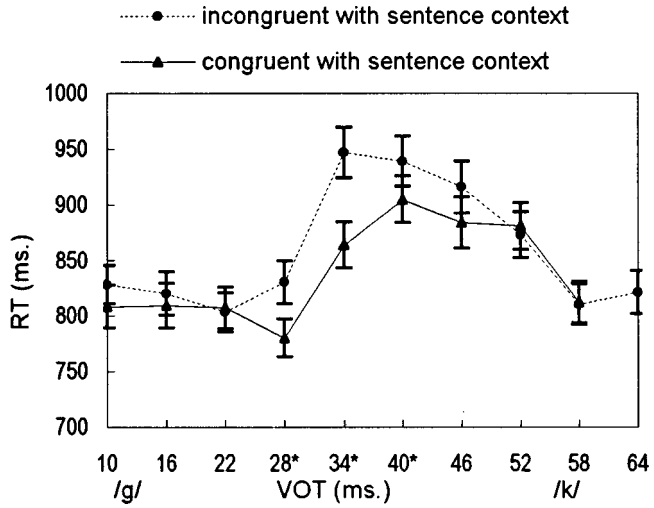

FIG. 4. Mean response time by acoustic parameter value and congruency of response with the biased sentence context. Congruent=GOAT identifications in the GOAT-biased context plus COAT identifications in the COAT-biased context; Incongruent=GOAT identifications in the COAT-biased context plus COAT identifications in the GOAT-biased context. Error bars indicate one standard error above and below the mean.

$=12.84$, $p<0.01$]. Additionally, at VOT=34 ms, response times differences due to sentence context were in the same direction as the group mean for 19 of the 30 subjects ($p=0.2$).

In order to analyze the data relative to the subject's response rather than the experimenter-determined condition, we partitioned the responses into two categories: a ''congruent'' category in which the identification matched the biasing context (i.e., ''goat'' identifications for GOAT-biased sentence contexts; ''coat'' identifications for COAT-biased sentence contexts) and an ''incongruent'' category in which identification and sentence context did not match (i.e., ''coat'' identifications for GOAT-biased sentences, etc.), see Fig. 4. A 10×2 ANOVA on response times showed main effects of VOT [$F(9,261)=15.32$, $p<0.01$] and congruency: $F(1,29)=7.61$, $p<0.01$, as well as their interaction [$F(9,261)=2.63$, $p<0.01$]. The simple effect of congruency at each VOT value was significant for three mid-range stimuli: VOT=28 ms [$F(1,29)=13.13$, $p<0.01$], VOT=34 ms [$F(1,29)=12.24$, $p<0.01$], and VOT=40 ms [$F(1,29)=6.36$, $p<0.02$].

An identification response could also be viewed in terms of congruency with acoustic information, but, because VOT values do not correspond to a single identification, we can only say that a ''goat'' identification is more congruent with the acoustic information at the shortest VOT endpoint than at the longest, whereas a ''coat'' identification is more congruent with the acoustics of the longest VOT value. For ''goat'' identifications, response times increased as the VOT got longer; but for ''coat'' identifications, the relationship was less clear. The mean response times for ''goat'' and ''coat'' identifications for each VOT and for the two different sentence contexts are shown in Fig. 5(a)–(b); note that the number of observations for each identification was far greater at the acoustically congruent endpoint than at its opposite. In fact, in Fig. 5(b) we see the root of the sentence context

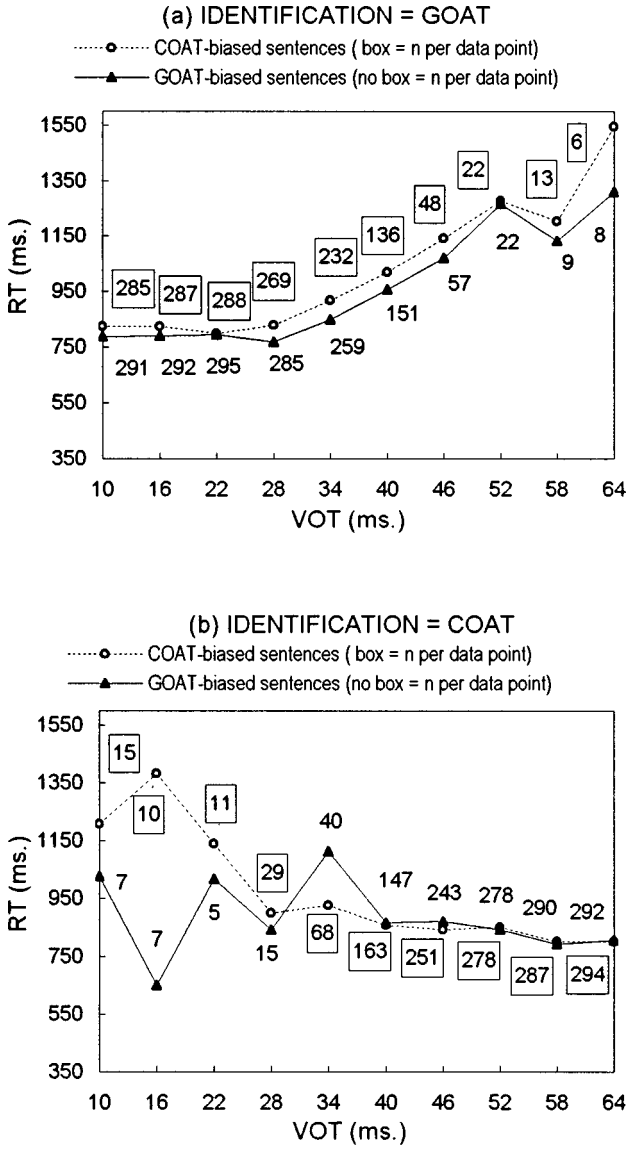

FIG. 5. Mean response time and number of observations (n) by VOT and context for (a) GOAT identifications only, and (b) COAT identifications only. Note that the n's are asymmetrical due to the identification function.

effect on RT for short VOT stimuli. That is, the increase in RT occurs only for the very few stimuli (<4% of the total) identified as ''coat'' despite very short VOTs. Although their numbers are small, the effect is still seen because their mean RT is over 300 ms slower than for ''goat'' responses to these same stimuli. Of those ''coat'' responses, twice as many occur in the COAT-biased context as in GOAT-biased context and their mean RT is fully 200 ms longer. When only ''goat'' responses to stimuli with 10-ms or 16-ms VOT are considered, the effect of sentence context on RT at the voiced endpoint disappears.

III. DISCUSSION

The results of this experiment confirm the influence of sentence context on phoneme categorization during sentence processing. Our data are much like the earlier results for biasing by lexical status (Connine and Clifton, 1987) and contrast with previous results for biasing by sentence context or monetary payoff (Connine, 1987; Connine and Clifton, 1987). Effects of local acoustic structure and sentence context on phoneme categorization confirmed the effectiveness of our stimuli and experimental task.

The observation that response times were also sensitive to local acoustic structure and sentence context confirmed their value as indicators of processing differences. If processing load increases with the degree of conflict between acoustic and contextual information then longer response times are predicted at the acoustically clear endpoints when contextually biased toward the opposite endpoint. This does not seem to be the case because endpoint response times are clearly fastest, regardless of context congruency, whether the biasing context is lexical status, monetary payoff, or sentence meaning. The longest response times are observed for intermediate VOT values which we interpret as an indication that more time or greater processing resources are needed for ambiguity resolution.

The principal criterion by which Connine (1987) and Connine and Clifton (1987) discriminated between early and late influence of context was the effect of the congruency of the response to the biasing context. When identifications are faster for congruent than for incongruent identifications only for boundary stimuli, the effect is thought to be early in perceptual processing. In contrast, when congruency influences only endpoint stimuli, the effect is thought to be post-perceptual. Both the present sentence context experiment and the Connine (1987) lexical status experiment showed an effect of congruency at the boundary, but not at the endpoints. In the monetary payoff experiment (Connine and Clifton, 1987), and the off-line sentence context experiment (Connine and Clifton, 1987), a congruency advantage was found at the endpoints, but not near the boundary. However, as Connine and Clifton point out in their discussion, the expected result of a ''pure'' post-perceptual response bias would be a congruency advantage for all stimuli. Whether the congruency effect represents a speeding up of congruent responses, or a slowing down of incongruent responses, the finding of any interaction between congruency and acoustic stimulus argues against a simple anomaly effect (longer times for ''incongruent'' responses in every case) because the balanced context conditions in each experiment and the relatively small identification differences, mean that ''mismatches'' are almost evenly distributed throughout the stimulus range. Our data suggest that sentence context acts in much the same way as lexical status and that both of these linguistic factors influence phonological processing.

The implications of these results for a larger theory of language comprehension depend mainly on what claims we are prepared to make about the place of our identification task in the time course of normal sentence processing. In a modular account, a sentence is constructed on-line by rapid, automatic sub-processes that use only domain specific information for initial processing (e.g., Fodor, 1983; Forster, 1979). A number of on-line studies have shown modularity for at least some language operations including access to multiple noun meanings (Swinney, 1979), access to multiple argument structures (Shapiro *et al.*, 1987, 1989), and gap filling (Swinney and Osterhout, 1990; Lewis *et al.*, 1998).

Since the words that are identified by phoneme categorization need to be available for ''higher level'' processes such as lexical access, structural analysis and semantic interpretation, according to this account, initial phonological analysis must be automatic and immediate, and should not be influenced by sentence context.

In an interactive account of sentence comprehension, word identification can change and develop over time as new information becomes available (for example, as in McClelland and Elman's 1986 TRACE model). If such a process is viewed as the satisfaction of multiple constraints (MacDonald *et al.*, 1994), probabilistic information from the acoustic characteristics of a stimulus could interact both with lexical characteristics of the word specified by a particular phoneme categorization and with contextual constraints on word selection. In this case, initial phonological analysis could be influenced by sentence context.

One important issue in the modularity-interactionism debate was not resolved by the present study: When in the time course of sentence processing did our observed context effects occur? In other words, did the results of our identification task indicate immediate, interactive context effects? An interactive account of initial phonological processing is possible in that biasing information from the sentence context was available prior to the presentation of the embedded target stimulus and could theoretically modify the criteria for phoneme categorization. On the other hand, identification tasks may not be sensitive to fast-acting, automatic processing of acoustic information because they require an explicit categorization decision prior to response; integration of contextual information before identification may be a consequence of task demands. In an ongoing experiment with the same stimuli, we use a cross modal lexical decision (CMLD) to an unrelated probe word that does not require an explicit decision about the target stimulus. Finding a VOT×Context interaction for CMLD times at the offset of the target stimulus would lend additional support to an interactive account of sentence processing in which context directly influences initial perception. Finding a VOT×Context interaction a few syllables after the target stimulus, but not at the target itself, would support a more modular account in which context exerts its effect only after initial context-independent phonological processing. Nevertheless, the results presented here are suggestive that sentence context can guide phonological processing during ongoing sentence analysis.

ACKNOWLEDGMENTS

Auditory-visual speech recognition by hearing-impaired subjects: Consonant recognition, sentence recognition, and auditory-visual integration

Ken W. Grant, Brian E. Walden, and Philip F. Seitz
Walter Reed Army Medical Center, Army Audiology and Speech Center, Washington, DC 20307-5001

(Received 19 March 1997; revised 10 December 1997; accepted 24 January 1998)

Factors leading to variability in auditory-visual (AV) speech recognition include the subject's ability to extract auditory (A) and visual (V) signal-related cues, the integration of A and V cues, and the use of phonological, syntactic, and semantic context. In this study, measures of A, V, and AV recognition of medial consonants in isolated nonsense syllables and of words in sentences were obtained in a group of 29 hearing-impaired subjects. The test materials were presented in a background of speech-shaped noise at 0-dB signal-to-noise ratio. Most subjects achieved substantial AV benefit for both sets of materials relative to A-alone recognition performance. However, there was considerable variability in AV speech recognition both in terms of the overall recognition score achieved and in the amount of audiovisual gain. To account for this variability, consonant confusions were analyzed in terms of phonetic features to determine the degree of redundancy between A and V sources of information. In addition, a measure of integration ability was derived for each subject using recently developed models of AV integration. The results indicated that (1) AV feature reception was determined primarily by visual place cues and auditory voicing+manner cues, (2) the ability to integrate A and V consonant cues varied significantly across subjects, with better integrators achieving more AV benefit, and (3) significant intra-modality correlations were found between consonant measures and sentence measures, with AV consonant scores accounting for approximately 54% of the variability observed for AV sentence recognition. Integration modeling results suggested that speechreading and AV integration training could be useful for some individuals, potentially providing as much as 26% improvement in AV consonant recognition. INTRODUCTION

For all but the most profoundly hearing-impaired individuals, auditory-visual (AV) speech recognition has consistently been shown to be more accurate than auditory-only (A) or visual-only (V) speech recognition. Although this is especially true when the auditory signal is distorted (e.g., due to hearing loss, environmental noise, or reverberation), the influence of visual cues on speech recognition is not limited to conditions of auditory distortion. Even with fully intact speech signals, visual cues can have an impact on recognition. McGurk and MacDonald (1976) demonstrated that when the auditory production of one consonant is synchronized with the visual production of another consonant, most observers will perceive a third consonant that is not represented by either auditory or visual modality. For example, when auditory /bɑ/ is presented with visual /gɑ/, the perceived result is often /dɑ/. This illusion, known as the ''McGurk Effect,'' occurs even when the auditory signal is perfectly intelligible.

Another example of the influence of visual speech cues on intact auditory signals occurs when listeners are asked to repeat unfamiliar phrases, as when learning a second language or when presented with grammatically complex passages. For instance, when asked to shadow the speech of a native French speaker, students with four years of French training performed significantly better when they were able to see the speaker's face as compared to when they could only hear his voice (Reisberg *et al.*, 1987). Similarly, when native speakers of English were asked to shadow passages from Kant's *Critique of Pure Reason* spoken by another native English speaker, performance was significantly better when visual cues were available (Reisberg *et al.*, 1987).

These brief examples suggest that the perception of speech is inherently multimodal. Cues extracted from both auditory and visual sources are integrated early in the perceptual analysis of speech, and this information is used without much regard to the sensory modality of origin (Massaro, 1987; Summerfield, 1987). Yet, in spite of the superior status of auditory-visual speech recognition relative to auditory-only speech recognition, recent explications of speech perception often omit, or only mention briefly, the role of visual speech information (Diehl and Kluender, 1989; Klatt, 1989; Stevens, 1989; Halle and Stevens, 1991; Greenberg, 1995; Lindblom, 1996; Ohala, 1996). In contrast, recent studies of automatic speech recognition have begun to emphasize the importance of incorporating visual speech information along with acoustic information to improve recognition performance, especially in noisy environments (Stork and Hennecke, 1996).

From an applied perspective, a theory of AV speech perception would be an extremely valuable tool for addressing the communication problems encountered by hearing-impaired individuals or by normally hearing individuals in

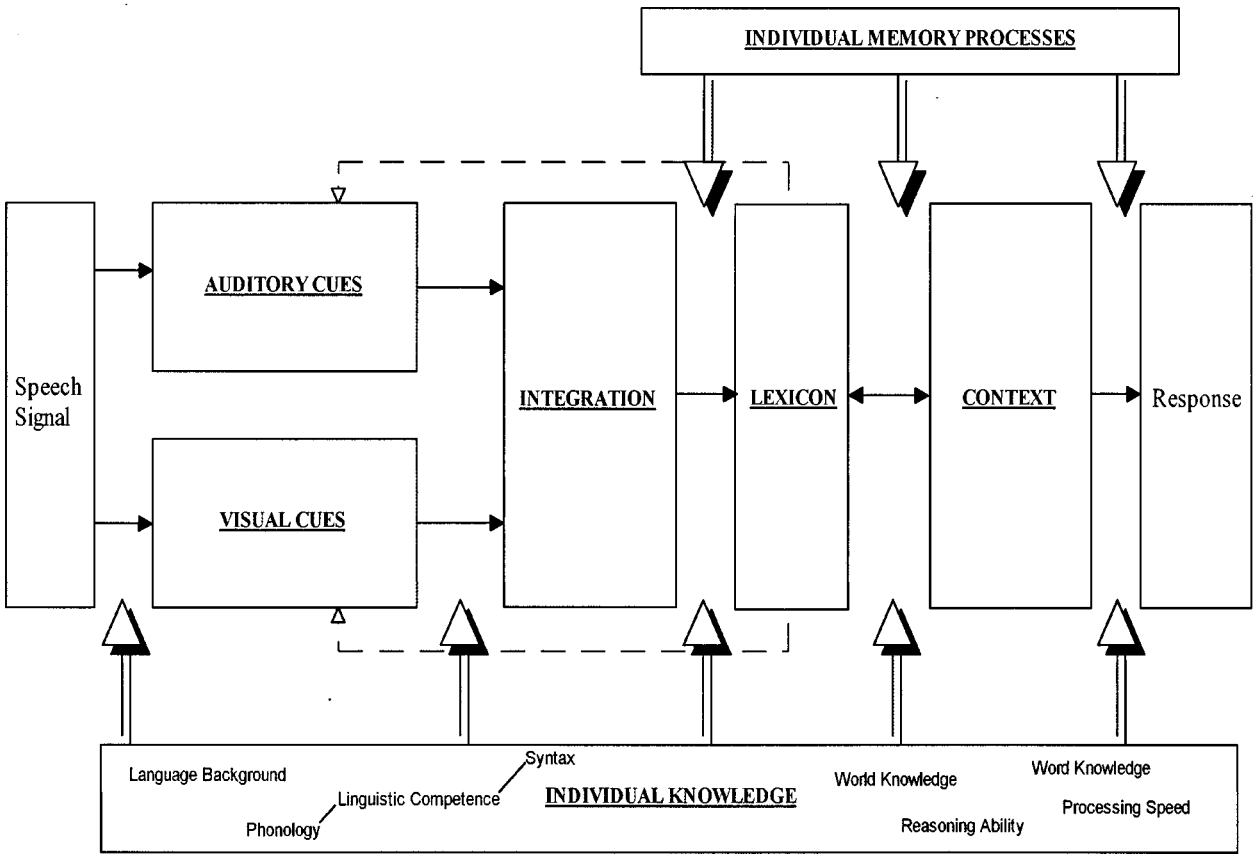

FIG. 1. Schematized framework of auditory-visual speech recognition.

noisy or reverberant environments. Such a theory would provide a conceptual framework that could serve as a guide for developing signal-processing strategies and/or rehabilitation programs when AV speech perception is less than perfect. Consider the simple conceptual framework shown in Fig. 1. A speech signal composed of both optical and acoustic information is presented. The listener-observer extracts signal-related segmental and suprasegmental cues from each modality, integrates these cues, and applies top-down semantic and syntactic constraints in an effort to interpret the message before making a response. The basic components, bottom-up signal-related cue extraction, integration, and top-down linguistic processes, are common to most speech perception theories (e.g., Liberman *et al.*, 1967; Stevens and House, 1972; Studdert-Kennedy, 1974). The major distinction drawn here from auditory-only theories of speech perception is that in an audiovisual communication environment, cues from the visual modality must be considered, and the integration of A and V cues, both within and across modalities, must be described (Massaro, 1987).

From this perspective, consider a hearing-impaired individual whose AV recognition of words and sentences is less than perfect. In order to evaluate the exact nature of the communication problem, it is necessary to determine whether the communication failure is due to poor reception of auditory and/or visual cues, difficulty in integrating A and V cues, difficulty in applying linguistic and contextual constraints, reduced working memory capacity, or a combination of these factors. If the problem is determined to be primarily difficulty in receiving A or V cues, signal-processing strategies to enhance the relevant cues may be used. If, on the other hand, the problem is determined to be difficulty in integrating A and V cues or difficulty in applying top-down language processing rules, then training and practice techniques may be applied. Simply knowing the individual's AV sentence or word recognition performance is not sufficient for determining a plan for rehabilitation.

In order to use the framework displayed in Fig. 1 as a guide for rehabilitation, three questions must be addressed: (1) What are the most important cues for AV speech recognition that can be extracted from acoustic and visual speech signals? (2) Is it possible to measure an individual's ability to integrate auditory and visual cues separate and apart from their ability to recognize syllables, words, and sentences? (3) What are the most important nonsignal-related ''top-down'' processes that contribute to individual variability in AV speech recognition? A brief discussion relating to each of these questions is presented below.

1. What are the most important cues for AV speech recognition that can be extracted from acoustic and visual speech signals?

Clearly, the answer to this question cannot come from studies of auditory speech perception alone. For example, auditory place-of-articulation cues, which are extremely important for A-only speech recognition, are not as important in AV speech recognition because this information is readily

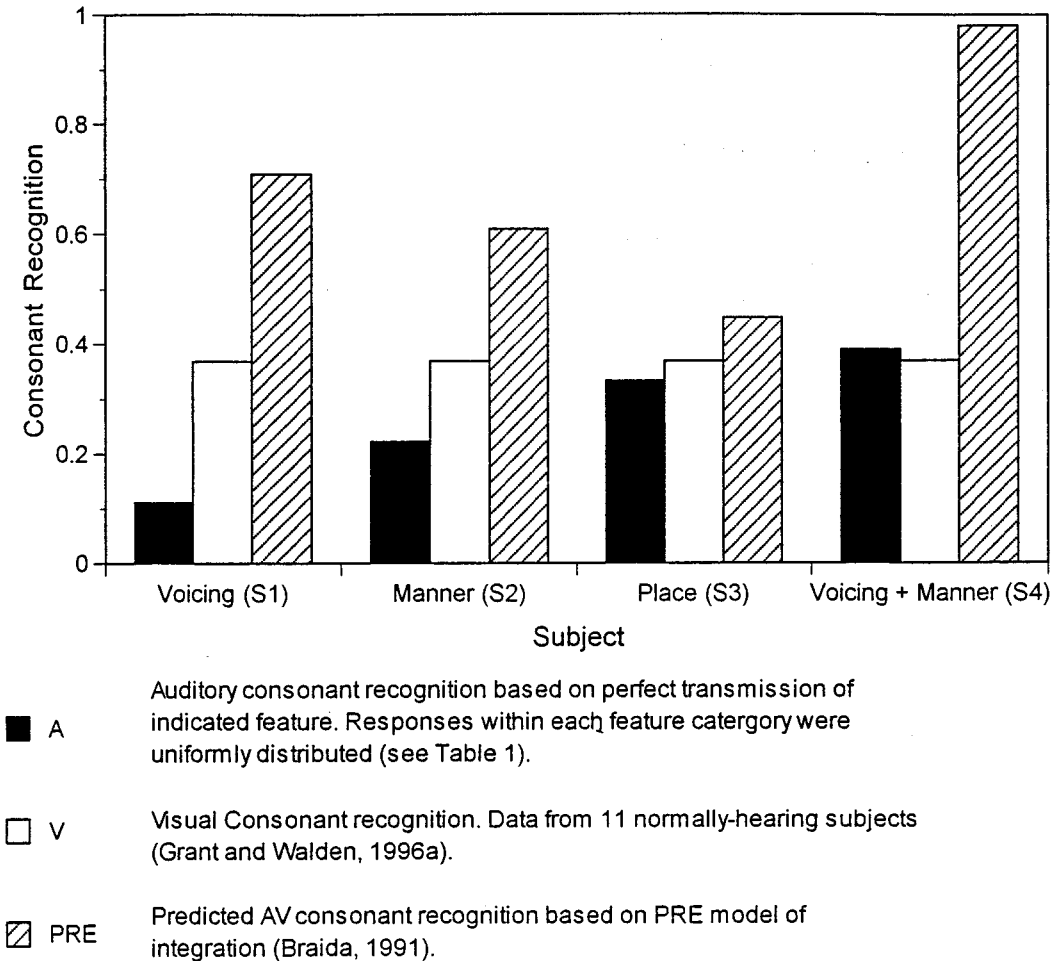

FIG. 2. Scores for A, V, and (predicted) AV conditions for four hypothetical subjects with average speechreading ability. Auditory-visual predictions were made with the PRE model using an average normal-hearing V consonant confusion matrix and an appropriate A confusion matrix with perfect recognition of the specified speech feature. Each set of bars represents a subject with perfect auditory feature recognition for voicing (S1), manner-of-articulation (S2), place-of-articulation (S3), and voicing-plus-manner (S4), respectively.

available through the visual channel. On the other hand, auditory voicing and manner-of-articulation cues are extremely important in AV speech recognition because this information is difficult to obtain visually. A careful accounting of the cues extracted from the separate unimodal conditions can reveal the degree of redundancy or complementarity between A and V cues. If A and V cues are redundant, there will be less benefit resulting from their combination than if the cues are complementary (Walden *et al.*, 1977; Grant and Walden, 1996a).

The relevancy of cue redundancy between A and V conditions as a predictor of AV performance is important for the present discussion because it forces us to recognize that when comparing two different listening conditions (or two listeners with different degrees of hearing loss, or two different hearing aids), the condition resulting in the higher rate of auditory intelligibility need not result in the highest AV score or the greater improvement when combined with speechreading. This point is illustrated graphically in Fig. 2.

Figure 2 shows predicted AV consonant recognition results for four different hypothetical subjects. For each hypothetical subject, three bars are shown. The black bar represents the auditory recognition score on a consonant identification task that would result from perfect recognition of either voicing (S1), manner-of-articulation (S2), place-of-articulation (S3), or the combination feature, voicing-plus-manner (S4). Table I shows the feature classification for the set of consonants used in this example. The auditory recognition scores (black bars) were calculated assuming perfect recognition of each specified feature and a uniform distribution of responses within each feature category. For example, for the hypothetical subject who receives perfect voicing information (S1), the confusion matrix shows a uniform distribution of responses among all voiced consonants and a uniform distribution of responses among unvoiced consonants. Since the subject is perfect in recognizing the voicing feature, there are no cases of voiced–voiceless confusions. Once constructed in this manner, the confusion matrix can then be scored for overall accuracy by simply observing the number of correct responses (lying along the main diagonal of the confusion matrix) divided by the total number of trials.

The unfilled bars are the same for each subject and represent consonant recognition performance of a typical speechreader (Grant and Walden, 1996a).[1] The shaded bars represent AV predictions made by Braida's Pre-Labelling Integration Model (1991).[2] Note that a subject who has perfect voicing recognition (S1) derives substantially more AV benefit (e.g., difference between AV and A recognition) accord-

TABLE I. Feature classification for voicing, manner, and place categories.

VOICING					
Voiced				Unvoiced	
b,d,g,m,n,v,ð,z,ʒ,dʒ				p,t,k,f,θ,s,ʃ,tʃ	
MANNER OF ARTICULATION					
Stop		Nasal	Fricative		Affricate
b,p,g,k,d,t		m,n	v,f,ð,θ,z,s,ʒ,ʃ		dʒ,tʃ
PLACE OF ARTICULATION					
Bilabial	Lingua-Velar	Lingua-Alveolar	Lingua-Dental	Lingua-Palatal	Labio-Dental
b,p,m	g,k	d,t,n,s,z	ð,θ	ʒ,ʃ,dʒ,tʃ	v,f

ing to Braida's model than subjects who obtain either perfect manner (S2) or-perfect place recognition (S3), even though these latter subjects have higher overall A recognition scores. Finally, a subject who obtains perfect voicing and manner recognition (S4) is predicted to have a nearly perfect AV score. This implies that hearing-impaired listeners with average speechreading skills who can extract voicing and manner information from the A condition may be expected to have high AV consonant scores, regardless of their overall A recognition score. Figure 2 also demonstrates that improvements in absolute unimodal recognition scores that may result from various forms of signal processing (e.g., hearing aids) may not produce the best bimodal recognition score.

2. Is it possible to measure an individual's ability to integrate auditory and visual cues separate and apart from their ability to recognize syllables, words, and sentences?

The recent development of quantitative models of multisensory integration (Massaro, 1987; Blamey *et al.*, 1989; Braida, 1991) has made it possible to derive measures of AV integration that are independent of the individual's ability to extract cues from the A and V modalities. These models make predictions of AV performance based on speech feature recognition or from the detailed patterns of confusions obtained for each separate modality. If these predictions are based on optimum processing models, then the extent to which the actual obtained AV performance approximates the predicted performance may be used as an index of AV integration skill. That is, subjects whose AV performance is well-predicted by the models are better at integrating A and V cues than subjects whose actual AV performance is overpredicted by the models.

Some of the integration models considered in this study are not optimum processor models, and observed AV scores can be higher than predicted scores. Nevertheless, deviations between predicted and obtained AV performance may still be used as an index of integration skill. For example, suppose that predictions from a particular model were based only on a subject's overall score from each separate modality and did not take into account the pattern of confusions generated in the A and V conditions. Even though such a model would likely underpredict real performance, the extent to which subjects' AV recognition scores exceed model predictions might indicate better integration abilities.

3. What are the most important nonsignal-related "top-down" processes that contribute to individual variability in AV speech recognition?

Individuals interpret speech signals in conjunction with stored linguistic knowledge (Lindblom, 1996). This knowledge base includes the individual's vocabulary and other properties of the lexicon, their knowledge of semantics and syntax, their use of word-level and sentence-level context to compensate for misperceptions and impoverished acoustic and visual information, and memory processes and strategies for lexical access based on partial information in the signal. Measures of variability for each of these sources of linguistic knowledge are likely to reveal interesting subject differences which may impact on AV recognition of speech. Unfortunately, this potentially important source of variability in AV performance continues to receive little attention in the literature.

The experiments reported here represent the first in a series of studies to evaluate the importance of these different factors (cue extraction, integration, top-down processing) in determining AV speech recognition. In the present study, we focus mainly on the first two factors and describe individual variability in AV consonant and sentence recognition by hearing-impaired persons in terms of two factors: the ability to recognize consonants auditorily and visually, and the ability to integrate A and V cues. Admittedly, consonant recognition represents only one class of several potentially important "bottom-up signal-related" factors (as compared to the recognition of consonant clusters, vowels, word and sentence stress, syllabification, etc.). One reason for choosing to investigate consonant recognition is that in English, consonants account for a large proportion of the total segmental information making up lexical items (Kucera and Francis, 1967). Furthermore, many of the acoustic cues that help distinguish one consonant from another are often of low intensity and involve rapid, short-duration spectral transitions making them difficult to hear under conditions of hearing-impairment or environmental distortion (e.g., noise or reverberation). These two attributes of consonants (frequency of occurrence in the language and acoustic characteristics) lead us to hypothesize that variability in consonant recognition will contribute strongly to variability in word and sentence recognition.

This study is divided into three main parts: obtaining measures of auditory (A), visual (V), and auditory-visual

(AV) consonant recognition, deriving a measure of auditory-visual integration ability from A and V consonant recognition data, and obtaining measures of A, V, and AV sentence recognition. All measures were obtained on individual hearing-impaired patients. The overall objective was to relate the variability in consonant recognition and AV integration ability to variability in AV sentence recognition.

I. METHODS

A. Subjects

Twenty-nine subjects between the ages of 41 and 88 years (mean age=65.0) were recruited from the patient population of the Army Audiology and Speech Center, Walter Reed Army Medical Center. All had acquired sensorineural hearing losses due primarily to noise exposure. The average three-frequency (500, 1000, and 2000 Hz) pure-tone threshold for the better ear was 33 dB HL (range: 0–63.3 dB HL re; ANSI, 1989). The average two-frequency (2000 and 4000 Hz) pure-tone threshold was 53.5 dB HL (range: 20–77.5 dB HL). No additional audiometric criteria were imposed in subject selection. Because variability in the patterns of auditory consonant confusions was important to the planned analyses, subjects with a variety of configurations and severity of hearing loss were included. In order to include a wide range of speech recognition abilities, potential subjects were initially screened on their ability to recognize IEEE Harvard sentences (IEEE, 1969) in noise [signal-to-noise ratio (S/N) of 0 dB]. Screening of subjects continued until 4–5 subjects with scores at each performance level of approximately 10%, 20%, 30%, 40%, 50%, and 60% correct were identified (i.e., 5 subjects at 10%, 5 subjects at 20%, etc.). All subjects were native speakers of American English and had normal or corrected-to-normal vision. None had prior experience as subjects of experiments involving visual or bisensory speech recognition. Although many of the subjects were experienced hearing-aid users, all testing was conducted binaurally under headphones with speech levels approximating 85 dB SPL. When eligible subjects were paid for their participation in the screening process, and if selected, during the main experiment.

B. Procedure

1. Consonant recognition

Consonant recognition was measured separately for A, V, and AV presentations. Speech materials consisted of eighteen medial consonants (/p,b,t,d,k,g,m,n,s,z,f,v,θ,ð,ʃ,ʒ,tʃ,dʒ/) surrounded by the vowel /ɑ/. Ten productions of each /ɑ/–consonant–/ɑ/ (aCa) stimulus were spoken by a female talker of American English and recorded on optical disk (Panasonic TQ-3031F). The audio portion of each production was digitized (16-bit A/D, 20-kHz sampling rate), normalized in level, and stored on computer (Vanguard 486). For auditory-visual presentations, the digitized computer audio and optical disk video portions of each production were realigned using custom auditory-visual control software. Alignments were checked using a dual trace oscilloscope to compare the original and digitized productions of each utterance and were found to be within ±2 ms.

Prior to testing, subjects were familiarized with the consonant set and the use of a touch screen in making responses. Care was taken to ensure that each subject understood the task and could make use of the eighteen consonant category labels. Auditory-visual practice blocks of 36 trials, each with trial-by-trial feedback, were presented binaurally through headphones (Beyer DT-770) at a comfortable listening level appropriate for each subject. Speech materials were presented in quiet with subjects seated in a sound-treated room facing a 19-in. color video monitor (SONY PVM 2030) situated approximately 5 ft from the subject. After one or two initial practice blocks, subjects were required to achieve performatice levels on three additional consecutive practice blocks of 92% correct consonant recognition or better. Only one subject (out of 30 tested) failed to meet this requirement and was eliminated from further testing.

Following familiarization training, data were obtained on consonant recognition in noise. On each test trial, a single aCa production was presented. The overall level of the speech signal was approximately 85 dB SPL. The aCa utterances were mixed with a speech-shaped noise matched to the average long-term spectrum of the stimulus set and presented at a S/N ratio of 0 dB. This level of noise was chosen to insure a sufficient number of recognition errors for the planned analyses. A different sample of noise was used for each of the 180 tokens (18 consonants ×10 productions). Each speech token began 50 ms after the noise started and ended 50 ms before the noise finished. Subjects were required to identify the consonant presented, selecting their response from a touch screen terminal displaying all 18 possible consonant labels. Subjects were tested in blocks of 72 trials. Ten blocks each were presented in the A, V, and AV conditions, yielding a total of 40 trials per consonant per condition. The order of A, V, and AV conditions was randomized for each subject. No feedback was provided.

2. Auditory-visual integration

Three recent models of auditory-visual speech recognition (Massaro, 1987; Blamey *et al.*, 1989; Braida, 1991) were used for estimating the efficiency with which individual subjects integrate A and V cues. Each of these models predicts AV recognition scores from A and V scores alone. Differences between predicted and obtained AV scores were used as a measure of each subjects' integration efficiency. Below, a brief description of each model is presented along with the methods used to derive individual integration measures.

a. Braida (1991)—PRE. In the Prelabeling Model of Integration, confusion matrices from A and V consonant recognition are subjected to a special form of multidimensional scaling (MDS) and interpreted within a Theory of Signal Detection (e.g., Green and Swets, 1966; Macmillan *et al.*, 1988). The model provides a spatial interpretation of the ability to distinguish between consonants analogous to that derived from traditional multidimensional scaling (Borg and Lingoes, 1987). However, unlike traditional MDS, the scaled distances between consonants in the separate A and V spaces are converted to a common metric, d', explicitly reflecting the correctness of responses. The decision process assumes a

comparison between stimulus attributes (modeled as a multidimensional vector of cues, $\vec{X}$) and prototypes or response centers ($\vec{R}$) in memory. Subjects are assumed to respond R_k if and only if the distance from the observed vector of cues $\vec{X}$ to $\vec{R}_k$ is smaller than the distance to any other prototype. A subject's sensitivity $d'(i,j)$ in distinguishing stimulus S_i from stimulus S_j is given by

$$d'(i,j) = \|\vec{S}_i - \vec{S}_j\| = \sqrt{\sum_{k=1}^{D} (S_{ik} - S_{jk})^2}, \tag{1}$$

where $\|\vec{S}_i - \vec{S}_j\|$ is the distance between the D-dimensional vector of cues generated by stimuli S_i and S_j.

In the present study, estimates of stimulus and response centers that best fit a given confusion matrix were obtained iteratively using a KYST procedure (Kruskal and Wish, 1978). For the first iteration, $\vec{S}$ and $\vec{R}$ are assumed to be aligned. Subsequent iterations attempted to improve the match between predicted and obtained matrices (using a x^2-like measure) by displacing slightly both stimulus and response centers. Each iteration assumed 5120 presentations per consonant token yielding a total of 92 160 trials per matrix. This number was selected to reduce the stimulus variability in each simulation to approximately 1/10th of the variability in the data. The MDS fits were further optimized by choosing either two- or three-dimensional solutions depending on which gave the best fit to the unimodal matrix.

Prelabeling model predictions for AV performance are made solely on the basis of unimodal performance. Assuming that A and V cues are combined optimally, the decision space for the AV condition is the Cartesian product of the space for the A condition and the space for the V condition. Thus the relation between a subject's sensitivity in the AV condition and the corresponding unimodal sensitivities, assuming no perceptual interference (e.g., masking or distraction) across modalities, is given by

$$d'_{\mathrm{AV}}(i,j) = \sqrt{d'_{\mathrm{A}}(i,j)^2 + d'_{\mathrm{V}}(i,j)^2}. \tag{2}$$

Predictions of AV consonant recognition were made using the A and V consonant recognition data described above and compared to AV consonant recognition obtained by individual subjects. Since Braida's Prelabeling Model is an optimum processor model, predicted AV scores will always equal or exceed observed AV scores. A subject's integration efficiency, as predicted by the model, was given by the difference between predicted and observed AV recognition scores (with zero difference indicating perfect integration).

b. Massaro (1987)—FLMP. In the Fuzzy Logical Model of Perception (FLMP), auditory and visual channels are considered to be independent sources of information about the identity of the AV stimulus. Continuously valued features are evaluated, integrated, and matched against prototype descriptions in memory, and an identification decision is made on the basis of the relative goodness of match of the stimulus information with the relevant prototype descriptions. In the multimodal case, each speech segment possesses a set of feature values for the auditory channel and a set of feature values for the visual channel. For example, in the syllable /bɑ/, the lips coming together represent a visual feature, whereas second and third formant transitions appropriate for /bɑ/ represent acoustic features. To relate these sets of informational values to each other, a common metric based on fuzzy truth values (Zadeh, 1965) is used. Truth values ranging between 0 and 1 are used to represent the goodness-of-fit between each particular feature in the information set and the prototypical feature value in memory. Although feature values are considered the basis for the match between a given speech signal and its prototypical representation, these values are not observed directly. Instead, they are inferred from the response patterns obtained from separate auditory-only and visual-only recognition experiments. To predict bimodal performance, auditory-visual feature values are assumed to be proportional to the product of unimodal feature values. According to Massaro (1987) and Massaro and Friedman (1990) a multiplicative combination of feature values predicts an optimal level of performance given multiple sources of information. The multiplicative rule for AV integration used by Massaro is given by

$$P_{\mathrm{AV}}(R_j|S_i) = \frac{P_{\mathrm{A}}(R_j|S_i) \times P_{\mathrm{V}}(R_j|S_i)}{\sum_{k=1}^{N} P_{\mathrm{A}}(R_k|S_i) P_{\mathrm{V}}(R_k|S_i)}, \tag{3}$$

where $P_{\mathrm{AV}}(R_j|S_i)$ is the conditional probability that response R_j is given when the AV stimulus S_i is presented, and $P_{\mathrm{A}}(R_j|S_i)$ and $P_{\mathrm{V}}(R_j|S_i)$ are the conditional probabilities for the A and V unimodal cases, respectively. The denominator is the sum of the conditional probabilities in the ith row of the confusion matrix and normalizes the feature values for the N responses to conditional probabilities.

In our implementation of the FLMP, a fixed form of the model was used where the parameter values representing the goodness-of-fit of any particular token (presented in either the A or V modality) to its prototypical memory representation are assumed to be equal to the unimodal performance level for that token.[3] In other words, the truth values were derived directly from the original confusion matrices for the unimodal conditions. For example, if a subject correctly identified auditory /bɑ/ 85% of the time, then $P_{\mathrm{A}}(R_{\mathrm{ba}}|S_{\mathrm{ba}}) = 0.85$. Similarly, if the subject responded ''va'' 10% of the time given this same auditory stimulus, then $P_{\mathrm{A}}(R_{\mathrm{va}}|S_{\mathrm{ba}}) = 0.10$, and so on. Thus the set of A and V conditional probabilities derived from the A and V confusion matrices were used directly with the multiplicative rule to predict AV responses.

Braida (1991) has shown that the fixed FLMP model makes reasonably good predictions of multimodal scores without systematically under- or over-predicting observed accuracy. However, the model has a tendency to underestimate AV performance when A performance is particularly poor and overestimate AV performance when A performance is relatively good. As with the PRE model, integration efficiency was defined as the difference between predicted and observed AV consonant recognition scores.

c. Blamey et al. (1989)—PROB. According to the model proposed by Blamey *et al.* (1989), AV speech recognition errors occur only when there are simultaneous errors in *both* A and V recognition. Model predictions are stated in

terms of percentage of information transmitted (%IT). Thus given the probability of an auditory error [1−%IT(A)] and visual error [1−%IT(V)], the AV error rate is given by

$$AV_{ERR}=(1-\%IT_A)(1-\%IT_V), \quad (4)$$

and the AV score is given by

$$1-(AV_{ERR}). \quad (5)$$

The advantage of this simple probabilistic model (PROB) is that it can be used to predict a wide range of speech recognition scores, including information transmission scores for speech features (e.g., voicing, manner-of-articulation, etc.), words, and sentence recognition scores. The disadvantage is that human observers often do better than the model predicts (Blamey *et al.*, 1989), suggesting that the model is not optimal. The Blamey *et al.* model represents a probabilistic combination of the A recognition response and the V recognition response made independently of each other. However, Braida (1991) showed that predicted AV recognition scores are generally higher when intormation from the two modalities are integrated before response labels are assigned. Thus actual observed AV scores that exceed those predicted by Blamey *et al.* (1989) are likely the result of the observers' use of prelabeling integration processes, and, the greater the deviation from predicted score, the greater the integration efficiency.

3. Sentence recognition

As with consonant recognition, sentence recognition was measured separately for A, V, and AV presentations. Speech materials consisted of the IEEE/Harvard (1969) sentences. These are 720 phonetically balanced low-context sentences each containing five key words (e.g., ''The *birch canoe slid* on the *smooth planks*''). The sentences are organized into 72 lists with 10 sentences in each list. These stimulus materials were filmed at the Massachusetts Institute of Technology using the same female talker used for the VCV materials and dubbed onto an optical disc (Panasonic TQ-3031F). The audio portion of the sentences were treated in the same manner as the consonants.

A and AV sentence recognition was measured at a S/N ratio of 0 dB. For AV presentations, the subjects viewed a 19-in. color video monitor (SONY PVM 2030) from a distance of approximately 5 ft.

The subjects were asked to write down what they perceived in A, V, and AV presentation modes. Subjects were encouraged to respond with as much of the sentence as they could, and to guess whenever they were uncertain. All sentences were scored for the percentage of key words correctly identified. A strict scoring criterion was used in which all tense (e.g., ''–ed'') and number (e.g., ''–s'') affixes were required to be correct for the key word to be correct. On the other hand, homophones were counted as correct (e.g., ''read'' for ''red'').

For each test condition (A, V, and AV), five lists of sentences (ten sentences/list) were presented. Thus each score was based on 250 words (5 words per sentence, 10 sentences per list, 5 lists per condition). The order of the test conditions and lists were randomized for each subject. No feedback regarding the correctness of responses was provided.

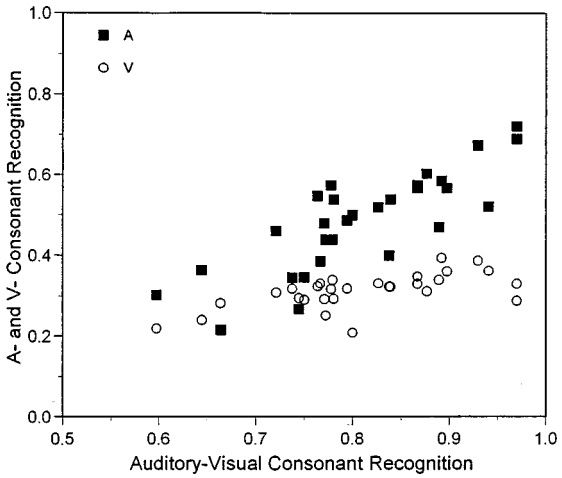

FIG. 3. A and V consonant recognition as a function of AV consonant recognition.

4. Summary

The specific question addressed by the various speech measures obtained in this study was how much of the individual variability in AV sentence recognition could be accounted for by variability in AV consonant recognition? Further, it was assumed that AV consonant recognition is determined primarily by auditory and visual cue extraction abilities and the efficiency at which the unimodal cues could be integrated. The ability to extract auditory and visual cues were determined by analyses of error patterns made in separate A and V consonant recognition tests. To measure integration ability, three models of integration (PRE, FLMP, and PROB) were used to predict AV consonant recognition scores from independent measures of A and V consonant recognition. Integration efficiency was defined as the difference between predicted and observed AV consonant recognition scores. This is the first report, as far as we are aware, to describe individual differences in AV integration efficiency, and how these differences may relate to speech recognition performance.

II. RESULTS

A. Consonant recognition

Variability in AV consonant recognition was examined in terms of A and V consonant recognition. In addition, consonant confusions made in each of the unimodal conditions were examined to determine the relation between AV recognition and unimodal feature recognition.

Focusing initially on overall recognition accuracy, Fig. 3 shows A, V, and AV consonant recognition scores for each of the 29 subjects. Auditory-visual recognition scores (displayed along the abscissa) ranged from 60% to 98% (mean =81%, s.d.=9.5%), whereas A recognition scores ranged from 20% to 74% (mean=49%, s.d.=12.3%). Speechreading (i.e., V-only) scores were less variable across subjects and

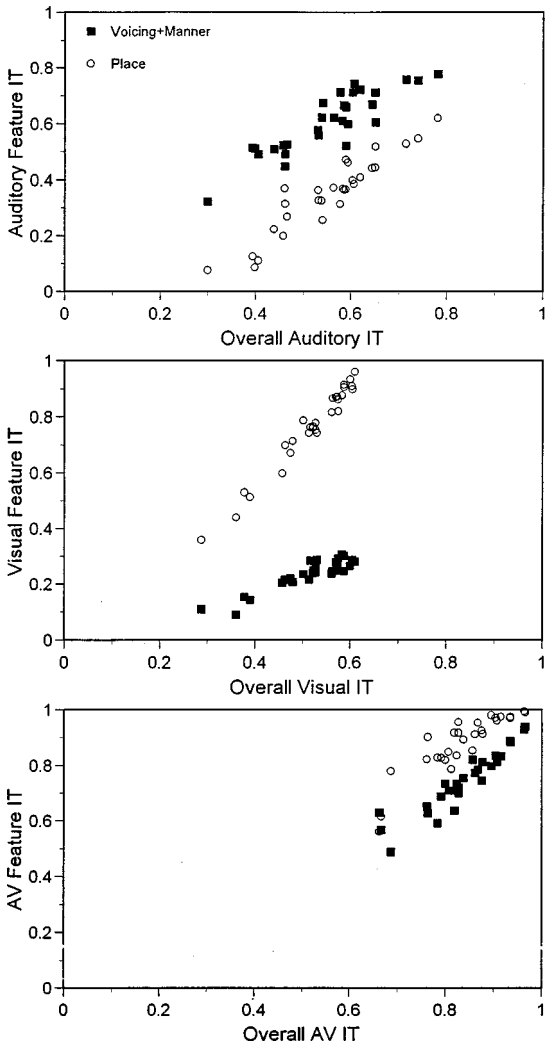

FIG. 4. Voicing-plus-manner and place information transmission for A, V, and AV modalities as a function of overall information transmitted (IT).

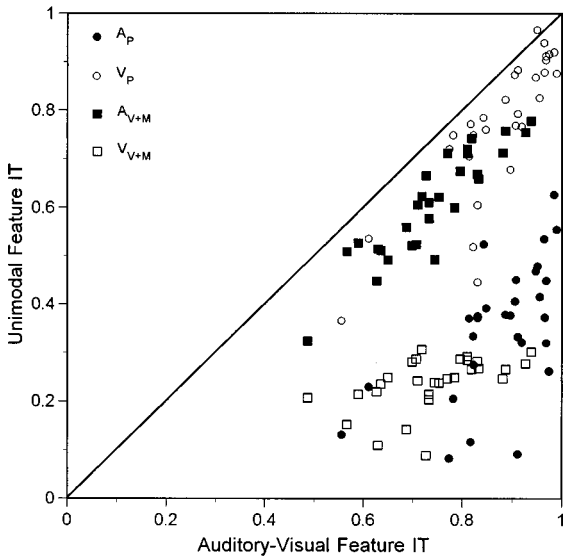

FIG. 5. A and V feature transmission scores as a function of AV feature transmission scores.

ranged from 21% to 40% (mean=31%, s.d.=4.3%). All subjects were able to benefit substantially from the combination of audition and speechreading with the mean performance difference between AV and A test conditions equal to 32% (s.d.=7%). For these materials, this amount of gain is roughly equivalent to a 5–6 dB improvement in signal-to-noise ratio (Grant and Walden, 1996a). Also apparent from the figure is the strong relation between AV and A scores ($r=0.82$) and the weaker relation between AV and V scores ($r=0.63$). Both of these correlations were highly significant ($p<0.001$).

The correspondence between unimodal and bimodal performance shown in Fig. 3 is based solely on overall recognition accuracy in each of the three receiving conditions. It is likely that even higher correlations between unimodal and bimodal performance would result if the patterns of A and V confusions were considered. Previous data obtained by Grant and Walden (1996a), as well as the predicted AV scores shown in Fig. 2, suggest that AV consonant recognition performance is determined in large part by the accuracy with which auditory voicing plus manner cues and visual place cues are extracted from the unimodal conditions. To investigate this, a feature-based information analysis (Miller and Nicely, 1995) was performed on the unimodal and bimodal confusion matrices of the 29 subjects. The accuracy of information transmission (IT) for a variety of speech features was determined, including a 7-category voicing+manner (V+M) feature and a 6-category place (P) feature as described in Table I. The three panels displayed in Fig. 4 show the results for the V+M and P features as a function of the overall IT for A (top), V (middle), and AV (bottom) conditions, respectively. As expected for auditory presentations (top panel) given the subjects' hearing losses and the relatively poor S/N, A_{V+M} cues (mean=0.61) were received more accurately than A_P cues (mean=0.35). In contrast (middle panel), V_P cues (mean=76%) were received more accurately than V_{V+M} (mean=0.24). In the AV condition (bottom panel), AV_P cues (mean=0.88) were received with greater accuracy than AV_{V+M} cues (mean=0.74). This is noteworthy in that place cues, as opposed to voicing or manner cues, have been shown consistently to be more susceptible to the deleterious effects of noise and hearing loss (Miller and Nicely, 1955; Rabinowitz *et al.*, 1996). The implications of this observation for hearing-aid development and rehabilitation will be discussed later.

An attempt was made to relate unimodal feature recognition to AV feature recognition to explore further the connection between A and V segmental cues and AV recognition. Figure 5 shows scatter plots of four unimodal-to-bimodal relations: AV_P vs A_P (filled circles), AV_P vs V_P (open circles), AV_{V+M} vs A_{V+M} (filled squares), and AV_{V+M} vs V_{V+M} (open squares). All four correlations were significant ($r \geqslant 0.53$, $p \leqslant 0.003$). However the strongest correlations were between AV_P recognition and V_P ($r=0.83$) and between AV_{V+M} recognition and A_{V+M} ($r=0.91$). This is not to imply that A_P cues did not contribute to AV_P recognition or that V_{V+M} cues did not contribute to AV_{V+M} recognition. In fact, by combining V_P and A_P scores into a single P score (e.g, by using the PROB model), the correlation with AV_P ($r=0.90$) is significantly higher than the correlation between V_P and AV_P. A similar analysis regarding

AV_{V+M} recognition showed that combining the two unimodal V+M scores hardly improved the correlation previously obtained with the A_{V+M} score alone ($r=0.93$). Therefore, in describing the AV feature IT for the 29 hearing-impaired subjects, AV_{V+M} recognition was determined primarily by A_{V+M} whereas AV_P was determined by the combined influences of V_P and A_P.

B. AV consonant integration

Auditory-visual consonant recognition is assumed to be determined primarily by the amount and type of A and V cues that can be extracted from the speech signal (unimodal cue extraction), and the efficiency with which these cues can be combined across the two modalities (bimodal integration). In order to separate these two factors, a measure of AV integration must be devised. In this section, three models capable of predicting AV consonant recognition from A and V consonant recognition are used to derive such measures. Each model is used to predict AV consonant identification accuracy for individual subjects. The differences between obtained and predicted scores are then used as measures of individual integration skill. It should be noted that subjects with relatively good integration skills need not achieve better overall AV recognition scores than subjects with relatively poor integration skills. As we are using the term, integration only refers to the ability to combine the cues derived from the separate modalities. Therefore, subjects with very poor A and/or V cue resolution might still be excellent integrators if they use these cues to their fullest potential in bimodal perception. The net result, depending on the amount of A and V cues recognized, might still be a relatively poor overall AV score. Conversely, subjects with excellent cue resolution but relatively poor integration skills may end up with a relatively high AV score by virtue of a high A or V score alone. These examples suggest that integration skill might be better related to AV benefit than to AV score. For the purpose of this study, AV benefit was defined as (AV-A)/(100-A), or the recognition improvement relative to the total possible improvement given an individual's A-alone score (Sumby and Pollack, 1954).

Predicted versus observed AV consonant recognition scores are shown in Fig. 6. AV predictions made by the PRE, FLMP, and PROB models of integration are shown separately in the top, middle, and bottom panels of the figure. The Pearson correlations between observed and predicted AV recognition scores were fairly similar for the three models: 0.89 for the PRE, 0.83 for the FLMP, and 0.89 for the PROB. As indicated by the position of the data points relative to the line $AV_{OBSERVED}=AV_{PREDICTED}$ shown in each panel, predictions by the PRE model were either equal to or greater than obtained performance, whereas predictions by the FLMP and PROB models generally underpredicted AV performance.[4] This was especially true for the FLMP when the input unimodal scores were low. In the fixed FLMP model, stimuli identified correctly in one modality but incorrectly in the other are predicted to be incorrect in the combined AV condition [see Eq. (3)]. As Braida (1991) noted, the fixed FLMP model does not properly account for structured errors and relies too heavily on unimodal accuracy. In contrast, the PRE model focuses more on the consistency of unimodal responses (as determined by MDS) and not necessarily on accuracy. Thus the PRE model makes a prediction of optimal performance (not necessarily optimal fit) and would therefore be expected to over predict observed scores.

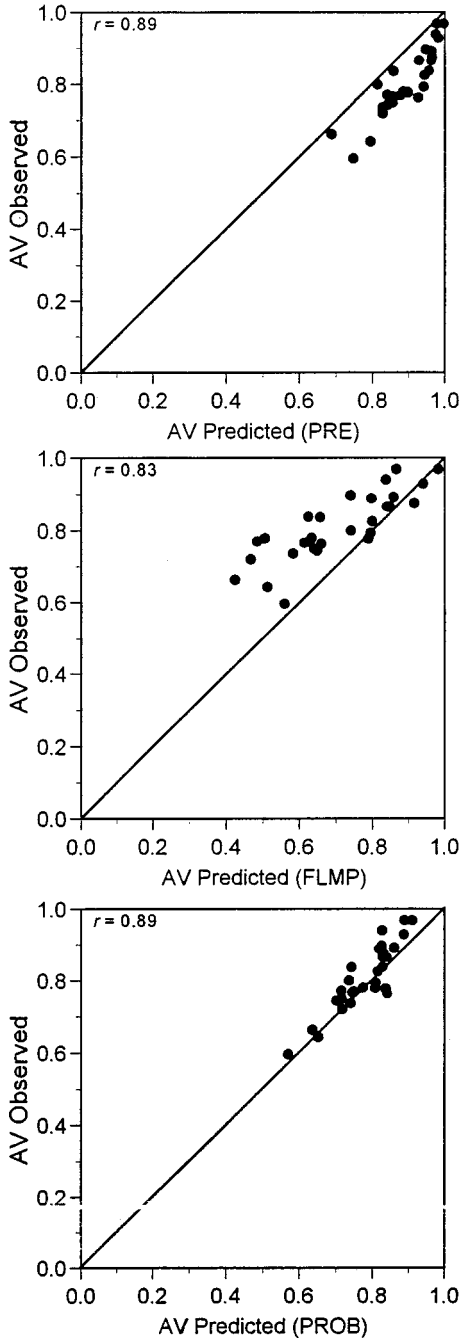

FIG. 6. PRE, FLMP, and PROB model predictions of AV consonant recognition.

In Fig. 7, the derived measure of integration skill (i.e., the difference between predicted and observed scores for individual subjects) is shown with respect to the amount of relative AV benefit obtained. When compared in terms of the ability to predict the relative benefit provided by speechreading, the derived measure based on PRE model predictions accounted for approximately 56% of the variance in relative

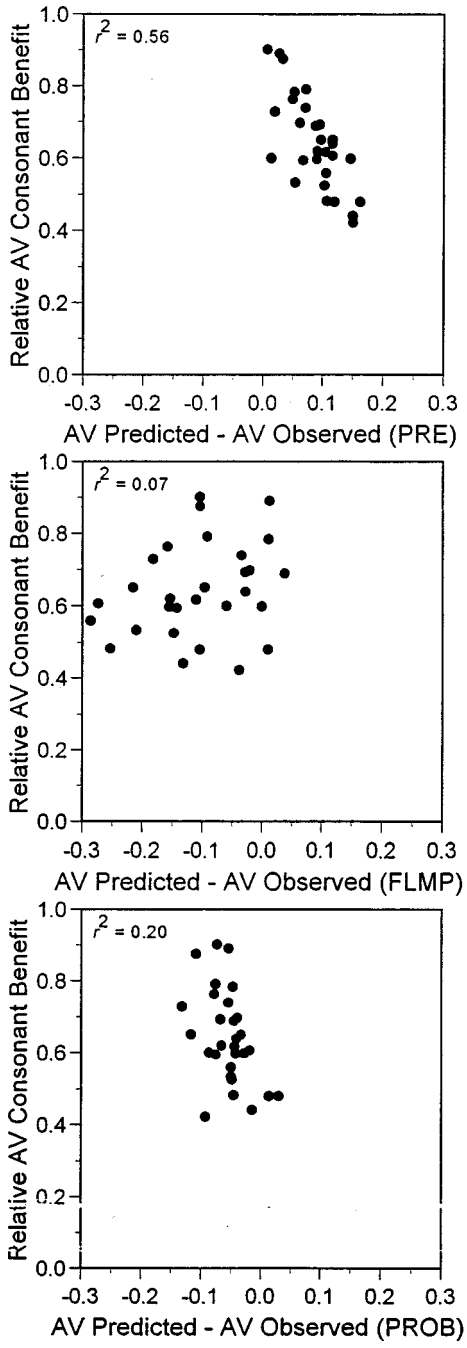

FIG. 7. Relation between derived integration measure ($AV_{PREDICTED} - AV_{OBSERVED}$) and relative AV benefit for consonants.

AV benefit. In comparison, the PROB model accounted for roughly 20% of the variance, whereas the FLMP accounted for about 7% of the variance. The correlations between derived measures of integration efficiency and relative AV benefit were significant for the PRE and PROB models, but not for the FLMP. Empirically, the PRE model appears to provide a better estimate of integration efficiency than either the FLMP or PROB model.

Because the PRE model predicts optimum AV recognition performance, anything less than perfect AV consonant recognition for subjects who are well predicted by the PRE model is probably due to poor cue extraction and not to poor integration. On the other hand, subjects whose AV consonant

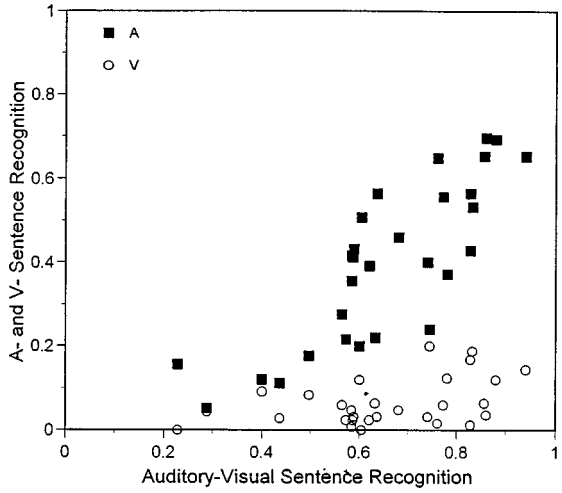

FIG. 8. A and V sentence recognition as a function of AV sentence recognition.

recognition scores fall below PRE model predictions may not be integrating all the unimodal cues available to them. For these subjects, improved AV speech recognition scores may be achieved by focusing on integration training in addition to cue extraction. The amount of AV improvement in consonant recognition that could be expected with integration training is indicated by the performance difference between predicted and observed AV scores shown along the abscissa in the top panel of Fig. 7. The average difference was 8.5% and the maximum difference was 16.1%.

C. Sentence recognition

Recognition results for IEEE/Harvard sentences are shown in Fig. 8. As in Fig. 3, A and V recognition results are shown in relation to AV recognition scores. Auditory-visual sentence recognition of key words (shown along the abscissa) ranged from 23% to 94% (mean=65.5%; s.d. =17.5%). Auditory sentence recognition ranged from 5% to 70% (mean=39.7%; s.d.=19.1%) and visual sentence recognition scores ranged from 0% to 20% (mean=6.5%; s.d. =5.6%). Although there was no appreciable correlation between the subject's A and V scores, and in spite of the very low speechreading scores overall, all subjects benefited from the addition of visual cues. Every subject's AV score was better than his/her A score, even when the V score was 0% correct. A strong correlation was evident between A and AV sentence recognition ($r=0.82$; $p<0.001$). The correlation between V and AV sentence recognition was also significant, but weaker ($r=0.44$; $p<0.02$).

The benefit obtained from combining A and V cues in sentence recognition varied substantially across individuals. To address this issue, relative AV benefit scores, (AV-A/(100-A), were computed for each subject. The average relative benefit was 44% (s.d.=17.8%) with a maximum of 83% and a minimum of 8.5%. The large individual differences in the amount of relative benefit received were only weakly related to the subject's A performance ($r=0.34$). A much better accounting of individual differences in relative AV benefit for sentences was provided by subjects' speechreading scores, in that better speechreaders obtained more AV

benefit for sentences ($r=0.72$).[5] The relatively strong correlation between V sentence recognition and relative AV sentence benefit, in conjunction with the weaker relation observed between visual consonant recognition and relative AV consonant benefit ($r=0.55$), suggests that better speechreaders of sentence materials are able to extract more visual information than the poorer speechreaders with regard to certain cues such as word segmentation and stress, both of which would prove useful in the AV sentence condition (Risberg, 1974; Risberg and Lubker, 1978; Grant and Walden, 1996b). Obviously, these cues would play a much smaller role in consonant recognition than in sentence recognition which might help explain the apparent greater significance of speechreading for AV sentences than for AV consonants.

A second possibility may be that the better speechreaders engage useful higher-level cognitive skills in addition to the bottom-up information extracted from the visual speech signal. With meaningful sentence materials, speechreading requires that subjects not only extract signal cues from visual speech movements, but form linguistic wholes from perceived fragments as well. This ability to perform *perceptual closure* (Wertheimer, 1938; O'Neill and Oyer, 1961; Watson *et al.*, 1996) is useful regardless of modality, especially when the input signals are ambiguous. Therefore, it is possible that better speechreaders of sentence materials have better perceptual closure skills than poorer speechreaders, which would facilitate AV sentence benefit.

D. Relations among consonant and sentence recognition

According to Fig. 1, auditory-visual consonant recognition is primarily a function of A and V cue extraction and cue integration. AV sentence recognition, on the other hand, is a function of A and V signal-cue extraction, cue integration, lexical processes, memory processes, and the use of linguistic and world knowledge in conjunction with semantic and syntactic context. If this conceptual framework is correct, then the proportion of variance in AV sentence recognition data not accounted for by AV consonant recognition is most likely due to individual differences in *top-down* speech recognition processes.

Figure 9 shows the relation between consonant recognition and sentence recognition for A, V, and AV conditions. In all three receiving modalities, the correlations were highly significant ($p<0.007$). For the A and AV conditions, respectively, 52% and 54% of the variance observed in sentence recognition was accounted for by consonant recognition. For the V condition, 25% of the variance in visual sentence recognition could be accounted for by visual consonant recognition. This reduction in the amount of variance explained for the V modality (compared to either A or AV modalities) is probably due to the relatively narrow range of scores observed for visual consonant recognition (mean $=31.2\%$, s.d.$=4.3\%$). In general, however, the data show that variability in A and AV sentence recognition is determined to a great extent by *bottom-up* processes related to cue extraction and cue integration.

With regard to individual differences in the benefit received from combining A and V cues in sentence recognition, the results suggested that speechreading ability, measured either with nonsense syllables or with meaningful sentences, was the most consistent unimodal predictor of AV sentence benefit. For example, measures of relative AV sentence benefit correlated significantly with visual consonant recognition ($r=0.66$, $p<0.001$) and with visual sentence recognition ($r=0.72$, $p<0.001$). In contrast, relative AV benefit was not significantly correlated with auditory consonant or auditory sentence recognition. Finally, although the correlations between measures of relative AV benefit for consonants and relative AV benefit for sentences was significant ($p=0.02$), relative AV consonant benefit accounted for only 18% of the variance in relative AV sentence benefit.

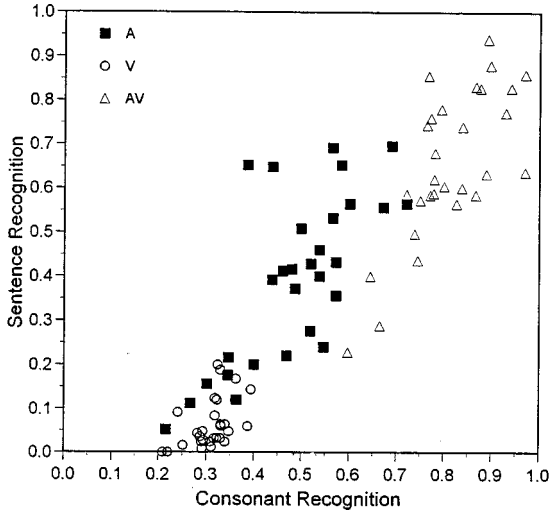

FIG. 9. Relation between consonant recognition and sentence recognition for A, V, and AV modalities.

III. DISCUSSION

The conceptual framework schematized in Fig. 1 highlighted a variety of *bottom-up* and *top-down* sources of information that are likely to be important in AV speech recognition. The general purpose of this work was to further delineate the various factors and perceptual processes that determine individual variability in AV sentence recognition. In this study, we focused on consonant recognition and AV integration at the segmental level and the relation between consonant recognition and the recognition of words in sentences.

Auditory-visual consonant recognition can be reasonably well described as a simple combination of visual place-of articulation cues and auditory manner-plus-voicing cues. This rather simple conception of the problem of predicting AV consonant recognition in individual listeners is supported by the results of Massaro's FLMP and Braida's Prelabeling Model of integration, and by earlier work by Grant and Walden (1996a). As shown in Fig. 2, model predictions of AV recognition given average speechreading skill, depend primarily on which speech features are resolved in the auditory condition, and not on the overall accuracy of auditory speech recognition. For example, individuals who receive only voicing or manner cues through audition are predicted to have higher AV consonant recognition scores

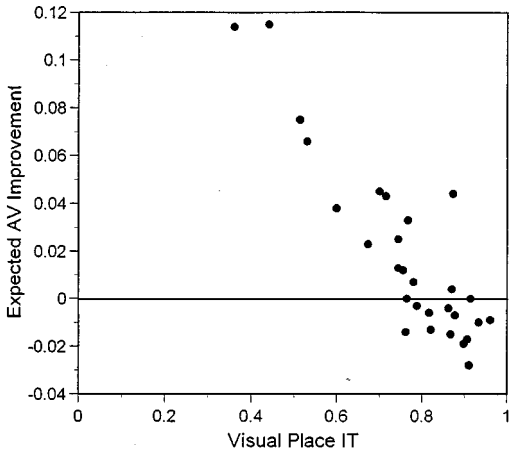

FIG. 10. Predicted AV consonant improvement that would likely result from speechreading training.

than individuals who receive only auditory place-of-articulation cues. These model predictions support the idea that integration of complementary A and V speech features results in higher AV recognition scores than integration of redundant features, as is the case when the A modality contributes primarily place-of-articulation cues. A similar conclusion can be drawn from the study by Grant and Walden (1996a). In that study, normal-hearing listeners were presented with filtered bands of speech in combination with speechreading. Low-frequency bands of speech, which conveyed primarily voicing and manner information, resulted in higher AV recognition of consonants than high-frequency bands which conveyed mostly place information. This was the case, even though the high-frequency bands were often more intelligible than the low bands when presented without speechreading.

In the present study, the ability to extract V+M and P cues from the A and V conditions was quite variable across subjects. For example, when compared to previous speechreading results obtained with normal-hearing subjects (Grant and Walden, 1996a), the HI subjects displayed a significantly wider range of performance for the recognition of V_P cues (36%–96% for the HI subjects as compared to 73%–94% for the NH subjects). For HI subjects with relatively low V_P recognition (below 70%) speechreading training would seem appropriate. Using Braida's model we can estimate the amount of AV improvement expected to result from such training. Model fits were computed for each HI subject using the average visual confusion matrix from Grant and Walden (1996a) in combination with individual auditory confusion matrices and compared to original model fits obtained with the subject's own visual confusion matrix. This average or *generic* visual matrix had a V_P score of 0.87 and represents conservatively what we feel can be achieved through speechreading training (Walden *et al.*, 1977). Figure 10 shows the predicted AV improvements obtained for each subject. According to this analysis, subjects with V_P recognition less than 0.7 would show improvements between 3% and 11.5%.

With regard to auditory consonant features, it is clear that strategies for improving the information transmission of the V+M feature need to be developed, either through auditory training or signal processing. For our subjects, the A_{V+M} feature was received more accurately than the A_P feature, whereas the AV_{V+M} feature was received less accurately than the AV_P feature. Note that the finding for AV feature recognition is precisely the opposite result of classic feature studies of auditory-only listening conditions (e.g., Miller and Nicely, 1955). Manner and voicing information can be represented by time-intensity envelope cues which tend to be more resistant to the effects of hearing loss or background noise than are the rapid spectral transitions and spectral shapes associated with A_P cues (Van Tasell *et al.*, 1987; Rosen, 1989). It is reasonable, therefore, for researchers and clinicians concerned with improving auditory speech recognition to advocate hearing aid fitting and other rehabilitative strategies to improve A_P reception (Rabinowitz *et al.*, 1992). However, to improve AV speech recognition, improving A_{V+M} reception (as opposed to A_P reception) needs to be the focus of rehabilitative efforts, assuming that the individual has at least average speechreading and integration abilities.

The integration processes by which A and V speech cues are combined are not well understood. The results of our efforts to measure this ability across HI listeners suggests that there is substantial intersubject variability in integration efficiency and that better integrators are likely to derive more AV benefit than poorer integrators, at least for consonant recognition.

The integration abilities of individual listeners currently are not subject to direct observation. Instead, they must be derived from speech recognition performance obtained from unimodal and bimodal receiving conditions, and models of the integration process. The approach used in this study was an attempt to partial out the contributions of information extraction and information processing as they relate to AV speech recognition. Braida's PRE model is a theoretically optimal integrator which produces the best possible recognition score for each subject, given their A and V consonant recognition data. The predictions of this model can be used, among other clinical applications, to estimate the performance that may be possible if the subject was able to integrate the available information from the two modalities perfectly. The difference between predicted and observed AV scores suggests that, on average, a gain of 8.5% (maximum gain=16.1%) could be expected for the subjects of this study with appropriate integration training. This model also allows us to test the effectiveness of certain rehabilitation strategies or signal processing algorithms with respect to predicted AV gain. For example, if we eliminated a particular auditory consonant confusion (e.g., /ɑbɑ/ vs /ɑvɑ/) through training or signal processing, it would be possible to calculate the predicted improvement in overall AV recognition score. Similarly, one could estimate the overall benefit of combining several rehabilitation strategies, such as speechreading training and integration training. For example, for the 14 subjects who either received less than 70% place information in the V condition or who were over-predicted by the PRE model by more than 10%, we would expect a potential combined training benefit (speechreading training and integration training) of 9% to 26% depending on the individual subject.[6]

In comparing speech recognition results with nonsense aCa syllables and IEEE sentences, significant correlations were found within receiving condition (i.e., $A_{CONS} \propto A_{SENT}$, $V_{CONS} \propto V_{SENT}$, and $AV_{CONS} \propto AV_{SENT}$). Especially noteworthy was the finding that over 50% of the variability in AV (or A) sentence recognition could be accounted for by AV (or A) consonant scores. In addition, the relative AV benefit for consonants was significantly correlated with the relative benefit for sentences ($r = 0.43$, $p = 0.02$). Thus AV recognition of IEEE sentences and the amount of benefit provided by visual cues to audition is determined, in large measure, by the recognition of medial consonants, which can be fairly well predicted by separate measures of A and V consonant recognition and a measure of AV consonant integration.

When discussing the relationship between AV consonant recognition and AV sentence recognition, it is important to consider the many differences between these two sets of materials. It is well known that fluent speech productions like the IEEE sentences and carefully articulated nonsense syllable productions like the vCv consonant set differ with regard to phonetic (speaking rate, segment duration, etc.), phonological (vowel neutralization, flapping, etc.), lexical, morphosyntactic, and semantic factors. These differences are likely to weaken the association between segment articulation scores and sentence intelligibility scores. In addition, they suggest several possible processes important for fluent speech recognition, such as the ability to use lexical, semantic, and grammatical constraints (Fletcher, 1953; Boothroyd and Nittrouer, 1988), short-term memory, and the processing speed required to make lexical decisions (Seitz and Rakerd, 1996), that may vary significantly across individuals. Given this array of different factors separating the recognition of nonsense medial consonants in a single vowel context from that of meaningful sentence materials, the strength of the observed association across HI subjects found in this study is quite remarkable.

In summary, individual performance on AV speech recognition tasks involving words or sentences ultimately depends on how lexical access is affected by information provided by auditory and visual sources, the processes by which information is integrated, and the impact of top-down contextual constraints and memory processes. Our efforts thus far to evaluate these factors in individual subjects have focused mainly on nonsense syllable recognition (consonant recognition and the recognition of selected speech features), the recognition of certain prosodic contrasts (Grant and Walden, 1996b), and segmental integration skills. These studies have shown that the benefit of visual cues in AV speech recognition can be readily interpreted in terms of the degree of redundancy between A and V cues, with greater redundancy leading to smaller benefits. Furthermore, there appear to be substantial individual differences regarding the efficiency with which A and V segmental cues are integrated. These differences in integration abilities can also lead to fairly large differences in the amount of AV benefit observed. Taken together, an accounting of the redundancy between A and V features and a measure of integration efficiency can account for the bulk of the variability in AV segment recognition. Additional work is required, however, to more fully account for the variability observed in the recognition of words and sentences. Ongoing efforts to expand this work to include the recognition of additional speech segments in different phonetic environments, multi-syllabic consonant and vowel sequences (to mimic speech rates found in fluent productions), measures of AV integration in connected speech, and measures of lexical redundancy and semantic context usage across individual subjects, will no doubt improve our overall understanding of AV speech recognition.

ACKNOWLEDGMENTS

This research was supported by Grant Nos. DC 00792 and DC 01643 from the National Institute on Deafness and Other Communication Disorders to Walter Reed Army Medical Center, and by the Clinical Investigation Service, Walter Reed Army Medical Center, under Work Unit # 2528. The authors would like to thank Dr. Louis Braida for fitting our consonant data with the Prelabeling Model of Integration. We would also like to thank Drs. Dominic Massaro and Michael Cohen for help in implementing the fixed form of the FLMP, and for numerous helpful discussions regarding theories of information extraction and information processing. Helpful comments on a earlier draft of the manuscript were provided by Dr. Winifred Strange and by two anonymous reviewers. All subjects participating in this research provided written informed consent prior to beginning the study. The opinions or assertions contained herein are the private views of the authors and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense.

[1]The visual confusion matrix used for these model fits was obtained using the same consonant stimuli used in the present study. The results of 11 normal-hearing subjects were pooled to form a single confusion matrix. The overall percent information transmitted (IT) was 55%. The percent place IT was 87%.

[2]AV predictions based on Massaro's (1987) Fuzzy Logical Model of Perception (FLMP) produced nearly identical results as those shown in the figure. Descriptions of the PRE and FLMP model are presented in the methods section.

[3]In Massaro's evaluation of the FLMP, response probabilities obtained from the unimodal A and V confusion matrices are treated as approximations to the auditory and visual truth values. The program STEPIT (Chandler, 1969) is used to derive a set of optimal feature values which are then used in conjunction with Eq. (3) to predict the AV response. This iterative process is accomplished with prior knowledge of the AV response probabilities by minimizing the average root mean square deviation between the predicted and obtained AV responses, the original and adjusted A responses, and the original and adjusted V responses. Thus by manipulating the original A and V response patterns by small amounts, application of the multiplicative rule results in a better fit than if the multiplicative rule were applied to the original unimodal matrices. This version of the FLMP is known as the variable FLMP. The variable FLMP although providing excellent fits to AV data, can fail to demonstrate differences among subjects with similar A and V matrices but different AV matrices. Such subjects are likely to be fit equally well by the variable FLMP model which, according to Massaro, suggests that the integration processes are similar. However, for the purposes of measuring individual differences in AV integration, the model needs to distinguish among subjects according to the efficiency at which A and V cues are integrated, even when subjects use similar integration processes.

[4]The number of subjects whose observed AV consonant scores exceeded their predicted scores was 25 and 27 for the FLMP and PROB models, respectively.

[5]Although the average sentence speechreading score was extremely low, there was nevertheless a range of scores between 0% and 20% correct to

support the correlations between speechreading performance and relative AV sentence benefit. It should be noted that with low-context IEEE materials, speechreading scores of 15%–20% reflect excellent speechreading skills.

[6]Estimates of training benefit assume that speechreading training would increase the number and recognition accuracy of place-of-articulation categories to that of the average normal-hearing subjects studied by Grant and Walden (1996a). Further, it was assumed that integration training would result in integration efficiency ratios (i.e., $AV_{OBSERVED}/AV_{PREDICTED}$) between 0.9 and 1.0.

An analysis of the effect of basilar membrane nonlinearities on noise suppression

Jayadev Billa

(Received 12 September 1996; accepted for publication 4 February 1998)

Computational models of the peripheral auditory system have largely modeled basilar membrane (BM) mechanics as a linear filter-bank-like entity. Recent mathematical work on the nature of auditory system noise suppression allows us to analyze and argue for the incorporation of BM nonlinearities into these models. This analysis shows that vowel perception improves with increasing presence of BM nonlinearities whereas consonant perception degrades with increasing influence of BM nonlinearities. Experimental results on tones and real speech corrupted by noise corroborate the analysis as well as suggest a novel approach to speech processing. © *1998 Acoustical Society of America.* [S0001-4966(98)04405-1]

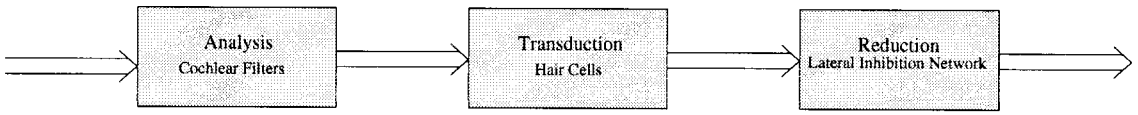
INTRODUCTION

Recent studies have conclusively shown the presence of nonlinearities in the basilar membrane (BM) [e.g., see Robles (1986)]. Nonlinearities in the basilar membrane result in a loss of sensitivity, i.e., broadening of basilar membrane filtering with increasing stimulus levels and has been observed by numerous groups [e.g., see review by Ruggero (1992)]. Although the presence of nonlinearities has long been known, early models essentially assumed the BM to be linear with the nonlinearities concentrated elsewhere (Seneff, 1986; Shamma *et al.*, 1986; Meddis and Hewitt, 1991). As a consequence, most models of the auditory periphery followed a linear filtering stage with the various nonlinearities assumed to be present within the auditory periphery. This type of modeling was able to capture most of the observed experimental results from studies of neural representation of sounds within various species. Work by Deng *et al.* (Deng and Geisler, 1987; Deng *et al.*, 1988) showed that the presence of a nonlinearity within the BM could capture certain salient characteristics of experimental neural data which cannot be captured by a linear BM model followed by nonlinearities modeled at the transduction stage. There is still much controversy over exactly where and how these nonlinearities occur within the BM. For this discussion, we limit ourselves to the effects of such nonlinearities, specifically the observed broadening of BM filtering with increasing stimuli levels.

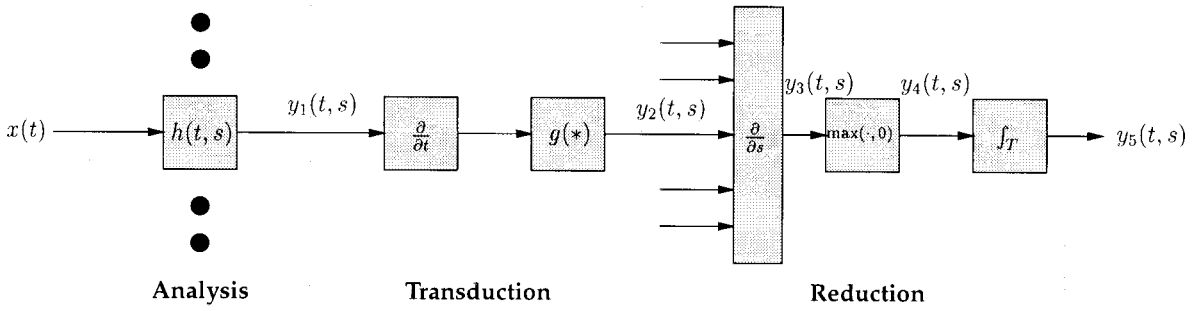
The noise suppression abilities of the peripheral auditory system (PAS) has been demonstrated by many groups, both in physiological experiments (Delgutte and Kiang, 1984a; Geisler and Gamble, 1989; Sachs *et al.*, 1983) and in the responses of models of the PAS (Deng and Geisler, 1987; Deng *et al.*, 1988; Deng and Kheirallah, 1993; Ghitza, 1988; Payton, 1988). This noise ''robustness'' is commonly attributed to the filtering action of the BM. Linear time-invariant filtering approaches have allowed several groups (Ghitza, 1988; Payton, 1988; Ghitza, 1992; Seneff, 1986) to obtain encouraging results for speech processing. Some researchers (Ghitza, 1993, 1994; Giguère and Woodland, 1994a, b) have incorporated BM nonlinearities into their models to accurately model data from physiological experiments. However, the lack of any compelling evidence that such an inclusion would help in applications, such as speech processing, provides little motivation for their integration into such models.

Recent work, initially by Yang *et al.* (1992) and later by Wang and Shamma (Wang *et al.*, 1993; Wang and Shamma, 1994), on the representation of sounds within the early auditory system provides insight into the nature of noise suppression by the PAS. Their work accounted only for the case of a linear time-invariant BM. In this work we account for the effects of basilar membrane nonlinearities, in particular, the broadening of BM filtering with increasing stimulus levels. We proceed by defining a suitable measure that responds to this broadening of BM filtering and accounting for it in our analysis. This analysis shows that in empirical models of the auditory periphery, BM nonlinearities act in a manner that strengthens perception of vocalic sounds such as vowels in noise but degrades perception of consonants such as fricatives supporting evidence from physiological studies such as Delgutte and Kiang (Delgutte, 1984; Delgutte and Kiang, 1984a, b, c, d) and Geisler and Gamble (1989). This extension is the essential point of this correspondence.

The organization of the paper is as follows: Section I briefly reviews the early auditory system model used in Wang and Shamma's (1994) original analysis. In Sec. II, we outline Wang and Shamma's analysis forming the background for our extension. Our analysis extending Wang and Shamma's work to account for basilar membrane nonlinearities proceeds in Sec. III. Demonstrations of the effect of nonlinear BM filtering on tone, natural vowel stimuli, and natural consonant stimuli are provided in Sec. IV. Finally in Sec. V we conclude with a brief summary and possible implications of this work in areas such as speech processing and recognition.



(a) Macroscopic view.



(b) Expanded view.

FIG. 1. The early auditory system model. A functional view of the peripheral auditory model is shown in (a), and an expanded view is presented in (b). The analysis stage corresponds to basilar membrane filtering modeled as a filter bank, the transduction stage to transduction of basilar membrane motion into neural firings in the auditory nerve and the final reduction stage corresponding to information extraction in higher areas of the auditory nervous system. See text for a detailed description.

I. REVIEW OF THE EARLY AUDITORY SYSTEM MODEL

The early auditory system constitutes the system that performs the initial transformation of auditory information (sound) from pressure differentials in air to the initial neural representations in the auditory nerve. These initial neural representations are then further processed at higher regions of the auditory nervous system. The interested reader is referred to a standard text such as Pickles (Pickles, 1988) for an in-depth introduction to the anatomy and physiology of the auditory system. Typically, models of the early auditory system are composed of three cascaded stages: analysis, transduction, and reduction as shown in Fig. 1(a). The model used in our analysis strongly follows the one described in Wang and Shamma (1994). The only modifications are that certain stages, which are not central to the analysis, have been discarded.

A. Analysis

Sound, in the form of pressure differentials in the surrounding air, impinges on the tympanic membrane setting up sympathetic vibrations which are then transmitted to the inner ear (cochlea) via the middle ear ossicles. The cochlea can be likened to a fluid-filled spiral tube separated into two primary ducts by the cochlear partition which consists of the basilar membrane (BM) and associated structures. The stiffness and width of the BM varies significantly from a narrow and stiff base to a much broader and compliant apex. The change in stiffness causes the BM to respond selectively to different frequencies, the base being most responsive to high frequencies and the apex most sensitive to low frequencies. This sensitivity results in a filtering action that decomposes the acoustic signal into spectral bands akin to a filter-bank decomposition but differing in the nonlinear intensity-dependent nature of BM filtering. The cochlea thus decomposes the input signal into constituent spectral components at different spatial locations in an orderly manner. See Pickles (Pickles, 1988) for a more detailed and in-depth exposition.

Functionally, one may model the BM as a linear time-invariant (LTI) filter bank and this is indeed the most common approach in computational models used in applications other than the actual modeling of the PAS. Such an approach has the advantage that it is relatively simple to implement, but suffers in that BM nonlinearities are completely ignored. These nonlinearities may be important in some applications like speech processing, indeed some models incorporating BM nonlinearities have demonstrated significant noise robustness, e.g., Deng *et al.* (Deng and Geisler, 1987; Deng *et al.*, 1988).

Our current model differs from many models of the auditory periphery in that the assumption of a linear and broad BM filtering has been discarded in favor of an explicit attempt to crudely model the BM filter bank as a dynamic system that changes its characteristics with sound-pressure level (SPL). This has allowed us to investigate in a tractable manner the effect that such BM nonlinearities has on the resulting peripheral auditory representation. We have indicated in the Introduction that BM nonlinearities affect filtering at high SPLs and at low SPLs the filtering is essentially linear. This may not be a commonly accepted view. However, due to the phenomenological nature of our model this course does not affect the analysis presented here, an argument for BM nonlinearities at low SPLs and progressive linearization of the BM still results in the same analysis.

Ideally one would like to model the filter bank as a dynamic system that changes its characteristics with sound-

pressure level. In practice, however, this is not a trivial issue [e.g., see Carney (1993) for one approach]. For the work presented, we make the reasonable assumption that the BM is LTI at a *particular* sound level. Thus in our implementation we use three different filter banks each of which represent the state of the BM filtering at one of three different sound levels. This approach is similar to that of Jenison *et al.* (1991) in that we try to capture the effect of BM nonlinearities by the use of several linear time-invariant filter banks. In later work, Jenison (1991) used a dynamic model which incorporated nonlinearities based on the responses of single auditory-nerve fibers directly into the model. We have, however, decided to follow the original idea in Jenison *et al.* (1991) in view of its simplicity. The choice of implementation of the nonlinear BM filter bank has no effect on the analysis itself, the phenomenological nature of analysis renders it valid for any implementation scheme.

If we denote the sound signal as $x(t)$, from Fig. 1(b), the output of the BM model is given as[1]

$$y_1(t,s) = x(t) *_t h(t,s), \tag{1}$$

where $*_t$ represents convolution in time and $h(t,s)$ the response of the cochlear filter at location s on the basilar membrane at any chosen sound level.

The filters chosen in our implementation were designed to be highly asymmetric and to resemble basilar membrane filters at high, moderate, and low sound-pressure levels. The filter for moderate sound-pressure levels is virtually identical to the one described in Wang and Shamma (1994) which was designed to produce the effects of upward masking and two-tone suppression. The filters for low and high sound levels were designed to follow the reasoning in Sec. III, i.e., to have no change in the high-frequency edge of cochlear filters and a marked change in the low-frequency edge of the cochlear filters. These filters were not designed with any considerations other than the ones described above. This is an overtly simplified model of the filtering stage, intended solely to provide simulation results in a tractable manner. As previously stated, the analysis presented here is independent of the implementation and addresses only the effects of the broadening of BM filtering without regard to the nature or physical process by which this broadening is achieved.

The cochlear filters responses are also related by a simple dilation (Wang and Shamma, 1994; Jenison *et al.*, 1991). This allows us to simply design a single seed filter and to obtain the remaining filters of the filter bank by dilating it. This results in filters that are equally spaced on a logarithmic scale. Mathematically:

$$H(\omega,s) = H_{\text{seed}}(a^s \omega) \tag{2}$$

for some constant a and seed filter $H_{\text{seed}}(\omega)$.

B. Transduction

Basilar membrane motion is transformed into neural firings through its coupling to the auditory nerve. Initially, the motion of the basilar membrane causes deflections in inner hair cell cilia. This ciliary displacement is transformed into a modulation of receptor potential which, in turn, modulates the release of a chemical neurotransmitter. The neurotransmitter release then results in depolarization of the auditory-nerve fibers innervating the inner hair cells.

These stages of fluid-cilia coupling, cilia deflection-electrical potential transformation, and neurotransmitter release can be effectively modeled as a three-stage model of transduction: a velocity coupling stage (a time derivative), a memoryless, compressive nonlinearity (a sigmoid-like function), and a low-pass filter in cascade.

The low-pass filter essentially removes frequencies above 4 kHz. For frequencies below 4 kHz, the low-pass filter is in its passband and phase locking is in effect. Under phase locking, neural firing patterns are largely governed by the more intense frequency components of the input stimulus. Phase locking is observed only for frequencies below 4 to 5 kHz, beyond which the inner hair cell receptor potentials can no longer effectively modulate the neurotransmitter release. Due to the high correlation between signal harmonics and neural firing under phase locking, the fine temporal variations in the structure of the cochlear filtered input signal are preserved. This retention of temporal variations by phase locking is important in the subsequent enhancement of phase cues by the lateral inhibition network (LIN) described in Sec. I C. As this analysis mostly concerns itself with the lower frequencies where phase locking is in effect and the low-pass filter is mostly in its passband we have ignored the filter in the current treatment.

The output of this stage can be written as

$$y_2(t,s) = g(\partial_t y_1(t,s)). \tag{3}$$

Consistent with the earlier analysis of Wang and Shamma, we consider the simplifying assumption of a high-gain nonlinearity, in which case, the nonlinearity reduces to a step function.

The justification for this essentially one of simplification. The original formulation allowed for a compressive nonlinearity to model the effects of the nonlinear transduction of ciliary displacement to ionic conductance (Shamma *et al.*, 1986). Further, this nonlinearity was described by a monotonically nondecreasing sigmoidal function (Shamma *et al.*, 1986; Wang and Shamma, 1994). The hair cell does have a finite dynamic range of about 30–40 dB. Below this range, the gain is negligible and, above it, there is negligible change in gain due to saturation of the hair cell response. Our approach here of replacing the sigmoidal nonlinearity with a high gain nonlinearity, the step function, allows us to develop a more tractable analysis. It should be noted that at most sound levels the nonlinearity is driven into its high gain region and thus this assumption does not significantly affect the analysis.

A comprehensive treatment of the model and background and justification for the assumptions can be found in Shamma *et al.* (1986); Yang *et al.* (1992); Wang and Shamma (1994).

C. Reduction

The neural firings produced by the depolarization of the auditory-nerve fibers are then passed on to the cochlear nucleus. The cochlear nucleus and in turn the higher levels of

the auditory nervous system integrate and process the information in the auditory nerve before finally extracting the biologically important acoustic features.

The current model uses a lateral inhibition network (LIN) to model the information enhancement and extraction process. Lateral inhibition networks are found in many biological systems and can be modeled (in their simplest form) as a single layer feedforward or recurrent neural network with mutually inhibitory weighting. A comprehensive overview of the present discussion can be found in Shamma (1985a, b, 1988) and Wang and Shamma (1994).

Essentially the LIN seeks to extract spatial cues and enhance the resulting representation by means of a spatial derivative operation which simply subtracts the output of adjacent channels. At low frequencies the average rates and synchrony patterns provide the spatial cue and for higher frequencies this is primarily due to the rate profiles which display peaks at the characteristic frequencies (CFs) that correspond to stimulus harmonics. The LIN presented in this paper was initially proposed by Shamma (1985b, 1988) and was able to extract key formant and harmonic features from neural firing patterns of the cat auditory nerve. The current model follows the one described in Wang and Shamma (1994). This spatial differential approach to enhancing the representation has been advocated in various forms by other authors. Holton *et al.*'s ''local time-domain phase-correlation'' approach suggests using a ''spatial filter'' on the output of local synchrony detectors to enhance formant information of vocalic segments (Holton *et al.*, 1992). This approach of synchrony detection and spatial filtering closely resembles the LIN based spatial cue extraction scheme presented here. Also relevant here is Huggins' phase model (Huggins, 1952) which suggested that the phase cues could be an effective information carrier. Following from the fact that for linear filters, rapid changes in amplitude response also correspond to rapid changes in phase response, Huggins' phase model shows that frequency components can be sharpened and extracted from the phase of damped input stimuli (Huggins, 1952). This is very similar to the current treatment whereby the LIN uses local phase shifts, which perform the function of frequency markers marking key frequency components, to extract spatial cues.

The current inhibitory network is implemented as a two-stage process. An initial spatial derivative stage that models the lateral coupling/inhibition within the LIN neuron layer and a half-wave rectifier that models the neuronal nonlinearity. This is followed by a temporal integration that mimics the inability of the auditory nervous system to follow rapid temporal variations. This deviates slightly from the original model as described in Wang and Shamma (1994) in that the spatial derivative is considered ''perfect'' as opposed to the ''leaky'' nature in the original formulation. Though this is a slightly unrealistic assumption it greatly simplifies the analysis and implementation and does not detract from the basic thrust of the analysis presented here. In fact the implementation of Wang and Shamma also makes this assumption.

Mathematically the LIN operation can be written as

$$y_3(t,s) = \partial_s y_2(t,s) \tag{4}$$

$$= g'(\partial_t y_1(t,s))\partial_s \partial_t y_1(t,s), \tag{5}$$

$$y_4(t,s) = \max(y_3(t,s),0), \tag{6}$$

$$y_5(t,s) = y_4(t,s) *_t \Pi(t), \tag{7}$$

where the final temporal integration stage has been denoted as a time convolution with a low-pass filter $\Pi(t)$. The spatial difference $\partial_s y_2(\cdot)$ is essentially a filtering operation. The notion of the LIN as a spatial difference filter will be used throughout this paper to further the analysis presented here.

The output of this stage $y_5(t,s)$, allowing for all our approximations and possible modeling errors, represents the sound as it would be portrayed to the higher regions of the auditory nervous system. This output is referred to as the auditory spectrum.

As mentioned earlier, under phase locking, fine temporal variations in the response are retained as phase cues. The LIN subsequently extracts and enhances these phase cues as a spatial operation (Shamma, 1985b). In regions where phase locking is no longer in effect, these cues are produced by the rate profile of neural responses, which show peaks at the appropriate CF (Shamma, 1985b). The auditory spectrum can be described as an enhanced measure of the synchrony content of the stimulus. Thus it retains the salient aspects of the incident sound, much like that provided by the Fourier transform but in a completely different manner.

The auditory spectrum described here is similar to two other approaches: the Ensemble Interval Histogram (EIH) approach (Ghitza, 1992) and the ''dominant frequency'' approach (Carlson *et al.*, 1975). The EIH is formed by passing sound through a set of cochlear filters each of which is followed by level crossing detectors, the output of the ensemble of level-crossing detectors then represents the firing activity in the auditory-nerve fiber array (Ghitza, 1992). The ''dominant frequency'' approach similarly possesses a cochlear filter bank but follows each channel filter with zero-crossing counting averaged over a 100-ms interval converted to frequency (Carlson *et al.*, 1975). A histogram formed by counting the number of channels which have the same frequency within a quantized range of 75 Hz then produces the ''spectrum'' (Carlson *et al.*, 1975). All these approaches deliver a representation of the frequency content by means of a measure of coherent neural activity in the auditory nerve. The notable difference between the current approach and that of others is the latter's emphasis on the temporal details conveyed by the nerve fiber without regard to the spatial details conveyed in the nerve fiber identity, i.e., ''temporal-nonplace'' approach versus the current ''temporal-place'' advocated here. The temporal-place approach is not unique to this work and has been described by others (Young and Sachs, 1979; Shamma, 1985b; Holton *et al.*, 1992).

The next section reviews the stochastic analysis of the model due to Wang and Shamma (1994) allowing for our modifications to the model as described above.

II. NOISE SUPPRESSION IN THE EARLY AUDITORY SYSTEM ASSUMING A LINEAR BM

If the sound signal is modeled as a zero mean random process it follows, from the analysis by Wang and Shamma

(1994), that all the outputs at various stages $y_1(t,s)\cdots y_5(t,s)$ will also be random processes that are not necessarily zero mean. For such a situation, assuming the properties of the filter $\Pi(\cdot)$ are known, it can be argued that $y_5(t,s)$ is a first-order statistic of the auditory spectrum defined as the ergodic mean of $y_4(t,s)$. The auditory spectrum is then characterized by $E[y_4(t,s)]$, which, for a monotonically nondecreasing nonlinearity $g(t)$, is given by Wang and Shamma (1994):

$$E[y_4(t,s)]=E[g'(U)E(\max(V,0)|U)], \tag{8}$$

where $U=\partial_t y_1(t,s)$ and $V=\partial_s\partial_t y_1(t,s)$.

For our prior choice of hair cell nonlinearity as a step function, (8) can be rewritten as in Wang and Shamma (1994):

$$E[y_4(t,s)]=E(\max(V,0)|U=0)f_u(0), \tag{9}$$

where $f_u(0)$ is defined to be the probability density of $U=0$.

Further, if we let the sound signal $x(t)$ be weakly stationary zero mean Gaussian and define r, σ_u, σ_v to be the correlation coefficient and the standard deviations of U and V, respectively, one can further reduce (9) to

$$E[y_4(t,s)]=\frac{1}{2\pi}\frac{\sigma_v}{\sigma_u}\sqrt{1-r^2}. \tag{10}$$

If we denote the spectral density of input sound $x(t)$ as $S_x(\omega)$ we also have

$$\sigma_u^2=\frac{1}{2\pi}\int|\omega H(\omega,s)|^2 S_x(\omega)d\omega, \tag{11}$$

$$\sigma_v^2=\frac{1}{2\pi}\int|\omega\partial_s H(\omega,s)|^2 S_x(\omega)d\omega, \tag{12}$$

$$r=\frac{\sigma_{uv}}{\sigma_u\sigma_v}, \tag{13}$$

$$\sigma_{uv}=\frac{1}{2\pi}\int\omega^2 H^*(\omega,s)\partial_s H(\omega,s)S_x(\omega)d\omega, \tag{14}$$

where from (2),

$$\partial_s H(\omega,s)=(\log a)\omega\partial_\omega H(\omega,s). \tag{15}$$

Now to estimate the noise-suppression properties of the auditory spectrum, consider the case of white Gaussian noise as input [i.e., $S_x(\omega)=1$]. We can write (10) as[2]

$$E[y_4(t,s)]=\frac{1}{2\pi}\frac{\sigma_{v|n}}{\sigma_{u|n}}\sqrt{1-r_n^2}, \tag{16}$$

where $\sigma_{v|n}$ and $\sigma_{u|n}$ are the standard deviations of U and V, respectively, in the presence of Gaussian white noise.

Now consider the presence of a tone of frequency ω_0 in the input with the noise, i.e., $S_x(\omega)=\sigma^2\pi\delta(\omega\pm\omega_0)+1$, σ^2 being equal to the signal-to-noise ratio (SNR). For this case, (10) reduces to

$$\sigma_v^2=\sigma_{v|n}^2,$$

$$\sigma_u^2=\sigma_{u|n}^2+\sigma^2|\omega_0 H(\omega_0,s)|^2=\frac{\sigma_{u|n}^2}{\beta^2},$$

$$r=r_n\beta,$$

with β defined as

$$\beta=\frac{\sigma_{u|n}}{\sigma_u}=\left(1+\left|\frac{\sigma\omega_0 H(\omega_0,s)}{\sigma_{u|n}}\right|^2\right)^{-1/2}. \tag{17}$$

All of which yields, for a tone in noise,

$$E[y_4(t,s)]=\frac{1}{2\pi}\frac{\sigma_{v|n}}{\sigma_{u|n}}\cdot\beta\cdot\sqrt{1-r_n^2\beta^2}. \tag{18}$$

From (17) and (18) one can see that for filter channels far from the tone frequency, the filter removes most of the spectral energy around the tone frequency, i.e., $H(\omega_0,s)\approx 0$ and β varies little, but for channels whose filtering retains most of the spectral energy at the tone frequency, β is significantly smaller than in the prior case. At the channel corresponding to the tone frequency itself, the tone falls in the passband of the differential filter, thus, $\sigma_{v|n}/\sigma_{u|n}$ is large relative to the neighboring channels. As a result the tone passes through the model retaining most of its spectral characteristics. The net effect on the auditory spectrum is then to ''suppress'' channels close to the tone frequency ω_0 while at the same time retaining the key spectral features, in this case the features of the tone.

Alternatively, from (10) a more intuitive characterization is possible. Noting that σ_u^2 and σ_v^2 can be associated with the spectral energy in the cochlear and differential bands, $E[y_4(t,s)]$ represents the self-normalized spectral profile and hence auditory spectrum. The term *self-normalized* arises from the fact that the spectral profile, the output of the BM, is divided by a smoothed spectral profile of itself, the output of the differential component (Wang and Shamma, 1994). This normalization is not easily quantified, as it depends very much on the spectral profile of the input signal. The enhancement (normalization) received by spectral peaks resolved by the narrow-band differential filter will be high, resulting in a ''heightening'' of spectral peaks, as the cochlear filter integrates energy in the neighboring valleys as well as at the peak. This results in an overall enhancement of the spectral representation of the stimuli.

In the presence of noise, it should be clear from the previous argument that enhancement occurs for SNRs that *at least* locally exceed 0 dB. This is not such a stringent requirement as it would seem, even at global SNRs$<$0 dB, the vocalic portions typically exceed the 0 dB SNR level. For example, consider a tone in noise, even when the global SNRs$<$0 dB, if we take any period over which the tone is present the spectrum will still show a strong peak at the tonal frequency. This peak will be enhanced more if we had band-passed the signal around the tonal frequency, thus locally increasing a relatively low global SNR. Unvoiced portions would, however, suffer significant degradation and would typically not be as enhanced as the vocalic portions. This is as much a function of the structural differences between voiced and unvoiced sounds as that of the signal energies. Most voiced stimuli have strong frequency components with relatively large signal energy due to their underlying periodicity whereas most unvoiced stimuli have weak frequency

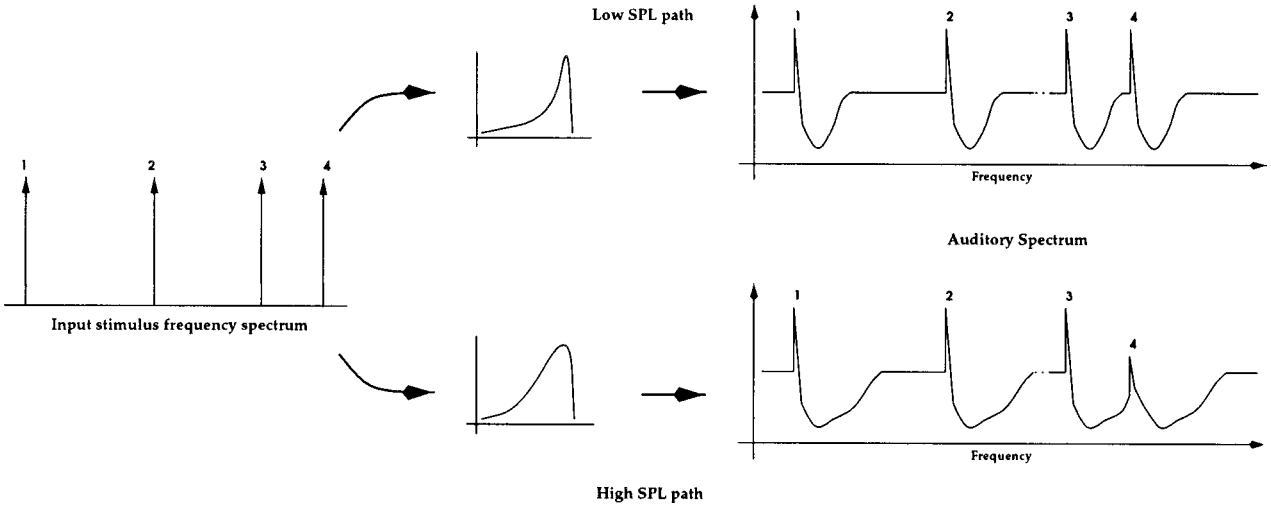


FIG. 2. An exaggerated demonstration of the auditory spectrum of a contrived input stimulus at low and high SPLs. The top path shows the auditory spectrum for low SPL input stimulus, the lower path, the auditory spectrum for a high SPL input stimulus.

components with relatively low signal energy spread out over the frequency range due to exactly the opposite, i.e., the lack of such periodicity.

Of interest here is the relationship with Young and Sachs' average localized synchronized rate (ALSR) representation (Young and Sachs, 1979). Both the current auditory spectrum and ALSR approaches use a spatial tonotopic representation to describe the stimulus spectrum. Briefly, to obtain a measure of frequency content at a particular frequency the ALSR algorithm ''filters'' the spectrum obtained via a Fourier transform of the period histogram of each fiber, by forming an average of the response of fibers whose CFs lie in a narrow band around that frequency. Their approach is to focus on the encoding potential in a single channel, the ro-

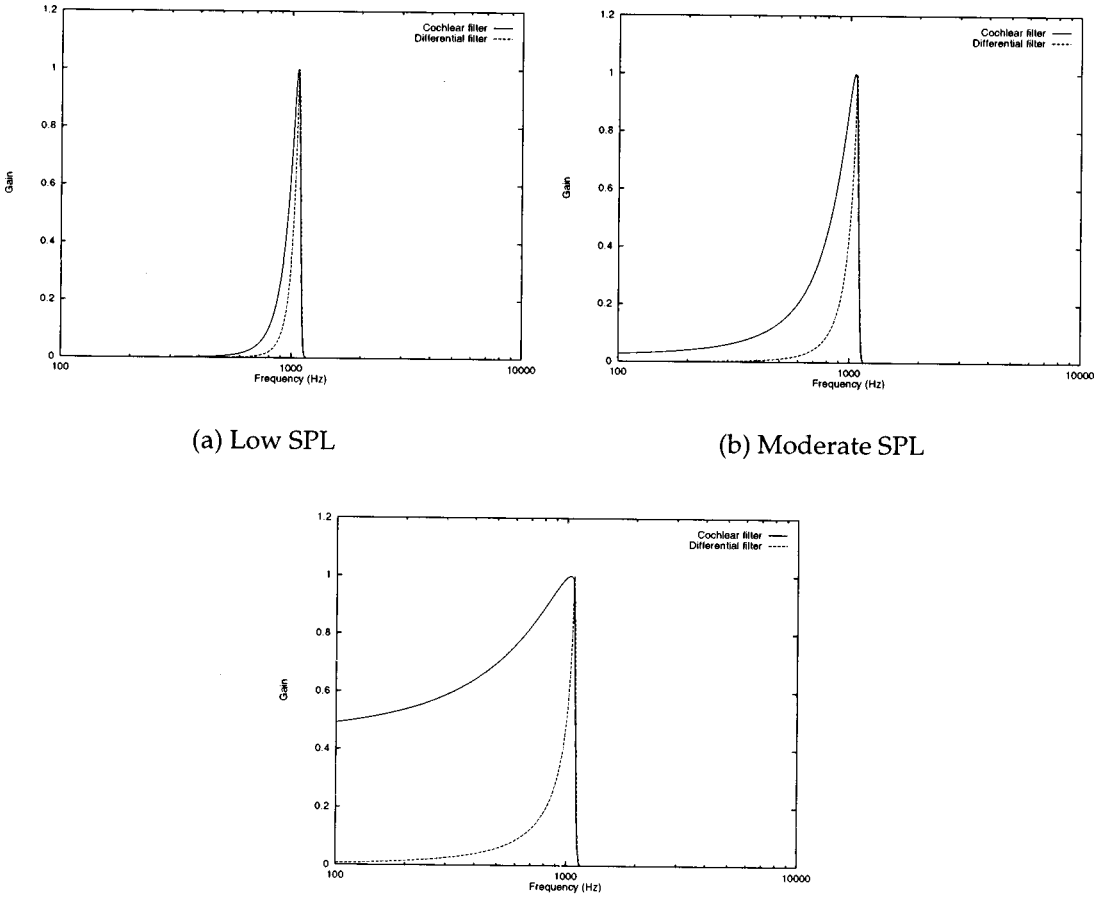

FIG. 3. Seed filters. The solid line is the magnitude response of the cochlear filter, the dotted line is the corresponding differential filter.

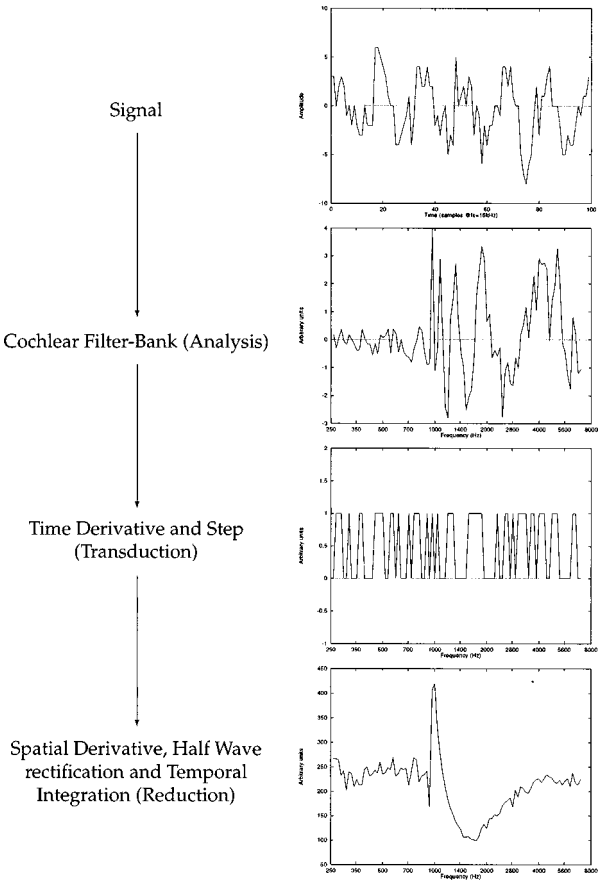

FIG. 4. A pictorial description of the procedure used to generate the auditory spectrum shown in Fig. 5(c) for a tone in noise at 0 dB SNR. The top panel shows the input stimulus, a 1-kHz tone in noise at 0 dB SNR. The next three panels show the output at each of the major stages of the model plotted as the CF's of cochlear channel (x axis) versus their output (y axis).

bustness arising from ''suppressing'' the encoding potential of other channels. The current analysis describes essentially the same idea with its *channel specific* self-normalization. There are also some key differences between the ALSR approach and the current treatment, the most important of which is the emphasis on cross-channel correlation in the current approach which the ALSR essentially ignores. The effect of the cross-channel correlation is to emphasize the parts of the spectral profile that show the most change.

The expressions above, due to Wang and Shamma (1994), form the basis of our analysis in the next section. Our goal is to describe the effect of basilar membrane nonlinearities, specifically those that result in the broadening of BM filtering, on the above analysis.

III. NOISE SUPPRESSION IN THE EARLY AUDITORY SYSTEM ASSUMING A NONLINEAR BM

In order to describe the effect of a change in filtering characteristics of the basilar membrane we need to define a suitable characteristic that responds to this change. One such characteristic is the average power of the filter channel $H(\omega,s)$ defined as

$$E[|h(t,s)|^2]=\int |H(\omega,s)|^2\, d\omega. \tag{19}$$

Further, let us define a *filter form factor*, Γ, as the ratio of the root average power of the filter and a fixed reference filter, i.e.,

$$\Gamma_s=\left(\frac{\int|H(\omega,s)|^2\, d\omega}{\int|H^{\mathrm{ref}}(\omega,s)|^2\, d\omega}\right)^{1/2}, \tag{20}$$

where the explicit dependence of Γ on the channel for which it is computed is shown.

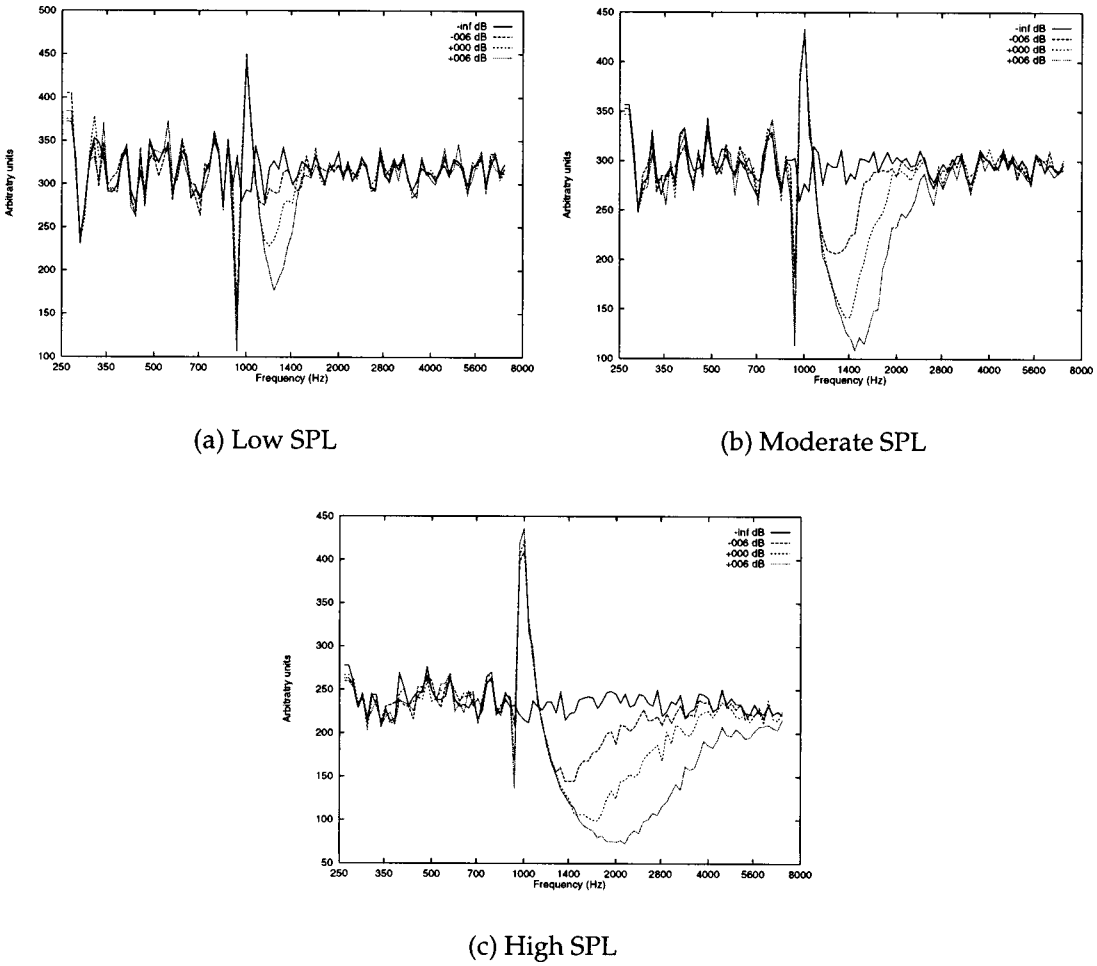
With this definition we can condense the complex nonlinear amplitude dependent behavior of BM filtering into a simple amplitude dependent constant, Γ. Though this simplification ignores the richness of BM nonlinearities it does, however, allow us to develop a reasonable and tractable analysis of its behavior.

We now contend that, for cochlear filters, the overlap is such that the differential filter is essentially independent of the originating cochlear filters, i.e., the nonlinearities only affect the cochlear filter. First, at least up to about 2 kHz, there is the observed lack of any appreciable change in the high-frequency edge of cochlear filters [e.g., the discussion in Secker-Walker and Searle (1990)]. Second, there is a high degree of overlap between the responses of adjacent channels. Assuming 3000 channels and equal logarithmic distribution of CFs in a human cochlea, the overlap between adjacent channels will still not exceed 100 Hz, compared to a maximum BW of approximately $\frac{1}{10}$ of an octave at normal conversational sound levels (Evans, 1982). Clearly a differential filter would possess a bandwidth (BW) significantly smaller than the originating cochlear filters at almost all sound levels. For these reasons we will associate the factor Γ exclusively with the increase in BW of the cochlear filter, all other effects such as those due to the increased energy in the channel due to increased sound level are completely ignored. This is not a strict assumption as the self-normalization eventually cancels out this additional channel energy. Also, following from fact that the LIN is a phase detector and from our notion of the LIN as a differential filter (see Sec. I C), if the phase is stable over a wide range of intensity it implies that the differential filter changes little over a wide range of intensity. Indeed, the phase of basilar membrane motion has been shown to be stable over wide ranges of intensity (Huggins, 1952; Kim *et al.*, 1980). This further supports our contention that the differential filter is essentially independent of the originating cochlear filters.

With these approximations, consider now the effect on r, σ_u, and σ_v for the case of a tone in noise. Only σ_u is directly influenced by our discussion and is specified by

$$\sigma_u^2=\frac{1}{2\pi}\int |\Gamma\cdot\omega H^{\mathrm{ref}}(\omega,s)|^2 S_x(\omega)\, d\omega, \tag{21}$$

σ_v remains unchanged following our arguments above. σ_{uv} remains unaffected as it is determined primarily by the differential filter. This follows from our prior discussion in that the cochlear filter is essentially constant over the region where the differential filter has appreciable response. The correlation r changes due to its dependence on σ_u. If we use superscript r^{ref} to denote the original parameters to which we would like to compare the changed parameters with, we have



(a) Low SPL

(b) Moderate SPL

(c) High SPL

FIG. 5. Noise suppression by a tone in noise.

$$\sigma_u = \Gamma \sigma_u^{\mathrm{ref}}, \tag{22}$$

$$\sigma_v = \sigma_v^{\mathrm{ref}}, \tag{23}$$

$$\sigma_{uv} = \sigma_{uv}^{\mathrm{ref}}, \tag{24}$$

and

$$r = \frac{\sigma_{uv}}{\sigma_u \sigma_v} = \frac{r^{\mathrm{ref}}}{\Gamma}. \tag{25}$$

Finally consider the effect on β,

$$\beta = \frac{\sigma_{u|n}}{\sigma_u} = \left(1 + \left| \frac{\Gamma \cdot \sigma \omega_0 H^{\mathrm{ref}}(\omega_0, s)}{\Gamma \cdot \sigma_{u|n}^{\mathrm{ref}}} \right|^2 \right)^{-1/2} = \left(1 + \left| \frac{\sigma \omega_0 H^{\mathrm{ref}}(\omega_0, s)}{\sigma_{u|n}^{\mathrm{ref}}} \right|^2 \right)^{-1/2}. \tag{26}$$

It is interesting to note that β is *independent of* the BM nonlinearities. This is understandable because β is simply a measure of the *relative* energy passing through the cochlear filter compared to the energy passing through the filter in the presence of noise. As such, the change in filter characteristics does affect both these energies, following our earlier discussion.

Now if we bring all these together we finally arrive at the following expression for $E[y_4(t,s)]$

$$E[y_4(t,s)] = \frac{1}{2\pi} \frac{\sigma_{v|n}^{\mathrm{ref}}}{\Gamma \cdot \sigma_{u|n}^{\mathrm{ref}}} \cdot \beta^{\mathrm{ref}} \cdot \sqrt{1 - \frac{r_n^{\mathrm{ref}^2} \beta^{\mathrm{ref}^2}}{\Gamma^2}}. \tag{27}$$

Now in this expression if we associate the Γ with β^{ref}, then even though β by itself does not change, the effect of the nonlinearities is such that it scales β in the resulting auditory spectrum.

Now for small β, $E[y_4(t,s)]$ is essentially proportional to β and from (27) the suppression is enhanced by a factor Γ, representing the increase in the filter bandwidth. It is therefore readily apparent that broad filters enhance peaks better than relatively narrow filters. Intuitively, in terms of phase locking, at low SPLs, where the filter bandwidths are mostly narrow, phase locking is significantly less widespread. This is appropriate when frequency content is more widely distributed or is present at frequencies beyond phase locking ($\geqslant$4 kHz) such as in voiceless fricatives. At higher SPLs, under broader BW filtering the opposite will hold and sounds with more localized frequency content such as vowels will benefit from the more widespread phase locking.

We can now quantify the relationship between BM nonlinearities with increasing stimulus levels. Consider the auditory spectrum of an input signal that has been presented at two sound-pressure levels: A spectral peak resolved by the differential filter will be enhanced, compared to one ob-

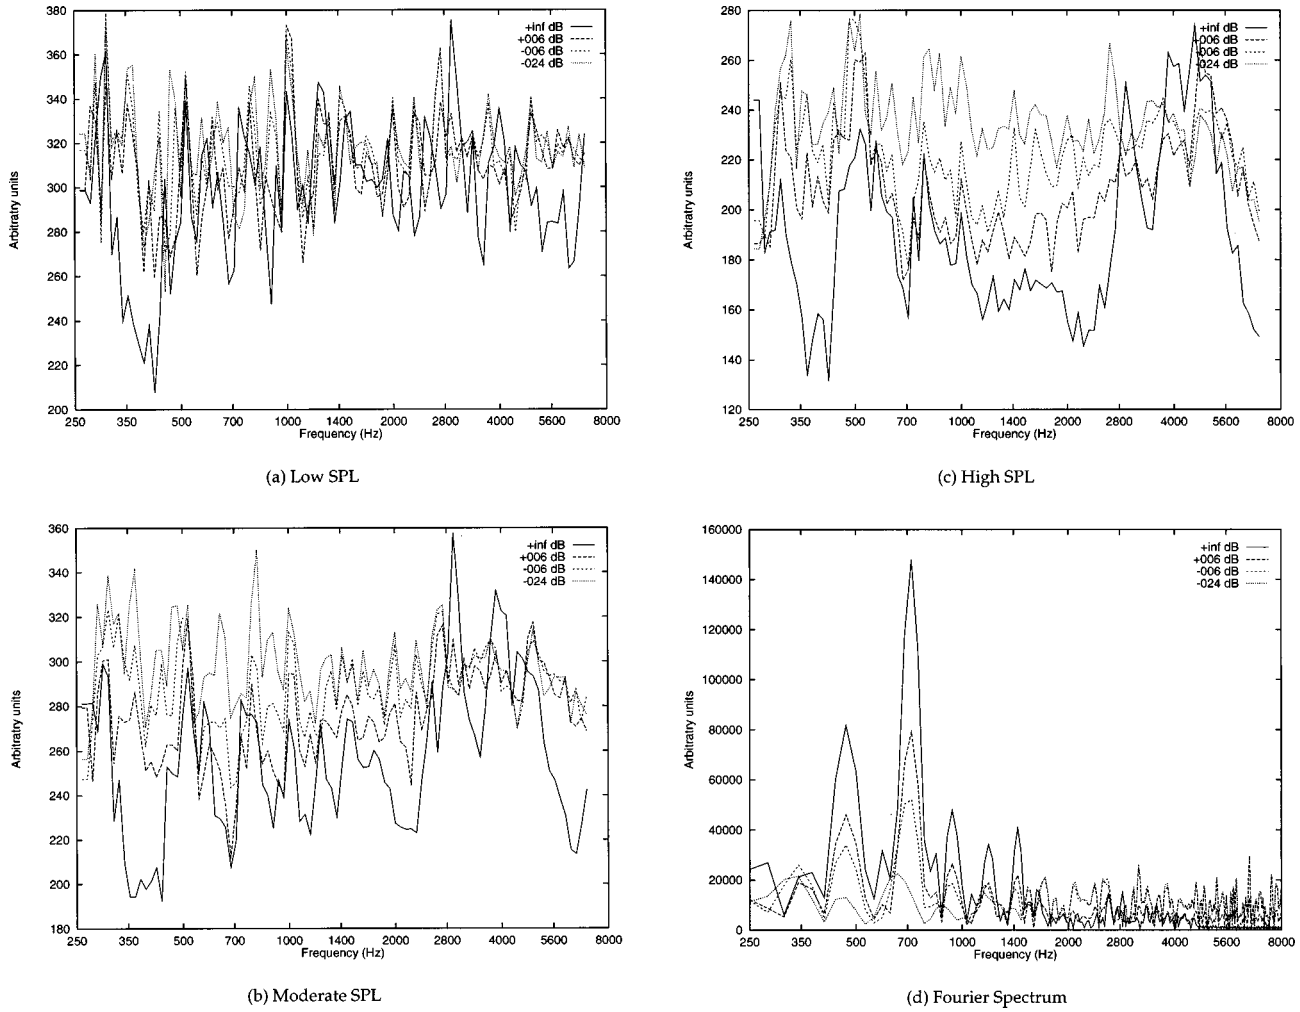


FIG. 6. Noise robustness of the auditory spectrum for vowel-like stimulus /aa/.

served at the lower sound-pressure level, if the increase of energy of the output of the wider cochlear filter does not result in inclusion of neighboring peaks. However, if the wider cochlear filter does result in inclusion of neighboring peaks the resultant spectrum will slightly attenuate the resolved spectral peak. Figure 2 presents a pictorial version of this argument, for an input signal consisting of four peaks, numbered 1–4. Peaks 1, 2, and 3 are relatively far apart compared to peaks 3 and 4. The top path shows the auditory spectrum if a low-SPL version of this input is presented to the model. There is a suppression region immediately following each of the peaks. The suppression regions are, however, too narrow to influence the neighboring peaks, even peaks 3 and 4. The peaks are thus, apart from the enhancement, faithfully reproduced in the resultant auditory spectrum. The lower path, describing the auditory spectrum at high-SPL shows a considerably more interesting picture. The suppression regions are noticeably larger. The first three peaks, 1–3, are unaffected as the suppression region, though large, is insufficient to influence them. However, peak 4 falls within the suppression region of peak 3, thus attenuating the peak, as described above. Such behavior is understandable considering that our perception of most voiced sounds (spectrally peaky) improves with increasing intensity levels even in the presence of noise. In addition, one can argue that with increasing stimulus levels, the considerable spread of spectral information of the spectrum results in a consistently ''whiter'' spectrum thus possibly accounting for the loss in perception of unvoiced sounds such as most consonants at high intensities. This is supported by physiological experiments such as Geisler and Gamble (1989), wherein for certain consonant-vowel syllables at various levels of noise, certain parts of the responses to consonant segments were more affected by noise than responses to vowel segments.

An interesting corollary follows from our discussion above, that of the relationship between the typical sound-pressure levels of various speech classes, Greenberg (1995) has recently suggested that the amplitude of spoken speech classes is governed by the robustness of the resulting auditory representation. Our argument above essentially indicates that consonants would suffer at higher intensities whereas vowel perception improves, thus tending to confirm his suggestion.

IV. EXPERIMENTAL RESULTS

To support the above analysis several experiments were conducted by passing various stimuli, including a pure tone in noise, a natural vowel, and several natural consonants, through the model. The input stimuli were preprocessed by

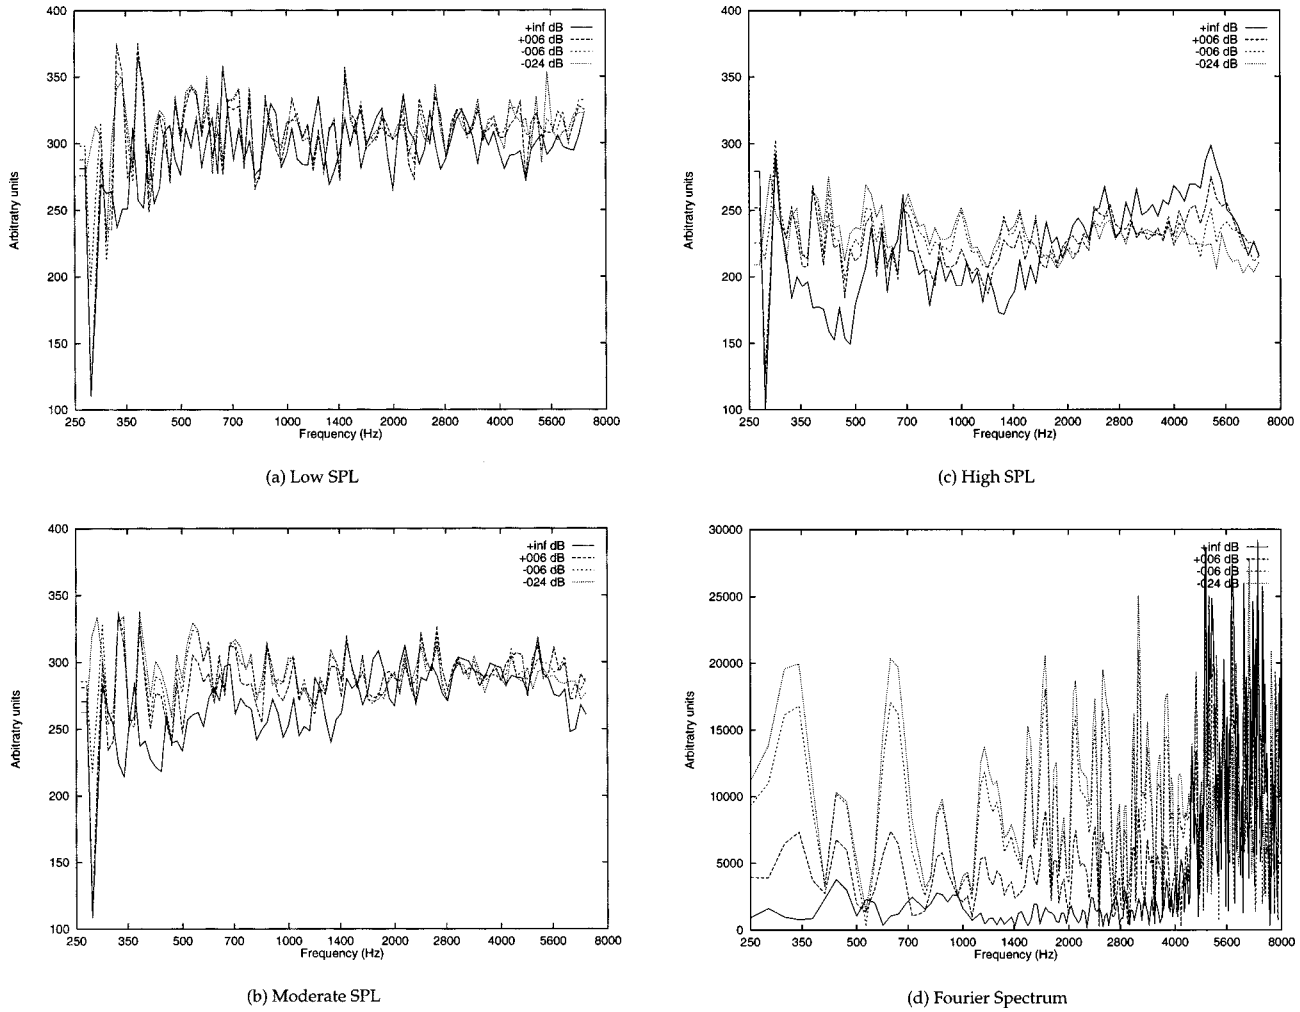

FIG. 7. Noise robustness of the auditory spectrum for fricative stimulus /s/.

adding Gaussian white noise to yield segments at varying SNRs covering the range $+\infty$ to -24 dB. The output of the model for the three cases of low, moderate, and high sound-pressure levels (SPLs) was obtained by passing the stimulus through the appropriate filter bank. The resulting auditory spectrum is then plotted with the cochlear filter CFs on the x axis and their output on the y axis for various stimuli. The auditory spectrum at the output of the model then provides a measure of nerve synchrony across the tonotopic array in response to such signals.

A. Implementation

Experiments were carried out on an implementation of the model described in Sec. II. The three filter banks used in our implementation are generated by the dilation of three seed filters. The three seed filters are assumed to represent the state of basilar membrane filtering at low, moderate, and high SPLs. Figure 3 shows the three seed filters used in this study, as well as their differential filters [using (15)]. As mentioned earlier in Sec. II A, the filter for moderate sound levels is virtually identical to the one described in Wang and Shamma (1994) and was designed to produce the effects of upward masking and two-tone suppression. The filters for low and high SPLs were designed to follow the reasoning in Sec. III, i.e., to have no change in the high-frequency edge of cochlear filters and a marked change in the low-frequency edge of the cochlear filters. While this is understandably a suboptimal representation of BM filtering, the simulation results do substantiate the analysis presented in the previous section.

Ninety-six filters, corresponding to dilation of the seed filters 2 oct down and 2.8 oct up, were generated to cover the frequency range extending from 250 to 7000 Hz.

A check was made on the viability of our analysis for these filters. Taking the seed filter for moderate sound levels as our reference filter, we found that for white noise, i.e., $S_x(\omega)=1$, σ_v of the filters at low and high SPLs was within $\pm 5\%$ of $\sigma_v^{\text{ref}} \cdot \sigma_u$ of the filters, however, was slightly less accurate, showing 7% deviation for the filter at low SPLs and 19% deviation for the filter at high SPL.

The remainder of the model is a straightforward implementation of a time difference, step, spatial difference, half-wave rectification, and integration in cascade following closely the details presented in Sec. I. Figure 4 provides a pictorial depiction of the process. The signal is first passed through a cochlear filter bank, the output of which is shown in the second panel of Fig. 4. The filter bank is prespecified, i.e., there is no automatic selection of which filter bank is to be used. A time difference of the filter-bank output is then

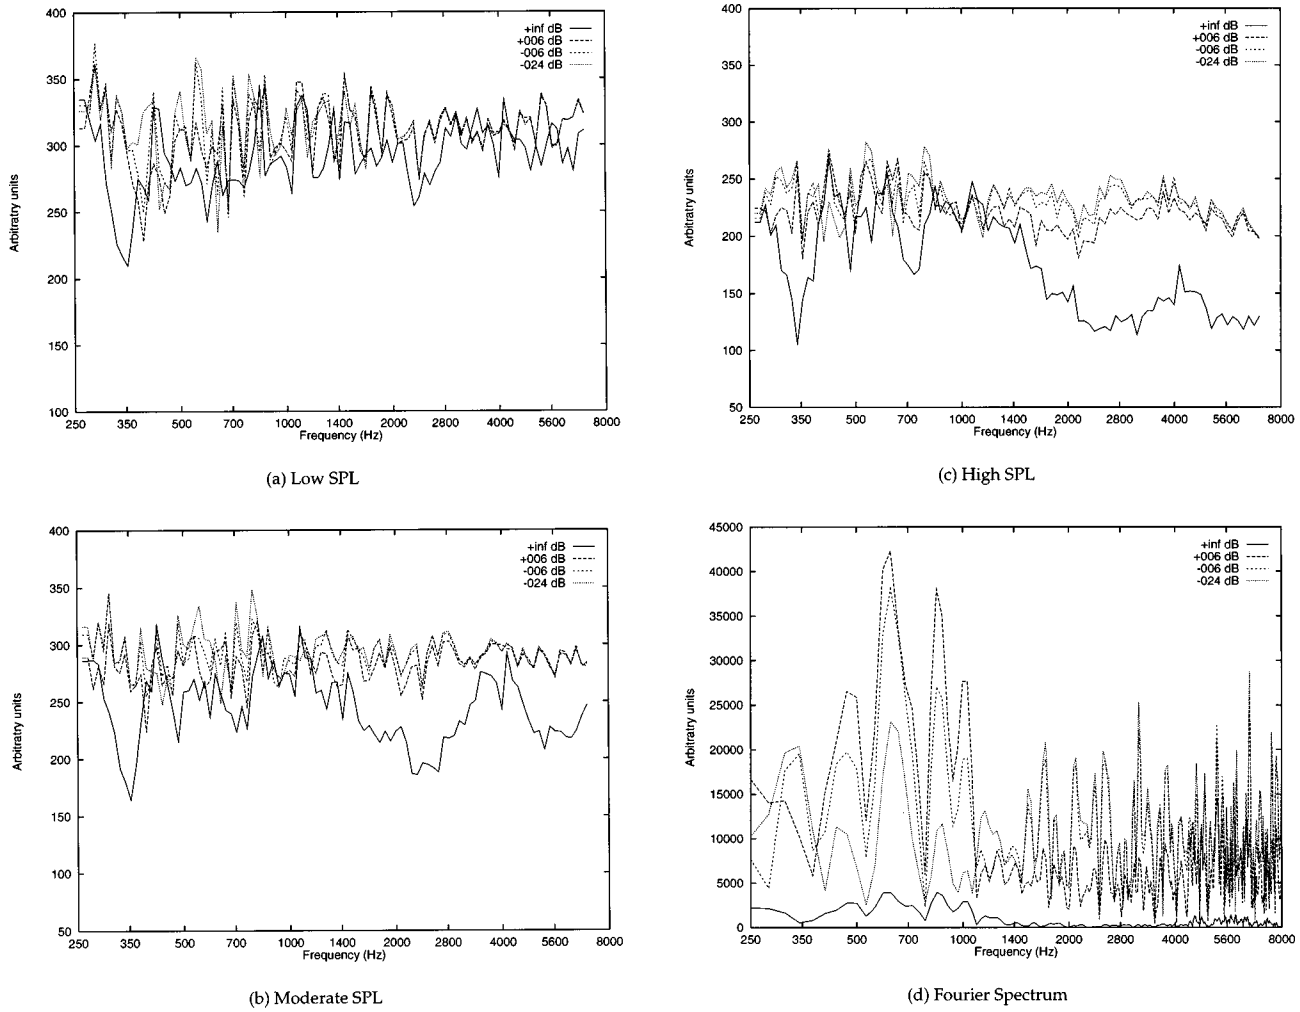

FIG. 8. Noise robustness of the auditory spectrum for stop stimulus /k/.

passed through a step. The output of this stage is shown in the third panel of Fig. 4. The spatial derivative is taken by subtracting the output of adjacent channels. Half-wave rectification and temporal integration of the output of each channel then yields the final auditory spectrum depicted in the bottom panel of Fig. 4. This corresponds to the 0-dB tone in noise auditory spectrum shown in Fig. 5(c).

B. Tone in noise

A tone of frequency 1 kHz was presented in a background of Gaussian white noise. The SNR of the combined signal was then adjusted in steps from $-\infty$ to 6 dB. Figure 5 shows the results of these experiments arranged according to their increasing filter form factor, Γ. The suppression regions are clearly visible as depressions following each of the tonal peaks. As expected from the analysis the suppression increased going from the filter with low Γ, the narrow bandwidth filter bank [Fig. 3(a)], to the filter with high Γ, the broad bandwidth filter bank [Fig. 3(c)]. The suppression is more evident on the high-frequency side of the tone due to the asymmetrical shape of the filters chosen in this study.

C. Vowel in noise

A segment of natural speech containing the phoneme segment /aa/ was extracted from the TIMIT corpus. This segment was then processed through the model at varying SNRs covering the range $+\infty$ to -24 dB. Figure 6 shows the auditory spectrum at a time corresponding to the middle of /aa/. Also shown is the Fourier spectrum of the segment for the same SNRs. Figure 6(c) shows the response at high SPLs, i.e., with broad BW filters, and shows its robustness with increasing noise levels. This corresponds well with physiological studies on temporal representations of such signals (Geisler and Gamble, 1989; Rhode and Greenberg, 1994).

For any particular set of filters the auditory spectrum is a fairly robust representation of this sound. Robustness being described as the auditory spectrum's ability to retain key synchrony features from $+\infty$ to -24 dB. Looking across the filters with increasing Γ, the robustness becomes more apparent. For the broadest filters the auditory spectrum retains its characteristics over all the SNRs considered, whereas for the narrowest filters the auditory spectrum shows much more variation in its characteristics.

This is consistent with reported results for synthesized

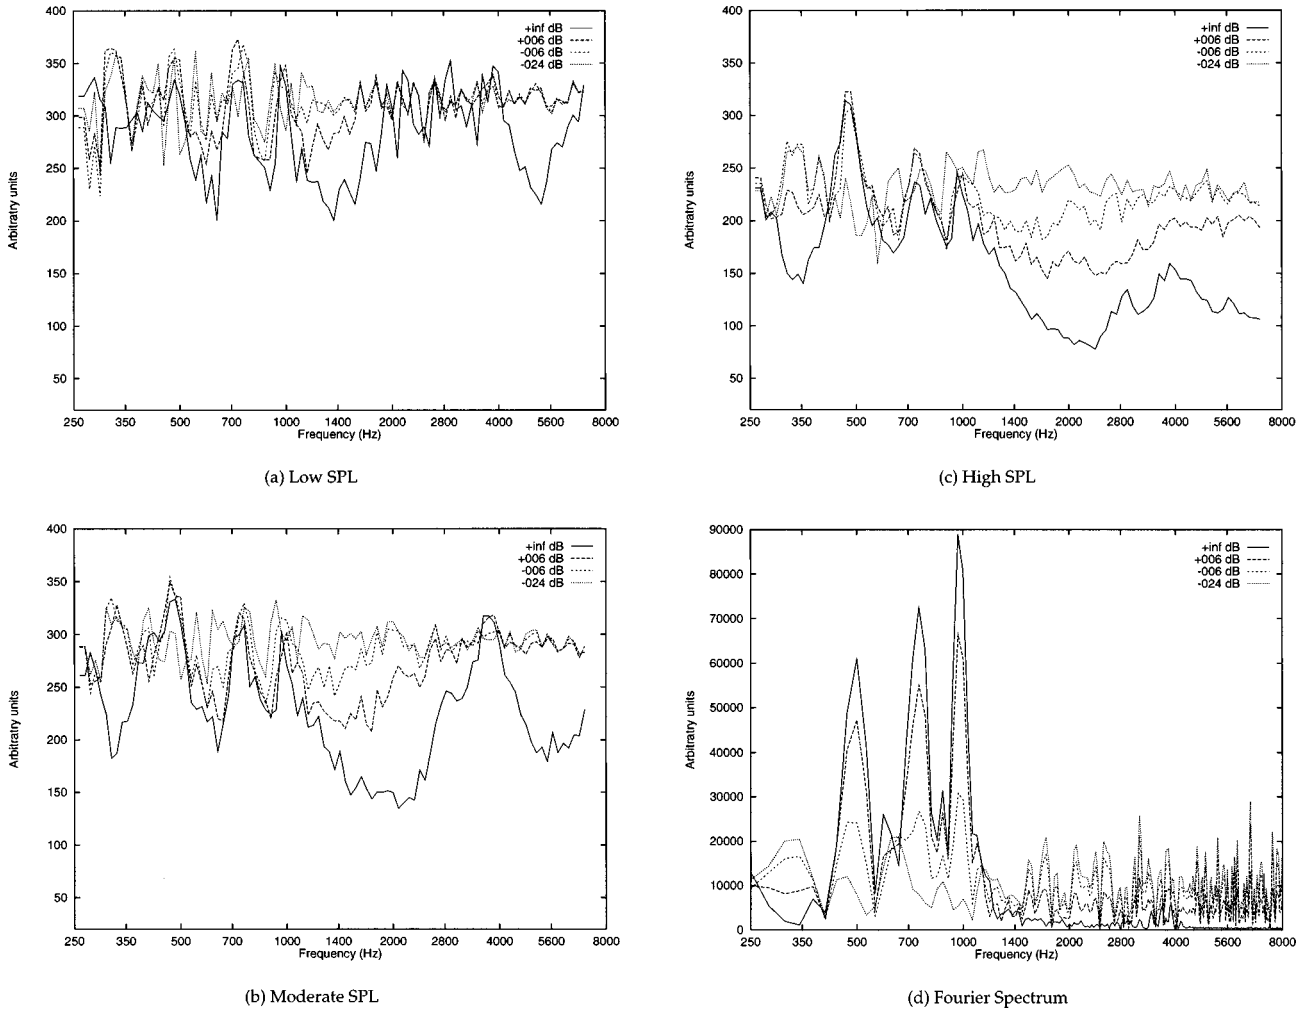

FIG. 9. Noise robustness of the auditory spectrum for liquid stimulus /l/.

vowels and vowel-like sounds at different SPLs in the presence of noise (Sachs *et al.*, 1983; Delgutte and Kiang, 1984a). Both these studies indicate that for increasing vowel SPL, the effect of noise on the temporal representation is small except at very low SNR levels. However, due to the differences in both the presented sounds and background noise a direct comparison cannot be made. The results do show strong encoding of the key frequency components of the acoustic signal. This is more so in the case of the response at moderate and high SPL levels [Fig. 6(b) and (c)].

D. Consonants in noise

Similar to the procedure followed for the vowel we extracted segments of natural speech corresponding to consonant classes: fricatives, stops, liquids, and nasals. The phonemes /s/, /k/, /l/, and /n/, respectively, were selected as exemplars of these segments from an utterance in the TIMIT corpus. The same utterance was used in the prior section. This was done to minimize any effects due to speaker variability. The segment was passed through the model after appropriate addition of noise to vary the SNRs through the range $+\infty$ to -24 dB. The auditory spectrum at the middle of these consonants is plotted in Figs. 7–10.

Fricatives, depending on whether they are voiced or unvoiced, have aperiodic, low intensity waveforms with most of the energy at high frequencies and some periodicity with formant characterization for voiced fricatives. Stops, on the other hand, are transient phonemes with dynamic spectra and cannot be easily described in terms of steady-state spectra. For the two exemplars chosen, /s/ and /k/, /s/ shows a lack of energy at low frequencies and possesses most of its energy at higher frequencies whereas /k/ due to its transient nature shows a varying spectral profile with an initial low-energy silence part followed by a noise burst. In view of this it is expected that broader filters will degrade the auditory spectrum by resulting in flat and smooth profiles with no distinguishing features for the fricative /s/ and for stop /k/. The output of the model for the three filter banks for fricative /s/ and stop /k/ are shown in Figs. 7 and 8, respectively. For fricative /s/, the auditory spectrum at the output of the low SPL model [Fig. 7(a)], shows much of the same characteristics with increasing noise level. However, the high SPL model [Fig. 7(c)] shows a progressively flatter profile with increasing noise level. This is also the case for stop /k/, where once again the high SPL model [Fig. 8(c)] shows a progressively flatter profile with increasing noise level com-

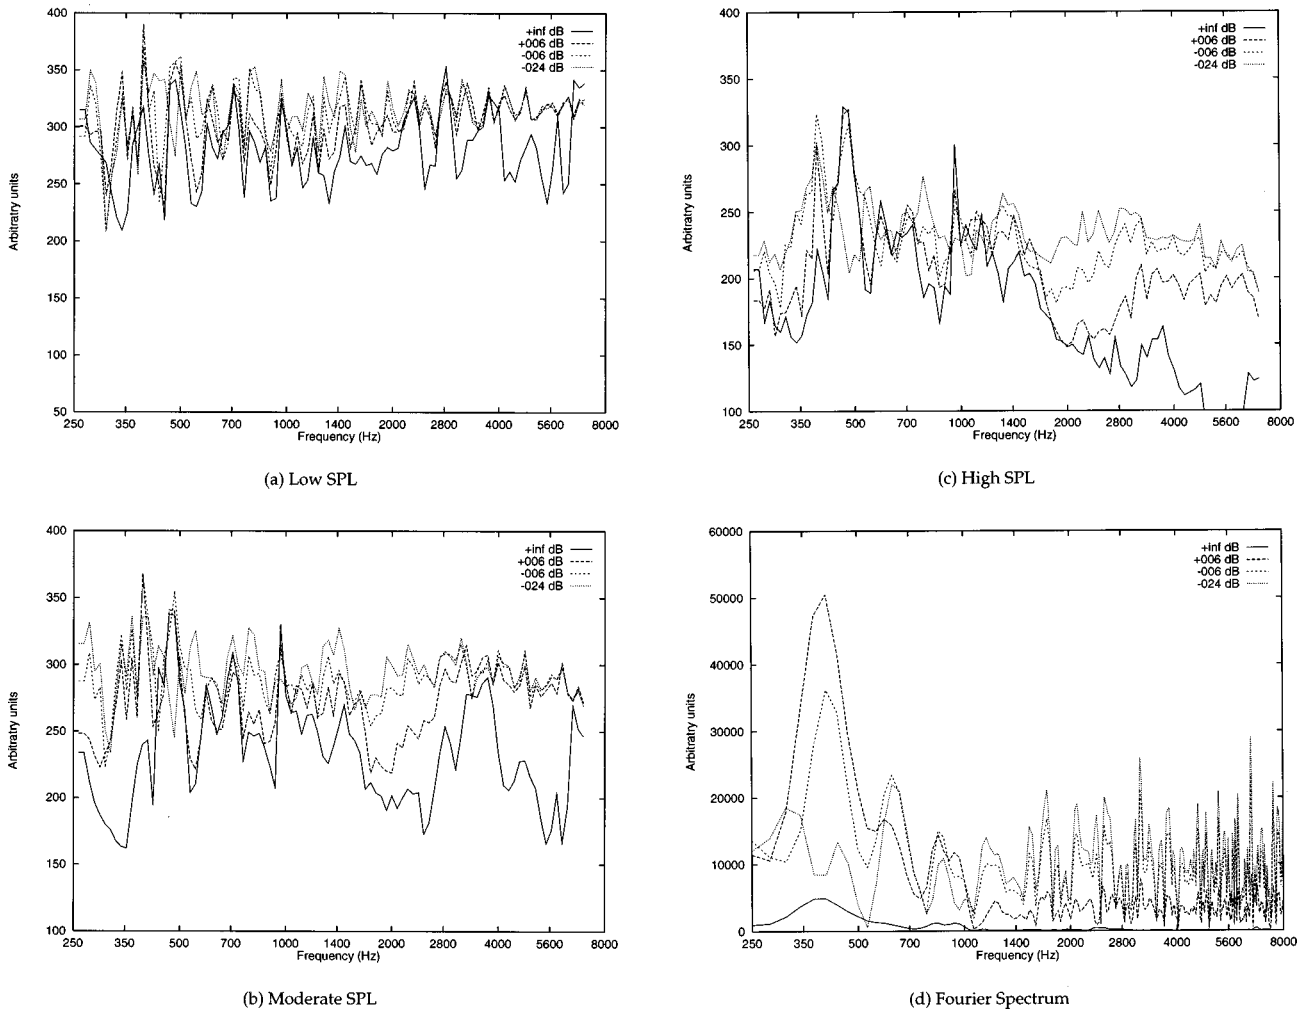

FIG. 10. Noise robustness of the auditory spectrum for nasal stimulus /n/.

pared to a more stable profile from the low SPL model [Fig. 8(a)].

Liquids are very similar to vowels in that they possess intense, periodic waveforms with most of the energy concentrated in the lower formants. However, they are weaker than vowels. Based on our discussion in Sec. III, signals with strong synchrony content will be enhanced with increasing Γ, i.e., by broader BM filters compared to narrower BM filters. Figure 9 shows the auditory spectrum output of the model at various SPLs and SNRs with the corresponding segmental Fourier spectrum. The formant information is clearly visible in the output of the broadest filter bank [Fig. 9(c)] at all but the highest noise level (-24 dB) while the narrowest filters [Fig. 9(a)] show a progressively less informative picture with increasing noise level. Again, the auditory spectrum is fairly robust at moderate and high SPLs due to the strong synchrony in the signal.

Nasals resemble vowels but are significantly weaker due to attenuation within the nasal cavity. The simulation results are shown in Fig. 10. As expected the auditory spectra show much of the same characteristics as vowels with strong formant encoding. The prominent first formant is visible at high SNRs at all SPLs, with the performance under noise degrading for filters with smaller Γ, i.e., narrower filters.

V. CONCLUSIONS

We have presented an extension to an earlier analysis of noise suppression within the early auditory system by Wang and Shamma. This extension accounts for the variation of basilar membrane filtering due to the nonlinearities of the BM with increasing SPLs. The validity of the approach was demonstrated by several experiments on real and synthetic sound stimuli.

Based on the analysis in Secs. II and III and the results presented in the previous section, it seems that one can conclude that sounds with strong periodicity such as vowels and vocalic consonants are enhanced with broadly tuned filters, the opposite holding true for aperiodic sounds (fricatives/stops). The analysis interestingly affords an explanation for why the sound levels of vowels and consonants tend to be separable by energy. It could be theorized that this difference in SPLs, and hence energy, could be a result of evolutionary constraints on biological auditory systems. This idea has been recently put forth by Greenberg (Greenberg, 1995). It would be interesting to see whether psychoacoustical studies confirm the analysis presented here. This effect may be an important cue in speech perception. The differences in encoding of sounds at different SPLs may indicate that there

are many cues available with the most informative being selected or emphasized over other cues under any given set of circumstances.

This work presents an analytical approach to the analysis of basilar membrane nonlinearities. The resulting analysis shows that vowel perception in noise improves as the BM filtering shows progressively broader tuning with increasing sound levels whereas consonant perception degrades with increasing sound levels. This conflict suggests that improved robustness can be achieved by the use of dual filter banks in applications such as speech recognition, an approach that is being actively pursued within our group.

ACKNOWLEDGMENTS

We deeply appreciate the help extended to us by Li Deng, Steven Greenberg, and Kuansan Wang by patiently answering our questions. We would also like to thank Steven Greenberg and Li Deng for their invaluable comments on earlier drafts of this paper.

[1]We have attempted to follow closely the notation of Wang and Shamma to clearly demonstrate the nature of our extension to their work.

[2]We concern ourselves only with $E[y_4(t,s)]$ as with the common assumption of short-time stationarity of speech, Wang and Shamma's and our choice of $\Pi(\cdot)$, $E[y_5(t,s)]$ and $E[y_4(t,s)]$ are related by a simple scaling constant.

Jet-wave amplification in organ pipes[a)]

Shigeru Yoshikawa[b)]
3-12-2-6304 Nagase, Yokosuka, 239, Japan

(Received 25 August 1997; revised 29 January 1998; accepted 5 February 1998)

An envelope-based method to estimate both the jet-wave amplification factor and the mouth-field strength in organ pipes is developed by using flow visualization of a smoked jet with a high-speed digital video camera. A theoretical envelope of wave growth, which is approximated using a negative displacement model of the jet drive, is compared with an experimental envelope derived from superposing many instantaneous shapes of jet deflection in the steady-state oscillation. The estimation results are presented in dimensional terms with respect to two particular models, where the flue-to-edge distances are, respectively, 15.8 and 10.2 mm, with a common flue thickness of 2.2 mm. In our experiment the jet velocity ranges from 7 to 33 m/s, the Reynolds number from 1000 to 5000, and the sounding frequency from 130 to 580 Hz. The amplification factor of organ pipe jets, estimated to lie in the 0.18–0.26-mm^{-1} range, tends to decrease and saturate with increasing blowing velocity in each oscillation mode; the mouth-field strength defined as the acoustic displacement amplitude, roughly estimated to be 0.5–1.5 mm, tends to increase and saturate with increasing blowing velocity. A hot-wire anemometer is then used to measure the mouth-field strength, whose value shows a good agreement with the estimated one. This result confirms the validity of our envelope-based method. A dimensionless representation of the experimental data is used to compare wave characteristics between an organ pipe jet and an acoustically perturbed free jet. The applicability of the spatial and temporal theories of jet instability is discussed to analyze them. If we can assume a Poiseuille flow at the flue exit and a subsequent Bickley jet, the spatial theory seems to be relevant to our organ pipe jets. However, for lack of a reliable experimental measurement of the jet half-thickness we cannot draw a definite conclusion about the wave characteristics of organ pipe jets.

INTRODUCTION

The physics of the sounding mechanism in organ flue pipes is still a challenging subject despite its long research history dating back to the pioneering works of Helmholtz[1] and Rayleigh.[2] The organ pipe shows the sounding characteristics as depicted in Fig. 1 of Coltman's paper.[3] The sounding frequency depends on the velocity (or the blowing pressure) of the jet issuing from the flue slit, and the stable frequency range for playing is restricted to a region of proper jet velocities. This relation between the jet velocity and the resulting tone frequency in the steady-state oscillation is well understood and established by many theoretical and experimental investigations.[4] However, how other jet characteristics, such as oscillation amplitude, are determined is not yet fully understood.

A few essential problems remain unsolved: (1) How is the sounding amplitude determined in the steady state? The jet drive model of Fletcher,[5] which is widely accepted, seems to be too simple to give an accurate value of the acoustic pressure amplitude in the pipe. Fabre, Verge *et al.*[6–10] took a more fluid-dynamical approach and took into account the effect of vortex shedding on the saturation. However, the calculation of the sounding amplitude in the steady states from the presaturated to the saturated regime is still incomplete. (2) How does the splitting between the pipe tone and the edge tone with increasing velocity cause the transition of the pipe tone to a steady state? (3) Which physical quantity stimulates and sustains the sounding process throughout? These problems have been attacked by several researchers, particularly by Coltman,[3,11] but we have no definite conclusions as yet.

The objective of this paper is to reconsider problem (1) above. The other problems will be approached in the future. The jet, which is the source of acoustic energy, exhibits a wavy motion over the mouth due to its inherent instability and the acoustic flow of the pipe resonance. However, we do not have sufficient knowledge of the amplification characteristics of the jet wave despite its crucial importance in determining the sounding amplitude. We do have experimental results obtained from an acoustically perturbed free jet,[12] where the pipe and the edge are excluded, but no experimental results on an organ pipe jet are available. So, more specifically speaking, the purposes of this paper are (a) the presentation of an experimental method and measurement data on jet-wave growth in organ pipes and (b) discussion of whether an acoustically perturbed free jet exhibits the same wave characteristics as an organ pipe jet or not.

[a)]A part of this paper was presented at the third joint meeting of the Acoustical Society of America and the Acoustical Society of Japan, 2–6 December 1996, Honolulu, Hawaii [J. Acoust. Soc. Am. **100**, 2843–2844(A) (1996)].

[b)]Present address: Department of Acoustical Design, Kyushu Institute of Design, 4-9-1 Shiobara, Minami-ku, Fukuoka, 815-0032, Japan; Electronic mail: shig@kyushu-id.ac.jp

The former (a) is given in dimensional terms using two organ pipe models (Secs. II–V), while the latter (b) is treated in a dimensionless way (Sec. VI). This is because the amplification factor (given in mm^{-1} throughout this paper) is not a universal quantity nor a simple constant for all organ pipe and free jets but depends on the frequency, the blowing pressure, and the jet dimensions, and also varies along the jet. If the amplification factor, nondimensionalized by the half-thickness of the jet, is expressed as a function of the Strouhal number, we may compare our results on organ pipe jets with previous results on free jets[12,13] as well as with the spatial[14,15] and the temporal analyses[16,17] of jet instability.

I. THEORETICAL APPROXIMATION

The jet-wave amplification factor in organ pipes will be evaluated using the negative displacement model proposed by Fletcher.[5] It is assumed that the jet deflection may be expressed as a superposition of a progressive wave due to jet instability and a spatially uniform oscillation displacement induced by the acoustical flow through the mouth:

$$\xi(x)=(v/\omega)\{-\cosh(\mu x)\sin[\omega(t-x/U_{\mathrm{ph}})]+\sin(\omega t)\}, \tag{1}$$

where $\xi(x)$ denotes the transverse displacement (z direction) of the jet at distance x from the flue exit. Also, t and ω are the time and angular frequency, respectively, and μ and U_{ph} denote the amplification factor and phase speed of the instability wave, respectively, while v is the transverse acoustic velocity of the mouth field. Spatial growth is here modeled as $\cosh(\mu x)$ instead of $\exp(\mu x)$ because the former gives a smoother curve at the flue, but neither expression is exactly correct. Moreover, both μ and U_{ph} are functions of x in a rigorous sense.

Equation (1) may be a good model for a free jet that passes through a standing wave field formed between two loudspeakers with opposite phases. Although the validity of Eq. (1) has not been confirmed experimentally for real organ pipe jets, Eq. (1) is a reasonably simple and practical representation of the jet deflection that describes our current knowledge. Therefore we postulate in this paper that Eq. (1) is valid.

Equation (1) yields the following expression for the envelope of positive and negative peak displacements:

$$\xi_{\mathrm{env}}(x)=\pm(v/\omega)[\cosh^2(\mu x) - 2\cosh(\mu x)\cos(\omega x/U_{\mathrm{ph}})+1]^{1/2}. \tag{2}$$

Approximating the second term in square brackets of Eq. (2) by $2\cosh(\mu x)$, we obtain the following expression:

$$\xi_{\mathrm{env}}(x)\approx\pm(v/\omega)[\cosh(\mu x)-1]. \tag{3}$$

While the spatial dependence of the envelope of Eq. (2) depends on the spatial wave number $k=\omega/U_{\mathrm{ph}}$ of the instability wave, that of Eq. (3) is simply governed by $\cosh(\mu x)-1$ apart from the v/ω term which is the absolute displacement corresponding to the strength of the mouth field. In other words, approximation (3) enables one to treat the amplification and phase delay of the jet wave separately.

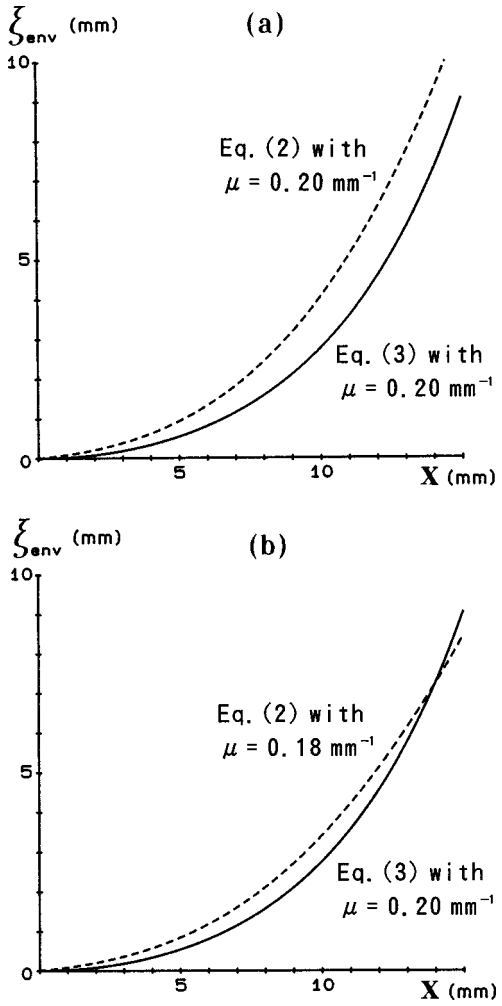

FIG. 1. Comparison of jet-wave envelopes. (a) Original Eq. (2) with $\mu=0.20\ \mathrm{mm}^{-1}$ (broken line) versus approximate Eq. (3) with $\mu=0.20\ \mathrm{mm}^{-1}$ (solid line); (b) Eq. (2) with $\mu=0.18\ \mathrm{mm}^{-1}$ (broken line) versus Eq. (3) with $\mu=0.20\ \mathrm{mm}^{-1}$ (solid line).

We will estimate the amplification factor μ based on this simpler Eq. (3) by comparing with the envelope shape obtained from our visualization experiment as discussed in Secs. III and IV. However, before proceeding to the experimental investigation, we need to evaluate the error arising from approximating Eq. (2) by (3). The absolute value of Eq. (2) is always larger than that of Eq. (3) for the same value of μ, while the $\cos(kx)$ dependence diminishes as μx becomes larger than one.

An example illustrating the approximation error is given in Fig. 1(a), where the mouth-field strength v/ω is assumed to be 1 mm for the comparison. Moreover, it is assumed that $\mu=0.20\ \mathrm{mm}^{-1}$ and $k=0.073+0.01x\ \mathrm{mm}^{-1}$ from our experimental results of an organ pipe model whose length and flue-to-edge distance are 120 cm and 15.8 mm, respectively. The value of $0.073\ \mathrm{mm}^{-1}$ in the above expression for k is calculated using $\omega=2\pi\cdot 133$ rad/s and $U_{\mathrm{ph}}=U_0=11.5$ m/s (measured at $x=0$). Also, the slowdown of U_{ph} is assumed so that k may be proportional to x (measured in mm) in order to make calculation easier. A proportionality constant of 0.01 is roughly estimated from our experiment. The k equals $0.231\ \mathrm{mm}^{-1}$ at the edge ($x=15.8$ mm), and implies U_{ph}

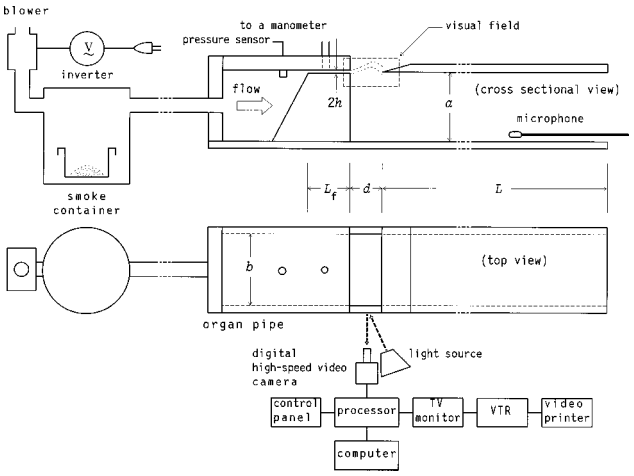

FIG. 2. Experimental setup for smoked-jet visualization and organ pipe geometry.

$=0.32\,U_0$ at the edge. The phase speed averaged over the mouth is reported to be about 0.4 to 0.5 times the jet speed at the flue in Refs. 4, 12, and 18, therefore the above expression for k is reasonable. The example of Fig. 1(a) indicates that approximation (3) gives an envelope magnitude which roughly corresponds to 0.75 times the magnitude given by Eq. (2) near $x=10$ mm (i.e., $\mu x=2.0$).

A closer match between the two is obtained if we apply a lower amplification factor ($\mu=0.18\ \mathrm{mm}^{-1}$) to Eq. (2) as indicated in Fig. 1(b). This means that the estimate of μ based on the theoretical envelope of Eq. (3) tends to be a little larger than that based on Eq. (2) for the same experimental envelope. However, the estimation error, about 10%, due to Eq. (3) is roughly equivalent to the resolution of the experimental data shown in Secs. III and IV. Thus we feel free to use the theoretical envelope of Eq. (3) to estimate the μ value of jet waves in organ pipes.

Of course, it is possible to directly estimate μ from Eq. (1). However, such an approach needs exact information about U_{ph} and a time (or phase) reference. Our envelope-based method using Eq. (3) is superior because of its independence of such information.

II. EXPERIMENTAL PROCEDURES

A. Flow visualization

Our experimental setup for jet-flow visualization is very simple and is shown in Fig. 2. The blowing pressure of a low-noise blower (Fuji Electric, type VFC206AN) is adjusted with an inverter (Fuji Electric, FVR-E9S), and steady pressures are obtained in the range 20–700 Pa. The smoke in a container, generated by many incense sticks and cigarettes, is driven by the blower. The smoked air is introduced into the foot of a model organ pipe through a rubber tube. The blowing pressure in the steady state is measured at this side of the flue slit using a manometer. The acoustic pressure is also measured inside the pipe at a position that is 7/12 of a pipe length from the farther pipe end.

The smoked jet that issues from the flue is observed with a high-speed digital video camera (Photron, HVC-11B or FASTCAM-hvc2) by shining the visual field with a 500-W spotlight. One camera (HVC-11B) can take digital pictures with a speed of 1297 pps (pictures per second) and stores a total of 2048 pictures in a 1.579-s duration. The other one (FASTCAM-hvc2) takes up to 1440 pps and can store 8192 pictures in a 5.69-s duration. The resulting picture consists of 128×64 pixels. Also, the latter one supports digital signal processing of the picture frames on a personal computer such as NEC PC-9801. The appropriate shutter speed is 1/5000 to 1/10 000 s for the former, while a speed of 1/110 000 s is automatically selected for the latter. The digitized data are recorded in a built-in memory, and replayed on a TV monitor with a speed of 2, 5, 10, 15, or 30 pps just after the recording. We can thus view slow-motion pictures of the jet waves at our convenience. Moreover, the interesting frames can be recorded on a VTR (8-mm video cassette, VHS video cassette, etc.) as analog data, and each frame can easily be printed out with a video printer.

B. Pipe geometry

Two experimental organ pipe models A and B are made of transparent acrylic resin (Plexiglas). A cross section of the models is shown in Fig. 2. Table I summarizes the basic model geometries. Both models have the same flue thickness (jet thickness) $2h=2.2$ mm and the same mouth width (jet width) $b=50.0$ mm. Model A has a longer cutup length (jet length) $d=15.8$ mm, while model B has a shorter one, $d=10.2$ mm. These relatively long cutup lengths are chosen to see wavy motion of the jet more easily (a very short cutup length of 4.02 mm was chosen by Fabre, Verge *et al.*[7–10] to investigate the vortex shedding in steady oscillation). Models A and B, whose physical lengths are 120.1 and 50.0 cm, have central frequencies of 134 and 286 Hz in their fundamental modes, respectively. The pipe cross section is almost square, however, its vertical side, a, is slightly different from the lateral side (mouth width) b. The offset h_0 between the flue centerplane and the pipe edge is nearly zero, but it is very difficult to accurately measure h_0 because of finite thickness of the edge tip. The flue channel length L_f is 100 mm ($L_f/2h=45.5$), and the edge angle is 16° for both models. Ears are not employed since they preclude the smoked-jet visualization.

III. WAVE CHARACTERISTICS OF THE JET

Wave characteristics of organ pipe jets are well known,[4] so only a brief explanation of them is given based on the examples of our visualization. Instantaneous shapes of jet deflections are visualized in Fig. 3 for the first mode of model A, while Fig. 4 shows the same for the second and third modes of model A. The first, second, and third modes, about 133, 268, and 406 Hz, are excited with blowing pressures of about 80, 240, and 640 Pa, respectively. They are visualized at intervals of 1/1297 s=0.771 ms. Also, note that ''0.00 ms'' in these figures is chosen arbitrarily during the period of steady-state oscillation.

Figure 5(a) indicates the centerplane of the planar jet shown in Fig. 3. Labels #1 to #7 in Fig. 5(a) correspond to those in Fig. 3. The centerplane is easily estimated as the midpoint of the thickness along the visualized jet. A thinner

TABLE I. Important dimensions of experimental organ pipe models.

Model		A	B
Cutup length	d (mm)	15.8	10.2
Flue thickness	$2h$ (mm)	2.2	2.2
Flue channel length	L_f (mm)	100.2	100.1
Mouth width	b (mm)	50.0	50.0
Offset	h_0 (mm)	~ 0	~ 0
Pipe length	L (cm)	120.1	50.0
Pipe side	a (mm)	49.0	49.2

smoke such as used in Fig. 3 made this estimation easier. Also, a smooth connection of these midpoints was applied to #4 to #7 in Fig. 5(a) because a small collapse was seen at some of the larger amplitudes.

Similarly, jet centerplanes at the second mode were estimated from the visualized results shown in Fig. 4 and superposed on Fig. 5(b). However, all of the centerplanes in Fig. 5(b) are not temporally consecutive. Only #3 and #4 in Fig. 5(b) correspond to those in Fig. 4. Others, #1′ to #3′, are consecutive, although they are taken from another sequence of the visualized result. Two remaining lines with no label are also taken from a different sequence.

A. Phase speed

The phase speed U_{ph} of the jet wave depicted in Fig. 5 is estimated as the speed with which the wave crest or the zero-crossing point progresses. For example, the wave crests of #1 to #5 in Fig. 5(a) are near the positions $x=4.3$, 7.8, 10.0, 12.0, and 13.5 mm, respectively. Therefore the jet wave progresses with the spatial steps of 3.5, 2.2, 2.0, and 1.5 mm per 0.771-ms time interval. The resulting phase speeds are thus 4.5, 2.9, 2.6, and 1.9 m/s within each time step. The initial jet velocity U_0 at the flue exit may be estimated from Bernoulli's law to be

$$P=(1/2)\rho U_0^2, \tag{4}$$

where P and ρ denote the blowing pressure and the air density, respectively. The blowing pressure was 80 Pa in the case of Fig. 5(a), so $U_0=11.5$ m/s. Consequently, we may consider that U_{ph} gradually decreases as $0.39U_0$, $0.25U_0$, $0.23U_0$, and $0.17U_0$ when the jet approaches the edge.

It should be noted that Eq. (4) is not valid for arbitrary configurations. If the flue channel is too long, there can be a significant friction loss which reduces U_0. In our case the channel length L_f ($=100$ mm) is quite long, although the pressure measurement was carried out at a distance of 10 mm from the flue exit. The pressure loss ΔP along a narrow channel can be roughly estimated as

$$\Delta P=[12\eta/(2h)^2]U_0\Delta l \tag{5}$$

assuming incompressible steady flow between stationary parallel plates.[19,20] In Eq. (5) η denotes the shear viscosity ($\eta=1.82\times10^{-5}$ Nsm^{-2} for the air at 20 °C) and Δl ($=10$ mm) is the distance between the position of pressure measurement and the flue exit. If we set $U_0=11.5$ m/s and $2h=2.2$ mm in Eq. (5), we have $\Delta P=5.2$ Pa $=0.065$ P for P=80 Pa. Also, the pressure measurement error is larger than 2 to 3 Pa depending on the steadiness of the air flow.

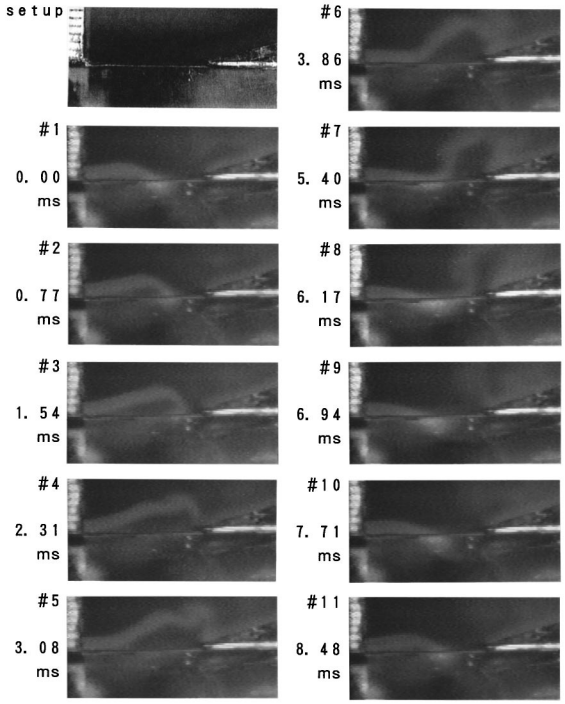

FIG. 3. Instantaneous shapes of the deflecting organ jet in steady-state oscillation (first mode of model A). The blowing pressure: 80 Pa; the sounding frequency: 133 Hz; the flue-to-edge distance: 15.8 mm; the flue thickness: 2.2 mm. As frame ''setup'' indicates, the flue exists at the left and the pipe edge at the right. A measure graduated in millimeters is attached on the outer wall above the flue. The time reference is arbitrary.

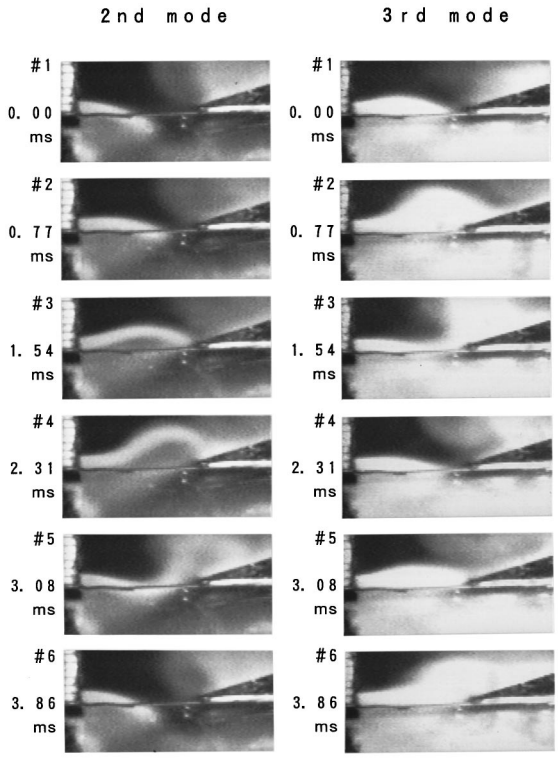

FIG. 4. Instantaneous shapes of the deflecting organ jet in steady-state oscillation (higher modes of model A). Left: second mode at the blowing pressure of 240 Pa and the frequency of 268 Hz; right: third mode at the blowing pressure of 640 Pa and the frequency of 406 Hz.

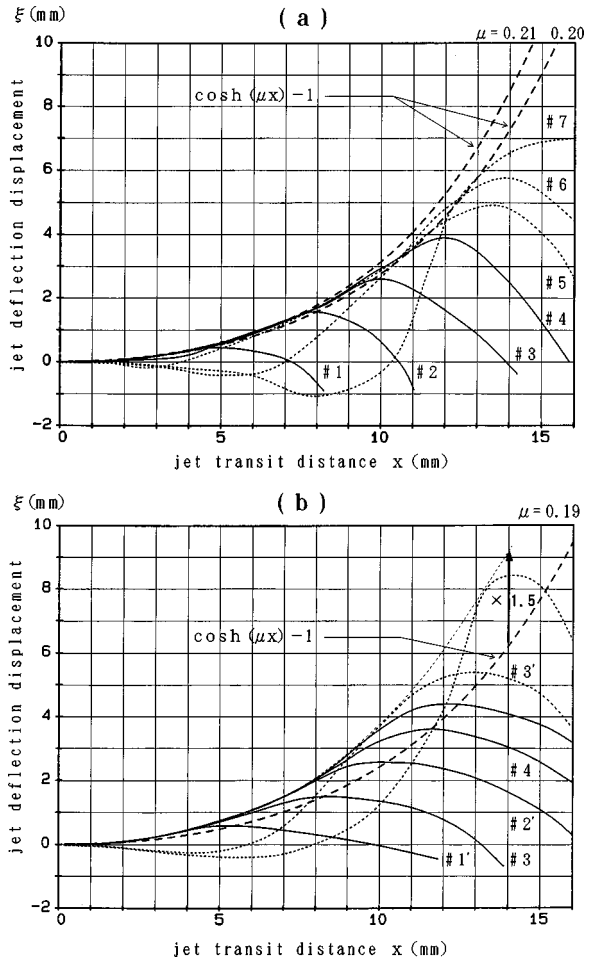

FIG. 5. Superposition of the deflecting jet centerplanes. (a) Superposition of frames #1 to #7 in Fig. 3; (b) superposition of various frames in the second mode (only labels #3 and #4 correspond to those in the left of Fig. 4). The thick broken line gives the theoretical envelope cosh $(\mu x)-1$; the thin broken line in (b) gives the experimental envelope. The unit of μ is mm^{-1}.

Therefore we can neglect the effect of viscous friction loss along the flue channel for the blowing pressure range in our experiment.

If we consider the zero-crossing point (that is, the crossing of the jet centerplane and the x axis of $\xi=0$), we have $x=7.2$, 10.6, 13.8, and 15.8 mm for #1 to #4 in Fig. 5(a), respectively. This yields decreases in U_{ph} of $0.38U_0$, $0.36U_0$, and $0.23U_0$. It is clear that U_{ph} considerably decreases as the jet approaches the edge. On the other hand, U_{ph} should be close to U_0 near the flue because there is no wavy crest. Therefore U_{ph} halfway between the edge and flue may be considered as an average phase speed, which is roughly estimated to be $0.40U_0-0.35U_0$ using the result of Fig. 5(a). Note that the expression for the spatial wave number k described in Sec. I B is based on the above experimental result and its simplification.

Similarly, we may estimate U_{ph} from Fig. 5(b). The wave crests of #3 and #4 give $U_{\mathrm{ph}}=0.24U_0$, where $U_0=20$ m/s. The crests of #1′ to #3′ give $U_{\mathrm{ph}}=0.31U_0$ and $0.21U_0$. These values based on the crest movement seem to be relatively small. However, the values based on the zero crossing are much larger. For example, #1′ and #2′ give a speed of about 8.4 m/s, which corresponds to $U_{\mathrm{ph}}=0.42U_0$. Since the temporal change of the acoustic pressure introduced into the pipe probably depends more on the zero crossing than on the crest, the phase speed of the jet wave may be estimated to be about $U_{\mathrm{ph}}=0.4U_0$ for the case of Fig. 5(b).

The estimate of U_{ph} from other data confirms that $U_{\mathrm{ph}}=0.4U_0$ holds approximately if we use the speed of zero crossing. This coincides with the past experimental results.[4,12,18] We will not discuss the phase speed of the jet wave any further in this paper.

B. Amplification

It is well understood from Fig. 5(a) that the jet wave forms an envelope between two bold broken lines, which are defined as $\cosh(\mu x)-1$ with amplification factors of $\mu=0.21$ and 0.20 mm^{-1}, respectively. The envelope seems to shift from $\cosh(0.21x)-1$ at the flue side to $\cosh(0.20x)-1$ at the edge side. This example shows a weak decrease of μ along the jet. Incidentally, the value of v/ω of the envelope in Fig. 5(a) may be estimated to be 1.0 mm.

Generally, we obtain results such as shown in Fig. 5(b) for the envelope. A thin broken line, which gives the envelope, does not fit any curve of $\cosh(\mu x)-1$ but does closely fit $\cosh(0.19x)-1$ if we multiply the envelope by 1/1.5. This means that the envelope can be expressed as $1.5[\cosh(0.19x)-1]$ mm. The value of 1.5 mm defines the mouth-field strength v/ω for the particular case of Fig. 5(b) when the x dependence of μ is ignored.

These two examples of the superposed jet waves suggest the approximate validity of Eq. (3) for the wave envelope. Hence we may estimate μ and v/ω at the same time by comparing the experimental envelope with the theoretical one approximated by Eq. (3).

IV. DERIVATION OF JET ENVELOPE FUNCTION

The above method of superposing the jet centerplanes is effective in estimating the jet envelope function defining the amplification factor μ and the mouth-field strength v/ω according to Eq. (3), but the process is rather tedious and time-consuming. Another simpler method is introduced in this section. Since the frames showing the jet waves in Fig. 5 are digitally memorized, the OR summation of these digital data yields a more direct superposition of jet waves. Examples are shown in Figs. 6 and 7 for models A and B, respectively.

Digitally superposed jet waves are shown in frames (a)–(f) for various blowing pressures in Figs. 6 and 7. Frames (g) and (h) on the right of Figs. 6 and 7 illustrate how the jet envelope function is derived. In frames (a)–(f) the x axis is drawn straightforwardly from the flue center labeled as ''0,'' and label ''e'' indicates the edge position.

The envelope of jet centerplanes (indicated by dotted lines in Figs. 6 and 7) is almost parallel to the outer fringe of the superposed jet waves as long as significant spreading of the jet can be neglected by using thin smokes for visualization. However, since it was not easy to make thin smokes for higher blowing pressures, jet spreading was appreciable for those pressures. This jet spreading is indicated by the convex shape of the jet fringes as shown in Fig. 6(e) and (f), which

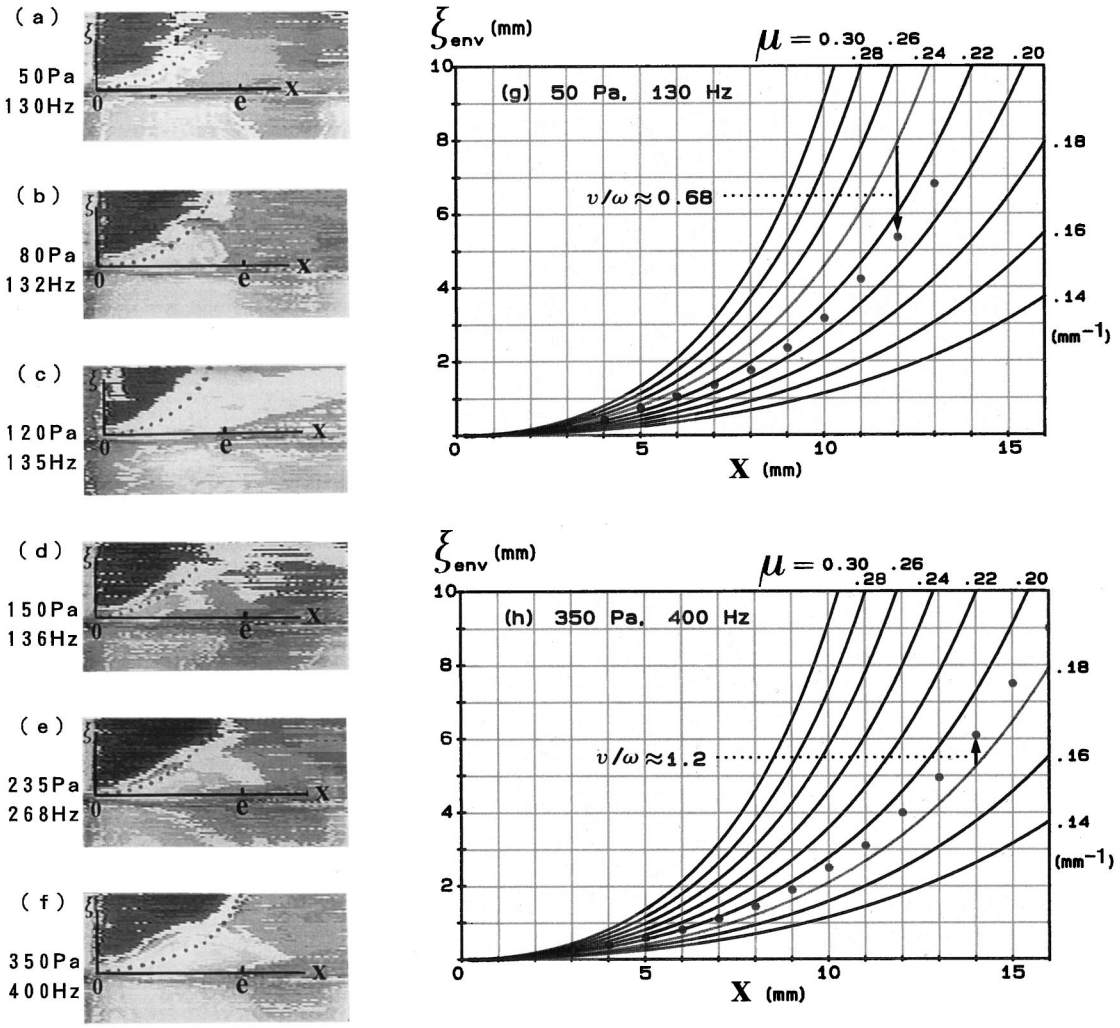

FIG. 6. Digitally superposed jet waves for various blowing pressures [(a)–(f)] and illustrations of how to derive the amplification factor μ and the mouth-field strength v/ω [(g) and (h)]. The envelope of jet centerplane is estimated by the dotted line. Organ pipe model A is used. The distance from ''0'' to ''e'' corresponds to 15.8 mm.

give examples of the second and third modes of excitation, respectively. However, it was possible to estimate the envelope of centerplanes because a darker portion was usually formed just below the fringe and it was used as a guide to guess the envelope. It should be also noticed that the roll-up of the jet often happens when the jet changes the direction of its transverse deflection after having reached maximum deflection. This roll-up was significant for low pressures as shown in Fig. 6(a), so we took care not to superpose rolled-up jets. Such neglect of the roll-up yielded a concavity of the fringe as shown in Fig. 6(d) and (e). However, this concavity did not cause any trouble in estimating the envelope of centerplanes. Of course, we may always refer back to the original jet waves when we run into trouble.

In Fig. 6(g) and (h) the estimated envelope of Fig. 6(a) and (f) are, respectively, shown by dots on a template, that is, curves of jet envelope function $\cosh(\mu x)-1$ for various μ values assuming that $v/\omega=1$. Figure 6(g) suggests a close fit of the dotted line to an envelope curve with $\mu=0.24\ \mathrm{mm}^{-1}$ when the magnitude ratio of the dotted line to that curve is about 0.68. This ratio determines $v/\omega=0.68$ mm. Also, Fig. 6(h) suggests that $\mu=0.18\ \mathrm{mm}^{-1}$ and $v/\omega=1.2$ mm. Following these procedures, we can derive the jet envelope functions of models A and B for various blowing pressures, using Figs. 6 and 7, respectively.

The results are summarized in Figs. 8 and 9 for models A and B, respectively. The abscissa denotes the jet blowing velocity U_0, which is given from the blowing pressure P according to Eq. (4). The values of μ and v/ω estimated from our flow visualization are indicated by an open circle and an open square, respectively. On the other hand, a closed square indicates a value of v/ω that was directly measured by a hot-wire anemometer. Our hot-wire anemometry method and result are described in the next section.

Flow visualization suggests the following general trends from the results shown in Figs. 8 and 9 concerning particular experimental models:

(1) The amplification factor μ tends to decrease and saturate to a given value as the oscillation of each mode shifts toward higher blowing velocities. (Although the limited data on the 3rd mode give the same value of $0.18\ \mathrm{mm}^{-1}$

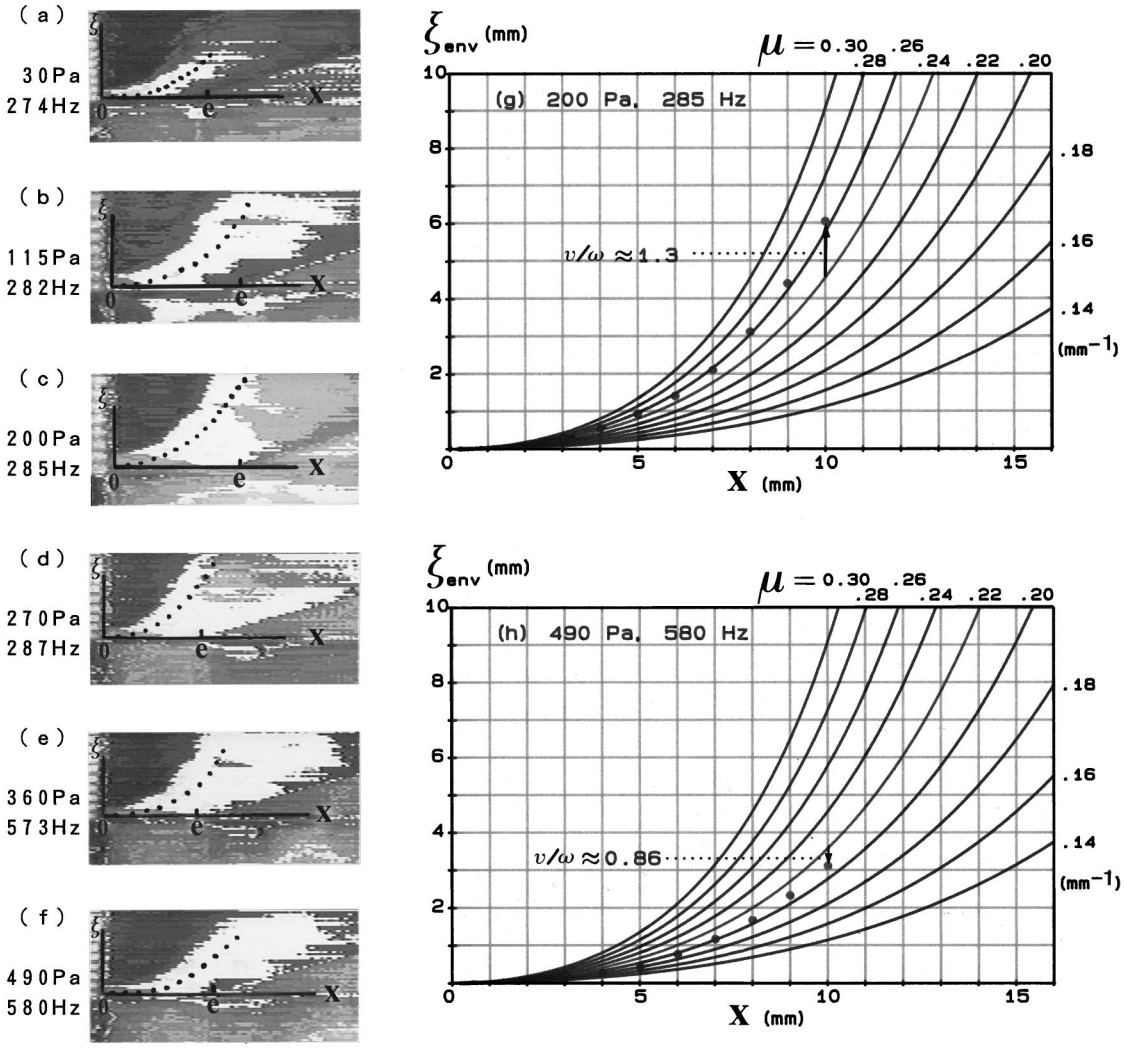

FIG. 7. Digitally superposed jet waves for various blowing pressures [(a)–(f)] and illustrations of how to derive the amplification factor μ and the mouth-field strength v/ω [(g) and (h)]. The envelope of jet centerplane is estimated by the dotted line. Organ pipe model B is used. The distance from ''0'' to ''e'' corresponds to 10.2 mm.

as shown in Fig. 8, they might be considered as a saturated state. Also, the data on the second mode of model B are not sufficient.)

(2) The averaged amplification factor is roughly estimated as 0.21 and 0.24 mm^{-1} for the jet of model A and B, respectively.

(3) The mouth-field strength v/ω, which means the displacement amplitude of the acoustic field at the mouth, tends to increase and saturate to a given value as the oscillation of each mode shifts toward higher blowing velocities. (An inclination to saturation is not so clear concerning the first and second modes of model A.)

(4) The averaged mouth-field strength seems to be almost mode independent and takes an approximate value of 1.2 mm for model A, while that for model B seems to be mode dependent and has values of 1.2 and 0.8 mm for the first and second modes, respectively.

Finally we would like to make a brief comment on the difference in the results from the superposition of the estimated jet centerplanes (cf. Sec. III) and from the direct OR summation of the digitally memorized jets (explained above). Both Fig. 5(a) given by the former method and Fig. 6(b) given by the latter method are based on data with a blowing pressure of 80 Pa, however, the sounding frequency is different by about 1 Hz between them due to a slight variation in the room temperature at which the experiments were performed. The former gave $\mu=0.20$ to 0.21 mm^{-1} and $v/\omega=1.0$ mm as indicated in Fig. 5(a); the latter gave $\mu=0.22$ mm^{-1} and $v/\omega=1.1$ mm as indicated in Fig. 8. Also, both Figs. 5(b) and 6(e) are for data at the same sounding frequency of 268 Hz. However, the blowing pressure is different by 5 Pa between them. This pair gave almost the same result of $\mu=0.19$ mm^{-1} and $v/\omega=1.5$ mm. The difference between these two examples might depend on the sounding condition. That is, the first example is in the presaturated condition, while the second one is almost in the saturated condition and should maintain a stable sounding. If these circumstances are considered, we may understand that both methods yield highly consistent estimations of the jet

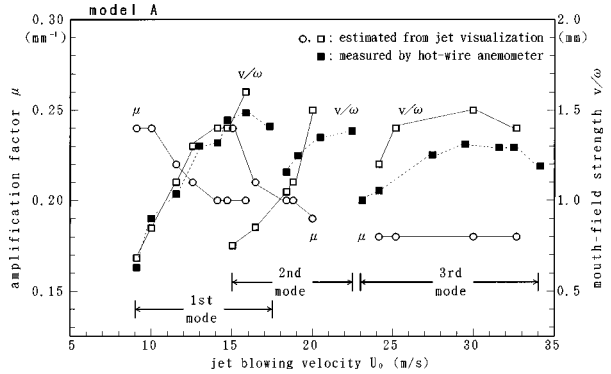

FIG. 8. The amplification factor μ and the mouth-field strength (absolute acoustic particle displacement at the mouth) v/ω of the organ pipe jet as functions of the jet velocity U_0 at the flue exit of model A.

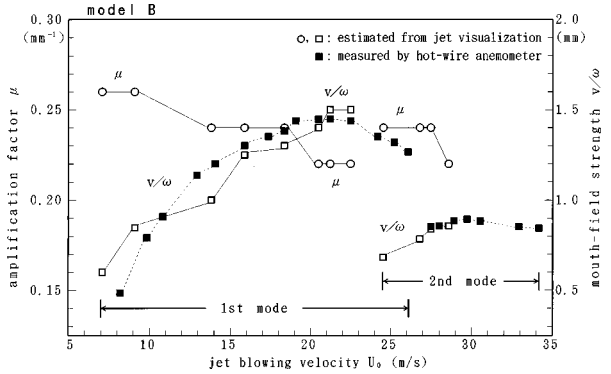

FIG. 9. The amplification factor μ and the mouth-field strength (absolute acoustic particle displacement at the mouth) v/ω of the organ pipe jet as functions of the jet velocity U_0 at the flue exit of model B.

envelope function. The expected estimation error is less than 10% according to the first example.

V. HOT-WIRE ANEMOMETRY OF MOUTH-FIELD STRENGTH

In order to confirm the validity of our OR summation method explained in the previous section, the mouth-field strength v/ω was determined from measurements of the acoustic particle velocity with a hot-wire anemometer and of the sounding frequency with a frequency counter. Since the position of a hot-wire probe at the mouth is very important, first we have to explain how we selected the probe position.

A. Preliminary experiment to select proper probe position

The position of a hot-wire filament, whose sensing part is 1-mm long and 5 μm in diameter, can be represented as its center position (x, y, z). The origin of the coordinate system is placed at the center of the flue slit. The x axis points towards the edge, the y axis along the flue width, and the z axis along the vertical of the mouth opening surface. Therefore the mouth opening is expressed as $0 \leqslant x \leqslant d$ and $-b/2 \leqslant y \leqslant b/2$ at $z=0$, the flue slit as $-b/2 \leqslant y \leqslant b/2$ and $-h \leqslant z \leqslant h$ at $x=0$ (cf. Table I).

Since the aim of the experiment is to measure the acoustic particle velocity, we have to avoid exposing the probe to the air-jet flow. However, the jet is deflecting with large amplitudes as shown in Figs. 3–7. Particularly, from Figs. 6 and 7 we know that proper positions for our measurement are limited to the flue side. On the other hand, if the probe is located far away from the mouth opening, the level of the acoustic particle velocity will decrease with increasing distance.

A constant-temperature type hot-wire anemometer (Kanomax model 1010) was used with a linearizer (model 1013), a dc voltmeter (model 1008), and a rms voltmeter (model 1015). Selectable bandpass filters are involved in the rms voltmeter. The output voltage of a hot-wire probe was calibrated using a small flow tank (probe calibrator, Kanomax model 1065) and a low-noise blower that was usedfor flow visualization. A linearized calibration curve was obtained with the aid of the linearizer. As the result, the output voltage of the anemometer from 0 to 5.0 V directly corresponded to the flow velocity from 0 to 5.0 m/s with sufficient accuracy. Such very low flow velocities were used to measure the acoustic particle velocity.

The data were taken while shifting the probe position step by step under a constant blowing pressure of 120 Pa and with the frequency of 133.7 Hz used for model A. The rms output of our hot-wire anemometer $V_{\rm rms}$ (bandpass filtration was applied between 100 and 200 Hz) is shown in Fig. 10, which gives the data when the probe was moved on the central x-z plane at $y=0$. It is clear from Fig. 10 that $V_{\rm rms}$ is strongly affected by the jet flow, whose speed is known from the dc voltmeter, when the probe is located at $z<6$ mm or $x>5$ mm. On the other hand, when the probe is located at $z>14$ mm, $V_{\rm rms}$ decreases as z increases. Also, when the probe is very close to the flue slit as $x=1$ mm, $V_{\rm rms}$ shows stronger z dependence than that at $x=3$ mm. This might be due to the entrainment of the flow along the wall surface above the flue. Consequently, an adequate region to measure the rms acoustic particle velocity $v_{\rm rms}$ at the mouth should be near $x=3$ mm and $z=8-10$ mm.

More data were taken as the probe was moved along the y axis with fixed $x=5$ mm and $z=4$ mm. The result indicated a reliable region of $-15 \leqslant y \leqslant 15$ mm. As the probe approached the pipe wall, $V_{\rm rms}$ clearly decreased and took a value of about 30% below the value in the reliable region when $y=\pm 25$ mm. Therefore the plane at $y=0$ should be the most reliable plane for the probe position. As the result, we located the probe at $(x,y,z)=(3,0,10)$ in mm units. At this position the rms output voltage $V_{\rm rms}$ should correspond to the rms value of the acoustic particle velocity $v_{\rm rms}$ concerning the first-mode oscillation of model A.

Similarly, other locations for the probe were sought depending on the oscillation mode and organ pipe model. The results gave almost the same position as that for the first-mode oscillation of model A. Therefore the probe was fixed to $(x,y,z)=(3,0,8)$ in mm units for the second and third modes of model A and the first and second modes of model B. A little bit smaller z position seemed to give a better result if a more rapid decrease in $v_{\rm rms}$ along z axis was considered because of shorter wavelengths in these oscillation modes.

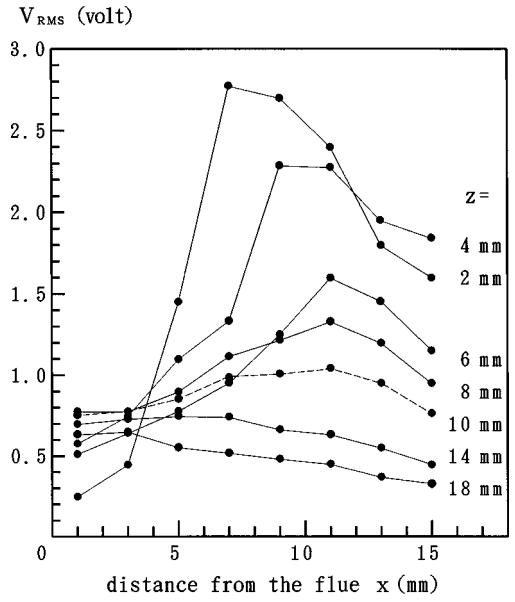

FIG. 10. The rms output voltage $V_{\rm rms}$ of the hot-wire anemometer at the mouth of model A. A hot-wire probe is shifted on the x-z plane at $y=0$. The blowing pressure of the jet is kept at 120 Pa, and the resulting tone frequency is 133.7 Hz.

B. Acoustic particle velocity at the mouth

According to the procedures above, the rms acoustic particle velocity at the mouth $v_{\rm rms}$ was measured as the rms output voltage $V_{\rm rms}$ of the hot-wire anemometer. The magnitude v, which was used to define the strength of mouth field v/ω in Eqs. (1) to (3), is given by multiplying $v_{\rm rms}$ by $\sqrt{2}$. The results of this v/ω are indicated by the closed square in Figs. 8 and 9 for models A and B, respectively. Note that a bandpass filtration was applied to detect only the fundamental component of the acoustic particle velocity in each oscillation mode.

Comparing the values of v/ω measured using the hot-wire anemometer with those estimated from flow visualization, we may see a good agreement between them except for the third mode in model A. This agreement implies that the method of deriving the envelope function of the jet wave from flow visualization (described in Secs. III and IV) is valid and is sufficiently accurate. An apparent overestimation by the flow-visualization method in the third mode of model A is possibly due to the spreading of thickly smoked jets.

The measurement result by the hot-wire anemometer well indicates the saturation tendency of the mouth-field strength. Although the measured v/ω of the fundamental component tends to decrease after having reached a peak level as shown in Figs. 8 and 9, the total level including higher harmonics (measured without filtration) is still increasing slightly. This possibly implies that the acoustic vortex shedding at the edge is a significant source of dissipation for the fundamental and is also a source of higher harmonics at saturation.[7–10] We had particular difficulty in obtaining a smooth jet-wave envelope near saturation, and the estimated data of μ and v/ω were lacking in Figs. 8 and 9. This was due to other jet waves which were generated by the second harmonic and superposed upon the jet waves generated by the fundamental.

VI. DISCUSSION

An envelope-based method to estimate both the jet-wave amplification factor and the mouth-field strength in organ pipes from flow visualization was demonstrated in previous sections. The experimental results were presented in dimensional terms for particular models. However, since the amplification factor is not a universal quantity as noted in the Introduction, we will use a dimensionless representation of data in this section to compare wave characteristics between organ pipe jets and free jets.

A. Organ pipe jet, free jet, and jet instability

Fletcher and Thwaites[1,2] did pioneering work on the measurement of the amplification factor on acoustically perturbed free jets. Their data are summarized in Fig. 11. Its abscissa is the Strouhal number,

$$\mathrm{St}=\omega h^*/U_0, \tag{6}$$

where h^* denotes the half-thickness of the jet. Note that their definition of the half-thickness b corresponds to our h^*, and that they used $U_{\rm ph}$ instead of our U_0. Therefore their kb corresponds to our 2 St if we assume that $U_{\rm ph}=U_0/2$ for simplicity. The data in Fig. 11 are based on such an assumption. It should be also noted that h^* is determined from the jet velocity profile in the cross-stream direction z. In addition, theoretical curves of the temporal analysis[18] (using the complex frequency) and spatial analysis[14] (using the real frequency) of the jet instability are shown in Fig. 11, where the velocity profile $\mathrm{sech}^2\,(z/h^*)$ of a Bickley jet is supposed. The data are closer to the curve of the temporal analysis for $\mathrm{St}<0.3$, although some data show anomalously large values for $\mathrm{St}>0.3$, which is contrary to the theoretical decrease.

On the other hand, very recently Nolle[13] investigated the characteristics of a free jet concerning the phase velocity and amplification factor using synchronous hot-wire measurements. His data on μh^* follows the spatial-analysis curve very closely over the range $0.03<\mathrm{St}<1$. Hence the acoustically perturbed free jet seems to share wave characteristics with the jet instability if it is described by the spatial analysis. Thus Nolle's result seems to endorse Verge's suggestion[8] that the spatial analysis[14] should be more relevant than the temporal analysis.[18]

However, it seems difficult to explain the discrepancy between the results of Nolle[13] and Fletcher and Thwaites[12] on the free jet within the framework of our current knowledge, although Nolle[13] realized a Bickley jet in his experiments, while Fletcher and Thwaites[12] had the profile only roughly approximating that of a Bickley jet in theirs. Also, it should be noted that the Bickley jet is the similarity solution for a fully developed laminar jet.[17] Therefore the Bickley jet cannot be well established when the jet transitions to turbulence.

The data shown in Figs. 8 and 9 are nondimensionalized and plotted in Fig. 12 except for a few to avoid overlapping. Since the measurement of the jet velocity profile was not done, h^* is supposed to be $h(=1.1\ \mathrm{mm})$ arbitrarily in Fig. 12. Note that the sounding frequencies of the models were as

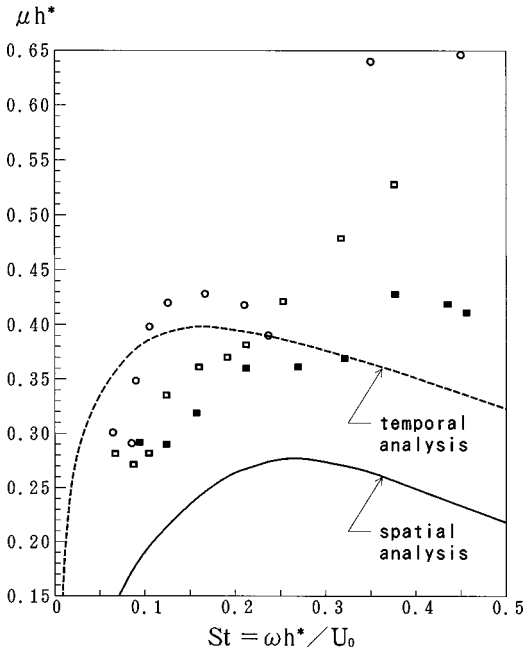

FIG. 11. Comparison of the dimensionless amplification factor μh^* of free jets (Ref. 12) with linear stability theory for a Bickley jet. The solid line: spatial theory; the broken line: temporal theory. Experimental data (Ref. 12) are shown by: ○ ($h^* \approx 0.7$ mm, $P = 100$ Pa), □ ($h^* \approx 0.45$ mm, $P = 80$ Pa), and ■ ($h^* \approx 0.45$ mm, $P = 40$ Pa).

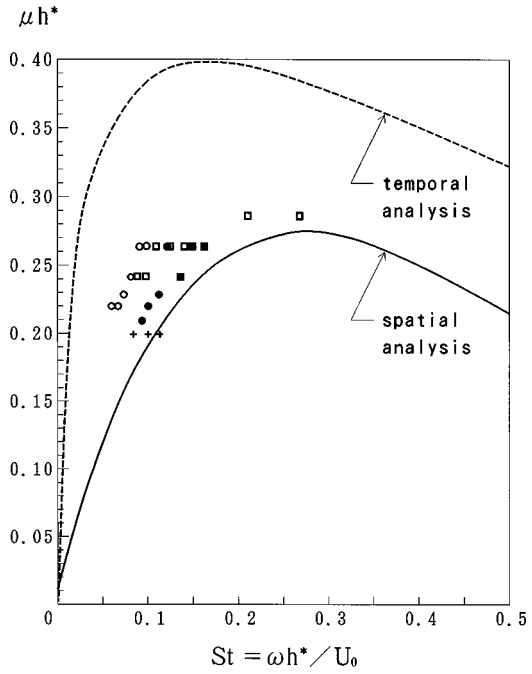

FIG. 12. Comparison of the dimensionless amplification factor μh^* of organ pipe jets with linear stability theory for a Bickley jet. The solid line: spatial theory; the broken line: temporal theory. The data of model A are shown by: ○ (first mode), ● (second mode), and + (third mode); the data of model B are shown by: □ (first mode) and ■ (second mode). The data are nondimensionalized supposing $h^* = h$.

follows: 130–136 Hz for the 1st mode of model A; 264–268 Hz for the second mode of model A; 400–406 Hz for the third mode of model A; 274–288 Hz for the first mode of model B; and 573–580 Hz for the second mode of model B. Also, note that the Reynolds number $\mathrm{Re} = 2hU_0/\nu$ (ν is the kinematic viscosity of the air, 1.51×10^{-5} m^2/s at 20 °C) extends from about 10^3 to about 5×10^3 in our experiments. We may thus consider that our jets are between laminar and turbulent jets.

The data of model A (open circle, closed circle, and ''plus'' for the first, second, and third mode, respectively) are distributed over a narrow range of St (from about 0.05 to 0.12) and indicate a sharp increase with increasing St except for the data of the third mode. On the other hand, the data of model B (open square and closed square for the first and second mode, respectively) extend over a wider range of St (from about 0.08 to 0.26) and indicate a more gradual increase with increasing St. The differences of data between two models may be attributed to the difference of d (the flue-to-edge distance) or nondimensionalized $d/2h$. Model A gives $d/2h = 7.2$ and model B gives $d/2h = 4.6$. Generally, a larger d requires a larger U_0 and a smaller ω (a larger pipe length L), that is, a smaller St. Unfortunately, the data for $\mathrm{St} > 0.3$ were not obtained because an experimental model of much smaller $d/2h$ blown with lower pressures was not provided.

It is important that our argument of dimensionless data analysis (shown in Fig. 12) is strongly influenced by the evaluation of h^*, which depends on the jet velocity profile at the flue exit and its subsequent change in the cross-stream direction.[8,9] Since we are lacking experimental results of jet velocity profile, we try to examine the sensitivity of the result shown in Fig. 12 for a change in h^*. Our organ pipe models have a long flue channel ($L_t = 100$ mm, $L_f/2h = 45.5$), so we probably have a Poiseuille profile with the parabolic distribution at the exit, which gives

$$h^* = (2/5)2h = 4h/5 \tag{7}$$

with the assumption that a subsequent velocity profile is given by a Bickley jet.[8,9] In Eq. (7) $2h$ defines the flue thickness, while Verge *et al.*[8] used h for the flue thickness and used b for h^*.

Sato[17] had experimental results showing $h \sim 0.8h^*$ for $x/2h < 7$ on the jets emerging from long channels ($L_t = 1100$ mm, $2h = 6$ and 10 mm, $U_0 = 10$ m/s, and $\mathrm{Re} = 4.0 \times 10^3$ and 6.6×10^3). Also, Ishizaka and Matsudaira[20] indicated that a Poiseuille profile was established as the distance from the channel inlet x' exceeded $x'_p = 0.028(2h)$ Re. So, we have $x'_p = 62$ mm for our organ pipe jet of $2h = 2.2$ mm and $\mathrm{Re} = 10^3$. Although the Reynolds number Re should be lower than 1.6×10^3 when the flue channel of our organ pipe models satisfies $x'_p < L_f (= 100\ \mathrm{mm})$, our organ pipe jet ($10^3 < \mathrm{Re} < 5 \times 10^3$) may be considered to have a Poiseuille-like profile at the flue exit and the relation of Eq. (7) holds as long as x is smaller than $7(2h) = 15.4$ mm.

On the other hand, if we have a uniform flow at the exit and a subsequent Bickley jet,[8,9]

$$h^* = (3/4)2h = 3h/2. \tag{8}$$

Fletcher and Thwaites[12] obtained $h^* \approx 1.4$ h for $P = 100$ Pa and $h^* \approx 1.8$ h for $P = 80$ and 40 Pa based on the measurement of the jet velocity profile. Their higher values of the ratio h^*/h might be attributed to a uniform flow at the exit. Consequently, it seems to be adequate to discuss the sensi-

tivity of our organ pipe jets to changes in h^* as given by Eqs. (7) and (8).

Figure 13 shows the result, where the data indicated in Fig. 12 ($h^*=h$) is roughly approximated by the thick solid line connecting the three points $(\mathrm{St},\mu h^*)=(0.05,\ 0.20)$, (0.18, 0.29), and (0.30, 0.29). The thick dotted and broken lines indicate the results when Eqs. (7) and (8) are applied to the data represented by the thick solid line, respectively.

Interestingly enough, the thick broken line ($h^*=3h/2$) in Fig. 13 roughly reflects the tendency of the experimental data in Fig. 11 except for a few anomalous data. On the other hand, the thick dotted line ($h^*=4h/5$) is close to the spatial-analysis curve for the jet instability. Theoretically, this thick dotted line seems to match our organ pipe jets because our long flue channel probably forms a Poiseuille flow at the exit. However, we do not know the exact changes of the subsequent velocity profile and of the velocity on the jet axis along our jets. Jet deflection with large amplitudes might also cause drastic changes in them. Hence we cannot draw a definite conclusion from Fig. 13 on whether an organ pipe jet shares wave characteristics with an acoustically perturbed free jet or not until we can obtain reliable experimental results along the jet.

Particularly, we should bear in mind the large deflection amplitudes of the organ pipe jets shown in Figs. 3–7 compared with the small free-jet amplitudes, which are at most equal to the jet thickness. The spatial and temporal theories of jet instability, which are linearized on the assumption of small amplitudes, may thus be applicable to free jets apart from the problem of which theory is more relevant. However, both theories might be inapplicable to organ pipe jets because of their nonlinear nature arising from their large amplitudes.

B. Stimulating source of jet deflection

Coltman[11] drew a seemingly contradictory conclusion about the source which initiates and sustains the oscillation of free and organ pipe jets. According to his result, the dominant source stimulating the jet wave is the transverse disturbance velocity in the flute and the transverse pressure gradient in free jet. Velocity and pressure-gradient models for organ pipes have been originally proposed by Coltman[18] and Yoshikawa and Saneyoshi,[21] respectively. Later Elder[22] developed a pressure-gradient model on the basis of the vibrating-diaphragm concept of the jet. Coltman[11] also rejected the negative displacement model of Fletcher.[5] See Ref. 13 for a more detailed and updated discussion on this problem.

However, the negative displacement model has been successfully applied in this paper, although its application is restricted to the jet envelope function in exact sense. This success might be illusive because Eq. (1) is only a semi-empirical relation. But, a good agreement of the mouth-field strength between envelope-based estimation and hot-wire measurement encourages us to reconsider the acoustic displacement as well as the acoustic velocity and the pressure gradient as the source of stimulation. We have to develop a radical new theory of the organ pipe jet deflection in the future based on fluid dynamics.

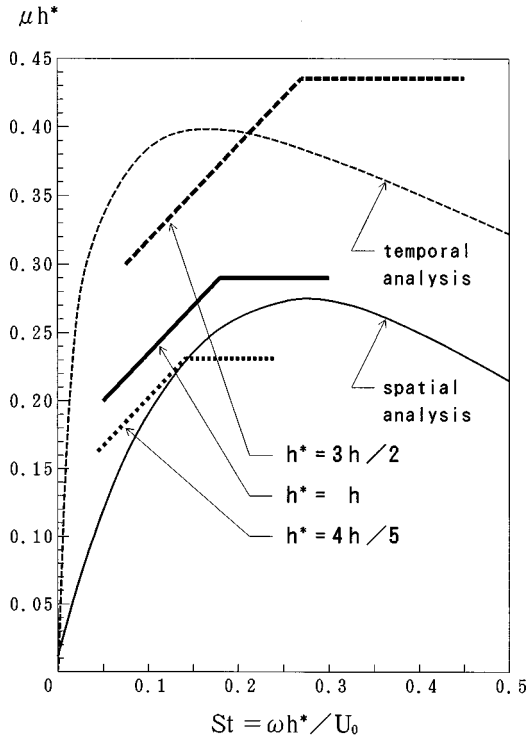

FIG. 13. Sensitivity of the experimental data shown in Fig. 12 (approximated by the thick solid line) for a change in the jet half-thickness h^*. The thick dotted line is for $h^*=4h/5$ (a Poiseulle channel flow and a Bickley jet) and the thick broken line for $h^*=3h/2$ (a uniform channel flow and a Bickley jet).

VII. CONCLUSIONS

The amplification factor of a growing jet wave in organ pipes was successfully estimated from flow-visualization data acquired with a high-speed digital video camera. The estimation was done by comparing the theoretical and experimental envelopes of jet waves in steady states. The theoretical envelope was approximated using the negative displacement model[5] to separate the amplification factor from the phase velocity and time reference of the jet wave. The experimental envelope was extracted by superposing jet waves visualized as instantaneous shapes (called streaklines) of lateral jet deflection. Theoretical approximation of the envelope tended to give an estimate of the amplification factor that was about 10% higher than the experimental one. We speculated that experimental error was below 10%.

Our envelope-based method gave an estimation of the mouth-field strength (defined as the absolute amplitude of the acoustic displacement) as well as the amplification factor. A good agreement of the mouth-field strength was obtained between envelope-based estimation and hot-wire measurement. This agreement confirmed the validity and reliability of our envelope-based method. As the result, the amplification factor was roughly estimated to be in the $0.18-0.26\ \mathrm{mm}^{-1}$ range, while the mouth-field strength was 0.5–1.5 mm in our two experimental models.

A dimensionless representation of our experimental data on the amplification factor was employed to discuss the

wavy nature of an organ pipe jet and an acoustically perturbed free jet. The importance of accurately estimating the jet half-thickness from the velocity profile was rerecognized when examining the sensitivity of our organ pipe jets for a change in the half-thickness. If it is valid to assume a Poiseulle flow at the flue exit and a subsequent Bickley jet, the spatial theory on jet instability seems to be relevant to our organ pipe jets.

However, definitive conclusions about the difference between organ pipe and free jets must be postponed until we can obtain experimental data on the half-thickness to determine the amplification factor more exactly. The spatial and temporal theories on jet instability, which are valid for small amplitudes of disturbance less than the jet thickness, might be inapplicable to large amplitudes of an organ pipe jet wave, which call for a nonlinear approach to proper analysis. Also, a brief comment on the source of stimulation of jet deflection was given, and our reconsideration of the acoustic displacement[5] as well as the acoustic velocity[18] and the acoustic pressure gradient[21,22] was encouraged.

ACKNOWLEDGMENTS

The author would like to show his sincere appreciation for helpful comments and kind suggestions for the manuscript and a great deal of encouragement from Professor Neville H. Fletcher of Australian National University, Professor A. Wilson Nolle of the University of Texas at Austin, Professor Samuel A. Elder of the U.S. Naval Academy, Professor Abraham Hirschberg of Technishe Universiteit Eindhoven, and Dr. Marc-Pierre Verge of IRCAM. The author is grateful to Professor James B. Cole of Tsukuba University for his careful editing of the English expression. The author is also grateful to Professor Keinosuke Nagai of Tsukuba University for his long-term support of hot-wire measurement. Finally, the author would like to express his acknowledgments to the anonymous reviewers, each of whom contributed relevant comments and valuable suggestions.

Acoustic anisotropy in bovine cancellous bone

A. Hosokawa and T. Otani
Department of Electrical Engineering, Faculty of Engineering, Doshisha University, 610-0321 Kyotanabe-shi, Japan

(Received 8 August 1997; accepted for publication 22 January 1998)

This paper presents the experimental results on the acoustic anisotropy in bovine cancellous bone. The propagation of both fast and slow longitudinal waves in bovine cancellous bone was experimentally examined in relation to the structural anisotropy, or the trabecular arrangement. Propagation speeds of the fast and slow waves were measured as a function of the propagation angle to the trabecular alignment, and theoretically estimated by use of Biot's theory for an isotropic medium. © *1998 Acoustical Society of America.* [S0001-4966(98)01605-1]

INTRODUCTION

Cancellous bone is comprised of a connected network of trabeculae, and can be considered an anisotropic medium due to the arrangement of the trabecular pattern. It is predicted that cancellous bone has an acoustic anisotropy in relation to the trabecular arrangement. In our previous paper,[1] the propagation of both fast and slow longitudinal waves in bovine cancellous bone was clearly identified when the acoustic wave travels parallel to the direction of the trabecular alignment. The purpose of the present paper is to reveal the relation between the propagation of the two waves and the structural anisotropy in cancellous bone.

An ultrasonic immersion technique is used to determine the propagation speeds of the fast and slow waves as a function of the propagation angle to the trabecular alignment. Theoretical discussion is performed by applying Biot's theory on the acoustic propagation in a fluid saturated porous solid.

I. THEORY

Biot proposed a phenomenological theory of acoustic propagation in a porous elastic solid saturated by a viscous fluid,[2,3] by considering a coupling between the solid and fluid. In Biot's theory, the average motions of both the solid and fluid parts are separately described. At high frequencies sufficient enough that the viscous skin depth $(2\eta/\rho_f\omega)^{1/2}$ is much smaller than the pore size a_0 (η is the fluid viscosity, ρ_f is the density of the fluid, and ω is an angular frequency), the two longitudinal waves have nondispersive speeds $\nu_{\text{fast,slow}}$ of the form[4,5]

$$\nu^2_{\text{fast,slow}}=2(HM-C^2)/\{(M\rho+Hm-2C\rho_f)\mp[(M\rho+Hm-2C\rho_f)^2-4(HM-C^2)(m\rho-\rho_f^2)]^{1/2}\}. \tag{1}$$

Here, H, C, and M are generalized elastic coefficients which can be related to the bulk moduli of the solid K_s, the pore fluid K_f, the bulk K_b, the shear moduli μ of the skeletal frame, and the porosity β.[6,7] β is expressed as

$$\beta=\frac{\rho_s-\rho}{\rho_s-\rho_f}, \tag{2}$$

where ρ is the total density and ρ_s is the density of the solid. In Eq. (1), m is the density parameter, which is used to account for the fact that not all of the pore fluid moves in the direction of the pressure gradient because of tortuosity or sinuosity, and is defined by the equation

$$m=\alpha\rho_f/\beta. \tag{3}$$

Here, α is the structure factor and it is determined by the relation given by Berryman[8] as

$$\alpha=1-r(1-1/\beta), \tag{4}$$

where r is a variable calculated from a microscopic model of a frame moving in the fluid.

According to Gibson,[9] the bulk K_b and shear moduli μ of the trabecular frame of cancellous bone are functions of the bone volume fraction $V_f(=1-\beta)$ and expressed as

$$K_b=\frac{E_s}{3(1-2\nu_b)}V_f^n, \tag{5}$$

$$\mu=\frac{E_s}{2(1+\nu_b)}V_f^n, \tag{6}$$

where n is a variable depending on the geometrical structure of the trabecular frame[9] and ν_b is the Poisson's ratio of the frame.

II. EXPERIMENTS

A. Specimen preparation and experimental method

Eleven cancellous bone specimens, about 20×20 mm in size and 9 mm in thickness, were cut from the distal epiphysis of bovine femora, with soft tissue (bone marrow) *in situ*. The density ρ of each specimen was measured using Archimedes' principle, and then the porosity β was calculated by Eq. (2). The density ρ_s of the solid bone was given by Lang as 1960 kg/m^3,[10] and are equivalent in value to bovine cortical bone. (The value of $\rho_s=2000\pm50$ kg/m^3 was measured by ourselves.) The density $\rho_f=930$ kg/m^3 of bone marrow was taken from our own work.[1] The trabecular arrangement was estimated by x-ray photography. An x-ray photograph of a typical trabecular structure in cancellous bone used in our experiments and its local coordinate system are shown in Fig. 1. The axes x_1, x_2, and x_3 are equivalent

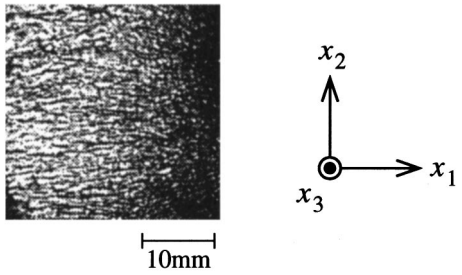

FIG. 1. X-ray photograph of bovine cancellous bone.

to the longitudinal, transverse, and sagittal axes in the general anatomic coordinates. The x_1 axis is in the main direction of the trabecular alignment, and x_2 and x_3 are perpendicular to the major direction of trabeculae. One of the eleven specimens had trabecular structure aligned parallel to the thickness direction and the others in the perpendicular direction. As we predict that air penetrates the narrow spaces between the trabeculae and soft tissue during the cutting and forming processes of the specimens, prior to experiments all specimens were saturated with water and decompressed to remove air bubbles.

The experimental arrangement of the ultrasonic immersion technique is shown in Fig. 2. A wide band (0.1–10 MHz) PVDF transmitter and a hydrophone were submerged in distilled water at $23.0 \pm 0.5\,^{\circ}\mathrm{C}$ at a distance of 90 mm apart. The specimen was then mounted between the transmitter and hydrophone. The transmitter was excited to emit an ultrasonic pulse wave with a center frequency of 1 MHz and the associated pulse waves, that propagate through the water/specimen/water system, were detected by the hydrophone. The output signal was amplified by a 40-dB preamplifier and displayed on a digital storage oscilloscope. The specimen was held at an angle θ_i to the ultrasonic beam as shown in Fig. 3. At oblique incidence on the surface of the specimen, an ultrasonic beam shift occurs in the y direction because of refraction, and has a displacement of

$$\Delta y = \frac{\sin(\theta_r - \theta_i)}{\cos\,\theta_r}\, d, \tag{7}$$

where θ_r is the angle of refraction and d is the thickness of the specimen. From this, time difference Δt of the signal

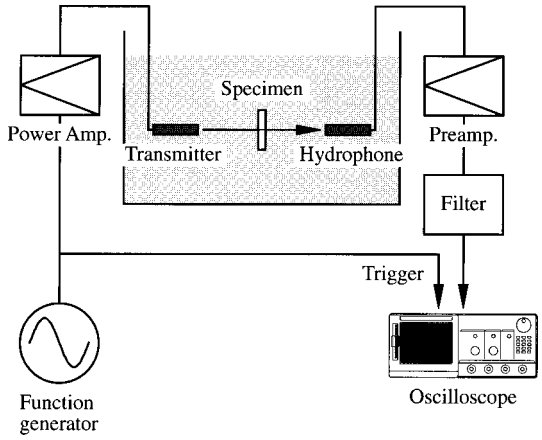

FIG. 2. Experimental arrangement of the ultrasonic immersion technique.

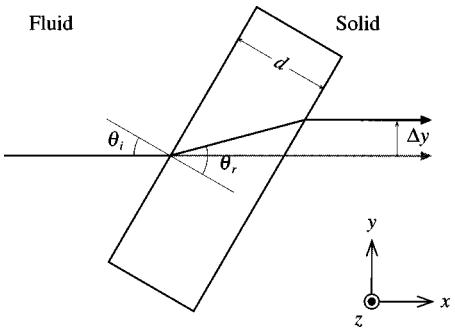

FIG. 3. Schematic drawing of refraction at fluid/solid/fluid interfaces.

with and without a specimen in the path of the ultrasonic beam is then

$$\Delta t = \left[\frac{\cos(\theta_r - \theta_i)}{\cos\,\theta_r}\, d\right] \frac{1}{\nu_0} - \frac{d}{\cos\,\theta_r}\,\frac{1}{\nu}, \tag{8}$$

where ν is the propagation speed of ultrasonic wave in the specimen and ν_0 the wave speed in water. The propagation angle, θ, to the trabecular direction equals the refracted angle θ_r if the trabeculae of the specimen are aligned parallel to the thickness direction. The propagation speed $\nu(\theta)$ in the specimen at an angle θ can be derived by measuring the ultrasonic beam shift Δy and the time difference Δt with Eqs. (7) and (8).

B. Experimental results

Figure 4 shows a pulsed waveform traveling only in water, and Fig. 5 pulsed waveforms traveling through the specimen of density $\rho = 1120\ \mathrm{kg/m^3}$ (porosity $\beta = 0.82$) with trabeculae aligned parallel to the thickness direction, at incident angles of $\theta_i = 0°$, 10°, 20°, and 30°. At incident angles of $\theta_i = 0°$, 10°, 20°, and 30°, the fast wave propagates at angles of $\theta = 0°$, 16°, 31°, and 44° to the trabecular alignment by refraction and the slow wave at $\theta = 0°$, 9°, 18°, and 27°. Both fast and slow longitudinal waves can be clearly observed at $\theta_i = 0°$ (or the x_1 direction shown in Fig. 1). As the angle θ_i of incidence increases (i.e., as the angle θ of propagation increases), the propagating time of the fast wave between the transmitter and hydrophone becomes slower. On the other hand, little change is observed in the propagating time for the slow wave. Accordingly, the fast and slow waveforms widely overlap in time at incident angles of $\theta_i = 20°$

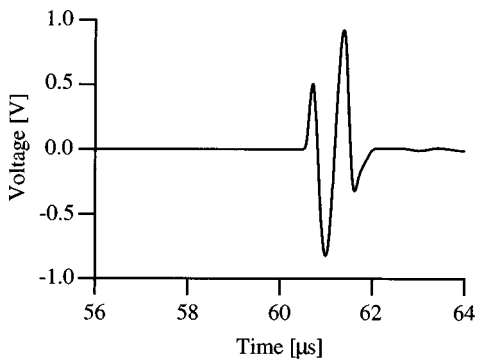

FIG. 4. Pulsed waveform with a center frequency of 1 MHz traveling in water.

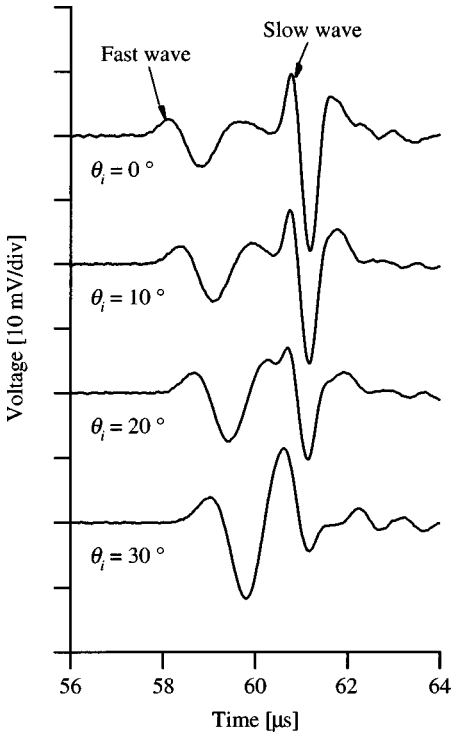

FIG. 5. Pulsed waveforms traveling through a cancellous bone with trabeculae aligned parallel to the thickness direction, at various angles θ_i of incidence.

and 30°. At oblique incidence on the solid surface, the shear wave can be generated in the solid by mode conversion. Although the experiments were carefully performed, the shear wave propagating through cancellous bone could not be observed at any angle of incidence. We therefore consider that the observed results are not affected by the generation of the shear wave. Figure 6 shows a pulsed waveform traveling through another specimen ($\rho = 1120$ kg/m^3) with trabeculae aligned in the perpendicular direction at normal incidence (or propagating at an angle $\theta = 90°$ to the trabeculae). In Fig. 6, the fast and slow waves completely overlap and are observed as if a single wave propagated. Both the fast and slow waves generally exist on propagating through cancellous bone.

The propagation speeds of the fast and slow waves were measured as a function of the propagation angle θ to the trabecular alignment. The specimen of porosity $\beta = 0.82$ with trabeculae aligned in the parallel direction was then used.

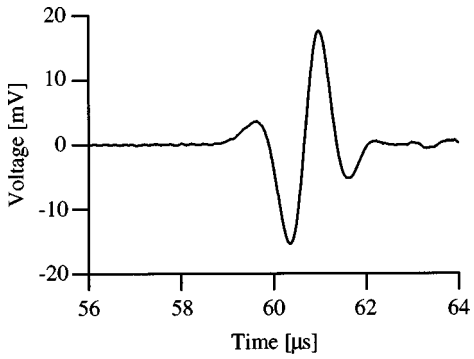

FIG. 6. Pulsed waveform traveling through a cancellous bone with trabeculae aligned perpendicular to the thickness direction, at normal incidence.

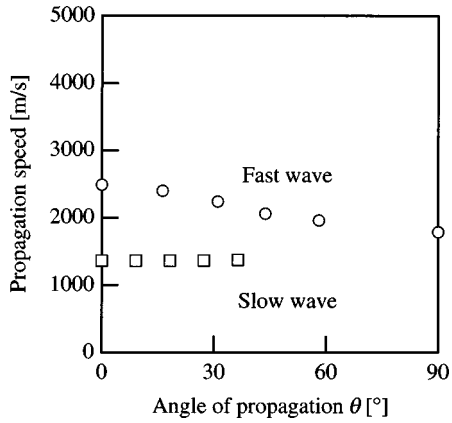

FIG. 7. Propagation speeds of fast and slow waves in cancellous bone as a function of propagation angle θ to the trabecular alignment.

For the measurement of the slow wave, a pulse wave with a center frequency of 3 MHz was used. The fast wave propagating in bovine cancellous bone is highly attenuated over 1.5 MHz.[1] At a frequency of 3 MHz, the signal of the fast wave is much weaker than that of the slow wave, allowing easy separation of the slow wave. Figure 7 shows the measured results. In Fig. 7, the propagation speed of the slow wave is almost constant, but the speed of the fast wave decreases and approaches close to that of the slow wave as the angle θ increases. Figure 8 shows the speed of the fast wave in the perpendicular direction to the trabeculae (or the x_2 direction) as a function of bone volume fraction V_f. Ten cancellous bone specimens with trabeculae aligned in the perpendicular direction were then used. No data for the slow wave was obtained in this case because the fast waveform completely overlaps that of the slow waveform. For comparison, our previous data[1] for propagation in the parallel direction (the x_1 direction) is reproduced in Fig. 9. In the range $V_f = 0.1-0.3$, the propagation speeds of the fast wave propagating in the perpendicular direction is much slower than that in the parallel. Slight scatters of the measured values are observed in both Figs. 8 and 9 because of the heterogeneity of the trabecular structure.

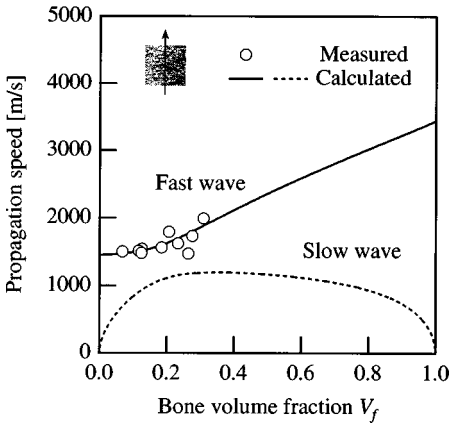

FIG. 8. Propagation speeds of fast and slow waves in cancellous bone with trabeculae aligned perpendicular to the direction of propagation, as a function of bone volume fraction V_f.

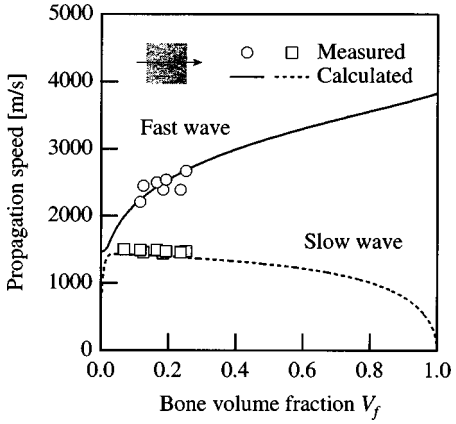

FIG. 9. Propagation speeds of fast and slow waves in cancellous bone with trabeculae aligned parallel to the direction of propagation, as a function of bone volume fraction V_f. This data first appeared in the Journal of the Acoustical Society of America (Hosokawa and Otani, 1997).

III. DISCUSSION

In our previous paper,[1] we attempted to apply Biot's theory for an isotropic medium to the ultrasonic wave propagation in bovine cancellous bone. By considering the trabecular structure in the direction of propagation, we could then apply Biot's theory for an isotropic medium to determine the propagation speeds of the fast and slow waves along the trabecular alignment. In the present paper, for comparison with our previous results, we attempt to investigate the wave speeds propagating in the perpendicular direction to the trabecular alignment by the same method.

Table I lists the values of the input parameters used in Biot's theory. The Young's modulus $E_s = 20$ GPa of the solid bone (cortical bone) were taken from work of Williams and Johnson.[11] The bulk modulus $K_f = 2.0$ GPa of bone marrow were taken from our own work.[1] The Poisson's ratio of the trabecular frame ν_{b21} (1 and 2 correspond to the x_1 and x_2 direction shown earlier in Fig. 1) was taken from the work of Williams and Johnson[11] and equals 0.23. The value of $r = 0.25$ was chosen by Williams.[12]

The values of n in Eqs. (5) and (6), which depends on the trabecular arrangement in cancellous bone, were estimated to fit the experimental data of the speed of the fast wave as a function of bone volume fraction V_f. This resulted in a value of $n = 2.14$ in case of propagation in the perpendicular direction to the trabecular alignment. For propagation parallel to the trabeculae, a value of $n = 1.46$ was obtained by the same method.[1] The propagation speeds of the fast and slow waves were calculated as a function of bone volume fraction V_f, using Eqs. (1)–(6). [For the viscosity of bone marrow, a value of $\eta = 1.5$ N s/m^2 was taken from the paper of McKelvie and Palmer.[13] Equation (1) is applicable to the propagation speeds in cancellous bone because the value of the viscous skin depth $(2\eta/\rho_f\omega)^{1/2}$ is 0.14 mm at 1 MHz and is much smaller than the pore size a_0 of cancellous bone used in our experiments, which vary from about 0.5 to 1.5 mm.] The calculated results for propagation in the perpendicular direction are shown in Fig. 8, with measured data. The results in the parallel direction are also shown in Fig. 9. We consider that in both Figs. 8 and 9 the measured values correspond well to the calculated values; with due consideration to the heterogeneity of the trabecular structure; although a slight scatter in the measured values is observed.

TABLE I. Input parameters of cancellous bone in Biot's theory.

Young's modulus of solid bone E_s	20 GPa
Density of solid bone ρ_s	1960 kg/m^3
Bulk modulus of bone marrow K_f	2.0 GPa
Density of bone marrow ρ_f	930 kg/m^3
Poisson's ratio of trabecular frame ν_{b21}	0.23
Variable r	0.25

As stated previously, the value of n depends on the direction of loading (or the direction of propagation) to the trabecular arrangement. Gibson derived by analyzing the mechanical behavior of cancellous bone that n has a value of 1 when cancellous bone is loaded along the direction of trabecular alignment, and a value between 2 and 3 in the transverse (or perpendicular) direction.[8] The values of n obtained in our experiments, $n = 2.14$ for propagation in the perpendicular direction to the trabeculae and $n = 1.46$ in the parallel direction, are slightly larger than Gibson's analytical results. This is because the trabecular orientations of the specimens used were partially heterogeneous. Here, the parameter n is the exponent of the power law for the elastic moduli of cancellous bone [see Eqs. (5) and (6)]. Accordingly, Biot's theory for an isotropic medium is applicable to the propagation speeds of both fast and slow waves in cancellous bone with anisotropic structure by considering the elastic moduli in the direction of propagation.

The decreasing amplitude of the slow wave with increasing incident angle θ_i (the propagation angle θ to the trabeculae) could clearly be observed in Fig. 5. Figure 10 shows the change in amplitude at 3 MHz of the slow wave as a function of the propagation angle θ. The propagation of the slow wave, which is related to the motion of the fluid in the pore spaces relative to the solid frame, significantly depends on the structure of the solid frame.[2,3] The fluid motion in the spaces parallel to the trabeculae is much smoother than the motion in the perpendicular spaces. From this observation of the slow wave, it is thus shown that the slow wave in cancellous bone is effectively generated by movement along the trabecular alignment.

IV. CONCLUSIONS

We have experimentally examined the acoustic anisotropy in bovine cancellous bone. It was shown that both fast and slow longitudinal waves generally propagate in cancellous bone. The propagation speed of the fast wave tends to be similar to that of the slow wave when the acoustic wave propagates at high angles to the trabecular alignment. The propagation speeds of the two waves propagating through a cancellous bone with trabeculae parallel and perpendicular direction could be estimated using Biot's theory for an isotropic medium by considering the elastic moduli of cancellous bone. Furthermore, the experimental results showed that the amplitude of the slow wave depends on the trabecular alignment, which means the trabecular structure contributes to the generation of the slow wave.

We conclude that cancellous bone has a strong acoustic anisotropy which is significantly related to the trabecular arrangement.

INTRODUCTION

In a paper published in this *Journal* (Chotiros, 1995), the author claims to have experimentally detected a Biot wave of the second kind propagating at a velocity near 1200 m/s in near-bottom sand. He justifies this claim by presenting numerical results obtained using the Biot theory with input parameters which purportedly model the physical conditions of the experiment. However, it appears that the author, in his efforts to obtain an output from the theory that matches the experimental results, has chosen certain parameters that are not justified on the basis of either theoretical considerations or historical experimental results. The purpose of this commentary is to discuss these inconsistencies and their consequences.

I. BIOT PARAMETERS

The Biot parameters used by the author are shown in Table I. In this table the column labeled ''Historical'' summarizes the range of parameters used by several different investigators who gave examples of Biot models for sand confined at low effective stress levels. Their work is described in Refs. 9–13 of the subject paper. In the column labeled ''Chotiros,'' the range of values chosen by the author in an effort to match the data at three different experimental sites is given.

The most striking differences between the historical parameters and the parameters chosen by the author are in the value of the frame bulk modulus, which is at least one order of magnitude larger than the largest historical value ($5.30E+09$ compared to $4.36E+08$ Pa) and the value of the bulk modulus of the grains, which is a factor of 5 smaller than the historical values. When the historical values of the parameters are used in the Biot equations to calculate the wave speeds of compressional waves of the first and second kind (Biot fast and slow waves) the slow wave, velocities never reach values larger than about 400 m/s (see Fig. 12 of the subject paper) which is much lower than the 1200 m/s which the author later attempts to associate with the Biot slow wave. Not surprisingly, when the revised parameters chosen by the author are used in the calculations, the predicted slow wave velocities increase to about 1200 m/s as can be seen from Fig. 14 of the subject paper. Unfortunately, some of the input parameters chosen by the author to force this result are inconsistent with essentially all of the prior theoretical and experimental studies regarding the response of granular media.

As a first example, if the author's value of frame bulk modulus, K_b, of $5.30E+09$ Pa and frame shear modulus, G, of $2.61E+07$ Pa are used to calculate the dilatational wave speed of the dry frame using

$$\nu_p = \sqrt{\frac{K_b + 4/3G}{\rho}}, \tag{1}$$

where ρ is the mass density of the dry frame given by $\rho = (1-\beta)\rho_r$, we obtain a value of 1833 m/s. This is larger than the speed of sound in water and much too large for any granular material confined at low effective stress levels such as those that would exist with only a meter or so of overburden pressure. In fact it is in the range one would expect for weak sandstone or sand subjected to an effective stress caused by several hundred meters of overburden. Moreover, if these values of the bulk and shear moduli are used to evaluate Poisson's ratio of the skeletal frame, a value of 0.498 is obtained whereas typical values of Poisson's ratio

TABLE I. Biot parameters used in subject paper.

		Historical	Chotiros
Bulk parameters			
porosity, β	···	0.36 to 0.47	0.36 to 0.40
grain density, ρ_r	kg/m^3	2650	2650
liquid density	kg/m^3	1000	1000
grain bulk modulus, K_r	Pa	3.60E+10 to 4.00E+10	7.00E+09
liquid bulk modulus, K_f	Pa	2.00E+09 to 2.30E+09	2.25E+09
Liquid motion			
viscosity	kg/m-s	1.00E−03	1.00−03
permeability	m^2	1.00E−10 to 6.49E−12	2.15E−10 to 4.99E−11
pore size	m	1.00E−05 to 5.00E−05	1.09E−04 to 4.99E−05
virtual mass constant	···	1.00 to 1.25	1.750 to 1.889
Frame response			
frame shear modulus, G	Pa	2.61E+07 to 1.19E+08	2.61E+07
shear log decrement	···	0.00 to 0.15	0.15
frame bulk modulus, K_b	Pa	4.36E+07 to 4.36E+08	5.30E09
bulk log decrement	···	0.00 to 0.15	0.075 to 0.15

from experiments where both shear and dilatational wave speeds (or shear and extensional or rod wave speed) are measured as a function of effective confining stress are usually less than about 0.2 for dry granular materials at relatively low confining stress [e.g., see Hardin (1978) and Gardner *et al.* (1964)]. A typical set of experimental data that illustrates the kind of response to be expected in both dry and water saturated sand is shown in Fig. 1. Numerous data sets similar to the one shown in Fig. 1 are scattered throughout the geophysical and geotechnical literature (e.g., see Lambe and Whitman, 1969, Fig. 12.8).

In Fig. 1 the curves for the dry-sediment response show that both the compressional-wave and shear moduli are affected in a similar manner by an increase in confining stress. As the macroscopic confining stress increases, intergranular forces at grain contacts increase with an attendant increase in the size of the minute areas of contact. This changes both the normal and tangential compliance at each contact, and hence, the macroscopic bulk and shear moduli of the assemblage of particles are changed. Theoretical studies of the response of granular media have been carried out by many investigators (e.g., see Deresiewicz, 1958 and Duffy and Mindlin, 1957) and they all predict a small-strain, dynamic response essentially similar to that shown by the experimental data of Fig. 1, with shear and dilatational wave velocity consistent with small values of Poisson's ratio. Minor differences between experiment and theory are due to the fact that it is very difficult to describe mathematically the precise geometry of a random array of particles of irregular shape that accurately describes real materials. However, the important thing to remember is that once the primitive geometric variables such as porosity, gradation and grain shape are specified, the macroscopic moduli of the skeletal frame (shear modulus, Young's modulus, bulk modulus, etc.) are all interrelated in a specific albeit complicated way and they cannot be chosen independently in an arbitrary way if they are to represent a specific granular aggregate. Since all of these moduli depend on *both* the normal and tangential compliance at the intergranular contacts, when either of these compliances is modified for whatever reason, all of the macroscopic moduli will be affected.

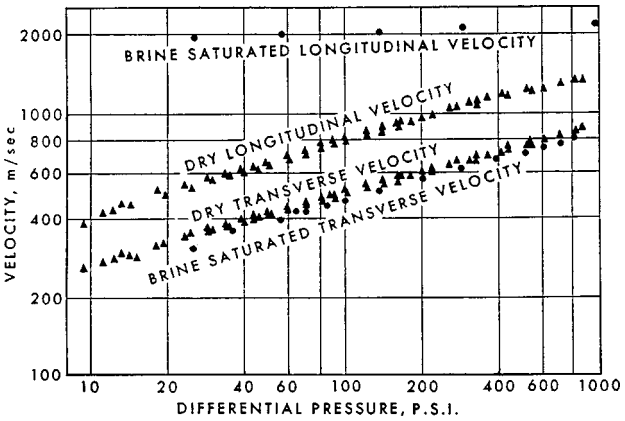

FIG. 1. Velocity of compressional and shear waves versus pressure in dry and brine saturated coarse sand (Hamilton, 1971).

The effects of fluid saturation are also illustrated by the results shown in Fig. 1. In this case, where the fluid saturant is water, there is very little change in the shear wave velocity indicating that the presence of fluid in the void space does not cause significant changes in the interparticle compliances and therefore we should also not expect large changes in the frame bulk modulus in the presence of water. On the other hand, there is a large change in the p-wave velocity because the voids are now filled with a relatively incompressible fluid and so the overall bulk modulus is also much higher. This kind of response is precisely what is predicted by the Biot theory in the general case or by the Gassmann equations (Gassmann, 1951), when fluid motion relative to the skeletal frame is neglected. In the latter case the bulk modulus of the two-component, water-saturated sediment acting as a closed system, is given by

$$K_{\text{Gassmann}}=\frac{(K_r-K_b)^2}{D-K_b}+K_b,$$

where

$$D=K_r(1+\beta(K_r/K_f-1)).$$

When this overall bulk modulus or an equivalent one from the more general Biot formulation is substituted into Eq. (1), it can be seen that the dilatational wave speed of a fully saturated sediment depends on the three bulk moduli K_b, K_r, and K_f as well as the porosity, β, and the mass density of the fluid and grains. In typical, near-bottom sediments with no cementation between grains, the dilatational wave velocity varies from values slightly less than water velocity to values in the range of 1600 to 1750 m/s depending largely on the porosity and on the compressibility of the fluid, with the shearing stiffness and compressibility of the skeletal frame playing a subordinate role. Moreover, in granular materials such as sand, it is impossible to accurately measure *in situ* porosity so that measurements of dilatational wave velocity alone generally do not lead to viable estimates of any of the input parameters. However in the present case, the author claims to have chosen K_b by back-figuring from a dilatational wave speed ''in the region of 1700 m/s'' and yet, in describing the experimental work, he estimates experimental variability to be as high as ± 300 m/s and makes no comment as to how porosities used in the calculations were determined and what variability might be expected. Finally it is easy to show that any number of different combinations of parameters will result in fast wave velocities in the region of 1700 m/s. In fact this is clearly illustrated by the author's own Fig. 12 where the computed velocities of the fast wave for all of the historical parameter sets fall within the right range without any resort to anomalously high values of frame modulus. Hence the choice of K_b resulting in a slow wave speed of 1200 m/s has the consequence of producing a model which has no physical meaning.

One additional point should be made regarding the experimental data presented by the author. Calculations of the amplitude of reflected and refracted waves for a p-wave incident to a sandy sea floor using the Biot theory (Stoll, 1977) show that the amount of energy partitioned into Biot waves of the second kind is very small (e.g., calculations for the sand model in Ref. 9 of the subject paper (Stoll and Kan, 1981) but never included in the final manuscript, indicate refraction amplitudes of the order of -40 dB relative to the displacement amplitude of the incident wave at normal incidence and even less at smaller grazing angles at a frequency of 1 kHz). This taken together with the fact that attenuation of slow waves is predicted by the theory to be very high, suggests that the amplitude of any slow waves reaching a sensor, even though it is only a few meters from the source, will be too small for reliable measurement given typical noise levels that would be produced by the prior passage of faster waves of the first kind. Hence the strong arrival that the author is trying to identify as a slow wave is further at odds with the predictions of the theory.

II. SUMMARY AND CONCLUSIONS

The Biot theory which describes the response of a porous medium saturated with a fluid is a phenomenological theory that correctly predicts the overall response of the medium based on the known response of the two separate components. It does not provide a direct link from microstructure to macroscopic behavior but rather requires the user to input a consistent and physically realistic phenomenological model for both the porous medium and the fluid as well as certain coupling ''factors'' that are inherently difficult to quantify. This puts a heavy burden on the user of the theory in that many of the thirteen or more input parameters are interrelated in a specific way and cannot be chosen independently without regard to the physics of deformation of the porous component, as appears to have been done in the present case.

It is the opinion of the writer that the author of the subject paper is not justified in his claim that a Biot wave of the second kind, with a wave speed of 1200 m/s, has been detected in a near-bottom sand deposit. This opinion is based on the fact that the author has used an unacceptable value for the bulk modulus of the skeletal frame and a questionable value for the bulk modulus of the individual grains. The very high value of frame modulus is completely incompatible with the shear modulus adopted and not justifiable on the basis of any accepted theory or experimental measurement. In addition, the grain bulk modulus obtained by the author experimentally (Molis and Chotiros, 1992) is significantly lower than all prior published measurements for typical polycrystalline materials obtained dynamically at low strain levels consistent with those in the experiments being discussed. Thus, while the values chosen for these two parameters force the Biot equations to predict a speed of 1200 m/s for the slow wave, they certainly are not representative of the material being modeled and therefore the calculated speed cannot be used to substantiate the author's interpretation of field experiments.

INTRODUCTION

The approach advocated in by Prof. Stoll,[1] which lead to the parameter values marked ''Historical,'' has worked well for porous materials with cemented frames, such as fused glass beads and sandstone, but it does not work for sand. Out of four measurable parameters, namely fast and slow compressional wave speeds, shear wave speed, and normal incidence reflection loss, the ''Historical'' parameter set is only able to match two, i.e., the fast compressional and shear wave speeds. It is unable to match measured values of either the slow compressional wave speed or the reflection loss. The parameter values, marked ''Chotiros,'' are uniquely able to match all four. The three wave speeds were addressed in the subject paper[2] and the reflection loss in a later publication.[3] The main issue lies with the values of the frame and grain moduli.

I. FRAME MODULI

The first part of the comments in Ref. 1 concerns the frame moduli, and it is based on the assumption that the bulk and shear moduli of the solid frame in the saturated condition must be the same as that of the dry condition. For unconsolidated sand the assumption is invalid, as shown below using the experimental data from Hamilton,[4] which is reproduced in Fig. 1 of Ref. 1. The Hamilton data contain the compressional (fast) and shear wave speeds of a sand specimen as a function of differential pressure, in both the dry and saturated conditions, which is a very rare and valuable combination of measurements. The differential pressure is defined as the external pressure applied to the grains, measured relative to the pressure of the pore fluid. The specimen was a sand of 0.7-mm mean grain diameter.

The shear wave speeds of the dry and saturated specimens may be inverted to give the frame shear modulus as a function of pressure. The shear wave equation[5] for a Biot medium is a simple equation which gives a unique solution for the shear modulus. The result is shown in Fig. 1. At high pressures, the shear modulus values for both the dry and saturated conditions are almost identical, but at low pressures, the difference is noticeable. The difference may be modeled as a negative pressure offset. It appears that saturation has reduced the value of the shear modulus by an amount equivalent to a constant reduction in pressure. (On a log–log plot, a constant offset produces a nonlinear shift that is more noticeable at the low end of the scale.) The cause is the capillary effect, which has a tendency to maximize the contact area between solid and fluid. In order to gain access to all unexposed solid surfaces, the fluid tends to force the solid grains apart, producing the equivalent of a negative pressure offset, giving a noticeable difference in shear modulus values at low pressures.

For the frame bulk modulus, the difference between the dry and saturated conditions is much bigger. Due to the surface roughness of sand grains, the grain–grain contact in the saturated condition may be characterized as a narrow fluid-filled gap bridged by a few solid contacts, as illustrated in Fig. 2. For a qualitative impression of sand grain surface roughness, the micrographs by Mack and Leistikow[6] are an excellent source. For modeling purposes, the grain–grain contact may be idealized as an equivalent fluid-filled gap of constant width, bridged by a single equivalent solid connection. In the dry condition, both compressional and shear stresses are channeled exclusively through the solid connection. In the saturated condition, the shear stress is still carried by the solid connection because the fluid is unable to support shear stress, but the compressional stress may be carried through both solid and fluid connections. It can be shown, as outlined in the Appendix, that there are two asymptotic conditions: a low-frequency regime in which the fluid in the gap can freely flow, and a high-frequency regime where the fluid is trapped and forced to support the compressional stress between the grains. The result is a stiffening of the grain–grain contact, analogous to the ''local flow'' model[7] for fluid saturated cracks in rocks. It is likely that the area of the fluid film is much greater than that of the solid connection and the result is a frame whose bulk modulus is very much larger than, and unconnected to, its shear modulus, and whose Poisson's ratio is very close to that of a liquid.

In support of the above argument, the compressional wave speeds shown in Fig. 1 of Ref. 1 were inverted to give the frame bulk modulus as a function of pressure, using Stoll's formulation[8] of Biot's theory and the previously obtained curve of frame shear modulus. The inversion was

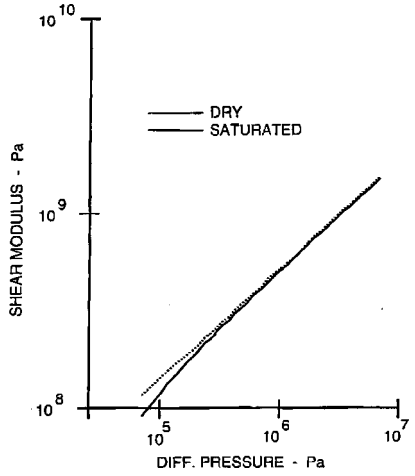

FIG. 1. Frame shear modulus as a function of differential pressure.

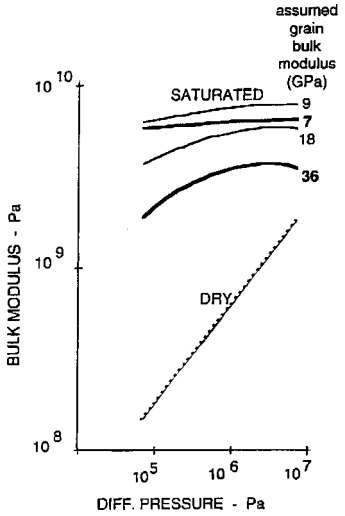

FIG. 3. Frame bulk modulus as a function of differential pressure.

done numerically using Newton's method. Although, theoretically, the equation gives several solutions for the frame bulk modulus, in practice only one solution is viable, and the convergence was rapid. The results are shown in Fig. 3. In the saturated case, since there is a strong dependence on the grain bulk modulus, the results for a number of assumed values of the grain bulk modulus are shown. It is noted that by using the ''Historical'' value of grain bulk modulus (36 GPa) the saturated and dry frame bulk moduli obtained are quite different, thus invalidating the assumption of equal moduli. The curve has the unusual behavior of increasing and then decreasing as pressure is increased; the bulk modulus of an elastic structure generally increases monotonically as a function of increasing stress.

When the ''Chotiros'' value of the grain bulk modulus (7 GPa) is used, the frame bulk modulus values are considerably greater than that of the dry condition, and increase monotonically with pressure. By applying these values to the grain–grain contact model illustrated in Fig. 2, the average fluid film thickness (a) was estimated to vary between 10 and 3 μ, and the area ratio between the solid and fluid connections (b^2/c^2) between 10 000 and 1000, over the indicated pressure range. This is an ongoing subject of research and a paper, with quantitative details, under preparation.

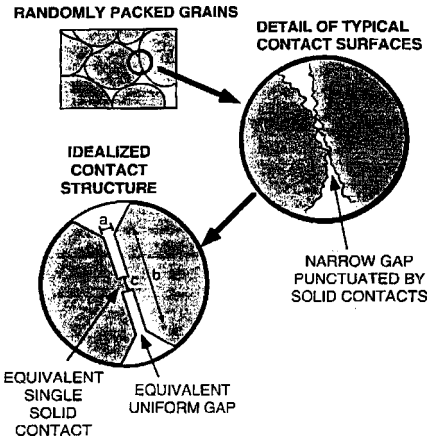

FIG. 2. Model of fluid-reinforced frame.

II. GRAIN BULK MODULUS

The second part of the comments in Ref. 1 concerns the grain bulk modulus. The ''Historical'' value of the grain bulk modulus is the one obtained from the sound speed in a solid quartz crystal. There are two main reasons why the operative value of grain bulk modulus is lower than the ''Historical'' value.

(a) Historically, it has been assumed that the bulk modulus of the materials that make up the frame is the same as that of the solid grains. In the foregoing, it was shown that a proportion of the pore fluid becomes an integral part of the frame, and hence of the grains as well. This has consequences on the operative value of grain bulk modulus. For example, at a porosity of 40%, if 10% of the pore fluid were counted as part of the frame, then the operative value of grain bulk modulus would go down from 36 to 18 GPa.

(b) So far, the discussion has been confined to a version of Biot's theory that was formulated by Stoll, but now it is necessary to go back to Biot's original equations. In Biot's original equations, the grain bulk modulus was not used directly. In its place were two other terms, the ''unjacketed bulk modulus'' and the ''coefficient of fluid content.'' The unjacketed bulk modulus is defined as the change in pore fluid pressure per unit change in the volume contained within the outer envelope of the frame, as measured in an unjacketed compressibility test.[9] The coefficient of fluid content is defined as the volume of fluid absorbed by a porous solid, per unit volume, per unit pore pressure increase, the inverse of which also has the dimensions of bulk modulus. Thus, there are three types of bulk moduli associated with the frame material. Biot and Willis[9] noted that if the porosity remains constant, independent of pore pressure, then the following relationship is applicable,

$$\gamma = f(c - \delta), \tag{1}$$

where γ is the coefficient of fluid content, f porosity, c compressibility of pore fluid, and δ compressibility of the solid material. In Stoll's formulation, this relationship is implicitly assumed, allowing the coefficient of fluid content to be eliminated entirely as an independent variable and the grain

bulk modulus to be substituted for the unjacketed bulk modulus.

The measurements by Molis and Chotiros[10] were also based on the above equation. The volume of fluid leaving a pressure chamber containing a mixture of sand and fluid was measured as a function of pore pressure, giving the coefficient of fluid content γ. Then, knowing the porosity f and fluid compressibility c, the grain bulk modulus δ was calculated using the above equation, and the values obtained were quite different from the ''Historical'' value.

It is quite possible that Eq. (1) may not be valid, as discussed by Biot and Willis. In this case, what was measured by Molis and Chotiros could no longer be equated to the grain bulk modulus. Deviations from Eq. (1) may take several forms, but the simplest is where an extra term δ_p is added. This term represents the tendency of the frame to absorb pore fluid as a function of pressure. The resulting equation is

$$\gamma = f(c - \delta - \delta_p). \tag{2}$$

A positive value of δ_p would indicate a situation where porosity increases with pore pressure. What was measured by Molis and Chotiros is no longer $1/\delta$, the grain bulk modulus, but the quantity $1/(\delta + \delta_p)$. Within the frame work of Stoll's formulation, the term δ_p is not permitted, but its effects may be simulated by a further reduction in the operative value of the grain bulk modulus.

It is very plausible that the contributions from both (a) and (b) caused the operative value of the grain bulk modulus to go from the ''Historical'' value to the ''Chotiros'' value, but more research is still needed for verification.

III. SUMMARY

The problem with the frame moduli values has been traced to the assumption that the frame moduli of the dry and saturated conditions must be the same. This assumption is not applicable to unconsolidated sand, as demonstrated by inversion of the data set in Fig. 1 of Ref. 1 for the frame moduli values; the frame moduli values obtained for the dry and the saturated conditions are quite different. A new submodel for the frame is under development, which recognizes the effect of restricted local fluid flow within each grain–grain contact in reinforcing the frame and producing an increased bulk modulus in the saturated condition. The shear modulus is also affected by the presence of the pore fluid but to a much smaller degree.

The problem with the grain bulk modulus value may be traced to two assumptions. The first is an implicit assumption that the bulk modulus of the frame material is equal to that of the solid grains. In reality, the frame is fluid-reinforced, which makes a small part of the pore fluid an integral part of the frame, resulting in a reduction in the net bulk modulus of the frame material relative to a purely solid frame, and hence an apparent reduction in the operative value of the grain bulk modulus. The second is an implicit assumption in Stoll's formulation of Biot's theory that porosity is independent of pore pressure. Biot's original equations used two parameters to represent the bulk properties of the frame material, one of which can allow for a change in porosity as a function of pore fluid pressure. This has two consequences: (a) what was measured by Molis and Chotiros can no longer be equated to the grain bulk modulus, as Hickey and Sabatier[11] correctly deduced; (b) postulating a porous solid in which porosity increases with pore fluid pressure, its effect, in the context of Stoll's formulation of Biot's theory, may be simulated by a further reduction in the operative value of the grain bulk modulus. These findings are consistent with those of Hickey and Sabatier.[11]

In summary, the ''Historical'' parameter set is incompatible with acoustic measurements, particularly the slow wave speed and attenuation and the normal incidence reflection loss. A new parameter set, that uniquely matches experimental measurements, referred to as the ''Chotiros'' parameter set, was found and published in the subject paper.[2] The new values of grain and frame moduli were controversial, as articulated in Ref. 1. Since then, progress has been made. Certain assumptions, that had been taken for granted in connection with Biot's theory, are found to be less than universal in their validity, but Biot's theory remains valid in its original form. Continuing within the context of Biot's theory, a new submodel for the frame, which includes a fluid-reinforced frame, and a revival of the coefficient of fluid content, is expected to resolve the controversy.

The underlying cause of the controversy lies in the definition of the boundary between frame and pore fluid. The division is not as simple as it seems. In Biot's equations, the pore fluid is regarded as a connected body of fluid that can move relative to the frame. Any part of the pore fluid that remains stationary relative to the frame and functions as an integral part of the frame must be counted as a component of the frame. Consequently, the operative grain and frame moduli are determined by the solid grains plus any part of the fluid that is held stationary relative to the frame. In some porous structures, all of the fluid is mobile, and this problem does not arise. In Gassmann's theory, this problem is unknown because no relative motion between frame and pore fluid is allowed.

ACKNOWLEDGMENTS

I thank Prof. Stoll for his interest in the problem and for the opportunity to discuss these very interesting issues. I thank C. J. Hickey and J. M. Sabatier, of the National Center for Physical Acoustics, for bringing the coefficient of fluid content to my attention, and for many useful discussions. This work is supported by the office of Naval Research, Code 321 OA.

APPENDIX: FLUID FILM BETWEEN TWO GRAINS

Consider a circular fluid film of thickness h, and radius r sandwiched in the contact area between two grains of sand. The passage of a sinusoidal compressional wave, at a frequency f, causes the distance between the grains, hence the film thickness h, to oscillate. A fraction x of the fluid will surge in and out of the contact region. In addition, the fluid may undergo a volumetric strain y. The lateral forces due to

the inertial reaction, u, and the viscous drag, v, associated with the moving part must balance the lateral compressional force w. Thus

$$|u|^2+|v|^2=|w|^2. \tag{A1}$$

Order of magnitude estimates of u, v, and w are approximately given by

$$|u|\approx x(2\pi f)^2\rho h\pi r^3, \tag{A2}$$

$$|v|\approx x(2\pi f)\eta\pi r^3/h, \tag{A3}$$

$$|w|\approx yK\pi rh, \tag{A4}$$

where ρ, η, and K, are density, viscosity, and bulk modulus of the fluid, respectively. Substituting from (A2), (A3) and (A4) into (A1), a ratio between x and y is obtained;

$$y^2/x^2\approx 4\pi^2r^4h^{-4}f^2K^{-2}(4\pi^2h^4\rho^2f^2+\eta^2). \tag{A5}$$

It is evident that as f tends to zero, y will be small compared to x, indicating that the fluid film will move freely with negligible volumetric strain. On the other hand, as f tends to infinity, x will be small compared to y, indicating negligible fluid flow and maximum volumetric strain, resulting in a compressional stress within the fluid that tends to resist changes in h, hence reducing the compressibility of the grain–grain contact.

(Received 10 July 1997; accepted for publication 29 January 1998)

A modal model, initially developed to modelize diffraction of electromagnetic waves by rectangular-groove gratings, is used to describe ultrasonic surface waves above the same structures in air. A simple analytical formulation which provides results comparable to the modal method is presented. Measurements performed on ultrasonic surface waves are compared to predictions obtained with the simplified formulation and the modal model. © *1998 Acoustical Society of America.* [S0001-4966(98)03105-1]

INTRODUCTION

A rectangular-groove grating is represented in Fig. 1, with a surface wave propagating in direction x, parallel to the surface of the structure, in air. The wave is purely evanescent in the direction z perpendicular to the surface. The losses are neglected inside the slits and in the free air. Acoustic[1–3] and electromagnetic[4–8] waves above these structures have been studied for a long time; many more works have been performed in the electromagnetic domain. The reflection of acoustic waves, and the behavior of surface waves, can be described by the same formalism as for the transverse magnetic (TM) waves. This property was known by Ivanov-Shits and Rozhin,[1] who used the work by Vajnshtejn,[9] but these authors were not very explicit in the description of their modeling. After Ivanov-Shits and Rozhin, in the domain of audible acoustics, the models developed for electromagnetic waves were ignored, and oversimplified models were used.

The equations that describe the acoustic field and a TM field if the structure is perfectly conducting are the same, provided the right equivalent quantities are substituted. The magnetic field has a single component H_y different from zero, and is perpendicular to the incidence plane xz of Fig. 1. The electric field lies in the xz plane and is defined, with the time dependence $\exp(-j\omega t)$, by

$$E_x = \frac{-j}{Zk}\frac{\partial H_y}{\partial z}, \tag{1}$$

$$E_z = \frac{j}{Zk}\frac{\partial H_y}{\partial x}, \tag{2}$$

where the characteristic impedance Z and the wave number k are given by

$$Z = (\epsilon_0/\mu_0)^{1/2}, \tag{3}$$

$$k = \omega(\mu_0\epsilon_0)^{1/2}. \tag{4}$$

In these equations, μ_0 and ϵ_0 are the vacuum magnetic and electric permeability. The boundary conditions are $\partial H_y/\partial x = 0$ on the plates, and $\partial H_y/\partial z = 0$ at the bottom of the slits, the electric field being normal to the conducting surface.

The description can be transposed to acoustics by replacing H_y by the pressure p, and E_x, E_z by the velocity components v_z, and $-v_x$, respectively. Equations (3) and (4) must be replaced by

$$Z = (\rho K)^{1/2}, \tag{5}$$

$$k = \omega(\rho/K)^{1/2}, \tag{6}$$

where ρ is the density and K is the bulk modulus of free air ($K = \gamma P$ where P is the atmospheric static pressure and γ the ratio of the specific heats). With this transposition, Eqs. (1) and (2) become

$$v_z = -\frac{j}{\omega\rho}\frac{\partial p}{\partial z}, \tag{7}$$

$$v_x = -\frac{j}{\omega\rho}\frac{\partial p}{\partial x}, \tag{8}$$

and the boundary conditions become $v_x = 0$ on the plates, and $v_z = 0$ at the bottom of the slits, which are the appropriate equations for the acoustic problem.

Simple expressions for the wave number components k_x and k_z that characterize the surface wave were obtained from the models by Hurd[4] and Vajnshtejn,[5] and can be transposed to acoustics. If the distance a between the blades is sufficiently small, k_z can be written[10]

$$k_z = jk\,\tan k\left(h - \frac{\log 2}{\pi}\,a\right), \tag{9}$$

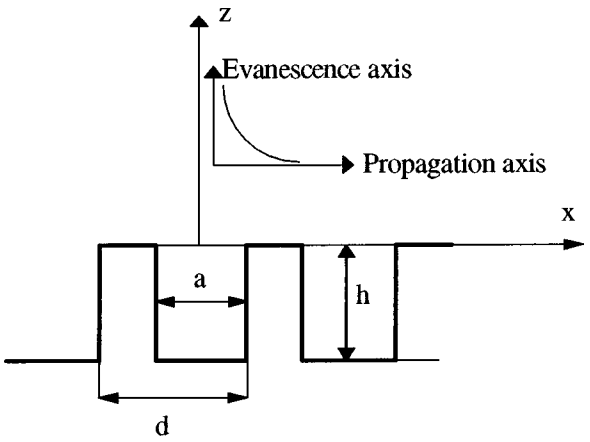

FIG. 1. A rectangular-groove grating. A surface wave that propagates in the x direction is represented over the structure.

$$k_x=(k^2-k_z^2)^{1/2}=k\left[1+\tan^2\ k\left(h-\frac{\log 2}{\pi}\,a\right)\right]^{1/2}. \tag{10}$$

This model is valid only for infinitely thin plates. A simple modal model, developed by Hessel *et al.*[6] in the context of electromagnetic waves, can be used for plates of finite thickness.

I. MODAL MODEL

The model was developed by Hessel *et al.*[6] to predict optical properties of metallic rectangular-groove gratings. Only a brief description of the model, transposed for acoustic waves, is presented. An incident acoustic wave that impinges upon the structure under an angle of incidence θ in the incidence plane xz (see Fig. 1) is related to a reflected wave and an infinite set of space harmonics scattered by the structure. Let $\hat{v}_i$, $\hat{v}_r$ and $\hat{v}_m$ the z components of the velocity field for these waves in the plane $z=0$. They can be written

$$\hat{v}_i=\hat{V}_i\hat{e}_i, \tag{11}$$

$$\hat{v}_r=\hat{V}_r\hat{e}_r, \tag{12}$$

$$\hat{v}_m=\hat{V}_m\hat{e}_m, \tag{13}$$

where $\hat{e}_i$, $\hat{e}_r$, and $\hat{e}_m$, are given by

$$\hat{e}_i=d^{-1/2}\exp(jkx\ \sin\ \theta), \tag{14}$$

$$\hat{e}_r=d^{-1/2}\exp(jkx\ \sin\ \theta), \tag{15}$$

$$\hat{e}_m=d^{-1/2}\exp\left[j\left(k\ \sin\ \theta+\frac{2\pi m}{d}\right)x\right]. \tag{16}$$

The pressure fields at $z=0$ for these waves are given by

$$\hat{p}_i=\hat{Z}_i\hat{v}_i, \tag{17}$$

$$\hat{p}_r=\hat{Z}_r\hat{v}_r, \tag{18}$$

$$\hat{p}_m=\hat{Z}_m\hat{v}_m, \tag{19}$$

where

$$\hat{Z}_i=\frac{jZ}{(\sin^2\ \theta-1)^{1/2}}, \tag{20}$$

$$\hat{Z}_r=-\hat{Z}_i, \tag{21}$$

$$\hat{Z}_m=\frac{Zk}{\hat{k}_m}. \tag{22}$$

The z wave number component $\hat{k}_m$ is given by

$$\hat{k}_m=j\left[\left(k\ \sin\ \theta+\frac{2\pi m}{d}\right)^2-k^2\right]^{1/2}. \tag{23}$$

In a slit, the acoustic field is a superposition of the different modes with z velocity field components at $z=0$ given by

$$v_0=V_0e_0, \tag{24}$$

$$v_n=V_ne_n \quad n\neq 0, \tag{25}$$

where

$$e_0=a^{-1/2}, \tag{26}$$

$$e_n=\left(\frac{2}{a}\right)^{1/2}\cos\left[\left(\frac{n\pi}{a}\right)\left(x+\frac{a}{2}\right)\right] \tag{27}$$

and the related pressure fields are given by

$$p_0=Z_0v_0, \tag{28}$$

$$p_n=Z_nv_n \quad n>0, \tag{29}$$

where

$$\begin{aligned} Z_0&=-jZ\ \cot(kh)\\ Z_n&=-jZ\,\frac{k}{k_n}\cot(k_nh) \quad n>0. \end{aligned} \tag{30}$$

The z wave number vector component k_n is given by

$$k_n=\pm j\left(\frac{n^2\pi^2}{a^2}-k^2\right)^{1/2} \quad n\neq 0. \tag{31}$$

In other slits, the field is identical, except for a phase shift $kd\ \sin\ \theta$ per cell. The continuity conditions in the $z=0$ plane for the z component of the velocity are

$$\begin{aligned} \hat{v}_i+\hat{v}_r+\sum_{m\neq 0}\hat{v}_m&=v_0+\sum_{n>0}v_n, \quad |x|<\frac{a}{2},\\ &=0, \quad \frac{d}{2}>|x|>\frac{a}{2}. \end{aligned} \tag{32}$$

For the pressure, within the aperture, the continuity equation is

$$\hat{p}_i+\hat{p}_r+\sum_{m\neq 0}\hat{p}_m=\sum_{n\geqslant 0}p_n, \quad |x|<\frac{a}{2}. \tag{33}$$

Equations (32)–(33) can be replaced by the set of linear equations

$$\begin{aligned} \sum_{n'\geqslant 0}V_{n'}\Big[&\hat{Z}_r\langle e_n,\hat{e}_r\rangle\langle e_{n'},\hat{e}_r^*\rangle\\ &+\sum_{m\neq 0}\hat{Z}_m\langle e_n,\hat{e}_m\rangle\langle e_{n'},\hat{e}_m^*\rangle-\delta_n^{n'}Z_n\Big]=-2\hat{Z}_i\hat{V}_i\langle e_n,\hat{e}_i\rangle \end{aligned} \tag{34}$$

where $\langle f,g\rangle$ is defined as the integral

$$\langle f,g\rangle = \int_{-a/2}^{a/2} f\cdot g\,dx. \tag{35}$$

Calculations have been performed with a truncated set of equations, by using 11 waveguide modes in the slit ($n \leqslant 10$) and 51 space harmonics ($-25 \leqslant m \leqslant 25$). The system of equations (34) can be rewritten

$$\sum_{n'} A_{nn'} V_{n'} = B_n, \quad n = 0,...,10. \tag{36}$$

Surface waves correspond to a singular system, because they are related to solutions with nonzero amplitude of Eqs. (36) without incident waves. The acoustic field above the structure consists in $\hat{v}_r$, and the modes $\hat{v}_m$. All these waves are evanescent in the z direction, but when $kd \ll 1$, the space harmonics are much more damped than $\hat{v}_r$ which is the dominant surface wave, with the x wave number component $k \sin\theta$ such as $\det[A]=0$, and $\sin\theta$ real >1 when losses are neglected. A simple program has been carried out to localize the zeros of $\det[A]$. It has been verified that with smaller bases for the space harmonics and the waveguide modes, the location of the zeros of $\det[A]$ was not noticeably modified for the different sets (a,b,h) considered.

II. A SIMPLE MODEL

If the contribution of the space harmonics for $m \neq 0$ and of the waveguide modes for $n > 0$ are not taken into account in Eqs. (34), the surface wave is related to

$$\hat{Z}_r \langle e_0, \hat{e}_r\rangle \langle e_0, \hat{e}_r^*\rangle + jZ\cot(kh) = 0, \tag{37}$$

which can be rewritten

$$-j\,\frac{Z}{(\sin^2\theta - 1)^{1/2}}\,\frac{4\sin^2\left(k\,\frac{a}{2}\sin\theta\right)}{ad(k\sin\theta)^2} + jZ\cot(kh) = 0. \tag{38}$$

For $ak \ll 1$, k_z and k_x are given by

$$k_z = jk\,\frac{a}{d}\tan(kh), \tag{39}$$

$$k_x = k\left(1 + \frac{a^2}{d^2}\tan^2 kh\right)^{1/2}. \tag{40}$$

When $a=d$, Eqs. (39) and (40) are very similar to Eqs. (9) and (10), h in Eqs. (9) and (10) being replaced by $h - a(\log 2)/\pi$. When porosity a/d is different from 1, it can be supposed that Eqs. (9) and (10) with an added dependence on porosity as in Eqs. (39) and (40) provide correct predictions for $k_x = k\cos\theta$ and $k_z = k\sin\theta$ from

$$k_z = jk\,\frac{a}{d}\tan k(h - a(\log 2)/\pi), \tag{41}$$

$$k_x = k\left(1 + \frac{a^2}{d^2}\tan^2 k(h - a(\log 2)/\pi)\right)^{1/2}. \tag{42}$$

In order to show the degree of validity of this hypothesis, $\sin\theta$ calculated with the modal model and with Eq. (42) is represented in Fig. 2 for a porosity a/d varying from 1 to 0.1, $d=1.1$ mm, $h=0.7$ mm, at 40 kHz. It appears that Eq. (42) provides a good order of magnitude for $\sin\theta$.

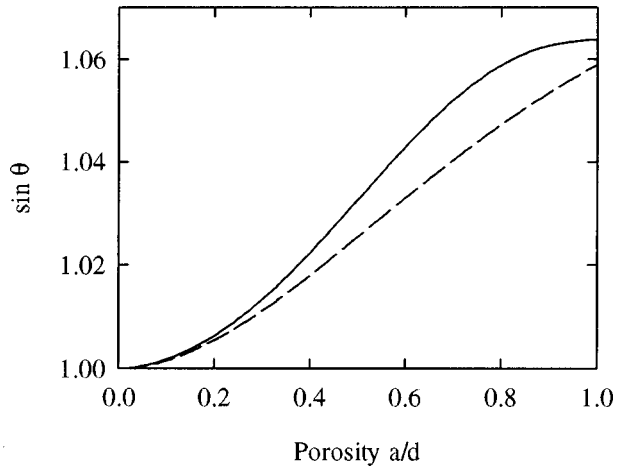

FIG. 2. Evaluation of $\sin\theta$ for $a=1.1$ mm, $h=0.7$ mm, at 40 kHz, from Eq. (42) — — —and from the modal model ———.

III. ILLUSTRATION

Measurements of the velocity of ultrasonic waves have been performed above a structure with $a=1$ mm, $d=1.1$ mm, $h=0.7$ mm from 20 kHz to 50 kHz. Velocity has been measured with ultrasonic bursts, and from interference patterns of standing waves, like in the pioneering work by Ivanov-Shits and Rozhin[1] at audible frequencies. More details on the experimental set up and the measurement technique can be found in Ref. 11. The velocity has been converted in equivalent $\sin\theta$, compared in Fig. 3 with the predictions obtained from the modal model and from Eq. (42). The agreement between experiment and predictions is good. Damping effects due to viscous forces and thermal

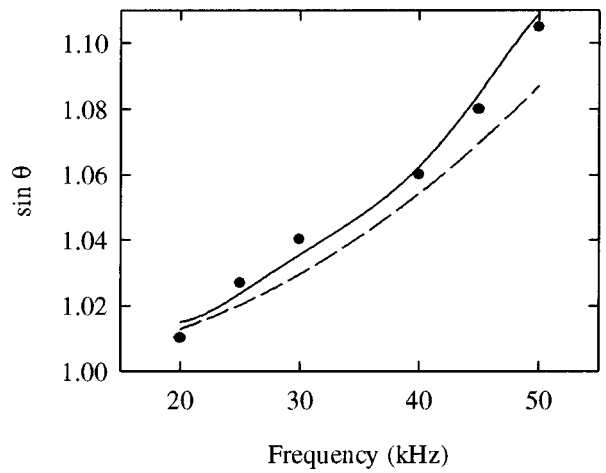

FIG. 3. Measured and predicted $\sin\theta$ for a $a=1.1$ mm, $d=1$ mm, $h=0.7$ mm. Measurement ●●●●●●●. Prediction from Eq. (42) — — —. Prediction from the modal model ———.

exchanges between air and the structure, which have not been taken into account in the calculations, can be neglected. It may be noticed that the space harmonics have not been observed, due to the strong damping in the z direction for these waves. For instance, for $m=1$, at 40 kHz, $k_z = j6.5 \times 10^3\ \mathrm{m}^{-1}$.

IV. CONCLUSION

A precise description of ultrasonic waves above rectangular-groove gratings can be obtained with a modal model initially developed in optics. The main characteristics of these waves can be obtained in a simpler way from a modified previous approximate result carried out for microwaves. The transposition of the previous works on electromagnetic surface waves to acoustics is easy and fruitful, and it is surprising that these works have generally been ignored by acousticians.

Comments on "A re-examination of risk estimates from the NIOSH Occupational Noise and Hearing Survey" [J. Acoust. Soc. Am. 101, 950–963 (1997)]

Robert A. Dobie
Department of Otolaryngology-Head and Neck Surgery, The University of Texas Health Science Center at San Antonio, San Antonio, Texas 78284-7777

(Received 14 April 1997; accepted for publication 22 January 1998)

The recent paper by Prince *et al.* [J. Acoust. Soc. Am. **101**, 950–963 (1997)] uses as a primary outcome measure an estimate of hearing handicap based on a weighted average of pure tone thresholds at 1, 2, 3, and 4 kHz. This choice is unusual and inadequately justified. If four equally weighted frequencies are to be chosen, the ANSI standard referenced by Prince *et al.* would suggest 0.5, 1, 2, and 4 kHz. If 1, 2, 3, and 4 kHz are chosen, the weights from ANSI 3.5, 1969 would be very different from those used by Prince *et al.*
[S0001-4966(98)00805-4]

PACS numbers: 43.50.Qp, 43.64.Wn [GAD]

The primary outcome variable in the paper by Prince *et al.* (1997) is the excess risk of ''hearing handicap'' (HH), using a weighted average of hearing threshold levels (HTLs) at 1, 2, 3, and 4 kHz to estimate hearing handicap. This choice of outcome variable is unusual and, I believe, inappropriate. Most state and federal workers' compensation programs use either 0.5, 1, and 2 kHz or 0.5, 1, 2, and 3 kHz; in the most recent survey known to me, *none* use the 1, 2, 3, and 4 kHz frequency combination recommended by a Task Force of the American Speech and Hearing Association (ASHA), and this recommendation apparently never became official ASHA policy, although it is one of ten frequency combinations mentioned as ''commonly used or proposed'' in a recent American National Standard (ANSI S3.44, 1996).

It is important to conceptually distinguish between HH and noise-induced hearing loss (NIHL). HH is conventionally defined as ''the disadvantage imposed by an impairment sufficient to affect the individual's efficiency in the activities of daily living'' (AAO-HNS, 1988). The American Medical Association (AMA, 1993) and ASHA use essentially identical definitions, although the AMA substitutes ''binaural impairment'' for HH. It follows that HH might well be estimated using HTLs at frequencies important for speech understanding, and this is indeed why the AAO-HNS and AMA recommend the 0.5, 1, 2, 3 kHz pure-tone average.

NIHL, on the other hand, would probably be most efficiently detected using the frequencies most affected by NIHL. In the early years of exposure, one might choose 3, 4, and 6 kHz, while for some middle-aged workers late in a noise-exposed career, lower frequencies might be better. As a compromise, the Occupational Safety and Health Administration uses the 2, 3, 4 kHz pure-tone average in their definition of a ''standard threshold shift,'' intended to detect NIHL.

Some readers may confuse the concepts of hearing handicap and an ideal detector of NIHL when they read in this paper that:

> ''definitions [of hearing handicap] that exclude the higher frequencies tend to be less sensitive to noise damage...the most suitable definition [of hearing handicap] may depend on the population characteristics, such as age, exposure duration, and degree of hearing handicap already accrued, as well as whether one chooses to identify preclinical or later stages of hearing handicap.''

These comments would be very appropriate if the first two uses of ''HH'' were replaced by ''standard threshold shift'' and the third and fourth were replaced by ''NIHL.'' HH is defined to be independent of etiology. Thus if some cause of hearing loss produced initial threshold shifts at 8 kHz, we might wish to measure those shifts to get an early warning of more communicatively significant changes to come, but we would not call these changes ''HH,'' because isolated threshold shifts at 8 kHz do not affect everyday speech communication.

Having selected HTLs at 1, 2, 3, and 4 kHz to estimate HH, Prince *et al.* (1997) applied weights to each frequency: 0.24, 0.38, 0.34, and 0.24, respectively. These weights were obtained by taking the values of Table 5 of the American National Standards Institutes method for calculating the articulation index, (ANSI S3.5, 1969), then multiplying by 100 (Prince, personal communication). That table gives weights for 15 one-third octave bands, and the four bands including 1, 2, 3, and 4 kHz contribute only 36% of the total contributions to intelligibility of the 15 bands whose center frequencies range from 200 to 5 000 Hz. It would not be surprising if readers inferred from the weights used by Prince *et al.* (1997) that 3 and 4 kHz contribute about as much (0.34 +0.24) to speech intelligibility as 1 and 2 kHz (0.24+0.38), and that frequencies lower than 1 kHz make negligible contributions, but that is not at all what Table 5 of ANSI S3.5 says.

Table 5 shows that the spectral ''center of gravity'' is about 1600 Hz, i.e., frequencies below 1600 Hz contribute about as much as frequencies above 1600 Hz. If we wished to further divide the spectrum into *four* equally contributing

bands, they would be approximately 200–800, 800–1600, 1600–2700, and 2700–5600 Hz. The four audiometric frequencies best representing each of these bands would be 500 Hz, 1 kHz, 2 kHz, and 4 kHz, not the frequencies chosen by Prince *et al.* If for some reason we insist on using 1, 2, 3, and 4 kHz, it would be most reasonable to use the logarithmic midpoints of the intervals between these frequencies (approximately 1.4, 2.4, and 3.5 kHz) to divide the spectrum into four bands that do *not* contribute equally: frequencies from 200 to 1400 Hz (corresponding to the 1 kHz HTL) contribute 44% of overall importance, while the other three bands (related to HTLs at 2, 3, and 4 kHz) contribute about 26%, 17%, and 13%, respectively. It should be noted that all of these calculations from Table 5 of ANSI S3.5 assume that frequency-importance functions for nonsense syllables, as opposed to continuous discourse, are appropriate for selecting frequencies and weights for estimating HH; frequency-importance functions for more realistic speech materials show crossover frequencies of about 1300 Hz for monosyllable words (Studebaker and Sherbecoe, 1991) and 1100 Hz for continuous discourse (Studebaker *et al.*, 1987).

Prince *et al.* (1997) do present some results based on frequency combinations of 0.5, 1, and 2 kHz and 1, 2, and 3 kHz, but these are relegated to ''sensitivity analyses.'' As expected, choice of frequencies affects the results (excess risk of HH, in this case). Nevertheless, the authors appear to have based their primary conclusions, that there is excess risk of HH at time-weighted average exposure levels both above 85 dB and also between 80 and 84 dB, on their weighted average of 1, 2, 3, and 4 kHz. As discussed above, I believe this to be an inappropriate method of estimation of HH.

(Received 29 October 1997; accepted for publication 22 January 1998)

Concern is raised by Dobie [J. Acoust. Soc. Am. **103**, 2734 (1998)] regarding a recent analysis [Prince *et al.*, J. Acoust. Soc. Am. **101**, 950–963 (1997)] of the NIOSH Occupational Noise and Hearing Survey data. Specifically, issues are raised concerning (1) definition of hearing handicap, (2) the use of frequency-specific articulation index (AI) weights applied to the binaural pure-tone average of 1, 2, 3, and 4 kHz, and (3) conclusions regarding significant excess risk based on this definition. We have reviewed the development of the definitions of hearing handicap and provide additional support for the use of a hearing handicap definition based on the binaural pure-tone average of 1, 2, 3, and 4 kHz and the weighting of specific frequencies. Furthermore, our definition of noise-induced hearing handicap is similar to one of several proposed by the International Standards Organization (ISO-1999, 1990) and the American National Standards Institute (ANSI S3.44, 1996). Additional analyses show that there is significant evidence of excess risk at daily exposure levels below 85 dB using any of the pure-tone average and/or weighting strategies we have examined. Hence we have provided additional support for our conclusions regarding exposure-response curves and we have reaffirmed that our methods are appropriate for the scope of our analysis. [S0001-4966(98)00905-9]

PACS numbers: 43.50.Qp, 43.64.Wn [GAD]

We are pleased to have the opportunity to clarify our rationale and methodology as it relates to three issues mentioned by Dobie (1998). These include (1) terminology and the use of hearing handicap, (2) use of articulation-based weights applied by frequency for the binaural pure tone average of 1, 2, 3, and 4 kHz, and (3) conclusions regarding significant excess risk based on the weighted and unweighted hearing handicap definition (Prince *et al.*, 1997).

I. DEFINITION OF HEARING HANDICAP

Dobie (1998) states that the choice of outcome variable (Prince *et al.*, 1997) is unusual and believes that it is inappropriate. The rationale for Dobie's statement appears to be that most state and federal workers' compensation programs use either a pure-tone average of 0.5, 1, 2 kHz or a pure-tone average of 0.5, 1, 2, 3 kHz and that ''none use the 1, 2, 3, 4 kHz frequency combination recommended by a Task Force of the American Speech and Hearing Association'' (ASHA, 1981).

We wish to clarify that this paper and its results were not to be applied nor were the analyses conducted for use by state and federal workers' compensation purposes. Our study was designed to evaluate damage-risk criteria for occupational noise exposure. The analysis focused on characterizing the dose-response relationship between cumulative noise dose and *noise-induced* hearing loss. Therefore its use to infer hearing handicap for compensation purposes is irrelevant to the scope of this analysis. In fact, our analysis specifically focused on ''noise-induced hearing handicap'' (NIHH) rather than ''hearing handicap'' which is independent of etiology.

Given this distinction, we believe it was appropriate to use the standard terminology for noise-induced hearing handicap used for this same purpose by international (ISO-1999, 1990) and American national standards (ANSI S3.44, 1996). The reference ISO-1999 and ANSI S3.44-1996 standards have defined hearing handicap as ''*a combination of hearing threshold levels at specified frequencies,*'' whereas ''*potential hearing impairment is directly assessed by the noise-induced permanent threshold shift (NIPTS) . . . for the exposure conditions and populations under consideration.*''

To better evaluate concerns regarding terminology, we revisited the literature relevant to the development of the 1959 American Academy of Ophthalmology and Otolaryngology (AAOO) definition which contained three frequencies (0.5, 1, and 2 kHz) and a 27 dB HL threshold for beginning handicap. Even before the adoption of the original AAOO (1958) rule, other rules for calculating percent hearing handicap had been employed, including one issued by the American Medical Association's (AMA) Council on Physical Medicine in 1947 (AMA, 1947). This method, called the Fowler–Sabine scale, used the four frequencies 512, 1024, 2048, and 4096 Hz but gave them weights of 15%, 30%, 40%, and 15%, respectively (Davis, 1978). In fact, Davis (1978) stated that this definition is a ''direct ancestor of the AAOO rules, which differ chiefly in their greater simplicity and their rejection of 4000 Hz from the calculation.'' According to Davis (1973), this method was revised in 1959 because ''it was essential to simplify the

[a]Industrywide Studies Branch, Division of Surveillance, Hazard Evaluations, and Field Studies.
[b]Risk Evaluation Branch, Education and Information Division.

more accurate but complicated Fowler-Sabine scale in order to gain acceptance. Otologists just wouldn't use the complicated table . . . .''

When the Occupational Safety and Health Administration (OSHA) promulgated its amendment for hearing conservation programs in 1981, the AAOO rule was criticized for including only three frequencies and for having a relatively high threshold for beginning handicap. The view at this time was that frequencies above 2 kHz clearly assisted the understanding of speech in noisy situations and this favored the inclusion of 4 kHz or at least 3 kHz in the calculations.

In light of mounting evidence that the higher frequencies were important for speech discrimination in nonideal conditions (distorted or with competing noise), the AAO (formerly AAOO) amended its formula to include 3 kHz (AAO, 1979). Later studies confirmed that hearing sensitivity above 2 kHz is critical for speech communication (Suter, 1985; Smoorenburg, 1992). A study by Phaneuf *et al.* (1985) confirmed that hearing sensitivity above 2 kHz was required to predict hearing disability and handicap. The study also reported that the highest precision in predicting ''judged hearing disability'' was obtained with a pure tone average of 1, 2, 3, and 4 kHz in the worse ear.

Terminology: Hearing impairment versus hearing handicap

In the original manuscript submitted to the journal, we used the term *hearing impairment* in a manner consistent with its use in the 1972 NIOSH criteria document (NIOSH, 1972) and with OSHA's definition of *material impairment of hearing* (46 Fed. Reg. 4082, 1981).[1] However, journal reviewers strongly recommended substituting *hearing handicap* to be consistent with the ISO-1999 (1990) and ANSI S3.44 (1996) standards. This seemed appropriate since additional analyses were included to compare the new NIOSH excess risk estimates to models used in these standards.

In our use of the term *hearing handicap*, the ears were given equal weighting and the frequency-specific pure-tone average was used to dichotomize the population into groups with and without hearing loss (as defined by OSHA and NIOSH). The proportions of workers with and without hearing loss were then compared to a reference value (based on ''control group'' pure-tone averages), a strategy consistent with recommendations of ISO-1999 (1990) and ANSI S3.44 (1996). Hence our definition of hearing handicap does not appear to be particularly unusual or inappropriate.

Our statements in the paper appear to be misinterpreted with regard to variation of excess risk estimates by definition of hearing handicap. To place the statements in their proper context, we discussed why the dose-response curves for NIHH may vary. We stated (Prince *et al.*, 1997) that:

''Hearing damage at 3 and 4 kHz is expected to occur sooner than loss at lower frequencies (0.5, 1, and 2 kHz). Definitions [of NIHH] that exclude the higher frequencies tend to be less sensitive to noise damage and may require longer durations of exposure to a given sound level to see significant excess risks in the population. Figures 4A and B suggest that the most suitable definition of hearing handicap may depend on the population characteristics, such as age, exposure duration, and degree of hearing handicap already accrued . . . . ''

There appears to be confusion regarding the concept of standard threshold shift and a criterion to prevent noise-induced hearing loss, for which OSHA and NIOSH ordinarily use the term ''material impairment of hearing.'' Dobie suggested that ''these comments would be very appropriate if *hearing handicap* was replaced by *standard threshold shift.*'' The purpose of *hearing handicap* (as meant here to represent material impairment of hearing), is quite different from that of *standard threshold shift.* While *hearing handicap* is used in the development of damage-risk criteria, a *standard threshold shift* refers to a change in hearing for an individual relative to a previous test and is used in the context of a hearing conservation program. The NIOSH Occupational Noise and Hearing Survey, a cross-sectional study, did not collect data on individual changes in hearing over time.

To further his arguments regarding our choice of frequencies, Dobie makes an analogy to the use of a single frequency (8 kHz). Dobie's comment that ''we wouldn't call these changes [at 8 kHz] 'HH' [hearing handicap] because isolated threshold shifts at 8 kHz do not affect everyday speech communication'' is specious. We never implied that 8 kHz or any single frequency is important for everyday speech communication. However, there is evidence that 3 kHz and 4 kHz are indeed important for speech recognition as are 1 kHz and 2 kHz. The fact that 3 kHz and 4 kHz are earliest and most severely affected by noise should not exclude them from our selection of a prevention criterion, but argue in their favor. Therefore, we consider it accurate to state that ''the addition of the most sensitive frequencies to a hearing handicap definition is a valid option if the goal is to have a measure that addresses both prevention and identification of noise-induced hearing handicap.''

II. USE OF ARTICULATION-BASED WEIGHTS FOR BINAURAL PURE-TONE AVERAGE

As mentioned previously, the idea of frequency-specific weighting is not a new concept (AMA, 1947). In our paper, the idea was conceived as an alternative that would balance the need to take into account both hearing sensitivity to noise-induced damage at 3 and 4 kHz and speech understanding. Since the frequencies do not contribute equally to speech recognition, as demonstrated by the research of French and Steinberg (1947) and others (Kalikow *et al.*, 1977; Suter, 1985; Quiggle *et al.*, 1959), a decision was made to weight the frequencies for the pure tone average with weights using the articulation index (ANSI S3.5-1969).

The articulation weights from Table 5 of ANSI S3.5-1969 were used as a relative guide to weighting the frequencies we chose to include in our definition of noise-induced hearing handicap. Given the importance of these four frequencies (1, 2, 3, and 4 kHz) in predicting noise-induced hearing handicap, we wanted to make some allowance for the relative contribution of each frequency. We were not using these data to represent 1/3 octave bands and do not have audiometric data corresponding to the 20 octave bands used in the calculation of the AI, or for each of the 15 1/3-

TABLE I. Excess risk percent by exposure level, age, duration exposed, and hearing handicap definition.

Daily exposure level (dB)	Hearing handicap definition: 1–4 kHz	1–4 kHz, AI weight[a]	1–4 kHz (alternate weighting scheme)[b]	1–3 kHz	0.5–2 kHz. (*AAOO definition*)	0.5–2 kHz. (*AAOO definition*)	0.5, 1, 2, 4 kHz (Fowler–Sabine weights)[c]

[a]AI-based were approximately 20%, 32%, 28%, and 20% for 1, 2, 3, and 4 kHz, respectively.
[b]Weights are 44%, 26%, 17%, and 13% for 1, 2, 3, and 4 kHz, respectively (Dobie, 1998).
[c]Weights are 15%, 30%, 40%, and 15% for 0.5, 1, 2, and 4 kHz, respectively (Davis, 1978).

octave bands. As calculated in Eq. (1) (Prince *et al.*, 1997), the hearing threshold level for the frequencies 1, 2, 3, and 4 kHz were given weights of approximately 20%, 32%, 28%, and 20%, respectively. In comparison to the unweighted binaural pure-tone average of 1–4 kHz, the AI-weighted version produced only minor changes in excess risks. These nominal changes in excess risk suggest that the unweighted binaural 1–4 kHz definition would also be adequate in describing the dose-response relationship. Most importantly, we have observed that nearly every other combination of frequencies and weightings examined results in the same or greater degree of excess risk.

III. CONCLUSIONS REGARDING SIGNIFICANT EXCESS RISK

Dobie appears to minimize the significance of our sensitivity analyses. Such analyses are important in exploring whether the inferences made from the data are consistent under different conditions or assumptions. The sensitivity analysis was a systematic method for evaluating modeling assumptions and decisions regarding the choice of definitions and use of frequency-specific weights.

Dobie states that in our analysis, excess risk estimates vary by choice of frequencies used, but that our primary conclusion, that ''there is excess risk of hearing handicap at time-weighted average exposure levels both above 85 dB and also between 80–84 dB,'' is based on the binaural AI-weighted pure-tone average of 1–4 AI definition, which he believes to be inappropriate. However, additional age-specific stratified analyses show that regardless of the definition of noise-induced hearing handicap (including the AAOO definition) used, our primary conclusions are supported. Table I shows additional analyses using several other definitions of noise-induced hearing handicap, all producing excess risk estimates that are higher than the binaural 1–4 kHz AI definition, particularly at daily exposure levels below 90 dB.

IV. SUMMARY

Based on the review of the literature and supporting data analyses, we conclude that Dobie's criticisms are tenuous. Further, we wish to reiterate that the results presented in our paper (Prince *et al.*, 1997) were not proposed as a basis of calculating hearing handicap for workers compensation purposes. Rather, our calculations were similar to those used by ANSI S3.44 (1996) and ISO-1999 (1990) in which the percentage of exposed workers with hearing handicap was based on a dichotomization of a binaural pure-tone average (i.e., average HTL$\geqslant$25 dB for selected frequencies) and compared to an appropriate control data base. These results may be used as a guide for developing occupational health standards for the protection of workers' hearing. The frequency-specific weighting was employed only as a relative guide to associate the pure-tone average with speech intelligibility and was not specifically advocated for use by state and federal compensation boards. Our analyses indicate that irrespective of the binaural pure-tone average definition or the frequency weighting used, excess risk estimates were similar or greater than the binaural 1–4 kHz AI definition of hearing handicap (Prince *et al.*, 1997).

ACKNOWLEDGMENTS

The authors gratefully acknowledge the advice of Dr. John R. Franks and Dr. Alice Suter in the preparation of this article.

[1]NIOSH (1972) used the term ''hearing impairment'' to define its criteria for maximum acceptable hearing loss, and OSHA later used a slightly modified term ''material impairment of hearing'' to define the same criteria (46 Fed. Reg. 4082, 1981). In this context, a worker was considered to have a material impairment of hearing when his or her binaural pure-tone average at the audiometric frequencies 1000, 2000, and 3000 Hz exceed 25 dB.

Species differences of distortion-product otoacoustic emissions: Comment on "Interpretation of distortion product otoacoustic emission measurements. I. Two stimulus tones" [J. Acoust. Soc. Am. 102, 413–429 (1997)]

M. L. Whitehead[a)]
University of Liverpool Veterinary Field Station, Leahurst, South Wirral L64 7TE, United Kingdom

(Received 14 October 1997; accepted for publication 20 January 1998)

In small mammals, there is convincing evidence for the existence of two discrete components of distortion-product otoacoustic emissions (DPOAEs), which have been called, variously, the active, low-level, or peak component, and the passive, high-level, or basal component. However, in humans, there is no convincing evidence for the existence of two analogous components of the DPOAE, at least for stimulus levels up to 85 dB SPL. These differences indicate that caution is required when generalizing from models of DPOAEs in small mammals to the human situation. [S0001-4966(98)00205-7]

PACS numbers: 43.64.Jb, 43.64Kc [BLM]

Mills (1997) presents a useful, simple model that explains several features observed in published measurements of distortion-product otoacoustic emissions (DPOAEs) in gerbils and rabbits (e.g., Norton and Rubel, 1990; Mills and Rubel, 1994; Whitehead *et al.*, 1992a, b, 1995). The model assumes that the total DPOAE signal consists of two components, one originating from the region of the peaks of the traveling waves in the cochlea, and the other originating basally in the cochlea. These ''peak'' and ''basal'' components correspond to what have previously been called ''active'' or ''low-level'' and ''passive'' or ''high-level'' DPOAE components, respectively.

An important feature consistently observed in rodents and rabbits is a notch in DPOAE growth functions. Specifically, for any one primary-frequency pair, the notch is seen at a constant L_1 of around 60–70 dB SPL, for any L_2 below about 50–60 dB SPL, as illustrated in the contour plots and 3-D plots DPOAE amplitude in Mills (1997; e.g., his Fig. 6) and other articles (e.g., Mills and Rubel, 1994; Whitehead *et al.*, 1992a, b, 1995). As noted by Mills, although the details of the notch vary slightly with stimulus-frequency parameters, the notch is seen at nearly all stimulus frequencies in almost all normal ears in small mammals. Phase measurements over the notch strongly suggest that it results from a phase cancellation of two discrete components (Whitehead *et al.*, 1992a, 1995; Mills, 1997). As such, the notch is perhaps the strongest evidence for the existence of two discrete DPOAE components in small mammals (Whitehead *et al.*, 1992a, b). In Mills' model the notch is reproduced by assuming that the peak and basal DPOAE components are 180° out of phase, resulting in a pronounced cancellation of the two components when they are of approximately equal amplitude.

In his Sec. IV D, Mills discusses the possible implications of his model for the assessment of hearing function, both in small mammals and humans. Mills' model may well be useful for interpreting DPOAE measurements in small mammals. However, the purpose of this letter is to point out that caution is required when extrapolating from models of small-mammal emissions to the human situation. This is because of substantial differences of the behavior of otoacoustic emissions between small mammals and humans. In particular, and with specific relevance to Mills' model, it is not clear from presently available data whether or not humans have two discrete DPOAE components that are equivalent to the active/low-level/peak and passive/high-level/basal components that have been demonstrated in rabbits and rodents.[1] In addition to the basic-science implications, this issue has relevance for the design and interpretation of clinical tests utilizing DPOAEs.

There are a number of pronounced differences in the behavior of DPOAEs, and of the other otoacoustic emission types, between humans and laboratory small mammals. In particular, in humans, at least for stimulus levels below 85 dB SPL, there is no highly consistent notch analogous to that observed at an L_1 of 60–70 dB SPL in small mammals. This can be seen, for example, in the contour plots of DPOAE amplitude in Whitehead *et al.* (1995; their Fig. 1). As discussed in Sec. III B of Whitehead *et al.* (1995), notches are sometimes seen in human DPOAE growth functions. However, they do not consistently occur within a narrow region of stimulus-level parameters for almost all stimulus–frequency pairs in all ears as in small mammals. In contrast, they are highly idiosyncratic, being seen only at some frequencies in any one ear, and varying greatly and more-or-less randomly (although mostly below 3 kHz) across ears in the frequencies and the stimulus levels at which they occur (e.g., He and Schmiedt, 1993). There is some association of these notches in DPOAE growth functions with the presence of spontaneous emissions and strong stimulus-frequency emissions around the frequency of the DPOAE (e.g., Wier *et al.*, 1988; Lonsbury-Martin *et al.*, 1990; Moulin *et al.*, 1992), suggesting that the notches observed in humans may

[a)]Address for correspondence: 46 Carlton Close, Parkgate, South Wirral L64 6RB, United Kingdom.

have a different origin to those in small mammals.

He and Schmiedt (1993) demonstrated that, in humans, notches in DPOAE growth functions are associated with pronounced idiosyncratic fine structure in the amplitude of the DPOAE as a function of frequency. The fine structure consists of ''ripples''—a series of peaks and valleys—that showed little or no saturation up to a stimulus level of $L_1 = L_2 = 65$ dB SPL. The pattern of fine structure tended to shift towards lower frequencies with increasing stimulus level. Thus, as stimulus level increases, a valley may shift down to a frequency at which there is a peak at a lower stimulus level. At such frequencies, there will be a notch in the DPOAE growth function if the DPOAE amplitude in the valley at a higher stimulus level is below the amplitude at the peak at a lower stimulus level.

The notches in DPOAE growth functions described in humans by He and Schmiedt (1993) show characteristics substantially different from those in rabbits and rodents. In rabbits and rodents, there is no idiosyncratic fine structure of DPOAE amplitude and, thus, no ripple of DPOAE amplitude as a function of frequency around the frequency of the notch (e.g., Whitehead *et al.*, 1992a). In humans, the specific valley in the fine structure associated with the growth-function notch is visible in the fine structure at stimulus levels lower and higher than that of the notch in the growth function. In rabbits and rodents, the growth-function notch, of course, is also seen as a local minimum in DPOAE amplitude as a function of frequency. However, in contrast to humans, this minimum is restricted to the narrow stimulus-level range of the notch, and is not visible at lower or higher $L_1 = L_2$ (e.g., Whitehead *et al.*, 1992a). Thus, whereas in humans the growth function notches are one reflection of a mechanism that operates to reduce DPOAE amplitudes in a narrow range of frequencies over a wide range of $L_1 = L_2$ in rabbits and rodents the notches only occur in that narrow range of $L_1 = L_2$ at which the two DPOAE components are $\sim 180°$ out of phase and approximately equal in amplitude. Mechanisms to explain the DPOAE fine-structure minima (and maxima) observed in humans include the mixing of DPOAE wavelets (e.g., Sun *et al.*, 1994), and the effects of reflection of cochlear-generated distortion energy from the DP-frequency place (e.g., Talmadge *et al.*, 1995; Brown *et al.*, 1996).

The species differences in the behavior of the DPOAE growth-function notches suggest that the notches in humans arise by a different mechanism from those in rabbits and rodents, and thus that the growth-function notches in humans are not necessarily evidence of discrete high-level and low-level DPOAE components.

Of the other significant differences between the otoacoustic emissions of humans and small mammals, the most pronounced are that spontaneous emissions are less prevalent in laboratory mammals than in humans, and that stimulus-frequency emissions are smaller whereas DPOAEs are larger in the small mammals, resulting in a 20–40-dB difference in the relative amplitudes of stimulus–frequency emissions and DPOAEs between humans and laboratory mammals (for review, see Whitehead *et al.*, 1996).

In humans, as in small mammals, the amplitudes of DPOAEs evoked by higher-level primaries are less reduced by trauma than are DPOAEs evoked by lower-level stimuli (for review, see Whitehead *et al.*, 1996). However, DPOAEs evoked by primaries of 75 dB SPL are reduced by various traumas in humans, and have been and are routinely and successfully used in clinical applications of DPOAEs by several groups. In the small mammals, DPOAEs evoked by 75 dB SPL primaries are regarded as dominated by the component variously called basal, high-level, or passive, and appear relatively unaffected by experimental traumas known to cause substantial hearing-threshold elevations (e.g., Mills and Rubel, 1994; Whitehead *et al.*, 1992b, 1995, 1996).

To summarize, whereas there is convincing evidence for two discrete DPOAE components in small mammals, there is no convincing evidence for discrete active/low-level/peak and passive/high-level/basal DPOAE components in humans, at least for those stimulus levels studied, i.e., up to 85 dB SPL. In the absence of a clear, consistent cancellation notch similar to that in rabbits and rodents, the overall picture of DPOAEs in humans is not that of two discrete components, but rather that of only one component which becomes gradually less vulnerable to trauma as stimulus levels increase (perhaps because of increasing saturation of the DPOAE generator). For this reason, models of DPOAE behavior in small mammals may not be directly applicable to the human situation.

What factors underlie these species differences of DPOAE behavior? I will briefly mention three possibilities. First, there may indeed be two discrete DPOAE components in humans, but which dominate the DPOAE over different stimulus-level ranges from those in small mammals (Whitehead *et al.*, 1995, 1996; Mills, personal communication). Thus, it may be the case that, in humans, the stimulus level at which the passive/high-level/basal component becomes dominant over the active/low-level/peak component is above 85 dB SPL. If so, then all of the available DPOAE data in humans would correspond to the active/low-level/peak component of small-mammal DPOAEs. According to this scenario, it is possible that, if human DPOAEs were measured at higher stimulus levels than previously used, they would show consistent notches at some L_1 above 85 dB SPL, similar to those seen at $L_1 \approx 65$ dB SPL in small mammals. In terms of Mills' model, such a finding could be interpreted as reflecting differences of cochlear-amplifier gain between species (Mills, 1997, personal communication).

A second possibility is that there is only one component to human DPOAEs. Mills (1997) makes the important point that the peak and basal DPOAE components observed in small mammals may actually be produced by exactly the same mechanism(s) within the cochlea. Thus, in his model, the two components effectively differ only in the shapes of the excitation patterns produced by the stimuli and, therefore, in the regions along the cochlea in which the DPOAEs are being produced. Further research is required to determine whether this is the case, or whether there are more fundamental, qualitative differences of generation of the two components seen in small-mammal DPOAEs. Nevertheless, in Mills' model, the distinction between peak and basal emissions lies in the precise vector summation, within various regions along the cochlea, of the contributions to the total

DPOAE from each point along the cochlear partition. Given the substantial differences in cochlear dimensions and the frequency range of hearing between humans and the laboratory small mammals, there is no *ad hoc* reason to suppose that this summation will be similar in humans to that in small mammals.

Finally, it is worth considering whether there may be more fundamental differences within the organ of Corti between mammalian orders. The outer hair cell, with its unique force-generation mechanism, appears to have evolved within the mammals—the other vertebrate classes do not have them. The evolutionary ancestors of the orders Lagomorpha and Rodentia split from those leading to the primates more than 100 million years ago. During this period, evolution could have resulted in subtle differences in the precise manner in which outer hair cells contribute to ''cochlear amplifier'' function and OAE generation. In this respect, it is worth noting the anatomical observation that humans and other primates have a more irregular arrangement of hair cells along the cochlea than do rabbits and rodents (for review, see Lonsbury-Martin *et al.*, 1988).

[1]There is, in fact, evidence for two components of DPOAEs in humans (see, e.g., Brown *et al.*, 1996). However, these do not appear to be analogous to the two components seen in small mammals. Rather, in humans, in addition to the ''main'' DPOAE component, there is a ''secondary'' component apparently originating from around the DPOAE-frequency place, and which may be thought of as an interaction of cochlear-generated distortion-products with the stimulus-frequency emission generator at the DP-frequency place. This secondary component shows different properties to both the active/low-level/peak and passive/high-level/basal components seen in small mammals.

PROGRAM OF

The 16th International Congress on Acoustics and 135th Meeting of the Acoustical Society of America

The Sheraton Seattle Hotel and The Westin Seattle Hotel • 22–26 June 1998

Technical sessions will be held at two hotels—The Sheraton Seattle and The Westin Seattle. The hotel where each session will take place is noted with an (S) for Sheraton or (W) for Westin after the room name in each session heading.

NOTE: *All Journal articles and Letters to the Editor are peer reviewed before publication. Program abstracts, however, are not reviewed before publication, since we are prohibited by time and schedule.*

MONDAY MORNING, 22 JUNE 1998 GRAND BALLROOM III (W), 8:00 TO 9:00 A.M.

Session 1aPLa

Plenary Lecture

James L. Flanagan, Chair
Research, Rutgers University, Busch Campus, Core Building 706, Piscataway, New Jersey 08855-1390

Chair's Introduction—8:00

Invited Paper

8:05

1aPLa1. Future directions in speech information processing. Sadaoki Furui (Dept. of Comput. Sci., Tokyo Inst. of Technol., 2-12-1, Ookayama, Meguro-ku, Tokyo, 152 Japan, furui@cs.titech.ac.jp)

Speech processing technologies, including speech recognition, synthesis, and coding are expected to play important roles in an advanced multimedia society with user-friendly human–machine interfaces. Speech recognition systems include not only those that recognize messages but also those that recognize the identity of the speaker. This paper predicts future directions in speech processing. It describes the most important research problems and tries to forecast where progress will be made in the near future and what applications will become commonplace as a result of the increased capabilities. The most promising application area is telecommunications. To solve various fundamental problems, a unified approach across speech recognition, synthesis, and coding is indispensable. Handling the common phenomenon of voice individuality from different aspects are: research on speaker adaptation in speech recognition, automatic speaker verification, voice conversion in speech synthesis, and the problems of very low-bit-rate speech coding quality variation from speaker to speaker. The methods that essentially solve such problems should be based on a common mathematical model. Research on the mechanism of speech information processing in our human brains, that is, how meanings of speech are understood and how speech is produced, is also crucial for epoch-making technological development in conversational speech understanding and natural speech synthesis.

Session 1aAA

Opera House Acoustics Workshop—CIARM, MCHA and Architectural Acoustics: Sound Field for the Audience, Part 1

Yoichi Ando, Cochair
Graduate School of Science and Technology, Kobe University, Rokkodai, Nada, Kobe, 657 Japan

Michael Barron, Cochair
Department of Architecture and Civil Engineering, University of Bath, Bath BA2 7AY, England

Chair's Introduction—9:15

Invited Papers

9:20

1aAA1. Spatial impression as measured in concert and opera auditoria. Michael Barron (Dept. of Architecture and Civil Eng., Univ. of Bath, Bath BA2 7AY, UK)

A coherent set of subjective experiments (published in 1973 and 1981) established the effect of spatial impression associated with early lateral reflections. The early lateral energy fraction was proposed as an objective measure. Some authors have preferred to use measures linked to cross correlation, presumably on the basis that this is probably closer to the mechanism used by the ear. The paper reviews the results of measurements of the early lateral energy fraction in 17 British concert spaces, as well as considering the measured results by Bradley in 13 North American concert halls. The discussion considers the relationship between early lateral energy fraction and hall width, the behavior of the measure close to the source and in both parallel-sided halls and fan-shaped halls. The design requirements for high spatial impression are also considered. The subjective effect of early lateral reflections is also influenced by sound level. The consequences for design of considering this additional variable in combination with the directional distribution will also be discussed. Spatial impression in concert halls and opera houses will be examined.

9:40

1aAA2. Effects of front/back energy ratios of early and late reflections on listener envelopment. Masayuki Morimoto (Environ. Acoust. Lab., Faculty of Eng., Kobe Univ., Nada, Kobe, 657 Japan, mrmt@kobe-u.ac.jp) and Kazuhiro Iida (Matsushita Comm. Ind., Yokohama, Japan)

A previous paper [M. Morimoto and K. Iida, J. Acoust. Soc. Am. **93**, 2282 (1993)] indicated that the listener envelopment (LEV) grows as the energy of reflections coming from the back of the listener increases. This paper investigates which is more effective for LEV, the F/B ratio of early or late reflections. In the experiments, a music motif is used as a source signal. The F/B ratios in the early and late reflections are changed independently, but the C value, the degree of interaural cross correlation, and the sound-pressure level of all sound fields are kept constant. The experiments were performed by using a paired comparison test. The task of the subjects was to judge which sound field had higher LEV. The experimental results indicate that the F/B ratio of both of the early and late reflections have an effect on LEV but that the latter is a little more effective for LEV than the former. This result suggests a relation between the perception of LEV and the law of the first wavefront.

10:00

1aAA3. Sound strength in concert halls: The role of the early sound field on objective and subjective measures. Jerald R. Hyde (Consultant on Acoust., Box 55, St. Helena, CA 94574)

A very important objective parameter in the acoustical understanding of concert halls is the total sound strength G which is essentially the acoustical ''gain'' of the space, normalized to source power. Measurement data are not well predicted by current theories and indicate that there must be other component factors of G in addition to the factors of distance (r) and room constant (A) of current theory. Measurements show that significant changes in G, independent of distance, are found to be directly proportional to the variation in the early reflected level G_{50} (refl.). To check this finding, a test was conducted by adding a reflector within the reverberant boundary of a hall. A significant increase in G was found in the seating area where the G_{50} (refl.) was increased. While this may seem obvious, current theory does not predict this. The factor G is therefore also found to be a function of early reflected energy where such energy acts in effect as an amplification of the source. The area receiving this early energy is energized by this amplification factor. Measurements show that specific design to provide the early reflected energy can increase G_{50} (refl.) by 2 to 3 dB and effectively amplify G by up to 2 dB. Subjective tests on the perception of loudness will be reported showing that these increases are quite significant and well above the subjective limit for loudness. A relationship with hall quality and improved ''intimacy'' is suggested with this design approach.

10:20

1aAA4. Subjective attributes for sound fields from a model of the auditory-brain system. Yoichi Ando, Hiroyuki Sakai, and Shinichi Sato (Grad. School of Sci. and Technol., Kobe Univ., Rokkodai, Nada, Kobe, 657 Japan)

Based on physiological responses, a model of the auditory-brain system may be proposed. The model consists of the autocorrelation mechanisms, the interaural cross-correlation mechanism between the two auditory pathways, and the specialization of human cerebral hemispheres for temporal and spatial factors of sound field. The specialization of the human cerebral hemisphere may relate to the highly independent contribution between the spatial and temporal criteria of sound fields on subjective preference judgments. In addition, based on the model, any other subjective attributes of sound fields can be described in terms of processes of the auditory pathways and the brain. For example, the phenomena of missing fundamental, loudness and coloration, the threshold of perception, and preferred delay of a single reflection are well described by the autocorrelation mechanism. The subjective diffuseness and ASW are described by the interaural crosscorrelation function. Even so-called ''cocktail party effects'' may well be explained by such specialization of the human brain, because speech is processed in the left hemisphere, and the directional spatial information is mainly processed in the right hemisphere. [Work was partially supported by the Ministry of Education, Grant-in-Aid for Scientific Research (C), 9838022, 1997.]

10:40

1aAA5. Reflected sound field by stage floors in the concert halls: Theoretical model analysis. Shinsuke Nakanishi, Kimihiro Sakagami, and Masayuki Morimoto (Environ. Acoust. Lab., Faculty of Eng., Kobe Univ., Rokko, Nada, Kobe, 657 Japan)

This paper theoretically analyzes a reflected sound field by the stage floor which is modeled as an infinite elastic plate with a point force excitation. Models of infinite elastic plates backed with either an air cavity or an absorptive cavity, which are often seen in stage floors of concert halls, are also considered. The far-field expression for the solution to the reflected field is derived by coupling the Helmholtz integrals for the sound fields surrounding the plate and the equation of motion for the plate. The main features of the reflected field are as follows: (1) A significant peak appears around the coincidence frequency. (2) The reflected field fluctuates due to interference between the reflection by the plate without the point force and the radiation from the plate excited by the point force. (3) The reflection characteristics show the panel absorption dip caused by a mass-spring resonance of the plate-cavity system and many small dips and peaks due to acoustic resonances of the back cavity. Effects of the parameters of the plate and cavity on the reflected sound field are discussed through numerical examples.

11:00

1aAA6. A fast room acoustical simulation algorithm based on the free path distribution. Michael Vorlaender (Inst. of Tech. Acoust., RWTH Aachen, 52056 Aachen, Germany, mvo@akustik.rwth-aachen.de)

A new algorithm is presented which provides estimates of impulse responses in arbitrary shaped rooms. It is applicable to any kind of room shape including nondiffuse spaces like workrooms or offices where, for instance, sound propagation curves are of interest. In the case of concert halls and opera houses it enables very fast predictions of room acoustical criteria like reverberation time, strength, or clarity. The algorithm is based on a conventional statistical ray tracing. However, a very low number of rays is used. During the ray tracing procedure, the distribution of free paths is recorded by considering the entire series of reflections per ray. Furthermore, the transition probabilities between free path classes and the absorption coefficients involved are stored. After the ray tracing, the free path distributions are evaluated by post-processing to create echograms. They include receiver-dependent direct sound and superposed exponential functions corresponding to classes of free paths. It is also possible to create reverberation tails without assuming *a-priori* diffuse sound fields and purely exponential decays.

Contributed Papers

11:20

1aAA7. The relationship between subjective preference for sound fields with vocal music and brain activity. Kiminori Mouri (Grad. School Sci. Technol., Kobe Univ., Rokkodai, Nada, Kobe, 657 Japan) and Yoichi Ando (Kobe Univ., Rokkodai, Nada, Kobe, 657 Japan)

The purpose of this study is to reconfirm the theory that the subjective preference for music sound fields depends on its autocorrelation function (ACF) of the source signal by means of analyzing continuous α-brain waves. Ando's theory describes that the most preferred delay time of early reflections and reverberation time are calculated by the effective duration (τ_e) of the ACF of music signals [Y. Ando, J. Acoust. Soc. Am. **74**, 873–887 (1983)]. On the other hand, it was demonstrated that the τ_e of the ACF of the α-brain wave range (8–13 Hz) from the left and right temporal lobes was changed by temporal factors relating to the subjective preference of sound fields [Y. Ando and C. Chen, J. Archit. Plann. Environ. Eng. AIJ **488**, 67–73 (1996); C. Chen and Y. Ando, *ibid.* **489**, 73–80 (1996)]. When a sound field has a constant delay time as a usual condition, it is assumed that continuous α-brain waves may be affected sequentially by the different running τ_e values of the ACF of the source signal.

11:35

1aAA8. New diagnostic system measuring orthogonal factors and calculating subjective attributes of sound fields in a real room. Masatsugu Sakurai (Yoshimasa Electron., Inc., Yoyogi, Shibuya, Tokyo, 151 Japan), Shinichi Aizawa (Yoshimasa Electron., Inc., Kobe, 657 Japan), and Yoichi Ando (Kobe Univ., Kobe, 657 Japan)

Based on the model of the auditory-brain system which consists of the autocorrelation mechanism, the interaural cross-correlation mechanism between the both auditory pathways, and the specialization of human cerebral hemispheres, a new diagnostic system was developed. The system works on a PC for Windows, thus there is no need for special additional devices. After obtaining the impulse response, four orthogonal factors including the SPL, the initial time delay gap between the direct sound and the first reflection, the subsequent reverberation time, and IACC are analyzed for the calculation of the scale values of global and individual subjective preference. In addition to the four factors, two more factors, τ_{IACC} and $\mathbf{W}_{\mathrm{IACC}}$, in the interaural cross-correlation function are figured out for evaluating the image shift of the sound source and the apparent source width (ASW), respectively. Also, the effective duration, τ_e, and fine structures of autocorrelation function of sound signals including the value of first maximum, ϕ_1, and its delay time τ_1, are analyzed. Keeping the

subjectively optimal condition, this system may be utilized for automatic control of sound fields by electroacoustic systems. The new system will be demonstrated at the presentation of this paper. [Work supported by the Ministry of Education, Grant-in-Aid for Scientific Research.]

11:50

1aAA9. Absorption by seating and audience—Whose figures, whose measurement method? Michael Barron and Steven Coleman (Dept. of Architecture and Civil Eng., Univ. of Bath, Bath BA2 7AY, UK)

Measuring the absorption coefficients of seating and audience is no easy matter because of the difference in size between auditoria and standard test chambers. An optimum test method remains still to be established. Two authors have published papers on this issue recently in the *Journal of the Acoustical Society of America*. The designer, though, is left confronted by contradicting figures and test proposals. Bradley (1992, 1996) has proposed a technique which involves measuring about five different configurations of seats to establish the absorption of infinite seat areas and absorption by the perimeter. Davies *et al.* (1994) deal with the perimeter absorption by testing with and without barriers placed over the front and sides of a test block of seating. Neither method is ideal; Bradley's depends on extrapolation to the smaller ratios of perimeter to area found in real auditoria, while Davies' method assumes that the barriers do not introduce any new problems of their own. Beranek in his new book (1996) has reanalyzed measured data from full-size concert halls to produce revised absorption figures. This paper seeks to find what common ground there is between the measurement methods and published data. It will draw on results of some tests on model seating in a model test chamber.

MONDAY MORNING, 22 JUNE 1998 GRAND BALLROOM A (S), 8:00 TO 10:30 A.M.

Session 1aAO

Acoustical Oceanography and Underwater Acoustics: Long-Range Propagation for Measurement of Ocean Processes I

Brian D. Dushaw, Chair

1aAO1. Acoustic thermometry of ocean climate: Comparison of acoustic, altimetric, and historical data. Robert C. Spindel (ATOC Group) (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105-6698, spindel@apl.washington.edu), B. D. Cornuelle, M. Dzieciuch, W. H. Munk, P. F. Worcester (Univ. California, La Jolla, CA 92093-0225), A. B. Baggeroer, D. Menemenlis, C. Wunsch (MIT, Cambridge, MA 02143), T. G. Birdsall, K. Metzger (Univ. Michigan, Ann Arbor, MI 48109-2122), C. Clark (Cornell Univ., Ithaca, NY 14850), J. A. Colosi (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543), D. Costa (Univ. California, Santa Cruz, CA 95064), B. D. Dushaw, B. M. Howe, J. A. Mercer, R. C. Spindel (Univ. Washington, Seattle, WA 98105-6698), and A. M. G. Forbes (CSIRO, Marine Labs., Hobart, Tasmania 7000, Australia)

Approximately 15 months of data are now available from the 75-Hz ATOC transmissions from the Pioneer Seamount off Half Moon Bay, CA to horizontal arrays at 11 U.S. Navy horizontal arrays in the northeast Pacific, two vertical arrays, one near Hawaii and the other near Kiritimati (Christmas) Island. The data demonstrate that ocean basin temperatures can be determined with millidegree precision. Travel time variations at tidal frequencies agree well with predicted values. Low-frequency travel time variations provide range and depth averaged temperatures that are comparable to seasonal temperature variations derived from historical oceanography (Levitus94). They are also comparable (but not identical) to temperature variations derived from contemporaneous sea surface height variations measured by satellite altimetry. Preliminary results of combining the acoustic and altimetric data in a numerical general circulation model of the North Pacific are also available.

8:25

1aAO2. Computation of *T*-phase coda. Catherine D. de Groot-Hedlin (Scripps Inst. of Oceanogr., UCSD, La Jolla, CA 92122-0225)

T-phases result from the conversion of seismic to acoustic energy at the seafloor in the vicinity of an earthquake epicenter. The time-frequency characteristics of *T*-phase coda are observed to be strongly dependent upon the bathymetry of the ocean floor in the source region; thus earthquakes from the same geographic area generate similar *T*-phase coda. In this study, detailed bathymetry and sound speeds computed from the Levitus atlas are used to simulate the *T*-phase amplitudes which would be recorded at distances of several thousand kilometers from these natural sound sources. It is hypothesized that seismic/acoustic coupling occurs over a distributed region of the ocean floor, with seismic energy being scattered into low-order modes in shallow water. Comparison with observed coda indicates that *T*-phase onset times and durations are modeled quite accurately with this simple method. The feasibility of using this method to determine accurate source times and locations for small suboceanic earthquakes, given natural ocean variability, is examined in this study.

8:45

1aAO3. Coherence analysis of multimegameter range ocean acoustic signals. Matthew Dzieciuch and the ATOC Consortium[a] (Scripps Inst. of Oceanogr., Univ. of California, San Diego, 1GPP-0225, 9500 Gilman Dr., La Jolla, CA 92093)

The quality of acoustic travel time measurements depends on the coherence of the signal as well as the bandwidth. Ocean acoustic signals exhibit coherence properties in four ways: in time, in bandwidth, and in vertical and horizontal extent. (These are conjugate to Doppler broadening, pulse time spread, and rms vertical and horizontal arrival angle.) These properties have recently been measured and can be compared for several different ranges (80–5000 km), center frequencies (28–250 Hz), and geometries (source on-bottom versus off-bottom). For signals of less than perfect coherence, techniques from communications theory can be used to improve the quality of travel time measurements by relaxing the resolution requirement. For instance, if the coherence bandwidth is less than the signal bandwidth, it is possible to consider subbands of the signal as separate measurements. How to best combine these measurements then depends crucially on the SNR. While acoustic thermometry has relied on electronically controlled sources, by allowing for the coherence structure of stochastic sources (such as T-phases, explosives, or marine mammals) an improved signal processing strategy may result. 1aAO4. Internal wave effects on single-frequency coherence, matched field processing, and adiabaticity. Kevin D. Heaney, Peter N. Mikhalevsky, Herb Freese (Sci. Applications Intl. Corp., 10260 Campus Pt. Dr., MS C4A, San Diego, CA 92121), and W. A. Kuperman (Scripps Inst. of Oceanogr., UCSD, La Jolla, CA 92093)

A set of PE calculations at various frequencies (10, 30, 75, and 150 Hz) through internal wave realizations was performed. To examine the range/frequency limits of coherent processing, the coherence against the range-independent PE was calculated every km out to 3000 km. The coherence between with and without internal waves drops to 0.8 (-2 dB) at ranges of 3000, 1800, 500, and 200 km for the 10, 30, 75, and 150 Hz, respectively. The sidelobe structure of matched-field processing results confirms these as range/frequency limits of matched-field processing. Vertical coherence as a function of range and frequency will be presented. The decomposition of the full field into normal mode amplitudes will be presented, as well as range limits for the adiabatic approximation. The validity of the first-order perturbation theory correction to the adiabatic approximation will be examined.

9:30

1aAO5. Modal leakage in range-dependent oceans. Arthur B. Baggeroer (MIT, 77 Massachusetts Ave., Bldg. 5-204, Cambridge, MA 02139) and Edward K. Scheer (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

The validity of the adiabatic approximation for modal propagation at low frequencies and over long megameter ranges is evaluated. A dynamical ocean model for the sound speed profile perturbations is superimposed upon a canonical Munk profile to represent a range-dependent ocean. The channel is excited with a single mode and propagated with the Collin's FEPE code which was tuned to conserve the energy in each mode in a range-independent ocean. Modal amplitudes were determined by projecting the field on the local range-dependent modes. If one uses displacements which correspond to nominal experimental levels in the Atlantic, mode coherence is maintained only for ranges less than 1 megameter at 75 Hz; the energy appears to approach equipartitioning. Results starting with mode 1 and mode 10 were qualitatively the same. If the displacements are reduced by a factor of three, possibly more representative of Pacific levels, modal coherence is maintained for more than four megameters.

1aAO6. Coupled-mode sound propagation in a range-dependent, moving fluid. Oleg A. Godin (School of Earth and Ocean Sci., Univ. of Victoria, P.O. Box 1700, Victoria, BC V8W 2Y2, Canada, ogodin@uvic.ca)

Full-field acoustic methods for current velocity inversion require accurate and efficient mathematical models of sound propagation in a range-dependent waveguide with flow. In this paper, an exact coupled-mode representation of the acoustic field is derived for the corresponding 2-D problem. To account for the physics of the problem, normal modes in a corresponding range-independent waveguide are chosen as the local basis. Unlike the motionless case, vertical dependencies of acoustic pressure in individual normal modes are not orthogonal in the presence of currents. To overcome this difficulty, a five-dimensional state vector is introduced. Orthogonality of the state vectors corresponding to individual normal modes is established. In terms of the state vector, the set of linearized equations of the hydrodynamics becomes a single differential equation of the first order with respect to the range coordinate. By using the orthogonality, coupled equations are derived for range-dependent mode amplitudes. The resulting mode-coupling equations have the same form as those known for motionless case, but values of mode-coupling coefficients differ. The contributions to mode coupling from horizontal gradients in the sound speed, density, and flow velocity are isolated and analyzed. [Work suported by NSERC and ONR.]

10:00

1aAO7. Inversion of multimegameter-range acoustic data for ocean temperature. Brian D. Dushaw (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105-6698)

Ocean sound speed (temperature) derived from ray travel times obtained from multimegameter-range acoustic transmissions may be inaccurate when the reference ocean state is inadequate for linearized inversion. When the reference (e.g., the Levitus atlas) is significantly different than the ''true'' ocean, the ray paths defined by that reference inaccurately represent the true sampling. In addition, natural oceanic variations, such as the evolution of a summer mixed layer, can significantly change the ray sampling. The guiding principle for inversion is that ray travel times associated with the inverse solution must match the measured travel times. Inversion of travel times relative to an arbitrary mean can be inaccurate. Accurate inversions may be obtained by iterative methods or by a better choice of reference ocean, but the solution of this nonlinear problem is not always obvious. Inadequate depth resolution for the vertical structure in the inverse solution can make calculation of travel times difficult. A linearizing time-dependent reference ocean can reduce the solution uncertainties since the *a priori* model variances are less. Simulations employing the Levitus ocean atlas, so that the ''true'' ocean state is known, are used to define the problems of nonlinear inversion and to find accurate inversion methods.

10:15

1aAO8. Ray tracing in a turbulent, shallow-water channel. Christian Bjerrum-Niese, René Lützen, and Leif Bjørnø (Dept. of Industrial Acoust., Bldg. 425, Tech. Univ. of Denmark, 2800 Lyngby, Denmark, cbn@ipt.dtu.dk)

A ray tracing model can be used to simulate sound (10–100 kHz) transmitted through shallow water. The phase of the ray arrivals, primarily given by travel time, may be mutually independent in such a multipath

transmission. Consequently, the transmission loss in a receiving point is randomly valued due to the coherent interference of the multipath arrivals. This problem can be overcome by incoherent summation of the multipath arrivals. However, knowing that nature behaves coherently, this method is not preferred. Instead, the channel can be regarded as dynamic by allowing microfluctuations of the sound speed. Specifically, the channel may be modeled as given by horizontal layers, each assigned with an individual turbulent dissipation rate, and a translation of this is performed into diffraction and phase fluctuation parameters, following DiIorio and Farmer [J. Acoust. Soc. Am. **96**, 1056–1069 (1994) and Flatté *et al.*, *Sound transmission through a fluctuating ocean* (1979)]. Amplitude and phase fluctuations of every ray are realized as samples of a random process. The results for the dynamic channel show a smoother and easier interpretable transmission loss behavior than for the static channel. Furthermore, it is observed that amplitude fluctuations generally exhibit Ricean fading. [Work sponsored by the Danish Technical Research Council.]

1aBV1. Flow function method for the display of streamlines on ultrasonic color flow image. Shigeo Ohtsuki (Precision and Intelligence Lab., Tokyo Inst. of Technol., 4259 Nagatuta, Midori-ku, Yokohama, 226 Japan) and Motonao Tanaka (Tohoku Welfare Pension Hospital, Sendai, 983 Japan)

Ultrasonic color Doppler technique is useful for the observation of the blood flow in heart. The information on blood flow by this technique is Doppler velocity, which is the velocity component in the direction of the beam emitted from the ultrasonic probe. The ultrasonic color Doppler image displays the distribution of Doppler velocity on an observation plane using red and blue corresponding to toward flow and away flow, respectively. Streamlines overlapped on ultrasonic color Doppler image are considered to be suitable for the quantitative evaluation of the characteristics of the flow. In this investigation, a new concept of the flow function is proposed in order to obtain streamlines on an arbitrary section of three-dimensional flow for visualizing and evaluating the characteristics of the flow. Flow function at a point on a plane is defined as the flow rate along a path from a reference point. This function is a multivalued function. The section of the three-dimensional display of the function at a constant value shows streamlines. The streamlines separated by an arbitrary unit flow can be fixed with the approximated point sources of the unit flow. These point sources are named simple sources. These simple sources are start points or end points of streamlines.

8:55

1aBV2. Noninvasive assessment of shear rate (WSR) in humans by means of ultrasound. R. S. Reneman, L. Kornet, S. K. Samijo, P. J. Brands (Cardiovascular Res. Inst. Maastricht (CARIM), Dept. of Physiol., Maastricht Univ., P.O. Box 616, 6200 MD Maastricht, The Netherlands), and A. P. G. Hoeks (The Netherlands)

An ultrasound technique to assess velocity and shear distribution in arteries noninvasively was developed . Accurate assessment of velocities close to the wall, a prerequisite for reliable determination of WSR, is achieved by tracking of the arterial wall and adaptive filtering of the wall signal. Velocity (v) distribution in the vessel is obtained by RF cross correlation of the signals in between the walls, and determination of dv/dr throughout the cardiac cycle provides shear distribution. Maximum dv/dr near the wall is taken as peak WSR and average shear over the cardiac cycle as mean WSR. Wall shear stress (WSS) is estimated by multiplying WSR by whole blood viscosity. The system also allows assessment of arterial diameter, diameter changes, and intima-media thickness (IMT). In studies on humans it could be shown that at a younger age in the common carotid artery (CCA) MWSS is close to 1.5 Pa, a value in agreement with minimal expenditure of energy. MWSS, however, is not optimally regulated, because it decreases with age. In the CCA, WSR close to the bifurcations were lower than and associated with larger IMT than more upstream. Reflections from downstream are held responsible for these differences in WSR.

9:15

1aBV3. Two-dimensional measurement of acoustic properties of tissue using 3 to 50 MHz ultrasound. Hiroyuki Hachiya (Dept. of Information & Comput. Sci., Chiba Univ., 1-33 Yayoi-cho, Inage-ku, Chiba, 263 Japan, hachiya@ics.tj.chiba-u.ac.jp), Shigeo Ohtsuki (Tokyo Inst. of Technol., Yokohama, 227 Japan), and Motonao Tanaka (Tohoku Kousei-Nenkin Hospital, Sendai, Japan)

Application of ultrasound has been expanded in the medical field and used widely for diagnosis. Acoustic properties such as the sound speed of a bulk wave in biological tissues are important parameters for quantitative characterization of living tissues. But the relationship between ultrasonic characteristics and pathohistological changes in tissues is poorly understood. To investigate the relationship, we have proposed a high-precision noncontact measuring method of acoustic properties of tissues using 3- to 50-MHz ultrasound. In this method, the travel time of sound through the sample, and the difference in travel times from the transducer to the rigid reflector with and without the sample are estimated based on frequency-time analysis which does not require physical contact of ultrasonic probes to living or freshly excised tissue specimens. The components of multipath propagation in tissues are decomposed in a frequency complex plane. The travel time and the time difference are estimated using all waveform information; rms error of sound speed is less than 3 m/s. Two-dimensional measurement of acoustic properties in rat and human tissues is performed using the noncontact measurement method. The relation between the acoustic properties change and the physical structure change in tissues is getting clear.

1aBV4. Three-dimensional Doppler ultrasound: A tool for the 21st century. Roy W. Martin (Anesthesiology and Bioengineering, Box 356540, Univ. of Washington, Seattle, WA 98195, rmartin@u.washington.edu), Dan Leotta, Xiang-Ning Li (Univ. of Washington, Seattle, WA 98195), and Trygve Hausken (Haukeland Univ. Hospital, Bergen, Norway)

Three-dimensional (3-D) ultrasound now offers a method to overcome former limitations of two-dimensional (2-D) Doppler. Important 3-D areas include the spatial delineation of the patency and pathways of blood vessels as well as the measurement of flow in them. In our laboratory a variety of 3-D uses has been investigated: detection and mapping of coronary arteries (3-D power Doppler, *in vitro*), mitral valve regurgitation (3-D color Doppler, *in vitro* and *in vivo*), and gastric flow (3-D color Doppler, *in vivo*). Several different 3-D approaches have been applied and results will be presented. However, in the future, it is believed that direct flow measurement can be achieved. Flow is equal to the integral of the velocities normal to a surface that cuts through a flow field. An arc of constant radius in a 2-D-sector scanner will inscribe an arc of a spherical surface, if rotated around the origin of the sector (e.g., multiplane transesophageal echocardiogram). The pulsed Doppler signals along the circumference of the inscribed arc represent the velocities normal to that surface. Integration of these velocities should provide direct measurement of the flow field cutting this inscribed surface. Algorithms for testing this strategy are under development.

1aBV5. Dynamic flow quantitation with spatial orientation guided digital color Doppler imaging: *In vitro* validation and initial *in vivo* experience. Xiang-Ning Li (Bioengineering, Box 356540, Univ. of Washington, Seattle, WA 98195, ning@u.washington.edu), Jing-Ming Jong, Trygve Hausken, Barbrina Dunmire, Bryan Goldman, Daniel F. Leotta, Kirk W. Beach, and Roy W. Martin (Univ. of Washington, Seattle, WA 98195)

The assumptions of geometric shape and uniform velocity profile prohibit the use of conventional Doppler methods for volume flow quantification with irregularly shaped nonvascular passages in space. A flow quantification method that integrates a three-dimensional (3-D) position and orientation sensing system with digital color Doppler imaging approach has been developed. Methods: The optimized ultrasound system settings were predetermined using a static, laminar flow model. The instantaneous flow rate was measured by the integration of the area-velocity product with angle correction. Initial *in vivo* studies quantified gastric emptying on five healthy volunteers 10 min after ingestion of a 500-ml meat soup, postprandially. Digital Doppler images were obtained continuously covering a transpyloric flow episode, immediately following the 3-D scan of the passage. The flow direction was derived from 3-D reconstruction using the centroids of two short-axis views. Results: *In vitro* validation showed the Doppler flow rates were within 10% for reference flow rates ranging from 6 to 30 ml/s. The average gastric emptying lasted 0.75 s with 3.0 ml in volume. Conclusions: With appropriate instrument settings, orientation determined digital Doppler can be used for the quantification of gastric emptying with adequate accuracy. This method minimized the angular ambiguity and geometric assumptions.

1aBV6. Assessment of vascular dialysis access with Doppler. Kirk W. Beach, Marla Paun, Suhail Ahmad, Mark Meissner (Univ. of Washington Medical Ctr., Box 356410, Seattle, WA 98195-6410), Robert Hickman, and Laurie Fauser (Children's Hospital, Seattle, WA)

Shunts between the arterial and venous systems are created to provide the blood flow required for hemodialysis. These shunts, created with interposed grafts or fistulas, often fail unexpectedly due to occluding thrombi. Such cases require surgical repair of the existing shunt or new shunt creation at an alternate site. Measuring pressure in the venous dialysis needle at a fixed flow rate is a standard method of surveillance. The method is not as effective as required because there is too much measurement variability. The variability is probably due to variability in placement of the dialysis needle. Neither ultrasonic duplex scanning nor x-ray angiography is viable for surveillance because the cost is too high. A simple ultrasonic Doppler method of measuring the change in flow between the dialysis needles as the dialysis pump is started and stopped can be used to compute the resistance of the graft during each dialysis. The cost is minimal, therefore making Doppler surveillance feasible. In addition, this method could be used to control the dialysis pump rate to an optimized value.

1aBV7. Using Doppler ultrasound to detect wall vibrations and flow velocity fluctuations in arteries. Melani I. Plett, Kirk W. Beach, and Marla Paun (Div. of Vascular Surgery, Dept. of Surgery, Univ. of Washington Medical Ctr., Box 356410, Seattle, WA 98195-6410)

Two arterial disorders, stenoses and perforations, result in fluctuations in both wall displacements and blood velocities that are not displayed by conventional ultrasound instruments. Wall vibrations with amplitudes on the order of a micron are too small to be displayed by M-mode. Narrowband velocity oscillations of less than 50-ms duration can easily be missed in viewing traditional Doppler spectral waveforms. Low-frequency velocity oscillations are attenuated by wall filters. Furthermore, the temporal relationship between flow velocities and wall displacements is not avail-

able in conventional systems, yet this relationship provides key information in studying stenoses and locating perforations. To simultaneously examine flow velocities and wall displacements in arteries, a customized ultrasonic, pulse-echo, multigate, quadrature phase demodulation system has been developed. The use of multigate, quadrature phase demodulation in the absence of a wall filter enables exploration of arterial behaviors temporally in the cardiac cycle with sufficient amplitude, frequency, and duration resolution to meet the rigorous demands of the analysis. Wall vibrations as high as 600 Hz with amplitudes less than a micron have been detected simultaneously with arterial jet velocities and flow oscillations. [This work was supported by a grant from DARPA, No. N00014-96-0630.]

Engineering Acoustics: Underwater Acoustic Calibration, Methods, and Devices

Arnie L. Van Buren, Chair
Naval Undersea Warfare Center, Code 216, Building 1171, 1176 Howell Street, Newport, Rhode Island 02841

Invited Papers

7:30

1aEA1. Towards new UK underwater acoustical measurement standards in the 21st century. Roy C. Preston and Stephen R. Robinson (Ctr. for Mech. and Acoust. Metrology, Natl. Physical Lab., Teddington, Middlesex TW11 0LW, UK, rcp@npl.co.uk)

The importance of establishing common measurement standards to support underwater acoustical calibration and testing in the UK, and therefore the need to demonstrate calibration traceability, has progressively grown over the last few years. In the UK, the National Measurement System provides the means of achieving traceability through the establishment and dissemination of primary standards of measurement. This paper will outline the progress made so far in establishing the UK's underwater acoustical measurement standards, and look forward to plans to extend the capability to cover the whole frequency range of interest, over the ranges of temperature and hydrostatic pressure applicable to simulated ocean conditions. The validation of these measurement standards will also be discussed.

7:55

1aEA2. Acoustic projector calibration in reverberant environments: A survey of USRD measurement technology. S. E. Forsythe and P. L. Ainsleigh (Naval Undersea Warfare Ctr., Newport, RI 02841)

The use of pressure- and temperature-controlled tanks for calibration of Navy projectors is a cost-effective alternative to open-water or at-sea measurements. The Underwater Sound Reference Division (USRD) of the Naval Undersea Warfare Center maintains a large closed tank which is temperature and pressure controlled. This tank, like all closed vessels, suffers from a major drawback: it is highly reverberant, especially at low-frequency operation, which precludes the possibility of making steady-state projector response measurements (especially for highly resonant projectors with low-frequency resonances) as would be possible in a large body of open water. This presentation surveys the techniques developed at USRD to ensure that measurements made in the tank are traceable to those that would be made for the same projector in open water. Three broad categories of approaches will be presented: (1) estimating the steady-state response using a model that represents only the pre-echo portion of the received data (transient modeling), (2) estimating the echo-free steady state using a multiple-arrival model that accounts for echoes in the received data (multipath modeling), and (3) characterizing the wave field using multiple hydrophones to separate the direct wave field from the wave field due to echoes (spatial processing). [Work supported by ONR.]

8:20

1aEA3. Low-frequency calibration in water-filled pipes. L. D. Luker and J. F. Zalesak (Underwater Sound Reference Div., Naval Undersea Warfare Ctr. Div., Bldg. 1171B, Rm. 205, 1176 Howell St., Newport, RI 02841-1708)

For many years the Underwater Sound Reference Division has developed ever more powerful means for creating desired sound fields inside water-filled pipes in order to calibrate transducers. Early efforts resulted in manually controlled calibration chambers approximately 2 m long, creating standing-wave fields or traveling-wave fields propagating along the axis of the pipe at frequencies from 0.1 to 4000 Hz. These calibrators have been modified in recent years to measure also the acoustic properties of material samples and the wave fields are now computer controlled. These systems were followed by pipe-shaped calibrators that are submerged in troughs of water for checking towed-array sensor elements. The latest calibrator to be developed is the Long-Line Hydrophone Calibrator (LLHC). This calibrator has a chamber length of 57 m and is capable of calibrating hydrophone line arrays up to 49 m long at temperatures from 2 to 35°C and hydrostatic pressures up to 6.9 MPa. The LLHC uses transducers distributed along its length to provide wave fields equivalent to plane waves arriving from any angle of incidence at frequencies from 5 to 700 Hz. Research is currently underway to increase the frequency range of the LLHC to above 200 Hz. [Work supported by ONR.]

8:45

1aEA4. A comparison of hydrophone calibration by free-field reciprocity and by optical interferometry. Stephen P. Robinson and Roy C. Preston (Ctr. for Mech. and Acoust. Metrology, Natl. Physical Lab., Teddington, Middlesex TW11 0LW, UK, rcp@npl.co.uk)

As the national standards laboratory in the UK, the National Physical Laboratory has established two primary standard methods for the free-field calibration of hydrophones. In the frequency range 500 kHz to 20 MHz, the primary standard is realized using optical interferometry; in the range from 5 to 500 kHz, it is realized by the method of three-transducer spherical-wave reciprocity. Although the ranges of the primary standards are defined as above, both methods can be used in the frequency range 200 kHz to 1 MHz, enabling a comparison to be undertaken between these two independent methods. The comparison was made by calibrating reference hydrophones using both methods and comparing the results. In general, the results agree to within ± 0.4 dB or better, well within the combined uncertainties of the methods. In this paper, a comparison of results is presented and a discussion given of the major sources of uncertainty in the methods.

9:00

1aEA5. An intercomparison of hydrophone calibrations within Europe. Stephen P. Robinson, Roy C. Preston, and Geraint J. Green (Ctr. for Mech. and Acoust. Metrology, Natl. Phys. Lab., Teddington, Middlesex TW11 0LW, UK, rcp@npl.co.uk)

Intercomparisons between different laboratories are an important way of validating calibration methods and indicating where improvements are required. This paper describes a European intercomparison of free-field hydrophone calibrations in the frequency range 10–315 kHz. A total of 12 participants from seven European countries took part by calibrating three reference hydrophones, with project coordination provided by the National Physical Laboratory, UK. The agreement between the results was generally encouraging, with a majority of the results lying within ± 1 dB of the Grand Mean. However, some large variations were observed which give cause for concern, and the uncertainties in the calibrations were typically underestimated by the participants with the maximum differences from the Grand Mean almost invariably exceeding the quoted overall uncertainties. A discussion is given of possible reasons for the disagreement, and of useful further work identified as a result of undertaking the intercomparison.

9:15

1aEA6. A simple two-projector procedure for producing impedance-controlled wave fields for transducer calibration. S. E. Forsythe and A. L. Van Buren (Naval Undersea Warfare Ctr., Newport, RI 02841)

When calibrating hydrophones in an open body of water, it is sometimes desirable to establish a local impedance in the vicinity of the hydrophone that is accurately known. Three examples that are often used are (1) an impedance characteristic of a plane wave in open water (the so-called rho-c condition), (2) a pressure-only field with no local particle velocity (infinite impedance), and (3) a velocity-only field with no local pressure (zero impedance). This presentation describes a simple apparatus consisting of two spherical sources (or sources that appear spherical at the frequency of interest) and the description of the ratio of drive amplitudes required to produce the desired impedance condition. The useful ensonified volume, that region over which the desired impedance condition holds, is described. Examples of application to the calibration of pressure-sensitive and pressure-gradient hydrophones are given. [Work supported by ONR.]

9:30

1aEA7. Underwater facility for automated experimentation and measurement. Carlos Ranz and Pedro Cobo (Instituto de Acustica, CSIC, Serrano 144 28006, Madrid, Spain, iacrg32@fresno.csic.es)

The underwater tank at the Instituto de Acustica, CSIC ($7.5\times4.5\times4.5$ m), was built in 1970; it had facilities useful for the work expected at that time. The tank had two bridges. In both bridges only the vertical coordinate and the 360° turn were automated. In current experimental work, including calibration, the actual instrumentation and the sensors' motion control, together with signal acquisition and manipulation, showed the need for a drastic change in the tank structure. The mechanisms of motion of both bridges are now fully automated and can be controlled via software. This control can imply positioning at a given field point, for any or both sensors, or along a specified trajectory, including mapping, in the four coordinates X, Y, Z, and angle. The new installation includes the simultaneous signal acquisition, the specific design of ''calibration pages,'' files management, storing of full working sessions, and remote control, e.g., through the web, of the whole tank, including operation and signal acquisition and management. The tank is expected to be inserted in the European facilities network. The new installation, funded by the PN-CYTMAR and CSIC, is described in this presentation.

9:45

1aEA8. Calibration and testing of a neutrally buoyant *u*-*u* intensity probe. Kevin J. Bastyr and Gerald C. Lauchle (Penn State Univ., Grad. Prog. in Acoust., P.O. Box 30, State College, PA 16804, zabour@acs.psu.edu)

The theory of operation and the methodology for calibration of an underwater acoustic intensity probe are explained. The intensity probe, which is classified as a *u*-*u* probe, consists of two moving coil velocity sensors mounted separately in neutrally buoyant, collinearly oriented bodies. This two-velocity sensor probe is used to determine intensity in a manner analogous to that of pressure gradient hydrophones. The acoustic intensity is shown to be the imaginary part of the cross spectrum measured between the output voltages of the velocity sensors, scaled by a complex, frequency-dependent calibration constant. Due to the vector nature of intensity, these complex calibration constants contain magnitude and phase information. To establish the calibration constant, an experiment was conducted that employed the *u*-*u* intensity probe and a reference pressure transducer in a standing wave tube. The intensity in the tube is known, and measurements made of this field with the *u*-*u* probe are in agreement with the prediction. [Work supported by the Office of Naval Research, Multi University Research Initiative on Acoustic Transduction, Materials, and Devices.]

10:00

1aEA9. Calibration of a neutrally buoyant *p*-*u* intensity probe. James A. McConnell (Penn State Univ., Grad. Prog. in Acoust., P.O. Box 30, State College, PA 16804, univibe@sabine.acs.psu.edu) and Gerald C. Lauchle (Penn State Univ., State College, PA 16804)

Theory and test methods are presented for calibrating an underwater acoustic intensity probe containing two pressure hydrophones and one moving coil velocity sensor. The intensity probe is classified as a *p*-*u* probe and is neutrally buoyant in fresh water. In contrast to *p*-*p* and *u*-*u* probes, it determines intensity via direct measurement of the acoustic pressure and particle velocity. Specifically, intensity is computed by adjusting the time-averaged rms cross spectrum between the transducer output voltages by an appropriate calibration curve. Because intensity is a vector quantity, both a magnitude and phase calibration is required. This is accomplished by a straightforward technique involving a single reference hydrophone and *a priori* knowledge of the acoustic field where the calibration is performed. A simple experiment was conducted using a standard-wave tube to verify the effectiveness of the calibration technique. In this experiment, the pressure and velocity sensors were calibrated, then

an intensity measurement was made. Results show that the calibration technique is highly effective. [Work supported by the Office of Naval Research and the Naval Air Warfare Center Aircraft Division via the DoD Small Business Innovation Research Program.]

1aEA10. Test chamber for determining damage thresholds for high-amplitude underwater sound exposure in animal models. Thomas N. Lewis, Peter H. Rogers, James S. Martin, George S. McCall II (The George W. Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0405), Joey G. Lloyd, Henry P. Cotten, and Gary W. Caille (Georgia Tech Res. Inst., Atlanta, GA 30332-0810)

In order to determine the effects of low-frequency underwater sound on small animal models it is desirable to expose them to well-characterized fields which closely simulate the (locally) plane-wave open ocean stimulus. It is also desirable to produce pure pressure and acceleration stimuli to isolate the effects of the individual components of the acoustic plane wave. It is necessary to produce sufficiently strong signals to enable damage thresholds to be determined. The range of frequencies over which such stimuli must be produced is quite broad since it must include the actual band of interest (100–500 Hz) to examine damage on a cellular and tissue level, as well as at scaled frequencies (~1–5 kHz) to examine the effects of organ structure. The problem is subtler than one might imagine because of the high compliance of the test animals due to the air in their lungs. The lungs will drastically alter the acoustic field in the chamber and change the loading on the sources and the chamber could alter the vibrational response of the lung. Careful consideration is required to ascertain what is required of the chamber to assure valid measurements and to determine the true effective sound pressure level.

1aEA11. A free-flooding rare-earth iron hexagonal transducer. Rong Rong Zhao (Shanghai Marine Electron. Equipment Res. Inst., 390 Jian Guo East Rd., Shanghai 200025, PROC, lpeng@stn.sh.cn)

This paper describes the development of a free-flooding rare-earth iron hexagonal transducer with an outer size of $\phi 160 \times 160$ and a weight of 4.9 kg. The vibrations of the rare-earth iron hexagonal transducer and the free-flooding water cavity in it are theoretically analyzed and discussed. The measurement result shows that the transducer may send out a source level of 185 dB, and the resonance frequency of the transducer drops down from 1.90 kHz in air to 0.85 kHz in water because of the cavity resonance. The free-flooding water cavity can therefore not only withstand the hydropressure, but also make the resonance frequency drop down considerably. The free-flooding rare-earth iron hexagonal transducer shows promise to be a lightweight, high-power sound source for operation at great depths in the ocean. [Work supported by CSSC.]

1aMU1. A flexible analysis/synthesis tool for transient signals. Tony S. Verma and Teresa H. Y. Meng (Elec. Eng. Dept., Ctr. for Integrated Systems, Stanford Univ., Stanford, CA 95305)

An overview of a flexible analysis/synthesis tool for transient signals that effectively extends the spectral modeling synthesis (SMS) parametrization of signals from sinusoids+noise to sinusoids+transients+noise is given. The extended model, by explicitly handling transients, provides a more realistic and robust signal analysis/transformation/synthesis tool. Although others have pointed out the need for partitioning SMS into sinusoids+transients+noise, they have not provided a flexible model for transients. The need for an explicit transient model arises because SMS analyzes a signal by first modeling the sinusoidal components of the signal. SMS then subtracts these sinusoidal components from the original signal leaving a residual signal that contains transients+noise. One drawback of SMS is it models this transient+noise residual solely as filtered noise. Our transient model, when used on this residual, first detects where possible transients occur, models the transients, then removes transients from the signal. This leaves a second residual that is slowly varying noise. Attacks are well preserved by the transient model and the noise model now works more effectively. Becuase the transient model is the frequency domain dual to sinusoidal modeling, it retains flexibility and allows for a wide range of signal transformations.

9:45

1aMU2. Lemur: A bandwidth-enhanced sinusoidal modeling system. Kelly Fitz and Lippold Haken (CERL Sound Group, Univ. of Illinois at Urbana—Champaign, Champaign, IL)

Lemur models sounds as a collection of partials having amplitude, bandwidth, and frequency envelopes. Bandwidth envelopes allow the neat representation of noisy parts of sounds which produce clutter in purely sinusoidal analyses. Lemur associates noise energy with sinusoidal components that are nearby in frequency. Bandwidth envelopes record the fraction of the partial energy that is attributable to noise energy, as opposed to sinusoidal energy. Amplitude envelopes are calculated to include the energy added by the

bandwidth association process. When partials are pruned from the model, in the analysis process or during editing, Lemur preserves the overall energy by distributing the removed partials energy among neighboring partials. For sounds with a good spread (in frequency) of partials, Lemur can represent noise energy in the appropriate spectral regions while retaining the manipulability and homogeneity of a purely sinusoidal model. This homogeneity is important for implementing certain kinds of model-domain behaviors and real-time timbral manipulation. Lemurs synthesis includes a spectral line widening technique to spread energy away from each partial's center frequency according to bandwidth envelope values.

1aMU3. Synthesis and control of synthesis using a generalized diphone method. Xavier Rodet (Responsable de l'Equipe Analyse/Synthese Head of the Analysis/Synthesis Team, IRCAM 1 place Stravinsky 75004 Paris, France)

Well known in speech synthesis, a diphone is a segment of sound extending from the middle of a phone to the middle of the next phone. More precisely, in order to allow for time and pitch modifications, a diphone is the set of synthesis parameters representing this segment in some given synthesis technique. A speech sentence is synthesized by concatenating diphones found in a dictionary. The concept of diphone has been extended into generalized diphone control in order to build musical phrases from dictionaries of sound segments by concatenating and articulating them. Sound segments stored in dictionaries can comprise any recorded sound as well as instrumental sounds. Any analysis–synthesis method such as source-filter synthesis, additive synthesis, or physical model can be controlled in terms of generalized diphones. Presented here are several important improvements to diphone control and synthesis implemented in a software named ''Diphone,'' such as hierarchical structure of sequences and subsequences of diphones, variable speed of transitions, various smoothing functions at diphone boundaries, etc. ''Diphone'' proved itself a very flexible and inspiring tool for composition and synthesis, which composers are using at IRCAM and outside of the institution.

1aMU4. Sound representation and modification with multiresolution sinusoidal models. Michael Goodwin, Paolo Pradoni, and Martin Vetterli (SGI, 2011 N. Shoreline Blvd., Mountain View, CA, mmg@esd.sgi.com)

In the standard sinusoidal model, the analysis and synthesis are typically carried out at fixed frame rates. This can result in representation error for signals with dynamic behavior. To improve the modeling performance for such signals, the sinusoidal analysis-synthesis can be carried out in a multiresolution framework based either on a filter bank structure or on adaptive time segmentation. In the latter method, which will be of primary interest here, the adaptation is guided by a metric such as rate-distortion. Such an approach improves the model accuracy while preserving the ability to carry out the rich class of modifications afforded by the standard sinusoidal model.

11:10

1aMU5. Timbre morphing and interpolation based on a sinusoidal model. Naotoshi Osaka (NTT Basic Res. Labs., Information Sci. Res. Lab., 3-1, Wakamiya, Morinosato, Atsugi-shi, Kanagawa, 243-01 Japan, osaka@idea.brl.ntt.co.jp)

There have been several attempts to synthesize the timbre in between two sounds. Several synthesis methods are reported to work well, but are not automatic throughout the whole process or are not precisely described if one wishes to trace the algorithm. An automatic algorithm of synthesizing morphed sounds and interpolated timbre has been reported. Two original sounds are analyzed using the M&Q algorithm. Correspondent partials of each sound are found using Dynamic Programming. Two synthesis methods are introduced using a sinusoidal model. One is to find correspondent partials within correspondent frames of two sounds. Then an interpolated partial of a new frame is calculated. Peak-to-peak match of sinusoidal parameters is done for a new frame and synthesized sounds are acquired. The other method is the one which changes the procedure sequence of the first method. Correspondence is considered for sequent partials and not a framewise signal. These two methods are compared with another simple synthesis method, that is, wave-to-wave interpolation of one pitch period. Total performance of sounds are discussed using subjective test results.

11:35

1aMU6. Tracking the frequency components of musical tones based on global waveform fitting. Yinong Ding (DSPS RDC, Texas Instruments, Inc., 8330 LBJ Freeway, MS 8374, Dallas, TX 75243, ding@ti.com)

A novel approach to estimating sinusoidal parameters of musical tones is presented. The proposed algorithm uses a combined quadratic polynomial phase sinusoid and residual signal model, and a waveform fitting criterion, as opposed to the traditional energy fitting one as employed by short-time Fourier transform-based approaches. The proposed algorithm obtains sinusoidal parameters by minimizing the squared difference between the original and the synthesized musical tones. The signal synthesis is implemented implicitly and the synthesis errors are taken into account while the sinusoidal paremeters are estimated. A number of different phase models proposed for music analysis and synthesis are reviewed and their pros and cons are identified. This analysis justifies the use of the proposed signal model. Experiment results for the analysis and synthesis of a variety of musical instrument tones such as piano, trumpet, french horn, flute, and violin are given to demonstrate the accuracy and effectiveness of the proposed algorithm. A VLSI architecture for sinusoid synthesis using the parameters obtained from the proposed algorithm is also given to provide a complete solution to the parametric modeling-based music analysis and synthesis.

12:00

1aMU7. Efficient synthesis model for bowed strings using a nonlinear bow–string interaction model. Julius O. Smith III (Music Dept., Stanford Univ., Stanford, CA 94305)

A digital simulation method for bowed strings was developed which combines features of preexisting ''digital waveguide'' and ''commuted synthesis'' methods. In both methods, sampled acoustic traveling waves are explicitly modeled in the string, and string losses are *lumped* at one or two points along the string for computational efficiency. In the digital waveguide case, the bow–string interaction model is based on the theory of McIntyre, Schmacher, and Woodhouse [J. Acoust. Soc. Am. **74** (1983)]. The commuted synthesis model [J. Smith, Int. Computer Music Conf., pp. 64–71 (1993)] interchanges the order of the string and body (assumed linear and time invariant), and therefore cannot support a nonlinear bow–string interaction model. However, according to theory and measurement of bow–string interaction, disturbances sent out by the stick–slip process along the string are fundamentally *impulsive* in nature. The proposed method consists of a full nonlinear dynamic model for the bow and string, without body, followed by an ''impulse prioritizer,'' which detects the most important impulsive events reaching the bridge, followed by a commuted synthesis model which drives a second string model with body impulse-responses initiated at the time and amplitude of each high-priority pulse.

Session 1aNSa

Noise: Non-Auditory Effects of Noise on Health

Lawrence S. Finegold, Cochair
AL/OEBN, Armstrong Laboratory, 2610 Seventh Street, Wright Patterson Air Force Base, Ohio 45459

Willy Passchier-Vermeer, Cochair
TNO, The Netherlands

Chair's Introduction—9:15

9:20–11:35
Panel Discussion

The session will consist of a panel discussion by a group of international scientists of the Non-Auditory Health Effects of Noise Exposure, plus presentation of two contributed papers on this topic. Both occupational and community noise exposure will be included in the discussion. Each of the invited panel members will initially provide a brief overview of their own work on the non-auditory health effects of noise. This will be followed by a discussion of issues related to the development of this area of research, including the advantages and disadvantages of various research methodologies and research design alternatives, the choice of specific health effects end points, and the transition of research data to governmental noise exposure policies.

Contributed Papers

1aNSa1. Study of noise levels in a neonatal intensive care unit. Chantal Laroche and Paula Fournier (Audiol. and Speech Lang. Pathol. Prog., Univ. of Ottawa, 545 King Edward, P.O. Box 450, Stn. A, Ottawa, ON K1N 6N5, Canada)

In the past few years, much interest has been focused on the integrated care approach, where noise is seen as an element which can compromise the normal development of newborns in neonatal intensive care units. The objective of this study was to develop a methodology evaluating the impact of training of the nurses, regarding noise levels existent within the neonatal intensive units of an Ottawa regional hospital. The method consisted of continuous noise level measurements performed by a computer (type 1 sound level meter), pre- and posttraining. $L_{\mathrm{Aeq,1sec}}$, as well as audio samples were recorded throughout eight work shifts. The average pretraining A-weighted noise levels were of 53, 61, and 65 dB, for the night, day, and evening shifts, respectively. These levels largely exceed the maximal A-weighted sound level of 45 dB, recommended by the World Health Organization to avoid negative effects on sleep. Throughout this study, it is likely that the training of nurses could contribute to the reduction of noise levels, but that interventions concerning noise control would also be necessary in order to ensure an acceptable sonorous ambiance for neonates requiring intensive care. 1aNSa2. Trading level for number in the laboratory: Differential effects of aircraft noise on cardiovascular activation, annoyance, and assessment of quality of life. Iris B. Mauss (Univ. of Duesseldorf, Dept. of Cybernetical Psych., 40225 Duesseldorf, Germany, mauss@uni-duesseldorf.de), Joachim Vogt (Univ. Dortmund, FB 14, 44221 Dortmund, Germany), and Karl Th. Kalveram (Univ. of Duesseldorf, Dept. of Cybernetical Psych., 40225 Duesseldorf, Germany)

As aircraft become quieter, the question arises to what extent the decrease in noise is convertable into an increase in the number of flight movements without enhancing psychological and physiological noise effects. Conventional reasoning has it that it suffices to keep constant the

energy equivalent noise level. In a 3×3 design combining three number conditions (3/9/27 overflights during 30 min) with three noise level conditions (aircraft types emitting 71/76/81 dB(A) per overflight), this assumption was tested, using three groups of 12 subjects each for the number conditions, and repeated measurements for the level conditions. Comparisons between the equal-energy conditions (e.g., 3×76 dB vs 9×71 dB) did not show any significant differences regarding systolic and diastolic blood pressure and heart rate. Regarding ratings for annoyance in the lab situation, results were the same with a slight tendency for underenergetic number effects, that means, more but softer aircraft were preferred. However, if the subjects imagined to reside in a region continuously exposed to the experienced noise, quality of living was assessed as slightly more negative for residential areas with nine overflights, and clearly more negative for 27 overflights, though energy was fixed. This suggests overenergetic number effects for living quality beginning at about 18 overflights/h.

Noise and Archtiectural Acoustics: Novel Approaches to Noise Control Barriers I

David C. Hothersall, Chair
Department of Civil and Environmental Engineering, University of Bradford, Bradford BD7 1DP, United Kingdom

Chair's Introduction—9:15

Invited Papers

9:20

1aNSb1. Excess attenuation by reactive obstacles at a noise barrier edge. Kyoji Fujiwara, Chul-hwan Kim, and Tomonao Ohkubo (Dept. of Acoust. Design, Kyushu Inst. of Design, Shiobaru 4-9-1, Minami, Fukuoka, 815-8540 Japan)

The excess attenuation by small obstacles with a reactive surface installed at the noise barrier edge was studied. So far, the absorbing obstacle has been used to obtain large attenuation, keeping the barrier height constant. It was found that an obstacle with a soft surface at the barrier edge can suppress noise more effectively than the absorbing one does. To realize this soft surface an arrangement of one-quarter wavelength acoustic wells was used. Although these acoustic wells behaved as the soft surface in a certain frequency range, at a barely lower frequency range the sound pressure level behind the barrier was amplified. To overcome this negative effect a new arrangement of wells tuned to several different resonance frequencies is studied. As a result, the excess attenuation by a small round obstacle of 53 cm width and 33 cm height installed at the edge of a 3-m barrier is about 4.7 dB (OA) at the ground 25 m behind the barrier. When the barrier has a T shape and is of 2 m width and 5 m height, the excess attenuation is 7 dB (OA). Details of the cross sections of these barriers will be presented.

9:50

1aNSb2. Jagged-edge noise barriers. Penelope Menounou, Ilene J. Busch-Vishniac, and David T. Blackstock (Dept. of Mech. Eng., Univ. of Texas at Austin, TX 78712-1063)

Experimental, numerical, and analytical investigations have shown that noise barrier performance can be improved by making the top edge randomly jagged. The incident noise is a spherical N wave (produced by a spark in our model experiments). See Ho *et al.* [J. Acoust. Soc. Am. **101**, 2669–2676 (1997)], and oral papers by (i) Menounou *et al.*, (ii) Ohm *et al.*, and (iii) Rosenberg *et al.*, all in J. Acoust. Soc. Am. **101**, 3075(A) (1997). In many, but not all, cases the jagged edge improves insertion loss by up to 5 dB. The most promising theoretical approach is to model the edge as a directive, crooked line source [paper (i) above]. Besides yielding predictions that agree favorably with measurements [paper (iii) above], the line source model helps in understanding the following results: (1) the jagged edge smears out the diffracted signal and makes the tail ragged, (2) insertion loss varies significantly with receiver position, and (3) the portion of the edge on the most direct path between source and receiver plays a very important role. Because the model is easy to apply, it is a promising and powerful tool for further research on jagged barriers. [Work supported by Texas Advanced Technology Program.]

10:20

1aNSb3. Comparison of calculated and measured data for the attenuation of improved noise barrier. Kohei Yamamoto (Kobayasi Inst. of Physical Res., 3-20-41 Higashi-Motomachi, Kokubunji, Tokyo, 185 Japan)

The comparison between calculated and measured data was made to the additional noise attenuation of a barrier with an absorptive device on the top edge. The attenuation was determined at a highway with a noise barrier of 3 m height. By the use of the boundary-element method (2D), noise attenuation due to the mounting of the device was estimated. The results showed an agreement between the calculated and the measured value. However, the calculated values showed fluctuation when they were plotted against distance.

10:50–11:05 Break

11:05

1aNSb4. Active control of traffic noise around barriers. Denis Duhamel (ENPC-CERAM, 6 et 8 Ave. Blaise Pascal, Cité Descartes, Champs-sur-Marne, 77455 Marne-la-Vallée Cedex, France)

Active control was previously found efficient to reduce noise behind barriers for compact and immobile sources [Omoto and Fujiwara, J. Acoust. Soc. Am. **94**, 2173–2180 (1993)]. For real road traffic there are usually many sources at quite different positions, so the sound pressure is very complex. It is simulated by an incoherent line source in which different point sources placed along a straight line radiate independently. The structure of the sound pressure, mainly the coherence properties, are calculated around the noise barrier. This is done by a boundary element method to get precise results for low frequencies and near the barrier. A good coherence is necessary to obtain an efficient active control. Simulations of active control systems are done for different placements and numbers of secondary sources. A sufficient number of sources is determined according to the frequency to get a significant attenuation. Simulations of feedback control near the top of the barrier are investigated and compared to feedforward control. For a feedforward control a reference signal is necessary which is difficult to provide because of the low coherence of the sound pressure. A sufficient number of sensor microphones and their positions are also determined in that case.

11:35

1aNSb5. Active noise barrier based on the boundary surface control. Shiro Ise (Nara Inst. of Sci. and Technol., Takayama 8916-5, Ikoma, Nara, 630-01 Japan, ise@is.aist-nara.ac.jp) and Hideki Tachibana (Univ. of Tokyo, Tokyo, 106 Japan)

Based on the principle of the boundary surface control, it is possible to make a surface which reflects acoustic energy flow by controlling the pressure and its gradient on the surface. In order to realize this method, a system has to be made using multiple speakers and multiple microphones. The system should be adjusted so that the output signals of the multiple microphones which are located on the surface considered to be the location of the barrier are minimized. By changing the distance between the microphones, the best effect of the active noise barrier can be obtained. For instance, in a level lower to the ground, many microphones are needed to control higher frequencies. On the other hand, in a level higher from the ground, it is not necessary to use so many microphones to control lower frequencies. The merit of this method is that the apparent height of the barrier, depending on the frequency considered, can be changed. In this paper, the active noise barrier based on the boundary surface control is introduced and the effect of this method is calculated using BEM.

12:05

1aNSb6. Traffic noise barrier overlap gap analysis. Lloyd A. Herman (Dept. of Civil Eng., Ohio Univ., 141 Stocker Ctr., Athens, OH 45701) and Craig M. Clum (Development Consultants Group, Duluth, GA 30136)

Sound propagation through the gap produced by two parallel vertical barriers with overlapped ends was formulated for traffic noise sources. The method accounts for sound propagated from vehicle source positions for a maximum of ten roadway lanes. Six receiver regions were considered based on potential receiver locations with respect to a gap. The analysis identified both source and receiver regions according to the mechanisms that influence noise propagation in the vicinity of an overlap gap, which can result in: direct rays, diffracted rays from the top edge of one barrier, diffracted rays from the top edge of both barriers, rays reflected between the barriers, and rays that are both reflected and diffracted. The derived method could be implemented using various equations for sound propagation. The results of using equations approved by the United States Federal Highway Administration (FHWA) for traffic noise propagation are given. Field measurements for up to 30 receiver positions from four overlap gaps were compared with uncalibrated predictions. The equivalent continuous levels, A weighted, were overpredicted by 2–3 dB. When the analysis was based on an octave band characterization of the source, the mean overprediction was reduced to less than 1 dB.

12:20

1aNSb7. Rubber crumb as an absorbent acoustical material. Jaime Pfretzschner and Rosa M. Rodriguez (Instituto de Acústica, CSIC, Serrano 144, Madrid 28006, Spain)

In order to contribute to the solution of the environmental problem created by the tire wasteways, the possibilities of using rubber crumbs of waste tires as acoustic absorbent materials have been studied in a systematic way. Experimental absorption coefficients of rubber crumb granulates with mesh diameters between 1.4 and 7 mm have been tested in Kundt's tube and in a reverberation room. Absorption coefficient values so obtained are compared with computational values afforded through mathematical prediction models that use the intrinsical parameters of porous material such as porosity, tortuosity, and flow resistivity, which were measured on layers of the respective materials. The good broadband acoustic absorption of the material encourages its use as an alternative to the current absorbent acoustic screens, used for the protection against traffic noise.

1aPAa1. Propagation of sonic booms through the atmosphere. Richard Raspet and Henry E. Bass (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677, raspet@next1.ncpa.olemiss.edu)

During the past 20 years the authors have been involved in developing physically based prediction calculations for sonic booms and other nonlinear atmospheric waves. Early work developed a calculation method for the effects of atmospheric absorption and dispersion on sonic booms in a quiescent atmosphere. The validity of this method has been confirmed by recent collaborative work with the University of Texas [J. Acoust. Soc. Am. **100**, 3017–3027 (1996)]. More recently, the authors have been working on a method of predicting the effect of turbulence on sonic boom waveforms in the planetary boundary layer. A Monte Carlo approach has been employed so that histograms of measured variables which are needed for environmental assessment can be developed, rather than a single average value [J. Acoust. Soc. Am. **99**, 147–152 (1996)]. This prediction method can be combined with the earlier sonic boom propagation algorithm to predict the ensemble of received waveforms at the ground, given the waveform in the vicinity of the aircraft, based solely on physical considerations.

8:20

1aPAa2. Atmospheric sound propagation near the ground. Conny Larsson (Dept. of Meteorol., Uppsala Univ., P.O. Box 516, S-751 20 Uppsala, Sweden, conny@big.met.uu.se)

The most important meteorological effects on sound propagation are refraction-ground attenuation, atmospheric absorption, and scattering by turbulence. The wind and temperature gradients cause refraction of the sound rays, and hence influence the sound level. The curvature of a nearly horizontal sound ray can be calculated by using measurements of wind and temperature. Atmospheric absorption is important for outdoor sound propagation. The absorption varies for different parts of the world. Results from some stations in Scandinavia are given. Atmospheric absorption for the high frequencies changes during different times of the year. The absorption for low frequencies varies both over the day and the year. The size of the annual and diurnal variance is frequency dependent. An increase in the accuracy of calculations of outdoor sound levels can be made by considering the local climate. The values of atmospheric absorption need to be calculated for the local climate instead of using some global mean value. The time has come to use data from local meteorological stations. Turbulence scatters sound into sound shadow zones and causes fluctuations of the phase and the amplitude of the sound waves.

1aPAa3. Effect of waveform distortion on sonic boom noise penetration into a flat ocean. Tracie J. Ferguson and Victor W. Sparrow (Grad. Prog. in Acoust., Penn State Univ., 157 Hammond Bldg., University Park, PA 16802)

The penetrating underwater sound field due to an N-shaped sonic boom incident on a flat ocean surface is well described by existing theory. However, in realistic situations, most of the waves that hit the surface are not perfect N waves but are distorted by such processes as atmospheric turbulence. In the present research, N waves are created that contain the same amount of energy as experimentally measured sonic booms produced by aircraft in the U.S. Air Force. Each signature is input to an algorithm recently presented by Sparrow and Ferguson [AIAA Paper 97-0486 (1997)] to calculate the respective underwater sound fields. By comparing the underwater wave shapes and plots of peak pressure with respect to depth, initial results of the effect of waveform distortion on sonic boom noise penetration into a flat ocean are determined. Preliminary figures show that waveform distortions at the surface cause a slightly greater penetration depth underwater. However, the magnitude of the effect is dependent on the incident sonic boom. [Work supported by Armstrong Laboratory, Air Force Materiel Command, USAF, under Grant No. F41624-96-1-0003.]

8:55

1aPAa4. Sonic boom in the shadow zone. François Coulouvrat (LMM, Univ. Pierre et Marie Curie, CNRS (URA 229), case 162, 4 pl. Jussieu, F75252 Paris Cedex 05, France)

The classical geometrical acoustics theory predicts the amplitude of sonic booms only within the carpet. Inside the geometrical shadow, the sound field is known to emanate from rays shed by creeping waves propagating along the ground. A new, nonlinear, time-domain formulation of diffraction effects inside the shadow zone is given. The resulting equation is analogous to an unsteady, two-dimensional, transonic equation. In the linear case, it can be solved, so that the dispersion equation for creeping waves is recovered. If only the least attenuated one is taken into account,

an approximate equation of Burgers-type describing the nonlinear propagation of the creeping wave can be deduced. A dimensional study indicates that nonlinear effects are small, except for small sound-speed gradients. A numerical simulation shows that the amplitude decay of the signal compares favorably with Concorde measurements made by ISL at Biscarosse in 1973, at least sufficiently deep within the shadow zone. [Work supported by Aérospatiale Aéronautique–Toulouse.]

9:10

1aPAa5. Statistical data of excess attenuation for long-range noise propagation over sea. Kazuo Konishi (Ken-On Eng., Inc., 1-17-1 Shofudai, Tarumi, Kobe, 655 Japan, ken-on@ta2.so-net.or.jp) and Zyuniti Maekawa (Environ. Acoust. Labs., Osaka, 531 Japan)

At an environmental impact assessment of a new planned airport on an artificial island, many data of excess attenuation were obtained in long-range (5-km) sound propagation over sea continuously for 14 months versus meteorological conditions. Unfortunately, as presented at Inter-Noise 96 and 97, clear relations were not found between them using both multiregression analysis and multidimensional quantification analyses. Although it is known that the sound-speed profile is one of the most effective factors in long-range sound propagation, it seemed to be difficult to obtain the profile sufficient to predict the sound propagation over sea. Furthermore, it is very difficult to predict the excess attenuation, possibly because of the existence of unpredictable turbulence in the atmosphere. Therefore, using the measured data, attempts were made to estimate the excess attenuation related to aircraft noise at a receiving point. After statistical analysis, it has become clear that the excess attenuation is almost positive, and negative only at night. This fact is very useful for the environmental impact assessment of the planned airport.

9:25–9:35 Break

9:35

1aPAa6. Sound propagation in a city composed with hexagonal periodic buildings. Judicael Picaut (Lab. Acoustique, Univ. Le Maine, B.P. 535, 72017 Le Mans France) and Jean Hardy (Univ. Le Maine, B.P. 535, 72017 Le Mans France)

The noise propagation in central parts of towns is a problem of major importance. Because of multiple reflections upon the buildings the background noise obeys to a diffusion law in place of a free propagation law. Usually the diffusion law is obtained by means of a random disposition of the buildings. The originality of this work is to show that this hypothesis can be avoided since the example given is composed with hexagonal periodic buildings, with a semidiffusing law for the reflections. A hexagonal geometry is used, cumulating the advantages of simplicity for the refections laws and avoiding the avenue effects. A numerical simulation shows that a diffusion occurs for the rays and the dependence of the diffusion coefficient from the geometrical dimensions of the streets, the complexity of the building façades is investigated. The model suggests that for a realistic case two parameters suffice to describe the noise propagation in a town: the diffusion coefficient depending of the complexity of the façades and the streets width and an attenuation coefficient depending of the sizes of buildings and of the attenuation properties of the reflecting surfaces and of the air.

9:50

1aPAa7. Scale model experiments on the insertion loss of wide and double barriers. Glenn J. Wadsworth and James P. Chambers (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

The insertion loss of wide and double barriers is investigated through scale model experiments. Such configurations are common in outdoor sound propagation problems such as highway barriers and raised or depressed roadways. The Biot–Tolstoy–Medwin time domain wedge formulation for multiple diffraction [J. Acoust. Soc. Am. **72**, 1005–1013 (1982)] is used to predict the acoustic field directly in the time domain. Evaluating the insertion loss at discrete frequencies or in octave bands is accomplished via the fast Fourier transform (FFT). Comparisons to other frequency based models will also be presented.

10:05

1aPAa8. Incorporation of inhomogeneous, atmospheric turbulence into numerical propagation calculations. D. Keith Wilson (U.S. Army Res. Lab., 2800 Powder Mill Rd., Adelphi, MD 20783, dkwilson@arl.mil)

Homogeneous, atmospheric turbulence is often synthesized for use in numerical propagation calculations (the parabolic equation, for example) by multiplying Fourier modes by random phases and then inverse transforming. This method can be generalized to inhomogeneous turbulence by multiplying the empirical orthogonal functions (EOFs) by random phases; in homogeneous turbulence the EOFs become the Fourier modes. The EOF technique is applied in this paper to the case of turbulence in a vertically inhomogeneous, atmospheric shear layer, where the integral length scale is proportional to the height. The EOFs are determined numerically, and then the turbulence is synthesized and incorporated into calculations of scattering into a shadow zone. The results are compared to previous calculations involving homogeneous turbulence.

10:20

1aPAa9. Nonlinear aspects of outdoor propagation of acoustic pulses produced by weak explosions. Antonio Moreno, Carlos de la Colina, and Francisco Simón (Instituto de Acústica, del C.S.I.C., Serrano 144, Madrid 28006, Spain, iacma15@pinar2.csic.es)

This paper deals with some nonlinear characteristics of acoustic pulses generated by weak explosions with regard to establishing a probe signal for the experimental study of ground characteristics and outdoor sound propagation. These explosions cover the intensity range of signals commonly used on experimental studies, e.g., studies of the impulse response of rooms and the transmission loss and absorption characteristics of noise barriers. After a brief introduction of time history and spectra of such signals, compared to linear pulses and nonlinear pulses of explosions of a higher nonlinear range particular attention is paid to air absorption up to 20 kHz. Evolution of the pulse signature as it propagates as well as global pick attenuation and attenuation in $\frac{1}{3}$ octave frequency bands are discussed compared to linear processes and well established nonlinear theories, offering as a conclusion a simple and practical model that accounts well for the transformations undergone by the pulse when it propagates under reference atmospheric conditions. These characteristics are intended as a reference for comparison of experimental studies on the influence of the ground and obstacles of different acoustic nature involved in propagation processes. 1aPAb1. Steady streaming from a noncompact sphere. Ashok Gopinath (Dept. of Mech. Eng., Code ME/Gk, Naval Postgrad. School, Monterey, CA 93943, gopinath@nps.navy.mil) and Eugene H. Trinh (NASA-JPL, Pasadena, CA 91109)

An analytical study has been conducted of acoustic streaming around a rigid sphere in a plane standing acoustic field under the noncompact sphere approximation. Under these conditions the sphere size is allowed to be comparable to the (radian) wavelength of the acoustic field, thus making the usually ignored compressibility effects significant in the flow. However, the amplitude of fluid oscillations is assumed small compared to the sphere size, and their ratio serves as the appropriate perturbation parameter in the matched asymptotic technique being used. The solution calls for a Helmholtz type decomposition of the velocity field into the sum of the gradient of a potential function, and the curl of a suitably vectorized stream function. The role of the nonlinear interactions of both the potential function and the stream function is pointed out, and the resulting streaming flow patterns are contrasted with those obtained in the incompressible case. This work would find application in determining transport rates in containerless processing using acoustic levitation with *ultrasonic* frequencies. [Work supported by NASA.]

1aPAb2. An acoustic radiometer. Timothy G. Simmons, Bruce Denardo (Dept. of Phys. and Astron., and Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677), Andrés Larraza, and Robert Keolian (Naval Postgrad. School, Monterey, CA 93943)

An electromagnetic radiometer is a well-known physics demonstration and toy. When exposed to light of sufficient intensity, the vanes rotate in the *opposite* direction if radiation pressure were the mechanism. That is, the reflective white side leads the absorptive black side. This occurs due to thermal effects associated with the gas in the bulb, and can be overcome only with a very high vacuum. To demonstrate the effect of radiation pressure, we have built an *acoustic* radiometer consisting of an aluminum T-beam with a 10-cm-square pane attached to each end. One side of a pane is acoustically reflective (aluminum) and the other is acoustically absorbing (foam). The device is pivoted with a V-jewel bearing and a steel pin, and is placed in a transparent chamber with a uniform broadband noise field (2.5–15 kHz). A minimum sound-pressure level of roughly 125 dB (re: 10^{-12} W/m^2), which yields a theoretical net force corresponding to 2 mg on each pane, produces rotation in the ''correct'' sense with the absorptive side leading the reflective side. The apparatus will be demonstrated during the talk. [Work sponsored by the Office of Naval Research.]

8:45

1aPAb3. An acoustic Casimir effect. Andrés Larraza, Christopher D. Holmes, Robert T. Susbilla (Dept. of Phys., code PH/La, Naval Postgrad. School, Monterey, CA 93943), and Bruce Denardo (Univ. of Mississippi, University, MS 38677)

Theoretical and experimental results are presented for the force law between two rigid parallel plates due to the radiation pressure of broadband acoustic noise. The noise is in the band of 5 to 15 kHz and has an intensity of 133 dB (re: 10^{-12} W/m^2). Good quantitative agreement is shown between theory and experiment. These results constitute an acoustic analog for the Casimir effect, which is the force experienced by two closely spaced uncharged conducting plates due to the quantum electromagnetic zero point field. In contrast to this case, however, band limited noise can cause the force to be *attractive* or *repulsive* as a function of the distance of separation of the plates. [Work sponsored by the Office of Naval Research.]

1aPAb4. Research of finite-amplitude acoustic pulse propagation in a thin capillary filled with a viscous-elastic fluid. Igor B. Esipov (N. Andreyev Acoust. Inst., 4 Shvernik str., Moscow 117036, Russia) and Vladislav G. Mikhalevich (General Phys. Inst., Moscow 117942, Russia)

Acoustic wave propagation in a thin capillary filled with a viscous fluid is accompanied by additional attenuation because of sound energy outflow to the capillary wall due to viscous forces. It is known that a whole class of fluids exists, which change their viscous properties (shift modulus) under the applied stress. It is the so-called Bingham fluids. The results of experimental research of wide frequency band sound pulse propagation in the capillary filled with a raw oil are presented. A pulse was generated by laser radiation. The amplitude of the pulse reached up to 1 MPa and its time duration was about 20 ns. Acoustic signal reception was provided by a PVDF gage and registered by a digital oscilloscope in the frequency range of 100 MHz. Experiment shows a kind of induced ''transparency'' for the high-amplitude sound pulse propagated along a capillary of 0.4-mm radius. This effect of acoustic-induced transparency of viscous fluid shows a rapid growth of high-frequency components of the sound signal passed through the capillary with respect to the growth of laser pulse energy. Meanwhile, for the small-amplitude sound signal propagation the linear relation between laser pulse energy and sound pulse amplitude is valid. [Work is partially supported by the Russian Foundation of Basic Research (project 97-02-17789).]

1aPAb5. Stabilization of a capillary bridge far beyond the Rayleigh–Plateau limit using active feedback and acoustic radiation pressure. Mark J. Marr-Lyon, David B. Thiessen, and Philip L. Marston (Dept. of Phys., Washington State Univ., Pullman, WA 99164-2814)

A liquid bridge between two solid surfaces is known as a capillary bridge. Long bridges naturally become unstable to a symmetric mode by bulging near one end while the opposite end thins. Suppression of this mode is important for managing fluids in low gravity. For a cylindrical bridge in low gravity of radius R and length L, the slenderness $S=L/2R$ has a natural (Rayleigh–Plateau) limit of π beyond which the bridge breaks. Using acoustic radiation pressure to control the bridge's shape, and an optical sensor to detect the bridge's shape, an active feedback system in simulated low gravity was constructed. This system stabilized bridges significantly beyond the Rayleigh–Plateau limit, with S as large as 4.3 [Marr-Lyon *et al.*, J. Fluid Mech., accepted for publication]. To be useful in low gravity, this technique will have to be modified to work on liquid bridges in air. In preparation for an experiment to be performed on NASA's low gravity KC-135 aircraft, acoustic resonators in air that have the required

property that the sound amplitude can be spatially redistributed rapidly are being investigated and tested in normal gravity using soap-film bridges filled with sulfur hexafluoride. [Work supported by NASA.]

1aPAb6. Surfactant-bearing drop dynamics in microgravity. Xiaohui Chen and Robert E. Apfel (Dept. of Mech. Eng., Yale Univ., 9 Hillhouse Ave., New Haven, CT 06520-8286, xhchen@minerva.cis.yale.edu)

Experiments of large amplitude nonlinear oscillations of axially symmetric surfactant-bearing (triton or bovine serum albumin) water drops with different initial aspect ratios and drop volumes were performed during the second United States Microgravity Laboratory, USML-2 in November 1995. Through the numerical simulation of the oscillations of these surfactant-bearing water drops using the boundary integral method, the surface dilatational viscosity and the surface shear viscosity are found to play a major role in these oscillations. How they influence the damping coefficient and the drop oscillation frequency will be presented. The numerical and analytical results and a physical picture of the relation between the surface viscosities and the damping coefficient will be described. In addition, the relation between the initial drop aspect ratio, the surface viscosities, and the surface rotational velocity will also be presented. [Work supported by NASA through JPL, Contract No. 958722.]

1aPAb7. The study of evaporation of multicomponent drops using the acoustoelectric levitator. Yibing Zheng, Robert Apfel, and Yuren Tian (Dept. of Mech. Eng., Yale Univ., New Haven, CT 06520, yibing.zheng@yale.edu)

The evaporation of single drops and drop arrays of multicomponent liquids is investigated using a novel acoustoelectric levitator. By simultaneous levitation and charging of the drops, 2D drop arrays with the drop diameters varying from 0.2 to 1 mm can be formed. Also by controlling both the acoustic and electric field intensities, arrays with different drop sizes and spaces between drops can be created. This allows us to study the interference effects among drops in an evaporating dense spray. Mixtures of different liquids such as alkanes (heptane, dodecane, and hexadecane) are studied. The evaporation rates of those mixtures with different molar ratios of components and different numbers of drops in an array are measured. The drop size and spacing are carefully controlled and varied. A video camera is used to record the drop size change with time, and the diameters of drops are calculated from the pictures. The results are compared with a theoretical analysis based on the diffusion-controlled evaporation model. [Work supported by NASA through JPL Grant No. 958722.]

10:15

1aPAb8. Particle separation by ultrasonic forces. Steven M. Woodside (Biotechnology Lab. and Dept. of Chemical and Bio-Resource Eng., Univ. of British Columbia, Vancouver, BC V6T 1Z3, Canada), Martin Groeschl, Ewald Benes (Institut fuer Allgemeine Physik, Technische Universitaet Wien, A-1040 Wien, Austria), Bruce D. Bowen, and James M. Piret (Univ. of British Columbia, Vancouver, BC V6T 1Z3, Canada)

A simple, effective device has been developed to separate mammalian cells from growth medium using the ultrasonic forces on suspended particles in a standing wave field. The ultrasonic force distribution in this acoustic separation device has been analyzed to provide a basis for further optimization and scale-up of the separation system. Measurements of the force distribution in the liquid using a microscope-based imaging system were compared to laser interferometric measurements of the velocity amplitude distribution on the transducer and reflector surfaces of the ultrasonic resonator. The axial force followed the surface velocity, being highest near the center, and approaching zero near the walls. The transverse force distribution and the local gridlike surface amplitude variation had characteristic wavelengths of 1.4 mm. These results suggest that the force distribution is determined predominantly by the response of the reflector and transducer to the standing wave. This understanding of the force distribution simplifies the modeling of particle retention and facilitates resonator design. By selection of appropriate resonator dimensions and construction materials, and modeling of the ultrasonic force on the particles, enhanced flow-through capacity and particle retention efficiency can be achieved.

1aPAb9. The two-dimensional acoustic standing wave and its application in coagulation of aerosols. Henryka Czyż (Inst. of Phys., Pedagogical Univ. of Rzeszów, 35-310 Rzeszów, Rejtana 16a, Poland, hczyz@atena.univ. rzeszow.pl)

The problem of motion of small solid or liquid particles suspended in gaseous medium (aerosols and smokes) has been studied intensively in connection with the technical application of acoustic coagulation for precipitation of gases. Along with its technical applications, the problem of motion of small particles in acoustic field (called the drift) is interesting by itself as one of the fundamental physical effects of sound. For theoretical and practical reasons, the two-dimensional standing-wave configuration seems to be of special interest. In the case when nodal and antinodal surfaces of the standing wave are convex, the particles move along some curves and gather in some particular points and not only in some planes. This means that one can obtain much greater concentration of particles in some definite regions than in the case of the plane standing wave. As a configuration of special theoretical interest it proposes the standing wave in a rigid elliptical cylinder with a strip-shaped source of uniform velocity distribution placed in the symmetry plane of the system. Some numerical examples will be presented during the conference [H. Czyż, Acustica **70**, 23–29 (1990)].

1aPAc1. Physical effects of macrosonic standing waves in oscillating cavities. Christopher C. Lawrenson, Thomas W. Van Doren, and Bart Lipkens (MacroSonix Corp., 1570 East Parham Rd., Richmond, VA 23228)

Previous work has demonstrated resonant macrosonic synthesis (RMS) for shaping pressure waves in oscillating closed cavities. Additional measurements of pressure waves are presented, with peak overpressures in excess of 400% of ambient pressure. Characteristic power consumption of various resonator shapes is presented. Resonator shape as well as pressure amplitude is shown to be important in determining power consumption. For a change in resonator geometry, one example shows a 765% increase in pressure amplitude for a fixed power delivery. The dependence on resonator geometry of hardening and softening resonance behavior is demonstrated by showing results for both different resonator shapes and different gases in the resonators. Physical effects of macrosonic pressures and particle velocities are demonstrated with pulverization of objects placed in the resonator cavity.

8:45

1aPAc2. Investigation of a particle velocity field in nonlinear standing waves. Yurii A. Ilinskii, Bart Lipkens, and Evgenia A. Zabolotskaya (MacroSonix, 1570 East Parham Rd., Richmond, VA 23228)

A one-dimensional model of nonlinear standing waves in an oscillating closed cavity has been developed at MacroSonix and was presented at the 1997 Acoustical Society meeting in San Diego. The present study focuses on the characteristics of the particle velocity wave field. Measurements of the particle velocity are very difficult to execute, but insight into the velocity field yields important information of the properties of an acoustical resonator. Waveforms and harmonic amplitudes of velocity as well as pressure waves along the resonator axis are calculated. Results are presented for three geometries: a cylinder, a cone, and a bulb-type resonator. The resonators are oscillated at the fundamental resonance frequency. Numerical calculations show that for dissonant resonators, in which harmonics of the fundamental frequency are not coincident with higher modal frequencies, Mach numbers on the order of 0.5 can be achieved, while for a cylindrical resonator Mach numbers are much more limited. For the resonators considered, the velocity waveforms have different characteristics: a shocked waveform for the cylinder, a sawtooth-type wave for the cone, and a disturbed sine wave for the bulb. An interesting result is that the velocity waveform is fundamentally different from the pressure waveform.

9:00

1aPAc3. Parametric excitation of a Helmholtz resonator. Wayne E. Prather, Bruce Denardo, and Richard Raspet (Dept. of Phys. and Astron., and National Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677, weprathe@olemiss.edu)

Parametric excitation of an oscillator results from the modulation of a parameter upon which the natural frequency of the oscillator depends. If the drive amplitude exceeds a threshold determined by dissipation, the response amplitude grows exponentially until it is saturated by a nonlinearity of the system. Hence, large amplitudes may be possible. An unsuccessful attempt to parametrically excite the fundamental mode of a Helmholtz resonator is reported. The apparatus consists of two equal-volume cavities connected by a U-shaped neck similar to a trombone slide, where the neck length is modulated at twice the Helmholtz frequency. In model systems, the effective quality factor diverges as the parametric drive amplitude approaches threshold from below. the extent to which a parametric drive amplitude is below threshold can thus be probed by performing a frequency sweep with a small-amplitude direct drive. However, the effective quality factor in our system is found to *decrease* as the parametric drive amplitude is increased, as a result of turbulence caused by the parametric drive. This indicates that parametric excitation by neck length modulation may not be possible. Current work on a Helmholtz resonator in which the cavity volume is modulated is also reported on. [Work sponsored by ONR.]

9:15

1aPAc4. Measurements of temperature and velocity oscillations in acoustic waves. Guadalupe Huelsz, Francisco Lopez-Alquicira, and Eduardo Ramos (Centro de Investigacion en Energia, AP 34 CP 62580, Temixco, Mor. Mexico, ghl@mazatl.cie.unam.mx)

Experimental techniques using cold and hot wire anemometry have been developed to measure acoustic temperature and velocity oscillations in gases, respectively, especially in the case where there is no imposed mean flow. The calibration of both instruments was made through the measurement of the pressure oscillation. Using these techniques the structures of thermal and viscous oscillatory boundary layers produced by an acoustic standing wave in air with 130-Hz frequency and pressure oscillation amplitude up to 200 Pa are determined. Experimental results are satisfactorily compared to theoretical results of a linear theory. The advantages and the limitations of these experimental techniques are discussed. [Partial support for this work has been provided by DGAPA-UNAM IN103197 and CONACYT G0044E projects.]

9:45

1aPAc5. Acoustic methods for transport properties measurements in gases. Keith A. Gillis, James B. Mehl, and Michael R. Moldover (NIST, Bldg. 221, Rm. A111, Gaithersburg, MD 20899, keith.gillis@nist.gov)

Two novel acoustic resonators have been developed, one for measuring the viscosity and a second for measuring the Prandtl number of gases. For viscosity measurements, a double Helmholtz resonator, called the Greenspan viscometer, is used. This resonator consists of two chambers connected by a small duct. The Greenspan viscometer has a single, isolated, low-frequency mode that is fitted to determine the gas' viscous diffusivity. The Greenspan viscometer may be used for absolute measurements if the dimensions of the duct and chambers are accurately known. Otherwise, the viscometer may be calibrated with argon or helium. For Prandtl number measurements, a cylindrical resonator that has been modified by inserting an array of short, parallel plates halfway between the

ends is used. The lower longitudinal modes of this resonator are fitted to determine the Prandtl number. The odd order modes are attenuated primarily by the viscous diffusivity; the even order modes are attenuated primarily by the thermal diffusivity. Detailed acoustic models of both resonators have been developed and are necessary to realize the full precision and accuracy of these techniques. Transport property measurements of several gases will be presented. [This work is supported in part by the Office of Naval Research.]

10:00

1aPAc6. Optical techniques for sound generation and detection in acoustic resonators. Giuliana Benedetto, Roberto M. Gavioso, and Renato Spagnolo (IEN Galileo Ferraris-Acoust. Dept., Strada delle Cacce 91, 10135 Torino, Italy)

The most reliable method for sound-speed measurement in gases is based on the use of acoustical resonators. The measurement consists of the determination of the resonance frequencies of the cavity in the presence of a stationary acoustic field. Usually, the source and the receiver are condenser microphones. The main limit of these transducers is their inability to be used in a hostile environment, so there is an increasing interest to develop remote optical techniques for sound generation and detection. In this paper it is shown that it is possible to generate the acoustical field through a photoacoustic effect on the interior surface of the resonator, achieving a measurement precision comparable to that obtained when the source is a 1/4-in. condenser microphone. As a further improvement, it is also shown that sound can be generated by a silicon micromembrane facing the cavity, optically excited at the rear side. Measurements have been performed in a cylindrical stainless steel resonator of about 572 cm^3; the light source is the 514-nm line of an Ar^+ laser. An effort is being made to investigate the possibility of also substituting the receiving transducer with an optical detection scheme, based on laser beam deflection.

10:15

1aPAc7. Numerical study of a one-dimensional resonant gas oscillation in a closed tube. Takeru Yano (Mech. Sci. Dept., Hokkaido Univ., Sapporo, 060 Japan, yano@lebes-me.eng.hokudai.ac.jp)

The one-dimensional resonant gas oscillation in a closed tube is numerically studied by solving Navier–Stokes equations of gasdynamics. Accurate numerical solutions are obtained by using an eighth-order Padé type compact finite-difference scheme without any artificial viscosity and the second-order Runge–Kutta method. The solutions show that a shock wave of sufficiently steep front is formed even in the case of $M=O(10^{-5})$, where M is the acoustic Mach number at the sound source located at one end of the tube. The evolution process from the initial state of uniform and at rest to a quasisteady state including a shock wave is analyzed. The result is compared with earlier works based on the first-order weakly nonlinear theory.

10:30

1aPAc8. The use of a subgrid-scale quasi-stationary approximation in finite-difference time-domain simulations to calculate the absorption by Helmholtz resonators. John De Poorter and Dick Botteldooren (INTEC, Univ. of Gent, Sint Pietersnieuwstraat 41, B-9000 Gent, Belgium)

To calculate Helmholtz resonators using a finite-difference time-domain (FDTD) simulation technique, one has to deal with two important difficulties. First, the determining structures of a Helmholtz resonator are typically subwavelength geometries with dimensions that are smaller than the FDTD cell size normally used for the wavelengths of interest. Therefore, the FDTD cell size should be reduced, resulting in a very high computational cost. On the other hand, the viscous absorption in the resonator neck influences the resonator behavior a lot and has to be included in the calculation. The first problem was solved by using a coarse FDTD grid but applying detailed simulated quasistationary pressure distribution to modify the FDTD equations in the neighborhood of the resonator neck. For the second problem the analytical solution for viscous boundary layer absorption was introduced into the FDTD equations. However, this solution is only correct for the viscous absorption near an infinite plate. Therefore, the calculated quasi-stationary solutions were applied to correct for the nonuniform velocity distribution in the resonator neck. The results are compared with both analytical solutions and with experimental results.

1aPP1. Absolute magnitude estimation of pitch. Andrzej Rakowski and Andrzej Miskiewicz (Chopin Acad. of Music, Okolnik 2, 00-368 Warsaw, Poland)

The pitch of 24 pure tones covering a frequency range of 63–12 500 Hz in 1/3-oct. steps was measured by absolute magnitude estimation. The tones were presented monaurally at a loudness level of 60 phons. Tone duration was 1 s. Sixteen music students, not possessing absolute pitch served as subjects. The experiment was carried out in individual listening sessions. The subjects were instructed to assign a number to the tone in such a way that their impression of how large the number was matched their impression of the pitch of the tone. The results show that the pitch function plotted in log–log coordinates against frequency is considerably steeper below than above 250 Hz. A similar shape of the pitch function was found in a previous study in which narrow-band noises were used [A. Rakowski, Proc. Fechner Day '97, pp. 91–96]. It is hypothesized that the change of the pitch function steepness at 250 Hz may also be observed in the perception of musical intervals. Intervals in low pitch registers may be perceived larger than those corresponding to the same frequency ratios in high-pitch registers.

9:30

1aPP2. Regular interval stimuli with more than one pitch. William A. Yost (Parmly Hearing Inst., Loyola Univ., 6525 N. Sheridan Rd., Chicago, IL 60626, wyost@luc.edu)

Iterated ripple noises (IRN) are an example of regular interval stimuli (RIS) that can have more than one pitch. IRN stimuli are generated by a cascade network of delay (d in ms), attenuate ($-1 \leqslant g \leqslant 1$), and add circuits. When $g = -1.0$ and the number of cascaded circuits (number of iterations) is less than four, the pitch of IRN stimuli has two values. The addition of two IRN stimuli, each generated with different values of d, can also have two pitches. Listeners were asked to discriminate between an IRN stimulus generated with $g = -1.0$ and the sum of two IRN stimuli with each IRN stimulus generated with a different value of d. Performance was measured as a function of the difference in the two values of d. The center value of d, g, and the number of iterations were also parameters of the experiments. For certain separations of d and for certain values of g, listeners had difficulty discriminating between the two stimuli. The discrimination procedure allows for an objective identification of the pitch of IRN stimuli when $g = -1.0$. The results will be discussed in terms of models of complex pitch. [Work supported by NIDCD and AFOSR.]

9:45

1aPP3. New experiments beyond the traditional Fourcin Pitch range. Johan Raatgever, Frans A. Bilsen, and Reshma Mungra (Appl. Phys. Dept., Delft Univ. of Technol., Delft, The Netherlands)

The Fourcin Pitch is a dichotic pitch phenomenon occurring when a white noise signal and its interaurally delayed replica (delay $T1$) are presented simultaneously with a second (uncorrelated) noise signal with interaural delay $T2$. Former experiments dealt with $T1$ between 2 and 10 ms, while $T2$ was kept at a value between 0 and 2 ms [Bilsen and Wesdorp, 8th ICA (1974)]. With proper polarities of the noises and the delays at opposite ears, the pitch would typically have a value corresponding to $1/(T1+T2)$ and the (lateralized) pitch image would correspond to the shortest delay ($T2$). In the present study, both delay times were chosen about equal and with a value above about 5 ms; again the delays were presented at opposite ears, but with equal polarities. It turned out that a pitch is perceived with a saliency estimated between the Fourcin Pitch and the dichotic repetition pitch (one noise source only), with a value corresponding to $2/(T1+T2)$, and with a (lateralized) pitch image corresponding to an interaural delay of $(T1-T2)/2$. This new result, also, can be explained by the central spectrum theory [Raatgever and Bilsen, J. Acoust. Soc. Am. **80** (1986)].

10:00

1aPP4. Comparing the accuracy of monotic and dichotic repetition pitch. Frans A. Bilsen, Han H. Dols, and Johan Raatgever (Appl. Phys. Dept., Delft Univ. of Technol., Delft, The Netherlands)

When white noise is added to its delayed replica, a pitch is evoked corresponding to the reciprocal value of the delay time (T). When the delayed replica is fed to the same ear, the pitch (monotic repetition pitch: MRP) is rather salient; when, instead, it is fed to the contralateral ear, the pitch (dichotic repetition pitch: DRP) is rather faint. MRP is readily explained by spectral information processing in the cochlea. For reasons of parsimony, DRP is assumed to be the result of central spectrum processing preceded by interaural (temporal) processing. The present paper reports measurements on the accuracy of pitch matching for both MRP and DRP. Because of the difference in saliency, a difference in accuracy might be expected, if pitch saliency and pitch accuracy would be positively correlated. It turned out that pitch accuracy, expressed as the relative standard deviation, is dependent on the delay time and the stimulus type. For T larger than about 20 ms (the infra pitch range) the accuracy is about 10% for both MRP and DRP. For T smaller than 20 ms (the pitch range), accuracy is about 0.5% for MRP and 3% for DRP.

10:15

1aPP5. Listeners' spectral weighting functions for pitch judgment. Huanping Dai (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131)

Two experiments were carried out to determine how listeners use spectral information in judging the pitch of harmonic complex tones. In particular, spectral weighting functions were obtained using a correlation technique in which random, independent perturbations were added to the frequencies of the spectral components. The correlation coefficient between the perturbations applied to a given frequency component and listeners' responses provides an estimate of the weight associated with that component. In the first experiment, all complex tones had the first 12 partials; the fundamental frequency was varied from 100 to 800 Hz. The obtained weighting function tended to show a peak for partials close to 600 Hz regardless of their harmonic numbers. In the second experiment, the fundamental was fixed at 200 Hz, and the number of partials was reduced by omitting the first two, four, or six partials. As these partials were excluded, the weights redistributed, with the maximum weight consistently going to the lowest partial present in the stimulus, i.e., at 600, 1000, or 1400 Hz. Overall, these spectral weighting functions reaffirmed the presence of a frequency dominance region, showing prominent influences on pitch judgment from low-ranked partials. [Work supported by NIH/NIDCD.]

10:30–10:45 Break

10:45

1aPP6. Pitch mechanisms for unresolved harmonics I: Duration effects. Louise J. White and Christopher J. Plack (Experimental Psych., Univ. of Sussex, Brighton, BN1 9QG, UK)

The experiment measured the effects of duration, fundamental frequency ($F0$), spectral region, and relative phase of harmonics on $F0$ discrimination for complex tones consisting of unresolved harmonics. The $F0$ discrimination was measured for complexes with durations between 20 and 160 ms, and with $F0$s of 62.5, 125 and 250 Hz. The complexes were bandpass filtered between either 2750 and 3750 Hz or between 5500 and 7500 Hz. Finally, either all the harmonics were in sine phase (SINE) or alternating harmonics had a cosine phase shift (ALT). The pitch of an unresolved ALT complex is one octave higher than that for an unresolved SINE complex with the same $F0$ [T. M. Shackleton and R. P. Carlyon, J. Acoust. Soc. Am. **95**, 3529–3540 (1994)]. For the SINE stimuli the improvement in $F0$ discrimination with duration was dependent on $F0$, with a larger effect of duration for the lower $F0$s. However, for the ALT stimuli the improvement with duration was the same as that for a SINE complex with twice the $F0$. Overall the results suggest that pitch, rather than $F0$ per se or spectral region, is the main determinate of the duration effect and also possibly of the integration time of the pitch mechanism.

11:00

1aPP7. Pitch mechanisms for unresolved harmonics II: Sensitivity to envelope phase. Christopher J. Plack and Louise J. White (Experimental Psych., Univ. of Sussex, Brighton, BN1 9QG, UK)

Introducing a phase change between two short bursts of a sinusoid can produce a pitch shift which corresponds to a shift in the peak of the long-term spectrum [I. V. Nabalek, Acustica **82**, 531–539 (1996)]. The present experiment examined whether a similar effect could be obtained for a complex tone consisting of unresolved harmonics where the phase change was applied to the envelope of the complex. For unresolved harmonics a pitch is heard corresponding to the fundamental frequency ($F0$) of the complex even though the $F0$ component is not physically present. It is likely that $F0$ is extracted from neural phase locking that provides a crude representation of the envelope of the complex (which repeats at $F0$). The complex consisted of the harmonics of a 250-Hz $F0$ filtered between 5500 and 7500 Hz. A phase advance of 0.75 $F0$ periods between two 20-ms bursts produced a downward pitch shift of almost 10 Hz when the

bursts were contiguous but no downward shift when the bursts were separated by a gap of 5 ms or more. The results are consistent with a long-term pitch mechanism sensitive to envelope phase that can be reset in response to discontinuities in the stimulus.

1aPP8. Cooperative behavior in the Fitzhugh–Nagumo neuron: Consequences for acoustic perception. Jonathan Tapson (Dept. of Elec. Eng., Univ. of Cape Town, UCT Private Bag, Rondebosch 7700, South Africa)

Recent studies have shown that a type of stochastic resonance, known as cooperative behavior, can occur in biological neurons. This behavior is characterized by phase locking between the pulse position modulation of the neuron's activation and weak sinusoidal input signals. The behavior is strongly influenced by the level of background noise in the system. Significantly, it is common for the phase of the neuron activation to lock on a subharmonic of any sinusoidal input stimulation or on subharmonics of a combination of tones. If the Fitzhugh–Nagumo neuron is simulated as an integrate-and-fire (Wiener) process, it can be shown that a single neuron demonstrates cooperative behavior modes which correspond to the known phenomena of acoustic perception (if the neural input is assumed to be a sonic stimulus). Most significantly, the perception of virtual pitch is apparent, as is the pitch shift effect. When presented with an amplitude modulated waveform, the neuron locks on peak features of the time representation of the waveform, thereby recreating the effects discovered by Schouten [Philips Tech. Rev. **5**, 286–301 (1940)]. It seems likely that this simple model explains some of the physiological bases for the nature of pitch perception.

11:30

1aPP9. The role of global processes in the perceptual cohesion of harmonic complex tones. Jeffrey M. Brunstrom and Brian Roberts (School of Psych., Univ. of Birmingham, Edgbaston, Birmingham B15 2TT, UK, J.M.Brunstrom@Bham.ac.uk)

Harmonic components typically fuse to form a single perceptual entity. Their spectral positions are consistent both globally, because of the regular pattern defined by the other components, and locally, because of their equidistance from adjacent components. This study explored the contribution of global regularity to harmonic fusion. On each trial, subjects heard a periodic complex tone, derived from a 14-harmonic complex, followed by an adjustable pure tone in a continuous loop. Either two, three, or four consecutive components (harmonics six and above) were removed from the original complex and replaced by a ''probe'' component, located at one of a set of regularly spaced positions spanning the gap created in the complex. Subjects were instructed to match the pitch of the pure tone to that of the probe. Generally, they were successful unless the probe coincided with a harmonic position in the complex, though to a lesser extent, this was true even when the probe matched a nonconsecutive harmonic position. This indicates that the cohesion established by a set of harmonics is not dependent upon spectral equidistance between adjacent components. Rather, the effects of this kind of spectral pattern can extend into a multicomponent gap in a harmonic series.

11:45

1aPP10. Accentuation of spectral pitch. Werner A. Deutsch (Acoust. Res. Dept. of the Austrian Acad. of Sci., Liebiggasse 5, A-1010 Vienna, Austria)

Lower harmonics of steady-state complex tones are resolved and produce individual spectral pitches when attention is focused to them. Attention to individual harmonics is enforced by sharp onset cues as simply switching partials on and off. Periodically rising and falling changes of the fundamental frequency of a complex tone (range: 1 oct, rate: 1–0.5 s) results in concurrent percepts. Initially accentuated spectral pitches of short duration are perceived followed by continuing integration of the partials into the complex tone according to the ''common fate'' rule. In comparison to the falling fundamental frequency phase higher partials accentuated during the rising phase are integrated faster. Concurrent spectral and fundamental frequency information exhibit a distinct pitch ambiguity transition immediately after the onset of the spectral pitch. The duration of the transition stage is assumed to reflect a kind of ''Gestalt'' generation time constant until the complex tone accepts its new incoming component. Raising the rate of fundamental frequency change to 4/s and more reduces the effect of the spectral pitch progressively. The pitch change of the complex tone dominates the spectral information. The concurrence is reduced furthermore when onsets are smoothed and consequently changes of timbre are perceived.

12:00

1aPP11. Perceptual segregation and pitch shifts of mistuned components in harmonic complexes and in regular inharmonic complexes. Brian Roberts and Jeffrey M. Brunstrom (School of Psych., Univ. of Birmingham, Edgbaston, Birmingham B15 2TT, UK)

It is unclear whether the perceptual segregation of a mistuned harmonic from a periodic complex tone depends specifically on harmonic relations between the other components. A procedure used previously for harmonic complexes [W. M. Hartmann, S. McAdams, and B. K. Smith, J. Acoust. Soc. Am. **88**, 1712–1724 (1990)] was adapted and extended to regular inharmonic complexes. On each trial, subjects heard a 12-component complex followed by a pure tone in a continuous loop. A mistuning of $\pm 4\%$ was applied to one of the components 2–11. Subjects adjusted the pure tone to match the pitch of the mistuned component. Near matches were taken to indicate segregation. The complexes were either harmonic, frequency shifted, or spectrally stretched. Performance in the inharmonic conditions was generally as accurate as in the harmonic condition. Small but consistent mismatches, pitch shifts, were found in all conditions. Their direction and size were similar to earlier findings for harmonic complexes. Subsequent tests using a range of mistunings showed that the perceptual segregation of components from regular inharmonic complexes could be sensitive to mistunings of 1.5% or less. These findings suggest that the effects of spectral regularity on auditory grouping are more general than those of harmonic relations.

1aSA1. Algebraic aspects of acoustic scattering. Elisabeth Fournier, Yves Decanini, Antoine Folacci, and Paul Gabrielli (URA 2053 CNRS, SDEM, Université de Corse, Faculté des Sci., BP 52, 20250 Corte, France)

Acoustic scattering by an arbitrary number of identical cylinders is studied. The S-matrix associated with such a system is obtained by extending the KKR method developed by Kohn, Korringa, and Rostoker in condensed matter physics. Calculations are carried out for various boundary conditions (soft, rigid, and elastic cylinders). Scattering resonances are the poles of the S-matrix. They are determined in the complex plane of the reduced frequency. Scatterers with discrete symmetries, such as: C_{2v} : two cylinders, C_{3v} : three cylinders located at the vertices of an equilateral triangle, C_{4v} : four cylinders located at the vertices of a square, are more particularly studied. Symmetries are reflected in the S-matrix, which reduces to a block diagonal form where the blocks are labeled by the irreducible representations of the symmetry group. This work is a step toward a complete study of chaos (linked to statistical properties of the S-matrix) in the context of multiple scattering.

8:15

1aSA2. Free and forced vibration of a multisupported string. Benjamin A. Cray (Naval Undersea Warfare Ctr., Newport, RI 02841)

This paper examines a simple model: the vibration of an infinite string resting on sets of periodic supports, which are modeled as linear spring-mass-damper systems. The qth set of periodic supports may be offset by a distance xq. These offsets can thus be used to create spatially distributed gratings along the length of the string. Both the free and forced responses are examined, with the objective of gaining an understanding of the vibration response that governs more complicated arbitrarily stiffened elastic structures.

8:30

1aSA3. Eigenvalues gap optimization with sensitivity criteria in coupled acoustic-structural systems. Walter P. Casas[a] (Mech. Eng. Faculty, Natl. Ctr. Univ. of Peru, paucar@fem.unicamp.br) and Renato Pavanello (State Univ. of Campinas, Sao Paulo, Brazil, pava@fem.unicamp.br)

The design optimization can be made following a hard repetitive time consuming process, through the analysis of the design with a few modifications in its parameters, until the required system is encountered. To solve this problem, it is better to use the sensitivity analysis, letting one evaluate the model performance without realizing new analysis. The purpose of this work is to optimize the gap between two eigenvalues in coupled acoustic-structure systems in order to avoid the resonance phenomena in a certain frequency interval, taking the thickness of the structural elements as control variables subject to one constant structural volume. The finite element method is used for discretization of the system, and one nonsymmetrical formulation up with Hermissian matrices in displacement of the structure and fluid pressure describes the system, being necessary to use the left and right eigenvectors concept. For simplicity the nonzero and nonrepeated eigenvalue case is considered. The sequential quadratic programming algorithm is used for the constrained nonlinear optimization, and in the optimization process is considered the modal sensitivity analysis to choose the more sensible parameters. The validity of the study is verified by applying it to a coupled bidimensional system. [a] Currently at UNICAMP-FEM-DMC.

8:45

1aSA4. A modal approach for the acoustic and vibration response of an elastic cavity with absorption treatments and mechanical/acoustical excitation. Noureddine Atalla and Michel Tournour (G.A.U.S., Dept. Génie Mécanique, Univ. de Sherbrooke, Sherbrooke, QC J1K 2R1, Canada)

The calculation of the acoustic and vibration response of an elastic cavity is considered. The presented technique couples a modal decomposition for the structure *in vacuo* and the cavity with a coordinate transformation to allow for efficient determination of the coupled modes. Using these coupled modes, it rewrites the coupled equations accounting for the impedance condition at the treated elastic walls, internal acoustic sources, and mechanical excitations in terms of a compact forced system. The theory behind the method is presented together with validations and numerical examples.

9:00

1aSA5. The effect of large structural perturbations on the response of structural-acoustic systems. Steven Hahn and Aldo Ferri (Georgia Tech, MS 0405, Atlanta, GA 30332, steven.hahn@me.gatech.edu)

Due to high sensitivity, first-order perturbation analysis of structural-acoustic systems can be inaccurate for large perturbations. Using high-order derivatives to create a Taylor series approximation for the perturbed solution can result in slow convergence or even divergence. A rational polynomial or Pade approximation may overcome the poor convergence of the Taylor series by canceling out the pole causing the poor convergence. In this study, a finite element framework is used to describe the structural-acoustic system. External radiation and scattering problems are accommodated by truncating the infinite fluid region using exponential decay infinite elements. Changes to a nominal model are introduced through a structural perturbation that modifies the nominal structural stiffness matrix. An efficient method for calculating the solution derivatives with respect to the structural perturbation is presented. A Taylor series expansion is constructed using the derivative information and the convergence criteria for the series is examined. The local solution and derivatives are then used to construct a Pade approximation. The method is illustrated using several numerical examples. The approximation is shown to be quite accurate for large perturbations even when there are one or more nearby poles and the Taylor series fails to converge.

9:15

1aSA6. Synthesis of the radiated sound field from a vibrating plate-strip with free edges. Kai-Ulrich Machens (Inst. of Tech. Acoust., Univ. of Technol., Berlin, Germany)

A multipole expansion in elliptical coordinates was employed to calculate the directivity pattern of the radiation from free vibrations of a plate-strip with free edges. The Helmholtz equation can be separated in elliptical coordinates and an exact solution for a cylindrical geometry with elliptical cross section can be constructed by Mathieu functions. The radiation problem was solved by mapping the normal velocity of the rectangular cross section of the plate-strip onto an acoustically equivalent elliptical cross section and applying a multipole expansion. A comparison between this method and a standard wave-number transform showed good agreement in the case of a baffled plate, which proved the validity of this procedure. The directivity patterns of baffled and unbaffled plates are compared in order to estimate the influence of hydrodynamic short-circuit around free edges on the radiation. The compact representation of the sound field by the source-strengths is advantageous for the determination of the interference of superimposed eigenmodes for radiation. For applications in active noise control, a direct optimization criteria for secondary forces with respect to the radiated soundpower was obtained. It permits the study of efficiency and stability of the active measure with regard to number and location of the secondary forces.

9:30

1aSA7. A modal formulation for an arbitrary submerged structure in a heavy acoustic medium. Pei-Tai Chen (Dept. of Naval Architecture, Natl. Taiwan Ocean Univ., Keelung, Taiwan, ROC)

The paper studies radiational and dynamic characteristics for an arbitrary elastic structure submerged in a heavy acoustic medium. The equation of motion for the coupled structural/acoustical system is formulated. In the equation, the acoustic loading is expressed as a symmetric complex matrix derived by a surface acoustic reciprocal principle. Due to the symmetric formulation, the ratio of the complex input power exerted by an external force yields an expression for the ratio of quadratic representations of the vibration velocity. A consideration of the stationarity leads to a symmetric eigenvalue problem, in which the eigenvalue is related to the radiation efficiency for the vibration velocity corresponding to the eigenvector. Based on the eigensolution, the forced vibration of the coupled system is decomposed into a set of mutual orthogonal equations where each equation represents a one-degree-of-freedom mass/spring/dashpot system having an impedance determined by the eigensolution. A spherical shell and a slender spheroidal shell are chosen as numerical examples to demonstrate the present analysis.

9:45

1aSA8. Finite-difference studies of structural–acoustic interaction. Ulf Kristiansen (Norwegian Univ. of Sci. and Technol., NTNU Acoust. Group, Dept. of Telecommunications, N-7034 Trondheim, Norway)

The behavior of an acoustic fluid coupled to an elastic structure has been investigated by a numerical technique, i.e., the finite-difference method. The technique is simple to apply and convert the governing differential equations to a system of simultaneous algebraic equations in mesh-point unknowns. The chosen example is a 2D cavity enclosed by three hard walls and a flexible beam. The coupled modes are calculated. To incorporate an external field, the beam is assumed to be situated in an infinite baffle. Coupling to the external field is done either by extending the finite-difference model to this region, or by a boundary element method. Different examples of forcing functions will be discussed: mechanical, acoustical, and turbulent flow. The presentation will also discuss how the errors inherent in this type of numerical approximation might be reduced. Higher-order finite-difference operators and Richardson extrapolation are two such techniques.

10:00

1aSA9. Dispersion-free finite-element methods for the Helmholtz equation. Paul E. Barbone (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington Ave., Boston, MA 02215) and Isaac Harari (Tel Aviv Univ., Tel Aviv, Israel)

The problem of dispersion in finite-element approximations of solutions of the Helmholtz equation are considered. Dispersion errors can accumulate over large propagation distances. Such error is sometimes called the ''pollution error.'' Via a one-dimensional example, it is shown that the dispersion error is linked to the fact that standard finite-element approximations are not optimal (in the sense of H^1 best approximation) for the Helmholtz equation. Thus to eliminate dispersion error in finite-element solutions, the problem of finding the H^1 projection onto a finite-element space of a field satisfying the Helmholtz equation is examined. In one dimension, exact optimality of the finite-element approximation is achieved, and thus exactly zero dispersion is obtained. This leads to a finite-element formulation that is nodally exact in one dimension on *any* linear mesh. In higher dimensions, or formulation is approximately optimal and nonsymmetric. The formulation itself yields an expression for the ''distance'' from optimality, related to the lack of symmetry. Examples are shown that demonstrate the performance of the method in one and two dimensions. [Supported by ONR.]

10:15

1aSA10. A wave-based prediction technique for vibroacoustics: Comparison with the finite-element technique and experimental validation. Paul Sas, Wim Desmet, and Dirk Vandepitte (Dept. of Mech. Eng., Div. PMA, Katholieke Universiteit Leuven, Celestijnenlaan 300B, B-3001, Heverlee, Belgium, wim.desmet@mech.kuleuven.ac.be)

In a coupled vibroacoustic analysis, a structural and acoustic finite-element model must be solved simultaneously. This results in a very large, nonsymmetrical coupled model, which requires a computationally expensive solving procedure. To reduce the size of a coupled model, a wave-based prediction technique has been developed. Instead of dividing the structural and acoustic domain into small elements and solving the dynamic equations within each element using simple approximating shape functions, the entire structural and acoustic domains are described by plane-wave functions, which are exact solutions of the structural and acoustic homogeneous wave equation. To these wavefunctions, particular solutions of the inhomogeneous wave equations are added, so that the governing dynamic equations are exactly satisfied. The contributions of the wavefunctions to the coupled vibroacoustic response are determined by applying the boundary conditions in a weighted residual formulation. The wave technique has been used for the prediction of the acoustic pressure in the cavity of a car breadboard model by applying the measured structural velocity distribution as boundary conditions to the car cavity. The prediction results of the wave model are compared with the finite-element predictions and the measured cavity pressure field.

Session 1aSC

Speech Communication: Speech Technology and Speech Reception (Poster Session)

Michael D. Hall, Chair
Department of Speech and Hearing Sciences, University of Washington, Box 357920, Seattle, Washington 98195-7920

Contributed Papers

All posters will be on display from 9:15 a.m. to 12:15 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 9:15 a.m. to 10:45 a.m. and contributors of even-numbered papers will be at their posters from 10:45 a.m. to 12:15 p.m. To allow for extended viewing time, posters will remain on display until 8:00 a.m. on Tuesday, 23 June.

1aSC1. Factors influencing the detection and intelligibility of speech in competing message environments. Mark A. Ericson (AL/CFBA, 2610 Seventh St., Wright-Patterson AFB, OH 45433-7901), Robert S. Bolia (Systems Res. Labs., Dayton, OH 45440), and W. Todd Nelson (Wright-Patterson AFB, OH 45433-7901)

While monitoring multiple conversations, a listener often needs to know not only what was said but who said what to whom. An exploratory investigation into these questions involved eight talkers saying similar, simultaneous messages. Four male and four female talkers speaking call sign phrases and logical phrases were digitally recorded. All phrases were adjusted in overall gain to have the same average power and onset time. Between one and seven competing messages were played back over loudspeakers in an anechoic chamber. Thereby, angular separation between the speech signal and speech babble was also a controlled factor. Physical attributes of the eight talkers' speech were analyzed using the Multi-Dimensional Voice Program from Kay Elemetrics. Nineteen acoustic attributes of the talkers' voice samples were quantified. Voice samples were analyzed during sustained phonation and continuous speech conditions. A correlational analysis was used to investigate which aspects of the talkers' speech facilitate detection and intelligibility against a cacophony of competing voices. The salient features of the eight talkers' voice samples will be discussed.

1aSC2. The enhancing effect of subsequent context in the perception of the sentence-initial word. Takayuki Kawashima (Dept. of Psych., Div. of Humanities and Sociology, Univ. of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, 113 Japan), Makio Kashino (NTT Basic Res. Labs, 3-1 Morinosato Wakamiya, Atsugi, Kanagawa, 243-01 Japan), and Takao Sato (Univ. of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, 113 Japan)

The authors examined whether the perception of the initial word in a Japanese sentence is enhanced by semantically related subsequent context. Phonemic restoration effects under periodic noise replacement were compared for two types of sentences. In the first condition, the initial word of a sentence was semantically predictable from the subsequent context (high-predictability condition). In the second condition, the initial word was not directly predictable from the subsequent context (low-predictability condition). The intelligibility of the sentence-initial words was higher in the high-predictability condition than in the low-predictability condition (58% vs 10%). On the other hand, the intelligibility of the subsequent portions was not significantly different between the two conditions (71.1% vs 66.3%). These results show that word perception can be enhanced by subsequent semantic context in Japanese.

1aSC3. Effects of context-sensitive phonetic variation and lexical structure on the uniqueness of words. Edward T. Auer, Jr. and Lynne E. Bernstein (Spoken Lang. Processes Lab., House Ear Inst., 2100 West Third St., Los Angeles, CA 90057)

Relatively little is known about the optical phonetic speech characteristics to which speechreaders are attuned. However, it is known that phonetic context does affect visual confusability of phonemes. In study 1, behavioral experiments were performed to examine effects of context-sensitive phonetic variation on the visual confusability of consonants and vowels. Hearing and deaf participants identified consonants or vowels presented in carefully constructed sets of nonsense syllables. Vowels were presented in four different consonant–vowel–consonant environments. Consonants and frequently occurring consonant clusters were presented in 14 different disyllabic nonsense words environments. These disyllabic environments varied target consonant position (initial, medial, and final) and target consonant adjacent vowel. Vowel identification was relatively accurate and insensitive to surrounding consonantal context. Consonant identification significantly varied as a function of both position and vowel context. In study 2, computational experiments were performed to assess the importance of patterns of context-sensitive visual confusability on the uniqueness of words in the language. The computational experiments in study 2 provide evidence that choice of a segmental intelligibility model does matter for modeling the uniqueness of words. However, the distribution of words in English substantially preserves lexical uniqueness even when phonetic variability is taken into account. [Work supported by NIH/NIDCD Grant No. DC02107.]

1aSC4. Amplitude modulation cues for perceptual voicing distinctions in noise. Brian P. Strope and Abeer Alwan (Dept. of Elec. Eng., UCLA, 66-147E Eng. IV, 405 Hilgard Ave., Los Angeles, CA 90095)

Fricatives are produced by forming a sufficiently narrow constriction in the vocal tract to generate a turbulent noiselike source. With voiced fricatives, vibrating vocal folds introduce low-frequency energy at the first few harmonics of the fundamental frequency. Measurements using the relative level of the first harmonic have been shown to be good indicators for voiced/unvoiced fricative distinctions [e.g., Pirello *et al.*, J. Acoust. Soc. Am. **101**, 3754–3765 (1997)]. In the current study, fricatives [s z] with the vowels [i a u] were recorded as CV syllables from four talkers. Perceptual thresholds for syllable detection and voicing distinction were measured in noise. Subjects were able to make reliable voicing distinctions at low SNRs after the fricatives were manually isolated from the vowels and spectral components below 3 kHz were removed. Temporal analyses indicate that during voiced fricatives the vibrating vocal folds can modulate the pressure source behind the constriction sufficiently to generate an acoustic pitch-rate amplitude-modulation cue in high-frequency regions. Predictions of the perceptual experiment's thresholds are evalu-

ated for psychoacoustic models of amplitude-modulation detection which use the standard deviation of the temporal envelope, modulation filter banks, and summary autocorrelograms. [Work supported by NIDCD Grant No. DC02033 and NSF.]

1aSC5. Effects of context on time-compressed speech intelligibility in older adults. Nancy Vaughan and Ronda Kasper (Washington State Univ., 601 W. First Ave., Spokane, WA 99201-0399)

The purpose of this study was to assess the effects of context on sentence intelligibility at high compression rates in older adults. A group of older participants listened to time-compressed low-predictability sentences from the SPIN-R test and high-context sentences from the Connected Speech Test (CST). Many studies have shown that speech intelligibility declines significantly at a 60% compression rate especially for older adults. An algorithm called the Synchronized Overlap Add (SOLA) has been shown to produce intelligibility scores above 80% on the CST for adults aged 65–75 years at 60% compression. This method uses an autocorrelation function to combine common elements in overlapping sequential frames of the speech signal, producing highly intelligible speech at high rates of compression. An apparently similar algorithm used in another study of older adults produced intelligibility scores around 50% for the low-predictability sentences of the SPIN-R test at a 60% compression rate. The question of whether the varying results of time-compressed speech intelligibility was due to differences in algorithms or to differences in context of the speech materials remains unanswered. The results of the current study are discussed in terms of speaker gender, context, and methods of time-compression.

1aSC6. Dichotic presentation of speech signal using a critical filter bank for bilateral sensorineural hearing impairment. D. S. Chaudhari and P. C. Pandey (Indian Inst. of Technol., Bombay, India)

Sensorineural hearing-impaired listeners face a particular problem in view of a decrease in the frequency resolving capacity of an ear due to the spread of masking of frequency components by adjacent frequency components. Filtering a speech signal by a bank of critical band filters and adding signals from alternate bands for presenting to the two ears is likely to reduce the effect of the spread of masking along the cochlear partition, and thus may help in improving the speech intelligibility. This processing scheme has been implemented with 18 critical bands for experimental evaluation through listening tests. The scheme was found to be helpful in improving recognition scores and transmission of speech features in listening tests with normal hearing subjects with simulated sensorineural hearing loss. Listening tests were carried out using 12 vowel–consonants–vowel and consonant–vowel nonsense syllables presented in quiet (no masking noise), on ten subjects with mild to very severe sensorineural hearing loss. The stimulus response confusion matrices were analyzed using relative improvement in recognition scores and information transmission analysis. The relative improvement in recognition scores is up to 25%. Information transmission analysis indicated that the overall improvement is contributed to by improvements in transmission of the speech feature of voicing, place, and manner. The mean response time has also been found to decrease significantly.

1aSC7. A new method of sequential information analysis for consonant perception. Chin Tuan Tan, Yit Chow Tong, and Joseph S. Chang (School of Elec. & Electron. Eng., Nanyang Technolog. Univ., Singapore)

A new method of information analysis which considers all entries in the confusion matrix is proposed for identifying important articulatory features for consonant perception. For a system of N features, the important features are selected sequentially in a series of iterations. In the first iteration, the feature whose transmitted information is maximum is selected. In the second iteration, the first feature is combined with each of the remaining $N-1$ features to form $N-1$ sets of two joint features. The second feature is selected by choosing the set of joint features which has the maximum transmitted information. The transmitted information for a set is determined by summing its unconditional transmitted information and a correction factor to account for redundancy. The third and subsequent important feature are selected in the same manner. The selection process terminates when the transmitted information for the selected set of joint features in the last iteration is equal to the maximum possible transmitted information for the confusion matrix. The proposed method of analysis was tested with several confusion matrices published in past research papers, and the results showed that it was able to select a common set of important features consistently across the confusion matrices.

1aSC8. Aural method of speech intelligibility enhancement. Wojciech J. Majewski (Inst. of Telecommunications and Acoust., Wroclaw Univ. of Technol., Wybrzeze Wyspianskiego 27, 50-370 Wroclaw, Poland, majewski@aipsa.ita.pwr.wroc.pl)

Among a variety of speech enhancement techniques, one subjective technique, called the Hollien binaural filtered (HBF) approach [Hollien, *The Acoustics of Crime* (Plenum, New York, 1990)], was proposed. It utilizes a special binaural hearing technique: The modified (usually filtered) speech signal is fed to the listener's dominant ear at a relatively high level and a low-energy unprocessed speech signal is simultaneously sent to the contralateral ear. Unfortunately, there were no investigations related to the effectiveness of this technique of speech enhancement. In the present paper the results of the experiments performed in order to quantitatively evaluate this method are presented. The speech material consisted of nonsense word lists. For each measuring condition, one list containing 100 nonsense words was presented to five experienced listeners. Due to possible applications of the HBF technique in forensic phonetics, poor quality recordings were examined. The major difficulty in the experiments as to obtain the improvement of speech intelligibility by means of conventional speech enhancement techniques. When, however, such technique yielded an increase in speech intelligibility score (the largest increase was 5%), then the HBF technique provided further speech enhancement, the largest increase was 8% and 12%, respectively, in relation to modified and unprocessed speech.

1aSC9. A training system to improve the usefulness of hearing aids. Takashi Ikeda (Kurume Natl. College of Technol., 1232, Komorino-machi, Kurume, 830 Japan), Akira Watanabe, Mitsuaki Hino, and Yuichi Ueda (Faculty of Eng., Kumamoto Univ., 2-39-1, Kurokami, Kumamoto, 860 Japan)

An audiovisual system was proposed previously. It can make the hearing-impaired notice phonemic cues by using vision together with hearing. In the preliminary experiments by a hearing impaired person with a prototype hearing aid, it was noted that the information of visualized speech could contribute to combine sound images and their understanding as phonemes. First, to generalize this method, a new type of training system that consists of a personal computer, audio equipment, training programs and data is presented. The system provides output sounds of hearing aid and visualized speech together automatically. Next, the results of experiments, which are conducted with the groups of hearing-impaired persons by sound of the single resonant analysis type hearing aid, are presented. The contribution of visual information in the training will be examined. Finally, it will be discussed that the design to realize a practical single resonant analysis type hearing aid is small enough to use in the field test.

1aSC10. Voice transmission through vibration pickups. Paolo E. Giua (CNR Istituto di Acustica, via Cassia 1216, Roma, Italy, I-00189)

Devices that pick up vibrations induced in the body by the speaker voice have been used in speech communication for many years in order to enhance intelligibility in noisy environments. This and other interesting applications seem to justify a study of this ''accelerometric'' speech in order to obtain useful correlations with the ''microphonic'' speech. Many factors seem to influence the voice spectrum of the accelerometric speech. A constant general factor is the low-pass filter effect of the acoustical bone conduction. But the main one seems to be the coupling of the voice to the bony transmission channel. This coupling is phoneme dependent. For instance, voiced stop consonants are more amplified than voiced fricatives, while vowels are modified according to their qualities. Moreover speaker features and accelerometer features are to be taken into account. The present results refer to an accelerometer inserted in the ear canal. Main features of this type of accelerometric speech are shown and intelligibility measurements as a function of speakers and their vocal effort are reported. An attempt to recover microphonic speech corrupted by noise by means of a simultaneous accelerometric speech is described.

1aSC11. Enhancing second formant identification in speech by listeners with significant hearing loss. Peggy B. Nelson and Sally G. Revoile (Univ. of Maryland School of Medicine, 16 S. Eutaw St., Ste. 500 Baltimore, MD 21201)

Listeners with significant hearing loss have consonant recognition abilities that appear limited by their inability to use spectral peak information in the higher frequencies, specifically in the highly informative second formant ($F2$) frequency region. For them, ensuring the audibility of speech may not result in full recognition of consonants and vowels that differ by $F2$ characteristics. In the current study, listeners with moderate to severe hearing loss identified naturally spoken consonant-vowel-consonant stimuli (CVCs) with a wide range of $F2/F1$ formant frequency characteristics at levels that ensured the audibility of the $F2$ region. CVCs were presented in three conditions: (a) unmodified, (b) filtered to enhance the $F1$ and $F2$ regions, and (c) frequency-modulated to transpose the $F2$ peak to a lower, more detectable frequency region. The amount of modulation for condition (c) was determined by measuring individual spectral peak detection thresholds for each listener using the rippled-noise method described by Summers and Leek (1994). Closed-set identification of the CVC stimuli was measured and consonant confusion matrices generated. The amount of improvement due to enhancing the spectral contrast and to transposing the $F2$ region will be reported. Correlations between listeners characteristics and enhancement due to contrast sharpening and/or $F2$ transposition will be reported. [Research supported by NIDCD K08-000124 and by the University of Maryland School of Medicine.]

1aSC12. Subjective versus objective intelligibility of sentences in listeners with hearing loss. Kathleen M. Cienkowski, Charles Speaks, and Amy S. McKee (Dept. of Commun. Disord., Univ. of Minnesota, 115 Shevlin Hall, Minneapolis, MN 55455)

The relation between estimated intelligibility and correct key-word repetitions of sentences was examined in listeners with normal hearing and hearing loss. The ten lists of CID sentences [S. R. Silverman and I. J. Hirsh, Ann. Otol. Rhinol. Laryngol. **64**, 1234–1245 (1995)] were arranged in two randomly ordered groups. Listeners were asked to complete two tasks: (1) rate the intelligibility of 50 sentences on a scale of 0% to 100%, (2) repeat each of the 50 sentences, which were scored as the number of key words repeated correctly. Sentences were presented at five signal-to-noise ratios, +6, +4, +2, 0, and −2 dB. The 0 dB S/N point was established by the method of adjustment using the revised speech intelligibility rating passages to reach a criterion of 50% intelligibility. Correlations of rated intelligibility and correct repetition of key words were 0.85 for listeners with normal hearing and 0.87 for listeners with hearing loss. These findings confirm earlier work [Speaks *et al.*, J. Speech Hear. Res. **15**, 590–602 (1972)] with listeners with normal hearing and demonstrate that listeners with hearing loss preserve the ability to rate intelligibility of speech.

1aSC13. Effects of stimulation mode on speech recognition by cochlear implant users. Qian-Jie Fu and Robert V. Shannon (Dept. of Auditory Implants and Percept., House Ear Inst., 2100 West 3rd St., Los Angeles, CA 90057)

This study investigated the effects of both mode of stimulation and frequency allocation on speech recognition in three subjects implanted with Nucleus-22 multichannel cochlear implant. A four-channel processor with continuous interleaved sampling speech processing strategy was implemented through a custom interface. The temporal envelopes from four broadbands were used to modulate 500 pps, 100 ms/phase pulse trains and then delivered to four electrodes 16, 11, 6, 1 with three stimulation modes: BP+1, BP+3, BP+5. Ten different frequency allocations were used and each frequency allocation mapped different insertion depths of these four electrodes based on Greenwood's place-to-frequency function. Results showed that the recognition score was highly dependent on the frequency allocation in all stimulation modes, indicating that it may be indispensable to match the frequency allocation to the tonotopic location of activated electrodes. Results also showed that a speech processor with BP+5 stimulation mode was more robust to the mismatching between the frequency allocation and tonotopic location of electrodes, indicating that a speech processor with more broad stimulation, such as a monopolar stimulation mode, may be advantageous for most cochlear implant users, especially for those who have either shallower insertion depth or uneven nerve survival patterns. [Work supported by NIDCD.]

1aSC14. Continuous assessment and modeling of speech transmission quality. Martin Hansen and Birger Kollmeier (AG Medizinische Physik, Universität Oldenburg, D-26111 Oldenburg, Germany, martin@medi.physik.uni-oldenburg.de)

This paper addresses the question of whether subjects are able to assess the perceived time-varying quality of speech material continuously. A method inspired by Hamberg and de Ridder [J. Opt. Soc. Am. A **12**, 2573–2577 (1995)] is presented by which subjects continuously rate the perceived speech quality by moving a slider along a graphical scale. In this way, temporal variations in quality can be monitored quantitatively and differences between, for example, alternative speech transmission systems, can be analyzed in an informative way. The usability of this method is illustrated with an experiment in which different sequences of sentences with a total duration of 40 s were degraded in quality with a modulated noise reference unit. The modulation depth was varied with time and the subjects task was to assess the perceived quality. The results show that subjects can monitor speech quality variations closely with a delay of approximately 1 s. The subjective results are discussed in view of a psychoacoustically motivated objective speech quality measure [Hansen and Kollmeier, ICASSP '97, 1387–1390 (1997)].

1aSC15. Coherence-based sub-band decomposition for efficient reverberation and noise removal in enclosed sound fields. Joaquin Gonzalez-Rodriguez and Javier Ortega-Garcia (Dept. of Audiovisual and Commun. Eng., E.U.I.T. Telecomunicacion, Univ. Politecnica de Madrid, Spain, jgonzalz@diac.upm.es)

The issue of speech enhancement in reverberant rooms has been extensively addressed. The use of sub-band decomposition through nested linear arrays has been shown to be very efficient for this task. Recently, the coherence/noncoherence nature of the sound field has been used to separate the wideband speech signal in two sub-bands, obtained from the sinc function that characterizes the diffuse field prediction for a given separation between microphones when many independent sources are present and the reverberation time is not too short. The processing scheme

proposed here takes advantage of both ideas. After a sub-band decomposition from a linear log-spaced 15 microphone array, a further subdivision is made in each processing band, dividing in a coherent sub-band, where a Generalized–Sidelobe–Canceller is applied, and a noncoherent sub-band, where a Wiener postfilter is used, resulting in a total of six analysis subbands. Promising results have being obtained with room simulations (image method), and further results are being obtained with the Carnegie Mellon University (CMU) multichannel-recorded database. The authors thank Dr. Finn Jacobsen (Technical Univ. Denmark) for his fruitful discussions about spatial coherence, and Dr. Richard Stern (CMU, PA, USA) for the multichannel database. [Work supported by CICYT under Project TIC97-1001-C02-01.]

1aSC16. Continuous digit speech recognition using subword unit HMM juncture. Jeh-Seon Youn and Kwang-Seok Hong (Dept. of Electron., Sung Kyun Kwan Univ., Chun-Chun Dong 300, Chang-An Gu, Kyung-Gi Do, Suwon 440-746, Korea)

In this paper, a new recognition system is described for digit strings of various length in Korean under fluent speech conditions using subword HMM juncture. A robust automatic recognition system for connected digit strings under spontaneous speech conditions is crucial for a number of applications such as voice dialing and credit card or personal identification numbers. It is thought that the recognition of connected digits is a relatively easy task, but the output of the recognizer must be a very exact transcription of the input speech. The process of recognition is to construct the database of digit string models by concatenating subword clusters not trained on target application through the typing task, avoiding the recording of training data each time the digit changes. Thus, the acoustic segments divide into N subword clusters, and each subword cluster generates the HMM model. The goal is to give users a flexible number recognition that can add new connected digits without collecting a new corpus or training new models, namely that can be easily modified for different applications with minimum amount of training and modification effort.

1aSC17. Stochastic word models for articulatorily constrained speech recognition and synthesis. John Hogden, David Nix (Los Alamos Natl. Lab., Los Alamos, NM 87545), Vincent Gracco, and Philip Rubin (Haskins Labs., New Haven, CT 06511)

Stochastic word models based on hidden Markov modeling (HMM) techniques are commonly used for speech recognition and are increasingly being used for speech synthesis. An alternate technique for generating stochastic word models using Maximum Likelihood Continuity Mapping (MALCOM) will be presented. MALCOM generates a stochastic model of speech assuming (1) that speech sounds are periodically emitted as a point moves smoothly through a low-dimensional space called a continuity map (CM), and (2) that the sound emitted at time t is a probabilistic function of the position of the point at time t. The assumptions underlying MALCOM are intended to mimic speech production in that (1) speech sounds are produced as the articulators move slowly through a low-dimensional articulator space, and (2) the speech sound produced at time t is a function of the articulator positions at time t. A method for finding CM trajectories (analogous to articulator trajectories) corresponding to a known sequence of phonemes will be shown, and how to use these trajectories as word models for speech recognition and synthesis will be shown. A preliminary test of the theory will be presented in which articulator trajectories estimate given phoneme sequences and phoneme temporal positions are compared to measured articulator trajectories.

1aSC18. Elliptical wave radiation from a curved waveguide. Rolphe F. Fehlmann (Swiss Software Eng. College, Morgartenstr. 2, CH-3012 Berne, Switzerland)

This paper deals with the investigation of the wave radiation properties of the resonance modes in 3-D curved waveguides. With the finite element method (FEM), a curved waveguide has been modeled and the computer simulations have shown that the wave radiation changes from circular waves in two dimensions to spherical waves in three dimensions, respectively, to beam formation. Interestingly enough, however, for some certain modes there exist elliptical and ellipsoidal waves, respectively. A visualization of these waves emanating from such nonaxisymmetric waveguide geometries is presented as pressure fields as well as phase fronts. This so far unknown elliptical field radiation is a phenomenon which future acousticians of the 21st century will have to cope with.

1aSC19. An efficient Korean speech recognition for name and digit on a communication network. Hyeon-Gu Lee and Kwang-Seok Hong (Dept. of Electron., Sung Kyun Kwan Univ., Chun-Chun Dong 300, Chang-An Gu, Kyung-Gi Do, Suwon 440-746, Korea)

The necessity of service using speech recognition goes on increasing day by day, but for the difficulty of speech recognition, the efficient application service is not activated yet. For the security of users and the convenient use of a disabled person, a desire for using speech about the user's name, ID number, or an account which is mainly used in service is increasing accordingly as the information and banking service on communication network increases. This paper presents the efficient Korean speech recognition method for name and digit string on a communication network. Because most of the traditional methods recognize the full name at once, there are some problems, in that they must have all patterns of the name or require very accurate segmentation of the phoneme, etc. So the unit of Korean spelling pronunciation that is contained in the name is recognized, and then a connection is made to the full name recognition. In the recognition of the digit, semisyllable and the combination of a connected semisyllable are used. That is, 20 semisyllables from 0 to 9 are used as the pattern of the start semisyllable or the end semisyllable of the digit string in recognition, and 100 connected semisyllables from 00 to 99 are used as the pattern of the connection part of each digit string. In comparison with the existing method, all names and digits, regardless of their kind and figure can be recognized.

1aSC20. A multilevel training procedure for speech recognition in noise. Chin Tuan Tan, Yit Chow Tong, Joseph S. Chang (School of Elec. & Electron. Eng., Nanyang Technolog. Univ., Singapore), and Lai Peng Chan (Audiological Services Clinic, Singapore)

A multilevel training procedure is proposed for automatic speech recognition in noise. In the multilevel training procedure, six levels of Gaussian noise, corresponding to six signal-to-noise ratios (SNR), were added to the training samples. The procedure was tested in three speech recognizers implemented, respectively, on the basis of the following three speech recognition techniques: dynamic time warping (DTW), discrete hidden Markov modeling (DHMM), and neural network (NN). The tests on the three recognizers were conducted using a common database for isolated word recognition of the ten digits. The results of the first series of the tests showed that when the recognizers were trained using clean training samples without noise and tested with noisy test samples with additive Gaussian noise, the performance of the three recognizers degraded significantly as the SNR decreased. In the second series of tests, the multilevel training procedure was applied. The results showed that, when the recognizers were trained with noisy training samples and tested with noisy test samples, the three recognizers were, in contrast to the first series, much better able to maintain their performance as the SNR decreased. The multilevel procedure is therefore effective in improving the performance of recognizers for automatic recognition in noise.

1aSC21. An implementation of the recognition system for Windows 95 commander. Seong-Kwon Lee and Soon-Hyob Kim (Dept. of Comput. Eng., Kwangwoon Univ., Wolgy-dong, Nowon-gu, Seoul, Korea)

This paper is a study on the window commander recognition system. The applied recognition algorithm is a one-stage/DP with DMS(dynamic multisection) model which generates a reference pattern and recognizes 60 commanders in Windows 95. From the results of experiments, the optimal recognition considering a tradeoff of real time is obtained by applying a DMS model with 20 section and 13 order PLP coefficients for feature parameter. The whole system is constructed by a soundblast card within an IBM-PC/586. After the commander is recognized, the commander is processed automatically. The references are made by five male speakers in a noisy laboratory environment. The recognition experiment is performed for 60 different commanders and the recognition rate was 96.2% in multispeaker independent.

1aSC22. Fractal modeling of a glottal waveform for high-quality speech synthesis. Naofumi Aoki and Tohru Ifukube (Res. Inst. for Electron. Sci., Hokkaido Univ., Sapporo, Japan, aoki@sense.hokudai.ac.jp)

From several psychoacoustic experiments, it is well known that the oversimplified glottal waveform degrades the quality of synthesized speech. For the enhancement of the quality of synthesized speech, it is desired to generate a glottal waveform in detail using an appropriate model which requires a few control parameters. In this study it is supposed that the differential glottal waveform, which is estimated by linear prediction filter, is modeled as a random fractal signal. The differential glottal waveform is regarded as the first integral of white noise whose frequency characteristic is approximated as -6 dB/oct. This signal can be interpreted as Brownian motion in terms of fractal theory. In order to generate random fractal signal, a kind of wavelet synthesis method called the midpoint displacement method is employed. Psychoacoustic experiments were conducted to examine whether or not the proposed method is effective. Experimental results indicate that the quality of original speech is fully preserved even if more than 90% of wavelet coefficients are replaced with a random fractal signal generated by the proposed method. The wavelet coefficients that cannot be replaced are to be the control parameters in this model.

1aSC23. Interactive Korean speech recognition for a mobile robot. Jae-Young Lee, Seok-Hyun Yoon, Kwang-Woo Chung, and Kwang-Seok Hong (Dept. of Electron., Sung Kyun Kwan Univ., Chun-Chun Dong 300, Chang-An Gu, Kyung-Gi Do, Suwon 440-746, Korea, kshong@yurim.skku.ac.kr)

This paper is a study on the implementation of a speech recognition mobile robot to which the interactive Korean speech recognition techniques are applied. The speech command uttered the sentential connected word and is asserted through the wireless mic system. This speech signal transferred LPC-Cepstrum and short-time energy which are computed from the received signal on the DSP board to a notebook PC. In the notebook PC, the DP matching technique is used for the recognizer and the recognition results are transferred to the motor control unit which outputs pulse signals corresponding to the recognized command and drives the stepping motor. It has been implicitly assumed that, for connected word recognition, each word in the string can be followed by any other word in the string. However, for some connected word recognition tasks, there is an explicit set of rules governing which words can logically follow other words to form valid sentences in the language. In this paper, a grammar network was applied to reduce the recognition speed of the recognizer, so that real time recognition is realized. The misrecognized command is revised by interface revision through conversation with the mobile robot. The recognition system asks the user for help whenever there are two or more recognition candidates whose likelihood scores are all high and it is difficult to resolve small differences in the string. The recognizer asks the user to verify the first choice decision; if it is not verified, the recognizer asks the user to verify the second choice, etc. Alternatively, the recognition system can list the confusing candidates and ask the user to choose the correct string based on the string index number in the list.

1aSC24. Synthesis of fricative sounds using an aeroacoustic noise generation model. Daniel J. Sinder, Michael H. Krane, and James L. Flanagan (CAIP Ctr., Rutgers Univ., Piscataway, NJ 08855)

Results from speech synthesis with an aeroacoustic fricative source model are presented. The source model, which is implemented in the time domain, is based on Howe's reformulation of the acoustic analogy [Howe, J. Fluid Mech. **71**, 625–673 (1975)]. It specifies the source as a function of flow conditions and the geometry of the vocal tract downstream from a constriction where a turbulent jet is formed. This is accomplished by combining elements of aeroacoustic theory and a model for jet behavior with a traditional model for wave propagation in the vocal tract. Using this formulation, the source strength, impedance, and spectrum can be determined through post-processing. The fricative model is implemented in an articulatory speech synthesizer. Evaluation of the resulting synthesis is emphasized. Comparisons are made with physical experiments in static configurations. Additionally, speech fricatives are compared with natural speech as well as synthetic speech from other models. These comparisons are made in the frequency domain and through listening tests in which fricatives in V-C-V sequences are judged for naturalness and intelligibility. [Research supported by NSF/ARPA IRI-9314946 and ARPA DAST 63-93-C-0064.]

1aSC25. Glottal source parameter estimation by comparison of measured signals with simulated signals. David G. Druker (Dept. of Speech Pathol. and Audiol., Univ. of Iowa, 361 East Sherman Ave., Salt Lake City, UT 84115, david.druker@hsc.utah.edu), Ingo R. Titze (Univ. of Iowa, Iowa City, IA 52242), and Brad H. Story (Wilbur James Gould Voice Res. Ctr., Denver, CO 80204)

Oral flow, electroglottographic (EGG), and photoglottographic (PGG) signals were simultaneously digitized from a single subject phonating sustained vowels. Analogous simulated signals—oral flow, vocal fold contact area, and glottal area, respectively—were produced by a driven, kinematic glottal source model coupled to a wave-reflection-type vocal tract. The vocal tract area function used in the simulation was estimated from magnetic resonance imaging (MRI) data previously published for the subject. This essentially removed the vocal tract as a confounding factor in the analysis. The measured and simulated signals were compared and an attempt was made to adjust model parameters so that the least-squared differences between the signals were minimized. The model parameters, which included subglottal pressure, vocal fold adduction, vocal fold convergence, and fundamental frequency were observed to be estimates for the glottal configuration and control parameters used by the subject.

1aSC26. SGP analysis of excised larynges in anechoic chamber. Paul F. Castellanos, Sang Hung, Craig Skinner (Div. of Otolaryngol., Head and Neck Surgery, Univ. of Maryland School of Medicine, Baltimore, MD 21201), and Samuel A. Elder (Dept. of Phys., U.S. Naval Acad., Annapolis, MD 21402)

Single glottic pulse analysis will be presented of experimental data obtained on excised larynges in an anechoic chamber. Attention is directed to understanding the nature of the acoustic source, and comparison will be made with data taken from live subjects. *In vivo* measurements include those taken in the chamber as well as those recorded by Sondhi tube.

1aSC27. Perceptual effects of spectral envelope and *F*0 manipulations using the STRAIGHT method. Hideki Kawahara (ATR HIP Labs., Wakayama Univ., Wakayama, 640 Japan, kawahara@hip.atr.co.jp) and Reiko Akahane-Yamada (ATR HIP Labs., Kyoto, 619-02 Japan)

A versatile speech manipulation method, STRAIGHT (Speech Transformation and Representation using Adaptive Interpolation of weiGHTed spectrogram) [Kawahara, ICASSP (1997)], was applied to natural speech in order to test the effects of speech parameter manipulations. STRAIGHT consists of three procedures called STRAIGHT-core, TEMPO (Temporal domain Excitation extraction using a Minimum Perturbation Operator) and SPIKES (Synthetic Phase Impulse for Keeping Equivalent Sound). STRAIGHT-core is a method to extract a smoothed time-frequency representation, which is free from interferences due to the source periodicity. TEMPO is used to extract *F*0 and other source-related information. SPIKES provides artificial ''naturalness'' to the synthetic speech. As a base line, resynthesized speech, using the STRAIGHT method, was found to provide equivalent ''naturalness'' compared to the original speech when no parametric modification was introduced. Simultaneous manipulation of the spectral envelope and *F*0 illustrated that stretching the frequency axis of the spectral envelope, using the quantity of the cubic root of *F*0 stretching, preserved ''naturalness'' the best. Perceptual effects of group delay used in the SPIKES procedure were also investigated. [Work supported by CREST (Core Research for Evolutional Science and Technology) of Japan Science and Technology Corporation (JST).]

1aSC28. Modeling and synthesis of the lateral consonant /l/. Adrienne M. Prahler (Res. Lab. of Electron. and Dept. of EECS, MIT, 50 Vassar St., Cambridge, MA 02139, aprahler@mit.edu)

The lateral consonant in English is generally produced with a backed tongue body, a midline closure of the tongue blade at the alveolar ridge, and a path around one or both of the lateral edges of the tongue blade. In prevocalic lateral consonants, the release of the closure causes a discontinuity in the spectral characteristics of the sound. Past attempts to synthesize syllable-initial lateral consonants using formant changes alone to represent the discontinuity have not been entirely satisfactory. Data from prior research has shown rapid changes in not only the formant frequencies but also in the glottal source amplitude and spectrum and in the amplitudes of the formant peaks at the consonant release. Further measurements have been made on additional utterances, guided by models of lateral production. Based on these data, new synthesis attempts have incorporated changes in source amplitudes, formant bandwidths, and the location of a pole-zero pair. Including these additional parameters improves the naturalness of the synthesized lateral-vowel syllables in initial perception tests. Results of listening tests indicating the relative importance of the various factors to the naturalness of the synthesized syllables will be reported. [Work supported in part by a LeBel Fellowship and by NIH Grant No. DC00075.]

1aSC29. End corrections in an acoustic model of the vocal tract. J. Dang (ATR HIP, 2-2 Hikaridai Seikacho Soraku-gun, Kyoto, 619-02 Japan)

Open end corrections are required in an acoustic model to compensate for the effects caused by abrupt area changes in the vocal tract, such as the open ends of the side branches and the opening between the teeth. The end corrections were studied by means of a number of mechanical models which imitated vocal tract geometries. The results showed that the end correction greatly depends on the local geometries in the vicinity of the open ends. On the basis of these measurements, two empirical formulas have been proposed to account for the acoustic effects of the geometries [Dang *et al.*, TR-H-219 (1997)]. In this study, these formulas were applied to morphological data of the vocal tract. The range of the open end correction coefficient (OECC) for estimating an accurate vocal tract transfer function was evaluated. The OECC of the nasopharyngeal port was found to be about 0.8 for the oral tract side and 0.3–0.6 for the nasal tract side. For the ostia of the paranasal cavities, the value was about 0.8 for the cavity side and 0.28 for the nasal tract side. An OECC of about 0.4 was sufficient to compensate for end radiation of the laryngeal tube outlet for front vowels.

1aSC30. Modeling the transitory behavior of speech using a time-varying transmission line. Amit S. Rane, Derrick C. Wei, Lisa E. Falkson, and Abeer A. Alwan (Speech Processing and Auditory Percept. Lab., Dept. of Elec. Eng., UCLA, 66-147E Eng. IV, 405 Hilgard Ave., Los Angeles, CA 90095, alwan@icsl.ucla.edu)

In this study, a transmission-line model of speech production [Rael *et al.*, J. Acoust. Soc. Am. **97**, S1(5) (1995)] is modified so that changes in the vocal-tract (VT) area functions, reflecting changes in the VT shape from one sound to another, are properly modeled. Each VT shape is divided into uniform cylindrical sections and each section is modeled by its equivalent transmission line comprising resistors (R), capacitors (C), and inductors (L). A radiation impedance terminates the transmission-line sections. For voiced sounds, the KLSYN88 glottal waveform [D. H. Klatt and L. C. Klatt, J. Acoust. Soc. Am. **87**, 820–857 (1990)] is used as input. The model is simulated in time and frequency by using the analog-circuit simulator HSPICE. To simulate the transitory characteristics of speech, different interpolations such as linear, cubic, and Fourier transform are used for area transitions. The interpolated values result in a ''sampled'' area function and the RLC elements of each section are varied according to these time-sampled values. These variations are accomplished by utilizing time-varying independent voltage sources. Examples using American English dipthongs will be presented. Formant frequencies (both steady state and transitions) of the synthesized and natural dipthongs are in close agreement. [Work supported by NSF Award IRI-95-03089.]

1aSC31. Pitch-synchronous decomposition of mixed-source speech signals. Philip J. B. Jackson and Christine H. Shadle (Dept. Electron. and Comput. Sci., Univ. of Southampton, Southampton SO17 1BJ, UK)

As part of a study of turbulence-noise sources in speech production, a method has been developed for decomposing an acoustic signal into harmonic (voiced) and anharmonic (unvoiced) components, based on a hoarseness metric [Muta *et al.*, J. Acoust. Soc. Am. **84**, 1292–1301 (1988)]. Their pitch-synchronous harmonic filter (PSHF) has been extended (to EPSHF) to yield time histories of both harmonic and anharmonic components. These corpus include many examples of turbulence noise, including aspiration, voiced and unvoiced fricatives, and a variety of voice qualities (e.g., breathy, whispered). The EPSHF algorithm plausibly decomposed breathy vowels, but the harmonic component of voiced fricatives still contained significant noise, similar in shape to (though weaker than) the ensemble-averaged anharmonic spectrum. In general, the algorithm performed best on sustained sounds. Tracking errors at rapid transitions due to jitter and shimmer were spuriously attributed to the anharmonic component. However, the extracted anharmonic component clearly exhibited modulation in voiced fricatives. While such modulation has been previously reported (and also in hoarse voice), it was verified by tests on synthetic signals, where constant and modulated noise signals were extracted successfully. The results suggest that the EPSHF will continue to enable exploration of the interaction of phonation and turbulence noise.

1aSC32. Automatic creation of CV templates for formant type speech synthesis based on HMM-based segmentation and syllable boundary detection. Takahiro Ohtsuka, Chang-Sheng Yang, and Hideki Kasuya (Faculty of Eng., Utsunomiya Univ., Utsunomiya, 321 Japan)

A formant type speech synthesis method has an enormous advantage in that it allows one to generate speech with various voice quality variations and talker individualities. But it has suffered from unnatural speech quality, not because of theoretical limitations but because of an incomplete set of rules for the synthesis. Any insufficient approximation to the acous-

tics causes degradation of the perceived quality of synthetic speech. A novel formant type speech synthesizer in Japanese based on concatenation of CV (consonant-vowel) formant-source templates obtained from natural utterances has been investigated, in which multiple sets of formant and voice source parameter values are used for each of the CV syllables. This paper describes an automatic method to create the CV formant-source templates from speech corpus. The ARX (autoregressive with exogenous input) analysis method is first used to automatically extract formant and voice source parameters and then an HMM based segmentation is performed to locate the CV segments. The segments are further analyzed to detect a starting point of the syllable. A distance measure is used to decide the number of templates needed for each of the syllables. The method is proved to be useful in creating CV templates by experiments performed on 503 Japanese sentences.

1aSC33. A study on natural-sounding Japanese phonetic word synthesis based on the pitch waveform concatenation. Yasuhiko Arai, Ryo Mochizuki (AVC Development Lab., CED, Matsushita Commun. Ind. Co., Ltd., 600 Saedo-cho, Tsuzuki-ku, Yokohama, 224 Japan, arai@adl.mci.mei.co.jp), and Takashi Honda (Meiji Univ., Kawasaki, 214 Japan)

A speech output system in which messages are composed by embedding some phonetic words in the prerecorded sentence patterns requires very natural-sounding phonetic words to be embedded. Especially in the case where a very large or an unlimited vocabulary is required, synthesis of very natural-sounding phonetic words would be desired. Therefore, a novel Japanese VCV-concatenation synthesis method based on the pitch waveform concatenation has been studied. The VCV waveforms are extracted from the VCV-balanced spoken word database and pitch waveforms are extracted by means of the excitation synchronous pitch waveform extraction method [Y. Arai *et al.*, ICSLP **96**, 1437–1440 (1996)]. The wavelength of each pitch waveform is modified depending on the pitch modification rate, and the global pitch contour of each VCV waveform is modified along with the target pitch pattern, while the microprosody and the small perturbation in pitch frequency inherent in that VCV waveform are retained. The auditory tests confirmed the superiority of the novel synthesis method. Finally, the advantage of the spoken word database, which consists of Japanese VCV-balanced word sets uttered forcibly by two pitch accent types (so-called type -0 and type $+1$ in Japanese) differently from the normal pitch accent, is discussed.

1aSC34. The Hablarte text-to-speech system. Helen E. Karn (Office of the Dean, Georgetown College, Georgetown Univ., Box 571003, Washington, DC 20057-1003, karnh@gunet.georgetown.edu)

This paper presents an overview of the architecture of Hablarte, an unrestricted text-to-speech system for Spanish which runs on DOS-based personal computers. The input to Hablarte is an ASCII text with conventional Spanish orthography and punctuation. The front-end text processing routines convert the input text's graphemes to phonemes, determine phonological phrases, syllable structure, and the location of primary stress, and assign prosodic values to the phonetic representation [H. E. Karn, ''Aspects of phonetics and phonology in a text-to-speech system for Spanish,'' Doctoral dissertation, Georgetown University, 1996]. The acoustic signal is generated by Mbrola v2.02, using the Spanish male diphone database and utilities of the MBROLA project [http://tcts.fpms.ac.be/synthesis/mbrola.html]. Evaluations of Hablarte's text processing components and sample audio output are given.

1aSC35. Pitch-controlled variable bitrate CELP speech coding. Robert Oberhofer and Frank Owens (Univ. of Ulster, Jordanstown, Co. Antrim, BT37 0QB, Northern Ireland, r.oberhofer@ulst.ac.uk)

Most research in efficient speech coding concentrated for many years on algorithms which produced a fixed bit rate. Fixed bit rates are, however, not a requirement for modern packet-based telecommunications and computer networks as well as voice storage applications. This makes the implementation of speech coders feasible, which adapt to the changing properties of speech for improved efficiency or quality. Variable bit-rate coding has therefore become the focus of considerable research activity in recent years [A. Gersho and E. Paksoy, ''Variable Bit Rate Coding,'' Signal Processing VII, Theories and Applications, EUSIPCO 1994, pp. 1169–1173; L. Zhang *et al.*, ''A CELP Variable Rate Speech Codec with Low Average Rate,'' ICASSP 1997, pp. 735–738; B. C. Xydeas, ''Source Driven Variable Bit Rate Prototype Interpolation Coding,'' ICASSP 1996, p. 220; B. Shen *et al.*, ''A Robust Variable-Rate Speech Coder,'' ICASSP 1995, p. 249]. While all of these coders focus on classification procedures for efficient bit allocation, the analysis frame size remains mainly static. The coder featured in this paper adapts the analysis frame size and bit allocation according to the pitch of the signal. A pitch frame extractor and classifier at the front end feeds the detected frame into the speech coding back end, which uses traditional CELP-based techniques [B. S. Schroeder *et al.*, ''CodeExcited Linear Prediction (CELP): High Quality Speech at Very Low Bit Rates,'' ICASSP 1985, pp. 937–940]. This approach allows the reduction of the bit rate from a constant 4800 bps (bits per second) with original CELP to typically 3200–4000 bps, depending on the speech situation. This figure is even reduced to typically 2600–3200 with the inclusion of Voice Activity Detection. The speech quality equals the quality of the original CELP coder.

1aSC36. Assessment of the intelligibility and perceived quality of speech produced by text-to-speech engines. Michael D. Hall, Erica B. Stevens, Richard Eyraud, Denise M. Padden, and Patricia K. Kuhl (Dept. of Speech and Hearing Sci., Univ. of Washington, Seattle, WA 98195, mdhall@u.washington.edu)

The intelligibility and quality of speech produced by current text-to-speech (TTS) engines was assessed using well-established tests of speech intelligibility. TTS engines included Microsoft's Whistler, AT&T's Watson, and Elan Informatique's ProVerbe. The speech intelligibility tests varied in complexity and in the degree to which syntax and lexical knowledge could aid perception. Stimuli included CVC words, semantically meaningful sentences, semantically anomalous sentences, and paragraphs representing different styles of discourse. Intelligibility was evaluated using transcription accuracy for isolated word and sentence items, as well as ratings of the clarity of articulation for word and paragraph items. Perceptual errors on word items also were analyzed by phoneme and word position (initial, medial, or final). Additional ratings were used to determine the perceived ''naturalness'' of meaningful sentences and paragraph items. Across levels of speech complexity, clear and consistent differences between TTS engines were obtained in terms of both intelligibility and naturalness. Possible explanations of the results will be discussed, as will potential areas where text-to-speech synthesis can generally be improved.

1aSC37. Acoustic-phonetic features for the automatic recognition of stop consonants. Ahmed M. Abdelatty Ali, Jan Van der Spiegel (Dept. of Elec. Eng., Univ. of Pennsylvania, 200 South 33rd St., Philadelphia, PA 19104-6390), and Paul Mueller (Corticon, Inc., King of Prussia, PA 19406)

Despite the recent successes in the field of automatic speech recognition, more research is still needed in order to understand the variability of speech and the acoustic characteristics of speech sounds in different contexts and for different speakers. In this paper, the acoustic-phonetic characteristics and the automatic recognition of the American English stop consonants are investigated. The acoustic features that exist in the literature are evaluated and new features are proposed. To test the value of the

extracted features, a knowledge-based acoustic-phonetic system for the automatic recognition of stops, in speaker independent continuous speech, is proposed. The system uses an auditory-based front-end processing and incorporates new algorithms for the extraction and manipulation of the acoustic-phonetic features that proved to be rich in their information content. Several features, which describe the burst frequency, formant transitions, relative amplitude, spectral shape, and duration, are combined in the recognition process. Recognition accuracy of 95% for voicing detection and 90% for place of articulation detection are obtained for TIMIT database continuous speech of multiple speakers from different dialect regions. The obtained results are analyzed and compared to previous work. [Work was supported by Catalyst Foundation.]

1aSC38. An 800 bps VQ-based LPC voice coder. Xianglin Wang and C.-C. Jay Kuo (Elec. Eng. Dept., USC, 3740 McClintock Ave., Los Angeles, CA 90089-2564)

In this paper, it is investigated how to efficiently apply VQ on LPC so as to realize a very low bitrate speech coder with reasonable speech coding quality. The coding bitrate has been pushed to 800 bps and the result is compared with that of a traditional LPC 2.4 kbps speech coder. In LPC10 standard(FS1015), scalar quantization is adopted to quantize the LPC parameters. However, when vector quantization is considered, the speech coding rate can be further reduced without obvious degradation of speech quality. In our coding scheme, instead of direct encoding of LPC parameters, LSF coefficients are encoded which are obtained from a transformation of LPC. In addition, in order to utilize the correlation among LPC parameters, three frames of speech are processed together so that some kind of prediction could be utilized. A weighted version of MSE is selected as the distortion measure in building the VQ codebooks and encoding. Also, due to their different characteristics, separate codebooks are built and used for voiced and unvoiced speech to better match their statistical properties. The result of our experiments shows that our 800 bps speech coding scheme can achieve similar quality to that of the LPC 2.4 kbps speech coder.

1aSC39. A study on the speech analysis and recognition for Korean children. Eunjung Park, Jieun Kam, Inchan Paek, Y. Kwon (Hanyang Univ., Ansan, Kyonggi-Do 425-791, Korea), K. S. Lee, and Sung-il Yang (Hanyang Univ., Ansan, Kyonggi-Do 425-791, Korea)

This paper describes a speaker-independent Korean ten-digit recognizer for males and females from 10 to 13 years old, who have a serious variation of speech characteristics. DHMMs with time normalized ten-dimensional LPC, CEPSTRUM, LSF coefficients, and ten-band energies in frequency domain as the feature vector are used. The pitch and formant informations are extracted to analyze speech characteristics. Through experiments, DHMM recognizer shows the performance of recognition rates, 67.1% (LPC vectors), 80.8% (CEPSTRUM vectors), 66.7% (band energies in frequency domain), and 83.8% (LSF vectors).

1aSP1. Signal models for broadband model-based array processors. Edmund J. Sullivan (Code 82101, Naval Undersea Warfare Ctr., 1176 Howell St., Newport, RI 02841) and James V. Candy (Lawrence Livermore Natl. Lab., L-156, Livermore, CA 94551)

The recently developed theory for broadband model-based acoustic array processing is based on a Kalman-type estimation scheme. Here two sets of equations are required; the state equations and the measurement equations. In the narrow-band case, the measurement equation is based on either a plane wave or curved wavefront monochromatic signal model. In the broadband case the signal model, i.e., the measurement equation, is represented as an autoregressive moving average (ARMA) process. In this approach the parameters of interest, which are the bearing and range, are combined with the ARMA parameters in a single state vector. This provides a scheme wherein these parameters are adaptively estimated in a recursive manner. However, the order of the ARMA process depends upon the spectral characteristics of the signal. In this study, various realistic broadband signal spectra are examined in terms of the required ARMA representations. Examples will be shown for several cases of representative surface ship radiation spectra.

8:15

1aSP2. Simulation of the effects of thermal turbulence on beamforming and time reversal techniques using Gaussian beam summation and Fourier modes superposition techniques. Christian Lhuillier, David Fiorina, Jean-Luc Berton (Commissariat a l'Energie Atomique, Cadarache, DER/SSAE/LSMR, F-13108 Saint-Paul-lez-Durance cedex, France, ssaelsmr@macadam.cea.fr), and Daniel Juve (Laboratoire de Mecanique des Fluides et d'Acoustique, UMR CNRS 5509, F-69131 Ecully, France)

In-service inspection of Fast Breeder Reactors will require submerged ultrasonic imaging devices. For this purpose, the CEA (French atomic commission) is developing an orthogonal imaging system, based on beamforming applied to two linear arrays. In order to evaluate the performance of this technique for realistic physical conditions, one must take into account the possible effects of weak thermal turbulence on the propagation and focusing of ultrasound. To achieve this study, a numerical model has been implemented. It is based on the Fourier modes superposition method to generate independent realizations of turbulent fields and on the Gaussian beam summation method to calculate the associated acoustic pressure fields induced by point sources. First, the model has been used to show the aberrations that are created in the focusing of a multielement transducer.

Second, the model has been used to verify the efficiency of the time reversal technique for the correction of these aberrations, in the case of slow temporal evolutions of the turbulence.

8:30

1aSP3. Advanced system identification techniques for acoustics enhancement. Yuchang Cao and Mark Poletti (Industrial Res. Ltd., Gracefield Rd., P. O. Box 31-310, Lower Hutt, New Zealand)

This paper proposes a novel scheme of adaptive system identification for acoustics enhancement applications. The proposed scheme incorporates a variable exponentially weighted-step-size LMS algorithm, called the VES algorithm, the time-average, and the group measurement methods. A key contribution of this study is the development of the VES algorithm based on the statistics of the overall varying characteristics of the estimate of room impulse responses. The modeling error of the VES algorithm can be reduced to -20 dB after only $2N$ iterations (N is the length of adaptive filter), about 4 times faster than the normalized LMS algorithm under the test conditions. The increase of the computation load of the VES algorithm is small. When the algorithm is employed in a multichannel system identification, the increase of the computation load is only about 10%. Since the identification scheme has to operate under strong interference in most cases, the time average and group measurement approaches have also been investigated and are suggested to be employed in the scheme to further improve the identification accuracy. The proposed techniques can be used to eliminate undesired feedback, equalize the frequency response, and allow the design of more advanced multichannel assisted reverberation systems, which can provide larger loudness and reverberant gains than conventional systems.

8:45

1aSP4. Convergence characteristics of frequency-domain LMS adaptive filters. Karl M. Reichard and David C. Swanson (Appl. Res. Lab., Penn State Univ., P.O. Box 30, State College, PA 16804, kmr5@psu.edu)

The frequency-domain implementation of the adaptive LMS algorithm offers several advantages over the time-domain LMS algorithm. The primary advantage is that the orthogonality of the individual bins in the signal spectra permit the implementation of a single complex LMS filter for each FFT bin independently, each with a separate convergence parameter. The result is a uniform rate of convergence for all FFT bins as opposed to the time-domain algorithm which converges only as fast as the dominant eigenvalue of the input data. An additional parameter which affects frequency-domain LMS convergence is the overlap between successive FFT buffers. It is shown that the maximum advisable overlap between FFT buffers is 50%. Greater overlap between FFT buffers can lead to oscillations (and even instability) in the adaptive algorithm. Experimental results are presented which illustrate the convergence characteristics of a frequency-domain adaptive active noise control system for several different types of reference inputs.

9:00

1aSP5. A simple genetic algorithm for active noise control. Antonio Minguez and Manuel Recuero (Inst. de Investigacion del Automovil (INSIA), Univ. Politecnica de Madrid, Ctra. Valencia km. 7, 28031 Madrid, Spain)

Genetic algorithms in active noise control (ANC) eliminates the need to know the cancellation path, necessary for a conventional gradient descent-type algorithm (such as filtered-x and filtered-U) to remain stable. However, genetic algorithms show some disadvantages: slow convergence, high residual error noise, and high computational complexity. This paper presents a simple genetic algorithm that improves these quality factors, simplifying the basic stages of the genetic algorithm: population size, selection, reproduction, and mutation. To reduce the algorithm computation the population size is low, 6 chromosomes (filter coefficients) maximum, and only the best chromosome is selected so the reproduction stage disappears. Next generation of chromosomes is generated mutating the selected chromosome with a variable random number which amplitude is directly proportional to the mean-squared error in the current generation. This variable mutation is the most important parameter because it determines the stability, the convergence, and the final residual level. Good results have been obtained for narrow-band signals in single (SISO) and multiple (MIMO) ANC configurations and with FIR or IIR filters. These results shows fast convergence, only four or five generations are necessary with very reduced populations (6 chromosomes in SISO systems and 2 to 3 chromosomes in MIMO systems) and an attenuation better than 20 dB.

9:15

1aSP6. Reducing sibilants in recorded speech using psychoacoustic models. Markus Sapp, Martin Wolters, and Joerg Becker (Institut für Elektrische Nachrichtentechnik, RWTH Aachen, 52056 Aachen, Germany)

Sibilants are a known problem in speech recording. Even though they can often be decreased by a different placement of the microphones, there still is the necessity for methods that reduce these artifacts. Therefore new investigations on sibilants in German, English, Spanish, and French have been made to describe their properties in time and frequency domain. To find an adaptive algorithm which considers these properties a reliable method is needed for detection and classification of the different kinds of sibilants. It is shown that the psychoacoustic unit ''sharpness'' is well correlated with the appearance of these sounds and that specific loudness, an intermediate step in calculating sharpness, can be utilized to get information about the spectral properties of each sibilant. An algorithm is presented which employs sharpness to detect sibilants and reduces them using variable filters.

9:30

1aSP7. Machine recognition of Hindi consonants and distinctive features using vector quantization. Pradip K. Das (Human Resource Development Group, Rm. No. 505, CSIR Complex, Dr. K. S. Krishnan Marg, New Delhi-110 012, India) and S. S. Agrawal (Central Electrons Eng. Res. Inst., CSIR Complex, Dr. K. S. Krishnan Marg, New Delhi-110 012, India)

This paper describes the results of experiments conducted to test the efficiency of the VQ algorithms to recognize and distinguish minute differences among consonant features of Hindi. The database was created by combining all the frequently occurring 29 Hindi consonants with vowel /a/ to form CV-type syllables and recorded by 20 male Hindi speakers. The acoustic features in the form of cepstral vectors were derived for each syllable file in the training set. For each syllable, the set of 20 codebooks for 20 speakers were first clubbed to form the universe for that syllable. The LBG algorithm was used to generate the codebook of size 64. Using the codebooks as reference templates the recognition rate was found to be 73.28% out of the total of 580 (29*20) test samples. Further analysis was carried out to see how different consonants were recognized when they were clubbed into different groups according to the manner and place of their articulation. The average recognition rate for the consonants corresponding to the same place of articulation and the same manner of articulation was found to be 83.38% and 76.25%, respectively. Results of detailed distinctive feature analysis carried out to find the differences in the rate of recognition are also discussed.

9:45

1aSP8. Synthesis of Hindi consonants with natural sounding quality using the PC-based Klatt synthesizer. Rajesh Verma and Shyam S. Agrawal (Central Electrons Eng. Res. Inst. Ctr., CSIR Complex, NPL Campus, Hill Side Rd., New Delhi 110 012, India)

This paper describes experiments conducted to synthesize Hindi consonants with natural sounding quality using the PC-based Klatt synthesizer. All the most frequently used 29 Hindi consonants have been synthesized in the form of CV and VC syllables. For this purpose, a detailed spectral analysis was carried out to determine minute acoustic differences among the various categories of consonants such as unaspirated/aspirated, voiced/unvoiced, dental/retroflex, liquid/trill, etc.. The synthesis was done using a modified version of the Klatt Synthesizer simulated on a PC. It uses about 60 parameters for the source and vocal tract variations in 5-ms duration. Variations in important parameters were made until a satisfactory quality of consonant was perceived and a clear distinction occurred with its cognate sound. For example, the distinction among dental plosives (t, th, d, dh) and retroflex plosives (t*, th*, d*, dh*) have been achieved by changing formant frequencies at the burst position, intensity of burst, and formant transitions from burst to the target vowel. Similarly the sound /r/ in Hindi takes various forms such as trill or fricative depending upon the context. This is a very special characteristic of /r/ in Hindi. In this same manner the special features of all the 29 consonants are discussed with references to their synthesis in five different vowel contexts.

10:00

1aSP9. A rejection method for the Korean isolated word recognition system. Dong-Hwa Kim (Dept. of Information and Commun., Miryang Natl. Univ., Nei 2 Dong, Miryang, Gyung Nam, 627-130, Korea, dhkim@arang.miryang.ac.kr), Hyung-Soon Kim, and Young-Ho Kim (Pusan Natl. Univ., Jang Jun Dong, Gyem Jung Gu, Pusan, 609-735, Korea)

The small vocabulary isolated word recognition systems as well as large vocabulary continuous speech recognition systems can be applicable in many areas. For the isolated word recognition systems to be deployable in actual applications, the ability to reject the out-of-vocabulary is required. This paper presents a rejection method which uses the clustered phoneme modeling combined with postprocessing by likelihood ratio scoring. Our baseline speech recognition was based on the whole-word continuous HMM. Six clustered phoneme models were generated using the statistical method, monophone clustering algorithm, from the 45 context independent Korean phoneme models, which were trained using the phonetically balanced Korean speech database. The performance of this method was assessed in terms of the out-of-vocabulary rejection rate and the accuracy on the pre-defined-vocabulary. The performance test for speaker independent isolated words recognition task on the 22 section names shows that this method is superior to the conventional postprocessing method, which is performing rejection according to the likelihood difference between the first and second candidates. Furthermore, these clusters phoneme models do not require retraining for the other isolated word recognition systems with different vocabulary sets.

1aUW1. A review of progress in acoustic telemetry and the challenges of the underwater channel. Arthur B. Baggeroer (MIT, Rm. 5-204, Cambridge, MA 02139)

High data rate acoustic telemetry in the ocean is limited by both bandwidth and reverberation. Attenuation limits the available bandwidth and most acoustic environments are dominated by reverberation which is spread in both delay and Doppler. The availability of low power VLSI electronics has had an enormous impact upon acoustic telemetry because the algorithms of digital communication systems could be implemented in oceanographic sensors which have severe constraints upon available energy and space. The first demonstration was the DATS (Digital Acoustic Telemetry System) for reverberant acoustic channels. It used MFSK with an (8,4) Hamming code, frequency hopping, and explicit synchronization of time and Doppler. Since then, (i) coherent signaling, (ii) source and channel coding, (iii) adaptive equalizers, and (iv) frequency and spatial diversity and networked configurations all have been used. Bit rates of 5–20 kbs at short ranges and 0.5–1 kbs at long ranges have been demonstrated. Higher rates can probably be obtained with forward error control methods; however, there the relatively slow speed of sound leads to some unique latency issues. Nevertheless, the availability of two-way links leads to acoustic telemetry networks which can be addressed just as any other node on a net. Some other interesting issues in acoustic telemetry concern increasing the data rate within the same bandwidth, low probability of intercept covert communications, methods for high Doppler situations, and network topologies which are robust to node outages. This presentation will provide a brief overview of acoustic telemetry and the evolving research areas, and present some of the challenges of the underwater channel.

8:35

1aUW2. Environmental impact on phase coherent underwater acoustic communications: A physics based approach. T. C. Yang and A. Al-Kurd (Naval Res. Lab., Washington, DC 20375)

Phase coherent acoustic communication systems, which employ joint adaptive channel equalization and phase-locking synchronization, have been shown to yield a much higher symbol rate (e.g., 2 kb/s at 3.5 kHz) by successfully tracking and updating time varying phase fluctuations in signals dominated by multipath components. This communication technique holds high promise for many applications. Its performance, however, can strongly influence (and could be limited by) the signal and noise fluctuation characteristics of the propagation channel. A statistical underwater acoustic communication model which incorporates random media propagation physics is needed to predict the performance of phase coherent acoustic communication algorithms. In this paper, the ocean acoustic propagation physics and signal processing issues which must be addressed to develop a physics-based performance prediction model are outlined. Acoustic communication simulation results for a dynamic underwater acoustic channel with time varying internal waves, fine and microfine structures, and surface waves are presented. Initial performance assessments (predictions) are given based on previously measured signal fluctuation statistics as characterized by the signal amplitude fading and phase spectra. [Work supported by the Office of Naval Research.]

8:47

1aUW3. Observations of coherence frequency and amplitude fluctuations in a shallow-water acoustic communications channel. Richard Shockley, Joseph Rice, Vincent McDonald (Space and Naval Warfare Systems Ctr., San Diego, Code D881, San Diego, CA 92109), Dale Green (Torrey Sci. Corp.), John Proakis (Northeastern Univ.), and John Newton (Polar Assoc., Inc.)

This work examines the statistics of a fading, dispersive shallow-water channel, specifically the distribution of amplitudes and the correlation between fluctuations in amplitude at different frequencies in the 8- to 12-kHz band. Signals considered include frequency-hopped, 50-ms duration, CW pulses and 500-ms linear FM chirps sent over a 15-m deep, 1-km range channel. Physical origins and implications for communications receivers of the observed non-Gaussian or non-Rayleigh behavior are briefly discussed. [Work supported by the SSC San Diego Independent Research Program, sponsored by the Office of Naval Research.]

8:59

1aUW4. Experimental performance of concatenated coding in shallow-water channels. Daniel Kilfoyle (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543, dkilfoyle@whoi.edu)

In a series of phase coherent underwater acoustic communication experiments near the New England continental shelfbreak, the coding gain realized by a concatenated outer block code and trellis coded modulation (TCM) inner code was measured and compared to ideal asymptotic limits. Viterbi decoding of the inner code was fully integrated into the adaptive decision feedback equalizer structure. Coding gain is typically not realized until after decision delays of several code constraint lengths. Delayed decisions for the tap update algorithm, however, degrades equalization performance. Two specific techniques were employed to mitigate this conflict, including linear extrapolation of the carrier phase correction and a unique evolution of the tap weights for each state of the Viterbi trellis. Coding gains were realized for both eight-level phase shift keyed (8 coding states) and 16 quadrature amplitude shift keyed (128 coding states) waveforms. Bit error rate as a function of output signal-to-noise ratio was computed to demonstrate practical, as opposed to asymptotic, coding gains. The extent to which coding increased the system performance envelope will then be discussed.

9:11

1aUW5. Comparative performance of nonbinary Viterbi and sequential decoding in adverse underwater acoustic channels. Dale Green, Richard Justice (Torrey Sci. Corp.), and Joseph Rice (Space and Naval Warfare Systems Ctr., San Diego, CA 92109)

The application of higher-order alphabets in convolutional forward error correction coding is discussed, specifically the use of Viterbi decoding to obtain maximum likelihood performance with short-constraint-length codes, and the use of Fano sequential decoding with long-constraint-length codes. It is demonstrated that both techniques perform very well even near the respective computational cutoff (Rcomp) region. An 8-ary, constraint-length-3 coder combined with Viterbi decoding provides probability of bit error in a Rayleigh faded channel on the order of 10^{-4} at Eb/No=11 dB. With an 8-ary, constraint-length-10 coder combined with Fano sequential decoding operating also at Eb/No=11 dB, the probability of undetected error may approach 10^{-12}. The probability of erasure is less than 10^{-4} with a reasonable amount of computer resources. Viterbi decoding with short-constraint-length codes produces occasional bit errors which may be corrected with the concatenation of a simple block code applied to the input message. Performance comparisons are drawn from a side-by-side analysis of the two using data obtained during telesonar experiments in San Diego Bay. [Work supported by the ONR 321 Sensors, Sources and Systems Program and SSC San Diego Contract No. N66001-96-C-6003.]

9:23

1aUW6. Signal fluctuation statistics and performance of phase coherent underwater acoustic communications: An experimental evaluation. A. Al-Kurd and T. C. Yang (Naval Res. Lab., Washington, DC 20375)

Underwater acoustic communications data using phase modulated signals were collected during the Littoral Warfare Advanced Demonstration 98-1 experiments. The signals were projected from both a drifting modem and from a towed frequency source. Data of several different baud rate were transmitted and used to (1) study the temporal variation of the acoustic impulse response of the ocean and (2) evaluate the performance of the phase coherent communication algorithm. The amplitude and phase variations are analyzed on a fast scale (within the transmission packet of 5 s) and a low scale (minutes to hours). The performance of the communication algorithm is correlated with the phase rate and amplitude fluctuation statistics, the signal-to-noise ratio, etc. The data are compared with simulation results and used to guide performance predictions. [Work supported by the Office of Naval Research.]

9:35

1aUW7. Adaptive array processing for acoustic communications through time-varying ocean channels. James C. Preisig (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

In many underwater environments, the acoustic communications channel is reasonably modeled using a micro/macro multipath model. While this model was developed by Flatte [S. M. Flatte, *Sound Transmission Through a Fluctuating Ocean* (Cambridge U.P., Cambridge, 1979)] and others to describe the effect which random channel fluctuations caused by linear internal waves have on propagating narrow-band acoustic signals, it provides a useful paradigm for modeling the effects of a wider range of environmental fluctuations on wideband communications signals. With this paradigm as a starting point, an analytic two-level model for the effect of random channel fluctuations is presented and compared with experimental data. Using the two-level model, a two-stage adaptive array processing algorithm is developed for processing acoustic communications signals. The algorithm exploits the space/time correlation structure of the received signals which is implied by the channel fluctuation model. The

performance of this algorithm in terms of both bit error rate and computational efficiency is analyzed and compared with that of other multichannel communications algorithms. [Work supported by the Office of Naval Research under Grant No. N00014-95-1-1316.]

9:47

1aUW8. Phase-encoded frequency-hopped signaling for underwater acoustic communications. Geoffrey Edelson (Sanders, A Lockheed Martin Co., Adv. Systems Directorate, P.O. Box 868, Nashua, NH 03061-0868) and Bradford Gillespie (Univ. of Washington, Seattle, WA 98195-2500)

Phase-coherent digital communications systems require complicated receivers to overcome the intersymbol interference caused by the time-varying multipath propagation of shallow-water acoustic channels. However, many of these channels feature ''sparse'' impulse responses in that the received signal arrives in distinct clusters separated by time periods in which little signal energy arrives at the receiver. If the phase-coherent message is divided into multiple ''minipackets'' such that the minipacket duration is shorter than the time span between the distinct multipath clusters, then the receiver configuration can be simplified considerably. The short packets may be frequency hopped so that a given frequency is vacated until subsequent multipath arrivals have died out. Each minipacket is decoded using a maximum-likelihood decoder. If each chip is not phase-encoded, the system reduces to a noncoherent frequency-hopped modulation technique. Experimental results are included to demonstrate the potential performance of this approach.

9:59

1aUW9. Doppler spread in an undersea acoustic transmission channel. Joseph Rice, Paul Baxley, Homer Bucker, Richard Shockley (Space and Naval Warfare Systems Ctr., San Diego, Code D881, San Diego, CA 92109), Dale Green (Torrey Sci. Corp.), John Proakis (Northeastern Univ.), and John Newton (Polar Assoc., Inc.)

This paper examines spectral dispersion of narrowband sound energy transmitted between two stationary, horizontally displaced, undersea, electroacoustic transducers. Any frequency smearing arises kinetically and is imparted by the aggregate motions of scatterers influencing the forward-propagated, physical channel. From this time-variant cause, hypotheses are drawn about the statistics of the spectrally dispersive effect. The hypotheses are tested by analyzing representative acoustic data in the 8–12-kHz band obtained from ocean experiments. To further study the phenomena, a numerical ray model is constructed with 3-D Gaussian beams, evolving sea–surface boundary, and dynamic volume inhomogeneities. The model represents the sea surface as a nonstationary mosaic of polygonal tiles, each reflecting energy with an appropriate Doppler shift. Evolution of the faceted sea surface is governed by assumed oceanographic processes. Spectral density is computed by accumulating the energy contributions at a specified receiver location. In conclusion, the implications of spectral dispersion on undersea acoustic signaling are summarized. [Work supported by the SSC San Diego Independent Research Program, sponsored by the Office of Naval Research.]

10:11

1aUW10. Doppler tolerant link. Anthony D. Matthews (Coastal Systems Station Dahlgren Div., Naval Surface Warfare Ctr., Code R21, 6703 W. Hwy. 98, Panama City, FL 32407, matthews_tony@ccmail.ncsc.navy.mil)

A specialized probe signal is used for environmental adaptation, frequency scaling, and alertment in an underwater acoustic digital communications link. The link is designed to permit one-way message traffic to be sent from a static node to a moving node. The moving node creates an unknown range rate within known range rate limits. Link design goals include power conservation, a bit error rate of 1/10 000, and tolerance of a 25 dBs noise field. Design parameters, simulation experiment results, and field experiment results (if available) are presented. [Sponsored by ONR.]

1aPLb1. Acoustical studies of the upper ocean boundary layer. David Farmer (Inst. of Ocean Sci., 9860 West Saanich Rd., Sidney, BC V8L 4B2, Canada)

Ocean surface processes control the vertical transfer of heat, mass, and momentum, affecting water properties and influencing climate. At higher sea states the upper ocean can be one of the most energetic environments on the surface of the planet, presenting special observational challenges to the oceanographer. Acoustical methods provide new approaches to upper ocean measurement and have already deepened our understanding of wave breaking, Langmuir circulation, and bubble distributions. High-frequency sonar images of bubble clouds delineate the patterns of near surface circulation while acoustic Doppler reveals the corresponding flow field; high-resolution coherent Doppler can resolve the microscale turbulent velocity fluctuations. Interpretation of ambient noise allows us

to sense wave breaking and presents an intriguing inverse problem requiring separation of sound generation and propagation effects. *In situ* acoustical sensors can now provide reliable determinations of bubble size distributions. Our experience with many of these techniques is limited, but significant advances can be expected through the combined application of diverse approaches to the study of this climatically sensitive boundary.

1pPLa1. Sound transmission through suspended ceilings. F. P. Mechel (Landhaustrasse 12, D-71120 Grafenau, Germany)

Suspended ceilings passing over a partition wall between adjacent rooms are a path of sound transmission from room to room for which, until recently, no analytical and satisfactory theory existed, although suspended ceilings are a common system of construction. The principal features of an analysis are outlined for the sound fields in the adjacent rooms, in the plates and absorber layers of the suspended ceiling and in the common plenum above the ceiling. The theory is based on a modal analysis. It not only shows the mechanisms of the sound transmission, which in contrast to common ideas, are quite different on the emission and on the receiving sides, but it also gives numerical results which agree (within the precision of measurements) with experimental data. The influence of geometrical parameters (e.g., plenum height, room width) and of material parameters (e.g., absorber layer thickness) can be demonstrated quantitatively.

1pAAa1. The development of room acoustical demands on operas within the last 50 years. Gerhard Müller and Helmut A. Müller (Müller-BBM GmbH, Robert-Koch-Str. 11, D-82152 Planegg, Germany)

After World War II, many destroyed operas in Europe required reconstruction. Since the period of the royal operas was past, architects tried to develop new shapes based upon the new social philosophy. For the acoustical planning, this has led to the following goals: (1) equal acoustical quality in all areas of the auditoria, (2) high speech intelligibility, and (3) uniform sound transmission from the pit and the stage to the audience. The deducted measures were the following: (1) application of an arenalike seating arrangement of the public to expose everybody to a strong direct sound, (2) low reverberation, and (3) reflection of sound energy to compensate the increasing distance of the listeners from the sound sources. These principles have led to the realization of slightly fan-shaped

rooms with a relatively small volume or additional sound-absorbing claddings. Surprisingly, these opera halls have been quoted worse than the old ones, by the musicians and the audience. The reason for the lower reputation of the operas, designed applying the rules of the 1950s, will be explained with the help of two examples in which improvements have been realized afterwards. The measured relevant room acoustical data will be presented and the differences discussed.

2:40

1pAAa2. Alternate venues for opera performances. Wagner started it . . . should we retreat now? Christopher Jaffe (Jaffe Holden Scarbrough Acoust., Inc., 114A Washington St., Norwalk, CT 06854, dcoppola@jhsacoustics.com)

Although there has been a resurgence of interest in opera over the last 15 years in America the current outlook for continued financial support for this form of musical theater as well as classic concerts is bleak. At one time opera was enjoyed by the unwashed as well as sophisticates and a number of today's creative opera directors are trying to appeal to a broader segment of the market. This paper will discuss the break with tradition that Richard Wagner and Adolph Appia succeeded in achieving at Bayreuth in terms of architectural acoustic design and how these changes were integrated with new approaches to scenic design and stage lighting. In addition, examples of contemporary opera companies that are creating a more intimate and emotionally powerful experience for their audiences by breaking out of the picture-frame productions of proscenium theater are given. Among these companies are the Colorado Opera and the Opera Theatre of Saint Louis.

3:00

1pAAa3. Orchestra pit acoustics: From Bayreuth to Broadway. Mark Holden (Jaffe Holden Scarbrough Acoust., Inc., 114A Washington St., Norwalk, CT 06854, mholden@jhsacoustics.com)

The design of orchestra pits for opera, ballet, and multiuse halls is examined from an historical perspective. The earliest orchestra pit designs for early European opera houses were open or ''bathtub'' pits holding few musicians on a single level. Pits remained similar until 1872 when Wagner's Bayreuth pit changed the musician/vocalist orientation by extending the pit below the stage edge in stepped tiers. Modern pit designs have varied from large ''bathtub'' pits (the Metropolitan Opera, San Francisco) to ''modified Bayreuth'' pits (Houston, Seattle, etc.) with varying degrees of success. Issues concerning musicians' comfort, loudness levels, and hearing loss are discussed along with ways to improve acoustics in the overhung area. Finishes and materials for walls, ceilings, and floors are discussed as well as adjustable acoustic panels, drapes, and walls that can be used to tune the pit for varying programs. Finally, solutions to the dilemma of Bayreuth versus Bathtub pits will be discussed.

3:20

1pAAa4. Why do traditional opera houses work so well for opera? Nicholas Edwards and David Kahn (Acoustic Dimensions, 24 Styvechale Ave., Coventry CV5 6DX, UK)

Most computer models of room acoustics assume geometric acoustics (as if sound behaves like light). This has assisted our understanding of how room shape (fan shape versus rectangular, for example) can affect the acoustics of concert halls. When one applies geometric acoustics modeling to the traditional opera house, typically all one finds is a single ceiling reflection. The geometric approach holds little promise for understanding the magic of opera house acoustics. One of the acoustical attributes ignored by the geometric model is edge diffraction of sound. Our research has shown edge diffraction to be essential in predicting the superior acoustics of the traditional opera house. We have developed an alternative to the geometric acoustics model based on edge diffraction. In a two-dimensional representation, the locus of points with equal delay time is an ellipse; in three dimensions, the locus is the volume of revolution of an ellipse. By studying where this ellipsoidal volume intersects with the balcony fronts, we can locate where, at any given time, the edge-diffracted sound is coming from. This model is applied to LaScala, and a ''movie'' is developed to show how the balcony front edges contribute to the sound that is heard.

3:55

1pAAb1. Measurement of objective criteria for performers in the ''Teatro di San Carlo'' opera house. Carmine Ianniello, Gino Iannace, Luigi Maffei, and Rosario Romano (DETEC–Univ. of Naples, Federico II, Piazzale Tecchio 80, 80125 Naples, Italy, maffei@unina.it)

In the last two decades some attention has been paid to the acoustics for performers in concert halls. The findings of these studies have shed some light on the structure of the sound field preferred for the ensemble. With respect to a concert hall, the performing condition is quite different in an opera house. Usually, the problems are related to: (a) the balance between singer(s) and the orchestra in the pit; (b) the ease of singing; (c) the ensemble of singers; (d) the ensemble of instrumentalists. To the knowledge of the authors no objective criterion has been suggested yet for (a). Some criteria are reported for the ensemble of instrumentalists (d). Useful information for (b) and (c) is reported in [A. H. Marshall and J. Meyer, Acustica **58**, 130–140 (1985)]. Although well aware of the lack of accepted objective criteria, which should be well correlated with subjective criteria for the above-mentioned topics, these authors report the results of measurements carried out in the ''Teatro di San Carlo'' in the aim of quantifying objectively some of the items (a)–(d). In particular, a criterion is suggested that is related to the comfort of singers on the basis of the study of Marshall and Meyer.

4:15

1pAAb2. Sound fields in orchestra pits. Juergen Meyer (formerly, Physikalisch-Technische Bundesanstalt, D-38116 Braunschweig, Germany, juergen.meyer@ptb.de)

The main problem for musicians sitting in opera house orchestra pits is the general loudness of the orchestral sound. The sound field occurring at the musicians' ears is not only affected by direct sound, early reflections, and reverberation, but—particularly for seats under the stage—by standing waves. Whereas direct sound and diffuse reflections appear to come from comparatively large distances, the sound due to standing waves is localized just around the head. Therefore, it is extremely disturbing for the players, impairing the tonal control of their own instruments as well as the ease of ensemble. Disturbing direct sound may be reduced (5–10 dB) by special screens directly behind the musician's head. Standing waves between the floor and cover of the pit are critical if the musicians' ears are in the neighborhood of the antinodes; this does not occur with the lowest mode, but for modes having two or three half-wavelengths, assuming the ears at a height of 1.15 m above the floor. Therefore, a distance between floor and cover of 2.0–2.75 m (or below 1.80 m) may be recommended, as in these cases only one disturbing mode occurs which can be damped by well-tuned absorption.

4:35

1pAAb3. Listening in the pit. Christopher N. Blair (ARTEC Consultants, Inc., 114 W. 26th St., New York, NY 10001)

Temporal masking effects are a controlling factor in the ability of performers to hear each other well. Difficulties in ensemble communication and perceived weakness of the acoustic response of the auditorium can be exacerbated by high early energy levels often found in orchestra pits. These problems become particularly acute in orchestra seating positions under stage overhangs. Drawing on experiences as an opera conductor as well as an acoustic designer, the author: (1) provides an overview of the psychoacoustic challenges facing the opera house designer relative to orchestra satisfaction; (2) explores, using architectural examples, the reasons why some pits are highly regarded by orchestras and conductors while others, even those similarly configured, are not; and (3) proposes protoptypical design solutions to improve the listening environment both inside the pit and elsewhere.

4:55

1pAAb4. Small-scale modeling of stage to pit balance: A pilot study. John P. O'Keefe (Aercoustics Engineering Ltd., 50 Ronson Dr., Ste. 127, Toronto M9W 1B3, Canada)

Measurements in full-scale auditoria have demonstrated that the acoustical balance between stage and orchestra pit sound sources is influenced by the seat dip phenomenon. In general, low-frequency balance favors the orchestra pit for listeners on the orchestra level and is about even for listeners on the balcony. Full scale measurements suggest that the rake of the floor and the presence of local (early) reflectors increase balance to the benefit of the singers on stage. A simple 1:24 scale model has been built to test these and other phenomena in a controlled fashion. Measurements have also been performed in small-scale models of existing theaters. Early findings confirm the influence of seat dip on stage to pit balance.

5:15

1pAAb5. Compromises in orchestra pit design: A ten-year trench war in The Royal Theatre, Copenhagen. Anders Chr. Gade (Dept. of Acoust. Technol., Tech. Univ. of Denmark, Bldg. 352, DK-2800 Lyngby, Denmark, gade@dat.dtu.dk) and Bo Mortensen (Royal Acad. of Fine Arts, Copenhagen K, Denmark)

The ''old stage'' of The Royal Theatre in Copenhagen—a classical horseshoe theatre with an almost flat audience floor and four balcony levels—is the primary opera and ballet theatre in Denmark. In the early 1980s the orchestra pit was enlarged and its size made flexible. However, in the following years this new flexibility caused a formal battle between the orchestra, the singers, and management, because each group had different interests as to how the pit should be configured for each new production. In the 1990s, increased concern about the musicians' hearing and the increase in the popularity of opera finally opened the way for a new renovation of the pit, which solved most of the problems. The paper describes the many lessons learned during the ten-year period in which the authors were involved with the case as acoustic consultants. Questions of how pit configuration influences mutual hearing and exposure levels in the pit, balance between singers and orchestra as judged by the audience, communication between stage and pit, as well as the influence of pit floor construction on orchestra timbre will all be illustrated by results of numerous objective measurements, subjective surveys, and computer simulations.

Contributed Papers

5:35

1pAAb6. Study on experimental equations for on-stage acoustics design. Shun-ichi Nakamura (Tokyo Natl. Univ. of Fine Arts and Music, Tokyo, Japan, ezn0255@niftyserve.or.jp)

The relationship between the configuration of an orchestra shell and the acoustics inside have been studied based on the results obtained from the impulse response analysis using scale models of a series of 27 different conditions. Three points on a time profile curve were chosen as the acoustic factors in order to represent the onset process, the stationary state, and the decay process of the reflecting sound field, respectively. The averaged values adopted for discussion have been calculated using the data of three 1/1 octave bands around 1 kHz measured at three different positions in the main part of a stage floor. A remarkable difference in acoustics is found in the onset process between the cases with and without sound diffusers on the inner surface of a stage enclosure, and in the decay process as well. A faster rising in the onset process introduced by sound diffusers is followed by a faster decaying. They have a close connection. Finally, it is found to be possible to derive the experimental equations which relate these factors to the size and the shape of an orchestra shell, considering also the effect of reflections from the audience side of a hall.

5:50

1pAAb7. Measurements of orchestra acoustics. How reflecting surfaces influence ''Klangfarbe'' and the possibility of playing in time. Tor Halmrast (Statsbygg, pb. 8106 Dep. N-0032, Oslo, Norway)

When investigating room acoustics, and also stage acoustics, most concern is often based on ''how much energy arrives in the time interval between time x and,'' and not on how these reflections are distributed within that time interval and how that affects the Klangfarbe and rhythmic conditions. The stage acoustics of the Oslo Concert Hall was measured (MLS) with and without the orchestra on the stage, and with different settings of reflecting surfaces to achieve a better ''ensemble'' feeling (TOR measurements: Through Orchestra Response). Reflecting surfaces above, behind, and to the side of the orchestra were examined, with a questionnaire for each musician and a number of tonemeisters in the audience area. Similar measurements of the stage acoustics were done also in several European halls on the tour of the Oslo Philharmonic Orchestra/Mariss Jansons including Gasteig/Munich and Musikverein/Vienna. For further analysis of the ability of playing in time, measurements were done in the Hall for the Norwegian Radio Orchestra, with analysis of both orchestra tutti and multichannel recording situations. The paper analyzes the aspects of playing together in an orchestra, and especially how different placements of reflecting and diffusing elements affect the Klangfarbe and rhythmic conditions, both for the orchestra and the audience.

All posters will be on display from 2:30 p.m. to 6:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 2:30 p.m. to 4:15 p.m. and contributors of even-numbered papers will be at their posters from 4:15 p.m. to 6:00 p.m.

1pAAc1. Measurements and modeling of commonly used resilient channels in lightweight floor structures. Jonas Brunskog and Per Hammer (Eng. Acoust., LTH Lund Univ., P.O. Box 118, SE-221 00 Lund, Sweden)

A common part in lightweight floor structures is resilient channels between the joists and the ceiling. The purpose of the channels is to lower impact sound transmission in a broad frequency band. The channels are normally complicated to describe accurately from a structural acoustic point of view. The intention in this paper is to describe the channels by means of a simple structural acoustical model. The channels are divided into two types of elements. The first element is a beam. The second constitutes the mounting of the channels to the joist. The two elements are treated and analyzed both separately and connected to each other. The measurements are done by mainly measuring the accelerations on stiff bodies on the top and bottom of the test sample. The procedure is then repeated with a new set of stiff bodies. From these measured values (four different) one can determine the global two-port description. As a check there is also the reciprocity. As a comparison a method is used where the actual point force acting on the spring is measured and used. The model can be used as a base for analyzing the acoustical behavior of the resilient channels.

1pAAc2. Evaluation of the flanking transmission in a scale model of two adjoining rooms. Alessandro Cocchi, Giovanni Semprini, and Simone Secchi (DIENCA, Univ. of Bologna, via Risorgimentoz, 40136 Bologna, Italy)

Flanking transmission is the sound propagation through the lateral structures of two adjoining rooms. Evaluation of this transmission is possible with a statistical model of two rooms that considers mainly the reduction in vibration transmission between the partition and the lateral structures. With this model, which is the object of a project of international standard (Pr EN 12354), it is possible to evaluate the transmission through each path, considered independent of each other. The research carried out at the Acoustics Laboratory of the University of Bologna has validated the CEN model by measuring the vibration reduction index and the sound transmission in a scale model. The vibration transmission index has been measured both with transient and steady excitation of the structures, the first by means of a hammer and the second of an electromagnetic shaker. The sound reduction index of each path of transmission has been calculated measuring the mean pressure level in the source room and the mean vibration level of each structure in the receiving room. The paper presents the validation of the model with a comparison of the different kinds of measurement techniques.

1pAAc3. Classical analysis of multilayered walls transmission loss in comparison with the F.E.M. and S.E.A. approaches. Marco Fringuellino and Claudio Guglielmone (Acoust. Dept., I.E.N.G. Ferraris, Strada delle Cacce 91, 10135 Torino, Italy)

Prediction models of the acoustical behavior of multilayered soundproofing walls are of increasing practical interest in the field of building trade, particularly for designing applications. This paper reports a classical approach to the problem, whose aim is the theoretical calculation of the transmission loss of acoustical insulating multilayered walls. The model is based on the straight compilation of the ''progressive impedance'' encountered by the acoustical wave in its propagation through the wall. The pressures ratios at the ending surfaces of each layer are then computable as a function of the progressive impedances obtained before. The same is true for the total ratio of the incident and transmitted pressure. The characteristic impedance and the propagation constant of each layer are needed as input parameters. The results of the classical analysis are compared with a set of measurements performed on multilayered soundproofing walls. At present an effort is being made to develop a Finite Element Method and a Statistical Energy Analysis approach of the problem, to compare these theoretical results with the classical ones on the same set of walls. The final aim is to show the accuracy, the advantages, and the main limits of each of these three methods.

1pAAc4. Optimizing techniques for field testing of buildings. George Dodd (Acoust. Res. Ctr., Univ. of Auckland, Private Bag 92019, Auckland, New Zealand, g.dodd@auckland.ac.nz)

As national building codes and acoustic comfort standards become more common as tools for quantifying and promoting acoustical quality in dwellings there is a greater need for field testing of buildings. The intent of this project is the promotion of a greater use of field testing by providing more convenient measurement methods. Primarily the focus has been on identifying the ideal sound source. Explosive sources using charges produced for use in powder powered tools have emerged as satisfying the majority of our needs. Continuing study is aimed at optimizing such a source. In particular, it needs to produce adequate power for measuring at the low frequencies required for implementing the new spectrum adaptation terms for the traditional single-figure ratings of building insulation.

1pAAc5. Loss factor at the boundary of a single-leaf wall under a vibrational field of diffused bending waves. Soichiro Kuroki (Faculty of Eng., Kagoshima Univ., 1-21-40 Korimoto, Kagoshima, 890 Japan, kuroki@aae.kagoshima-u.ac.jp) and Masahito Yasuoka (Univ. of Tokyo, 1-3 Kagurazaka, Shinjuku, Tokyo, 162 Japan)

The internal loss factor (eta_{int}) is an important parameter in the case of calculating the transmission loss of a panel by using SEA (statistical energy analysis). Though energy loss at the edge is fairly large in practical walls, eta_{int} have been ordinarily treated including the edge loss. So it must be necessary to treat quantitatively the energy loss at the boundary of the wall. In this paper, assuming that a panel in excitation is a two-dimensional vibration field of diffused bending waves, a formula of the decay time of a panel is deduced. The subject for experimental study is an aluminum panel mounted in the opening between transmission suite. The panel is excited by a piezoelectric ceramic diaphragm. Vibrational decay time is measured by the impulse response method. The calculation method of the energy absorption coefficient and loss factor at perimeter is indicated by using measured values of decay time and sound radiation.

1pAAc6. Transmission loss measurement of multilayered partitions in time domain. Andre L. Cherman and Roberto A. Tenenbaum (Acoust. and Vib. Lab, Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil)

Transmission loss through single-layered partitions depends on the superficial specific mass *m* of the material. A multilayered partition has, at each interface, an impedance jump that improves its transmission loss. Due to these characteristics, multilayered partitions can provide better sound insulation than a single-layered partition with the same thickness, being much lighter. In this work an experimental setup was built to study the transmission loss of a sample inside a duct. The partition is inserted between two sections of the duct and a pulse is generated at one side. The incident and the transmitted signals are captured by free-field microphones, and the time domain series, acquired with a two channel digital oscilloscope, provides the transmission loss. The impedance of the materials tested was found experimentally and compared with tables, when available. The experiment was performed in order to evaluate transmission loss in single-, double- and three-layered partitions. The experimental results were compared with numerical simulation using the software LAYER, developed in our laboratory, showing good agreement.

1pAAc7. A safe method of truncating an echogram calculated by a sound ray technique. Jean J. Embrechts (Natl. Fund Sci. Res., Dept. of Acoust., Univ. Liege, Sart Tilman, B28, B4000 Liege 1, Belgium, jjembrechts@ulg.ac.be)

A recent international test of room acoustics computer simulations (presented by Prof. Vorlander at the 1995 ICA Congress in Trondheim) has shown the deviations that can occur between several programs when they are calculating the same acoustical parameters. Beyond data evaluation, the method of deriving these parameters from a computed echogram may be of significant importance. Therefore, the different steps in the calculation of the echogram by a sound ray technique are analyzed. In particular is shown the influence of the time discretization step (dt) and of the late part of this diagram (the tail) on the parameters T30 and EDT. An algorithm is proposed to reduce their influence. It consists in the truncation of the echogram at a well-chosen instant, independent of dt. Indeed, the tail of the echogram is greatly affected by statistical errors, and it is replaced by a linear decay, with a precisely defined slope, which is also independent of dt. The acoustical parameters are finally derived from this modified echogram. This algorithm is compared with other crude truncation procedures. It is shown that it significantly enhances the stability of the calculated results. Its performance is limited by the definition of T30 and EDT themselves.

1pAAc8. Sound sources and simulation software in room acoustics. Catherine Semidor and Leonie Couthon (ERIAC, Ecole d'Architecture et de paysage de Bordeaux, Domaine de Raba, F 33405 Talence Cedex, France, catherine.semidor@bordeaux.archi.fr)

There is a lack of data in directivity, power, and phase, and most of the time software users have no data at their disposal, so they use an omnidirectional sound source, or they calibrate the simulation with the measurements they operated *in situ*. But the use of the room is correlated to the kind of source that emits inside of it, so it is fundamental to know the statistical characteristics of emission of real sound sources. In this article, a survey about the way sound sources are taken into account in simulation software is proposed. Then an analysis is presented of a three-dimensional recording of real sound sources (musical instruments), to access to data in power and directivity, which tries to respond to the questions raised. And finally, the results obtained with different simulation software are presented. In conclusion, the need for standardization of sound source data is discussed.

1pAAc9. Applying the equivalent source method to the sound radiation from musical instruments in rooms. U. Peter Svensson, Mayumi Nakano, Kimihiro Sakagami, and Masayuki Morimoto (Environ. Acoust. Lab., Faculty of Eng., Kobe Univ., Rokko, Nada, Kobe, 657 Japan)

Musical instruments often have rather complicated radiation characteristics which have been documented for the case of free-field radiation. This paper studies the effect of the source location relative to the room boundaries on the sound radiation from musical instruments in rooms. The musical instrument is modeled by the equivalent source method, or source substitution method, so that the real source is replaced by a set of simpler sources which approximately reproduces the vibrations on the instrument's surface. A single corner with rigid walls is used to model the effects of the room boundaries on the sound radiation. As an example, a tympani is studied and theoretical expressions for its surface vibrations are used as input data. The directivity, and total power output, are then studied for various source locations. Possibilities for simplified source directivity modeling for room acoustical simulation are discussed.

1pAAc10. A study of the reverberant field in rooms with various absorptions, including prediction of spatial variation. Linda P. Franzoni (Ctr. for Sound & Vib., Dept. of Mech. & Aerosp. Eng., N. C. State Univ., P.O. Box 7910, Raleigh, NC 27695-7910)

The sound fields of two rectangular rooms of different size and proportion have been studied using a computer simulation. Point sound sources and absorbing walls are mathematically modeled and the wave equation is solved, the direct-field is removed, and the result is an exact calculation of the reverberant field in the room at any spatial location. Both the overall volume-averaged sound-pressure level and the spatially varying cross-sectional averaged levels are computed and compared to theoretical results. A new theoretical result for the spatial variation is developed using an energy balance applied to cross-sectional slices of the room. Good agreement is shown between this result and the calculated values. The same theory gives overall levels by integrating cross-sectional averages, this is compared to classical results (Sabine, etc.) and to the computer generated data. An improvement can be made to the classical theory by reducing the source power to account for first reflections. Some experimental results will also be presented for comparison. [Work sponsored by NSF.]

1pAAc11. Studying room acoustics using a monopole-dipole microphone array. Durand R. Begault and Jonathan S. Abel (San Jose State Univ., MS 262-2, NASA Ames Res. Ctr., Moffett Field, CA 94035)

The use of a sound field microphone for examining the directional nature of a room impulse response was reported recently [R. Essert, J. Acoust. Soc. Am. **100**, 2837(A) (1996)]. By cross-correlating monopole and colocated dipole microphone signals aligned with left–right, up–down, and front–back axes, a sense of signal direction of arrival is revealed. The current study is concerned with the arrays ability to detect individual reflections and directions of arrival, as a function of the cross-correlation window duration. If this window is too long, weak reflections are overlooked; if too short, spurious detections result. Guidelines are presented for setting the window width according to perceptual criteria. Formulas are presented describing the accuracy with which direction of arrival can be estimated as a function of room specifics and measurement noise. The direction of arrival of early reflections is more accurately determined than that of later reflections which are quieter and more numerous. The transition from a fairly directional sound field at the beginning of the room impulse response to a unidirectional diffuse field is examined. Finally, it is shown that measurements from additional dipole orientations can significantly improve the ability to detect reflections and estimate their directions of arrival. [Work supported by NASA.]

1pAAc12. Audibility of edge diffraction in auralization of a stage house. Rendell R. Torres and Mendel Kleiner (Chalmers Rm. Acoust. Group, Dept. of Appl. Acoust., Chalmers Univ. of Tech., S-41296 Gothenburg, Sweden, rendell@ta.chalmers.se)

A recent model for edge diffraction based on physical acoustics was applied to the auralization of a source in a stage house. In this paper the results of two methods of comparison (computation of frequency responses and evaluation of binaural listening tests) are used to judge the audibility of diffraction effects associated with such geometries. The computed impulse responses are also compared via binaural listening tests with measured impulse responses from a physical scale model. Current results indicate that, from an auralization standpoint, first-order diffraction is significantly more influential than second-order diffraction, which can lie more than 45 dB below the direct or specularly reflected arrivals. Thus, higher-order (and computationally more prohibitive) edge diffraction calculations may possibly be simplified or even neglected in auralization programs. [Work supported by Axel & Margaret Axson Johnsons Stiftelse, Sweden.]

1pAO1. Constraints on ocean internal wave spectra from long-range acoustic transmission data. John Viechnicki, Michael G. Brown (Appl. Marine Phys., Rosenstiel School of Marine and Atmospheric Sci., Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149), and the ATOC Group[a)]

Both full wave and ray-based predictions of acoustic wavefields at long range in deep ocean environments are compared to their measured counterparts, including the SLICE89 and AET data sets. The environment for these experiments was characterized by weak climatological range-dependent sound-speed structure, weak mesoscale structure, and moderately strong (typical) internal-wave-scale variability. The acoustic measurements are used to provide constraints on the statistics of the internal wave field, using the Garret–Munk spectrum as a starting point. Our attention is focused on the following parameters to which our simulations are sensitive: the strength parameter E, the mode number cutoff $j_{\max}$, and the horizontal wave-number cutoff values $k_{\min}$ and $k_{\max}$. [Work supported by ONR.] [a)]The ATOC Group: A. B. Baggeroer, T. G. Birdsall, C. Clark, J. A. Colosi, B. D. Cornuelle, D. Costa, B. D. Dushaw, M. Dzieciuch, A. M. G. Forbes, B. M. Howe, D. Menemenlis, J. A. Mercer, K. Metzger, W. H. Munk, R. C. Spindel, P. F. Worcester, and C. Wunsch.

1:45

1pAO2. Measurements of the travel-time bias caused by internal waves. Matthew Dzieciuch and the AST Group[a)] (Scripps Inst. of Oceanogr., Univ. of California, San Diego, 9500 Gilman Dr., La Jolla, CA 92093)

Theoretical work and computer simulations predict that the travel-time of acoustic signals is biased by the ocean internal wave field. The path integral theory for scattering predicts that the size of the travel time bias depends on the logarithm of the center frequency of the acoustic signal. A recent experiment, in which two acoustic signals with different center frequencies were transmitted simultaneously, makes it possible to measure the bias experimentally. Preliminary results suggest that the bias is about 50 ms at 3500-km range, which is roughly as large as expected. [a)]The AST group is T. G. Birdsall (U. Michigan), B. M. Howe (U. Washington), J. A. Mercer (U. Washington), K. Metzger (U. Michigan), R. C. Spindel (U. Washington), and P. F. Worcester (SIO).

2:00

1pAO3. Basin-scale internal-wave tomography using a large-aperture vertical array. John A. Colosi (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543), Bruce D. Cornuelle, Matthew A. Dzieciuch, Walter H. Munk, and Peter F. Worcester (Scripps Inst. of Oceanogr., La Jolla, CA 92093)

Basin-scale acoustic transmissions which are received at a large-aperture vertical line array (VLA), like those deployed for the Acoustic Thermometry of Ocean Climate (ATOC) program, provide several acoustic fluctuation observables that can be used for internal-wave tomography. A single receiver provides observations of wavefront travel-time variance, pulse time spread, and temporal signal coherence. A VLA adds the observations of vertical wavefront coherence and modal time spread and time coherence. The combination of wavefront and modal observations provides tomographic vertical resolution of average internal-wave energies as a function of depth. In addition, vertical and temporal wavefront coherences are complementary observations, since spatial and temporal internal-wave variabilities are related through the dispersion relation. Also, vertical and temporal coherences help test the assumption of a separable internal-wave spectrum in terms of frequency and vertical wave number. First efforts to combine several of these acoustic fluctuation observations from the ATOC North Pacific VLAs in an internal-wave tomographic analysis will be presented. Directions for future research will be discussed.

2:15

1pAO4. A statistical theory of low-frequency sound propagation through internal waves. Alexander G. Voronovich (NOAA/ERL/ETL and Univ. of Colorado/CIRES, 325 Broadway, Boulder, CO 80303, agv@etl.noaa.gov)

A statistical theory of propagation of low-frequency sound waves through stochastic internal wave (IW) field is suggested. This theory is based solely on the weakness of sound scattering over distances of the order of correlation radius of IW field. Estimates show that a corresponding small parameter is of the order of a few percent for sound frequencies up to 50–100 Hz. Hence the theory is quite adequate for practically interesting cases. The governing equations include both average field and cross correlators of acoustic modes and are generally 3D. Those equations are finite difference rather then differential. This allows one to avoid making rather restrictive assumptions which can be easily violated. However, in the appropriate limit those equations reduce to standard ''couple power equations'' by Dozier and Tappert. Decrement of attenuation of average mode amplitudes is linearly related to the spacial spectrum of IW. Thus, by measuring propagation of tonal low-power sound signals over distances of a few hundred kilometers with the help of mode-resolving line vertical arrays, it is possible to infer in detail spacial spectrum of different IW modes (a task which would be extremely expensive to solve with the help of traditional contact measurements).

2:30

1pAO5. Partially saturated transmission scintillation and the bias of the sonar equation. Nicholas C. Makris (MIT, Rm. 5-204, 77 Massachusetts Ave., Cambridge, MA 02139, makris@keel.mit.edu)

The statistical properties of partially saturated ocean-acoustic intensity measurements are analyzed. This extends and generalizes previous analysis for completely saturated measurements [J. Acoust. Soc. Am. **100**, 769–783 (1996)]. While the random component of the instantaneous field is a circular complex Gaussian random process in both saturated and partially saturated cases, a purely deterministic component is added in the latter but not the former. In both cases, the random component may contain a fluctuating signal as well as noise. The present analysis, therefore, is relevant not only to transmission scintillation but also to the general analysis of deterministic signals in additive noise. Analytic expressions are derived for the probability distributions and moments of finite-time averaged intensity and log-transformed intensity as a function of the time-bandwidth product of the measurement. From these, general formulas are obtained for the bias of the sonar equation and the standard deviation of the logarithmic measures commonly used in ocean acoustics. Asymptotic expressions are also derived for the various distributions examined and their moments.

2:45

1pAO6. 1000-km square scale propagation from ocean acoustic tomography experiment in the Kuroshio Extension region. Hidetoshi Fujimori, Iwao Nakano, Toshiaki Nakamura, Guan Yuan (Japan Marine Sci. and Technol. Ctr., 2-15 Natsushima-cho, Yokosuka, Kanagawa, 237 Japan), Takashi Kamoshida, and Akio Kaya (Oki Electric Industry Co. Ltd., 4-10-3 Shibaura, Minato-ku, Tokyo, 108 Japan)

An ocean acoustic tomography observation was carried out at JAMSTEC (Japan Marine Science and Technology Center) in the Kuroshio Extension region, east of Japan, from July to September 1997. In this observation, five transceivers (consisting of a sound source and hydrophone array) were used and arranged 28°−36° N, 143°−154° E area. The longest distance between transceivers was about a 1000-km range and moored about a 1100-m depth. These transceivers were communicated to eight times (in August) or four times (in July and September) a day of each other and a time series of 1000-km square propagation data in this observation area were recorded and analyzed.

3:00–3:15 Break

3:15

1pAO7. Preliminary results from a large-scale 3-D tomography experiment in the Kuroshio Extension region. Gang Yuan, Hidetoshi Fujimori, Toshiaki Nakamura, Iwao Nakano (Japan Marine Sci. and Technol. Ctr., 2-15 Natsushima-Cho, Yokosuka, 237 Japan), Takashi Kamoshida, Tatsuo Zaima, and Akio Kaya (Oki Electric Industry Co. Ltd., Shibaura 4-10-3 Minato-Ku, Tokyo, 108 Japan)

A large-scale three-dimensional acoustic tomography experiment has been conducted in the Kuroshio Extension region from July to September 1997. Five 200-Hz transceivers were moored in the 1000-km-diam region approximately centered at 33° N, 149° E. Larger-scale environmental surveys (XCTD, CTD, XBT, and ship-boarded ADCP) were conducted along several acoustic transmission sections during the deployment and recovery cruises. The purpose of this study is to show the results of the preliminary analysis of this data. The stochastic inversions provide the time evolution of the large-scale three-dimensional temperature fields. The 4-D temperature fields dynamically show the variability of Kuroshio Extension with high time resolution. An active and resolvable mesoscale cold eddy is present with variability typically dominated by motions with spatial scales of 100–200 km. The 2-D temperature field along a 1000-km section derived from acoustic data agreed well with that determined from the XCTD measurements during the deployment cruise. The preliminary results of the data analysis suggest that it is possible to monitor 4-D structures of the large-scale ocean (1000×1000 km) by tomographic measurements (five transceivers giving ten paths), which is very difficult and almost impossible to do by traditional point measurements.

3:30

1pAO8. Monitoring temperature variability along the California coast using acoustic tomography. Thierry Morvillez, Ching-Sang Chiu, and Curtis A. Collins (Dept. of Oceanogr., Naval Postgrad. School, Monterey, CA 93943, chiu@nps.navy.mil)

The electronic emissions of a low-frequency sound source placed by the Acoustic Thermometry of Ocean Climate (ATOC) project on Pioneer Seamount were monitored by a bottom-lying receiver on Sur Ridge from April 1996 to February 1997. The processed signals show a stable arrival pattern that was repeated in all the transmissions during the 11 months. Using the processed data, a tomographic analysis to study the coastal ocean variability along this California transmission path was conducted.

Systematically, the analysis involved forward acoustic modeling of the arrival structure using ray theory, associating the observed arrivals with the modeled arrivals, extracting the travel times of the arrivals, inverting the travel times for temporal and spatial temperature changes, and interpreting the observed temperature variations. In particular, the tomographic estimate was compared to the temperature and wind measurements from an *in situ* mooring deployed by the Monterey Bay Aquarium Research Institution (MBARI). The comparison shows that the tomographic estimate is of high quality and that the observed temperature variations were linked to coastal upwelling and downwelling events. The data, methods, and results, demonstrating fully the feasibility of using tomography to study coastal temperature variability in central California on a long-term basis, are presented.

3:45

1pAO9. Ocean acoustic tomography using explosive charges to observe the submerged mesoscale oceanic variability in the East Sea of Korea. Jung Yul Na, Sang Kyu Han (Dept. of Earth and Marine Sci., Hanyang Univ., 1271 Ansan, 425-791, Korea), and Taebo Shim (Agency for Defense Development, Chinhae, 645-600, Korea)

A tomography system consisting of aircraft-deployed shots as sources and a vertical line array moored by a receiver ship was used to survey a large area (120×120 km) where a mesoscale warm eddy appears frequently. The position of the shots was measured by the GPS on the aircraft and the detonation time (or depth) was monitored by sonobuoys which had been deployed close to the shot position. Results show that individual multipaths between a shot and the receiver contain substantial information for a vertical slice of the ocean with a warm eddy. With high accuracy, GPS positioning of shot locations, and receiver position, this rapidly deployable system can be used for monitoring the submerged structure of the warm eddy during the period of diffusive SST in summer in the East Sea of Korea. [Work supported by KOSEF.]

1pAO10. Three-dimensional classical dynamics of acoustic rays in a quasirealistic ocean. Michael A. Wolfson (Earth Systems Sci. Ctr., Penn State Univ., University Park, PA 16802) and Steven Tomsovic (Washington State Univ., Pullman, WA 99164-2814)

Simulations on multimegameter range scales are presented for the dynamics of classical acoustic rays in a three-dimensional ocean waveguide which contains sound-speed inhomogeneities derived from an ocean general circulation model. The inhomogeneities include scales equal to and larger than mesoscales (>20 km). Both horizontal and vertical two-dimensional deterministic ray propagation through mesoscale environments are known to exhibit chaotic behavior in the sense of exponential divergence of neighboring trajectories that are initially infinitesimally separated. The extra degree of freedom provided by an acoustic phase speed that is fully three dimensional allows a richer, more complex structure to be revealed. We use a Hamiltonian prescription for the ray dynamics to reveal this structure geometrically via the phase space evolution of the associated Lagrangian manifold. The linear transformation matrices for this system which describe how elements of phase space volume distort under the action of the dynamics are examined for a large subset of trajectories. It is shown that their associated exponential rates of divergence vary orders of magnitude. The relative importance of horizontal versus vertical folding in the trajectory manifolds is also discussed.

1pBV1. Acoustic microscopy in pathological specimens. Mike Halliwell, Joe Eavis, Peter NT Wells, and Jem Berry (Bristol Univ., Bristol, Medical Physics, Bristol General Hospital, Bristol BS1 6SY, UK)

The application of acoustic microscopy to biological targets is extremely limited. Devices operating at gigahertz frequencies have been proposed as replacements for conventional light microscopes with the advantage of utilizing unstained specimens. However, there remains the inconvenience of sectioning and very slow scanning speeds. Applications to unsectioned, thick specimens of unstained tissues with a view to reconstructing three-dimensional images remain uninvestigated. A 60-MHz scanning acoustic microscope was constructed with two coaxial transducers separated by about 10 mm. Linear and compound scans were performed throughout a specimen volume of about 5 mm^3. Standard pulse-echo slices, velocity maps, highly compounded images, and three-dimensional representations of the specimen were produced. Water-filled airways, in fetal lung, of 40 μm diameter were visualized, and compounding was found to yield this resolution in both axial and lateral directions. Three-dimensional images demonstrated airway morphology. Acoustic scanning microscopy has been shown to be feasible in 5 mm^3 soft tissue specimens. The images demonstrate pathological features in fresh unstained material. Potential for three-dimensional reconstruction of pathological morphology remains to be explored. [Work was supported by the Foundation for the Study of Infant Death.]

2:00

1pBV2. Tissue harmonic imaging in cardiology and radiology applications. Michalakis A. Averkiou, James R. Jago, David N. Roundhill, and Jeffry E. Powers (ATL Ultrasound, P.O. Box 30003, Bothell, WA 98041)

Harmonic imaging, the formation of ultrasound images from the harmonic components of the sonification signal, has been used in diagnostic ultrasound applications that utilize microbubble contrast agents. In the presence of microbubbles the harmonic signals are mainly due to nonlinear bubble oscillations. Recently, harmonic imaging has been applied without contrast agents, the harmonic signals arising from nonlinear propagation. Near-field artifacts and aberrations are reduced, and tissue borders are enhanced. The harmonic signals are at a lower amplitude and suffer more attenuation than the fundamental. However, the wide dynamic range, digital architecture, and signal processing capabilities of modern diagnostic ultrasound systems make it possible to utilize this tissue-generated harmonic energy for image formation. The nonlinear parabolic wave equation is used to model tissue propagation. A time domain numerical solution for a nonaxisymmetric source function is presented. Theory and experiments demonstrate harmonic generation in tissues. *In vitro* animal tissue experiments and *in vivo* collected radio frequency data are shown. A novel broadband pulsing scheme that uses two pulses with a phase difference of 180° is introduced, which results in cancellation of the propagated fundamental component and doubling of the second harmonic. Cardiac and abdominal harmonic images are shown.

2:20

1pBV3. Optical Sonography™, a new method of diagnostic imaging. George F. Garlick (Adv. Diagnostics, Inc., 2400 Stevens Dr., Ste. C, Richland, WA 99352)

The characterization of Optical Sonography™ has been measured and is reported. This new soft tissue imaging method, which utilizes the capabilites of acoustical holography, passes a plane wave of ultrasound through the tissue which imposes phase and amplitude information on the wave. This wave then carries information of the three-dimensional structure of the soft tissue being imaged. When combined with an ultrasonic reference wave, an acoustical hologram is formed which is reconstructed with coherent light (hence the name Optical Sonography™) to provide a real time image of the soft tissue. With Optical Sonography™ the image resolution is determined by the wavelength of sound interacting with points in the tissue rather than the focus size of the ultrasound as in the reflective mode. Thus theoretical limits of resolution are achievable; comparative resolution images will be presented. In addition, since over 99% of the ultrasound intensity passes through soft tissue interfaces, greater sensitivity is achieved. Imaging results using Optical Sonography™ will be presented.

2:40

1pBV4. Ultrasonic focusing and steering through the skull: Toward brain imaging. Mickael Tanter, Jean-Louis Thomas, and Mathias Fink (Laboratoire Ondes et Acoustique, E.S.P.C.I., Universit C5 Paris VII, U.R.A. C.N.R.S. 1503, 10 rue Vauquelin, 75005 Paris, France, michael@clara.loa.espci.fr)

The time-reversal method has been experimentally applied to the focusing through the skull bone. This technique needs the knowledge of the Green's function of a dominant scatterer available in the medium. Moreover, it is shown that the skull induces severe attenuation of ultrasound and reduces the efficiency of the time-reversal approach. Nevertheless, an improvement of time-reversal processing for ultrasonic waves focusing through an aberrating and absorbing layer can be achieved. When the attenuating layer is located close to the array, this method consists of inversing the amplitude modulation before the time-reversal operation. Conversely, when the attenuating layer is located some distance away from the transducer array, numerical backpropagation is used to discriminate between the amplitude modulations resulting, respectively, from interference and absorption. Moreover, although time reversal is only self-adaptative to the artificial source implanted inside the imaging volume, this method is generalized to steer the ultrasonic beam on other points surrounding this acoustic source. This process has already been applied to hyperthermia through the skull bone and it can be applied to noninvasive brain imaging.

1pBV5. High resolution ultrasound imaging system for soft tissues. S. G. Ye, X. Z. Liu, X. F. Gong, W. Y. Zhang (Inst. Acoust. and Lab. Modern Acoust., Nanjing Univ., Nanjing 210093, PROC), Y. Q. Jia, and X. Y. Tan (Jiangsu Cancer Hospital, Nanjing 210009, PROC)

The great interest in high resolution (higher than 0.1 mm axially and 0.3 mm laterally) ultrasound imaging systems for application to the skin, eye, intestinal wall, etc., gives rise to the development of a high resolution ultrasound imaging system. In this study, the high resolution ultrasound imaging system with a frequency range from 20 to 40 MHz was developed. In the system described here, the different resolutions were obtained by means of the focused transducers with different center frequencies in the frequency range mentioned above. In designing and fabricating the PVDF transducer, the KLM equivalent circuit including internal loss was developed and the influence of the PVDF film and backing materials on the transducer characteristics were analyzed as well. The experimental results were compared with the analyzed results. High resolution ultrasound imaging of some soft tissue samples was obtained. Besides the ultrasound parameters such as speed of sound, the attenuation coefficient and backscattering coefficient were measured in the frequency range from 20 to 40 MHz. [Work supported by NSF of Jiangsu Province, China.]

1pBV6. Inverse imaging of the breast using a conjugate gradient-neural network technique. Xiaodong Zhang, Shira L. Broschat, and Patrick J. Flynn (School of Elec. Eng. and Comput. Sci., Washington State Univ., P.O. Box 642752, Pullman, WA 99164-2752)

Early detection of a breast tumor greatly improves the chances of survival. Thus it is important to develop high-resolution imaging techniques capable of detecting small tumors. In this paper, an ultrasound imaging technique is presented that is based on solving the two-dimensional inverse scattering problem. An object is reconstructed using an iterative algorithm that combines the conjugate gradient method and a

neural network (CGNN) approach. The neural network technique exploits prior knowledge of the statistical characteristics of the different tissues inside the breast to enhance the performance of the conjugate gradient (CG) method. The CGNN algorithm has been tested on two small models simulating a breast tumor surrounded by glandular tissue. One model presents a tumor 3 mm in size and the other a tumor 1 mm in size. Results show that the CGNN algorithm is more accurate than the CG method. In addition, convergence occurs more rapidly; with the CGNN algorithm approximately 40% fewer iterations are needed to obtain the inverse solution. The CGNN method also appears to be robust to noise. Results are still reasonably good for a signal-to-noise ratio of 35 dB. Numerical results will be presented and discussed. [Work supported by NSF and the Carl M. Hansen Foundation.]

1pBV7. A filter-based pulse-echo coded-excitation system for real-time cardiac imaging. Emad S. Ebbini, Jian Shen, and Idris Elbakri (Dept. of EECS, Univ. of Michigan, Ann Arbor, MI 48109-2122)

A new filter-based approach to pulse-echo imaging capable of parallel processing of multiple image lines has been developed. A major application of this approach is in true real-time 3D imaging, e.g., in cardiac imaging. The new approach utilizes a set of coded waveforms on transmit and conventional beamforming on receive. The transmitted codes produce a coded wavefront in the region of interest (ROI) and the receive beam is designed to be wide enough to allow echoes from the ROI to be received while rejecting echoes from outside the ROI. Image formation is achieved using a filter bank structure (post-beamforming) with every filter designed to extract echoes from a given direction in the ROI. The filter bank is derived from a regularized pseudoinverse operator of the (discretized) propagation operator from the ROI to the receiving array. Image reconstructions from speckle-generating phantoms using the new approach demonstrate its robustness and its potential in medical imaging applications. A complete description of the algorithm and its fundamental spatial and contrast resolution limits will be presented with illustrative experimental data. System architectures for robust real-time implementation will be discussed. [Work funded by NIH Grant HL57167.]

1pBV8. Main error sources in ultrasound transmission tomography imaging. Krzysztof J. Opielinski and Tadeusz Gudra (Inst. of Telecommunication and Acoust., Wroclaw Univ. of Technol., Wybrzeze Wyspianskiego 27, 50-370 Wroclaw, Poland)

Ultrasound transmission tomography (UTT) consists in the usage of information included in ultrasonic pulses penetrating through an object in order to reconstruct sectional images of its inner structure. The contrast in the images corresponds to the distribution of local values of the acoustic parameter measured in projections. The measurement errors usually distort the tomographic image of the inner object structure. How different measurement errors are manifested and how big the changes they bring about in the reconstructed tomographic image can be fundamental for the determination of the ultrasound transmission tomography application range. The main sources of errors in ultrasound transmission tomography are the measurement accuracy and geometry, the ultrasonic refraction, the changing of measurement conditions, the measurement method, the reconstruction algorithm, and the disappearance of the receiving signal. Some different tomographic measurement errors (caused by the above-mentioned sources) were computer simulated and compared with the real ones. The influence of these errors on the ultrasonic tomographic imaging was shown. All of these errors refer to the run-time measurements in the parallel ray projection geometry using the convolution and backprojection algorithm for the image reconstructions.

1pBV9. Aggressive region growing filtering for speckle reduction in ultrasound images. Yan Chen (Siemens Med. Systems), Ruming Yin, Patrick Flynn, and Shira Broschat (Washington State Univ., Pullman, WA 99164-2752)

Speckle noise is present in all conventional ultrasound images, and complicates the process of diagnosis as it can mask small but diagnostically significant features. Speckle reduction techniques can be applied prior to image formation [e.g., Chen *et al.*, J. Ultrasound Imag. **18**(2), 122–139 (1996)] or after image formation. Post-formation techniques can be implemented in software, whereas pre-formation techniques generally require hardware modifications. The approach described here is applied after image formation, and consists of two steps. In the first step, small ''seed'' regions are defined around each pixel in the image, and a homogeneity criterion is used to guide a procedure which identifies the maximal-size homogeneous region containing the pixel of interest. Once determined, this region is smoothed using a truncated arithmetic mean filter. Results on synthetic and real images demonstrate that this method preserves the sharpness of image edges yet reduces speckle noise, and compares well with weighted median filtering [Loupas *et al.*, IEEE Trans. Circuits Syst. **236**, 129–135 (1989)] and homogeneous region growing median filtering [Koo and Park, J. Ultrasound Imag. **13**, 211–237 (1991)]. [Work supported by NSF and the Carl M. Hansen Foundation.]

4:30

1pBV10. Image-based calculation of elevational B-scan separation. Jochen Krücker, Theresa A. Tuthill, Gerald L. LeCarpentier, J. Brian Fowlkes, and Paul L. Carson (Dept. of Radiology, Univ. of Michigan Medical Ctr., Kresge III, 200 Zina Pitcher Pl., Ann Arbor, MI 48109-0553, jokr@umich.edu)

A speckle decorrelation technique was extended to high-frequency imaging to calculate the elevational (out of plane) separation of B-scan images. Pure speckle images were obtained with a 13-MHz, 1.5-D array in an elevational sweep over a phantom in 25-μm steps. For each pixel the plane-to-plane autocorrelation function was computed for a number of frames and fit to a Gaussian to find the depth-dependent scaling factor between the rate of speckle decorrelation and the actual frame spacing. From this the frame separation in sets of images containing speckle and structure was determined. To avoid using specular signals the mean intensity over standard deviation was employed to automatically detect areas of speckle. Based on the speckle decorrelation in these regions and using a 200*300 pixel subimage the frame spacing (100 μm) was calculated with 2% accuracy. The error increased with decreasing number of pixels and increasing separation of the frames. The technique can now be combined with high frame rate techniques to determine the elevational transducer motion during complex-motion 3-D scanning of the breast. [Work partially supported by the U.S. Army, Medical Contract DAMD17-96-C-6061 and the German Academic Exchange Service.]

1pEA1. Acoustic detection of a non-metallic object embedded in a ground material. Hasson M. Tavossi and Bernhard R. Tittmann (Penn State Univ., Dept. of Eng. Sci. and Mech., State College, PA 16802)

The preliminary results of acoustic detection of a nonmetallic object embedded in a ground material model at a shallow depth is investigated. The frequency range of the acoustic wave is optimized to the composition of the ground material model to obtain minimum attenuation of the received signal. The investigation considers both theoretical and experiment aspects of the problem to provide a better understanding of the interaction of the acoustic waves with the ground model and the embedded nonmetallic object. One part of the theory is aimed at finding the optimal acoustic signal with maximum ground penetration as a function of frequency, band width, signal energy, and other wave characteristics. The other part of the theory considers ground material characteristics such as grain size and contact areas, density, rigidity, and porosity. In the experimental investigation both through-transmission and pulse-echo methods are used. The results include the relationship between the optimal frequency for maximum amplitude of the received signal, wave velocity, band-width, incident direction, signal energy, attenuation, ground material, and the embedded object characteristics.

1pEA2. High-frequency imaging of thickness degradation in steel containment vessels and liners. Joseph E. Bondaryk (Eng. Technol. Ctr., 200 Boston Ave., Ste. 2500, Medford, MA 02155, bj@arctic.mit.edu)

An area of concern in some nuclear power plants is thickness degradation of embedded steel containments just below the interface where the steel enters concrete. This is an area which cannot be examined by traditional UT testing, due to the inaccessibility imposed by the concrete. In this numerical feasibility study, high-frequency vibrational sources placed above the interface are used to excite elastic waves in the steel, which propagate into the embedded area. The waves that reflect and scatter from the surface roughness caused by thickness degradation are detected and used to determine and map the degradation of the steel. A range-dependent, stratified layer, wave-number integration based, numerical model (OASES) is used to calculate the field in the scenario. Decomposition of the field into longitudinal, shear, and surface waves is used to determine the optimal transducer orientations for transmit and receive. [Work supported by the Nuclear Regulatory Commision.]

1pEA3. The piezoelectric implant method compared to classical ultrasonic spectroscopy: Application to the monitoring of polymer curing. Agnes Raquois, J. Mohamed Tabellout, Jacques Emery (Gr. Ultrasons. Lab. de Chim. et Phys. des Materiaux Polymeres, UMR CNRS 6515, Univ. du Maine, 72035, Le Mans, France, ultrason@aviion.univ-lemans.fr), and Yves Jayet (GEMPPM-INSA, 69621 Villeurbanne Cedex, France)

Previous studies have described an original method enabling the *in situ* real time monitoring of a composite polymer structure by means of an inserted piezoelectric sensor. An analytical one-dimensional model has demonstrated that the electrical impedance of such an inserted element depends in particular on the acoustical parameters of the surrounding media. Then, by solving the inverse problem by means of a nonlinear optimization algorithm, it is possible to determine these acoustical parameters characteristic of the materials in contact with the inserted piezoelectric plate. This technique has been applied to the monitoring of the cure of gel-forming and glass-forming polymers such as polyurethanes and epoxies and compared to classical ultrasonic spectroscopy method. Thus it is possible to detect chemical evolution, transitions, and damage phenomena in such systems, provided that the material is homogeneous in the ultrasonic field or in the area surrounding the piezoelectric element. Particular attention has been focused on a polyimide (PMR-15) which is used as a matrix for composites in high-temperature applications. [Work supported by SNECMA/HISPANO-SUIZA.]

1pEA4. Interface wave source concepts for a seismic sonar concept. Frederick E. Gaghan, Steven R. Baker, and Thomas G. Muir (Phys. Dept., Naval Postgrad. School, Monterey, CA 93943-5000)

A seismic sonar concept is being developed which employs guided interface (Rayleigh or Scholte) waves to detect objects buried in sea floor and beach sediments. These waves have the desirable characteristics for this application that (1) they are localized near the interface and (2) the propagation from a compact source is cylindrical. As a result, the wave intensity on targets of interest is enhanced and the reverberation suppressed, compared to a bulk wave. To selectively excite Rayleigh or Scholte waves, a harmonic source employed at the interface must excite elliptical particle motion in the vertical and propagation, or radial, directions. Several such source concepts will be described. Results to date of field tests employing these sources in narrow-band pulse tests will be described. [Work supported by ONR Code 321OA.]

2:00

1pEA5. Approximate computational model for sound generation due to unsteady flows in pipes. Michael Krane, Daniel Sinder, and James Flanagan (CAIP Ctr., Rutgers Univ., Piscataway, NJ 08855)

A model for the generation of sound due to unsteady vortical flow in pipes of varying cross-sectional area is described. The model is based upon Howe's acoustic analogy and an approximate model for the vorticity field. This formulation allows the sound generation to be specified in terms of properties of the unsteady behavior of the vortical flow and the potential flow solution for the pipe that would exist in the absence of vortical inhomogeneities. The approximate model for vorticity formation and evolution is presented, and the potential flow solution is obtained from the axial duct shape. Computed estimates of the time evolution of both a jet passing through a pipe constriction and the sound this flow produces are presented and compared to experimental data. [Research supported by NSF/ARPA IRI-9314946 and ARPA DAST 63-93-C-0064.]

2:15

1pEA6. Acoustic-wave detection by optical beam deflection. James N. Caron, James B. Mehl (Dept. of Phys., Univ. of Delaware, Newark, DE 19716-2570, jcaron@udel.edu), and Karl V. Steiner (Univ. of Delaware, Newark, DE 19716-3144)

Audio-frequency acoustic signals in gases have been detected by measuring the bending of an optical beam directed through the gas to a custom-built position-sensitive photodetector. The beam deflection is caused by a transverse acoustic density gradient, and can be calculated when the acoustic field is known. The spectrum of a cylindrical resonator was recorded using both a calibrated microphone embedded in one end of the cylinder, and deflection of a laser beam passing through the center of the cylinder along a diameter. Beam deflection is expected for the first plane-wave mode of the resonator and other modes having nonzero average transverse density gradients along the beam path. The observed beam deflections were in qualitative agreement with calculations for all modes which could be resolved. For the first plane-wave mode, the measured and calculated deflections agreed within a few percent. Refinement of this technique could be applied to the absolute calibration of microphones. The beam-deflection technique was found to be sufficiently sensitive for the recording of voice and musical instruments, both in digital form on laboratory instruments and on audio tape. [Work supported by the Army Research Office.]

2:45

1pEA7. Laser-based ultrasonic NDE using gas-coupled laser acoustic detection. James N. Caron, Yuqiao Yang, James B. Mehl (Dept. of Phys., Univ. of Delaware, Newark, DE 19716-2570, jcaron@udel.edu), and Karl V. Steiner (Univ. of Delaware, Newark, DE 19716-3144)

An optical beam-deflection technique has been applied to the ultrasonic inspection of materials. The technique is similar to air-coupled detection, except the airborne wave is detected through beam deflection instead of with an electro-acoustic transducer. It is a noncontact, laser-based, detection technique that does not depend on reflection of the detection laser beam from the surface. It is thus independent of the surface optical properties of the material under test, and is particularly suitable for testing polymer/graphite composites, which have rough surfaces of poor optical reflectivity. The beam is directed parallel to the surface of a solid material under investigation and is incident on a custom-built position-sensitive photodetector. A wave is radiated from the surface into the surrounding gas during reflection of elastic waves in the solid. The transverse acoustic density gradients cause a beam deflection which is clearly observable with the photodetector. Applications of gas-coupled laser acoustic detection (GCLAD) with laser ultrasound generation will be illustrated with (1) waveforms showing numerous, well-resolved echoes, (2) C-scans showing subsurface defects, and (3) surface acoustic waves. The samples tested include several types of polymer/graphite composites. [Work supported by the Army Research Office.]

1pEA8. Direct detection of acoustic waves by laser light diffraction and proposals of the optophone. Yoshito Sonoda (Dept. of Elec. Eng., Kyushu Tokai Univ., 9-1-1 Toroku, Kumamoto 862, Japan, ysonoda@ktmail.ktokai-u.ac.jp)

The conventional light diffraction method cannot be applied to the measurement of the acoustic waves with a long wavelength, where the diffracted optical waves propagate in the penetrating optical beam and cannot be measured because of the disturbance by the latter. In this study, the Fraunhofer diffraction method, which was developed as a new means to detect the electromagnetic radiation scattered within the penetrating light beam in the plasma-nuclear fusion research, is applied to the measurement of acoustic waves. It is experimentally demonstrated that the acoustic wave with a wavelength longer than 8.5 mm can be detected by a visible laser of 5 mW, and the amplitude of the electrical output signal from a photodiode is linearly proportional to the sound pressure and the probe laser power, as predicted by the theory. The frequency property and directivity of the optical sound-antenna are roughly estimated by the preliminary experiment. Furthermore, the Optophone (the optical microphone) of various types are proposed as a new acoustic detection method.

3:15

1pEA9. Nondestructive SAW technique of acoustic transient spectroscopy to study deep centers in semiconductor heterostructures. Peter Bury and Igor Jamnický (Dept. of Phys., Žilina Univ., 010 26 Žilina, Slovak Republic, bury@fel.utc.sk)

A new technique of acoustic deep level transient spectroscopy (A-DLTS) using a high-frequency transverse acoustoelectric signal produced by a surface acoustic wave (SAW) electric field was used to study deep centers in semiconductor heterostructures. The basic idea of the presented A-DLTS technique is connected with the fact that the time development of the acoustoelectric response signal arising from the interaction between the SAW electric field and free carriers at heterostructure interface after an injection bias voltage pulse has been applied reflects relaxation processes associated with the thermal recombination of excited carriers moving toward their equilibrium state. The technique of computer evaluation of isothermal acoustoelectric transients applying the date compression algorithms [P. Bury and I. Jamnický, Acta Phys. Slovaca **46**, 693–700 (1996)] was used to calculate deep center parameters as activation energies and capture cross sections. The technique has been applied for both Si MIS and GaAs/AlGaAs heterostructures. [Work supported by Grant of Slovak Ministry of Education No. 1/4261/97.]

3:30

1pEA10. Acoustic spectroscopy of deep centers in high resistivity GaAs using a light beam generated interface. Peter Bury (Dept. of Phys., Žilina Univ., 010 26 Žilina, Slovak Republic, bury@fel.utc.sk)

An acoustoelectric effect on a light beam generated interface of high resistivity Cr-doped GaAs is used as a probing tool to study bulk deep centers using acoustic deep-level transient spectroscopy (A-DLTS). The space charge inhomogeneity, produced by the illumination of part of the photoresistive semiconductor by weakly absorbed light, can be generated by applying a high-frequency electric field in the proper conditions for the fast mode shear acoustic wave. The amplitude of such a generated acoustic wave depends on the concentration of free carriers excited from the deep centers at the light–dark interface. When the illumination of the semiconductor is turned off, the photoexcited carriers recombine thereby establishing thermal equilibrium and temperature dependence of the time develop-

ment of the amplitude. The acoustoelectric response signal is then investigated to determine the deep centers' parameters. The A-DLTS technique, based on the computer evaluation of acoustoelectric isothermal transients registered after the excitation illumination [P. Bury and I. Jamnický, Acta Phys. Slovaca **46**, 693–700 (1996)], was used to calculate activation energies and capture cross-sections of deep centers in Cr-doped GaAs. [Work supported by Grant of Slovak Ministry of Education No. 1/4261/97.]

MONDAY AFTERNOON, 22 JUNE 1998 METROPOLITAN BALLROOM (S), 1:00 TO 3:00 P.M.

Session 1pED

Education in Acoustics: Take Fives—Sharing Ideas for Teaching Acoustics

Thomas D. Rossing, Chair
Physics Department, Northern Illinois University, DeKalb, Illinois 60115

Do you have a novel demonstration, a new laboratory experiment, a favorite video, a recorded sound example, or a new idea for teaching acoustics that you would be willing to share with your colleagues? At this session, there will be a sign-up board for scheduling the presentations. No abstracts are printed, although some presenters may have handouts to distribute to their colleagues. You may sign up for more than one presentation (but not consecutively); presentations are strictly limited to 5 minutes. Keep them short! Keep them fun!

MONDAY AFTERNOON, 22 JUNE 1998 FIFTH AVENUE ROOM (W), 2:15 TO 6:00 P.M.

Session 1pMU

Musical Acoustics and Psychological and Physiological Acoustics: The Purposeful Use of Nonlinear Distortion in Musical Performance: The Eric Dolphy/Jimi Hendrix Celebratory Session

Edward M. Burns, Chair
University of Washington, JG-15, 1417 NE 42nd Street, Seattle, Washington 98105-6248

Chair's Introduction—2:15

Invited Papers

2:20

1pMU1. Some nonlinear aspects of the ear as a sound detector and a sound emitter: Comparisons with properties of musical instruments. Arnold Tubis, Carrick L. Talmadge (Dept. of Phys., Purdue Univ., West Lafayette, IN 47907), and Glenis R. Long (Purdue Univ., West Lafayette, IN 47907)

A compressive nonlinearity in the mechanics of the cochlea is responsible for (1) the dynamic detection range of about 120 dB; (2) the level-dependent modification of the ability to detect one tonal component in the presence of another (masking); (3) the stabilization of cochlear self-oscillations, which are associated with sounds broadcast from the ear (spontaneous otoacoustic emissions); and (4) the psychoacoustic detection and detection in the ear canal of frequency components (intermodulation distortion products) not present in the original acoustic signal. The spontaneous otoacoustic emission spectra are characterized by quasi-regular frequency spacings, with some ears having over 30 narrow-band spectral peaks. The intermodulation distortion level is higher than that claimed for mediocre stereo systems and varies with frequency. Several interesting analogies between the modeling of otoacoustic emissions and the sound spectra of musical wind instruments are discussed. [Work supported by NIDCD.]

2:45

1pMU2. Deliberate use of distortion in singing. Ingo Titze (Dept. of Speech Pathol. and Audiol. & The Natl. Ctr. for Voice & Speech, Univ. of Iowa, Iowa City, IA 52242)

Singers are able to create aperiodic vibration of the vocal folds by either desynchronizing the primary oscillators (the vocal folds) or by engaging secondary sound sources (the false vocal folds, the aryepiglottic folds, or the velum). The desynchronization of the primary oscillators can be accomplished by creating a slight left-right asymmetry and then using the vocal tract (an acoustic oscillator) to entrain one vocal fold, leaving the other vocal fold to oscillate independently. Other aperiodicities can be created by driving the

vocal folds at large amplitudes (with the critical parameter being A/L, the amplitude to length ratio of the vocal folds). In this mode of distortion, the highly nonlinear stress-strain characteristics of the vocal fold tissues are exploited. Infant cries, shouts, and groans are characteristic of this type of nonlinearity. Some videotaped examples and some computer simulations will be given to illustrate these phenomena.

3:10

1pMU3. An acoustical appreciation of the extended performance aspects of Eric Dolphy's musical craft. Douglas H. Keefe (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131)

The late 1950s and early 1960s was an era of rapid innovation in jazz in which musicians transformed the compositional and improvisional form of the music. While instrumentalists have incorporated extended performance techniques in a unique manner from the beginning of jazz, an important aspect of the avant garde movement was the breadth of innovation in woodwind instrument performance. Eric Dolphy was a pioneer in this respect, a virtuoso performer of the alto saxophone, bass clarinet, and flute, who helped bring the latter two instruments into prominence within jazz as solo instruments for improvisation. Literal acoustic distortion is present in woodwind multiphonics used by Dolphy and others, produced not merely by using unconventional fingerings and changes in embouchure, but also by alterations in the resonances of the player's vocal tract [Wilson (1996)]. Aesthetic distortions include the sheer temporal complexity of melodic lines, which cannot be separately resolved by many listeners, and the inclusion of speechlike and bird-song elements within extended musical forms lacking a conventional harmonically related musical structure. Such factors contribute to the overall artistic impact of this music.

3:35

1pMU4. Eric Dolphy's playing style in the Vienna Art Orchestra's performance. Alexandra Hettergott (Inst. of Wiener Klangstil, Univ. of Music, Singerstrasse 26a, A-1010 Vienna, Austria)

Aiming on the very musical expression intended, ''tone colorist'' Eric Dolphy in his developed avantgarde jazz playing style on alto sax and bass clarinet as well as on flute makes use of several extraordinary playing techniques (e.g., multiphonics). In musically portraying him [*Nine immortal non-evergreens for Eric Dolphy*, Amadeo 537 096-2], the now 20-year-old Vienna Art Orchestra in a postmodern way renders Dolphy's compositions in their very performance style, adopts and adorns his melodies typically performed in a highly expressive, noise-inducing way with their own instruments' rich means of expressions, allowing also for brass instruments. Consequently, the bass clarinet in *Hat and Beard* is given in solos of trumpet, trombone, and alto sax, the flute in *Gazzelloni* reflected in both trumpet and f- horn solos, or the alto sax in *Straight Up and Down* expressed in solos of either trumpet, trombone, and alto sax, respectively. In sound analyses along with sound examples the paper compares several of Dolphy's playing techniques in his original late recordings (1964) with the recent performances by the Vienna Art Orchestra (1995), focusing on the wind instruments' (unusual) sounds as part of the personal aesthetics of expression in both model Dolphy and the Vienna Art Orchestra.

Invited Papers

3:50

1pMU5. When bad amplification is good: Distortion as an artistic tool for guitar players. Tilmann Zwicker (Feldstraße 5, D-82057 Icking, Germany) and Søren Buus (Northeastern Univ., Boston, MA 02115)

This presentation surveys the development of and the approaches to distortion for electric guitars, which plays an extremely important role in modern popular music, particularly in Rock, Blues, Jazz, and Pop. The signal processing for guitar amplification has always included nonlinear effects that are usually heard as distortion, but also lends other important characteristics to the guitar tone. Originally, distortion occurred as musicians tried to coax more volume out of their amplifiers than they were designed to deliver. However, this ''design flaw'' soon became a tremendous asset. Guitarists discovered that, if handled properly, distortion gave their instruments an expressive, harmonically rich, and highly controllable voice rivaling that of horn players. Today, distortion for electric guitars has been cultivated to the extent that it is deliberately designed into every guitar amplifier. Characteristics of electric-guitar signals and distortion devices will be discussed and illustrated with examples. The reasons why distortion is a desirable artistic tool and related psychoacoustic aspects also will be discussed.

4:15

1pMU6. Jimi Hendrix' use of distortion to extend the performance vocabulary of the electric guitar. James J. Fricke (Experience Music Project, 110-110th Ave. NE, Ste. 550, Bellevue, WA 98004)

Experience Music Project is an interactive music museum scheduled to open in Seattle in 1999. Sound Lab, the hands-on portion of the museum, will use a variety of exhibit techniques to lead the visitor to explore music composition and performance, the technology of popular music making, and the physical principles involved in sound production and reproduction. The role of acoustics and signal processing in the development and realization of these exhibits is discussed. Jimi Hendrix, who pioneered the use of electronic effects in extending the expressive vocabulary of the electric guitar, is central to one planned exhibit. Hendrix' ''Drivin' South'' guitar solo from 1967 is presented as an example of the extended expressive possibilities afforded by a highly overdriven, amplified electric guitar. This use of distortion for artistic effect is analyzed, and the performance is compared to an undistorted performance of the same piece. The electronic means for achieving the distorted guitar sound is presented using artifacts from EMP's Jimi Hendrix collection, and the resulting signal modification is demonstrated and analyzed.

4:40–4:55 Break

4:55–6:00 Dolphy/Hendrix Memorial Jam

Following the formal session there will be a jam session in which several of the presenters will participate, along with local musicians expert in the techniques pioneered by Dolphy, Hendrix, and others.

Noise: Impulse Noise Assessment

Paul D. Schomer, Chair
U. S. Army Construction Engineering Research Laboratory, P.O. Box 9005, Champaign, Illinois 61826-9005

Chair's Introduction—2:15

Invited Papers

2:20

1pNSa1. Impulse noise and startle. Ian H. Flindell (Inst. of Sound and Vib. Res., Univ. of Southampton, Southampton, UK)

It is well known that impulsive noise caused by gunfire, explosive devices, and high speed overflight by aircraft at low altitudes can cause an acoustic startle effect (ASE). The ASE is one of many possible startle effects which are normally associated with unexpected stimuli. The ASE always consists of a sequence of largely defensive reflex actions with physical, physiological, and psychological components. It is generally accepted that the ASE can be a direct contributor to accidents in inherently risky situations, but what is more controversial is the possibility of some, presently undefined, linkage to longer term health effects. Based on a critical review of the literature, this paper reports some general findings on the possible theoretical bases for any such linkage and makes a number of suggestions for future research. The available evidence suggests that if there is such a linkage, it must be mediated either through individual differences in reactivity and habituation, or through the less well-specified ''general stress hypothesis.'' The fact that many of the direct physiological responses observed in the ASE are not generally considered harmful in other contexts, such as exercise, is likely to be an important consideration.

2:40

1pNSa2. Comparison of procedures for the quantification of the impulsivity of environmental sounds. Giovanni Brambilla (CNR Istituto di Acustica, via Cassia 1216, I-00189 Roma, Italy, gianni@idac.rm.cnr.it)

Any procedure for the quantification of the impulsivity of environmental sounds should meet the following requirements: (i) sufficiently adequate in describing the human perception of impulsivity; (ii) easy to perform in the field by means of basic instrumentation or in the laboratory without requiring expensive apparatus and too much time. Among the several procedures proposed in the last decade, those more frequently used or promising have been considered in this paper and compared to one another. For this purpose data collected in earlier European studies have been reanalyzed. The data considered refer to 26 environmental sound stimuli heard in laboratory at 55 L_{Aeq} level for 20 s by a number of people varying between 48 and 112 subjects. The subjective data on clear perception of impulsivity have been related to the selected descriptors, such as LAI-LAS, increment, etc. The potential of these objective parameters in describing the perception of impulsivity, as well as the determination of the threshold value for the onset of impulsivity, has been investigated by means of their correlation with the subjective data and determination of sensitivity and peculiarity of each descriptor.

3:00

1pNSa3. On fitting functions to data for the percent of a community highly annoyed by noise such as impulsive noise. Paul Schomer (U.S. Army Construction Eng. Res. Labs., P.O. Box 9005, Champaign, IL 61826, schomer@uiuc.edu) and Karl Hirsch (Inst. for Noise Protection, Duesseldorf, Germany)

Survey respondents ''highly annoyed'' (HA) typically are categorized as those responding in the top 30% on an anchored numerical scale or in the top two categories on an adjectival scale. The percent HA typically ranges from 0% to 40%. At higher percents HA (e.g., $>15\%$), the noise stimulus is clear and dominant and the reliability to the percentage values is high. At low percentages, the reliability is low. Some respondents may be annoyed any time they hear a sound. Depending on the number of such respondents, the percent HA can vary greatly on a percentage basis (4% HA versus 2% HA is a change of 100%). Therefore, alternatives to using small percentages HA (e.g., $<10\%$) are considered when fitting transition functions to HA data. One method is

to approximate the transition function by three asymptotes. The transition (sloped) asymptote would be fit by the 50% point and the slope when the percentages HA were large. Another way to avoid small percentages HA is to consider the group ''little annoyed'' or ''happy.'' This category might include the bottom two categories on a five-point adjectival scale or the bottom 30% on a numerical scale. This paper explores these issues.

3:20

1pNSa4. On the rating of high-energy impulsive sounds: Optimization of a level-dependent conversion procedure with the help of new field survey results. Joos Vos (TNO Human Factors Res. Inst., P.O. Box 23, 3769 ZG Soesterberg, The Netherlands, vos@tm.tno.nl) and Edmund Buchta (Inst. für Lärmschutz, Düsseldorf, Germany)

A few years ago, Schomer [Noise Control Eng. J. **42**(5), 179–191 (1994)] developed a new rating procedure for high-energy impulsive sounds, in which a level-dependent conversion of the *C*-weighted sound exposure levels (CSELs) of the impulses into *A*-weighted sound exposure levels (ASELs) of equally annoying vehicle sounds was applied. In a recent reanalysis, Vos [Noise Control Eng. J. **45**(3), 123–131 (1997)] showed that at least for artillery sounds, the optimal parameter values to be used in this level-dependent conversion procedure were different from those suggested by Schomer. The experimental results from a new field survey on the community response to artillery and road-traffic sounds (Buchta and Vos, these proceedings) provide a new opportunity to optimize the conversion procedure. The present effort is especially interesting because here, in contrast to previous analyses, large sets of different CSEL values per noise zone are available (for most of the zones the impulses originating from tens of different firearm/shooting range combinations were considered), and the annoyance ratings for the impulsive and road-traffic sounds had been determined with similar questions and for the same group of respondents, facilitating a comprehensive estimate of the adequate parameter values.

3:40–3:55 Break

3:55

1pNSa5. Community response to artillery and road-traffic sounds—A new field survey. Edmund Buchta (Inst. für Lärmschutz, Arnheimerstrasse 107, D-40489 Düsseldorf, Germany, e.buchta@t-online.de) and Joos Vos (TNO Human Factors Res. Inst., Soesterberg, The Netherlands)

With the help of a questionnaire, subjective reactions to artillery sounds (muzzle bangs mainly from 120- and 155-mm caliber weapons, detonating high-explosive shells, and other explosions) were determined for over 400 respondents divided among 17 different residential areas. Also, for the same respondents, the subjective effects of (local) road-traffic sounds were determined, enabling a comprehensive comparison of dose–response relations for the, typically, high-energy impulsive sounds and the road-traffic sounds. For the sake of comparison with other field surveys, the noise dose for the shooting sounds was expressed as the yearly average *C*-weighted day–night level (L_{Cdn}), and that for the road-traffic sounds was expressed as the *A*-weighted day–night level (L_{Adn}). Similarly, for both sound types the community response in each residential area was expressed as the percentage of respondents being ''highly annoyed.'' From the comparison of the two dose–response relationships it could be concluded that for numerically equal L_{dn} values, the artillery sounds were more annoying than the road-traffic sounds. Overall, the difference is equivalent to the change in annoyance produced by a 5-dB shift in either L_{Cdn} or L_{Adn} of the sounds.

Contributed Papers

4:15

1pNSa6. Effect of low-frequency content on the rate of growth of annoyance of impulsive sounds. Sanford Fidell, Karl Pearsons, and Laura Silvati (BBN Technol., 21128 Vanowen St., Canoga Park, CA 91303)

Since useful field studies of the annoyance of high energy impulsive sounds are costly and difficult to conduct, comparatively little is known empirically about community response to high energy impulsive noise exposure. Several attempts have therefore been made to generalize the results of controlled exposure studies of the relative annoyance of impulsive and nonimpulsive noises to community-level analyses. Although such studies have yielded a range of level-dependent growth functions for the annoyance of impulsive sounds, it is commonly observed that the annoyance of impulsive sounds increases more rapidly with level than that of nonimpulsive signals. The findings of a recent set of paired comparison judgments, in which the very low-frequency content of sonic booms was accurately reproduced, suggest that the steep slope of human hearing sensitivity at low frequencies may provide a good account for the common observation, at least for the case of sonic booms. If this is so, then *ad hoc* ''adjustments'' to the annoyance of impulsive sounds based on rise time, crest factor, and similar waveform characteristics may be superfluous. [Study supported by U.S. Air Force Air Combat Command.]

4:30

1pNSa7. Prediction of the difference between CSEL and ASEL of blast sound for correlation purposes with annoyance. Karl W. Hirsch (Inst. für Lärmschutz, D-40489 Duesseldorf, Arnheimer Str. 107, Germany, ifl.acoustics@t-online.de)

ISO-TC43/SC1/WG45 plans to have three categories of impulsive sound sources for purposes of noise ratings. Each category, ''ordinary impulsive'' (adjustment 5 dB), ''highly impulsive'' (12 dB), and ''high-energy impulsive'' (significantly more than 12 dB to ASEL) sound, will receive the indicated adjustment to its measured SEL. But these adjustments based on categories of sources do not take into account the change of ''impulsiveness'' with propagation. This omission raises uncertainties—especially for high-energy blast sounds. Recently published proposals by Buchta and Vos use the differences between CSEL and ASEL at the receiver to determine impulse adjustments that correlate with annoyance. However, this level difference is not reliably obtained by measurement because the spectrum is influenced by local properties of the ground due to superposition, and because the A-weighted levels are close to the background noise level at typical receiver distances. For blasts from explosive sources (e.g., demolitions, weapon firing), this paper presents a theoretical approach to predict CSEL-ASEL using an energy concept

forthe sound spectrum. This approach yields an expected value for the dif-ference between C- and A-levels that depends on the acoustical energy of the sound at the source and on the frequency-dependent attenuation along the propagation path.

4:45

1pNSa8. A further test of the relevance of ASEL and CSEL in the determination of the rating sound level for shooting sounds. Joos Vos (TNO Human Factors Res. Inst., P.O. Box 23, 3769 ZG Soesterberg, The Netherlands, vos@tm.tno.nl)

In a previous study on the annoyance caused by shooting sounds [Vos, Proc. Internoise '96, **5**, 2231–2236], it was shown that an almost perfect prediction of the annoyance, as rated indoors with the windows closed, was obtained on the basis of the weighted sum of the outdoor A-weighted and C-weighted sound exposure levels [ASEL (L_{AE}) and CSEL (L_{CE})] of the impulse sounds. Basically, the annoyance (y) was given by $y=c+\alpha L_{AE}+\beta\cdot\Delta L\cdot L_{AE}$, in which $\Delta L=L_{CE}-L_{AE}$. In that study, just one type of facade attenuation (FA) was simulated. In the present study, the annoyance was determined for four FA types that varied from low (windows slightly opened) to very high (20 dB at 16 Hz to 50 dB at 8 kHz). Again, the sounds were produced by firearms ranging in caliber from 7.62 to 155 mm, and were presented at different levels. In all four FA conditions, the annoyance could be very well predicted by the equation given above, multiple r^2 varied from 95% to 97%. Relative to the prediction on the basis of ASEL only, the increase in r^2 varied from 7% in the slightly opened windows condition to 55% in one of the high FA conditions. It was concluded that for the determination of the rating sound level, the acoustic parameters ASEL and CSEL are very powerful.

5:00

1pNSa9. Impulse noise metrics and their application to noise from low-flying military jet aircraft. G. Kerry, P. D. Wheeler, T. I. Hempstock (Telford Inst. of Acoust., Univ. of Salford, Salford M5 4WT, UK), and D. J. James (HQ PTC, RAF Innsworth, Gloucester GL3 1EZ, UK)

It is recognized that noise from fast low-flying military jet aircraft is a major factor in the public concern over military low-flying training operations. While much research has been carried out worldwide, potential health risks from noise and environmental noise nuisance remain poorly understood. Part of the difficulties arise in quantifying the exposure and in selecting appropriate risk or tolerability criteria. Much depends on the nature of the noise. This review investigates the definitions and characteristics of impulsive noise and the various metrics in current use for assessing both hearing hazards and environmental annoyance and considers their application to noise from low-flying military jets.

5:15

1pNSa10. Wideband noise signatures from low-altitude military jet overflights. C. Lomax, G. Kerry (Telford Inst. of Acoust., Univ. of Salford, Salford M5 4WT, UK), and D. J. James (HQ PTC, RAF Innsworth, Gloucester GL3 1EZ, UK)

Public concern about the noise from low-altitude military jet overflights and its alleged effects on the health and annoyance of those overflown has resulted in some restrictions on flying activities at low level, even bans within some countries, being imposed. Much past research into aircraft noise emissions has been based on band-limited noise measurements. Full pressure signatures are required if all possible noise effects are to be fully understood. In 1995 a series of trials was completed in the UK under controlled conditions, and typical wideband noise signatures obtained for a variety of speeds and heights of a Tornado aircraft. Samples of these signatures are presented and the various pertinent characteristics highlighted. The question as to whether these signatures should be considered impulsive is discussed.

2:20

1pNSb1. Scale modeling of railway noise barriers. David C. Hothersall, Kirill V. Horoshenkov, and Philip A. Morgan (Dept. of Civil and Environ. Eng., Univ. of Bradford, Bradford, West Yorkshire BD7 1DP, England, dchothersall@bradford.ac.uk)

Noise barriers are an efficient way of reducing the noise from railways, particularly the noise produced in the region of the rails and wheels. Several designs of noise barrier have been suggested in the literature which aim to improve the insertion loss over that obtainable from a plane screen of the same height. The positioning of these barriers is governed by the limitations imposed by the structure gauge of the railway. Scale modeling has been carried out in a humidity-controlled anechoic chamber at a scale of 1:20. Appropriate materials have been selected to model the impedance of the track ballast, absorbing barrier surfaces and grassland at the reduced scale. To model the interaction between the side of the train and the barrier realistically, models appropriate for a high-speed train cross section have been used. Experimental results for the insertion loss of shaped and multiple-edge barriers are compared with the results from numerical modeling. The efficiency of each of the designs is assessed. The generation of time histories for the passage of trains and the calculation of noise indices are considered.

2:50

1pNSb2. Specific problems on the use of noise barriers on viaducts. Jean-Pierre Clairbois, Peter Houtave, and Vincent Trefois (Acoustical Technologies Ave., Brugmann, 215 B-1050 Brussels, Belgium)

Whatever the location of highways or high-speed roads is (urban, suburban, country), we frequently encounter viaducts or bridges. Building noise barriers on viaducts is not a simple matter, mainly for 3 important reasons: aesthetic, safety and stability, and the problem of viaduct joints. Aesthetically, the wish is to reduce the height of the barriers. One also very often wishes to use transparent barriers: for that case, these reflecting materials can degrade the performance of the barrier, either due to the effect of parallel reflecting walls, or due to the reflections which occur with high sided vehicles passing close to these. One should then achieve a specific study of the shape and materials that have to be used in such an application, not forgetting that each case is different. Another important problem occurring with the barriers on viaducts is that, once the barrier is effective and reduces the noise originally coming from the traffic on a viaduct, one could listen back to the noise due to bad noisy joints, noise coming from below viaducts, and not protected with the barriers. This paper will present some measurements and design studies made in such situations.

3:20

1pNSb3. Source type effect on the efficiency of noise barriers. Philippe Jean (Ctr. Scientifique et Technique du Bâtiment, 24, Rue Joseph Fourier, 38400 Saint-Martin-d'Hères, France)

The use of numerical techniques such as the Boundary Element Method (BEM) is well suited for the study of noise barriers of complex shapes. Full studies, up to 4000 Hz, can only be done with 2D approximations, where the geometry of the problem is infinite, which is a realistic approximation for noise barriers. It also implies that the sources are infinite coherent line sources, which is a gross approximation for traffic noise. Recent transforms have been presented in the literature to overcome this last restriction. Simple integrals of 2D results now permit the rapid consideration of any combination of point sources or infinite incoherent line sources. Such transformations have been tested with a BEM code based on a variational formulation. The efficiency of different screen modifications is analyzed in the light of these more realistic source representations, and the importance of such developments is assessed by comparing the results with the classical coherent source approximation.

3:50–4:05 Break

4:05

1pNSb4. A new *in situ* method for the acoustic performance of road traffic noise reducing devices. Jean-Pierre Clairbois (Acoustical Technologies Ave., Brugmann, 215 B-1050 Bruxelles, Belgium), Jacques Beaumont (ENTPE/LASH F-6951 Vaux-en-Velin Cedex, France), Massimo Garai (DIENCA / Universita di Bologna, Bologna, Italy), and Gerold Schupp (IBP fhG, Stuttgart, Germany)

When they drew the European standards for ''road traffic noise reducing devices'' (NRD), the members of CEN/TC226 (road equipments)/WG6 (antinoise devices) found problems in using ISO 354 and ISO140 for characterizing sound absorption and airborne sound insulation of NRD. The problems are due to the fact that these standards have been drawn for building products, used inside buildings. The measurement of the sound absorption under a reverberant field does not reflect the real absorption coefficient found with road traffic. In addition, many road administrations wish to get a field test method for testing installed products. A European funded research (''ADRIENNE'') has been started in January 1995 and finished in December 1997 with the objectives to be able to measure the *in-situ* sound absorption and airborne sound insulation of NRD for the widest range of existing products (i.e., flat and nonflat ones). This paper shall present the results of the research, which is based on the combination of MLS signal and signal analysis, a substraction technique to enlarge the lowest reliable frequency limit, and a specific window. The fundamental method has been developed with three laboratories, and initial validation with eight laboratories shows promising results for a future standard.

1pNSb5. Full-scale model investigations into insertion loss of highway noise barriers under different atmospheric conditions. Scott D. Hansen, Courtney B. Burroughs, and Kenneth E. Gilbert (Grad. Prog. in Acoust. and Appl. Res. Lab., P.O. Box 30, University Park, PA 16802)

The insertion loss of highway noise barriers can change significantly with atmospheric conditions. The insertion loss of a 14×80-ft tongue and groove wooden barrier constructed at the Pennsylvania Transportation Institute test track near State College, PA was measured under different atmospheric conditions. Point sources consisted of pure tones and random noise. Both sources and receivers were held at fixed distances from the barrier. Wind and temperature profiles were estimated from measurements using similarity theory. Measurements were taken as winds varied in both direction and strength for different temperature profiles. Results from parabolic equation model calculations of the propagation over the barrier are compared to the measured data. A statistical analysis of the changes in the insertion loss measurements is performed. This study demonstrates the effects of atmospheric conditions on the insertion loss of the barrier.

1pNSb6. An innovative approach to predict sound field in a complex outdoor environment. Shahram Taherzadeh, Kai M. Li, and Keith Attenborough (Eng. Mech. Discipline, The Open Univ., Milton Keynes MK7 6AA, UK)

It is well known that the fast field program (FFP) is an accurate numerical scheme for calculating the sound field above a flat ground and in a range-independent environment. On the other hand, the boundary ele-

ment method (BEM) is most superior for a situation with complicated boundary conditions, such as the presence of noise barriers. However, the successful application of the BEM requires an accurate Green's function. This requirement somewhat limits the general applicability of the BEM only to the condition of homogeneous medium or other media with a simple sound-speed profile where analytical Green's function exists. In order to predict the propagation of sound in a complex outdoor environment, a hybrid method is developed that combines the advantages of the BEM and the FFP. In this numerical scheme, the sound field for an inhomogeneous medium is first computed by the FFP. The numerical result is then applied as the input Green's function for use in the BEM. The new hybrid scheme, fast field boundary element method (FFBEM), is used to investigate the performance of sound barriers and screens in upwind and downwind conditions. 1pPAa1. Surface waves over a convex impedance ground. Kai Ming Li and Qiang Wang (Eng. Mech. Discipline, Faculty of Technol., The Open Univ., Milton Keynes, UK)

Laboratory experiments are reported for the study of surface waves above a convex impedance surface. Monopole, horizontal dipole, and vertical dipole sources are used in these experiments. The model ground surface is an open-meshed rubber mat with a hole size of 22-mm square and 12-mm depth. The rubber mat is then laid on a rigid masonite curved surface. There are generally good agreements between measurements and predictions based on the residue series theory. In an earlier theoretical study [see J. Acoust. Soc. Am. **89**, 107–114 (1991)], Raspet *et al.* have identified the contribution due to the surface wave poles. However, the present experimental results have suggested that the surface wave pole contributions not only contain the surface waves but also include the creeping waves. The experimental results also show that there are two groups of waves, which are well separated, arriving at different times. The earlier group of waves may be attributed to the creeping waves, while the later group of waves is identified as the surface waves. [Work supported by EPSRC and an Open University Studentship.]

1pPAa2. Modeling the effects of refraction and diffraction on wave propagation in a 3D, turbulent atmosphere medium. Kenneth E. Gilbert and Xiao Di (Appl. Res. Lab. and Grad. Prog. in Acoust., Penn State Univ., P.O. Box 30, State College, PA 16804)

In ocean acoustic modeling, it has been established that many nonturbulent, deep-water propagation problems can be treated by the ''$N\times$2-D'' approximation, where 2-D ''slices'' are computed along N radials. In the atmosphere, the validity of the $N\times$2-D approximation is questionable because of ever-present, multiscale turbulence. In this paper, a new approach that allows the inclusion of multiscale turbulence in practical calculations is presented. The approximations that are physically motivated by the relative contributions of refraction and diffraction in multiscale turbulence are discussed. It is shown, for example, that for horizontal atmospheric structures larger than 10's of wavelengths, horizontal diffraction is negligible, and the $N\times$2-D approximation suffices. For smaller turbulence structures, horizontal diffraction is a dominant effect and must be accounted for. The theoretical/numerical method presented allows efficient calculations for both large- and small-scale 3-D atmospheric structure. Numerical examples are given to illustrate the phenomena involved. [Work supported by DARPA and the Pennsylvania State University Applied Research Laboratory.]

2:00

1pPAa3. Scattering of acoustic impulse waveforms by turbules. Charles G. Don and Ian D. McLeod (Dept. of Phys., Monash Univ., VIC 3168, Australia)

When a short duration acoustic pulse propagates through the atmosphere its waveform can be markedly altered. Some are broadened, others have increased peak heights while occasionally ''inverted'' regions occur in the tail. In an effort to explain such changes, scattering by a turbuloid characterized by a Gaussian profile was considered. The effective size of the turbuloid, s, can be estimated from the correlation length, L, of the wind speed trace obtained as the pulse was propagating. The strength of the turbuloid, q, can be positive or negative, depending on whether the wind speed decreases or increases, while its magnitude depends on L as well as the number of turbuloids and the standard deviation of the refractive index variation. The received pulse waveform is sensitive to the values of s, q, and the position of the turbuloid relative to the source. By appropriate adjustment of the parameters, many of the observed waveforms can be reproduced; the choice of parameters giving some insight into the conditions which must have existed in the atmosphere during propagation.

2:15

1pPAa4. Sound propagation through time-dependent random media. Ph. Blanc-Benon, K. Wert, and D. Juvé (Ecole Centrale de Lyon, LMFA UMR CNRS 5509, BP 163 69131 Ecully Cedex, France, acous@selene.mecaflu.ec-lyon.fr)

In recent years, several authors have studied the impact of turbulence on sound propagation through numerical simulations. Currently, these simulations model the turbulence using a frozen turbulence hypothesis and a random Fourier modes (RFM) technique, such that the turbulent fluctuation at any point in the medium (either scalar or vectorial in nature) is calculated from the sum of a limited number of time-independent random Fourier modes. The RFM technique is quite easy to implement, and has been used to make accurate predictions of ensemble-averaged sound-pressure level for atmospheric propagation. In this paper, the extension of the RFM method to include simple time evolution of the fluctuations is presented. However, this method produces fields that do not satisfy the Navier–Stokes equations and thus cannot exhibit either the dynamics or the structures found in atmospheric boundary layer (ABL) turbulence. The desire to include ABL turbulence characteristics in simulations of atmospheric propagation has led to consideration of large eddy simulations (LES) for turbulence modeling. Here, numerical simulations obtained using both turbulence models in conjunction with a parabolic equation solver to calculate time-evolving acoustic fields, which are subsequently ensemble averaged to determine statistical characteristics, will be presented. [Work supported by CNRS/NSF and IDRIS under project 960742.]

1pPAa5. Acoustic measurements in an airport environment and the identification of the sound radiated by aircraft wake vortices. Neal Fine (Eng. Technol. Ctr., 240 Oral School Rd., Mystic, CT 06355-1208), Frank Rees, and William Von Winkle (Flight Safety Technol., Inc., New London, CT 06320)

Results are presented of an effort to measure the sound generated by aircraft wake vortices. The objective of the research is to estimate the spectral shape and source levels characteristic of the sound generated by aircraft wakes during approach and landing. Measurements were made at JFK airport in August 1997, for various aircraft, using three Bruel & Kjaer outdoor microphones. The data were recorded to tape, and spectrum analysis was performed using a B&K portable spectrum analyzer. The three microphones were placed near the beginning of runways 13L and 22L, arrayed in several configurations parallel to and perpendicular to the runway centerline. Initial spectrum analysis of the data revealed a prominant broadband ''hump'' in the one-third octave sound-pressure level spectra, centered at approximately 50–60 Hz for a B-747 landing (with a bandwidth of roughly 20–30 Hz). The timing of the hump is consistent with that expected for wake vortex sound and it is hypothesized to be generated by the wake vortices. Cross correlations between microphones arrayed parallel to the runway will test this hypothesis. Additional data, which are to be recorded in January 1998, will also aid in identifying the wake vortex sound characteristics.

2:45

1pPAa6. Spectral element analysis of sound propagation in a muffler. Wen-Hwang Lin and Munir M. Sindir (Rocketdyne Div., The Boeing Co., P.O. Box 7922, 6633 Canoga Ave., Canoga Park, CA 91309-7922)

This paper presents a novel numerical method based on the least-squares spectral element formulation to analyze sound propagation in an expansion-chamber muffler with and without a mean flow. The method solves the linearized acoustic field equations derived from the full Navier–Stokes equations. Effects of the mean flow on the acoustic wave propagation in the muffler were taken into consideration. The method solves the first-order acoustic field equations in a finite number of elements which represent the chamber muffler. Within each element the method first approximates the solutions to these equations by a series of unknown coefficients with known basis functions, forms the residual of the approximation, and then minimizes the integral of the squares of the residual with respect to the unknown coefficients. The resultant system equations were discretized by the spectral element method for spatial derivatives and by the dual time stepping for the temporal derivative. Finally, the algebraic equations were solved by a Jacobin preconditioned conjugate gradient method. Numerical results were presented for pressure contours and transmission loss of sound waves propagating at various frequencies in the muffler. These results were compared with the analytical values available, and the comparison showed very good agreement.

3:15

1pPAa7. The effects of turbulent intermittency on scattering for varying degrees of saturation. David E. Norris (Grad. Prog. in Acoust., Penn State Univ., University Park, PA 16802, norris@essc.psu.edu), D. Keith Wilson (U.S. Army Res. Lab., Adelphi, MD 20783-1197), and Dennis W. Thomson (Penn State Univ., University Park, PA 16802)

Atmospheric turbulence is inherently inhomogeneous and intermittent. Periods of high activity are embedded in periods of relative calm. The local spatial and temporal changes in sound speed associated with intermittency increase the likelihood of measuring large values of scattered acoustic signals. Previous work successfully predicted the probability density functions (pdf) of fully saturated, scattered signals measured within an acoustic shadow zone [Wilson *et al.*, J. Acoust. Soc. Am. **99**, 3393–3400 (1996)]. The more general case, in which the scattered signal is partially saturated, was considered in this paper. A theory was developed through the use of the Rice–Nagakami pdf. There are two free parameters: one to describe the degree of intermittency, and a second to describe the degree of saturation. For validation purposes, outdoor propagation measurements were made over a flat, hard ground at a range of 283 m, and at frequencies from 90 to 500 Hz. Calculated and measured intensity pdf's were compared and found to be in excellent agreement. Both the intermittency and saturation increased with frequency, with the scattering at 500 Hz being almost fully saturated.

3:30

1pPAa8. The effects of atmospheric turbulence on the cross correlation between wind and travel time fluctuations. David E. Norris (Grad. Prog. in Acoust., Penn State Univ., University Park, PA 16802, norris@essc.psu.edu), Leif Kristensen, Jakob Mann (Risø Natl. Lab., Roskilde, Denmark), Dennis W. Thomson, and David C. Swanson (Penn State Univ., University Park, PA 16802)

Previous measurements over flat, hard ground showed strong coherence in received acoustic phases across frequencies from 90 to 660 Hz [D. E. Norris and D. W. Thomson, J. Acoust. Soc. Am. **101**, 3102(A) (1996)]. A recent test program was conducted at the same site in which concurrent acoustic and wind data were recorded. Similar coherences in the phase and travel time fluctuations were observed, and cross correlations between wind and travel time fluctuations were calculated. A theory was developed to predict the cross correlations by considering the effects of the two-dimensional horizontal wind spectrum on the direct source–receiver path. The theoretical parameters include the horizontal separation between the acoustic and wind sensor positions, and the bearing offset between the wind and propagation directions. Calculated and predicted cross correlations were compared and found to be in good agreement. The bearing offset was found to significantly influence both the magnitude and shape of the cross correlations.

3:45

1pPAa9. Acoustic determination of scale and structure constants in fluctuating fluid. Volker Mellert and Bernhard Schwarz-Roehr (Dept. of Phys., Univ. of Oldenburg, D-26111 Oldenburg, Germany)

The power spectrum of tubulence (e.g., fluctuating wind, **v**, and temperature T) is characterized by structure constants, which are related to scale and strength of fluctuation. The von Kármán spectrum is a common model for atmospheric turbulence, and is determined by intensity and scale parameters c_v^2 c_T^2 and L_0. The quantities are usually measured by recording time series, e.g., of **v** and T, at one location. Required is a frozen turbulent structure, being carried along the sensor by an average flow. This measuring method fails if the average movement of the fluid is insufficient. However, sound waves provide an easy and fast tool for determining the desired parameters. The complex amplitude $A(\mathbf{r})$ of the wave is changed by the refractive index fluctuations. Successive wavefronts ''see'' different spatial representations of the turbulence. Evaluating the statistics of this ensemble yields the desired parameters, provided a theory of wave propagation through turbulence is available. Based on the parabolic equation method, analytical results have been derived allowing for the calculation of the structure constants (Ostashev *et al.*, accepted for publication in J. Acoust. Soc. Am.). Spatial correlation $\langle A(\mathbf{r}_1)\cdot A(\mathbf{r}_2)\rangle$ yields c_v^2, c_T^2, and L_0 acoustically. Results are compared with ''classical'' sensor measurements in the atmospheric boundary layer.

4:00

1pPAa10. Model experiments and predictions of sound field in a downward refracting medium. Qiang Wang and Kai Ming Li (Eng. Mech. Discipline, The Open Univ., Milton Keynes, UK)

Laboratory experiments are conducted to investigate the diffraction of sound by concave surfaces for both monopole and dipole sources. The cylindrical concave surface in an otherwise homogeneous medium is used to simulate an outdoor situation corresponding to a downward refracting medium. A normal mode solution is developed to predict the sound field diffracted by the curved surface. The analysis is based on a conformal transformation in which a stricter analogy is established. Analytical expressions for dipole sources are deduced directly from that for a monopole source. Furthermore, the normal mode solutions are validated by comparison with that due to the boundary element method. Finally, the experimental results are compared with the normal mode predictions for an exponential sound-speed profile as well as a bilinear sound-speed profile. [Work supported by EPSRC and an Open University Studentship.]

4:15

1pPAa11. Inclined acoustic sounding of the atmospheric boundary layer. Igor P. Chunchuzov (Inst. of Atmospheric Phys., 3 Pyzhevskii per., Moscow 109017 Russia)

The method of inclined acoustic sounding of the atmospheric boundary layer has been proposed and realized experimentally. The method is based on the phenomena of the waveducted sound propagation along ground surface under the presence of the positive wind shear. In the experiment the wind velocity profiles and their large-scale time fluctuations were continuously controlled with the SODAR up to the height of 300 m and with the anemometers placed at the mast of 56 m height. The fluctuations of the acoustic pulse travel time with the periods in the range of 3–30 min were measured between the special pulse generator and the three receivers placed on the ground surface 2.5 km apart from each other, forming a horizontal triangle antenna. The obtained cross coherence and phase spectra between the pulse travel time and the wind velocity fluctuations show a peak of coherence with the maximum of about 0.8 to 0.9 for the period of 8 min. Such low-frequency wind velocity fluctuations near the ground surface are thought to be caused by the gravity wave modes propagating in the stable stratified troposphere with the periods close to the Brunt–Vaisalla period. The inclined acoustic sounding is proposed to be used for the acoustic tomographic monitoring of the three-dimensional wind field in the atmospheric boundary layer.

4:30

1pPAa12. Calculation of sound reduction by a screen in a turbulent atmosphere using the parabolic equation method. Jens Forssén (Dept. of Appl. Acoust., Chalmers Univ. of Technol., Gothenburg, Sweden)

Results from applying a Crank–Nicholson parabolic equation method (CNPE) are presented in situations with a thin screen on a hard ground in a turbulent atmosphere, and with the acoustic source at ground level. The results are evaluated by comparison with Daigle's model, which uses the sound scattering cross section by Tatarskii together with diffraction theory. The results show a fairly good agreement for situations where the receiver is above ground, thus indicating that both methods are applicable to the problem. When the receiver is at ground level the two methods lead to significant differences in insertion loss since only the PE method predicts that turbulence causes an increased sound level in the case without a screen. For the situations considered in the paper a turbulent atmosphere shows a significant influence on sound reduction by screens. 1pPAb1. Scattering by partially buried shells. Raymond Lim (Coastal Systems Station Dahlgren Div./Naval Surface Warfare Ctr., Code R22, 6703 W. Hwy. 98, Panama City, FL 32407-7001)

An extension of a previously derived transition-matrix solution for acoustic scattering by a three-dimensional elastic obstacle partially buried at a water/sediment interface [Lim, J. Acoust. Soc. Am. **99**, 2498 (1996)] was carried out and numerically executed to allow for the obstacle to be layered. The formulation adapts an approach previously used to improve convergence for high-aspect-ratio obstacles in a homogeneous fluid host, where spherical harmonics were employed to expand the exterior surface fields of the object [A. Boström, J. Acoust. Soc. Am. **76**, 588–593 (1984)]. Although the analytical solution is expected to be exact, numerical stability is best if the obstacle layering is smooth and obeys certain convergence restrictions. In particular, for surface fields expanded in basis functions of spherical geometry, the origin-centered sphere that circumscribes the inner boundary of each homogeneous obstacle layer should never overlap the origin-centered sphere that inscribes its outer boundary. While this restriction becomes a problem for elongated shells, the acoustic response of spherical shells or shells with near-spherical cores can be calculated. Results are presented to examine the dynamics of partially buried shelled obstacles.

1:15

1pPAb2. Visualization of the energy flux in an ensonified fluid-loaded elastic sphere. Cleon E. Dean and James P. Braselton (Phys. Dept., P.O. Box 8031, Georgia Southern Univ., Statesboro, GA 30460-8031)

The energy flux in an ensonified fluid-loaded elastic sphere is visualized by its Poynting vector field in both its instantaneous real and time-averaged complex forms. The instantaneous Poynting vector field is shown in both freeze-frame and animated versions. The instantaneous Poynting vector field can be used to follow the propagation of elastodynamic waves in the elastic sphere. The complex Poynting vector field, which is a time-averaged representation of the energy flow, is shown in terms of separate real and imaginary parts. The real part of the complex Poynting vector field shows the traveling wave component of the elastodynamic wave in the ensonified sphere. The imaginary part of the complex Poynting vector field shows the standing wave part of the elastodynamic wave in the ensonified sphere. The patterns formed by the Poynting vector field, in both its instantaneous and the real and imaginary parts of the complex form, can be identified with the various modes of the ensonified sphere and used to explain the physical processes going on inside the ensonified sphere.

1:30

1pPAb3. Experimental measurements and theoretical modeling of acoustic scattering by a cube. Victor F. Humphrey, Jingdong Zhang (Dept. of Phys., Univ. of Bath, Claverton Down, Bath BA2 7AY, UK), and Paul A. Chinnery (Winfrith Technol. Ctr., Winfrith, Newburgh, Dorchester, Dorset DT2 8X5, UK)

Acoustic backscattering can be used to assess quantitatively the size and concentration of suspended sediments above the seabed. This technique depends on a knowledge of the backscattering form function for the scattering particles, which for simplicity are normally assumed to be spheres. In order to investigate the scattering from other shapes a series of measurements have been made of the acoustic backscattering behavior of both nonmetallic (glass) and metallic (steel) cubes over a wide frequency range. A laboratory system using a parametric array was used to make measurements between 20 and 200 kHz on cubes of side 20 mm, corresponding to ka values up to 10. Results are presented for a range of incidence angles involving incidence on a face, an edge, and a corner. At higher frequencies elastic resonances are observed, while at lower frequencies the average form function shows characteristics similar to those due to creeping waves on a sphere. The results are compared with theoretical predictions obtained with a boundary element model and a combined finite element/boundary element model. The agreement is observed to be very good. [Work partially supported by the MAST program of the EC, contract MAS3-CT95-0017 (TRIDISMA).]

1:45

1pPAb4. Direct and inverse obstacle scattering by shape deformation. Dilip N. Ghosh Roy, Jeremy A. Warner (SFA, Inc., 1401 McCormick Dr., Landover, MD 20785, dilip@acoustics.nrl.navy.mil), and Luise Couchman (Naval Res. Lab., Washington, DC 20735-5350)

The results of direct and inverse scattering of plane acoustic waves from penetrable and impenetrable objects are reported here. It is assumed that the scatterer boundary is a superposition of an arbitrary deformation on an underlying simple geometry. The direct problem is solved via the Padé extrapolation of the boundary variations. This results in solving only certain algebraic recursion relations and requires neither Green's function nor integral representations. The inverse problem of recovering the obstacle's shape and material parameters from the far-field scattering data is solved by Gauss–Newton minimization. The calculation of the scattered field and its Jacobian involves no more than solving a series of Helmholtz scattering problems in the same domain, namely, exterior to the simple shape instead of the iteratively updated deformed surfaces, leading thereby to substantial computational simplifications. Moreover, since no integral equation is used, the ambiguity in the solution because of the interior eigenvalues does not arise. Several two-dimensional obstacles of various shapes are inverted for their boundaries as well as their material parameters of mass density and wave number. Finally, the procedures described can be extended straightforwardly to transmission and three-dimensional problems.

2:00

1pPAb5. An alternative derivation of Howe's (1975) formula for the scattering of hydrodynamic flow into sound by solid bodies. Dan Lin (KT35, M. W. Kellogg Co., 601 Jefferson Ave., Houston, TX 77210) and Alan Powell (Univ. of Houston, Houston, TX 77204-4792)

An alternative way to derive the Green's function in the presence of a solid body is presented and applied to the case of scattering of hydrodynamic flow into sound. This method utilizes an imaging system of a point source outside a solid sphere. The ''incident potential'' and the ''scattered potential'' are obtained in terms of velocity potentials from the original source and the image sources. The total potential and the Green's function can then be easily derived. The resultant Green's function $G=\delta(t-\tau-|\mathbf{x}-\mathbf{Y}|/c)/(4\pi|\mathbf{x}-\mathbf{Y}|)$ is exactly the same as that derived by Howe [J. Fluid Mech. **67**, 597–610 (1975)] while the physical meaning is much more clear and less mathematics is involved. Here, **x** is the vector from the origin to the observation point, and **Y** is the incompressible flow vector potential in the presence of the solid body. For the case of scattering of hydrodynamic flow into sound, the above Green's function is substituted in Lighthill's solution $p(x,t)=\rho_0\int(\partial^2 u_i u_j/\partial y_i \partial y_j)G\,dV\,d\tau$. The far-field scattered acoustic pressure is then obtained in terms of flow vorticity ζ and the vector stream function Ψ_x for a unit potential flow around the solid body in the x direction: $p(x,t)=(\rho_0/4\pi xc)\partial^2/\partial t^2\int\Psi_x\cdot\zeta(t-|x|/c)dV$, as given by Dowling.

2:15

1pPAb6. Interaction of an acoustic plane wave with a circular elastic plate in water. Yannick Eudeline, Hugues Duflo, Jean-Louis Izbicki, and Jean Duclos (L.A.U.E. Pl. R. Schuman, 76610 Le Havre, France)

An experimental investigation of the interaction of an acoustic plane wave with a circular elastic plate is presented. The experimental setup consists of a duraluminum 2-mm-thick disk with different values of the radius (between 10 and 50 mm). Monostatic and bistatic experiments are performed. In the first case a transducer turns around the disk (in the perpendicular plane), sends the incident wave, and receives the diffracted signal in each observation direction. In the second experiment we use two transducers, the emitter and the receiver which turns around the circular plate. In each observation direction, we have calculated the FFT of the diffracted signal for frequencies lower than 3 MHz. We have represented the results in a two-dimensional image in which appears the spectral response of the plate. Two kinds of results are obtained: (i) Lamb waves propagation on the plate which are detected by their angular reemission of energy in water, (ii) particular frequencies are also detected close to eigenfrequencies of the circular plate in vacuum.

2:30

1pPAb7. Scattering by an elastic cylinder buried in a sedimentary fluid media. Arnaud Coatanhay and Jean-Marc Conoir (L.A.U.E., Université du Havre et CNRS (UPRESA 6068), Pl. R. Schuman, BP 4006, 76610 Le Havre, France, coatanha@iut.univ-lehavre.fr)

A new method for predicting the acoustic field scattered by an infinitely long elastic cylinder buried in a sedimentary fluid media is developed. The cylinder is parallel to the interface and the incident wave propagation direction is perpendicular to the cylinder axis. The method describes the interaction between the cylinder and the interface in modal theory. The approach is based on a generalized method of images which is originally restricted to rigid and soft plane interfaces. In this way, the acoustic field in sediment can be expressed as two cylindrical waves series whose emitting centers are symmetric with respect to the interface. The acoustic field transmitted by the plane interface is then calculated with the use of the steepest descent method. The goal is to detect buried objects by analyzing the resonances. At quite a high frequency, a good agreement is observed with regard to experiments.

2:45–3:00 Break

3:00

1pPAb8. Transient diffraction of a plane step pressure pulse by a hard sphere. H. Huang (Consultant, Bowie, MD 20715) and G. C. Gaunaurd (Naval Surface Warfare Ctr., West Bethesda, MD 20817-5700)

Transient diffraction of sound pulses by a sphere is a classical problem extensively studied in acoustics (and in EM) for nearly a century. In spite of this volume of work, a satisfactory treatment of the sound field in the neighborhood of the shadow boundary is not available, and it is still one of the unsolved problems of diffraction theory [see comments in F. Friedlander, *Sound Pulses* (1958), p. 148]. To our knowledge, no treatment of this case has yet appeared. The modal series solution for this situation is presented here. The time histories of a sufficiently large number of terms of the modal series are accurately computed; a task that is possible today due to the existence of better computers and of more sophisticated computational algorithms. The Cesàro summation method [E. Whittaker and G. Watson, *Modern Analysis* (1965), p. 155] is used to completely eradicate the Gibbs' phenomenon effect. This approach yields the diffracted field in the entire space-time domain. In particular, a complete treatment of the diffracted sound field is developed for a hard sphere insonified by a step pressure pulse, including the neighborhood of the shadow boundary where, heretofore, no analytical solution exists.

3:15

1pPAb9. Bistatic sonar cross sections and time-frequency signatures of simple targets insonified by an acoustic pulse. Guillermo C. Gaunaurd (Naval Surface Warfare Ctr., Carderock Div.—Code 684, West Bethesda, MD 20817-5700) and Hans C. Strifors (Defense Res. Establishment (FOA 6), S-17290 Stockholm, Sweden)

The area of acoustics is concurrently trying to develop the concept of impulse sonar. Using a time-frequency approach the very broadband echoes generated by a target when such devices are used can show the time evolution of the resonance features that identify the target. This will enhance the target recognition capability of the traditional sonar cross section (SCS). To this end, the bistatic scattering interaction of acoustic pulses of short duration with targets of simple shapes are studied. The targets are solid spheres and spherical shells. To model the output of an impulse sonar, the waveform incident on the target is a short, ultrawideband pulse that consists of a few sinusoidal cycles within a Blackman window. For each target the bistatic SCS is displayed as a function of frequency and bistatic angle. Analyzing the scattered waveform when the designed short pulse is incident on each target for a few selected bistatic angles gives information of how and how much scattered pulses are affected by the scattering direction, or the relative location of the transmitter and receiver. The methodology developed by us could be used to assess the performance, including the possibility of target recognition, of any impulse sonar system.

3:30

1pPAb10. New results for diffraction from an impedance wedge. Andrew N. Norris (Rutgers Univ., 58 Brett Rd., Piscataway, NJ 08854-8058, norris@jove.rutgers.edu) and Andrey V. Osipov (Inst. of Radiophysics, St. Petersburg State Univ., Uljanovskaja 1-1, Pedrodvorets 198904, Russia)

Acoustic diffraction from the tip of a wedge with impedance boundary conditions is a well covered topic, with extensive work reported in the 1950s. One of the main quantities of interest is the diffraction coefficient, D, for plane-wave incidence. Some new, simple, and useful results for the diffraction coefficient are reported. It will be demonstrated that D factors into the product of three terms: (1) the amplitude at the tip for a unit plane-wave incident from the direction of interest, (2) the same amplitude for a plane wave coming from the observation direction, and (3) an expression involving only trigonometric functions. Furthermore, the magnitudes of the tip, or edge, amplitudes (1) and (2) are very simple if the faces of the wedge are purely reactive (imaginary impedances). The simplicity

of the formula for D allows us to answer questions such as: Can the diffraction vanish if the impedances of the wedge faces are properly chosen? The answer is generally in the affirmative, at least for selected incidence and observation directions. These findings will be illustrated by several examples and applications will be discussed.

3:45

1pPAb11. Physical nature of the first circumferential wave of a Lucite cylinder immersed in water. Farid Chati, Fernand Léon, and Gérard Maze (LAUE, UPRESA CNRS 6068, Université du Havre, Pl. R. Schuman, 76610 Le Havre, France)

Acoustic scattering from a Lucite cylinder of infinite length immersed in water and excited by a normal incident plane acoustic wave is investigated at low frequencies. Numerical calculations and experiments are performed for a cylinder with a radius $a=0.01$ m. The experimental results are obtained with the method MIIR. The resonances of the first circumferential wave are easily isolated in the frequency range 100–300 kHz. A good agreement is obtained between experimental and theoretical results. First, in order to analyze the physical nature of vibration modes associated with this wave, the evolution of the resonance location and that of their corresponding widths are investigated theoretically when the fluid density is perturbated. Contrary to aluminum or steel cylinders, the computed calculus in vacuum are not in good agreement with the experimental results related to the first wave. The detection of this wave depends mainly on the outer fluid. Second, the dispersion curves of the phase velocity for this wave are considered. A noticeable difference of the phase velocity toward the high frequency is observed when the fluid density is modified. The phase velocities toward the high frequency, in the presence and in the absence of water, enable us to characterize this wave.

4:00

1pPAb12. A new model to predict echoes of large, smooth targets, with finite dimension transducers, at a low cpu cost. Jean-Luc Berton, Cecile Riffard, Christian Dominjon (CEA, CE Cadarache, DER/SSAE/LSMR, 13108 St. Paul lez Durance Cedex, France, berton@brandy.cad.cea.fr), and Dominique Dedieu (Ecole Centrale de Lille, 59651 Villeneuve d'Ascq Cedex, France)

A model called SYTRAC.L, for the prediction of echoes from large, hard reflectors, facing finite dimensions transducers, is proposed. For great reflectors, the introduction of the acoustic ray theory allows low cpu costs and more reasonable memory needs, with comparison with other methods where a numerical integration is performed on the reflector, since this integration is eliminated. In a first stage, this model does not take into account reflector edge diffraction effects, but these are being introduced with GTD approaches. The validation of the formulation and of the numerical implementation was done by comparison with analytical results in two canonical configurations. Experimental comparisons for plane and cylindrical reflectors have also been performed. This model is used to estimate the accuracy of telemetries on large structures, at distances less or greater than the far-field limit. As an example, results of a parametric study of echo characteristics from cylindrical and plane targets are described according to their distance and tilting.

4:15

1pPAb13. Prediction of echoes from small targets: Modelization and application to a telemetry problem. Cecile Riffard, Jean-Luc Berton, and Claude Estienne (CEA, CE Cadarache, DER/SSAE/LSMR, 13108 St. Paul lez Durance, Cedex, France, berton@brandy.cad.cea.fr)

A model for the prediction of echoes from finite dimension transducers and targets was developed on the basis of a formulation published by other authors. The numerical implementation in the context of telemetries on small axisymmetrical targets was validated by comparison with simulation results available in the literature. In the context of telemetry in liquid sodium, the calibration of ultrasonic celerity may be done by measurement of the difference of time of flight between two small targets at given distances. Diffraction effects exist, due to the superposition of delayed contributions of the centers and edges of both the transducer and the target. Thus, the shapes of the echoes of both targets may be different from each other. The study of the resultant error on the difference of time of flight, according to the geometry of the system, constitutes the second part of the paper. The so-called ''diffraction error'' remains acceptable for a 40-mm transducer illuminating a 30-mm-diam target at normal incidence at 4.5 MHz, even if they are separated by only 300 mm, which is clearly nearer than the far-field limit.

4:30

1pPAb14. Matrix theory of elastic resonance scattering. Myoung S. Choi and Yong M. Cheong (Non-Destructive Evaluation Team, Korea Atomic Energy Res. Inst., P.O. Box 105, Yusong, Taejon 305-600, Korea, mschoi2@kaeri.re.kr)

A fundamental matrix theory is developed for the exact isolation (in both magnitude and phase) of resonance amplitudes contained in the elastic field scattered by a penetrable target. Similarities and differences between this matrix theory and the classical resonance scattering theory [L. Flax, L. R. Dragonette, and H. Uberall, J. Acoust. Soc. Am. **63**, 723–731 (1978)] are discussed. The matrix theory is then applied to cylindrical and spherical fluid-filled cavities, and analytical expressions for the resonance amplitudes are derived. In the vicinity of resonance frequencies, the resonance amplitude expressions have forms similar to the Breit–Wigner formula. In order to check the validity of the matrix theory, numerical calculations are performed for a cylindrical water-filled cavity in an aluminum medium. Resonance spectra of the cavity are presented for some partial waves and their characteristics are also discussed.

1pPAc1. New symmetries and conservation laws for lossless KZK equation. Oleg A. Sapozhnikov (Dept. of Acoust., Phys. Faculty, Moscow State Univ., Moscow 119899, Russia, olegs@na.phys.msu.su) and Andrei G. Kudryavtsev (Moscow State Univ., Moscow 119899, Russia)

The Khokhlov–Zabolotskaya–Kuznetsov (KZK) equation is widely used to describe intense acoustic beams. No general analytical solution has been obtained for this nonlinear equation, so numerical methods are usually employed. Known analytical approaches are associated with various approximations. An additional powerful mathematical tool is group analysis that enables the finding of general symmetrical properties of differential equations. These symmetries help to generalize known analytical and numerical solutions, to derive new solutions, and to obtain conservation laws. In this work, results of group classification of the KZK equation with arbitrary nonlinear term are presented. It is shown that the KZK equation can be written in Euler–Lagrange form. All the classical Lie symmetries (geometric symmetries) are found and some classes of Lie–Backlund symmetries are considered. The largest number of the symmetries corresponds to the cases of quadratic and cubic nonlinearities. Besides scaling and translation groups of symmetries, there exist additional transformation groups which are not evident from the physical point of view. Examples of obtaining new solutions and deriving reduced equations are presented. New conservation laws for intense acoustic beams are obtained using the Noether theorem. 1pPAc2. Nonlinear wave propagation from a discrete annular array: Theory. Steven G. Kargl (Appl. Phys. Lab., Univ. of Washington, 1013 N. E. 40th St., Seattle, WA 98105), Ronald A. Roy, and Patrick Edson (Boston Univ., Boston, MA 02215, ronroy@bu.edu)

Theoretical investigations of finite amplitude wave propagation from bounded beam sources has been considered by Lee and Hamilton [J. Acoust. Soc. Am. **97**, 906–917 (1995)] as well as others. These researchers have restricted their analyses to a source geometry of either an unfocused circular piston or a weakly, spherically focused circular piston. When the peak pressure does not exceed approximately 150 MPa, the Khokhlov–Zabolotskaya–Kuznetsov (KZK) nonlinear parabolic wave equation yields numerical solutions in agreement with experiments. However, little research has been reported on finite amplitude wave propagation from an array of discrete sources. Time domain simulations, based on the KZK equation, will be discussed for an eight element discrete annular array immersed in fresh and sea water. The source signal is typically a short sine wave tone burst with a center frequency of 500 kHz. The transitions from linear acoustics to nonlinear acoustics will be discussed, and comparisons between a spherically focused circular source and a properly phased array will be presented. While some data from recent experiments may be shown, the scope of this talk will be restricted to the theoretical treatment and the numerical simulations for the discrete annular array. [Work supported by ONR.]

2:30

1pPAc3. Nonlinear wave propagation from a discrete annular array: Experiments. Patrick Edson, Ronald A. Roy (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, ronroy@bu.edu), and Steven G. Kargl (Univ. of Washington, Seattle, WA 98105)

To date, efforts to model nonlinear wave propagation from a bounded beam source have chiefly been concerned with unfocused and weakly focused circular piston sources [Lee and Hamilton, J. Acoust. Soc. Am. **97**, 906–917 (1995)]. When the peak pressure does not exceed approximately 150 MPa, the Khokhlov–Zabolotskaya–Kuznetsov (KZK) nonlinear parabolic wave equation yields numerical solutions in agreement with experiments. However, little research has been reported on nonlinear wave propagation from an array of discrete sources. Theoretical and experimental results for an eight-element annular array will be presented. The source signal is typically a ten-cycle sine wave tone burst with a center frequency of 500 kHz. The outer diameter of the array is 0.14 m, and the surface areas of the elements are equal. While theoretical predictions will be shown, the experimental aspects of this research will be emphasized. [Work supported by ONR.]

2:45

1pPAc4. On the asymmetric waveform of shock waves in high-amplitude focused sound fields. Halvor Hobaek (Dept. of Phys., Univ. of Bergen, Allegt. 55, N-5007 Bergen, Norway)

The asymmetric shape of shock waves generated in high-amplitude sound fields, where the peak positive pressure tends to be much higher in amplitude than the peak negative pressure, is well known. Numerical simulations based on the KZK equation show excellent agreement with experimental observations of the field from a focusing circular sound source with a pronounced asymmetry. This equation accounts for diffraction, absorption, and nonlinear effects. Thus the asymmetry must be due to diffraction, because the plane wave limit of the KZK equation (Burgers' equation), accounting for nonlinearity and absorption only, predicts symmetric waves (if the initial sound is sinusoidal). However, experimental

results indicate that the shock front is strongly connected with the contribution from the central part of the source, while diffraction gives rise to the edge wave which propagates independently of the shock, these two signals can easily be distinguished. Spectral analysis of the measured waveforms on the axis show that each harmonic component has an almost constant phase offset (a symmetric *N* wave has none). The edge wave can have negligible influence on this phase shift. Thus the question is, how does diffraction cause asymmetry? Results on the analysis of this problem will be presented.

3:00

1pPAc5. The parametric efficiency of a bifrequency focusing Gaussian nonlinear source. M. Serhat Özyar (Dept. of Elec. and Electron. Eng., Middle East Tech. Univ., Ankara, 06531, Turkey, ozyar@rorqual.cc.metu.edu.tr)

The field distribution from a bifrequency focusing nonlinear source was calculated. The simple formulation of Novikov *et al.* [''Nonlinear underwater acoustics,'' ASA, 86–90 (1987)] for the Gaussian wavefront was adopted for simulations. Radius of aperture or beamwidth (a), radius of curvature (D), mean primary frequency ($f_m=(f_1+f_2)/2$), and difference-frequency ($f_d=f_1-f_2$) are essential parameters describing the performance of a parametric focusing source. The geometrical ratio D/a and the down–shift were varied between 5 and 200 by changing f_d and the resulting difference–frequency pressure wave and primary intensity distributions were plotted against the propagation axis for $D/a=2$. A similar calculation was repeated for $f_d=50$ kHz by varying f_m. Separate effects of D and a were also investigated where the down–shift ratio was fixed to 20. Results were plotted for D/a: 1–4. Finally, an efficiency was defined as $\eta=$(parametric pressure)/(primary intensity). It was presented that η made a peak in the prefocal region and reached to a minimum value at the geometrical focus. The variation of η in the postfocal region was also discussed.

3:15

1pPAc6. Generation of harmonics in the near field of finite amplitude sources. Eugeniusz Kozaczka and Grayna Grelowska (Naval Acad., ul. Smidowicza 71, 81-919 Gdynia, Poland, ekoz@amw.gdynia.pl)

It is well-known that the fine structure of the near field brings difficulties to both the theoretical and the experimental investigations. However, in many applications the phenomena occurring in the near field are the most important ones. It is caused by such a measurement setup arrangement and the choice of the parameters of used transducers that the measured or diagnosed objects are situated in the near field. The paper presents the results of the experimental investigations of the finite amplitude wave radiated by mono- and biharmonic sources of different radiating apertures. The measurements were carried out in the near field of the transducer using the high-precision device which controlled the movement of the receiver. The pressure was measured using a 1-mm-diam PVdF needle hydrophone. The results of investigations will be presented as the 3-D distribution of a primary wave and its harmonics. The distributions of chosen harmonic will be shown in planes perpendicular to the acoustic axis of the transducer or along this axis. The experimental results were compared with the numerical ones.

1pPAc7. Raman–Nath diffraction caused at the focal point of a concave type transducer. Y. Watanabe, H. Miyaki, and K. Fujita (Dept. of Electron., Doshisha Univ., Kyotanabe 610-0321, Kyoto, Japan, kwatanab@mail.doshisha.ac.jp)

To estimate the intensity of sound pressure in the vicinity of the focal point of a concave type transducer, Raman–Nath diffraction caused at the focal point of a concave type transducer is theoretically and experimentally discussed. Sound field, near the focal point, including the acoustic nonlinearity, is theoretically calculated by using the KZK equation. Light intensity of zeroth order Raman–Nath diffraction is also calculated as a function of the sound pressure at the focal point. In the high intensive sound region, it is found that the acoustic nonlinearity makes the light intensity curve disappear at the local peaks. The He–Ne laser whose beam spot diameter is 1.2 mm is supplied as a light source. Light intensities of the zeroth-order Raman–Nath diffraction caused at the focal point are observed by changing the driving voltage of the transducer. The experimentally obtained graph shows the relatively same pattern compared with the theoretically calculated one. The sound pressure at the focal point is estimated by fitting those two results. It is confirmed that the sound pressure estimated by the optical method shows good agreements with the estimated one by the hydrophone measurements.

1pPAc8. Parameter sensitivity in nonlinear and dissipative time-reversed acoustics. Claes M. Hedberg (Mech. Eng., Univ. of Karlskrona/Ronneby, Karlskrona, Sweden, claes.hedberg@hk-r.se)

Time-reversed nonlinear acoustics has shown that a propagated signal retains information about the original signal after shock formation and even after merging of shocks. This information is naturally very dependent on the accuracy of the measured or calculated data. Presented here is a more detailed analysis of the estimation of the dimensionless parameters in the problem: the original amplitude, the distance traveled, and the dissipation over nonlinearity ratio. The robustness of alternative methods and their sensitivity to noise and incomplete data are investigated.

4:15

1pPAc9. ''Induced transparency'' of an acoustical waveguide containing a liquid with nonlinear viscosity. Oleg M. Zozulya (N. Andreyev Acoust. Inst., 4 Shvernik str., Moscow 117036, Russia)

Sound propagation in an acoustical waveguide containing a liquid that depends on a shear rate $\dot{\gamma}$ viscosity is considered. A number of rheological models adequately representing such dependence in a wide range of $\dot{\gamma}$ variation are well known (power law, Carreau model for stuctural viscosity, etc.). In most of the models viscosity decreases with the increase of $\dot{\gamma}$. It can result from the destruction of some internal microstructures in the liquid and their self-reconstruction with a reduction of load (as, e.g., in a sol–gel transition). For such liquids the effect of ''induced transparency'' for intense sound waves is expected. In this work the effect is determined for harmonic waves, propagating in an acoustical waveguide with cross–section dimensions that are small in comparison with the sound wavelength. The dependence of viscosity on $\dot{\gamma}$ is taken into account by retention of the first nonlinear term in the expansion of shear tension σ_τ in shear rate $\dot{\gamma}$: $\sigma_\tau=\eta\dot{\gamma}-\xi\dot{\gamma}^3$, where η and ξ are linear and nonlinear parameters of viscosity, respectively. Sound attenuation in acoustical waveguides is due to the partial transmission of acoustical energy to the viscous waves being generated in the vicinity of waveguide walls. It is shown that the nonlinear viscosity gives rise to the effective viscous wave self-interaction, which results in the reduction of the energy dissipation. The application of the effect to the measurements of the nonlinear viscosity parameter is considered and the importance of this parameter for the evaluation of the oil quality is discussed. Work was partially supported by the Russian Foundation of Basic Research (project 97-08-17789).]

4:30

1pPAc10. Application of the three-wave interaction to the problem of acoustical monitoring of complicated media. Samuil A. Rybak and Oleg M. Zozulya (N. N. Andreyev Acoust. Inst., 4 Shvernik str., Moscow 117036, Russia)

In a nonlinear medium with resonant dispersion the three-wave interaction is considered. The medium consists of oscillators distributed in eigenfrequency range. The quadratic nonlinearity is taken into account in surrounding compressible medium. The three-wave interaction in such medium is sensitive to the changing of the medium parameters. Space and time scales of energy transfer among the interacting waves are determined. The eigenfrequency distribution leads to the effective Landau attenuation of wave amplitudes and results in finite time interaction among waves. On the other hand, this finite time permits the same efficiency of interaction not only for waves exactly satisfying the resonant conditions but also for wave packets. In the particular case of Lorentz distribution the influence of the distribution parameters on the energy transfer is determined. Some exact solutions expressed in special functions describing the three-wave interaction are obtained. [Work was partially supported by Russian Foundation of Basic Research.]

4:45

1pPAc11. Application of nonlinear interaction of sound waves in sound reproduction. Weiguo Dong, Qunli Wu, and Shih Fu Ling (School of Mech. and Production Eng., Nanyang Technolog. Univ., Nanyang Ave., Singapore 639798)

Audio sound reproduction using the nonlinear interaction of sound waves is investigated. Special emphasis is given to the sum and difference frequencies generated by the nonlinear interaction of two sound waves in a duct. The numerical and experimental results for scattered sum and difference frequency sound are presented and compared. The relationship between the difference frequency and the two primary sound waves are studied. It is found that the flat frequency response of the difference frequency can be achieved by adjusting the amplitudes of two primary waves. Finally, the sound reproduction using a single bi-frequency source is also investigated. The results for sum and difference frequency generation of this case are compared with those of the dual sources.

1pPP1. Frequency-dependent saturation in inner hair cell responses. M. A. Cheatham and P. Dallos (Audiol. and Hearing Sci., The Hugh Knowles Ctr., Frances Searle Bldg., Northwestern Univ., Evanston, IL 60208)

Inner hair cell (IHC) recordings are made in guinea pig from cochlear turns 2, 3, and 4 where best frequencies (BF) are approximately 4000, 1000, and 250 Hz, respectively. Input–output functions for the ac receptor potential are measured for inputs at, below, and above the BF of each recording location. Although all responses saturate at high intensities, the response magnitude at which saturation occurs depends on stimulus frequency. For example, in turn 2 more linear responses are observed below BF while in turn 4 a different pattern emerges. At this apical recording site, which responds preferentially to very low frequencies, IHCs exhibit more linear behavior above BF. In other words, response magnitude at saturation exceeds that measured for inputs at and below the BF of the cell. The reasons for this dependence on BF are evaluated by comparing input–output functions for ac responses recorded intracellularly from IHCs and extracellularly from the organ of Corti fluid space. [Work supported by Grant No. 5 R01 DC00089, National Institute on Deafness and Other Communication Disorders, National Institutes of Health.]

2:30

1pPP2. Linear and nonlinear modeling techniques for cochlear mechanics. Karl Grosh (Dept. of Mech. Eng. and Appl. Mech., Univ. of Michigan, Ann Arbor, MI 48109-2125), Anand Parthasrathi (Univ. of Michigan, Ann Arbor, MI 48109), and Alfred Nuttall (Oregon Health Sci. Univ., Portland, OR)

New experimental techniques have made possible the measurement of the cochlear response to electrical, mechanical, and acoustical stimuli as never before possible. By controlling the various inputs to the cochlea, these measurements hold the promise for delivering sufficient information for developing morphologically based cochlear mechanics models capable of representing the amplification and nonlinear dynamics seen in the data. Nonlinear dynamics takes the form, for example, of harmonic generation and compression. Activity may take the form of outer hair cell mediated force generation. These new data in part motivate the need for new modeling techniques to accurately and efficiently simulate the response arising from the morphology and possible activity of the cochlea. In this paper, hybrid methods are presented for three-dimensional cochlear models which generalize to include activity and nonlinearity in a straightforward fashion. These methods are based on modal–finite element and boundary element–finite element hybrid methods. This approach enables the inclusion of as much structural inhomogeneity as needed for the accurate simu-

lation of the underlying response. The framework for the inclusion of activity, nonlinearity, and inhomogeneity (e.g., radial variation in morphology) is given. Results for time harmonic forcing (e.g., stapes motion) are presented.

2:45

1pPP3. Rejecting a cochlear-partition model with constant mass. Timothy A. Wilson (Dept. of Elec. Eng., Univ. of Memphis, Memphis, TN 38152)

The question of whether a simple low-order, linear, passive model of cochlear-partition dynamics can account for ''global'' (overall stiffness change, range of best frequencies and best places) and ''local'' (peakiness of frequency- and place-selectivity, amount of phase-angle change around the best place or frequency) attributes of cochlear response to tones in Békésy's observations in cadavers remains unresolved. With answering that question the goal, a simple stiffness-damping-mass model of cochlear-partition dynamics with constant mass and exponentially varying stiffness and damping, was investigated computationally using a box-cochlea model of cochlear hydrodynamics. Constrained only by Békésy's reported change in stiffness by about two orders of magnitude, the model's global and local response attributes were determined over a reasonably exhaustive set of mechanical parameter values. It was found that the only combinations of mechanical parameters resulting in reasonable cochlear maps had magnitude-response shapes neither qualitatively resembling nor quantitatively consistent with observations by Békésy or anyone else, postmortem or *in vivo*.

3:00

1pPP4. Determination of roots of eikonal equation for WKB solution in cochlear models. Anand A. Parthasarathi (Dept. of Biomed. Engr., Univ. of Michigan, Ann Arbor, MI 48109, anand@engin.umich.edu), Karl Grosh (Univ. of Michigan, Ann Arbor, MI 48109-2125), and Alfred L. Nuttall (Oregon Health Sci. Univ., Portland, OR 97201-3098)

The WKB-theory-based asymptotic methods have been used to obtain solutions to analytical cochlear models [E. de Boer, Phys. Rep. **105**(3), 141–226]. The local wave number for this solution is obtained as the root of the eikonal equation or the dispersion equation. For a three-dimensional rectangular model, multiple complex roots exist, which could give rise to additional waves on the basilar membrane. However, previous results were based on a single root locus determined using initial estimates obtained from the long-wave approximation. In this study, the winding-number integral technique [P. R. Brazier-Smith and J. F. M. Scott, J. Sound Vib. **145**(3), 503–510] is used to obtain a definitive identification of the multiple roots and their dependence on the number of acoustic cross modes. *A priori* information about the characteristics of the dispersion relationship was used to obtain an initial estimate of the search region. Thereafter the region was refined and the roots located using moments of the winding integral and secant iterations. It was found that higher-order roots are strongly evanescent away from the resonance location. Also, as the number of acoustic cross modes of the duct increases, more roots appear. The influence of these roots on the solution will be discussed.

3:15

1pPP5. A signal detection theoretic analysis of the Carney model of auditory processing. Leslie M. Collins and Lisa C. Gresham (Dept. of Elec. and Comput. Eng., Box 90291, Duke Univ., Durham, NC 27708-0291, lcollins@ee.duke.edu)

Computational models of human auditory processing provide a platform on which to apply signal detection theory (SDT) directly to the ''output'' of various peripheral processes. Theoretical performance predicted by standard SDT analyses which do not incorporate such models often substantially exceeds measured performance. These discrepancies are commonly compensated for by adding a physiologically unspecified source of ''internal noise.'' By applying SDT to auditory models it is possible to evaluate whether the performance predicted at various stages of the auditory system provides a more accurate estimate of human performance than standard approaches which incorporate internal noise. Our previous work indicates that integrating SDT with a deterministic model of the human auditory system affords theoretical performance predictions that match experimental measurements more closely than traditional approaches. In the work presented here, SDT is integrated with Carney's model of auditory processing [Carney, J. Acoust. Soc. Am. **93** (1993)]. This model incorporates physiologically based models of the basilar membrane and inner hair cell mechanisms, as well as a nonhomogeneous Poisson process to model nerve discharge times. The performance predicted by this model is presented, and its relationship to previous results and to modeling assumptions is discussed. [Work supported by NIH.]

3:30

1pPP6. Signal detection theoretic analysis of auditory processing: Phase uncertainty and multiple channel integration. Lisa C. Gresham and Leslie M. Collins (Dept. of Elec. and Comput. Eng., Box 90291, Duke Univ., Durham, NC 27708-0291, lcollins@ee.duke.edu)

Traditionally, psychophysical data has been predicted either by constructing models of the peripheral auditory system or by using signal detection theory. The resulting theoretical detection performance is often substantially greater than experimental results and has been explained by adding ''internal noise'' to the system in a somewhat *ad hoc* manner. An integrated approach combining both a physiologically based auditory model and classical signal detection theory has been shown to produce more accurate predictions of experimental data. The discrepancy that still exists may be due, in part, to the two unrealistic assumptions that the system is deterministic and that a single channel with the highest signal-to-noise ratio determines detection performance. The work presented here investigates the impact of phase uncertainty and multiple channel integration on predicted detection performance. More accurate predictions of experimental data are obtained, particularly after the first two stages of the auditory model, when phase uncertainty is added to the auditory input signal and the resulting output signals are analyzed using the integrated approach. Integrating information across multiple channels increases the predicted performance, albeit not substantially, suggesting that the single-channel approximation is not a significant source of discrepancy between theoretical and experimental results. [Work supported by NIH.]

3:45–4:00 Break

4:00

1pPP7. A descriptive model of under- and over-shoot patterns in the temporal masking function of a narrow-band noise. C. Formby, J. C. Rutledge (Div. of Otolaryngol.—HNS, Univ. of Maryland School of Medicine, Baltimore, MD 21201), M. G. Heinz (Harvard–MIT, Cambridge, MA 02139), L. P. Sherlock, and I. V. Alexsandrovsky (Univ. of Maryland School of Medicine, Balitmore, MD 21201)

Complex temporal patterns of under- and over-shoot (i.e., enhanced and diminished detection) at onset and offset of a 200-ms, 400-Hz-wide noise masker (2500 Hz center frequency) have been reported for a temporal masking paradigm [Formby *et al.*., J. Acoust. Soc. Am. **102**, 3161(A) (1997)]. The paradigm measured detection of a 5-ms sinusoidal signal (1900 or 2100 Hz) at 43 temporal positions preceding, during, and following the masker. Efforts to model under- and over-shoot patterns in the temporal masking functions will be considered. The modeling strategy is similar to that used in the study of vestibular adaptation [Formby *et al.*, 21st Meeting of Association for Research in Otolaryngology, 1988], and allows for quantification of the relative amplitudes, time constants, and delays of excitatory and adaptive processes. Linear combinations of exponential functions are used to represent the effects of excitatory masking and adaptation. Suppression and adaptation of suppression may also play roles in the masking process. These effects can be evaluated in our scheme by including corresponding exponential functions to represent the processes. The least-squares fitting model will be described and parameter estimates for the model will be presented for a range of masker levels. [Work supported by ONR.]

4:15

1pPP8. Detection of an increment in a single-frequency component of a noise background as a function of increment frequency and duration. C. Formby (Div. of Otolaryngol.—HNS, Univ. of Maryland School of Medicine, Baltimore, MD 21201), M. G. Heinz (Harvard–MIT, Cambridge, MA 02139), and I. V. Aleksandrovsky (Univ. of Maryland School of Medicine, Baltimore, MD 21201)

Increment detection thresholds for a single-frequency component were measured over a range of increment frequencies (250–6000 Hz) and durations ($T=10$–500 ms) in a 500-ms, 6000-Hz-wide noise. The noise spectrum level was either constant ($N_0=40$ dB) or randomly varied (between $N_0=20$ and 40 dB) from interval to interval. Preliminary results reveal performance for each increment frequency to be similar for the fixed- and random-level conditions. Detection thresholds for $T=10$ ms are largely independent of frequency and correspond to S-N_0 values of 17–18 dB, whereas corresponding S-N_0 values measured for long duration increments increase at a rate of 3 dB/oct for increment frequencies between 500 and 4000 Hz. The latter finding is consistent with changes in the critical ratio. This ratio is assumed to be based on an absolute energy cue, which is inconsistent in the random-level condition. Temporal integration (TI) functions fitted to the normalized detection data reveal less integration with increasing increment frequency from 500 to 4000 Hz. When the detection results are corrected for the apparent ''critical ratio'' effect, the TI functions are largely independent of increment frequency. [Work supported by ONR.]

4:30

1pPP9. A unified theory of two-tone suppression and upward-spread of masking. Jont Allen and Deep Sen (AT&T Labs-Res., 180 Park Ave., Florham Park, NJ 07932)

Low-frequency two-tone suppressors (TTS) [Sachs and Abbas], and the upward spread of masking, have traditionally been treated as separate phenomena. We postulate that both these well-known response measures are due to nonlinear (NL) cochlear compression. Furthermore, we attribute this NL compression to a changing basilar membrane (BM) stiffness, which varies inversely with hair cell stimulus. A 65 dB SL low-frequency tonal masker/suppressor excites a broad basal region of the cochlea uniformly, raising the threshold of high-frequency probes throughout this portion of the cochlea. Sufficiently intense low-frequency maskers/suppressors cause a reduction in the stiffness in the base of the BM, resulting in the probe characteristic frequency shifting towards the base. This basal NL shift of the BM response, combined with high-pass filtering by the tectorial membrane, results in an attenuated basal hair-cell response. This change in gain accounts for the expansive slope of the upward spread of masking, having a maximum slope of 2.4 dB/dB. This slope implies a compression proportional to pressure to the $0.8\approx 2/2.4$ power. The same model explains TTS if we treat the CF tone as the probe and the suppressing tone as the masker. The rate of growth of suppression, in this case, is also known to reach a maximum of 2.4 dB/dB [Delgutte].

4:45

1pPP10. Equal-loudness relations at high frequencies: Implications for loudness growth. Rhona Hellman (Auditory Percept. Lab., Dept. of Psych., Northeastern Univ., Boston, MA 02115, hellman@neu.edu), Hisashi Takeshima (Sendai Natl. College of Technol., Sendai, 989-31 Japan), Yoiti Suzuki, Kenji Ozawa, Takanori Yamaguchi (Tohoku Univ., Sendai, 980-77 Japan), Yusaku Sasaki (Sendai Natl. College of Technol., Sendai, 989-31 Japan), and Toshio Sone (Tohoku Univ., Sendai, 980-77 Japan)

Equal-loudness relations spanning a wide range of sensation levels (SL) were measured by the method of adjustment for 12 pairs of frequencies from 1 to 16 kHz. Sensation levels were based on individual thresholds measured prior to the equal-loudness determinations by an adaptive 2IFC procedure. To test for transitivity, three reference frequencies at 1, 3.15, and 5 kHz were used. Below 8 kHz, the matching results were well described by a linear function with a slope of 1.0; at higher frequencies, the functions became increasingly curvilinear. Near threshold and at moderate SLs the loudness of a tone at 12.5 kHz and higher increased more rapidly than the loudness of the lower-frequency reference tone; at high SLs it increased more slowly. The dependence of the slope of the matching function on level was most pronounced at 16 kHz. Moreover, nearly perfect transitivity was observed. The reduction in slope at high SLs is consistent with recent evidence that severely restricting the spread of excitation to high frequencies decreases the tone's rate of loudness growth [R. P. Hellman, J. Acoust. Soc. Am. **96**, 2655–2663 (1994)]. [Work supported by the Japanese Ministry of Education, Science, Sports, and Culture.]

5:00

1pPP11. Global and continuous judgments of sounds with time-varying intensity: Cross-modal matching with a proprioceptive input device. Patrick Susini (Inst. de Recherche et de Coordination Acoustique/Musique (IRCAM), 1 Place Igor Stravinsky, F-75004 Paris, France) and Stephen McAdams (IRCAM, F-75004 Paris, France)

Conventional psychophysical methods such as paired comparisons and psychophysical scaling present problems in the case of real-time perceptual evaluation of long-duration nonstationary sounds. In order to obtain loudness profiles of such sounds and to determine their relation to global loudness judgments, a continuous judgment method was employed using cross-modal matching of loudness with muscular force in a proprioceptive input device. This device was perceptually calibrated with 1-kHz stationary pure tones using S. S. Stevens' cross-modal matching paradigm. The loudness scale is equivalent to that obtained with ratio and magnitude production methods. The device was then tested on pure tones varying in intensity from 10 to 53 s. In order to observe the different memory processes involved in the global evaluation, several types of contours were used with from one to three peaks. The global judgment was influenced both by the duration and the level of the last contour peaks. The continuous judgment task also appeared to entail an auditory and gestual learning of the signal contour.

5:15

1pPP12. On the effects of a subharmonic masker on the loudness of a pure tone. Kenji Ozawa (Res. Inst. of Elec. Commun., Tohoku Univ., 2-1-1 Katahira, Aoba-ku, Sendai, 980-8577 Japan, ken@sone.riec.tohoku.ac.jp), William S. Hellman (Boston Univ., Boston, MA 02215), Yoshinori Inoue, Yôiti Suzuki, and Toshio Sone (Tohoku Univ., 2-1-1 Katahira, Aoba-ku, Sendai, 980-8577 Japan)

Loudness matching functions between a 1-kHz tone in quiet and in the presence of a 70 dB(SPL) 0.5-kHz subharmonic masker were studied to determine the alterations in loudness due to intensity shifts at the stimulus frequency arising from the generation of the second harmonic of the masker. Such effects are understood to be due to a quadratic nonlinearity occurring in the inner ear transduction process. In the experiment, masked thresholds were measured at 30° phase angle intervals of the stimulus. Matching functions were obtained for phase conditions corresponding to minimum and maximum thresholds. Both the shape of the matching functions and their relative displacement from each other were consistent with the predictions of the vector summation model [Clack *et al.*, J. Acoust. Soc. Am. **52**, 536–541 (1972); Schubert, J. Acoust. Soc. Am. **45**, 790–791 (1969)]. Assuming that the threshold shifts were due to constructive and destructive interference between the 1-kHz tone and the second harmonic of the masker, a single effective matching function was constructed by means of the vector summation model. This calculation demonstrated the ability of loudness matching to probe nonlinear cochlear mechanisms. Matching functions generated from several proposed loudness functions were compared with the data.

1pSA1. Sound scattering by a fluid-loaded finite cylindrical shell. Aleksander Klauson, Jaan Metsaveer (Dept. of Mech., Tallinn Tech. Univ., Ehitajate tee 5, Tallinn EE-0026, Estonia), Nicolas Touraine, Dominique Decultot, and Gerard Maze (LAUE URA CNRS 1373, Univ. of Le Havre, Pl. R. Schuman, 76610 Le Havre, France)

Let a thin-walled finite cylindrical shell with the hemispherical end caps be immersed in a fluid medium. The shell contains structural inhomogeneities like radial solders and internal ribs and is excited by an axisymmetric pressure load. The paper deals with the numerical and experimental investigation of the sound-pressure field scattered by the shell and its internals. The numerical solution of the problem is based on the finite element method (FEM) with the use of the thin shell theory elements. The Green's function of the structure is obtained by the FEM and is further used in the boundary element solution scheme using both physical and modal coordinates. Flexural and membrane type eigenmodes of the fluid-loaded structure can be determined and identified. A time-domain solution to the problem obtained by the inverse Fourier transform gives echo-signals of the sound scattered by the structure. Individual pulses in the echo-signal help to localize structural inhomogeneities and to appreciate their importance in the scattered sound field. The membrane type vibrations are shown to be substantially modified by the internal solders and substructures. Experimental investigation is performed for a steel target immersed in a water tank and the numerical results correlate well with the experiment.

1pSA2. Meridional and helical ray contributions to backscattering by tilted cylindrical shells: High-frequency tone burst and wide bandwidth measurements and interpretation. Scot F. Morse and Philip L. Marston (Dept. of Phys., Washington State Univ., Pullman, WA 99164-2814, morse@mail.wsu.edu)

When viewed in the frequency-angle domain, the backscattering by truncated thick cylindrical shells in water exhibit various ridges of high backscatter. These enhancements are associated with leaky waves excited on the shell and can be described in terms of meridional and helical rays. The enhancements are not present for a rigid scatterer of the same shape and may be important for interpreting high-frequency sonar echoes. Previous work [Morse *et al.*, J. Acoust. Soc. Am. (to be published)] has shown that these enhancements are not limited to near broadside incidence but can extend to end-on incidence in the coincidence frequency region. Results of broadband and tone burst measurements of these enhancements are presented. High-frequency tone bursts may be used to separate the meridional ray enhancement from the generally weaker helical ray enhancement. The general angular width of the meridional ray enhancement may be explained using an approximate ray theory [Marston, J. Acoust. Soc. Am. **102**, 358–369 (1997)]. The amplitude of the backscattered meridional ray depends on the leaky wave reflection coefficient at the end of the cylinder which appears to be affected by mode conversion near mode thresholds. [Work sponsored by the Office of Naval Research.]

1:30

1pSA3. A method of target characterization based on the analysis of Scholte–Stoneley and Lamb-type waves scattered by submerged fluid-filled thin-walled shells. Alessandra Tesei, Warren L. J. Fox, Alain Maguer, and Arne Løvik (SACLANT Undersea Res. Ctr., La Spezia, Italy)

The scattering inverse problem is addressed as a powerful aid to target classification. Broadband sonar signals are used to insonify submerged elastic objects, and signal processing techniques are applied to the backscattered response. Cylindrical fluid-filled thin-walled shells are considered. The ka range is (2,50). One characteristic of target echoes playing a major role at low-intermediate frequencies is the resonance contribution, which depends on the target's elastic properties. Here resonance information is extracted by algorithms based on autoregressive (AR) spectral estimation techniques. Assuming a target as a linear acoustic system, AR modeling is used for estimating its poles and, among them, resonance modes which are identified on the basis of resonance scattering theory. Previous investigations on scattering by thin plates and shells demonstrated the existence of fluid-born Scholte–Stoneley waves and shell-born Lamb-type waves. Here, from the study of these waves and internal reflections, a set of equations are formulated which correlate resonance characteristics with geometrical and geophysical target parameters. The algorithms are shown to succeed in estimating parameters such as the shell outer radius, material, and wall thickness. Simulated and real data backscattered by cylinders at broadside are considered. Analyzing simple-shaped objects is seen as preliminary for characterizing more complicated targets.

1:45

1pSA4. Scattering from fluid-loaded elastic targets near penetrable sediments. Garner Bishop and Judy Smith (Naval Undersea Warfare Ctr., Newport, RI 02841)

A T-matrix formalism developed for plane-wave scattering from a fluid-loaded elastic spherical shell near a rough fluid elastic interface [J. Acoust. Soc. Am. **101**, 767–788 (1997)] is generalized to include scattering from targets for which a T-matrix is known and constructed on a spherical wave basis, and from the interface of penetrable sediments for which a T-matrix is known and constructed on a Weyl plane-wave basis. A variety of numerical results are obtained for plane-wave scattering from elastic spheres and elastic spherical shells, as well as a finite elastic cylinder with hemispherical end caps near rigid, soft, fluid, elastic, poroelastic, and layered fluid sediments with planar boundaries that demonstrate some of the effects' target-boundary scattering on resonant and nonresonant scattering.

1pSA5. Convolution formulation for high-frequency leaky wave scattering enhancements for solids and shells with truncations: Evaluation of the surface integral and experimental and computational tests. Philip L. Marston, Karen Gipson, and Scot F. Morse (Dept. of Phys., Washington State Univ., Pullman, WA 99164-2814)

Leaky waves reflected at truncations of elastic objects in water can cause high-frequency backscattering enhancements for ranges of orientation angles [Morse *et al.*, J. Acoust. Soc. Am. (accepted for publication)]. The backscattering can be much greater than for rigid objects having the same shape, size, and orientation. Such enhancements are relevant to the interpretation of sonar images and are usually associated with relatively flat portions of the outgoing wavefront. The typical leaky wave attenuation length can be much less than the largest dimension of the scatterer, rendering global resonances to be unimportant. One approach to approximating these enhancements is to evaluate a two-dimensional convolution integral for the outgoing leaky wave amplitude on the surface [P. L. Marston, J. Acoust. Soc. Am. **102**, 358–369 and 1628–1638 (1997)]. In some cases this integral may be approximated as a one-dimensional integral. It is also necessary to approximate leaky wave reflection coefficients at truncations and to evaluate a propagation integral for the far-field amplitude. Some mechanisms to be discussed give large enhancements from reflected Rayleigh waves on tilted cylinders and cubes and from Lamb waves on cylinders. [Work supported by the Office of Naval Research.]

1pSA6. Vibroacoustical modeling and modal analysis of a double wall panel. Stan Josef Pietrzko (EMPA Swiss Federal Labs, Ueberlandstrasse 129, CH 8600 Duebendorf, Switzerland)

In this paper results are reported of analytical and experimental vibroacoustical modal analysis of a double wall panel. Both mechanical vibrations of panel walls as well as the modal behavior of acoustical field in cavity were identified. Special interest was focused on identification and modeling of interaction and coupling between vibratory behavior of the walls and acoustical field in the cavity and their influence on drop of the transmission loss of the panel, as measured in the laboratory. The identification was carried out using a set of combined vibratory and acoustical frequency response functions measurements as response due to random noise force and controlled volume velocity source. The identified global complex modes of the panel and an estimated model of the panel employing general parameters were of high quality. It was confirmed by very good orthogonality of the identified vibratory and acoustical mode shapes and high correlation values between the measured and synthesized frequency response functions. This result provides a robust basis for the numerical study of the transmission behavior of the panel in the low-frequency range. Application of this result on optimum placement of force actuators to increase of transmission loss over a lower-frequency range by means of active noise and vibration control will be presented.

2:30

1pSA7. Angular distribution of incident sound energy for estimating the sound transmission loss of multilayered panels. Hyun-Ju Kang, Hyun-Sil Kim, Jae-Seung Kim, Sang-Ryul Kim (Korea Inst. of Machinery and Mater., P.O. Box 101, Yusung, Taejon 305-600, Korea), and Jeong-Guon Ih (Korea Adv. Inst. of Sci. and Technol., Science Town, Taejon 305-701, Korea)

The sound transmission coefficient in the diffuse field depends on the angular distribution of the incident sound energy. Although the field incidence formula has suggested that instead of the random incidence formula, the determination of the limit angle near the grazing incidence is very empirical and various limit angles have been defined by many researchers until now. This angle is especially important when dealing with the sound transmission loss of multilayered panel systems. In order to find the angular energy distribution of the incident sound in the actual test situation, a numerical simulation by using ray tracing is performed for the bounding surfaces of a sphere and a reverberation chamber. The results show that the sound energy distribution of the incidence angle on a bounding surface may be approximated to the Gaussian distribution. Sound transmission losses are predicted by utilizing the concept of the Gaussian distribution of the incidence energy for various single and multilayered panels and they agree very well with experimental results.

3:00

1pSA8. An analytical model for bandlimited response of vibroacoustic systems. K. S. Sum and J. Pan (Dept. of Mech. and Mater. Eng., Univ. of Western Australia, Nedlands, Western Australia 6907)

In this paper, an analytical method for predicting bandlimited time-averaged energies in vibroacoustic systems is presented. A vibroacoustic system is considered where a flexible boundary structure is directly excited by some external forces and an enclosed sound field is driven through an acoustic-structural coupling. This method allows for the reduction in computational effort compared to the classical modal coupling method especially for analysis in the medium frequency range where there is a large number of dominant acoustic and/or structural modes. The vibroacoustic problem is also extended to consider cases of structure-borne sound where the sound field is subject to coupling with various vibrating boundary structures. The prediction accuracy of the present method will be compared to the classical modal coupling method and its computational efficiency is demonstrated by means of numerical examples.

3:15

1pSA9. Optimization procedures for strain sensing in active structural acoustic control. Patrice Masson and Alain Berry (G.A.U.S., Mech. Eng. Dept., Univ. de Sherbrooke, Sherbrooke, QC J1K 2R1, Canada, Patrice.Masson@gme.usherb.ca)

Many active structural acoustic control strategies which are based on the minimization of the radiated acoustic power are defined in the wave number domain to exploit the fact that only supersonic structural wave number components are radiating sound. Discrete sensors are more appropriate for this purpose as they allow the ability to distinguish between the structural components on two-dimensional structures. However, the use of such sensors may require extensive real-time computation, as the displacement field has to be reconstructed from the strain field in order to compute the radiated acoustic power. Two approaches are herein proposed to optimize the calculation of the radiated acoustic power. The first one allows the calculation of the radiated power *directly* from the strain field, without requiring any reconstruction of the displacement field. The second approach is directed toward the optimization of the radiated power calculation by using a wavelet transform of the displacement field, thus avoiding the Fourier transform and the integration of the radiating components. Experimental control results are presented using different types of strain sensors mounted on a simply supported beam. It is shown that in that case, a significant gain in computation time can be obtained using the proposed approaches without sacrificing the control performances.

3:30

1pSA10. Measurements and modeling of the transient acoustic field at impacted plates. Antoine Chaigne, Christophe Lambourg (ENST, Signal Dept., 46 rue Barrault 75634 Paris Cedex 13, France), and Staffan Schedin (Luleå Univ. of Technol., Div. of Exp. Mech., S-97187 Luleå, Sweden)

A comparison between measured and simulated transient acoustic fields generated by thin impacted plates is reported. The plate is modeled by using finite difference methods and the radiated pressure is obtained by solving the Rayleigh integral [Ch. Lambourg and A. Chaigne, J. Acoust. Soc. Am. **101**(A) (1997)]. The results are evaluated in the form of the spatial pressure distribution at instants short after the excitation. Experimentally, a lead bullet (0.5 g, 100 m/s) is fired towards a cantilever steel plate ($300\times30\times1$ mm). The duration of the impact is estimated by using a high-speed camera that can register several million frames per second.

An interferometric comparison of the change in optical path length of two holographic recordings, captured before and shortly after the impact, gives a 2-D projection of the acoustic field. A double-pulsed ruby laser, emitting light pulses of short duration (30 ns), is used as light source [S. Schedin, A. O. Waahlin, and P. Gren, J. Acoust. Soc. Am **99**, 700–705 (1996)]. A high degree of similarity is observed between measured and simulated sound field, except in the close vicinity of the impact point. It is presumed that the discrepancies are due to nonlinear effects which are not included in the model.

3:45

1pSA11. Near field acoustic source identification based on numerical models and operational pressure data. Paul Sas and Peter Mas (Dept. of Mech. Eng., Div. PMA, Katholieke Universiteit Leuven, Celestijnenlaan 300B, B-3001 Heverlee, Leuven, Belgium, paul.sas@mech.kuleuven.ac.be)

When pressure measurements are taken in the near field of possible sources, a global inversion of an input–output model of the acoustic medium can be accomplished to calculate the source velocities, and thus to identify the main noise radiating parts. The acoustic medium can be represented by a frequency response function (FRF) matrix which can either be derived analytically based on a point source assumption, or experimentally under laboratory conditions, as well as numerically using a finite or a boundary element model. The operational source velocities can be calculated by multiplying the inverted FRF matrix with the vector of operational pressure measurements. The inversion process, however, is usually an ill-conditioned problem. Regularization techniques based on a singular value decomposition can be used to solve for the ill-conditioned nature of the inverse acoustic problem. In this paper, the applicability of numerically derived FRF models using the boundary element modeling technique, is shown for the calculation of the velocities at the boundary of a source model, based on operational pressure measurements. The results are compared with near field acoustic holography calculations, and the usefulness of an L-curve criterion for the selection of the optimal regularization parameter is indicated based on simulations as well as experiments.

4:00

1pSA12. Visualization of the sound field generated by a plate-cavity coupled system using acoustic holography. Sea-Moon Kim and Yang-Hann Kim (Ctr. for Noise and Vib. Control, Dept. of Mech. Eng., Korea Adv. Inst. of Sci. and Technol., Taejon 305-701, Korea)

In most cases of structural-acoustic problems, it is reasonable to assume that structural vibration is not influenced by the surrounding fluid. In these cases, the vibration of the structure is solved first, then the radiation sound field is calculated by simply applying the Kirchhoff–Helmholtz integral equation. However, this assumption is no longer satisfied when structural stiffness is small or fluid impedance is comparable to it. In this situation the vibration and acoustic fields are to be solved simultaneously. Although many researchers have studied this structural-acoustic coupling problem, there are still difficulties in solving the problem analytically or even numerically. In this study, visualization of sound field by a geometrically simple system (plate-cavity coupled system) is performed experimentally in order to figure out the coupling mechanism between fluid and structure. The system is excited by a speaker, and both internal and external sound pressures are measured. The acoustic holographic method is used to estimate the sound field. The results exhibit that there are frequencies where both plate and cavity are strongly coupled as well as ones where the plate can be considered rigid. Visualization that shows acoustic power flow between the internal cavity and external field enables us to understand the fluid-structure coupling mechanism.

1pSC1. Building acoustic models for speech recognition. Francesco Scattone (Dragon Systems, 320 Nevada St., Newton, MA 02160, francesco@dragonsys.com)

This paper reviews the methodology currently used at Dragon Systems to build a speech recognition system for a new language, with particular focus on the training of acoustic models. Issues concerning the selection and use of suitable speech corpora are discussed and experimental results from recent experiences in developing large vocabulary continuous speech recognizers in several European languages are reported.

2:40

1pSC2. Spoken language technology research at Microsoft. X. D. Huang (Microsoft Res., Redmond, WA 98052)

The goal of ongoing work is to develop spoken language technologies for use by a broad audience of computer users and in a wide range of applications. The current work in support of this broad objective falls into four main areas: speech recognition technology code-named Whisper (Windows Highly Intelligent Speech Recognizer); speech synthesis technology code-named Whistler (Windows Highly Intelligent Stochastic Talker); spoken language understanding technology code-named Leap (Language enabled applications); and the Microsoft Speech Software Developer's Kit that facilitates full integration of speech into applications. This paper describes ongoing R&D effort and technical challenges in these areas. Not only are technology components being created that can be shared for the whole spoken language system, but also solutions are being created for application developers to author compelling speech-

enabled applications. To realize this vision of speech enabling the whole computer, not only should critical technology components be improved (i.e., Whisper, Whistler and Leap), but also a tighter integration of these spoken language technology components should be evangelized with broader applications and interfaces to enhance and extend the entire user experience. A number of groups have started developing SAPI-compliant technology components and applications such as telephony, wireless PDA, accessibility, and desktop agent. More information can be found in http://research.microsoft.com/stg.

3:00

1pSC3. Recent activities in spoken language processing at LIMSI. Jean-Luc S. Gauvain (LIMSI-CNRS, BP 133, 91403 Orsay Cedex, France)

This paper summarizes recent activities at LIMSI in speech recognition and its applications. The LIMSI recognizer, which has state-of-the-art performance, uses phone-based continuous density HMM for acoustic modeling, and word and class backoff n-grams for language modeling. Acoustic model adaptation techniques (PMC, MAP, MLLR) are used to reduce the mismatch between test and training conditions, in particular through unsupervised adaptation. While the main goal of speech recognition is to provide a transcription of the speech signal as a sequence of words, the same basic technology can be applied to other areas. This recent work is oriented towards automatic systems for information access and for automatic indexation of audiovisual data. In the former case, the speaker-independent, continuous speech recognizer is embedded in a spoken language dialog system for travel information on an information kiosk (ESPRIT MASK) or by telephone (LE ARISE). User trials highlight the importance of appropriate dialog strategies for satisfactory performance. The latter case is a challenging application for LVCSR as the data contain segments of various acoustic and linguistic natures (prepared/spontaneous speech, studio/telephone quality, background noise/music). Word error rates on this data (about 30%) appear to be sufficient for indexation and retrieval purposes.

3:20

1pSC4. Recent advances in speech recognition at IBM research. Ponani S. Gopalakrishnan (IBM T. J. Watson Res. Ctr., P.O. Box 218, Yorktown Heights, NY 10598)

This paper will review the work going on at the IBM T. J. Watson Research Center on speech recognition systems dealing with real world speech data. Such data includes voice mail messages, broadcast news data, and live interaction with natural language systems. Many problems need to be addressed in order to improve speech recognition accuracy, including speaking style, accents, spontaneous speech phenomena, and different acoustic environments. Some of the methods used for detecting the signal and background condition, fast adaptation to new environments, and for handling pronunciation variations in spontaneous speech will be outlined. Speech recognition results on a variety of materials will be presented and analyzed, with a discussion of the significant problems that remain to be solved in order to obtain acceptable recognition performance on such material.

3:40

1pSC5. Research and development of robust speech recognition. Kiyoaki Aikawa (NTT Human Interface Labs., 1-1 Hikarino-oka, Yokosuka-shi, Kanagawa, 239 Japan)

This paper describes recent research and development activities on robust ASR (automatic speech recognition) in NTT Human Interface Laboratories. ASR system design has been changing from the experimental to the commercial level. A relevant issue in achieving practical ASR is the robustness against environmental noise, and speaker and circuit differences. Adaptation technique has been widely investigated for improving the robustness. It should be noted that customers or users generally prefer simple procedures and quicker response. Thus real time speaker/noise adaptation is getting more and more popular. Confidence measure is also effective in enhancing speech recognition performance by rejecting out-of-vocabulary words, lip, and breath noises. Another relevant issue is how to quickly reach the goal of the human-machine dialog via the telephone without visual information. The voice quality through a telephone is not good enough to provide perfect syllable intelligibility even for a human. This suggests that an appropriate human-machine dialog is needed to support an ASR system in acquiring the information or request intended by the user. Recent research topics including spectral estimation, dialog control, and other new approaches related to above discussion will be shown in the presentation. ASR application examples and related problems will also be shown.

4:25

1pSC6. 21st century user interfaces within the telecommunication industry: Speech processing is the key. Jay Wilpon (AT&T Labs Res., 180 Park Ave., Rm. D-123, Florham Park, NJ 07932)

As we move into the 21st century, several market factors will play a key role in the success of telecommunication-based services. Such factors include: The merging of the computer and telephony industries is moving ahead at an ever-increasing pace. Barriers-to-entry for new companies wishing to enter traditional telephony businesses are dropping. The union of the computer and telephony industries will lead to effective integration of voice, traditional data, and video, enabling the creation of new services that are more robust, intelligent, and accessible than services that are currently available. People will not be asking for technology, they will be asking for a simpler and easier lifestyle. Given these factors, what will differentiate 21st century telecommunications services from each other are innovative, compelling 21st century user interfaces that create a media center unifying emerging desktop services with

traditional telephony services. Such user interfaces will lead to smarter services. As networks automatically learn their customers' needs and wants, and customers invest their time to learn these intelligent user interfaces, a bond will be formed. Key to this vision is the availability of robust large vocabulary speech recognition, spoken language understanding, and text-to-speech synthesis technologies that allow customers to access information and each other anywhere, anytime.

4:45

1pSC7. Natural speech dialogue systems. Volker Steinbiss (Philips GmbH Forschungslaboratorien, Weisshausstr. 2, 52066 Aachen, Germany)

The application of speech recognition and understanding to real-life situations generates new scientific problems. To illustrate the latter, the example of an automatic switchboard system is given that can be used in a very natural communication style. It is based on a high-end speech recognizer that outputs a word lattice which is subject to further evaluation by a speech understanding and a dialogue component. Although word error rates are above 20% for this task, the integration of additional knowledge sources like the telephone directory and the dialogue history can add to both the acoustic and the language model in order to achieve highly improved performance. As recognition is not perfect, the user has to confirm what the system understood. In order to avoid lengthy confirmations, it was requested to base the level of confirmation (repeated question, explicit or implicit confirmation) on the probability that the request was understood correctly. This was formulated within the statistical framework of speech understanding and successfully implemented into our prototype system. The degree of reliability controls the further dialogue flow. Other useful applications of this reliability measure will be described.

5:05

1pSC8. Recent advances in speech recognition for spontaneous speech translation. Y. Sagisaka (ATR ITL, 2-2 Hikaridai Seikacho Soraku-gun Kyoto, 619-02 Japan)

Speech recognition research for speech translation at ATR will be reviewed. For spontaneous speech recognition, new methods for parameter extraction will be shown that yield acoustic measures to allow discriminative acoustic model training. A new HMM state-sharing algorithm (ML-SSS), fine-acoustic modeling using stochastic segment models, and recurrent neural networks will also be described. The MAP-VFS speaker adaptation techniques will be presented in the context of speaker clustered acoustic models. As for language modeling, variable order N-gram models and task adaptation of language modeling will be described. In addition, further research efforts on pronunciation modeling and training using error characteristics will also be reviewed. Finally, an outline of the continuous speech recognition system (ATR-SPREC) for spontaneous speech will be presented, along with a review of recent recognition experiment results.

5:25

1pSC9. Speech recognition trends and predictions, or, do we need text? Patti J. Price (Speech Technol. and Res. Lab., SRI Intl., EJ147, 333 Ravenswood Ave., Menlo Park, CA 94025, pprice@speech.sri.com)

Speech is the means of communication used first and foremost by humans. Automatic speech recognition capabilities are still far from those of humans, particularly with respect to degradation in the face of noise, nonnative speakers, and casual speech styles. However, significant advances have been achieved in recent years; automatic speech recognition capabilities now permit us to use speech as an interface for dictation and for information access. In such applications, the interactivity of the system allows the person to adapt to the system (and the system to adapt to the user). The real challenge of the information age is using speech not just as a medium for information access, but as itself a source of information, wherever speech occurs. Examples include: voice annotation for later retrieval, sorting and prioritizing voice messages, access to voice recordings of meetings without the need to take minutes, and access to broadcast media. Speech technologies in support of such applications include not just speech recognition, but also speaker recognition, topic spotting, gisting, and summarization. This talk will survey the state of the art and recent trends in speech as a source of information.

5:45

1pSC10. From speech recognition to understanding: Shifting the paradigm to achieve natural human–machine communication. B. H. Juang (Bell Labs, Lucent Technologies, 600 Mountain Ave., Murray Hill, NJ 07974)

Automatic speech recognition has made substantial progress in the last decade due to applications of statistical methods. The task of speech recognition is often described as converting a sequence of sounds into a sequence of linguistic events (words). This is in essence transcription: given an acoustic signal, the system determines which word it represents. The implicit assumption in this traditional formulation of speech recognition is that the speech is well-formed, free from extraneous components such as disfluency, partial words, repairs, hesitation, etc. The statistical framework that supports the formulation is the Bayes decision theory. For natural human–machine communications, however, it is expected that the spoken input to the system will inevitably contain extraneous components, treatments of which have to be developed in a broadened framework utilizing the Neymann–Pearson Lemma. The departure also inspired a new formulation based on the signal detection theory for robust speech understanding. In this talk, the rationale for the new formulation will be discussed and new results towards speech understanding using the detection-based (as opposed to the transcription-based) approach will be presented. It will be shown that the new approach achieves substantial improvements in accuracy for natural but ill-formed utterances over the conventional approach.

1pSP1. Improvement of pitch detection using a signal specific analyzing wavelet. Yoshifumi Chisaki (Dept. of Comput. Sci., Kumamoto Univ., 2-39-1 Kurokami, Kumamoto City, Japan, chisaki@cs.kumamoto-u.ac.jp), Tsuyoshi Usagawa, and Masanao Ebata

Many methods of a speech enhancement system in a noisy environment have been studied. A wavelet transform performs better in analyzing speech than a fast Fourier transform at the point of frequency resolution when the purpose is focused on the pitch detection. Analyzing wavelets, such as Gabor, are derived from a mathematical approach, which have characteristics of low, high, and bandpass filters. In this paper, a modified wavelet transform is proposed. A signal which has characteristics of the target signal is applied to an analyzing wavelet. This signal-specific analyzing wavelet includes not only amplitude and phase for each frequency but also the relationship of harmonic components and a periodic fluctuation of pitches. In addition, the wavelet transform is arranged to use a signal-specific analyzing wavelet for tracking pitches. This method is useful not only for the pitch detection but also for the representation of the fluctuation. Experiments are performed by using both a Gabor function and a signal-specific analyzing wavelet changing both vowels and a band-limited noise. As a result, the ratio of pitch detection was improved by comparing a signal-specific analyzing wavelet with a Gabor wavelet transform. The ratio was recovered over 40% in case of SNR=0 dB.

2:35

1pSP2. Comparison between DyWT- and EGG-based estimation of glottal closure instant for speech signal. Jongwon Seok, Youngho Son, and Keunsung Bae (School of Electron. and Elec. Eng., Kyungpook Natl. Univ., Taegu 702-701, Korea)

Recently, wavelet transform has found many applications. Mallat has shown that, with a proper choice of wavelet function, the local maxima of wavelet transformed signal indicate the position of the signal sharp variation points. Since the glottal closure causes sharp changes in the derivative of air flow in the glottis and transient in the speech signal, wavelet analysis can be used for detection of glottal closure instant (GCI) from the speech signal. It is known that the point of maximum negative value in a differentiated EGG signal agrees well with the closing time of the vocal folds. Due to the limited practical utility of the EGG signal, however, a speech-only-based GCI detection method is still needed. In this paper, GCI detection algorithm based on the dyadic wavelet transform (DyWT) is proposed and experimental results are shown. Using the EGG signal as a reference, experimental results are analyzed and discussed for evaluation of its performance. Preliminary experimental results show that DyWT-based GCI detection method has some speaker dependency and wavelet transformed speech signal at scale 4 gives more reliable GCI information than that of others. [This work has been partially supported by a grant from Korea Science and Engineering Foundation (KOSEF 971-0917-103-2).]

2:55

1pSP3. A novel end-point detection method for noisy speech signal. Jongwon Seok and Keunsung Bae (School of Electron. and Elec. Eng., Kyungpook Natl. Univ., Taegu 702-701, Korea)

This paper presents a novel and robust end-point detection algorithm in the presence of noise. Zero crossing rate and energy of the speech signal have been the most widely used features for locating the end point of an utterance. Most detection algorithms with these parameters work quite well in the high signal-to-noise ratio environment, but they show very poor performance with background noise, i.e., in the low signal-to-noise ratio environment. Therefore robust end-point detection under a noise condition still remains an unsolved problem. A new detection measure based on a discrete wavelet transformed speech signal is proposed. As a detection parameter, the sum of standard deviations of wavelet coefficients in the first and weighted fourth scale are used. Since the new feature parameter enhances high-frequency components of the weak fricative sounds, better discriminating between speech segments and background noise is possible. Experimental results and examples demonstrate that the proposed method is more effective than traditional methods in capturing word boundary even in noisy environments. [This work was supported partially by Korea Telecommunication Inc. and Korea Science and Engineering Foundation (KOSEF: 971-0917-103-2).]

3:15

1pSP4. Speech enhancement by a Kalman filter based on wavelet transformation coefficients. Ryouichi Nishimura, Yôiti Suzuki, Toshio Sone (Res. Inst. Elec. Commun., Tohoku Univ., Sendai-shi, 980-8577 Japan), and Futoshi Asano (Electrotechnical Lab., Ibaraki-ken, 305-0045 Japan)

A new speech enhancement technique based on Kalman filtering and wavelet transformation is proposed. A problem in using a Kalman filter for speech enhancement lies in how to construct and to estimate the state transition matrix. Considering that wavelet transformation can well localize the speech energy in the time-frequency domain in the presence of noise, wavelet coefficients are used here for this purpose. That is, the state and observation vectors are expressed by matrices which have column vectors consisting of wavelet coefficients calculated from densely overlapped frames. Then the state transition matrix is calculated from a single state matrix postmultiplied by the inverse matrix of the preceding state matrix. These matrices are obtained from a speech signal enhanced by existing algorithms such as MMSE. This enhancement process does not need to correctly estimate a speech signal itself but needs just to supply the correct differentials of state matrices. A computer simulation was conducted to evaluate the performance of the proposed method. The result shows that the signal processed by the proposed method generally gives a better subjective impression while physical evaluation by use of the ''signal to deviation ratio'' becomes worse.

3:35

1pSP5. Time variation characterization of a nonstationary time series. Nai-chyuan Yen (CLY Assoc., 2109 Rampart Dr., Alexandria, VA 22308-1537)

The Fourier transform of a nonstationary time series has the difficulty of providing a proper physical interpretation of the signal as the physical attributes and dynamics associated with the time series may consist of several transients that are different in their nature. The time series analysis method developed by NASA [N. Huang *et al.*, ''The Empirical Mode Decomposition and The Hilbert Spectrum for Nonlinear and Nonstationary Time Series Analysis'' (to be published)] has a unique approach to adaptively break down the nonstationary time series into the sum of several simple mode functions. Each single mode function can then be expressed in terms of an analytical signal whose amplitude and phase can both be varied with time. Those time variations can be related to the abrupt changes associated with dynamic systems. Such a time variation characteristic can be used to observe the occurrence of a transient event even in a nonstationary process. Applications of this technique to observe various types of acoustic signals in noisy environments are discussed.

3:55

1pSP6. Comparison of methods for analysis of cyclostationary noise. Karel Vokurka (Tech. Univ. of Liberec, Dept. of Phys., Halkova 6, CZ-461 17 Liberec, Czech Republic, karel.vokurka@vslib.cz)

A great number of machines work cyclically. Hence the noise they generate is cyclostationary. A traditional approach to this noise analysis is based on an assumption of its stationarity. This assumption implies continuous time averaging. Unfortunately in this way a certain amount of information concerning, e.g., time-frequency distribution, is lost. Methods have been looked for to preserve this information. They all are based on periodic time averaging and the resulting statistical characteristics are known as gated spectrum, cyclic correlation, cyclic autospectrum, double autocorrelation, double autospectrum, etc. Each of the methods has its advantages and disadvantages. These may concern processing time, hardware requirements, frequency resolution, occurrence of artifacts (cross terms), and others. In this paper the methods are analyzed and compared and possible improvements in their performance are suggested. [Work supported by the Grant Agency of the Czech Republic and by the European Commission.]

1pUW1. Localized wave pulses in the Keyport experiment. David H. Chambers and D. Kent Lewis (Lawrence Livermore Natl. Lab., P.O. Box 808 L-372, Livermore, CA 94551, chambers2@llnl.gov)

Localized wave (LW) pulses were produced using a standard Navy array in the anechoic tank at NUWC Keyport. The LW pulses used were the MPS pulse first derived by Ziolkowski, and a new type of pulse based on a superposition of Gaussian beam modes. This new type is motivated by a desire to make a comparison of the MPS pulse with another broadband pulse built from solutions to the wave equation. The superposed Gaussian pulse can be described by parameters which are analogous to those describing the MPS pulse. The directivity patterns and the axial energy decay between the pulses are compared. The behavior of the pulses are found to be similar so that the superposed Gaussian could be another candidate in the class of low diffractive pulses known as localized waves.

1:20

1pUW2. Localized wave generation with a standard underwater array. D. Kent Lewis, David H. Chambers (Lawrence Livermore Natl. Lab., 7000 East Ave., L-372, Livermore, CA 94550), and Richard W. Ziolkowski (Univ. of Arizona)

Recent work at the NUWC Keyport has generated localized waves using Navy field equipment. The array, a rectangular arrangement of tonpiltz elements, was driven with precompensated signals to generate sound covering a decade of usable bandwidth. The elements were grouped by radius from the center and excited by signals designed specifically for each radius, for a total of 7 radii. Results of the angular scans show a narrowed beam pattern and lowered side lobes relative to design signals. Results of axial range scans show an increase in directivity of more than an order of magnitude over array specific tone bursts. Frequency analysis shows that the main beam is an octave wide while the surviving side lobes are narrow bandwidth.

1:35

1pUW3. An inexpensive light-weight ocean acoustic research array. Garry J. Heard (Defence Res. Establishment Atlantic, P.O. Box 1012, Dartmouth, NS B2Y 3Z7, Canada, heard@drea.dnd.ca)

Current and past research arrays built at the Defence Research Establishment Atlantic (DREA) have been intended for indefinite and repeated use. Building, maintaining, and using these arrays has been expensive in terms of both money and labor due to the rugged construction practices, complicated electronics, and materials. With the reduced resources available in most laboratories today, there is considerable need for cheaper research array systems that are easily maintained and deployable from a variety of platforms: from Zodiacs to full-sized AGOR vessels. This paper describes the initial development of a light-weight research array that is expected to meet the requirements of the Ocean Acoustics Group at DREA. The array uses epoxy resins for most of the structural components, has a serial-digital bus, has low-power requirements, is easily reconfigured, and is essentially disposable, although the intention is to reuse the array in whole or in part as long as it remains serviceable. The prototype array, which is scheduled for sea testing in July 1998, will be a bottom-deployed 500-m aperture horizontal line array with 16 channels sampled at 2048 Hz.

1:50

1pUW4. Optimal array element localization. Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC V8W 3P6, Canada, sdosso@uvic.ca) and Barbara J. Sotirin (Naval Command, Control and Ocean Surveillance Ctr., San Diego, CA 92152-5001)

Measuring ocean acoustic fields at an array of sensors allows the application of advanced signal processing methods such as beamforming and matched-field processing. However, these methods require accurate knowledge of the positions of individual sensors. Typically, an acoustic survey is required to localize the sensors, a procedure referred to as array element localization (AEL). AEL generally consists of measuring the traveltimes of acoustic signals transmitted from a series of known positions to the sensors to be localized. These traveltime data can then be inverted for estimates of the sensor locations using a linearized inversion algorithm. An important issue in AEL is designing the configuration of acoustic source positions: a well-designed source configuration can produce substantially better AEL results than a poor configuration. In this paper, a procedure is developed to determine optimal AEL source locations for arrays of any configuration. This procedure minimizes the condition number of the Jacobian matrix of partial derivatives on which the linearized inversion is based. Minimizing the condition number in effect minimizes the magnification of data (traveltime) errors into model (sensor position) errors in the inversion. Monte Carlo simulations verify that optimal AEL source configurations can lead to significant improvements in sensor localization.

2:05

1pUW5. Detection and tracking of a moving source with application to real data (SWELLEX). Stacy L. Tantum and Loren W. Nolte (Dept. of Elec. Eng., Duke Univ., Box 90291, Durham, NC 27708-0291)

The optimum uncertain field tracking algorithm (OUFTA) incorporates knowledge of source motion as well as uncertainty in the propagation environment [S. L. Tantum and L. W. Nolte, ''Tracking and localizing a moving source in an uncertain shallow-water environment,'' J. Acoust. Soc. Am. **103**, 362–373 (1998)]. It is shown how detection, tracking, and adaptivity to an uncertain environment can be formulated within a unifying and optimal framework. Performance results and trade-offs are presented for simulated data. Results are also presented using this approach with low signal-to-noise ratios and real data (SWELLEX). [Research supported by ONR.]

2:20

1pUW6. Characterization of fault processes in central Arctic ice. Catherine Stamoulis and Ira Dyer (Dept. of Ocean. Eng., MIT, Cambridge, MA 02139)

Fault processes in Arctic ice are characterized by particle motion, propagation, and radiation. Estimates of these can be achieved through analysis of individual acoustic events induced by the faults. Thus data from a central Arctic experiment were analyzed. Particle velocity, displacement, and rise time, which characterize particle motion, were estimated through integration of the acoustic signals in the time domain. Particle displacement was in the range $O(10^{-4})$–$O(10^{-2})$ m, significantly lower than that of earthquake-induced faults; particle velocity was 1–67 cm/s, on average 50% lower than that of a displacement discontinuity in rock. Fracture speed, strike angle, and source dimensions, which characterize fault propagation, were estimated in the frequency domain. Fracture speed estimates were in the range 200–1100 m/s. This wide range suggests either multiple fault mechanisms or a single mechanism at different stages in its propagation. Source dimensions were determined from the displacement spectra of the second integral of the signals, with source length 0.7–100 m, and depth 0.4–4 m. Finally, the radiation characteristics were estimated and tensile and shear fracture were identified, both in the low (10–100 Hz) and mid (100–350 Hz) frequency ranges.

2:35–2:50 Break

2:50

1pUW7. Time-reversal mirror with variable depth focusing. Hee Chun Song, William A. Kuperman, William S. Hodgkiss (Scripps Inst. of Oceanogr., Univ. of California, San Diego, La Jolla, CA 92093-0238), T. Akal, C. Ferla (SACLANT Undersea Res. Ctr., 19138 La Spezia, Italy), and Darrell R. Jackson (Univ. of Washington, Seattle, WA 98105)

Recent time-reversal mirror (TRM) experiments conducted in the Mediterranean Sea demonstrated variable range focusing using the frequency-range invariant property in a shallow-water waveguide [Song *et al.*, J. Acoust. Soc. Am. **102**, 3171(A) (1997)]. The technique involves retransmitting the data at a shifted frequency according to the desired change in focal range in almost real-time fashion. As opposed to the variable range focusing, there does not appear to be an environmentally independent elegant solution for variable depth focusing. However, a method based on knowledge of the environment, which translates to being able to compute the acoustic modal structure, permits a focal depth shift. The method involves projecting out the important modes received at the vertical source–receive array (SRA) and appropriately altering their excitation to focus at another depth. In the May 1997 experiment, some limited results demonstrated that this method is feasible. Comparison of data with simulations and theoretical analysis will be presented and discussed. [Work supported by ONR.]

3:05

1pUW8. A piecewise matched-field tracking algorithm. Michael J. Wilmut (Dept. of Mathematics and Comput. Sci., Royal Military College, P.O. Box 17000 STN Forces, Kingston, ON K7K 7B4, Canada) and John M. Ozard (Defence Res. Establishment Atlantic, Victoria, BC V9A 7N2, Canada)

Efficient matched-field tracking (MFT) algorithms have been successfully applied to both simulated and measured data. They have been used to track sources moving linearly or on a circular path at constant speed and heading. The input to the tracker is a set of ambiguity surfaces, contiguous in time, generated by matched-field processing. Previously described MFT algorithms assume that the track start and end times are known *a priori*; this restriction is removed in the piecewise MFT algorithm described here. In a series of simulations it is shown that the statistically significant tracks can be found provided the track signal-to-noise ratio is greater than 10. Their unknown start and end times are in error by one surface or less most of the time. The algorithm is then applied to find track segments for simulated sources moving linearly, or on a circular path. The path segments were of unknown duration and heading.

3:20

1pUW9. Effects of environmental mismatch on Bartlett sidelobe broadband interference structures. Aaron M. Thode, Gerald L. D'Spain, Hee Chun Song, and William A. Kuperman (Marine Physical Lab., Scripps Inst. of Oceanogr., Univ. of California at San Diego, La Jolla, CA 92093-0205)

When a series of perfectly matched range-independent Bartlett surfaces (computed over small increments of frequency) are stacked and then sliced along a constant depth, the resulting sidelobe contours in the range-frequency plane display interference patterns that converge to the correct range [Thode *et al.*, J. Acoust. Soc. Am. **102**, Pt. 2 (1997)]. The existence of these patterns can be derived from waveguide invariant principles [e.g., G. A. Grachev, Acoust. Phys. **39**, 33–35] and their physical meaning interpreted using a time-reversal argument [Song *et al.*, J. Acoust. Soc. Am. **102**, Pt. 2 (1997)]. Several qualitative effects of environmental model mismatch on these patterns have been observed: pattern translation along the range axis, frequency-dependent warping, and ''ghost'' contours that converge to the range origin instead of the true source range. Translational shifts are produced by certain mismatch parameters (e.g., waveguide depth) associated with invariant theory. Warping at low frequencies is generated by a mismatched bottom sound speed, and can be explained

using ''effective depth'' concepts [G. L. D'Spain, 15th Int. Cong. Ac. Proc., 231-4]. ''Ghost'' patterns arise when the modeled environment contains more modes at a given frequency than the actual environment. A time-reversal hypothesis for their convergence to the range origin is suggested. [For Underwater Acoustics Best Student Paper Award.] [Work sponsored by ONR.]

3:35

1pUW10. A parabolic equation-based backpropagation algorithm for matched-field processing. David J. Thomson, Gordon R. Ebbeson, and Brian H. Maranda (Defence Res. Establishment Atlantic, P.O. Box 1012, Dartmouth, NS B2Y 3Z7, Canada)

In applications of matched-field processing (MFP) to passive sonar, signals measured on a hydrophone array due to a source at some unknown position $\mathbf{x}_s=(r_s,z_s)$ are correlated with signals predicted by a propagation model (replicas) due to a source at a given position $\mathbf{x}=(r,z)$. This matching is carried out for many assumed $\mathbf{x}$'s within a search region (range, r and depth, z) to form a (normalized) ambiguity surface whose peak value provides an estimate of $\mathbf{x}_s$. For an N-element array, reciprocity is invoked to reduce the computational effort to computing N replica fields at each point on the search grid. In this paper, a matched-field processor proposed by Tappert *et al.* [J. Acoust. Soc. Am. **78**, S85 (1985)] is revisited that combines measured data with PE starting fields to effectively backpropagate an (unnormalized) ambiguity surface outwards from the receiving array. This unnormalized processor generates the ambiguity surface N times faster than the normalized one. The effectiveness of the backpropagation algorithm is examined by applying it to some multi-tonal data obtained during the Hudson Canyon experiment. Issues relating to normalization and incoherent/coherent frequency averaging are discussed.

3:50

1pUW11. Regularized matched-mode processing. Nicole E. Collison and Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC V8W 3P6, Canada, collison@uvic.ca)

Far-field acoustic propagation can be modeled as a discrete set of propagating normal modes. In this case, the measured fields can be decomposed into their modal components, providing the basis for matched-mode processing (MMP). Modal decomposition is a discrete linear inverse problem that is inherently nonunique and can be unstable. Thus standard MMP generally requires the entire water column to be densely sampled (i.e., more sensors than modes) with relatively low noise. However, the inversion can be stabilized using the method of regularization to include *a priori* information based on the replica excitations at each trial source location of the search grid. The regularized approach gives an optimal match for each grid point for both dense and sparse arrays and noisy data. Regularized matched-mode processing (RMMP), MMP, and matched-field processing (MFP) are compared for a number of different array configurations, including dense and sparse arrays that span all or part of the water column. The comparison is carried out for a realistic shallow-water environment which includes elastic geoacoustic properties and an environmental noise model. [For Underwater Acoustics Best Student Paper Award.]

4:05

1pUW12. A modified grid method for matched-field localization. Ling Xiao, Renhe Zhang, and Lianghao Guo (Natl. Lab. of Acoust., Chinese Acad. of Sci., Beijing 100080, PROC, zrh@public.east.cn.net)

A modified grid method (MGM) for matched-field localization is proposed in the paper. It is a practical version of the seed division algorithm (SDA). It adopts the ideal that searches in a coarse grid at first and then regionally fines the grid. The fining process is implemented by SDA. This so-called MGM is tested in the paper by seven two-dimensional global optimization problems. The tests show that MGM is more efficient than the normal grid method. Besides, it is more efficient than some other randomized methods which are currently used today. A numerical test is carried out for matched-field localization in deep ocean. It is based on MGM and WKBZ [Zhang *et al.*, Chin. J. Acoust. **13**, 1–12 (1994)]. The result shows that MGM can greatly upgrade the computational velocity and improve the localization's precision. [Work supported by NSF of China.]

1pPLb1. Adapted waveform analysis in sound processing. Ronald R. Coifman (Dept. of Mathematics, Yale Univ., New Haven, CT)

Adapted Waveform Analysis [R. Coifman *et al.*, *Wavelet Analysis and Signal Processing*] is a processing toolkit extending the traditional spectrogram and Fourier methods by adapting to local structures in audiosignals. The various libraries of waveforms such as localized cosines and wavelet packets permit a flexible time/frequency analysis and give rise to a ''mathematical musical transcription'' of sound. The waveforms considered could be viewed as musical notes with characteristic duration, pitch, amplitude, and

time localization. They are tied to fast computational algorithms which enable a fast search for an optimally efficient transcription of a clean simple signal as a mathematical ''score.'' More complex signals are then orchestrated as superposition of scores. Various applications to sound, compression, automatic speech segmentation for recognition, structural sound denoising and music restoration [with J. Berger and M. Goldberg, ''Removing Noise from Music Using Local Trigonometric Bases and Wavelet Packets,'' J. Audio Eng. Soc. **42**(10) (1994)] will be provided. Moreover the relations between efficient waveform transcription and fast numerical analysis for acoustic design and simulations [B. Bradie *et al.*, ''Fast Numerical Computations of Oscillatory Integrals Related to Acoustic Scattering,'' Appl. Comput. Harmonic Anal. **1**, 94–99 (1993)] will be indicated.

2aPLa1. Noninvasive ultrasonic surgery. Gail R. ter Haar (Phys. Dept., Royal Marsden Hospital, Sutton, Surrey SM2 5PT, UK, gail@icr.ac.uk)

The millimeter and submillimeter wavelengths of megahertz ultrasound in tissue mean that this form of energy can be brought to a tight focus in the body at a distance from the acoustic source. If the energy carried by the ultrasonic beam is sufficiently high, then it is possible to destroy tissue lying within the focal region, while sparing adjacent and overlying tissues. Typical peak intensities at the focus for ablation of tissues using 1–2 s exposure times are 1 kW/cm^2. For a focused bowl transducer with focal length 15 cm, 8 cm in diameter, operating at 1.7 MHz, the focal region is ellipsoidal in form, with axial length 15 cm and diameter 1.5 mm. A number of different exposure methods may be used to ablate clinically useful tissue volumes. Focused ultrasound is capable of selectively destroying tissue at depth without the need to expose the site of interest surgically. The mode of tissue destruction is primarily thermal in origin, temperatures in excess of 60 °C being induced very rapidly. This type of cellular damage is capable of destroying both normal and malignant cells, and of occluding selected blood vessels. Potential applications for this technique lie, among others, in urology, oncology, and fetal medicine.

2aAAa1. On the preferred delay time of a single reflection for cellists. Shin-ichi Sato, Yoichi Ando (Grad. School of Sci. and Technol., Kobe Univ., Rokkodai, Nada, Kobe, 657 Japan), and Saho Ota (Kobe Univ., Kobe, 657 Japan)

In order to attain a knowledge of designing the stage enclosure in a hall, the subjective preference of sound fields with a single reflection for alto-recorder players has been reported [I. Nakayama, Acustica **54**, 217–221 (1984)]. In this study, subjective preference judgments of sound fields with a single reflection were performed by cello players. It is examined whether or not preferred delay time of reflection is dependent on the effective duration (τ_e) of the autocorrelation function (ACF) of the music signals performed by each player and the amplitude of the reflection. [Work was supported by the Grant-in-Aid for Scientific Research JSPS.]

8:05

2aAAa2. A study of improvements to acoustical conditions for singers. Dennis Noson (107 North 77th St., Seattle, WA 98103, noson@worldnet.att.net)

While numerous recent studies have been reported on improving stage acoustics for orchestral performers, the preferred acoustical conditions on performing stages for singers has received limited attention in the past 30

years, with pioneering studies by Nakamura and Marshall. A series of acoustical modifications has been proposed for a Seattle church to improve the acoustics for both the listeners and the performing choir. An investigation was made, within the constraints of the existing acoustical environment of the church, to determine what direction the acoustical modifications should take to improve conditions of ensemble and balance among the singers while simultaneously improving the sound field for the audience. Acoustical conditions were modified both by adding temporary reflecting panels and introducing simulated reflections with strategically located loudspeakers. The results indicate a potential for noticeable improvement in the existing chancel acoustics, with most of the benefit applying to the singers rather than the listeners. Comparison will be made between the measured changes to the sound field and the predicted response of the singers using Ando's theory of subjective preference.

8:20

2aAAa3. Some recent experiences with the acoustical design of orchestra pits. Dennis Paoletti, Kurt Graffy, and Larry Tedford (Paoletti Assoc., Inc., 40 Gold St., San Francisco, CA 94133)

A number of recent projects including work for the San Francisco and Houston Operas have included acoustical designs for new and/or renovated orchestra pits. This paper will review some of those projects, their criteria, design, measurements, and evaluations.

8:35

2aAAa4. The virtual orchestra; pedagogical and creative issues. Frederick W. Bianchi (Humanities Dept., Music Div., Worcester Polytechnic Inst., 100 Institute Rd., Worcester, MA 01609) and Richard H. Campbell (Worcester Polytechnic Inst., Worcester, MA 01609)

The interactive multichannel computer music system known as the ''Virtual Orchestra'' has been used several times in professional opera and theater as an alternative to a live pit orchestra. The technical issues associated with this emerging technology, and the logistical problems of implementing it are presented in a companion paper. This paper describes the equally important issues regarding the creative and pedagogical impact this technology will have on the industry. In particular, the paper suggests that many of the fundamental premises of opera production will change as the industry begins to retool. This would include the way opera is rehearsed and performed, how it is created and disseminated, and how it will adjust to the changing demographics of the country. In addition, the paper addresses the notion of the technologist/musician and examines the role of education and professional training in computer music and musical acoustics.

8:50

2aAAa5. The virtual orchestra; acoustical and audio engineering issues. Richard H. Campbell (Elec. and Comput. Eng. Dept., Worcester Polytechnic Inst., 100 Institute Rd., Worcester, MA 01609) and Frederick W. Bianchi (Worcester Polytechnic Inst., Worcester, MA 01609)

The multichannel MIDI system known as the ''Virtual Orchestra'' has been used several times in the pit for the performance of opera, and recently demonstrated at an ASA regional chapter meeting in Boston. This paper discusses technical issues such as the selection of the types of loudspeakers and their placement in the pit, the amplifier power requirements, and the sound level calibration for each instrumental section based on a mezzo-forte norm. ''Wolf'' tones caused by understage extension cavities and other pit deficiencies can be easily modified within the MIDI computer program or with external equalization. Ideas are presented for the use of this new tool with respect to an acoustic freedom heretofore unavailable to orchestrators of musical theater works. The computer operator's ability to follow in real time the conductor's direction in nuance and tempo guarantees a cohesive performance synchronized with the singers and the dramatic action.

9:05

2aAAa6. The effect of early reflection on players in a concert hall. Kanako Ueno (Dept. of Architecture, Tokyo Univ., 7-3-1 Hongou, Bunkyo-ku, Tokyo, Japan, ueno@iis.u-tokyo.ac.jp), Fumiaki Satoh (Chiba Inst. of Technol., Narashino-shi, Chiba, Japan), Hideki Tachibana (I.I.S. of Tokyo Univ., Minato-ku, Tokyo, Japan), Takahiko Ono (Ono-Sokki Co., Midori-ku, Yokohama-shi, Kanagawa, Japan), and Mariko Senju

In order to investigate the effect of hall response on players, field measurements on the stage of a concert hall and laboratory experiment using digital simulation technique were performed. In the field experiment, the subject, a professional violinist, was asked to play and to make comments on her acoustical impression of five points on the stage. As a physical measurement, impulse responses were obtained at the same points by using omni-directional loudspeakers as a sound source and an omni-directional microphone and directional microphones as receivers. As a result, it has been found that not only the strength of the early reflections but also their direction influences the subject's impression. In the laboratory experiment (anechoic chamber), the sound field was modeled and synthesized by using a 13 channel reproduction system; ambient reverberation judged as being natural was provided by simple digital reverberators and different strength and direction of early reflections were obtained by real-time convolvers. For a constant value of reverberation, several conditions with a different level and direction of the early reflections were created. For each condition, the violin player was asked to make similar judgments as in the field experiment. The results of two experiments were examined.

2aAAb1. Boxes and sound quality in an Italian opera house. Alessandro Cocchi, Massimo Garai, and Carla Tavernelli (DIENCA, viale Risorgimento 2, 40136 Bologna, Italy, massimo.garai@mail.ing.unibo.it)

The sound field in the boxes of an 18th century Italian opera house was studied by means of binaural measurements and computer simulations. The differences in listening between the boxes and the stall is best described by the values of ITDG, clarity, and spatial criteria resulting from the measurements. The periodic variation of the ITDG along the boxes depends also on the reflections coming from the ceiling. The best boxes for clarity and spatial impression are found in very different positions. Computer simulation supports these conclusions and helps in understanding the two different mechanisms by which the boxes influence the sound field in the hall: the equivalent sound absorption of the boxes and the periodic structure of the box-covered walls. A validated computer model allows one to forecast how the sound field in the historical theater could be if some interior lining were added to the boxes, trying to restore the velvet lining which was supposed to exist in ancient times.

9:45

2aAAb2. Measurements of the polarization of sound energy at the mouth of boxes of an Italian opera house. Domenico Stanzial, Davide Bonsi, and Nicola Prodi (CIARM c/o CNR-Cemoter Acoust. Dept., via Canal Bianco 28, I-44044 Ferrara, Italy)

The measurement of a newly discovered property of sound energy, the polarization [Stanzial *et al.*, J. Acoust. Soc. Am. **99**, 1868–1876 (1996)], has been carried out for the first time inside an opera house. Since energy polarization is due to the distributions of wavefronts passing through the measurement point, the analysis of this quantity allows one to obtain a precise picture of the effect of sound reflections at the receiving location. The highly symmetric architectural structure of an Italian opera house has been thus investigated at the opening of some boxes and the energy polarization has been compared with the sightline from each box to the stage. Furthermore, a third octave band frequency analysis in the range 100–5000 Hz has been accomplished that allows the visualization of the frequency-dependent behavior of the reflections' distribution.

10:05

2aAAb3. Measurements in an opera house: Comparison between techniques and instrumentation. Patrizio Fausti, Roberto Pompoli (Dipartimento di Ingegneria, Univ. of Ferrara, Via Saragat 1, I-44100 Ferrara, Italy), and Angelo Farina (Univ. of Parma, Parma, Italy)

In room acoustics, many objective parameters to quantify subjective impression have been introduced. These quantities can be measured using a wide variety of powerful tools and instrumentation. The results can be influenced by the measurement techniques and instrumentation used. Furthermore, the results also depend on the position and condition of the hall in which the measurements are made. With the aim to obtain a procedure to qualify a room acoustically, and in particular an opera house, which gives comparable and reproducible results all over the world, an extensive measurement campaign was made. The procedure takes into account the measurement techniques, the instrumentation, the measurement positions, and the condition of the audience and the stage. Comparisons were made both between different tools (real-time analyzer, DAT, PC-board) and different kinds of acoustic excitation (stationary, impulsive, pseudorandom). Furthermore, comparisons were made in different conditions of the stage and pit (e.g., empty, with the presence of orchestra tools and/or musicians). In this paper the results of the measurement campaign are presented and a proposal is submitted for the discussion.

10:25

2aAAb4. Individual subjective preference of listeners for vocal music sources in relation to the subsequent reverberation time of sound fields. Hiroyuki Sakai (Grad. School of Sci. and Technol., Kobe Univ., Rokkodai, Nada, Kobe, 657 Japan), Hiroshi Setoguchi (Miyama Conceru, Kagoshima, 899-66 Japan), and Yoichi Ando (Kobe Univ., Kobe, 657 Japan)

The purpose of this study is to evaluate subjective preference of a simulated sound field by listeners in changing subsequent reverberation time T_{sub} using vocal music sources. Previously, a great deal of effort has been made on the study using music or speech [for example, Ando *et al.*, Acustica **50**, 134–141 (1982); J. Acoust. Soc. Jpn. **39**, 89–95 (1983)]. In addition to subjective preference judgments, the α-waves' range of the continuous brain waves (CBW) in relation to the specialization of human cerebral hemispheres is also evaluated [C. Chen and Y. Ando, J. Archit. Plann. Environ. Eng., AIJ **489**, 73–80 (1996)]. In this paper, subjective evaluation using vocal music sources, which is often played in concert halls and opera houses, has been examined. Subjective preference tests were conducted changing T_{sub}, which is one of the four objective parameters in relation to subjective preference of sound fields. Individual differences of subjective preference as well as global preference are discussed. [Work was partially supported by the Ministry of Education, Grant-in-Aid for Scientific Research (C), 9838022, 1997.]

Invited Papers

8:00

2aAB1. Scale effects as constraints in insect sound communication. Henry Bennet-Clark (Dept. of Zoology, Oxford Univ., S. Parks Rd., Oxford OX1 3PS, UK)

Calling insects have problems of optimizing range and maintaining the specificity of the call. Higher frequencies are more easily refracted and reflected by objects in the environment. Smaller insects have less muscle power and also, because of the small sound source size, higher frequencies are radiated more efficiently than lower frequencies. In open air or water, the sound spreads spherically and decays by the inverse square law. If the sound can be confined to a sheet it decays as the inverse of range while within a rod it decays due to viscous losses; such calls are usually rather simple pulses and rely on initial time of arrival because of multiple pathlengths in the environment. With airborne sounds, those in the range from 1 to 10 kHz tend to have sustained pure-tone components and a specific pattern of pulses which propagates well; but with higher frequencies pulses tend to become briefer and, once again, to rely on time of arrival of the onset.

8:25

2aAB2. Acoustic detection and identification of insects in soil. Richard Mankin (USDA-Agric. Res. Service, Ctr. for Medical, Agricultural, and Veterinary Entomology, P.O. Box 14565, Gainesville, FL 32604)

There is considerable practical need for user-friendly, inexpensive devices that detect and quantify insect populations in environments hidden from visual observation. One approach that has been used with varying success has been to detect the insects through the sounds or vibrations they generate for communication or through noises that are produced incidentally during feeding and general movement. The ability to precisely monitor soil insect populations is limited by interference from background noise and the high rate of attenuation of sound in soil. This paper describes experiments using different sensors and analysis techniques for detection of insects in soil in an agricultural environment. Results from different sensors are compared, and the spectral and temporal patterns that can be used to distinguish the target insects from noise and nontarget soil organisms are discussed. The use of accelerometers attached to 20–30-cm nails appears to be a low-cost, user-friendly method to locate and monitor the size of infestations of soil insects that tend to group together in clumps.

2aAB3. Two-tone suppression of the ultrasound induced startle response in a cricket. Hamilton E. Farris and Ronald R. Hoy (Sec. Neurobiology and Behavior, Mudd Hall, Cornell Univ., Ithaca, NY 14850, hef1@cornell.edu)

For the ground cricket, *Eunemobius carolinus*, frequencies >20 kHz elicit an acoustic startle response during flight. No startle responses are elicited by single pulses of low-frequency stimuli. However, simultaneous presentation of a low-frequency signal with ultrasound can suppress the startle response. The effect of frequency on suppression was measured for seven frequencies (3–9 kHz) at four intensities of the startle stimulus (40 kHz): 5, 8, 10, and 12 dB above startle threshold. Suppression was tuned to frequencies near 5 kHz. This effect of frequency on suppression diminished slightly at the higher ultrasound intensities, however. Because suppressor growth (change in suppression dB versus change in 40-kHz dB) was >1 for 5–7 kHz and >1 for 3 to 4, 8 to 9 kHz, equal suppression curves flattened at the highest ultrasound levels. Startle threshold de-

creases with increases in ultrasound duration, and temporal integration time constants were estimated to be 32 ms. In nonsimultaneous presentations, however, no suppression occurs when the suppressing tone is >2 ms after and >5 ms before the ultrasound stimulus. These times suggest that across-channel integration time is shorter than within-channel integration. [Supported by NIMH.]

9:10

2aAB4. Synchrony in cricket calling songs: Models of coupled biological oscillators. Timothy Forrest (Dept. of Biol., Univ. of North Carolina at Asheville, Asheville, NC 28804), Joel Ariaratnam, and Steve Strogatz (Cornell Univ., Ithaca, NY 14853)

Snowy tree crickets produce a rhythmic acoustic signal composed of short chirps. The chirp rhythms are very regular and dependent on temperature. When signaling in groups, males synchronize their chirps. The rhythmic signals of these tree crickets were used as a model of a ''biological oscillator.'' The phase responses of males to single probe stimuli similar to the male calling song were measured. The phase response curves (PRC) of males showed both strong (type 0) and weak (type 1) resetting. PRCs differed depending on amplitude, duration, and frequency of the resetting stimuli. In other experiments, males could adjust their natural periods by as much as 15% when phase-locking (1:1) to an entrainment stimulus. Signaling behavior of males was compared with a simple model of coupled oscillators. The phase resetting was not consistent with the simplest resetting model, in which the male's phase shift is completed after one cycle of the chirp period. In addition, a simple iteration of the PRC could not simulate the phase-locking observed in the entrainment experiments indicating that the acoustic coupling between males differs from a simple resetting model.

9:30–9:45 Break

9:45

2aAB5. Functional anatomy of the middle ear of insectivores. Matthew J. Mason (Dept. of Zoology, Univ. of Cambridge, Downing St., Cambridge CB2 3EJ, UK)

An electrical model has been constructed of the middle ear of land mammals [Hemilä *et al.*, Hearing Res. **85**, 31–44 (1995)]. This model can roughly predict the nature of air hearing in an animal, given the values of certain anatomical parameters for that animal. In the present study, light microscopy was used to investigate the anatomy of the middle ears of some representative members of the Insectivora. The nature of air hearing in these mammals was predicted, using an augmented version of the model. The model predicts that within the family Chrysochloridae (golden moles) there are genera (e.g., *Chrysochloris* and *Chrysospalax*) that have ears which appear to be very poorly adapted to the impedance-matching function required for efficient air hearing. The structure of the relatively enormous mallei of golden moles in these genera suggests that their ossicles are primarily adapted towards transmission of gound vibrations. A mechanism of ossicular inertia has been proposed. The electrical model predictions imply that subterranean mammals may be preadapted to evolve a more efficient mechanism for bone conduction of ground vibrations. Certain unusual features of the middle ear apparatus of other subterranean mammals may be interpreted in this light. [Work supported by B.B.S.R.C.]

10:05

2aAB6. Acoustics of the avian vocal tract. Neville Fletcher (Res. School of Physical Sci., Australian Natl. Univ., Canberra 0200, Australia, neville.fletcher@anu.edu.au) and Alex Tarnopolsky (Australian Defence Force Acad., Canberra 2600, Australia)

The avian vocal tract can appropriately be modeled on a source-filter basis, with the pressure-controlled syrinx valve providing the wideband harmonic source and the vocal tract the linear passive filter. This filter consists of four parts: the bronchial tubes above the syrinx valves, the trachea, the mouth with included tongue, and the beak. Each of these can be modeled and its behavior calculated quantitatively using standard methods [Fletcher, *Acoustic Systems in Biology* (Oxford U. P., New York, 1992)]. The long trachea defines the main resonance frequencies, upon which the bronchial resonances impose formant bands. The mouth, the cross section of which can be varied by changing the tongue position, influences particularly the frequencies of the first two tracheal resonances, but also the harmonicity of the upper system resonances. The beak behaves as a slotted tapered transmission duct, and contributes an end-correction to the system, the magnitude of which is a strong function of both beak gape and frequency. This paper reports the numerical results of such a theoretical analysis, compares these with experimental measurements upon appropriate model systems, and discusses the implications of the results for the understanding of avian vocalization.

10:25

2aAB7. Bioacoustic correlates of female choice in European starlings. Timothy Q. Gentner and S. H. Hulse (Johns Hopkins Univ., Dept. of Psych., Baltimore, MD 21218)

The elaborate structure of male European starling song suggests that it is a trait under heavy sexual selection pressures, and the results of several studies in both the laboratory and the field have identified song as the only male characteristic correlated with female choice in this species. However, previous studies have failed to isolate the bioacoustic feature(s) of song that are important for mating decisions and preferences in female starlings. An operant apparatus that reinforces a natural approach response to potential nest sites with different male starling songs is used to demonstrate that female preference is positively correlated with song bout length but not repertoire size (two features that normally covary). Further, this preference for longer song bouts is made in such a way that the absolute length of a bout cannot be the feature upon which the preference is based. A method for quantifying the temporal structure and stereotypy in male starling songs is presented using information theory, and it is shown that these measures correlate very closely with different song bout lengths. The importance of song bout stereotypy for female preference is then tested using synthetic stimuli or operant apparatus.

2aAO1. The Scripps Pier Bubble Experiment of 1997 and overview of rip events and their effects on acoustics measurements. Jerald W. Caruthers, Paul A. Elmore, Stephen J. Stanic (Naval Res. Lab., Stennis Space Center, MS 39529), and Ralph R. Goodman (Appl. Res. Lab., Penn State Univ., State College, PA 16804)

An experiment to determine the dynamics, distributions, and acoustic effects of bubbles in shallow water just offshore from active surf was performed in the Spring of 1997. The region of interest was just North of the pier at the Scripps Institution of Oceanography. An area from a few tens of meters to a thousand meters from the beach was instrumented by several researchers. An effort was made to acquire a comprehensive dataset of coastal dynamics, bubble distributions, and acoustic propagation. A major emphasis was placed on a smaller region approximately 400 m^2 in area and about 300 m offshore, where most of the instruments were clustered. The purpose of this paper is to provide an overview of the experiment, a summary of the runs made over the several days of experiments, and a context for the observed rip events based on an acoustic device known as the ''Delta-Frame.'' Two rip events (Run 5, event starting about 14:48 PST 7Mar97 and Run 7, event starting about 15:38 PST 8Mar97) selected for coordinated analyses and presentations to follow will be highlighted. [Work supported by ONR.]

9:40

2aAO2. Vertical profiles and horizontal scales of bubble clouds in the surf zone as measured with a distributed array of upward-looking sonars. Peter H. Dahl (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98195), Jerald W. Caruthers, and Stephen J. Stanic (Naval Res. Lab., Ocean Acoust. Branch, Stennis Space Center, MS 39529)

A collaborative, multi-institute experiment was recently performed in the vicinity of the Scripps Pier, whose goal was the study of bubble-field generation, transport, and distribution, as influenced by surf zone conditions. The collaboration produced an ensemble of instrumentation at the site for measuring bubbles, ambient noise, temperature and salinity, currents, and surface waves. This paper emphasizes data gathered by APL-UW using a set of four upward-looking transducers (frequency 240 kHz), which simultaneously measured vertical profiles of acoustic volume scattering from bubbles from four locations. The primary locus of measurement activity was defined by NRL-SSC's triangular frame (Delta Frame) and the four transducer locations for the APL-UW system bracketed this region. The transport of bubbles via rip currents emerged as a key feature surf zone bubble environment. Images of volumetric backscattering strength versus time and depth reveal episodic events (by way of increased scattering level) which last O(100) s and can occur in intervals of O(10) min. Time lags for increased scattering at the four locations were consistent with a seaward flow of rip currents equal to $\sim$0.25 m/s. Other features of the data that complement the single-depth measurements made from the Delta Frame will be discussed. [Work supported by ONR.]

10:00

2aAO3. Bubble generation and dispersion in the surf zone. Svein Vagle, David Farmer (Inst. of Ocean Sci., 9860 West Saanich Rd., Sidney, BC V8L 4B2, Canada), and Grant Deane (Scripps Inst. of Oceanogr., La Jolla, CA 92093)

A combination of horizontal Doppler imaging, underwater microphotography, and *in situ* acoustical measurements are used to examine wave propagation, wave breaking, bubble cloud formation, and dispersion in the surf zone near Scripps Pier. Wave breaking is interpreted in terms of the evolution in wave properties between the end of the pier and a sensor tripod mounted in the surf zone. The position of the breaking zone is tracked from sharp discontinuities in the horizontal imaging sonar. Bubble size distribution is measured both photographically and with an acoustical resonator. From time to time the imaging Doppler sonar shows bubble clouds moving offshore from the surf. The observations provide a framework for model analysis of bubble generation, advection, and dispersion in the surf zone.

10:15

2aAO4. Bubbles and surf zone oceanography. Eric J. Terrill and W. Kendall Melville (Marine Physical Lab, Scripps Inst. of Oceanogr., 8605 La Jolla Shores Dr., M. S. 0230, La Jolla, CA 92093-0230)

Breaking waves in the surf zone entrain high-density clouds of bubbles which are subsequently transported offshore via rip currents and turbulent diffusion. The presence of the bubbles presents a complex problem for acousticians interested in the propagation of natural and man-made sound in this shallow water regime. To investigate the acoustical properties of this area, a multi-investigator experiment was performed near the Scripps Pier in March 1997. A broadband acoustic technique, developed at the Marine Physical Laboratory, was deployed in a four-channel configuration in water of 6-m depth. Each channel of the system allows the determination of the bubble size distributions at a discrete depth via inversion of the measured sound speed and attenuation. Analysis of the data shows high concentrations of bubbles advecting offshore via rip currents, resulting in acoustic attenuations ranging from O(1)–O(100) dB/m. Vertical gradients

were observed in the bubble concentrations. Simultaneous measurements of the wind, waves, and currents provide a synoptic view of the overlying oceanography during the course of the experiment. Results of the experiment will be discussed in the context of the transport of surf-generated bubbles through the measurement site.

10:30–10:45 Break

10:45

2aAO5. Void fraction and bubble distributions near surf zones. Ming-Yang Su (Oceanogr. Div., Naval Res. Lab., Stennis Space Center, MS 39529)

Extensive measurements of void fraction and bubble size density due to wave breaking both inside and outside surf zones were made by the Naval Research Laboratory during two joint experiments sponsored by ONR: the Scripps Bubbles/Acoustics Experiment at Scripps Institution of Oceanography, March 1997, and the Sandy Duck '97 Experiment at the Army CERC Field Research Facility, Duck, NC, Sept.–Oct. 1997. Using a new technique that employs swing bar void fraction staffs anchored on the sand bottom, the new data show very strong tidal effects on the vertical distributions of void fraction. Data will also be presented on the temporal evolution of bubble size density (radius $=15$–1200 μ) during local storms. Finally, some new results on direct correlation of acoustic noise intensity using a hydrophone with co-located void fraction measurement will be presented.

11:00

2aAO6. Tomographic reconstruction of evolving bubble fields in the Scripps Pier bubble experiment. Daniel Rouseff and Frank S. Henyey (Appl. Phys. Lab., College of Ocean and Fishery Sci., Univ. of Washington, Seattle, WA 98105, rouseff@apl.washington.edu)

The Delta Frame, designed and operated by NRL-SSC, was a major component of the 1997 Scripps Pier shallow water bubbles experiment. The frame supported two sources and eight receivers. Acoustic travel time and attenuation were measured at eight frequencies between 39 and 244 kHz over the resulting 16 intersecting ray paths. Paths ranged in length from 2.5 to 8.6 m. For a given transmission sequence, the measurements at a particular frequency can be combined using tomography to yield a quantitative cross-sectional image of the ensonified region. By generating images for successive sequences, the temporal evolution of the medium can be visualized. A tomography algorithm [D. Rouseff and F. S. Henyey, J. Acoust. Soc. Am. **101**, 3032 (1997)] is applied to the Delta Frame data. The images are produced for time periods during the experiment where the bubble field was probed by other independent measurements. Tomography results are compared to the other measurements. [Work supported by ONR.]

11:15

2aAO7. Effects of bubbles on high-frequency sound propagation in very shallow water. Paul A. Elmore, Jerald W. Caruthers, Stephen J. Stanic (Naval Res. Lab., Stennis Space Center, MS 39529), and Ralph R. Goodman (Appl. Res. Lab., Penn State Univ., State College, PA 16804)

The results of an experiment performed off the research pier at the Scripps Institute of Oceanography that measured the acoustic effects of small bubbles in very shallow water (6 m) are discussed. The results presented are in coordination with researchers who conducted other measurements simultaneously. During the experiment, rip currents passed through a field of measurement instruments 300 m offshore. These rip currents were laden with bubbles created in the surf between the instruments and the shore. Pulse signals, between 39 and 244 kHz, were propagated to 10 m through the bubble clouds. The effects of these rip currents on the spatial distributions of the resulting acoustic attenuation are discussed. From the attenuation data, bubble populations are calculated by an iterative procedure based on the well-known resonant bubble approximation. [Work supported by the Office of Naval Research.]

11:30

2aAO8. A novel approach for obtaining bubble dissolution measurements at sea. Russell Costa (Naval Undersea Warfare Ctr., Newport, RI 02841), Ronald A. Roy (Boston Univ., Boston, MA 02215), Kerry W. Commander, Victor B. Johnson, and Andrew C. Colbert (Naval Surface Warfare Ctr., Panama City, FL 32407-7001)

A hybrid system for measuring the dissolution of gas bubbles in an oceanic environment was developed utilizing the Coastal Systems Station's Light Scattering Bubble Counter (LSBC). The LSBC independently measures flow velocity and bubble size, and is capable of distinguishing bubbles from particulate matter. In the hybrid system, the dynamic range of the LSBC measurements is 50 μm to about 300 μm in radius. The system is filled at depth (30 feet maximum without internal pressurization) and initially purged of all free gas. Pneumatically controlled valves are used to establish a closed recirculating system in which a flow can be generated in either direction using a large-volume peristaltic pump driven at low-volume velocity. Clear air is forced through a ceramic fritted disk to create the initial bubble population. This bubbly mixture is recirculated through the system at a nominal flow rate of 22 l/min, which corresponds to a velocity of 30 cm/s through the LSBC aperture. The bubble radii are continuously measured using the LSBC, resulting in time-dependent bubble size distributions. These distributions are used to estimate bubble dissolution rates for the size range indicated. [Work supported by ONR.]

11:45

2aAO9. Analysis of free bubble cloud scattering data from the Lake Seneca experiment. J. Gregory McDaniel, Ronald A. Roy, Andrew D. Gephart (Dept. of Aerosp. and Mech. Eng., Boston Univ., Boston, MA 02215), and William M. Carey (MIT, Cambridge, MA 02139)

In the fall of 1991, Carey, Roy *et al.* conducted a series of experiments at the Seneca Lake test facility which measured the frequency-dependent scattering from submerged bubble clouds. Preliminary results reported by Roy *et al.* [J. Acoust. Soc. Am. **92**, 2993–2995 (1992)] showed that certain features of the high-frequency backscatter data were consistent with single-bubble scattering while the low-frequency results were consistent with collective oscillations of the bubble cloud. A monopole resonance scattering peak was evident that scaled with the bubble cloud volume and the mixture sound speed. Additional analysis showed that the evolving target strength of the cloud as it rose through the insonating acoustic beam showed signs of an interference effect [Carey and Roy, Proc. 2nd Euro. Conf. on Underwater Acoust., European Commission, Luxembourg, 207 (1994)] which could explain the differences between calculated and measured scattering strengths. Advanced signal processing and modeling techniques have been developed to enable the removal of experimental artifacts caused by: (1) uncertainties in the range geometry, (2) coherent electrical noise in the processing electronics, and (3) acoustic reverberation within the test volume. The resulting corrected backscattering target strengths will be reported and discussed. [Work supported by ONR.]

12:00

2aAO10. Sound radiation by a bubble encountering a vortex ring. Ali R. Kolaini (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677, ali@sparc.ncpa.olemiss.edu)

The dynamics of a bubble and subsequent acoustic radiation interacting with a vortex ring created by an underwater nozzle are studied both theoretically and experimentally. The velocity field of the flow containing the bubble may be represented as a ''basic flow'' related to the vortex ring and a ''secondary flow'' related to the bubble motion [G. Chahine, 20th Symposium on Naval Hydrodynamics (1994)]. The ''bubble flow'' is assumed to be irrotational satisfying the Laplace equation. The vortex related velocities are given by the stream function and are taken into account by imposing ''correct'' kinematics and dynamic boundary conditions at the bubble surface. The interaction of the bubble with a vortex ring has been shown to cause severe deformation. Under special circumstances the deformed bubble may be at resonance with these vortex filaments and

force it to radiate sound to the far field. The boundary integral technique (BIT) is employed to solve governing equations. The BIT is utilized to simulate the ''bubble flow,'' its surface distortions and subsequent acoustic radiation. The critical parameters responsible for the acoustic re-excitation of the bubble encountering the vortex filaments are discussed in some details. Some conclusions are arrived at on the acoustical characteristics of the bubble encountering a fully developed turbulent flow field. [Work supported by ONR.]

9:20

2aBV1. Biological effects of ultrasound. Wesley L. Nyborg (Phys. Dept., Univ. of Vermont, Burlington, VT 05405)

Ultrasound has considerable potential as an agent for modifying cells and tissues. This comes partly from its capability to produce temperature elevation in desired spatial and temporal patterns. It also comes partly from its capability to produce cavitation in one or more of its diverse forms and, in addition, partly from the action of radiation forces, radiation torques, and acoustic streaming. In some situations, several mechanisms are involved and may interact with each other; for example, cavitation can produce heat in a medium, and the resulting temperature rise will affect the cavitation activity. Understanding these and other mechanisms has been, and promises to be, helpful in developing applications of ultrasound to therapy, surgery, and biotechnology, as well as in formulation of criteria for safety in medical procedures involving ultrasound. In this review, examples will be given to which the mechanisms are relevant, and recent developments will be discussed.

9:40

2aBV2. Therapeutic ultrasound. Lawrence A. Crum, Michael Bailey, Kirk Beach, Michael Caps, Stephen Carter, Wayne Chandler, Robin Cleveland, Scott Helton, Peter Kaczkowski, George Keilman, Roy Martin, Pierre Mourad, Ronald Roy, Udo Schmiedl, Brent Stewart, and Shahram Vaezy (Univ. of Washington, Seattle, WA 98105)

Although diagnostic ultrasound is now a multibillion dollar a year industry, the therapeutic applications of ultrasound were initially thought to have more promise. Indeed, the Fry brothers were performing brain surgery on human patients in the early 1950s, and with considerable success. However, therapeutic ultrasound has still not yet gained its promising potential. Recently, there has been an enormous resurgence of interest in this topic, and several major projects are underway at various facilities around the world. Our own substantial efforts in this area at the University of Washington are reviewed, with brief discussions of topics in lithotripsy, ultrasound-enhanced drug delivery, HIFU surgery, and acoustic hemostasis. [Work supported in part by DARPA and the NIH under Grants DK-43881 and R43HL57739.]

10:00

2aBV3. Acoustic liver cauterization: A potential tool for bloodless surgery. Roy Martin (Anesthesiology and Bioengineering, Box 356540, Univ. of Washington, Seattle, WA 98195, rmartin@u.washington.edu), Shahram Vaezy, Scott Hilton, Michael Caps, Peter Kaczkowski (Univ. of Washington, Seattle, WA 98195), George Keilman (Sonic Concepts, Woodinville, WA 98072), Steve Carter, Wayne Chandler, Pierre Mourad, Kirk Beach, and Lawrence Crum (Univ. of Washington, Seattle, WA 98195)

Liver surgery is hampered by the difficulty in controlling hemorrhage, particularly the slow oozing from injured hepatic surfaces. Conventional cauterizing fails in this situation. Bleeding from incisions made in animal livers using high-intensity focused ultrasound (HIFU) by volume cauterizing along the surface of the incision has been successfully stopped. The question arose: Could bleeding be avoided during surgery by precauterizing a thick surface around a region to be resectioned prior to the actual resectioning? The livers of anesthetized rabbits (4) and pigs (3) were treated in this manner under a protocol approved for animal studies at the University of Washington. Two HIFU transducers (3.3 and 3.5 MHz focused at 3.5 and 5.5 cm, respectively) were used for the treatment.

Cauterized strips around a region appeared white. The tissue to be resectioned was removed by cutting along the distal border of the strips. No oozing from the liver parenchyma was observed. Bleeding occurred only in the larger vessels (>2 mm inside diameter) present in the cauterized region. Since these size vessels are easily ligated the method appears to be clinically feasible. Survival studies are needed to learn about the possibilities of rebleeding after abdominal closure or unknown healing difficulties.

2aBV4. High-intensity focused ultrasound transducer design for surgical and hemostatic applications. George W. Keilman (Sonic Concepts, 20018 163rd Ave. NE, Woodinville, WA 98072) and Peter J. Kaczkowski (Univ. of Washington, Seattle, WA 98105-6698)

A resurgence in interest in the application of high-intensity focused ultrasound (HIFU) to surgical problems is due in part to significant improvements in imaging modalities for targeting the delivery of ultrasound. The wide variety of potential applications under consideration necessitates a refinement of transducer design to accommodate often conflicting constraints. The need to deliver substantial power to a small target zone requires high focal gain to minimize collateral damage, and yet must be balanced with the need for small transducers in many procedures. In general, the choice of operating frequency, transducer aperture and focal depth, convenient acoustic coupling methods, waveform selection, and amplifier characteristics must all be adjusted to best fit the application. This presentation will discuss such tradeoffs in any HIFU transducer design, and will also address particular techniques for coupling and cooling transducers which deliver hundreds of watts of acoustic power. Transducer efficiencies of over 85% have been routinely achieved by judicious selection of matching layers and tuning networks, while maintaining over 50% relative bandwidth, for center frequencies spanning the range from 1 to 10 MHz. Transducer requirements for array-based systems, motivated by clinical needs, will also be discussed. [Work funded by DARPA/ONR.]

10:35

2aBV5. Acoustic field of a device for noninvasive pressure wave therapy in orthopedy. Eckard Steiger, Thomas Dreyer (Inst. für Hoechstfrequenztechnik und Elektronik/Akustik, Univ. Karlsruhe, D-76128 Karlsruhe, Germany, eckard.steiger@etec.uni-karlsruhe.de), and Juergen Mayer (Storz Medical AG, CH-8280 Kreuzlingen, Switzerland)

The Storz Minilith SL1 is a device specially designed for the treatment of orthopedical indications as tendinosis calcarea, tennis or golf elbow, heel spurs, or supra spinatus syndrome. A cylindrical electromagnetical source generates an intense ultrasonic pulse, which is focused by means of a parabolical reflector. Measurements in the focal region are performed in degassed water using a fiber-optic probe hydrophone. The whole process of pulse radiation from the source over nonlinear propagation including reflection to the focusing is simulated too. The underlying full wave model is based on a specially developed finite difference in time domain method. Excellent agreements of measured and computed pressure wave profiles in the focal region validate the model. The generation of shock waves in dependence on the energy setting of the therapy device is studied. Further investigations are made to consider the interaction of the SL1-pulse with human tissue structures as they occur in medical applications.

10:50

2aBV6. *Ex vivo* studies of the effect of high-intensity focused ultrasound on whole human blood. Sandra Poliachik, Susanah Bloch, Michael Bailey, Peter Kaczkowski, Robin Cleveland, Pierre D. Mourad, Tyrone Porter, Lawrence A. Crum (Univ. of Washington, Appl. Phys. Lab, 1013 NE 40th St., Seattle, WA 98105, pierre@apl.washington.edu), Wayne L. Chandler (Univ. of Washington, Lab. Medicine, UW Medical Ctr.), and George W. Keilman (Sonic Concepts, Woodinville, WA 98072)

A surgical application of high-intensity focused ultrasound (HIFU) is hemostatis. In this application, both tissue and blood will be subjected to HIFU. What will happen to blood? The intent of this study is to explore via experiment some of the bioeffects of HIFU on whole human blood. A 1.1-MHz piezoceramic source with a 60-mm radius of curvature and 100-mm aperture was used. Special acoustically transparent containers were made of handmade, low-density polyethylene tubing. Phenomena studied included hemolysis, morphologic changes in erythrocytes, white blood cell differential, and platelet activation, all as a function of acoustic intensity and dosage. Intensities up to 6000 W/cm^2 were used in cw pulses of one second. The bioeffects noted above were correlated with temperature and a passive acoustic measure of bubble activity within the blood created by the ultrasound. Under the acoustic conditions considered for this work, nonthermal acoustic effects were most strongly associated with bioeffects. [Work sponsored by DARPA.]

2aBV7. Shaping of focused ultrasonic beams to expedite thermal necrosis in tumor therapy. Frederic L. Lizzi (Riverside Res. Inst., 330 West 42nd St., New York, NY 10036, lizzi@rrinyc.org)

Ultrasonic tumor therapy employing focused beams shows great promise for treating tumors by producing spatial matrices of thermal-necrosis lesions. A practical problem involves the long time required to treat extended tumor volumes. To treat ocular tumors, our laboratories are investigating beams with asymmetric shapes to expedite the production of lesion matrices. The beams are generated using rectangular strip electrodes plated on spherical-cap ceramic transducers. The phase and amplitude of the strip excitation voltages are controlled to launch beams whose focal-zone patterns consist of a sequence of lobes confined within elliptical, rather than circular, cross sections. A simple theoretical model has shown that thermal diffusion between these lobes can produce lesions with elliptical cross sections; lesion matrices would be readily produced by translating such transducers along the short axis of the lesion cross section, thereby causing necrosis in broad regions. The concept has been verified in *in-vitro* experiments (in liver and the ocular lens) and in *in-vivo* exposures of human tumor explants in nude mice. [Work supported by NIH Grant EY10369.]

11:25

2aBV8. An image-guided ultrasound phased array system for noninvasive surgery. Emad S. Ebbini, Philip D. VanBaren, and Claudio Simon (Dept. of EECS, Univ. of Michigan, Ann Arbor, MI 48109-2122)

An integrated image-guided therapeutic phased array system for noninvasive surgical applications is being developed. The therapeutic array utilizes piezocomposite transducer technology and operates (therapeutically) at 1 and 2 MHz. It has 64 elements on a spherical shell with a geometric center at 100 mm from its apex. The array was shown to be capable of producing well-defined thermal lesions in tissue media at depths from 40 to 60 mm and to scan therapeutic foci up to ±15 mm from its geometric center.

Image guidance is provided by a modified diagnostic ultrasound scanner which, in addition to providing standard B-scan images of the target region, provides real-time images of the temperature rise due to the therapeutic beam. The temperature information is obtained using a correlation based algorithm for echo displacement estimation, which can be directly related to local variation in tissue temperature due to the therapeutic beam. A complete description of the system will be given along with illustrative examples of image-guided tissue ablation and temperature estimation and control. In addition, experimental data demonstrating the use of the therapeutic array in an imaging mode will be presented. [Work funded by NIH Grant CA66602.]

11:45

2aBV9. MRI monitoring and control of focused ultrasound surgery. Kullervo Hynynen, Nathan McDannold, Todd Fjield, and Douglas Daum (Div. of MRI, Dept. of Radiology, Brigham and Women's Hospital, Harvard Med. School, 221 Longwood Ave., Boston, MA 02115)

The clinical and animal tests of focused ultrasound surgery have shown significant variation between the effectiveness of the same power sonications. Therefore, it has become important to seek methods to monitor the *in vivo* ultrasound exposures. One of the most promising methods is the use of magnetic resonance imaging (MRI) to detect the temperature elevation. In this paper the calibration and accuracy of MRI thermometry will be presented. The *in vivo* mapped temperature distributions allow the thermal exposure of the tissue to be estimated. These estimates have been compared with the tissue coagulation produced in muscle and brain tissues *in vivo*. The results show that the lesion boundary is predicted with the resolution of the MRI voxels. This has significant clinical value since the MRI thermometry can be used to control the treatment on-line. These experiments allowed comparison of the accuracy of the theoretical models for predicting the temperature elevation and tissue necrosis *in vivo*. Similarly, the MRI thermometry was used to investigate the temperature buildup during multiple sonications and evaluate the performance of new applicators such as phased arrays *in vivo*.

9:20

2aEA1. Influence of air loading and dissipation on plate transducer amplitude. Arthur Ballato (U.S. Army Commun.-Electron. Command, Fort Monmouth, NJ 07703-5201, a.ballato@ieee.org)

Air-loaded plate transducers driven piezoelectrically are used in a variety of modern applications such as optical modulators, microactuators, and certain types of resonant acoustic sensors and frequency control elements. For these uses it is necessary or desirable to know the maximum mechanical amplitudes obtainable, and how these are limited by the various internal dissipation mechanisms and the loading of the ambient fluid. Internal conduction, dielectric, and acoustic viscosity losses are incorporated, and, by introducing of a complex piezoelectric coupling coefficient, changes in critical frequencies and amplitudes are traced with variations in type and size of dissipation mechanism, and the ambient loading. The analysis also shows that the unavoidable interfacial stresses existing between the crystal plate surfaces and the exciting electrodes can become exceedingly large at the frequencies commonly used for frequency control of cellular communications. Because the various devices covered usually form components of an overall circuit design, a number of alternative equivalent electrical circuits are also provided whereby the physics of these structures may be rendered and readily interpreted in network terms.

9:45

2aEA2. Absolute amplitude measurements using a capacitive receiver. M. A. Breazeale (Univ. of Mississippi, Natl. Ctr. for Physical Acoust., University, MS 38677)

Absolute acoustical amplitudes can be measured in solids with a capacitive receiver. Amplitudes as small as 10^{-4} Å$=10^{-14}$ M have been measured. A system is described with dimensions used for frequencies between 5 and 60 MHz. Two special innovations are described: low-temperature measurements which require adjustment of the spacing of the capacitor and high-sensitivity measurements (amplitudes smaller than 10^{-14} M) which are accomplished by using a dielectric to prevent electrical breakdown.

10:10

2aEA3. Silicon micromachined ultrasonic transducers. B. T. Khuri-Yakub (Edward L. Ginzton Lab., Stanford Univ., Stanford, CA 94304-4085, khuri-ya@ee.stanford.edu)

This paper presents a novel type of ultrasonic transducer that is made by silicon micromachining. Transducers for both air-borne and immersion applications are made from parallel plate capacitors whose dimensions are controlled through traditional integrated circuit manufacturing methods. Typical dimensions of the capacitors are: gap =1 micron (vacuum or air), membrane thickness =1 micron (silicon nitride or polysilicon), and diameter =50 microns. A large number of small elements are connected in parallel to make a transducer. Transducers for air-borne ultrasound applications have been operated in the frequency range of 1–11 MHz, while immersion transducers have been operated in the frequency range of 1–20 MHz. Theoretical modeling calculations of the transducers and their electrical input impedances will be presented. The theory predicts a dynamic range of over 140 dB for both air and immersion applications. Different processing methods for fabricating the transducers and the merits of the different approaches will be presented. Finally, the results of transducer operation both in air and water with over a 100-dB dynamic range will be presented.

10:35

2aEA4. Air transducers with high acoustic impedance. Lawrence C. Lynnworth (Panametrics, Inc., 221 Crescent St., Waltham, MA 02154, lynnworthl@panametrics.com)

High-Z air transducers evolved from several industrial transducers. These predecessors include (a) acoustic emission and angle-beam NDT contact transducers; (b) flowmeter transducers for high-pressure methane, hot refinery gases, and corrosive flare gases; and (c) transducer arrays for monitoring hot corrosive gases flowing at Mach 0.1 in smokestacks of ϕ3–13 m. This peculiar ancestry accounts for their unusual high-acoustic-impedance construction. By not employing low-Z air-backed radiating membranes, transducer bandwidth, response time, and sensitivity are sacrificed. The solid, robust construction, however, offers some compensating features: tolerance to wide ranges in pressure and temperature, including rapid rates of change (thermal shock, depressurization); corrosion resistance; operable with standard lab equipment, without bias voltage; mounting options where the transducer forms part of the pressure boundary, or where it is outside the pressure boundary. Clamp-on air flow applications at one bar include small wind tunnels and plastic pipes. Acoustically isolated pairs measure secondary flow components (crossflow, circulation) in a plane perpendicular to the pipe axis. Flow applications include gases such as air, mild steam (pending) or other hot, pressurized, or corrosive fluids. Air-coupled measurements of transmission characteristics of wood or other low-density solids, and air-ranging, are readily demonstrated with the low-Z transducers.

2aEA5. Ultrasonic capacitance transducers for flow and temperature tomography in air. David A. Hutchins (Dept. of Eng., Univ. of Warwick, Coventry CV4 7AL, UK, dah@eng. warwick.ac.uk), William M. D. Wright (Univ. College Cork, Cork, Ireland), David W. Schindel (N.R.C., Ottawa, ON K1A 0R6, Canada), and Peter W. Carpenter (Univ. of Warwick, Coventry CV4 7AL, UK)

Capacitance transducers have been constructed that can operate at frequencies of up to 2 MHz in air, over a wide bandwidth, and with good efficiency. These have been used to propagate signals in air across regions containing variations in air flow and temperature. A source and receiver pair were scanned along a set of projections under computer control, allowing various ray paths across a chosen cross section to be selected. For each location, the received waveform was digitized and recorded, and the propagation time determined from cross-correlation techniques. The data were then used to form tomographic images, which corresponded to variations in either temperature or flow speed, both of which affect the local acoustic velocity. In one experiment, an air-jet was imaged at various distances from the nozzle. In another, the temperature variations in air above a hot metal tip were determined. Images will be shown for both sets of experiments, and the usefulness of the technique discussed.

11:15

2aEA6. Ultrasonic air-coupled capacitance transducers using thin mica films. Paul Ingleby (Dept. of Eng., Univ. of Warwick, Coventry CV4 7AL, UK, es2041@eng.warwick.ac.uk), David A. Hutchins, Andrew G. Bashford (Univ. of Warwick, Coventry CV4 7AL, UK), and David W. Schindel (N.R.C., Ottawa, ON K1A 0R6, Canada)

Micromachined air-coupled capacitance transducers have been manufactured using anisotropically etched silicon backplates and commercially available mica films. Devices developed using 20-μm-thick insulating layers have yielded frequencies of up to 400 kHz. However, new devices using mica with a thickness of approximately 4 μm will deliver characteristics similar to existing transducers employing polymeric dielectric films. This will result in wideband behavior and bandwidths extending from approximately 100 kHz to 2 MHz. Mica-based devices have several advantages over capacitance transducers with polymer films due to the robust physical characteristics exhibited by this type of material. Improved thermal characteristics and lower porosity allow this type of device to be employed in a variety of conditions in which the performance of the polymer films would be impaired. Results of experiments performed in air at a range of temperatures from ambient to 400 °C will be presented. This will demonstrate the versatility of such devices in terms of both sensitivity and bandwidth.

11:30

2aEA7. Recent developments in air-coupled ultrasonic capacitive transducers for NDE. Craig S. McIntyre, David A. Hutchins (Dept. of Eng., Univ. of Warwick, Coventry CV4 7AL, UK, esrna@eng.warwick.ac.uk), and David W. Schindel (Inst. for Aerosp. Res., Natl. Res. Council, Ottawa, ON, Canada)

A new design of an air-coupled capacitive ultrasonic transducer has been developed that could have potential for use in NDE experiments, particularly when the pulse-echo method is employed. The design is based on a standard capacitive transducer, except the newly developed device has two concentric, backplate elements with a common membrane. Each of the elements is electrically isolated from the other, allowing one to be used as a source of ultrasound, while the other is used as a detector. This yields a device containing both a source and receiver of ultrasound within the same structure. Experiments have shown that the device performance depends on which of the elements is selected to be source and receiver, size of the bias voltage employed, surface of the backplates, and membrane material utilized. Initial studies have shown that the device is capable of detecting the front face echo from various material samples, and these results are contained within this paper. There has also been some investigation of the signal quality when capacitive devices have been placed within an enviroment containing a range of pressures above standard atmospheric pressure. Applications of this work include measurements in high-pressure gas pipelines.

Invited Papers

7:45

2aMU1. Fluid dynamic aspects of human voice and brass instruments: Implications for sound synthesis. Pelorson Xavier (Institut de la Commun. Parlee, ESA CNRS 5009, 46 av. F. Viallet F-38031 Grenoble, France), Msallam Regis (Institut de Recherche et de Coordination Acoustique Musique, F-75004 Paris, France), Gilbert Joel (Institut d'Acoustique et de Mecanique, F-72017 Le Mans Cedex, France), and Hirschberg Avraham (Tech. Univ. of Eindhoven, NL-5600 MB Eindhoven, The Netherlands)

The challenge of physical models of musical instruments is to provide a global description of a highly complex instrument which has to be accurate but simple enough to be numerically implemented. For this purpose, a logical approach is to extract, from a theoretical or experimental study, what are the most important phenomenon involved which are thus to be taken into account. Two examples of such an approach are given by the physical models of human voice and brass instruments presented here. Although both instruments share in common the same basic principle, a self-oscillating source coupled with a resonator, crucial physical aspects are quite different. It is shown that, for brass instruments, the lips' self-sustained oscillations are mainly driven by the acoustical coupling, therefore the simpliest one degree of freedom model for the lips is sufficient. In the case of voicing, the acoustical feedback, although effective, is not sufficient to maintain self-sustained oscillations. A more elaborated vocal-folds model is needed. Regardless of the sound source, the description of the resonator is also discussed. While, for voice simulations, significant improvement can be gained using a two-dimensional linear theory, nonlinear propagation is sometimes to be taken into account for brass instruments.

8:10

2aMU2. The effect of wall materials on the timbre of brass instruments. Robert W. Pyle, Jr. (11 Holworthy Pl., Cambridge, MA 02138-4509)

It has long been thought by players and instrument makers that the material from which a brass instrument is made influences the tone quality and playing characteristics of the instrument. For instance, the brochure of a maker of custom trombones describes bells made of three alloys: yellow brass (70% Cu, 30% Zn), having the ''clearest sound, sharpest articulation,'' gold brass (85% Cu, 15% Zn), with ''warm sound, rounded articulation,'' and red brass (90% Cu, 10% Zn), with ''warmer sound, covered articulation.'' The bells are made in three metal thicknesses: light weight, with ''flexible tone, rapid response,'' standard weight, with ''balanced tone, even response,'' and heavy weight, with ''firm tone, stable response.'' Most players agree with these statements. This model of trombone is made so that bell sections can be interchanged while leaving the remainder of the instrument intact. The present paper reports the results of measurements under playing conditions on several different bells. Comparisons of steady-state behavior are made via the transfer function between sound pressure in the mouthpiece cup and an on-axis point outside the bell. An attempt will also be made at the rather more difficult task of characterizing the attack transient.

8:35

2aMU3. The effect of wall properties on the timbre of organ pipes. Judit Angster (Fraunhofer-Institut fur Bauphysik, Nobelstr. 12, D-70563 Stuttgart, Germany, angster@ibp.fhg.de), Gyvrgy Paal, Walter Garen (Fachhochschule Ostfriesland, Constantiaplatz 4, D-26723 Emden, Germany), and Andras Miklss (Fraunhofer-Institut fur Bauphysik, D-70563 Stuttgart, Germany)

The influence of the wall vibrations on the timbre of flue organ pipes is one of the most disputed questions of organ building. Wall vibrations of metal and wooden labial pipes have been investigated by using miniature piezoelectric accelerometers and optical noncontact vibrometers. Both free and forced vibrations have been studied. Two sets of diapason pipes that were built with different wall properties but identical dimensions have been voiced to very similar speech and timbre, then vibration and sound spectra and attack transients were recorded. While large differences have been found in vibration spectra, hardly any change in the sound signal was observed. Similar investigations have been performed on wooden pipes. In this case the voicer ''tuned'' the side wall resonances in order to make the sound richer in overtones. The effect of this ''tuning'' on the vibration and sound spectra has been investigated. The ''tuning'' resulted in a significant increase of the vibration amplitude, while the radiated sound-pressure level decreased and the overtones became relatively stronger.

9:00

2aMU4. Acoustically driven sinuous instability of a planar air jet. A. W. Nolle (Dept. of Phys., Univ. of Texas, Austin, TX 78712-1081)

The sinuous instability wave of a planar air jet is excited by localized acoustic flow across the nozzle. Phase velocity and the growth exponent are found from synchronous hot-wire measurements made beyond the excited region, where the profile is approximately sech squared. In the observed range of scaled radian frequency, 0.02–1.33 (the stability limit), results agree with real-

frequency (spatially growing) analysis but not with complex-frequency (temporally growing) analysis, which predicts smaller phase velocity at low frequencies. In further tests, the acoustic driving signal is independent of downstream distance, as in an organ pipe. The jet deflection is then the sum of acoustic convection and of the instability wave, summing to zero at the nozzle, as proposed by Fletcher, Elder, and others. The instability-wave theory applies to linear behavior in the inviscid limit and therefore to a hypothetical nonspreading jet. The local velocity profile width must be considered in relating to a physical jet. In a flue organ pipe oscillating at equilibrium amplitude the jet deflection at the lip exceeds the range of validity. Direct sound generation by the jet is investigated briefly.

9:25–9:35 Break

9:35

2aMU5. Jet wave amplification in organ pipes. Shigeru Yoshikawa (Dept. of Acoust. Des., Kyushu Inst. of Design, 4-9-1 Shiobara, Minami-Ku, Fukuoka, 815 Japan)

The amplification factor of an air jet waving over the mouth is estimated from flow visualization of the smoked jet, where the velocity ranges from 7–33 m/s, the Reynolds number from 1000–5000, and the sounding frequency from 130–580 Hz. The jet length is 15.8 and 10.2 mm in two models, while the jet thickness is 2.2 mm in both. The estimation is carried out by comparing the visualized envelope of jet waves with a simplified theoretical one. The envelope is visualized by the OR summation of the digitally memorized frames showing the instantaneous deflection taken with a speed of 1440 frames per second. Furthermore, the strength of mouth field defined as the acoustic displacement amplitude is derived from the envelope-based estimation. A hot-wire anemometer is then applied to measure this mouth-field strength, whose value shows a good agreement with the estimated result. The amplification factor of organ jets was estimated as 0.26 to 0.18 (1/mm); the mouth-field strength as 0.5 to 1.5 mm. A nondimensionalized representation of the relation between the amplification factor and the blowing velocity in our organ-pipe jets roughly agrees with the theoretical curve based on the linearized spatial analysis of jet instability.

2aMU6. Interpretation of shear material properties of vocal fold mucosal tissues with Fung's quasilinear viscoelastic theory. Roger W. Chan and Ingo R. Titze (Natl. Ctr. for Voice and Speech, Dept. of Speech Pathol. and Audiol., The Univ. of Iowa, Iowa City, IA 52242, roger-chan@uiowa.edu)

Fung's quasilinear viscoelastic theory (QLV) [Y. C. Fung, *Biomechanics* (Springer-Verlag, New York, 1993), pp. 277–292] has been successfully applied to model the time- and history-dependent properties of a variety of biological soft tissues in the passive state. In particular, the hysteresis or damping curves of many soft tissues remain relatively insensitive to the rate of deformation (strain rate or frequency) across several decades of variation. This insensitivity to frequency cannot readily be accounted for by traditional discrete models of linear viscoelasticity. Rather, Fung's QLV provides a mathematically powerful framework in which a continuous stress relaxation spectrum can be used to model the relatively flat damping characteristics. The shear properties of human vocal fold mucosal tissues were measured with a rotational rheometer. Data on complex dynamic shear modulus, complex dynamic viscosity, and damping ratio as functions of frequency were obtained. It was found that vocal fold mucosal tissues show the shear-thinning behavior and have a relatively flat damping curve typical of biological soft tissues. Theoretical predictions based on the QLV matched well with the empirical data. The results suggest that the vocal fold mucosa can be modeled by the QLV under small-amplitude oscillation conditions. [Work supported by NIH Grant No. P60 DC00976.]

10:15

2aMU7. Theoretical and experimental investigation of the air-driven free reed. James P. Cottingham (Phys. Dept., Coe College, Cedar Rapids, IA 52402)

The free reed is the excitation mechanism for several families of instruments, including the reed organ and harmonium, the harmonica, the accordion and concertina, and the Asian free reed mouth organs. While most studies of reed behavior have concentrated on reeds which are either inward-striking (closing) and outward-striking (opening), free reeds do not fit neatly into either category and can exhibit behavior characteristic of either opening or closing reeds, depending on certain details of the reed configuration. Some characteristics of free reed behavior, in particular the relation between frequency and blowing pressure, have been modeled by adapting Fletcher's analysis of musical instruments driven by a reed mechanism [N. H. Fletcher, Acustica **43**, 63–72 (1979)]. In addition, a variety of measurements of reed motion have been made, including experimental determination of measurements of reed position and phase using proximity sensors. These are compared with observations of the near-field sound as well as with predictions based on theoretical considerations.

10:30

2aMU8. Material and obsolescence on flute tone quality. Alessandro Cocchi and Lamberto Tronchin (DIENCA— CIARM Univ. of Bologna, Viale Risorgimento, 2 40136 Bologna, Italy, tronchin@ciarm.ing.unibo.it)

The rule of material and obsolescence on flute tone quality has been discussed for a long time among musicians and flute makers. Mozart himself made use of crystal flutes in some of his works (Rondo', K617, Adagio, K356). From an acoustical point of view, since Boehm's work of 1832, the effect of material on flute tone quality has not been investigated, until researches of recent years [Coltman (1971); Chapuis (1991)]. In this work the research has been carried out measuring impulse responses inside the tube of the flute. Two different flutes have been utilized, i.e., a light-alloy flute and a silver flute. The MLS sequences, with homemade software, have been utilized, gathering impulse responses in two different positions in the tube, in order to verify the variation of sound field. From the impulse responses a frequency analysis has been obtained, which pointed out that the silver flute contains more high frequency and shorter transient than the light-alloy flute. Starting from the impulse responses, sound example of difference in sound quality has finally been obtained.

2aNSa1. Active attenuation of fan noise in an air-conditioning duct. Ondrej Jiricek and Petr Konicek (CTU-FEE, Dept. of Phys., 166 27 Prague, Czech Republic)

In this paper, the results of an investigation on using ANC systems in a duct will be presented. This system was used to reduce the noise of the axial-flow fan used as the noise source. The system was based on the adaptive digital signal processing controller. The attenuation of noise at low frequencies was achieved. This research represents a part of the project focused on the improvement of working conditions in operating theaters.

8:50

2aNSa2. Studies on a new type of silencer for air ducts. Fathy B. Shenoda (Dept. of Acoust., Natl. Inst. for Standards, Giza-Egypt, P.O. Box 136 Giza, Code No. 12211) and Reda N. Haroun (Dept. of Acoust., Natl. Inst. for Standards, Giza, Egypt)

The research work deals with a study of a specific type of silencer previously designed and tested by Shenoda. It consists of a rectangular duct, which is treated at its side walls with a gradually variable flow resistance. It was realized by increasing the perforated area along the duct wall combined with an homogeneous sound absorbing material. Based on the assumptions that only plane waves propagate in the duct, ignoring the effect of the mean flow velocity (very low) and applying linear acoustic equations, the sound propagation in such a silencer was studied. Therefore the wave impedance, the sound reflection coefficient at the input of the silencer, and the transmission loss introduced by it were calculated, measured, and compared with a silencer of comparable dimensions which is treated with a constant flow resistance along its length. To optimize the design different configurations were theoretically studied, computed, and compared. An important result: The silencer performance depends on a unique design parameter, namely, the silencer characteristic area. The methods of realizing a variable wall flow resistance were introduced. The effect of using different kinds of sound absorbing materials and changing the graduality of the variable flow resistance were measured.

9:10

2aNSa3. Noise of cleanroom recirculation systems. Mei Q. Wu and Colin G. Gordon (Colin Gordon & Assoc., 411 Borel Ave., Ste. 425, San Mateo, CA 94402)

Recirculation air systems are used by the microelectronics industry as the primary source of unidirectional air flow in cleanrooms. The commonly used recirculation systems include: (1) packaged air handlers, which include centrifugal or plug (plenum) fans, generally located at fan deck level above the cleanroom; (2) fan-tower recirculation systems, consisting, most often, of vertically mounted vaneaxial fans arranged along the cleanroom perimeter; (3) individual fan-filter units, in which the HEPA or ULPA filters are combined with small direct drive blowers, supported by the ceiling suspension system; and (4) minienvironments, which create superclean conditions around individual tools within a less clean ''ballroom.'' In this paper, the commonly used recirculation systems will be described, typical sound power levels and spectrum characteristics of the systems will be presented, the natural noise attenuation along the air flow paths will be listed, the theoretical models for predicting noise levels in a cleanroom will be introduced, and noise mitigation means which can be integrated into different systems will be discussed. Also presented will be the typical noise levels measured in operating cleanrooms.

9:30–9:45 Break

9:45

2aNSa4. Noise and vibration characteristics of cleanroom fan filter units. Mei Q. Wu and Colin G. Gordon (Colin Gordon & Assoc., 411 Borel Ave., Ste. 425, San Mateo, CA 94402)

Fan filter units (FFU's) are used increasingly by the microelectronics industry to provide recirculation air in cleanrooms. Such units usually consist of one or more direct-drive blowers located in a small discharge plenum and a HEPA or ULPA filter. There may be several hundred FFU's in a large cleanroom. The noise and vibration generated by FFU's differ greatly between manufacturers. Since it is difficult to apply external noise and vibration mitigation, it is important to select an FFU model with appropriate noise and vibration levels, so that a cleanroom served by these units will meet the prespecified noise and vibration criteria. Unfortunately, FFU manufacturers usually do not provide enough information for predicting the FFU generated sound-pressure spectrum or vibration in a cleanroom. In this paper, simple noise and vibration measurement methods will be described, which can be used as a basis for specifying FFU performance without special testing facilities. Measured data will be presented for a number of units. Procedures will be demonstrated to predict the performance of a cleanroom which uses FFU's as the primary source of recirculation air.

10:05

2aNSa5. Design and acoustic characteristics of an anechoic chamber with high-power heating or cooling and sound field free transform system. Weicheng Yang and Jiahua Yang (Res. Inst. of Household Elec. Appliance of China, No. 6 Yuetan Beixiaojie, Beijing 100037, PROC)

In this paper, the design and the acoustic characteristics of an anechoic chamber with high-power heating or cooling condition and sound field free transform system are summarized. Moreover, during the construction of the anechoic chamber, the following technical problems have been solved successfully. (1) Under 15 kW heating or cooling energy load being released by the sound source in the anechoic chamber, the adjusting to the temperature and the humidity can be completed. (2) Through the

moving of the mobile sound absorption plane, two anechoic chambers can be combined into one anechoic chamber, one semi-anechoic chamber, or one octant semi-anechoic chamber. Its sound field characteristics conform to the standard ISO 3745. (3) During the normal state, the background noise in the anechoic chamber is less than 23 dBA.

10:25

2aNSa6. Hand-held analyzer systems for building acoustics and sound intensity/sound power. Peter Larsen (Bruel & Kjaer, Skodsborgvej 307, DK-2850 Naerum, Denmark, plarsen@bk.dk)

Two new applications have been developed for a hand-held analyzer: Building acoustics and sound intensity/sound power. The building acoustics application is designed for measurements of airborne and impact sound insulation and reverberation time. The sound intensity application is used for sound power measurements, noise source location, noise mapping, and building acoustics. Both applications we used with complete systems consisting of all the necessary parts to simplify the measurement task and provide the user with all results immediately at the measurement site. There is no need for postprocessing. The measurements can be done according to a wide selection of international and national standards. The paper will describe the use of both applications in solving a problem in building acoustics. The building acoustic application will be used to detect a problem with poor sound insulation of a wall. Then, the intensity technique is used to determine the cause of the problem. Both applications use a built-in noise generator in the hand-held analyser with wireless transmission to an amplifier/loudspeaker. The paper will focus on the various design features that have been incorporated to ensure easy, secure, and flexible use.

Chair's Introduction—8:00

Invited Paper

8:05

2aNSb1. A Hong Kong approach to control noise from outdoor entertainment activities. P. S. Ng, Sam W. H. Wong, Y. K. Kam, and K. S. Chan (Environ. Protection Dept., The Government of the Hong Kong Special Administrative Region of the People's Republic of China, 46th Fl., Revenue Tower, Wan Chai, Hong Kong)

With 6.5 million people living on some 1000 square kilometers of land, about 70% of which are hilly terrains, one could imagine how difficult it would be in planning compatible land use. High-rise residential blocks surrounding sports ground are not uncommon in Hong Kong. They should co-exist harmoniously if the latter is intended solely for recreational sports. Hong Kong, being a cosmopolitan city, hosts many kinds of outdoor entertainment activities of cultures and many are held frequently in these sports grounds owing to the absence of purpose-built outdoor venues for these activities. With increasing environmental expectations, complaints against noise from these activities are on the rise. Special considerations will have to be struck between efficient use of land and adequate noise protection of the nearby noise-sensitive receivers. This paper describes the various outdoor entertainment activities being held in Hong Kong, their noise generation characteristics, and the approaches taken to control the noise.

2aNSb2. Annoyance and health effects of entertainment noise. C. G. Rice (Inst. of Sound and Vib. Res., The Univ., Southampton SO17 1BJ, UK)

There is no doubt that over the past 20 years awareness in the possible adverse annoyance and health effects which can result from entertainment and leisure activities has increased, and the topic is becoming more worthy of research effort in its own right. A review of the literature has established certain knowledge base gaps in the causal relationships between such noise and its adverse effects. Indeed, apart from noise-induced hearing loss there appears to be a lack of in-depth research from which unequivocal quantitative conclusions can be drawn. While damage to hearing from certain activities has been established, in general nonauditory health effects are not apparent although annoyance effects and provoked violence are becoming increasing causes of major concern. However, bearing in mind the relatively low integrated noise exposures which personally accrue from participation in and exposure to entertainment and leisure noise activities, care should be taken not to overemphasize the adverse effects to the prejudice of the other positive benefits created by participating in such activities.

8:40

2aNSb3. Proactive concert sound management: The essential ingredient for community acceptance of outdoor concert venues. Richard G. Cann (Grozier Tech. Systems, Inc., 157 Salisbury Rd., Brookline, MA 02146-2032) and William J. Cavanaugh (Cavanaugh Tocci Assoc., Inc., Sudbury, MA 01776)

Residents living adjacent to outdoor music venues have often objected to sound emissions. With increased sound power now available from loudspeakers, the situation is exacerbated, threatening the existence of music venues. Venues have demonstrated that by using a fixed installation sys-

tem to manage and control concert sound emissions effectively, the friction with the community can be reduced substantially. An essential ingredient of the amelioration process is making automatic sound emission reports available to amphitheater sound engineers and management as each concert proceeds. Sharing these same reports with citizen activists immediately after each concert helps develop trust. Case histories will be presented.

8:55

2aNSb4. Entertainment park noise control devices. Alessandro Cocchi and Giovanni Semprini (DIENCA, V.le Risorgimento 2, 40136 Bologna, Italy, alessandro.cocchi@mail.ing.unibo.it)

A big entertainment park is operating with noisy attractions near the Garda lake, a pleasant land where people go not only for amusement but also to relax, especially during holiday time. Noise measurements have been made during different periods of daytime and a noise map has been developed taking into account the difference of level between the top of the noisiest attraction and the windows of the most exposed house. Starting from this computerized model, and knowing the emission spectrum of the most relevant sources, it has been possible to design some noise control device useful for reducing the noise exposure level restricted to the exposed houses alone: This was possible combining earth barriers and a hot windstream.

9:10

2aNSb5. Comparison of predicted and measured noise levels for refinery units. Frank H. Brittain (Bechtel Corp., 50 Beale St., San Francisco, CA 94105) and Mark M. Gmerek (The Boeing Co., P.O. Box 3707, Seattle, WA 98124)

Predicting noise levels from new refinery units is a vital part of environmental assessment and designing units to meet noise limits. The accuracy of those noise predictions is a very important concern. The simplest way to assess the accuracy of predictions is to compare predicted and measured noise levels. This is usually difficult, because measured levels are strongly affected by noise from adjacent units and by atmospheric effects on sound propagation. Further, actual noise levels of significant sources often deviate from expected levels used in the noise prediction model. Thus to meaningfully compare predicted and measured levels, the actual noise source levels for the major sources, atmospheric conditions, and noise levels from adjacent units must all be accounted for. Predicted and measured levels are compared for two large refinery units. Measurements were made at locations where noise from adjacent units has little effect and close enough so that atmospheric conditions have little impact on the measured levels. Measured operational noise levels of major sources were used to update the noise prediction model. Accuracy of the predictions is evaluated.

9:25

2aNSb6. Acoustic modeling and simulation of an urban substation. Eduardo Bauzer Medeiros and Gia Kroeff (Dept. de Eng. Mecânica da UFMG, Av. Antônio Carlos 6627, 31270-901, Belo Horizonte-MG, Brazil, flugzbau@oraculo.lcc.ufmg.br)

Demographic growth has often resulted in a disorganized occupation of large urban areas. Regions which were previously empty started to be populated, frequently resulting in an increasingly more common proximity between residential construction and industrial installations. As a consequence, very serious environmental problems have occurred, including those caused by acoustic emission from industrial installations. A common problem these days is the disturbance caused by electric substations closely positioned to residential buildings. The disregard for acoustic effects during the design stage can still be observed in some of the older substation designs, particularly in areas previously far from city centers. In some countries, such as Brazil, a systematic acoustic evaluation of substations only started in the 1980s, with the main bulk of the work still under development. This paper describes some of the joint work being carried out on noise control by the researchers of Universidade Federal de Minas Gerais and CEMIG (the state power administration). The initial definition of a series of acoustic elements, followed by the discussion of the governing equations, is considered. The computational implementation of the resulting model is presented, aimed at the definition of the most convenient noise control strategy. Finally, a few results obtained at a real substation are considered, including some experimental results obtained during actual operation.

9:40

2aNSb7. Environmental pollution and noise control of two power generator sets placed into a recreation area. Victor Rastelli, Nila Montbrun, and Alexis Buoza (Departamento de Mecánica, Universidad Simón Bolivar, Caracas 1080-A, Venezuela)

This paper deals with the noise control of two power generator sets of 545 kW each, located in a Venezuelan resort. The generator sets made a noise level of 73 dB(A) at a distance of 47 m from the source, where are located the guest rooms. This level was far from the legal regulations for allowable environmental conditions. A noise enclosure with air silencers was proposed to reach a final level of 53 dB(A) at the guest accommodations. Two aspects must be taken into account, the noise reduction and the ventilation specifications of the generator sets, in order to keep the operational temperature. The final noise level was measured at 54 dB(A) and the pressure loss of the silencers was well placed into the ventilation specifications.

9:30

2aPAa1. The effect of mass transfer on sound propagation in cylindrical tubes using the low reduced frequency approximation. Craig J. Hickey and Richard Raspet (Dept. of Phys. and Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677, chickey@olemiss.edu)

The theory for sound propagation in a gas/vapor mixture contained in a cylindrical tube is investigated. The tube is assumed to have a rigid wall covered by a thin film of water. This thin film of water acts as a source/sink for the mass and the heat associated with the vapor. This problem has been previously solved in the high- and low-frequency limits using the Rayleigh eigenmode method [Y. Mao and J. M. Sabatier, J. Acoust. Soc. Am. **96**, 3254(A) (1994)]. However, the interpretation of these results is limited by their complexity. This formulation of the problem parallels the low reduced frequency approximation work of Tijdeman [J. Sound Vib. **39**, 1–33 (1975)]. In contrast to the earlier results an easily interpreted analytical solution for the propagation constant is obtained. The parameters governing the propagation of the sound waves are the shear wave number, Prandtl number, Schmitt number, and the reduced frequency. The limits of small and large shear wave number provide useful insight into the behavior of the gas/vapor mixture. Examples of air/water and helium/water mixtures will be discussed. [Work supported by ONR.]

9:45

2aPAa2. Measurement of the radiation impedance of a pipe with a circular flange. Jean-Pierre Dalmont (Laboratoire d'Acoustique, Université du Maine, 72085 Le Mans Cedex 9, France) and Cornelis J. Nederveen (Acacialaan 20, The Netherlands)

The radiation of an open pipe with an infinite flange, as well as that of an unflanged pipe has been explicitly calculated by, respectively, Norris and Sheng [J. Sound. Vib. **135**(1), 85–93 (1989)] and Levine and Schwinger [Phys. Rev. **73**, 383–406 (1948)]. The radiation of real tubes, i.e., with a finite wall thickness or a finite circular flange, is not accurately known. The aim of the present measurements is to determine the radiation of tubes with various flanges and their frequency dependence. The radiation impedance has been deduced from the measurements of the input impedance of a short tube. As the differences between the different situations can be very small, the impedance sensor must be accurately calibrated. Results are reproducible and are in good agreement with a calculation using a boundary elements method (software, Rayon). It is observed that the curves obtained are not limited by the case of the infinite flange and the case of the unflanged pipe. This is probably caused by a resonance effect due to the diffraction at the edges of the flange.

10:00

2aPAa3. Boundary-integral-equation methods for accurate calculation of acoustic fields. James B. Mehl (Dept. of Phys., Univ. of Delaware, Newark, DE 19716-2570, jmehl@udel.edu)

Acoustic fields near solid boundaries can be approximated by solutions of the Helmholtz equation subject to Neumann boundary conditions on the boundaries. For closed, axisymmetric geometries, the boundary-value problem can be expressed as a one-dimensional integral equation. Boundary shapes can be represented exactly in this formalism. With current code, numerical solutions can be obtained for shapes formed by rotating plane figures made up of mixtures of straight and circular line segments. Numerical solutions to the integral equation were determined by using cubic-spline approximations to the velocity potential Ψ. This procedure enabled both Ψ and the tangential acoustic velocity Ψ' to be determined with high precision. In calculations of the fields within ducts near the orifices, with modest ($\sim$200) numbers of boundary elements, approximate values of Ψ' were found which were smooth over five orders of magnitude. The technique was used to calculate fields near the duct ends and to evaluate inertial and resistive end effects, for both baffled and unbaffled duct ends. The effects of rounding sharp edges has been evaluated through the use of circular-arc boundary elements. [Work supported in part by the Office of Naval Research.]

10:15

2aPAa4. Numerical study of sound field radiated from a circular duct with an open end. Zhichi Zhu, Anqi Zhou, Dongtao Huang, and Qing Guo (Dept. of Eng. Mech., Tsinghua Univ., Beijing, 100084, PROC, zzc-dem@mail.tsinghua.edu.cn)

A dispersion-relation-preserving (DRP) scheme for computational acoustics has been developed in recent years. This scheme is of high accuracy and can preserve the original dispersion relations of governing equations so that a good global acoustic solution can be ensured. However, the scheme is usually not only very complex but also problem dependent. In this paper, a unified DRP scheme for both internal and boundary points is developed for solving the sound field radiated from a circular duct with an open end. This unified DRP scheme is further applied to obtain the sound fields numerically in three different cases, namely, without flow and flange, without flow but with flange, and with flow and flange. In addition, relevant reflection efficiencies are also predicted at various Helmholtz numbers. Satisfactory comparisons of the predicted reflection efficiencies with data from other studies are illustrated. It is also shown that the numerical method with the DRP scheme presented in the paper is successful.

10:30

2aPAa5. Experimental investigation on nonlinear standing waves by two tube structure. Ke Liu and Dah-You Maa (Inst. of Acoust., Academia Sinica, P.O. Box 2712, Beijing 100080, PROC)

Nonlinear standing waves have been studied in a structure consisting of two lengths of tubing with different diameters. The measurement system of the experiment is presented. A new high-power loudspeaker driver (300 W) is used as a sound source to excite the large tube of 45 mm diameter through a small hole near one end which is closed. Preliminary nonlinear theory is proposed, and a resonance diagram of the tube structure is given. The main properties of nonlinear standing waves were obtained. At the end of smaller tube, a sound-pressure level (SPL) of nearly 177 dB has been obtained with a low distortion. The phenomena of saturation and properties of the output at the end of the smaller tube as well as their relation with the input were investigated. Increasing the diameter of

the structure directly with a modern high-power loudspeaker produces high intensity in a more extended space. Experiments are in progress. [Work supported by the National Natural Science Foundation of China.]

10:45

2aPAa6. Influence of airflow on sound propagation in a curved tunnel. Hiroyuki Imaizumi and Takehiro Isei (16-3 Onogawa, Tsukuba, Ibaraki, 305 Japan)

Measurements were made to examine influences of airflow on propagation attenuation of sound in a curved tunnel. The speed of airflow varied in width direction of the cross section of tunnel, and the values were from around 1 to 3 m/s. Sound attenuation upwind was less than that downwind at high frequencies up to the receivers that are in sight of the source. The tendency agrees with sound attenuation measured in a straight tunnel with airflow [H. Imaizumi *et al.*, J. JSSE **31**, 228–239 (1992)]. Difference of the attenuation gradually became small in the same frequency region at receivers that are out of sight from the source. Numerical calculations by means of a ray tracing method were applied to propagation attenuation of sound in a curved two-dimensional plane. Transmission losses of sound energy calculated only from reflection times of the sound rays on the inner wall were compared under each propagation condition. The transmission loss downwind was larger than upwind up to the receivers that are in sight, while the difference of both became small at the further receivers due to the rapid increase of the reflection times of rays. The calculation results qualitatively agree with the experimental measurements.

11:00

2aPAa7. Acoustic propagation in the presence of an arbitrary flow. C. J. Peyret (ONERA/MFE/DSNA, 29 Ave. de la division Leclerc, 92322 Chatillon, Cedex, France)

The study of acoustic propagation in a lined duct in the presence of an arbitrary flow remains open. Duct acoustic propagation in the presence of flow is generally computed assuming some particular properties of the flow and simplifying the duct geometry to find an appropriate wave equation. For instance, the Lilley or Phillip equation can be deduced this way. However, a unique partial differential equation based on the acoustic displacement vector allows a nonhomogeneous flow in an arbitrary duct geometry to be taken into account. This equation was first established by Galbrun in 1931. After recalling the Galbrun equation, a method to solve it is presented. The method uses the Lagrangian properties in order to apply the finite elements method. Different boundary conditions may be introduced. The solution of the Galbrun equation is compared to the solution of the Lilley equation in the case of modal propagation in a lined duct in the presence of a shear flow. Both results are in good agreement, and validate the method used to solve the Galbrun equation.

11:15

2aPAa8. Propagation of vibration waves in a pipe. Mihail-Dan F. P. Simion (Dept. of Machines — Tools, Univ. Polytechnica Bucharest, 313 Splaiul Independentei, 77206, Bucharest), Gabriela-Cristina D. Simion, and Florian-Paul Simion (Univ. Polytechnica Bucharest, 313 Splaiul Independentei, 77206, Bucharest, simion@freddy.cib.pub.ro)

Our studies concerning propagation of vibrations inside a pipe presume a behavior analysis for a continuous medium, but also a dynamic study of elastic medium. A diagram for describing the behavior of a viscoelastic medium is represented with emphasizing properties of material. In our case energy is transmitted through propagation of longitudinal pressure waves. Every particle of medium is vibrating around its equilibrium position. The relation for deformations dependence on tensions are determined, taking into account a medium with negligible viscosity. Propagation velocity for longitudinal and transversal plane waves are computed, by aiding Navier equations. A ratio between longitudinal waves propagation velocity and transversal waves propagation velocity equal to 1.87 for $v = 0.3$ is obtained.

2aPAb1. Simple model for temperature gradient formation in a short stack. Ralph T. Muehleisen (Dept. of Civil, Environ., and Architect. Eng., Univ. of Colorado, Boulder, CO 80309) and Anthony A. Atchley (Penn State Univ., P.O. Box 30, State College, PA 16804)

There has been much analytical, numerical, and experimental work investigating steady-state thermoacoustic phenomenon. However, much less work has been done on time-dependent problems such as the evolution of the thermoacoustic temperature gradient in a short stack of plates. If the time scale of the acoustics is much shorter than that of the thermodynamics of the stack itself, the acoustics can be assumed to be in steady state while the temperature gradient in the stack is formed. With this assumption, the thermoacoustic heat flux between the stack plates will be of the form $Q = (C_1 + C_2 \partial T/\partial x) p^2$. This gives rise to a temperature gradient that rises exponentially in time with a time constant proportional to the thermal conductivity of the stack and the acoustic pressure squared. There is an additional exponential temperature rise from viscous heating. The model is shown to match measured temperature gradients very well. [This work was supported by the Office of Naval Research and the American Association for Engineering Education.]

9:45

2aPAb2. Performance measurements of a thermoacoustic refrigerator driven at high amplitudes. Matthew E. Poese and Steven L. Garrett (Grad. Prog. in Acoust., P.O. Box 30, State College, PA 16804, matt@sabine.acs.psu.edu)

Since the power density in a thermoacoustic device is proportional to the square of the acoustic Mach number, there is strong motivation to design thermoacoustic refrigerators to operate at larger pressure amplitudes. Measurements will be reported of a modified version of the space thermoacoustic refrigerator (STAR) [Garrett *et al.,* ''Thermoacoustic refrigerator for space applications,'' J. Thermophysics Heat Transfer **7**, 595–599 (1993)] driven at pressure amplitudes two to three times as large as reported in 1993. The results of these measurements will be compared to both a DELTAE computer model of the low-amplitude (linear) performance and one that includes turbulent flow in the duct regions of the device. An overview of the instrumentation, including a measurement of exhaust heat with an absolute accuracy of 65 mW, will also be presented. [Work supported by Office of Naval Research.]

10:00

2aPAb3. Extended performance measurements for SETAC. Anat Grant and Steven L. Garrett (Penn State Univ., P.O. Box 30, State College, PA 16804, anat@sabine.acs.psu.edu)

The Shipboard Electronics ThermoAcoustic Cooler (SETAC) was built at the Naval Postgraduate School in Monterey, CA. In a demonstration at sea aboard the U.S.S. DEYO in April 1995, SETAC was used to provide 419 watts of useful cooling power across a stack temperature difference $T_{\text{hot}}-T_{\text{cold}}=30\ ^{\circ}\text{C}$ with an acoustic input power of 227 watts. New data spanning a wider range of temperature difference and heat load will be presented and compared to a DELTAE model. [Work supported by the Office of Naval Research.]

10:15

2aPAb4. Solar/heat-driven thermoacoustic engine. Reh-lin Chen and Steven L. Garrett (Grad. Prog. in Acoust. and Appl. Res. Lab., Penn State Univ., P.O. Box 30, State College, PA 16804)

With its abundance and cleanliness, solar energy has been harnessed to generate power using various techniques. A thermoacoustic engine is described which was built, instrumented, and tested to demonstrate use of solar power to generate acoustic power. Sunlight is collected using a 3-ft-diam acrylic Fresnel lens and focused on one end of a ceramic ''stack.'' This engine has a total length of 40 cm and resonates at around 420 Hz. To permit testing on the abundant cloudy days in Pennsylvania, an electrical heater was also built and installed to provide a reliable thermal energy source for indoor measurements. Experimental results are in reasonable agreement with a DELTAE model. When running in solar mode, as a $\frac{1}{4}$ wavelength open end resonator, the measured acoustic SPL can reach 120 dB easily at 1 m away from the open end on a clear day. The onset of sound generation can be achieved even with a 1-ft-diam Fresnel lens. While an impressive demonstration in terms of sound output, despite modest efficiency, real solar energy conversion will be improved with inert gas mixtures at higher pressures. [Work supported by ONR, lens provided by G. W. Swift.]

10:30

2aPAb5. Thermoacoustic refrigeration demonstration. Ray Scott Wakeland and Steven L. Garrett (Grad. Prog. in Acoust., Penn State Univ., State College, PA 16801, garrett@sabine.acs.psu.edu)

A portable device for demonstrating thermoacoustic cooling is developed using off-the-shelf components: the Morel MW-142 5-in. woofer and the Selenium HL14-25 horn. Acoustic peak pressure amplitudes of 19 kPa (19% of mean pressure) have been measured (without stack) using atmospheric air as the working fluid. Measurements of spectra, quality factors, stack temperature differences, and heat pumping capacity are compared to DeltaE models. Use of off-the-shelf components leads to design considerations not encountered in full-scale devices. For example, the high mechanical resistance of the driver, which was intended for audio reproduction, dictates against making the driver coresonant with the resonator, as is common when the driver is designed for operation at a specific frequency. [Work supported by NSF and ONR.]

10:45–11:00 Break

11:00

2aPAb6. Precision measurements of thermoacoustics in a single pore. Gabriela Petculescu and Larry A. Wilen (Dept. of Phys. and Astron., Ohio Univ., Athens, OH 45701, wilen@helios.phy.ohiou.edu)

Continuing experiments designed to look at thermoacoustic effects in a single pore will be described. A volume-modulation technique is employed to measure the complex compressibility of a gas in the pore directly. When a temperature gradient is imposed on the pore, the complex compressibility is sensitive to thermoacoustic effects which can be measured to high precision. These effects depend on both thermal and viscous properties of the gas. Measurements on different gases and mixtures of gases will be presented and compared to predictions of the theory. [Work supported by Ohio University Research and Sponsored Programs.]

11:15

2aPAb7. Time-average temperature distribution in a circular thermoacoustic pore. George Mozurkewich (Ford Motor Co., Maildrop 3028, P.O. Box 2053, Dearborn, MI 48121-2053, gmozurke@ford.com)

The time-average temperature distribution in a thermoacoustic pore, such as one pore of a thermoacoustic stack, is calculated. The analysis applies to straight pores of arbitrary shape but is limited to the acoustic and short-stack approximations. A partial differential equation for temperature is found by applying conservation of energy to the standard expression for time-average energy flux. Previous solutions for parallel-plate pores [G. Mozurkewich, J. Acoust. Soc. Am. **103**, 380–388 (1998)] are extended to pores of circular section. A heat-transfer coefficient is defined by $h_1=q(z)/\Delta T(z)$, where q is the rate of heat transfer into the pore interior per unit area of pore wall, ΔT is the temperature difference between pore wall and pore centerline, and z is the axial coordinate. This coefficient is independent of z provided z is not too close to an end of the pore. Results will be given for the shapes of the radial eigenfunctions and for the variations of eigenvalues and h_1 with pore size and Prandtl number.

11:30

2aPAb8. Linear resonant duct thermoacoustic refrigerator having two regenerator stacks. Yong Tae Kim, Sang Joon Suh (Acoust. and Vib. Group, Korea Res. Inst. of Standard Sci., P.O. Box 102, Yusong, Taejon 305-600, Korea), and Min Gon Kim (Dept. of Phys., Hankuk Univ. of Foreign Studies, Wangsan, Mohyun, Yongin, Kyungki 449-791, Korea)

The measurements of acoustically generated temperature difference between the two ends of a TAC (thermoacoustic couple) in a resonant tube are made using the similar method suggested by Atchley *et al.* [J. Acoust. Soc. Am. **88**, 251–263 (1990)] with a ceramic TAC cylinder. The linear duct was made of PVC pipe with an inner diameter of 30 mm and 680 mm long. Measurements are made for a frequency range of 150–350 Hz in atmospheric air along the TAC length from 2.5 to 10 cm with a 1-cm step. The unknown information of ceramic can be obtained from nonlinear fitting of experimental data with the equation reported by Atchley *et al.* From the result of this experiment and prediction by theory it is found that the direction of acoustic heat transport is altered at the point of a quarter of a wavelength. From the hint of the above experiment, a newly designed thermoacoustic refrigerator having two regererator stacks is tested.

11:45

2aPAb9. Theory of nonlinear acoustic waves in a thermoacoustic prime-mover. Pierrick Lotton, Vitalyi Gusev, Hélène Bailliet, and Michel Bruneau (Lab. d'Acoustique, IAM—UMR 6613, Univ. du Maine, av. O. Messiaen, 72085 Le Mans Cedex, France, lotton@laum.univ-lemans.fr)

An equation describing stabilization of oscillations in a thermoacoustic prime-mover was derived: $\partial V/\partial t - V(\partial V/\partial \tau) + (A-D)(\partial V/\partial \tau) = \sqrt{2/\pi} A \int_{-\infty}^{\tau} (\partial V/\partial \tau')[d\tau'/(\tau-\tau')] + V + D(\partial^3 V/\partial \tau^3)$. In this equation, particles velocity V, ''slow'' time t, and ''fast'' time τ are normalized; parameters A and D depend on temperature distribution inside thermoacoustic stack. The third term on the left-hand side (lhs) describes a shift in resonance frequency of a half-wavelength resonator caused by a stack installation. The third term on the right-hand side (rhs) describes sound velocity dispersion when the stack is acoustically thin. The first term (if $A>0$) and the second term on the rhs describe sound amplification due to quasiadiabatic interaction of acoustic and thermal waves. The first term on the rhs contributes also to dispersion. Particular analytical solutions were found and computer modeling was applied for the analysis. Conditions when a shock front formation caused by acoustic nonlinearity (the second term on the lhs) is the dominant mechanism for the saturation of wave amplitude were determined. [Work supported by DGA.]

TUESDAY MORNING, 23 JUNE 1998 GRAND BALLROOM II (W), 7:45 TO 10:45 A.M.

Session 2aPP

Psychological and Physiological Acoustics: From Ear Canal to Cortex—Clear Cuts and Old Growth (Poster Session)

Robert S. Schlauch, Chair
Department of Communication Disorders, Univerity of Minnesota, 115 Shevlin Hall, Minneapolis, Minnesota 55455

Contributed Papers

All posters will be on display from 7:45 a.m. to 10:45 a.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 7:45 a.m. to 9:15 a.m. and contributors of even-numbered papers will be at their posters from 9:15 a.m. to 10:45 a.m. To allow for extended viewing time, posters will remain on display until 12:00 noon on Wednesday, 24 June. A cash bar will be set up near these posters from 6:15 p.m. to 7:30 p.m. on Tuesday, 24 June.

2aPP1. Temporal versus spectral cues in AM detection. Martin E. Rickert and Neal F. Viemeister (Dept. of Psych., Univ. of Minnesota, 75 East River Rd., Minneapolis, MN 55455)

Several recent studies have shown that modulation thresholds for detecting sinusoidal AM are approximately constant out to much higher modulation frequencies for tonal carriers than for broadband noise carriers. It has been suggested that with tonal carriers there is a range of modulation frequencies for which both temporal (envelope) cues and spectral cues are used for detection. The present study attempts to assess the relative importance of these cues. Modulation thresholds for AM, quasifrequency modulation (QFM), and beats were measured for modulation frequencies of 8–512 Hz and carrier frequencies of 2 and 5 kHz. The results indicate that at intermediate modulation frequencies, AM thresholds are approximately constant while those for QFM and for beats decrease with increasing modulation frequency. This indicates that the detection of AM is not based solely on temporal cues. The implications of these findings for envelope detection and modulation filter-bank models will be discussed. [Work supported by NIDCD Grant No. DC00683.]

2aPP2. Estimates of temporal resolution at low and high spectral frequencies. David A. Eddins (Psychoacoust. Lab., Dept. of Speech and Hearing Sci., Indiana Univ., Bloomington, IN 47405, deddins@indiana.edu)

The auditory system must encode dynamic acoustic stimuli throughout the audible spectrum. This coding is limited by the temporal resolution of the ear. Unfortunately, the results of several investigations disagree on the way in which temporal resolution varies with stimulus frequency. While gap-detection thresholds measured with sinusoidal signals change little over the frequency range of 200–2000 Hz, gap and amplitude modulation detection with narrow-band noise is more variable. Eddins [J. Acoust. Soc. Am. **93**, 470–479 (1993)] showed that modulation detection is not frequency dependent from 500 to 4400 Hz, however, there are few measures of modulation detection above this frequency range. In the present experiment, thresholds for modulation depth were obtained as a function of modulation frequency. Narrow-band noise carriers had upper- cutoff frequencies ranging from 3200 to 12 800 Hz and bandwidths from 400 to 3200 Hz. Temporal modulation transfer functions (TMTF) demonstrated the typical low-pass characteristic. The form of the TMTF did not vary with noise bandwidth or frequency region from 3200 to 9600 Hz. Sensitivity to modulation increased with increasing bandwidth. For lower modulation frequencies, thresholds were slightly reduced at 12 800 Hz. These results indicate that modulation detection varies little over a very broad range of frequencies.

2aPP3. Detecting irregularity of envelope modulation. Stanley Sheft (Parmly Hearing Inst., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626)

The ability to detect periodic irregularity in the temporal envelope of a modulated stimulus was measured with a 2IFC procedure. Irregular amplitude modulation (AM) was generated with a periodic phase modulation (PM) of the sinusoidal modulator of wideband noise. The modulation index of the PM was adaptively varied in terms of delta envelope rate to determine the threshold to just detect the PM of the sinusoidal amplitude modulation (SAM). Base SAM rate ranged from 4 to 256 Hz. For each SAM rate, the PM rate ranged from 2 to half the SAM rate. The PM waveshape was either sinusoidal or had linear ramps with slope varied across conditions. At low SAM rates, PM waveshape had little effect with

thresholds across conditions rising with PM rate. At higher SAM rates, an effect of waveshape was obtained; thresholds were highest at lower PM rates with a steeply sloping linear-ramped PM. For the other PM waveshapes at the higher SAM rates, thresholds were roughly constant across change in PM rate. Results suggest two rate regions in processing AM with the regions separated at roughly the corner frequency of the temporal modulation transfer function. [Work supported by NIH and AFOSR.]

2aPP4. Effects of carrier level on the processing of highly detectable envelope fluctuations. Magdalena Wojtczak and Neal F. Viemeister (Dept. of Psych., Univ. of Minnesota, 75 East River Rd., Minneapolis, MN 55455)

A modified 2AFC matching procedure was used to measure the modulation depth that yielded similar perceived envelope fluctuations for different carrier levels. In one case, the standard was a 60-dB SPL 1-kHz tone that was amplitude-modulated at 16 Hz, with a modulation depth that produced highly detectable envelope fluctuations. The comparison had the same carrier and modulation frequencies as the standard, and its level ranged from 15 to 85 dB SPL. The data indicate that the higher the carrier level, the less modulation was needed to produce the same perceived fluctuation depth. For broadband noise carriers, however, the data indicate that approximately the same modulation depth was needed to obtain subjectively similar envelope fluctuations for all carrier levels tested. These results are similar to those observed for detection of AM, and they suggest that the level effects seen for detection extend to suprathreshold AM processing, i.e., Weber's law for broadband noise and a ''near-miss'' for sinusoidal carriers. [Work supported by NIDCD Grant No. DC00683.]

2aPP5. Variations of the leaky-integrator model and validation with detection of sinusoidal and percentage duty-cycle modulated noise. John A. Nelson (Commun. Sci. and Disord., Jesse Jones Commun. Ctr., The Univ. of Texas, Austin, TX 78712-1089, john-a-nelson@uiowa.edu) and Ruth A. Bentler (The Univ. of Iowa, Iowa City, IA 52242)

The leaky-integrator model is commonly used to describe auditory temporal processing. In the current study, the low-pass filter and decision device of the model were investigated. Maximum-to-minimum envelope magnitude, rms envelope power, envelope fourth moment, and envelope crest factor were implemented as potential decision devices [E. A. Strickland and N. F. Viemeister, J. Acoust. Soc. Am. **99**, 3638–3646 (1996)]. Model predictions demonstrated interaction between the decision device and low-pass filter cutoff frequency. To validate model variations, detection thresholds of sinusoidal and percentage duty-cycle modulated broadband noise were measured at octave frequencies 2–512 Hz for listeners with normal hearing. To ensure subjects responded exclusively to temporal cues, the modulated noise was compensated for overall average power. Further, an intensity roving technique was used between observation intervals. The data show low-pass transfer function characteristics across all modulation functions. A two-line regression fit of the data revealed that the cutoff frequency, slope, and overall gain varied as a function of the duty-cycle modulation function. The nonlinear growth of the various decision devices as a function of the low-pass filter is used to explain individual variability among subjects. [Work supported, in part, by the American Academy of Audiology Student Investigator Award.]

2aPP6. Comodulation masking release with tone pips added out of phase to the valleys of a sinusoidally amplitude modulated pure tone. Deborah A. Fantini, Roel Delahaye, and Ray Meddis (Dept. of Psych., Essex Univ., Wivenhoe Park, Colchester CO4 3SQ, England, deb@essex.ac.uk)

Two studies of comodulation masking release (CMR) investigated the influence of temporal position of brief signals added to a modulated on-frequency band (OFB) [Grose and Hall III, J. Acoust. Soc. Am. **85**, 1276–1284 (1989); Moore *et al., ibid.* **87**, 1683–1694 (1990)]. The former reports mixed results as to whether flanking bands (FBs) modulated to the same depth as the OFB elicit more CMR than 100%-modulated FBs. The latter reports that when antiphase signals are added to valleys of 50%-modulated OFBs, thresholds with correlated FBs are *poorer* than with quadrature-phase FBs. In the present paper, signals were three antiphase tone pips added to valleys of a 50%-modulated 700-Hz pure tone. Thresholds were obtained with the OFB and 6 FBs, modulated at 10 Hz. FBs were comodulated or in quadrature phase with the OFB, at either 50% or 100% depth. With 50% FBs, subjects performed *better* with comodulated than with quadrature-phase FBs. With 100% FBs, performance in the comodulated condition improved, and in the quadrature-phase condition was impaired, relative to 50% FBs. These results indicate that CMR *can* occur when antiphase signals are added to valleys of 50%-modulated OFBs.

2aPP7. Comodulation masking release: The effect of the characteristics of noise bands presented before and after a signal. Lee Mendoza (Dept. of Commun. Sci. and Disord., Louisiana State Univ., 163 M&DA, Baton Rouge, LA 70803, lmendoz@unix1.sncc.lsu.edu), Joseph W. Hall III and John H. Grose (Univ. of North Carolina, Chapel Hill, NC 27599)

CMR was measured as a function of masker duration in three conditions. In the first condition, a 400-ms pure-tone signal was presented in the temporal center of comodulated masking bands ranging in duration from 400 to 1200 ms. No effect of masker duration was observed: CMR was equivalent to that found in continuous maskers. In the second condition, continuous independent bands identical in spectra to the comodulated bands were gated off before, and on following, the comodulated bands. The presence of the independent bands reduced CMR considerably. Increasing the duration of the comodulated bands increased CMR somewhat; however, CMR was still substantially smaller than that observed without the independent bands. In the third condition, band limited noise spanning the same range as the comodulated bands was substituted for the independent bands. The bandlimited noise had little effect on CMR. In a second experiment, independent bands were gated on for various durations preceding spectrally identical 400-ms comodulated bands masking a 400-ms signal. As the duration of the independent bands increased, CMR decreased. Based on these results, it appears that CMR is not entirely the result of processing only information concurrent with the signal. [Work supported by NIH-NIDCD and Louisiana Board of Regents.]

2aPP8. Perception of roughness in harmonic multitones. Andrzej B. Dobrucki and Maurycy J. Kin (Inst. of Telecommunication and Acoust., Wroclaw Univ. of Technol., Wyb. Wyspianskiego 27, 50-370 Wroclaw, Poland)

This paper presents results and problems of perception of mixed modulation (MM) in harmonic multitone for higher modulating frequencies (70 and 200 Hz), and a 5-harmonics complex. Results indicated that perception of frequency modulation at the presence of the threshold values of amplitude modulation is different than the perception of amplitude modulation at the presence of the threshold values of frequency modulation. It means that two mechanisms of perception for these kinds of modulation exist. It turns out that for perception of this kind of modulation, the hearing system uses two sidebands produced by modulation process, but the high sideband seems to be more important than the low one. Another phenomenon is the perceptual grouping mechanism: for some of the modulated partials MM can be perceived as an additional pitch occurring in multitones, which usually is out of tune for fundamental frequency of the complex. The summation of the partials in one critical band takes place, which suggests that a specific pitch for that partial could be changed

and this is a simple way to detect these simultaneous fast changes in the amplitude and frequency of the modulated components from the musical point of view.

2aPP9. A model of auditory image flow. I. Architecture. Neil P. McAngus Todd (Dept. of Psych., Univ. of Manchester, Manchester M13 9PL, UK, todd@hera.psy.man.ac.uk)

A model is presented here based on the theory that the auditory cortex computes the spatio-temporal power spectrum of the auditory image flow [D. Heeger, ''Model for the extraction of image flow,'' J. Opt. Soc. Am. **4**, 1450–1470 (1987)]. A computational implementation of the model has the following components: (1) a gammatone filter-bank spaced on the ERB rate scale; (2) an orthogonal, ERB spaced modulation filter-bank which generates a 2-D modulation map which is then low-pass filtered; and (3) a population of causal 3-D spatio-temporal Gabor filters which compute the spatio-temporal power spectrum of the image sequence. The cortical filters are organized into families such that each member of the family occupies the same spatial-frequency band but has a different spatio-temporal orientation. The spatial frequencies range from 0.05 cycles erb^{-1} to 0.4 cycles erb^{-1}. The temporal frequencies range from ± 0.5 to ± 64 Hz. The spatio-temporal power spectrum may be visualized by replacing each image pixel with the output of all filters centered at the pixel arranged in frequency and orientation bands, somewhat like orientation columns in the visual cortex. This model may be applied to modulation perception and auditory grouping.

2aPP10. A model of auditory image flow. II. Detection of amplitude and frequency modulation. Neil P. McAngus Todd (Dept. of Psych., Univ. of Manchester, Manchester M13 9PL, UK, todd@hera.psy.man.ac.uk)

In order to evaluate the cortical model proposed in Todd [these proceedings] it was applied to the phenomenon of modulation detection. It was assumed that a discrimination task involves the correlation of the spatio-temporal power spectra of two image sequences, such as may occur in a typical 2A-2IFC procedure. The correlation was computed by $k(1-r)$, where r is the product moment correlation, for four different modulation frequencies, 4, 16, 64, and 256 Hz at four modulation depths for both AM and FM of a 1000-Hz carrier of 1000-ms duration against the image power spectrum of an unmodulated 1000-Hz 1000-ms tone. The obtained measures were then linearly regressed (with no intercept) as a function of the square of the modulation index. In all cases $k(1-r)$ gave a good fit ($R^2 > 0.95$) for both AM and FM. For each of the modulation frequencies the slope of the regression could be used to estimate the model thresholds. The model shows the correct behavior for AM and FM detection. This mechanism, it is suggested, may provide an account of modulation detection interference since low spatial-frequency filters span several ERBs.

2aPP11. Role of pinna cavities in median plane localization. Kazuhiro Iida (AVC Res. Lab., Matsushita Comm. Ind., 600 Saedo, Tsuzuki, Yokohama, 224 Japan, kiida@adl.mci.mei.co.jp), Motoki Yairi, and Masayuki Morimoto (Kobe Univ., Nada, Kobe, 657 Japan)

This paper investigates the role of pinna cavities in median plane localization. First, sound image localization tests were carried out under the conditions of progressively occluding three pinna cavities: scapha, fossa, and concha. Second, HRTFs were measured under the same conditions as those of the localization tests. Finally, the results of the localization tests and those of HRTFs measurements were compared. The results of the localization tests and the HRTFs measurements show: (1) Concha plays a great role in median plane localization regardless of the source elevation. (2) The amplitude spectrum of HRTFs shows a significant change in cases of concha occlusion. The comparisons of these results suggest that (3) the spectral cue in median plane localization is mainly formed by concha. (4) However, the degree of localization error which was caused by the occlusion of the pinna cavities depends on the subjects.

2aPP12. The influence of different speech segments on spatial localization. Brian L. Karlsen (Ctr. for Personkommunikation, Aalborg Univ., Frederik Bajersvej 7, DK-9220 Aalborg, Denmark, blyk@get2net.dk)

Numerous researchers have investigated to what degree humans are able to localize different sounds in the horizontal plane. Much of this work has focused on human response to simple sounds, like pure tones, white noise, and click trains, the underlying assumption being that responses to more complex stimuli could be inferred from a combination of responses to the simple stimuli. It was decided to investigate this for speech segments. Specifically, it was hypothesized that subjects would display a difference in localization ability for CVs containing some consonant manner groups rather than others. A number of Danish CVs were used as target stimuli in a horizontal localization task. The CVs were simultaneously masked by a diffuse white noise field. All subjects were normally hearing. The subjects were asked to determine from which clock position they heard a speaker, and to respond as fast as possible by pressing the corresponding button on a clock face. Final results are expected to confirm the hypothesis in full and indicate that there is indeed a difference in localization ability between the different consonant manner groups.

2aPP13. Underwater sound localization: Role of interaural time and intensity differences. Pierre Bovet (Lab. de Psych. Cognit., Univ. de Genéve, 9 route Drize, 1227, Carouge, Switzerland), Carolyn Drake (CNRS URA 316, Univ. Rene Descartes, 75006, Paris, France), François Bernaschina (Univ. de Genéve, Carouge, Switzerland), and Sohpie Savel (CNRS URA 316, Paris, France)

In theory, underwater sound localization is very limited compared with that in air. Most cues are greatly reduced underwater: Interaural time differences are divided by four (due to faster sound propogation in water) and intensity differences are greatly reduced because signal conduction to the inner ear mainly occurs through skull bone condition, making the head transparent. However, preliminary studies indicate some localization abilities in scuba divers. An azimuth identification task was conducted in Lake Leman. At a depth of 10 m, 14 divers indicated which of eight transducers located every 45 was generating a sound (400 Hz, 6 kHz, or white noise). Results indicate: (a) correct estimates were highest for lateral positions (left and right) and poor for median positions (front and back), (b) performance was high for 400 Hz and white noise but low for 6-kHz signals, and (c) head movements did not appear to facilitate localization. Thus the best localization abilities were observed in positions with highest interaural time differences, suggesting that, contrary to theoretical predictions, temporal binaural cues must be at least partially functional. However, the fact that localization was poor for high-frequency signals suggests that interaural intensity differences do not play a significant role.

2aPP14. A new model for binaural signal detection. Jeroen Breebaart, Steven van de Par, and Armin Kohlrausch (IPO-Ctr. for Res. on User–System Interaction, P.O. Box 513, NL-5600 MB Eindhoven, The Netherlands)

Most present-day binaural models make use of coincidence detectors following an internal delay, so-called crosscorrelation models. We present a new modeling approach based on a subtractive mechanism as found in excitatory–inhibitory type neurons in the auditory pathway. This approach transforms, for each auditory filter, time-domain waveforms into a time-varying two-dimensional activity pattern, where each unit within that pattern has a characteristic interaural time delay and intensity difference. Limits of resolution are modeled by adding the same amount of internal noise to each unit. From this activity pattern, several features of the stimu-

lus can be extracted, such as the apparent lateralization and the presence of a test signal within a masker. For modeling binaural detection it is assumed that a test signal must induce a significant change within the internal representation in order to be detectable. Depending on the condition, detection is limited by internal noise ($NoS\pi$) or by external fluctuations ($N\rho S\pi$, $\rho \leqslant 0.95$). This model can be used as an artificial observer in the same way as described by Dau *et al.* [J. Acoust. Soc. Am. **99**, 3615–3622 (1996)] for monaural signals.

2aPP15. Further evidence for the influence of peripheral compression on binaural detection. Steven van de Par and Armin Kohlrausch (IPO-Ctr. for Res. on User–System Interaction, P.O. Box 513, NL-5600 MB Eindhoven, The Netherlands)

Binaural detection at high frequencies depends on the envelope statistics of the masker. Van de Par and Kohlrausch [J. Acoust. Soc. Am. **101**, 3104 (1997)] proposed that this results from the compressive response of the basilar membrane which can be shown to reduce interaural intensity differences (IIDs) strongest in stimuli with flat masker envelopes. To further test the effect of compression, the same experiment was repeated at 500 Hz. Results show that binaural detection at low frequencies is much less dependent on masker envelope statistics as compared to high frequencies. This was expected because at low frequencies, besides IIDs, interaural time delays can be used for signal detection, which are not affected by compression. In addition, psychometric functions for the discrimination between 4-kHz NoSo and $NoS\pi$ stimuli were measured as a function of the S/N ratio for stimuli of 20 and 65 dB SPL using a 250-Hz-wide masker. The psychometric functions were rather symmetric around a 0 dB S/N ratio at low SPLs, but asymmetric at 65 dB SPL favoring discrimination at a negative S/N ratio. Such an asymmetry at high stimulus levels is predicted, if the detection cue is a change in the interaural correlation of the compressed envelopes.

2aPP16. A model of auditory localization in noise using neural networks. Scott K. Isabelle (Dept. of Psych., Wright State Univ., Dayton, OH 45435), James A. Janko (Ball Aerosp. and Technologies Corp., Fairborn, OH 45324), and Robert H. Gilkey (AL/CFBA, Wright-Patterson AFB, Dayton, OH 45433-7901)

Janko *et al.* [*Binaural and Spatial Hearing in Real and Virtual Environments*, edited by Gilkey and Anderson (Erlbaum, Hillsdale, NJ, 1996), pp. 557–570] used neural networks to describe auditory localization and found that data in quiet were insufficient to discriminate among models. To further constrain the models, localization in the presence of a spatially fixed masker is considered here. The wideband targets and maskers were filtered by head-related transfer functions, then by a gammatone filter bank. A model for binaural interaction similar to that of Lindemann [J. Acoust. Soc. Am. **80**, 1608–1622 (1986)] was used to process the filterbank outputs. The inhibited cross-correlation output of the binaural processor was sampled and used as input to a neural network (e.g., 24 correlation lags at each of 13 frequency channels for 312 input nodes). The network was trained using back propagation to estimate the target location in quiet, then tested on targets in noise at several values of signal-to-noise ratio (SNR). The network was also trained across several values of SNR. Results are compared to localization in noise by humans [Good and Gilkey, J. Acoust. Soc. Am. **99**, 1108–1117 (1996)]. [Work supported by AFOSR F49620-95-1-0106 and the Ohio Board of Regents.]

2aPP17. On the difference between absolute and relative auditory distance perception. Hae-Young Kim, Yôiti Suzuki, Shouichi Takane, Kenji Ozawa, and Toshio Sone (Res. Inst. Elec. Comm., Tohoku Univ., Sendai-shi, 980-8577 Japan)

Absolute distance perception in the absence of information about intensity and reflections from boundaries is quite difficult [B. G. Haustein, Hochfrequenztech. u. Elektroakustik **78**, 46–57 (1969)] but is possible to achieve if a sound source exists within the distance of around 1 to 2 m from a listener. In the presence of multiple sound sources, however, some cues can be derived by comparing information from different sources. From this point of view, it is important to study relative distance perception between sounds from multiple sources to investigate general distance perception in auditory system. Thus using the same experimental setup, two kinds of listening experiments about the absolute and relative distance perception were conducted. In the experiment for relative distance perception, a subject was asked to report the perceived distances of two sound sources presented successively with an interval of 2 s by using a rating scale with seven categories. The results of absolute distance perception showed that the perceived distance of a sound image significantly increases with the increase of actual distance of the sound source up to around 1.2 m. On the other hand, the results of the relative auditory distance perception showed that the perceived distance significantly increases up to 2 to 3 m.

2aPP18. Auditory motion aftereffects with a two-component adapter. Hisashi Uematsu and Makio Kashino (NTT Basic Res. Labs., 3-1, Morinosato-Wakamiya, Atsugi, Kanagawa, 243-01 Japan)

Auditory motion aftereffects have been used to investigate mechanisms used to detect changes in interaural time differences (ITDs). In this paper, auditory motion aftereffects with two-tone adapters were used to examine how the ITD-change information from each frequency band is integrated. In the experiment, a complex tone with 250- and 500-Hz components was used as an adapter. The magnitude of the auditory motion aftereffect for a physically stationary 500-Hz test tone was measured using various combinations of direction and adapter component. Apparent sound movement was produced by varying only ITDs. The results showed no difference in the magnitude of the aftereffect between the 500-Hz tone adapter and the complex adapter when the two components moved toward the same direction. On the other hand, the aftereffects disappeared when the two components of the adapter moved in opposite directions. This suggests that the integration of ITD-change information from each frequency band is not a simple linear summation. Mechanisms of across-frequency integration will be discussed.

2aPP19. Echolocation by moving and stationary listeners. Michael S. Gordon, Lawrence D. Rosenblum, and Luis Jarquin (Dept. of Psych., Univ. of California, Riverside, Riverside, CA 92521, rosenblu@citrus.ucr.edu)

It has long been known that human listeners can echolocate a sound reflecting surface as they walk towards it [e.g., Supa *et al.*, Am. J. Psychol. **57**, 133–183 (1944)]. There is also evidence that stationary listeners can determine the location, shape, and material of nearby surfaces from reflected sound [Rice, Science **155**, 656–664 (1967)]. The current research tested whether there is an advantage of listener movement for echolocating as has been found for localization of emitted sounds [Ashmead *et al.*, J. Exp. Psychol.: Hum. Percept. Perform. **21**, 239–256 (1995)]. Two groups of blindfolded subjects were asked to echolocate a 3×6 ft wall while either moving or stationary. After echolocating, the wall was removed, and subjects were asked to walk to where the wall had been. Subjects in the moving and stationary groups echolocated for the same amount of time and for each of four distances. Results showed that moving group subjects were more accurate than stationary group subjects for some distances. These results might be a function of useful time-to-arrival acoustic information available to moving listeners.

2aPP20. Reflectance measurements of the contralateral acoustic reflex input–output function. M. Patrick Feeney (Ohio Univ., School of Hearing and Speech Sci., Lindley Hall 218, Athens, OH 45701) and Douglas H. Keefe (Boys Town Natl. Res. Hospital, Omaha, NE 68131)

Available data suggest that the acoustic reflex reduces the transmission of sound through the middle ear in humans at frequencies below 1000 Hz. Wideband (0.2 to 10 kHz) reflectance, complex admittance, and absorbed power were used to measure the input–output function of the contralateral acoustic reflex in four adults. Broadband noise was used as a reflex activator. Measurements were taken at reflex threshold and in 5-dB increments above up to 112 dB SPL in one subject. The power transmission loss grew approximately 2.5 dB for every 5-dB increase in the activator above reflex threshold. Admittance measurements generally mirrored these changes below 1000 Hz with decreases in equivalent volume, conductance, and complex admittance. There was an increase in admittance with the acoustic reflex at frequencies from 1000 to 4000 Hz in agreement with Rabinowitz [Ph.D. thesis, MIT, 1977]. An unexpected decrease in energy reflectance was observed for one subject in a notch centered at 5600 Hz, near the zero crossing for equivalent volume, which suggests that the activation of the acoustic reflex increased the power delivered to the middle ear at that frequency. [Work supported by Ohio University Research Committee Grant No. 97-14, Ohio University CHHS SA Award, and NIH Grant No. DC00520.]

2aPP21. Vibration measurement of the tympanic membrane using the time-averaged speckle pattern interferometry. Hiroshi Wada, Masataka Takeuchi, Koji Hozawa (Tohoku Univ., Sendai, Japan), Takashi Gemma (Nikon Corp., Tokyo, Japan), and Makoto Nara (Nikon Technologies, Inc., Tokyo, Japan)

In this study, using the time-averaged electronic speckle pattern interferometry, the sinusoidal phase modulation technique by a direct modulation of laser injection current, and the digital image processing technique, an attempt was made to develop a system for measuring a small vibration in nanometer order. The vibratory responses of the guinea pig's tympanic membrane were measured. At the frequency of 1500 Hz, the whole part of the tympanic membrane vibrated almost in phase. The maximum amplitude was about 30 nm. At the frequency of 2500 Hz, the tympanic membrane had two local maxima in the posterior and inferior portions. At the frequency of 3000 Hz, the four peaks around the manubrium were seen. The number of the peaks increased with an increase in frequency and the vibration mode became more complicated. The results of this study indicate that the vibration amplitude is detectable in nanometer order by this system even when the stimulus level is small, e.g., 60 dB SPL. Consequently, the system developed by our group has a potential for clinical applications. [Work supported by the Ministry of Education of Japan.]

2aPP22. Filter shapes for brief signals as a function of preceding stimulation. Elizabeth A. Strickland (Dept. of Audiol. and Speech Sci., Purdue Univ., West Lafayette, IN 47907)

The threshold for a brief probe tone in a broadband noise was measured as a function of probe frequency (1 or 4 kHz) and masker level (0–40 dB spectrum level). The probe was always presented 2 ms after the onset of the masker, and the masker was preceded either by silence, or by a precursor with the same spectrum and level as the masker. For each subject there were some conditions in which probe threshold was higher with no precursor than with a precursor (overshoot), and some conditions in which probe threshold did not differ with the presence of a precursor. Filter shapes for the same brief probes were then measured using the notched noise method. The probe was always presented with a 2-ms delay from the onset of the notched-noise masker. The masker was preceded by silence or by a precursor. The probe level was set 10 dB above the threshold measured for a given condition in the overshoot experiment. A comparison will be made of filter shape and the presence or absence of overshoot. [Work supported by NINCDS.]

2aPP23. Variable-duration notched-noise experiments in a broadband-noise context. Jim J. Hant, Brian P. Strope, and Abeer A. Alwan (Speech Processing and Auditory Percept. Lab., Dept. of Elec. Eng., UCLA, 66-147E Eng. IV, 405 Hilgard Ave., Los Angeles, CA 90095)

To model the confusion of short-duration speech signals in noisy environments, it is important to characterize how humans resolve the spectral components of short-duration signals in background noise. Toward that end, a variable-duration notched-noise experiment was conducted in a noise context. Broadband noise preceded and followed a tone and notched noise of similar duration. Thresholds were measured at four durations (10, 30, 100, and 300 ms), two center frequencies (0.6, 2.0 kHz), and five relative notch-widths (0.0, 0.1, 0.2, 0.4, 0.8). At 0.6 kHz, 10-ms thresholds decrease 6 dB across notch-widths while 300-ms thresholds decrease over 35 dB. These durational trends are similar but less pronounced at 2 kHz. In a second experiment, the short-duration notched noise was replaced with a flat noise, which provided an equivalent amount of simultaneous masking to that of the first experiment, and thresholds dropped by as much as 20 dB. A simple filtering model with either a linear or nonlinear combination of simultaneous and nonsimultaneous masking is unable to predict these results. Instead, it appears that the elevated thresholds at short durations are dependent on the spectral shape of the simultaneous masker, implying reduced frequency selectivity. [Work supported by NIH-NIDCD and The Whitaker Foundation.]

2aPP24. Comparison of psychophysical and single-unit thresholds in response to electrical stimulation of the cochlea in guinea pig. Bryan E. Pfingst, Lisa M. Montney, and Sanford C. Bledsoe (Univ. of Michigan, Kresge Hearing Res. Inst., 1301 East Ann St., Ann Arbor, MI 48109-0506, bpfingst@umich.edu)

Recent studies have shown that the spatial pattern of currents used on individual channels of cochlear implants can have a large effect on speech recognition and other measures of electrical-stimulus perception. This study is one of a series that seeks to understand the neural patterns of response underlying these effects. Guinea pigs were deafened in one ear by local perfusion of an antibiotic and implanted with an electrode array in the scala tympani. Psychophysical strength-duration functions (detection threshold versus electrical pulse duration) were obtained in guinea pigs trained using positive reinforcement, operant conditioning techniques. Single-unit data were obtained from inferior colliculus in the same animals, or in guinea pigs deafened and implanted in a similar manner. In these preparations, thresholds for neural responses were near the psychophysical thresholds at all phase durations, and the thresholds for the most sensitive neurons were several dB below the psychophysical detection thresholds. Thus, the paradoxical discrepancies between neural responsiveness and behavioral stimulus detection observed in previous comparisons made across animal models do not occur in this preparation. This seems to be a useful preparation for determining the spatiotemporal patterns of neural activity that underlie electrical-stimulus perception. [Work supported by NIH-NIDCD Grant No. DC00274.]

2aPP25. Physiological correlates of the ''mean-term'' auditory adaptation. N. G. Bibikov (N. N. Andreyev Acoust. Inst., Moscow 117036, Russia)

In psychophysics, adaptation is defined usually as a decline of loudness of steady stimulus as a function of time. It occurs over periods ranging from seconds to minutes. Recent psychophysical data show that during a ''mean-term'' adaptation period (the first 30 seconds of the sound) the detection of amplitude changes considerably improves. Physiological correlates of ''mean-term'' adaptation in single units located in different regions (cochlear nucleus, superior olive, *torus semicircularis*) of the auditory system of the immobilized frog *Rana temporaria* are explored. Driven responses to long-duration pure tones and AM tones decreased over time periods ranging from milliseconds to minutes. The adaptation

increased at the upper levels of the auditory system. The response to pure tone stimuli declined more rapidly than the response to AM tones. For AM stimuli the adaptation increased as the modulation depth decreased. The considerable enhancement of the phase locking to the sound envelope could be observed during the first 10–15 s of the AM tones with low modulation indexes. The effect of phase-locking enhancement during the mean-term adaptation matched some psychoacoustical findings. [Work supported by the RFBR.]

2aPP26. Mechanisms underlying recovery from forward masking in electrical stimulation. Monita Chatterjee (Dept. of Auditory Implants and Percept. Res., House Ear Inst., 2100 W. Third St., Los Angeles, CA 90057)

In normal hearing, adaptation is hypothesized to be closely related to recovery from masking. In electrical stimulation, adaptation at the inner hair cell synapse is absent. However, refractory mechanisms can result in an adaptationlike decrement at high stimulation rates. Shannon [J. Acoust. Soc. Am. **88**, 741–744 (1990)] found that normalized psychophysical forward masking functions were similiar in normal and electric stimulation, and suggested that the mechanisms underlying forward masking are primarily retro-cochlear. Recovery from forward masking was studied in five Nucleus-22 cochlear implant users. Results were found to be strongly subject-dependent. In general, a rapid decay in the first 15 ms after masker offset, and a slow decay persisting up to 200 ms after masker offset, were observed. Under some conditions, plateaus and nonmonotonicities were observed in the region of transition between the two processes. Recovery was independent of masker level. Masker duration, pulse rate, and masker-probe spatial separation strongly influenced the relative weight of the rapid component. The amount of masking near masker offset did not determine the time course of recovery. It is hypothesized that the rapid mechanism is due to auditory nerve refractoriness, while the slow mechanism is likely to be more central in origin. [Work supported by NIDCD.]

2aPP27. Neurophysiological and psychophysical measures of duration discrimination in normal-hearing adults and adults with cochlear implants. Patricia G. Trautwein, Curtis W. Ponton, Betty Kwong, and Michael D. Waring (House Ear Inst., 2100 West Third St., Los Angeles, CA 90057)

The ability to discriminate duration contrasts (a first approximation of voice onset time differences) was evaluated in adult cochlear implant users and normal-hearing adults using a neurophysiological response (the mismatch negativity—MMN). The MMN is an evoked response generated by a deviant stimulus when embedded in a series of standard homogeneous stimuli. Magnitude of the MMN correlates with psychophysical discrimination thresholds indicating that the MMN provides a measure of perceived acoustic change [Kraus *et al.* (1996)]. The MMN thus provides a neurophysiological correlate of acoustic discrimination. The present study compared an objective statistical measure of MMN magnitude to psychophysical measures in response to duration differences of brief auditory stimuli. A ten-click train was paired with shorter trains to create an oddball sequence. The selected duration differences were similar to voice onset time differences that distinguish voiced from voiceless speech phonemes. The MMN magnitude was measured at four scalp-electrode locations. The relationship between neurophysiological and psychophysical thresholds was determined and comparisons were made between the normal-hearing adults and adults with cochlear implants. While some similarities were found, the results suggest that the sensitivity to duration differences differs between normal-hearing and cochlear implant subjects.

2aPP28. Spectro-temporal influence on auditory cortical evoked potential thresholds. Ann Clock Eddins (Auditory Physiol. Lab., Dept. of Speech & Hearing Sci., Indiana Univ., Bloomington, IN 47405, aeddins@indiana.edu)

Previous studies from our laboratory have shown that auditory cortical evoked potential thresholds (N1-P2) decrease with increasing stimulus duration. Similar to behavioral studies of auditory temporal integration, N1-P2 threshold improvement was greater for 1000-Hz than 4000-Hz stimuli. It is unclear whether spectral splatter at short durations contributed to the threshold differences across frequency. The present study investigated spectro-temporal influence on N1-P2 thresholds by manipulating the stimulus rise–fall time, total duration, and stimulus type. Thresholds were estimated in three temporal conditions to compare stimuli with equal rise–fall (2 ms) but different total durations (8, 36 ms), and stimuli with different rise–fall (2, 16 ms) but equal total durations (36 ms). Broadband noise bursts and 1000-Hz tones were used to test each temporal condition. Preliminary results show that thresholds for both noise and tonal stimuli decrease with increasing total duration. No significant differences in threshold were observed as a function of rise–fall time nor were significant differences observed as a function of the stimulus type. The results suggest that N1-P2 thresholds are determined primarily by changes in total duration and that thresholds for short durations at 1000 Hz are not adversely affected by spectral splatter. [Work supported by NSF.]

2aPP29. Psychometric functions for gap detection. Mary Florentine (Commun. Res. Lab., Dept. of Speech-Lang. Pathol. and Audiol. (133FR), Northeastern Univ., Boston, MA 02115), Søren Buus, and Wei Geng (Northeastern Univ., Boston, MA 02115)

To determine the form of psychometric functions for gap detection, three normal listeners were tested at octave frequencies from 0.25 to 8 kHz using a constant-stimulus procedure with a cued yes–no paradigm. The gaps were carried by bandpass noises with an overall level of 85 dB SPL and a bandwidth equal to three auditory-filter bandwidths. To avoid audibility of spectral splatter, the bandpass noise was presented in a complementary notched-noise masker with a spectrum level 10 dB below that of the signal and a bandwidth equal to nine auditory-filter bandwidths. Gap durations were chosen randomly from one of six fixed values (seven at 0.25 kHz) ranging from 0.5 Minimal Detectable Gap durations (MDG) to 2 MDGs (2.8 MDGs at 0.25 kHz). An inaudible gap of 0.5 ms was included as a control condition. Although the false-alarm rate varied among the listeners, the slopes of the psychometric functions were quite similar. The slopes increased as the test frequency increased up to 2 kHz, but remained constant at the higher frequencies. These results indicate that stimulus variability is not important in determining gap-detection thresholds at 2 kHz and above.

2aPP30. Suppression and the upward spread of masking. Andrew J. Oxenham (Northeastern Univ., 360 Huntington Ave., Boston, MA 02115, oxenham@ipo.tue.nl) and Christopher J. Plack (Sussex Univ., Brighton BN1 9QG, UK)

For signals well above a masker in frequency, signal level at threshold grows more rapidly than masker level, leading to the upward spread of masking (USM). It is unclear whether USM is due to a relative increase in masker excitation or an increase in suppression with increasing masker level. Thresholds were measured using a 4-kHz signal, gated with a 10-ms Hanning window. The masker was a 500-Hz-wide random Gaussian noise, centered at either 4 kHz (on frequency) or 2.4 kHz (off frequency) and gated with 2-ms ramps. Masker levels ranged from 50–90 dB SPL. In simultaneous-masking conditions, the signal was temporally centered in a 400-ms masker. In nonsimultaneous conditions, where no suppression should occur, the signal was in a brief gap between two 200-ms maskers. Results are qualitatively consistent with an explanation based on the characteristics of the basilar-membrane input-output function. At higher signal levels, the differential compression of masker and signal produces USM

even in nonsimultaneous conditions (no suppression). At low signal levels (below about 40 dB SPL) the basilar-membrane response to single tones is nearly linear and nonlinear USM is only observed in simultaneous-masking conditions. [Work supported by the Wellcome Trust and the Royal Society.]

2aPP31. Intensity discrimination of ramped and damped tones. Robert S. Schlauch, Dennis T. Ries, Jeffrey J. DiGiovanni, Sara Elliot (Univ. of Minnesota, Minneapolis, MN 55455), and Shari L. Campbell (Univ. of Georgia, Athens, GA 30602)

Intensity discrimination of 1.0-kHz tones that had exponentially ramped or damped envelopes was measured as a function of duration and level. Standard levels ranged from near threshold to 90 dB SPL and durations ranged from 10 to 200 ms. Just-noticeable differences for some subjects were smaller for damped tones than for ramped tones for the same duration and level. For these conditions, damped tones showed more temporal integration than ramped tones. This result is somewhat surprising given that the subjective duration of ramped tones increased by a factor of 100 for stimuli ranging from 10 to 200 ms, whereas the subjective duration of damped tones increased by a much smaller factor of 28 over the same range of durations. Possible physiological and cognitive explanations for these differences will be discussed. [Work supported by NIH-NIDCD R29 DC01542.]

2aPP32. Preferential detection of rising versus falling intensity. John G. Neuhoff and Jennifer Wess (Dept. of Psych., Lafayette College, Easton, PA 18042)

An increase in intensity caused by the approach of a sound source can signal an ecological threat or opportunity, and therefore a potentially important event. A receding source produces a pattern of decreasing intensity change and a potentially less important event. Therefore preferential responding by an organism to rising intensity stimuli may provide a selective advantage. To investigate the hypothesis that listeners respond preferentially to rising intensity stimuli, listeners were presented with white-noise samples that either rose or fell dynamically 20 dB (SPL) in intensity. Stimulus duration ranged from 0.5 s to 1.5 s, and onset of intensity change ranged from 0 s to 1 s. In a speeded 2AFC task listeners had to determine whether intensity rose or fell. Results show that listeners detected increases in intensity more quickly and more accurately than equivalent decreases. The findings are consistent with the interpretation that the auditory system processes some acoustic events according to a set of ecologically defined priorities.

2aPP33. Detection of differences in rate of frequency change in gliding tones. John Madden (Dept. of Commun. Sci. and Disord., Univ. of North Dakota, Grand Forks, ND 58202)

The purpose of the study was to measure discrimination for glides in frequency, based on discrimination of rate of frequency change. Changes in frequency transition span and duration were eliminated as confounding cues by using signals of equal frequency span and duration that smoothly changed in rate at the half-way point in their duration. That is, each signal consisted of a first segment at one rate of frequency change, a brief rate transition segment, and a second segment at another rate of frequency change. The listeners compared a standard signal during which there was no change in rate (a linear glide) with a target signal during which the second segment changed at a greater rate than the first. The task was to indicate which signal changed in rate. Discrimination thresholds were obtained for signals with a range of center frequencies, frequency spans, and durations. Both up- and down-glides were used. Preliminary results indicate that discrimination thresholds are relatively constant for center frequencies from 0.5 kHz to 2 kHz, but increase by a factor of 2.5 at 6 kHz. [Work supported by Research Grant Number 1 R15 dc 02662-01 from the National Institute on Deafness and Other Communication Disorders, National Institutes of Health.]

2aPP34. Contribution to the study of the audiometrical scores sources of 20 variation. Marielle Bruyninckx, Saefda Hamache, and Bernard Harmegnies (Dept. of Speech Commun., Univ. of Mons, 18 place du Parc B7000, Mons, Belgium, marielle.bruyninckx@umh.ac.be)

This paper summarizes the development and the presentation of a discrimination test of the relative height of two pure sounds. Sixty pairs of sounds have been presented to 68 subjects. The elaboration of these pairs was based on a selection of ten initial stimuli that were paired according to three different intervals: octave, 1/3 octave, and 11/24 octave. These stimuli were then presented by pairs to the subjects in a random way, according to an ascending or a descending sequential structure. The aim of this work is to test: whether the paired sounds' presentation order (ascending or descending) has, or has not, an effect on the subjects' results; whether the kind of frequential interval is a determining factor in the subjects' discriminatory abilities; whether the musical education plays a role on performances (in comparing musicians' and nonmusicians' performances). Together with measurement of reliability, the results show that: it is easier to discriminate sounds in an ascending structure, whatever the frequential intervals may be; there is no significant difference between 1/3 octave, octave, or 11/24 octave intervals; the musicians present better discriminatory abilities than the nonmusicians concerning the ascending structure pairs, but worse abilities when the structure of the pairs is descending.

2aPP35. Hawkins and Stevens revisited at low frequencies. Adrianus J. M. Houtsma (IPO, Eindhoven Univ. of Technol., P.O. Box 513, 5600 MB Eindhoven, The Netherlands, houtsma@ipo.tue.nl)

The classical data on masking of pure tones by white noise [J. E. Hawkins, Jr. and S. S. Stevens, J. Acoust. Soc. Am. **22**, 6–13 (1950)] yield a nonmonotonic critical ratio function that increases at low and at high frequencies. Modern bandwidth estimates of auditory filters, however, yield equivalent rectangular bandwidth (ERB) functions that are monotonic with frequency. This apparent discrepancy has sometimes been interpreted as evidence for frequency-dependent detection efficiency in the auditory system. Another possible reason for the discrepancy, however, could be the fact that the classical data were measured with headphones that needed substantial correction at low frequencies to compensate for acoustic leakage. To test this, the Hawkins and Stevens experiment was repeated with Etymotic ER-2 insert phones over a frequency range from 30 to 8000 Hz. An adaptive forced choice, as well as a Bekesy tracking procedure, was used. The resulting critical ratio function shows monotonic dependence on frequency, down to 90 Hz, similar to the ERB function. This appears to make critical ratio data, in principle, consistent with ERB data measured with notched-noise techniques, and largely eliminates the need for a frequency-dependent detection efficiency in the auditory system.

2aPP36. The perception of three tone patterns by Indian and American listeners. Nandini Iyer, Evelyn M. Hoglund, and Mari Reiss Jones (Ohio State Univ., Dept. of Speech and Hearing Sci., 51 Pressey Hall, 1070 Carmack Rd., Columbus, OH 43210)

Serial identification of three tone patterns by Indian and American listeners was investigated in three experiments. Six pitch patterns combined a high-frequency (H) and a low-frequency tone (L) (e.g., H, H, L or L, L, H). The first experiment presented all patterns at each of three different tempi (fast, medium, and slow trial blocks) with blocks presented in either ascending or descending order of tempi. Each pattern occurred six times (randomly) within a block. The second experiment investigated

the differences in pattern perception between musicians and nonmusicians among the previously tested Indian and American listeners. In the third experiment, frequency separation between the high and low tones was investigated at two different tempi. A repeating cycle of three tone patterns was presented for identification and streaming thresholds were determined for Indian and American listeners. Preliminary results indicate that the two groups of listeners differ in their ability to identify three tone patterns. These differences were affected by the listeners' musical background. Frequency separation and tempo also differentially affected pattern perception among the two groups of listeners.

2aPP37. Tempo perception: The multiple-look strategy is limited by a short temporal window. Nathalie Panissal-Vieu and Carolyn Drake (Lab. de Psych. Exp., CNRS URA 316, Univ. Rene Descartes, 28 rue Serpente, 75006, Paris, France)

Previous studies [Drake and Botte (1993)] indicated that sensitivity to tempo changes in isochronous sequences improves as the number of intervals in the sequence increases. Further studies suggested that this multiple-look process only works within a limited temporal window of 0.5 or 2 s depending on the tempo of the sequence [Panissal-Vieu *et al.* (1995)]. This temporal window represents the time required to extract all the necessary temporal information (mean interval duration and dispersion). Two experiments investigated how this mental representation is used to make temporal judgements. In a 2 AFC paradigm, trained listeners identified the slower of two isochronous sequences. The number of intervals was varied in either the first or second sequence, with the temporal window saturated in the other sequence. The number of intervals required to saturate the temporal window of the first sequence varied with tempo, as predicted. However, only three intervals were required in the second sequence. These results suggest a buildup of a stable and accurate memory trace during the first sequence which is subsequently compared with the first two intervals of the second sequence. There is no need to recalculate the memory trace for the second sequence.

2aPP38. Investigations and analysis of assessment word for sound quality attaching importance to high-order sensation. Tomoharu Ishikawa, Shingo Fuyuki, and Makoto Miyahara (School of Information Sci., Japan Adv. Inst. of Sci. and Technol., 1-1 Asahidai, Tatsunokuchi-machi, Nomi-gun, Ishikawa-Ken, 923-12 Japan)

The standpoint of our research is to evaluate subjectively the sound quality of sound-reproducing systems by evaluating deep emotions which are brought by the sounds of music and speech. In evaluating sound qualities, assessment words that express the emotive meanings which have arisen in an evaluator's mind are used. The importance of sound reproduction is the transmission of ''mind'' that a musician wants to send. Therefore the assessment words which can represent the high-order sensations of the sender need to be obtained. Not only conventional assessment words but also assessment words which represent high-order sensation have been investigated and then analyzed. The method is as follows, (1) 35 representative assessment words by the KJ method from 1322 assessment words which were obtained by surveying audio publications over the past three years were obtained. (2) Psychological distances among 35 representative assessment words have been analyzed by the MDS method, and four clusters by hierarchical clustering have been obtained. (3) Independent to (2) above, representative assessment words by the public attention evaluation method have been scored and ranked. (4) The important assessment words which are strongly correlated with the overall sound quality have been selected.

2aPP39. Factor analysis of the perception of the evaluation of environmental sounds using adjectives describing sound quality, emotional state, and information carried by sounds. Toshio Sone, Kôji Abe, Kenji Ozawa, and Yôiti Suzuki (Res. Inst. of Elec. Comm., Tohoku Univ., Sendai-shi, 980-0812 Japan)

In order to investigate into the perception of environmental sounds, a psychoacoustic experiment was carried out. The experiment was performed with the SD (semantic differential) method using 66 environmental sounds for 39 pairs of the descriptive adjectives in Japanese. These pairs of descriptive adjectives are roughly divided into three groups. One of them was adjectives describing sound quality that had been used in similar studies reported so far. The other groups were adjectives describing emotional states of evaluators due to the sounds and information carried by sounds in addition to them. The new adjectives were selected for explaining a more general state of perception of the environmental sounds. As the result of a factor analysis, five factors were obtained. Three of them were factors describing ''aesthetic state,'' ''volume,'' and ''brightness'' of sounds. These factors correspond to the three well-known factors describing sound quality. Other than these, two new factors were derived: a factor concerning information on environment and a factor concerning the significance of sound. Moreover, it was shown that emotional states produced by environmental sounds correlate with the factor concerning the aesthetic state.

2aPP40. Sound quality estimation using hearing sensation. Soon-Hyob Kim (Kwang Woon Univ., Wolgaedong, Nowongu, Seoul, Korea, inphase@chollian.dacom.co.kr)

This paper is on a study of objective sound quality estimation by using human hearing sensation. Until now, the sound quality estimation has been done by subjective methods by people. Unfortunately, it depends on environment and condition of the human ear. So it was difficult to tell exactly how sound quality was. This study was performed to make objective estimation of sounds, regardless of the factors. In this paper, six parameters were defined, which are related to the sound quality: loudness, sharpness, fluctuation strength, roughness, pleasantness, and annoyance, and signal processing methods for them were developed. In this way, a simulator was implemented that measures human hearing sensation. To prove objectiveness of the simulator, the simulator results were compared with subjective test results which were given by people. As a result, the average error rates were 8.1% in loudness, 12% in sharpness, 20% in fluctuation strength, 18.5% in roughness, 5.5% in pleasantness, and 19% in annoyance. The overall average error rate was 13.7%, which showed that the simulator is very useful.

2aPP41. Analysis of annoyance of low-frequency beat inside a vehicle. Klaus Genuit (HEAD acoustics GmbH, Ebertstrasse 30a, 52134 Herzogenrath, Germany)

Because station wagons have a greater volume than sedan vehicles, low-frequency acoustic effects (''humming'') very often occur in the frequency range between 30 and 50 Hz. This is not only unpleasant, but can lead to physiological changes in the driver due to specific properties of the acoustic signals. The mechanisms may be very varied: Excitation frequencies can be produced by the powertrain, exhaust system, or wheel suspension and are transmitted via the mounting points. Resonances in the regarded frequency range may well be present along these transmission paths. The spectral components thus arriving at the structure are radiated into the car interior via various ''loudspeakers,'' such as floor panels, roofs, or doors. Moreover, for particular frequencies some loudspeakers may show special resonances or the volume of the vehicle interior results in amplification. During field trials, excitation mechanisms and transmission paths were investigated using the combination of Artificial Head and multichannel measurement technology that allows subjective evaluation of various models. Playback of the Artificial Head signals, however, is not only via headphones, but via a special ''sound car'' which also creates low-frequency excitation of airborne and structure-borne noise. This en-

ables a connection to be made between the frequencies at the driver's ear giving cause for complaint and the various excitation points. Moreover, the use of a two-dimensional laser vibrometer enables a connection to be made between vibrating structures and the annoying sound components a driver is hearing.

2aPP42. Spectrum contrast and noise annoyance. Anna Preis (I.I.S. Univ. of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo, 106 Japan)

According to the computational view, the identification of a sound event by the auditory system consists of processing the information it extracts from the temporal pattern and frequency spectrum. The fine structure of the frequency spectrum facilitates, among other things, the determination of the relative amplitudes of the partials. The auditory system uses the values of these amplitudes to compute the total loudness of the sound event by summing the specific loudness of each partial across a set of critical bands. This correlates well with experimental data of perceived loudness. The present study investigates whether the auditory system makes use of other information contained in this spectrum. The tested hypothesis stated that the auditory system detects change in the relative amplitude of the partials. It was assumed that these changes can be traced in experimental data of perceived annoyance of noise. The experimental results show that the best correlation between the reported annoyance and calculated values was obtained for the average absolute value of the second derivative of the weighted specific loudness calculated as a function of the critical-band rate scale. This specific loudness was weighted by the function introduced in sharpness calculation [W. Aures, Acustica **59**, 130–141 (1985)].

2aPP43. Detection and discrimination of amplitude-modulated signals in noise. King Chung (Northwestern Univ., 2299 N. Campus Dr., Evanston, IL 60208/House Ear Inst.), Fan-Gang Zeng (House Ear Inst., Los Angeles, CA), and Beverly A. Wright (Northwestern Univ., Evanston, IL)

Comodulation masking release demonstrated improved detection of pure-tone signals in amplitude-comodulated noise bands [Hall *et al.*, J. Acoust. Soc. Am. **76**(1), 50–56 (1984)]. However, in most real-world situations, signals such as speech sounds are comodulated and noises such as cocktail party and traffic noises are not. Two experiments were designed to examine whether comodulation of signals can lead to improved signal detection in noise. Experiment I used a 2AFC method to measure detection threshold of a 2/3-oct-spaced, five-tone complex in pink noise. The complex tones were either amplitude comodulated or randomly modulated. Results from three normal-hearing listeners showed no difference in detection threshold between amplitude-comodulated and randomly modulated conditions. Experiment II used a method of constant stimuli to measure the psychometric function of discriminating six vowel-like stimuli in pink noise. These vowels consisted of three formant-frequency sinusoids which were unmodulated or amplitude-comodulated or randomly modulated by a 125-Hz sinusoid simulating the voice pitch. While no difference was observed between comodulated and randomly modulated conditions, the psychometric function for the nomodulation control condition was shifted by 4–6 dB toward lower signal-to-noise ratios. A possible explanation is that auditory fibers phase-lock to formant-frequencies of the unmodulated stimuli and to the fundamental frequency of the modulated stimuli.

Chair's Introduction—9:15

Invited Papers

9:20

2aSA1. Product design and structural acoustics. Richard H. Lyon (RH Lyon Corp, 691 Concord Ave., Cambridge, MA 02138)

If, by structural acoustics the analysis and understanding of noise and related problems through an understanding of mechanical vibration is meant, then structural acoustics has a very long history in product design through the application of isolators and structural damping to products. But the greatest amount of research and methods development has been focused on fairly large commercial and military structures like submarines, aircraft, and spacecraft. The resources for, attention to, and methods for structural acoustics that has been available in these and the automotive industries has not been present for the industries that make most of the products each of us deals with daily. Structural acoustics as applied to hairdryers, vacuum cleaners, and lawnmowers presents challenges in both understanding and cost that the technical community can respond to. For example, designers would like to predict sound from CAD drawings. Such a need can be an inspiration to some of us. This presentation will provide examples of the need and some possible responses.

2aSA2. Wind noise challenge in the automobile industry. Jen-Yuan Her (Ford Motor Co., Dearborn, MI 48121) and William B. Coney (BBN Technologies, Cambridge, MA 02138)

Aerodynamically generated noise during vehicle operations is of increased importance for automobiles as operating speeds increase and design improvements reduce noise contributions from the powertrain and road tire interaction. Wind noise reaches the interior through a variety of mechanisms, including the aeroacoustic penetration and aerodynamic excitation of vibration, and its radiation of sound from vehicle greenhouse (roof, windshield, side glasses, and backbite) and underbody. Although vehicle wind noise

performance keeps improving, the fundamentals of wind noise generation and transmission paths still remain uncertain. Instead of relying on measurements on hardware, the recent development of the practical CAE approach, which is different from direct CFD plus FEA simulation, may shed light on solving the puzzle from the statistical energy analysis (SEA) point of view. This paper raises issues to be solved in vehicle-shape-related wind noise root-cause understanding and prevention using SEA. Wind noise mechanisms such as vehicle body wall pressure fluctuations (pseudonoise) generation, its scaling law, and interaction with body structure are examined in detail. Challenging issues such as the identification of low wave number contribution versus convective ridges of pseudonoise to structure excitation and how sound is radiated to driver's and passengers' ears are discussed.

10:10

2aSA3. Brake-noise challenge in the automobile industry. Shih-Emn Chen and Jen-Yuan Her (Ford Motor Co., Dearborn, MI 48121)

Brake noises generated during vehicle operation are caused by nonlinear structural behavior that is difficult to model analytically. Noises, predominantly contact related, falling in this group can be classified into two categories based on the frequencies at which they occur: (1) brake squeal in kHz ranges; (2) brake moan and groan in 100–300 Hz range. These noises may often be accompanied by structural instability caused by some, if not all, of the following phenomena: (1) lining deformation; (2) negative slope in friction-velocity characteristic; and (3) stick-slip. In addition to the aforementioned phenomena, coupled resonance of brake components is also a necessary condition of the brake-noise generation. Currently, vehicle brake-noise design prevention is still based on a trial and error basis. No reliable design prevention tool is yet established. Although computer simulations were sometimes used to predict the structural instabilities, no clear understanding of the link between structural instabilities and radiated noise has been established. The major challenge to automobile noise control engineers will be to establish a noise radiation model which could identify the influence of the key design parameters on the noise level.

2aSA4. Integration of small transducers in commercial products. Jarmo Hietanen (Nokia Res. Ctr., P.O. Box 100, FIN-33721 Tampere, Finland, jarmo.hietanen@research.nokia.com)

Miniaturization of electronic devices requires smaller components as well as a higher level of integration. Whenever audio acoustics is involved, as in mobile phones, it is exactly the acoustics components that offer the largest challenge in this respect. There are physical limitations to how small those components can be made, and with present methods of integration, even the smallest acceptable size is still too large. Progress in material research is expected to offer new possibilities for solving problems in further integration of components, e.g., microphones. In the development of silicon microphones, new materials and processes are utilized already. Decreasing the size of components and systems makes the problem of vibration coupling through structures more severe. Furthermore, in smaller components there are a number of physical effects to be accounted for, not only in practice but also in numerical simulation models of these systems. An example of this is the effect of viscosity when predicting acoustic performance of the system. Normally viscosity is neglected, but in very narrow ducts, for example, viscosity causes significant effects. Very small components and systems cannot be expected to operate physically, as do their larger predecessors.

2aSA5. Complex resonances of elliptic cylinders. Stéphane Ancey, Antoine Folacci, and Paul Gabrielli (URA 2053 CNRS, SDEM, Université de Corse, Faculté des Sci., BP 52, 20250 Corte, France)

Complex resonances of elliptic cylinders of arbitrary eccentricities (including the limit cases of the circular cylinder and the strip) are exactly determined by solving the Helmholtz equation with the Sommerfeld's radiation condition at infinity and various boundary conditions on the scatterer. Resonances are then fully classified along the two irreducible representations A_1 and A_2 of the symmetry group C_2 of the scatterer. This spectrum of resonances is also asymptotically recovered (i) by using the ordinary geometrical theory of diffraction, and (ii) by applying the method of the Gutzwiller–Voros spectral determinant. This last technique could be developed in acoustic multiple scattering. Indeed, in this context, because of the complexity of the system of rays and its chaotic behavior, ordinary geometrical theory of diffraction fails to provide accurate results.

11:15

2aSA6. Acoustic scattering by a three-cylinder scatterer: Theoretical and experimental study of resonances. Paul Gabrielli, Yves Decanini, Antoine Folacci, and Elisabeth Fournier (URA 2053 CNRS, SDEM, Université de Corse, Faculté des Sci., BP 52, 20250 Corte, France)

Acoustic scattering by a system of three identical parallel cylinders, located at the vertices of an equilateral triangle, is theoretically, numerically, and experimentally studied by emphasizing the role of the symmetries of the scatterer. Incident and scattered fields are expanded over the different irreducible representations of C_{3v}, the symmetry group of the scatterer. From the boundary conditions, an infinite set of four linear complex algebraic equations is obtained, where the unknown coefficients of the scattered fields are uncoupled. As a consequence, the form function is calculated for various incidence and observation angles, and the positions of the scatterer resonances are numerically determined in the complex plane of the reduced frequency. New types of resonances appear. A physical interpretation of these resonances by the phase-matching of geometrical and surface waves along closed paths is given by using the geometrical theory of diffraction. These resonances are experimentally observed for elastic cylinders immersed in water. The work is a step toward a complete study of chaos (associated with the system of rays) in the context of multiple scattering.

11:30

2aSA7. Bandpass filters for the evaluation of short reverberation times. Malte Kob (Inst. of Tech. Acoust., RWTH Aachen, Templergraben 55, D-52056 Aachen, Germany, kob@akustik.rwth-aachen.de)

In building acoustics, evaluating the sound insulation of building elements suffers from rather bad reproducibility. The reason is the energy flow between the building element and the surrounding structure of the test laboratory. To get more reproducible measurements, it is desirable to measure the loss factor of the element, e.g., by evaluation of the reverberation time of the structure. Unfortunately, the evaluation of decreasing reverberation times T_{60} of building elements, for instance in one third octave bands is distorted by a growing influence of the applied bandpass filter. In literature a minimum permissible product of the bandwidth and the reverberation time of the filter $B \cdot T = 16$ can be found but no error in the estimation of T_{60} beyond this limit is given. A maximum admittable error depending on the $B \cdot T$ product is derived for several filters used in

real time analyzers. An optimized filter according to the IEC 1260 standard is developed and results of simulated and measured short reverberation time evaluations are presented. Other possibilities of the investigation of the loss factors and their practical use are discussed.

2aSA8. Piezoelectric thin shell theoretical model and eigenfunction analysis of radially polarized ceramic cylinders. D. D. Ebenezer and Pushpa Abraham (Transducer Group, Naval Physical and Oceanograph. Lab., Naval Base, Kochi 682 004, India, root@drnpol.ren.nic.in)

A piezoelectric thin shell theoretical model of radially polarized ceramic cylinders is first developed. An eigenfunction approach is then used to determine the displacement, stress, electric field, and input electrical admittance of the cylinder. In the model, the effect of bending strain is included and it is assumed that the electric field varies linearly between the electrodes. The electrostatic condition is then used to express the electric field in terms of the displacement. Next, the equations of motion and the boundary conditions are derived by using Hamilton's variational principle. They have the same form as the corresponding equations for a thin elastic shell and are solved after expressing the frequency-dependent displacement as the sum of the static displacement and a weighted sum of the eigenfunctions of the short-circuited cylinder. The eigenfunctions are determined here by using a general method and, therefore, cylinders with arbitrary boundary conditions can be analyzed. It is shown that experimental resonance frequencies and input electrical admittance of free-free cylinders are in good agreement with those computed here and that the electric field is in good agreement with results obtained by other investigators who used a numerical method to solve the equations.

2aSC1. Limit cycle dynamics in prosody. Fred Cummins (Dept. of Linguist., Northwestern Univ., Evanston, IL 60208)

Compared to music, juggling, dancing, etc., speech may seem to be only weakly rhythmic. New experimental evidence suggests, however, that rhythmic constraints on the timing of certain speech events can be quite strong. This is particularly clear when subjects repeat a phrase in time with a periodic stimulus. Mode locking, mode switching, and hysteresis have all been documented, thus showing hallmarks of the hierarchical entrainment among two periodic cycles. These cycles are coextensive with independently motivated prosodic units, the foot (or prosodic word), and the intonational phrase. It appears that this repetition task induces a second-order limit cycle dynamic in each of these units. [Work supported by the Indiana University Graduate School and the Andrew W. Mellon Foundation.]

8:25

2aSC2. Temporal correlates of foot-level timing in English and Japanese. Keiichi Tajima and Robert F. Port (Indiana Univ., 322 Memorial Hall, Bloomington, IN 47401)

Languages of the world are felt to be spoken with different kinds of rhythm. But what is the basis for this impression? Notions like ''stress-timed'' and ''syllable-timed'' have been difficult to verify experimentally because rhythm in spoken language rarely yields consistent temporal regularities. Experiments were conducted in which native English and Japanese speakers repeated phrases using a specified rhythm in time with an auditory metronome. Results demonstrate that temporal correlates exist for prosodic units approximately the size of the ''foot,'' consisting of one relatively strong syllable followed by zero or more weak syllables. Strong (foot-initial) syllables show greater temporal stability than do weak (foot-internal) syllables when the timing of syllables was perturbed by manipulating inherent segmental durations. This is found for both English and Japanese. However, in English, increasing the foot size by the addition of weak syllables is accompanied by compensatory shortening only within the foot, while in Japanese, compensation occurs both within and between adjacent feet, suggesting a weaker role for this unit. By eliciting speech in a rhythmic context, such as ''speech cycling,'' both language-general and language-specific properties of speech rhythm can be directly measured.

8:45

2aSC3. Attention, rhythmicity, and expectancy. Mari Reiss Jones (Dept. of Psych., 142 Townshend Hall, Ohio State Univ., Columbus, OH 43210)

It seems plausible that body gestures created by ourselves and other living things may derive from some underlying periodic processes. Motor rhythms are ostensibly measurable. The case for *attending having a rhythmic aspect* is more challenging, in part because attention is not directly observable. So the question is asked: ''How does an approach that posits internal (nonobservable) oscillators actually explain attention?'' Three steps are considered. The first considers that attending primarily involves selectivity. Visual attention theories often relate selectivity to space; attention is focused at one place not another. Significantly, few theories of auditory attention exist. But surely in speech and music, attention can operate selectively in time; it can be targeted to one temporal location, not another. The second step requires that nonlinear oscillators describe selective attending in time. That these models deliver is evident in several recent oscillator models, including an elegant one developed by Ed Large. Step three involves connecting oscillator activities to measurable behaviors that reflect attending. Listeners are primed with auditory patterns, only some of which display rhythms predicted to facilitate temporal expectancies accounted for by oscillator entrainment. The talk centers on these experiments, their outcomes, and implications for a theory of dynamic attending.

9:05–9:20 Break

9:20

2aSC4. Context effects in time discrimination. J. Devin McAuley (Dept. of Psych., 142 Townshend Hall, Ohio State Univ., Columbus, OH 43210)

Music and speech processing exemplify skilled perception of temporal patterns, as both require an ability to make fine-grained comparisons of relative duration. Clock theories of time perception have been used to model the discrimination of isolated durations successfully, by assuming that temporal resolution is determined by the statistical variability of an independent central timing process. However, the explanatory power of the clock model has been shown to be limited when applied to more naturalistic tasks such as the detection of a temporal deviation embedded within a temporal pattern. This paper discusses an entrainment theory of time discrimination that is based on the concept of coupled oscillators. The theory accounts for a number of contextual effects in time discrimination which have been problematic for clock models. The theory also applies equally well to the discrimination of isolated durations. An important link is demonstrated between fast and slow tempos, short and long durations, and early and late onset of a comparison sequence which only becomes clear when one assumes that the relevant psychological variable in time discrimination is relative phase.

9:40

2aSC5. Categorization of temporal intervals. Edward W. Large (Dept. of Psych., Univ. of Pennsylvania, Philadelphia, PA 19104)

The rhythms of music and speech comprise sequences of temporal intervals separating the onsets of component events (e.g., notes and syllables). The perception of rhythmic patterning in such sequences involves the identification of distinct interval categories. Notating a musical rhythm, for example, relies upon the perception of nominal relationships between time intervals (e.g., 2:1, 3:1). Such categorization appears robust to perturbations that alter the absolute duration of temporal intervals. Thus it makes sense to ask whether the perception of categorical temporal relationships is ''categorical perception.'' The answer depends not only on the ability to make category judgments, but also on the differential discriminability of temporal intervals. Entrainment models propose that perceived onset time depends upon onset phase relative to an internal oscillation [Large and Kolen, Conn. Sci. **6**, 177–280 (1995); McAuley, Proc. Cog. Sci. Soc., 615–620 (1996)]. Such models predict discrimination performance, however, they do not address categorization. This paper presents an extension of entrainment models that addresses categorization: In addition to relative phase dynamics, it explicitly considers the amplitude dynamics of internal oscillations. It captures existing data on interval categorization and makes new predictions regarding categorization and discrimination performance. Tests of the predictions are discussed.

10:00

2aSC6. Models for entrainment of neural rhythms. Bill Baird (Dept. of Mathematics, Univ. of California, Berkeley, CA 94720)

Psychological results suggest that motor and perceptual behavior are organized by neural rhythms with periods from seconds to tenths of a second. It appears that their entrainment to external speech and music or to internal motor coordination rhythm is essential for effective performance. It is proposed that theta-alpha sensory-motor cycles (5–15 Hz) form the basis of these rhythms. They generate and entrain rhythmic motor output or temporal perceptual expectancies. It is hypothesized that cortical EEG and event-related potentials (ERPs) reflect thalamic biasing currents. The cortical evoked potential is a 5–15 Hz signal whose peaks and troughs correlate with stages of cortical information processing in sensory-motor tasks. Cortical rhythms are found in visual, auditory, and somatosensory areas as well as the hippocampus and reticular system that entrain to periodic inputs. If the arrival of an auditory stimulus is regular, it has been shown that 5–12 Hz auditory activity becomes phase locked *in advance of the target stimulus* to the expected arrival time. Our model of rhythmic expectation accounts for this since the theta-alpha rhythmic cycles constitute a fast clock that adjusts phase and frequency to match stimulus arrival, and longer period cycles are derived from this base clock.

9:20

2aSP1. Implementation of real-time acoustic communications systems. David Herold, Robert Nation, Geoffrey Edelson, and Eric Will (Sanders, A Lockheed Martin Co., Adv. Systems Directorate, P.O. Box 868, Nashua, NH 03061-0868)

Over the past several years, the field of underwater acoustic (UWA) communications has been focusing on bandwidth efficient phase coherent modulation techniques. In this application, practical communication algorithms, and thus their implementations, are still maturing. In addition to the computer-intensive algorithms used to track and decode these acoustic data, the systems may incorporate compression, coding, and error-detection schemes to provide usable communication links. Several programs are currently underway to utilize these developments in fieldable systems. In this paper, an overview of the signal processing requirements for UWA communications is provided, as well as some constraints placed on these systems by specific applications. The effect of these requirements on overall system design and implementation is outlined.

9:50

2aSP2. An adaptive processing structure for integrated active-passive sonars deploying cylindrical arrays. Amar C. Dhanantwari (Dept. of Elec. and Comput. Eng., Univ. of Western Ontario, London, ON N6A 5B9, Canada) and Stergios Stergiopoulos (Defence and Civil Inst. of Environ. Medicine, North York, ON M3M 3B9, Canada)

The paper details the development and implementation of an adaptive processing structure for integrated active–passive sonars deploying cylindrical arrays. The main concept includes decomposition of the computationally intensive multidimensional beamformer into two simple modules, which are line and circular array beamformers. Thus, the multidimensional beamforming process can now be divided into coherent subprocesses which lead to efficient implementation in real-time sonar systems. Furthermore, the application of spatial shading to reduce the side-lobe structures can now be easily incorporated. Moreover, the new approach makes the implementation of adaptive schemes in multidimensional sensor arrays practically achievable. The proposed adaptive processing concept has been implemented in an integrated active–passive real-time sonar deploying a cylindrical array. Real data results from the adaptive and conventional beamforming outputs of the cylindrical array sonar system demonstrate the superior performance of the adaptive beamformer in suppressing the reverberation and cluttering effects in active sonar applications. Moreover, for passive sonar applications, the adaptive processing provides substantially improved angular resolution performance as compared with that of the conventional beamformer. Both these two performance improvements for a cylindrical array sonar are of particular importance for mine hunting operations.

10:35

2aSP3. Sound ranging of impulsive sources in air. Brian G. Ferguson (Defence Sci. and Technol. Organisation, P.O. Box 44, Pyrmont 2009, Australia)

A passive sound ranging method based on wavefront curvature is described where the impulsive sound of a rifle firing is received at three spatially separated collinear sensors. Estimating the differential time-of-arrival (or relative time delay) of the acoustic wavefront at each pair of adjacent sensors enables the range and bearing of the source to be estimated. The temporal variability in the polar coordinates of the source is presented for real data and the system errors affecting the accuracy of the measurements are discussed. The time delay estimation technique is then applied to the passive ranging of an impulsive sound source located in the far field, where the wavefront curvature technique is no longer appropriate as the arriving wavefront is planar. For the plane-wave arrival case, the range of the sound source is estimated from the angle-of-arrival estimates at two widely spaced known locations. The source position estimated by the acoustic method is compared with the source position determined by standard surveying methods. The nonstationary behavior of the sound propagation medium leads to variability in the source localization parameters which is presented for the acoustic data collected during artillery firings.

11:05

2aSP4. Active target detection in the ocean: Optimizing performance and cost. Zoi-Heleni Michalopoulou (Ctr. for Appl. Math. and Statistics, New Jersey Inst. of Technol., Newark, NJ 07102)

The goal of this work is to design a processor for underwater target detection with superior performance to the commonly used matched filter without the efficiency penalties of the optimal filter. The theoretically optimal filter for active detection in the ocean is a correlator between the received signal and the convolution of the transmitted signal and the impulse response of the ocean. This filter is seldom employed because of the considerable computational overhead. The practically preferred method is a standard matched filter that correlates the transmitted signal to the received signal. It is computationally efficient but analytically suboptimal because it ignores the effects of the propagation medium on the transmitted signal. The standard filter is also preferable because of its attractive property of portability across environments, this feature stemming from deliberate disregard of the physics of the propagation medium. Here, the potential for improving detection performance is explored through modified matched filters that retain the portability property but do not resort to the exhaustive multiparameter grid searches of the optimal filter. [Work supported by ONR Ocean Acoustics, through Grant No. N000149710600.]

11:35

2aSP5. Implementation of a broadband, environment-sensitive detector in real-time systems. Georgios Haralabus (SACLANT Undersea Res. Ctr., Viale San Bartolomeo 400, 19138 La Spezia, Italy)

Active systems, such as Low-Frequency Active Sonars (LFAS), have extensively used the matched filter method for detection purposes. This model-free technique is designed to maximize the signal-to-noise ratio of known signals irrespective of the nature of the waveguide. However, shallow water and dense multipath conditions often distort and obscure the matched filter output to a point at which reliable detection is not possible. The objective of this project is to investigate the implementation of a Channel Sensitive Processor (CSP) in real time systems. The performance improvement of the conventional matched-filter processor by exploiting characteristics of the medium is demonstrated both in an ambient noise and a reverberation-limited environment. It is clearly shown that environmental mismatch poses the primary problem in applying the CSP in real-time systems. Environmental uncertainty can be overcome by utilizing global search methods in conjunction with the CSP detector. In implementing such a scheme, the balance between potential advantages and concomitant disadvantage of inefficiently long real-time processing is examined.

Underwater Acoustics: Propagation, Ambient Noise, and Imaging (Précis Poster Session)

Evan K. Westwood, Chair
Applied Research Laboratories, University of Texas, EVG, P.O. Box 8029, Austin, Texas 78713-8029

Chair's Introduction—9:15

Contributed Papers

In this session, an oral summary of each paper will be presented followed by a poster session. All posters will be on display, and all contributors will be at their posters, from 11:10 a.m. to 12:10 p.m.

9:20

2aUW1. Comparisons of simultaneous signal reception over long range among hydrophones with unlike acoustic geometries. H. M. Walkinshaw (Box 72, Peapack, NJ 07977)

Propagation measurements were made to six hydrophones installed offshore Bermuda at depths from 430 to 2450 fm. Four were bottomed onslope or at basin depth; two were suspended, one at the sound channel axis and one 30 m above the deep bottom. Both impulse sources (charges detonated at 18 and 240 m) and a continuous wave (cw) transducer towed at 120 m were used. The 800-nm track began 40-nm south of Bermuda at midpoint of the ensemble of hydrophones and ended off St. Thomas beyond the Puerto Rican Trench. The bottom receiver at 430 fm had the lowest transmission loss; the deep basin hydrophone the highest. Arrival order identification from shot processing for all hydrophones showed performance depended on the degree to which the local bottom slope enabled a receiver to intercept both up and downcoming ray paths. Suspension *per se* was not significant. Energy partition among arrival orders indicated one arrival carried about 50% of received signal strength. About five arrivals were needed before 90% of the total signal was collected, suggesting broad ocean coverage is unavoidably linked to coping effectively with multipath propagation. [Work supported by NavElecs.]

9:25

2aUW2. The form of the normal mode that ensures escape with certainty from a surface channel. Edward R. Floyd (10 Jamaica Village Rd., Coronado, CA 92118-3208)

Surface channels trap those rays that are reflected internally before reaching a deep sound channel according to classical geometric ray tracing. In the wave representation, some leakage of trapped normal modes does occur. Recent advances in wave propagation [E. R. Floyd, Anal. Fond. L. Broglie **20**, 263–279 (1995)] have shown that a wave function having subbarrier energy but with a particular compound modulation in amplitude and wave number does tunnel through a barrier with certainty and without reflection. Herein, a normal mode with a particular compound

modulation is shown to escape from a surface channel with certainty and without reflection. These normal modes with compound modulations, which may be unfamiliar to many workers, are solutions to the wave equation. The investigation considers a bottomless sound velocity profile, $C(z)$, whose reciprocal square, $C^{-2}(z)$, forms a surface channel over the deep sound channel by two piecewise-continuous linear segments. The findings are generalized to include various surface and deep sound channels. While the quantum tunneling problem was originally solved in a trajectory representation [analogous to rigorous ray tracing, cf. E. R. Floyd, J. Acoust. Soc. Am. **80**, 877–887 (1986)], herein a wave representation is used.

9:30

2aUW3. Spatial coherence of sound in convergence zones and shallow zones in the South China Sea. Dinghua Guan, Renhe Zhang, Zhenge Sun, and Yan Wang (Natl. Lab. of Acoust., Inst. of Acoust., Chinese Acad. of Sci., Beijing 100080, PROC, zrh@public.east.cn.net)

Some results of a horizontal spatial coherence experiment of sound propagation in the South China Sea were presented. Average water depth is over 4000 m and the depth of axis of the underwater sound channel is 1200 m. Explosive sources were discharged at depths of 7, 100, 200, and 1000 m. Signals were received at a horizontal receiving array of seven hydrophones with an overall length 410 m at a depth of 200 m. Distances between hydrophones are 10, 20, 40, 80, 160, and 1000 m. It is found that at the direct arrival zone and the convergence zones the sound field has good horizontal coherence. At the direct arrival zone the radius of coherence is larger than 200 m. At the first convergence zone the radius of coherence is larger than 250 m. At the second, third, and fourth convergence zones for frequencies lower than 1000 Hz the radii of coherence are larger than 250 m. When the sound source is placed at the shadow zones, the radius of horizontal coherence is less than 100 m, much lower than at the convergence zones. This experiment shows that a horizontal array can be used for beam forming with high spatial gain and good directivities at convergence zones.

9:35

2aUW4. Pulse propagation in random media. Dalcio K. Dacol (Naval Res. Lab., Washington, DC 20375-5320)

Wave propagation in randomly fluctuating media is a problem of continuing interest in ocean acoustics. Usually the work done in this field is carried out in the frequency domain since there are powerful techniques to study wave scattering in the frequency domain, while time-domain formulations are notoriously more difficult to use and obtain results. Nevertheless, our intuition about wave phenomena is much better when discussing such phenomena in a space-time formulation than in a space-frequency formulation. In this presentation wave propagation in a weakly and randomly fluctuating medium is discussed entirely within the space-time formulation. McDonald and Kuperman derived from the wave equation an approximate time-domain progressive wave equation which is the equivalent in the space-time formulation of the well-known parabolic wave equation in the space-frequency formulation. A path integral representation for the solution of this equation is used here to study wave propagation in random media. The weakly inhomogeneity assumption yields an approximate evaluation of the path integral for the Green's function thus allowing an analysis of the time-dependent statistics of acoustic fields propagating through random media. [Work supported by ONR.]

9:40

2aUW5. Time series analysis of propagation in range-dependent shallow-water environment. Finn B. Jensen, Francesco Bini-Verona, Peter L. Nielsen (SACLANTCEN, Viale S. Bartolomeo 400, 19138 La Spezia, Italy, jensen@saclantc.nato.int), and Peter Gerstoft (UCSD, La Jolla, CA 92093-0704)

One track of the Formiche_97 shallow-water experiment in the Mediterranean involved broadband propagation over a sloping bottom with water depths varying between 120 m at the 16-element receive array and 600 m at the end of the 35-km track. The 0.82-kg SUS charges were detonated at two depths, 18 and 90 m, and at range intervals of around 1.2 km. Signals were recorded over a bandwidth of 50–5000 Hz on hydrophones covering the full water column. Detailed environmental measurements were also performed. Using state-of-the-art numerical modeling tools it was demonstrated the degree of accuracy with which broadband signals can be modeled in complex ocean environments, after having first fine-tuned the sediment parameters via a broadband acoustic inversion. The forward model used is a modified version of the ORCA code [Westwood *et al.*, J. Acoust. Soc. Am. **100**, 3631–3645 (1996)], which uses adiabatic mode theory combined with frequency-interpolation techniques to efficiently compute the broadband frequency response of the propagation channel. The broadband inversion was done using the SAGA code [Gerstoft, SACLANTCEN Rep. SM-333 (1997)], which does parameter optimization via a directed Monte Carlo search based on genetic algorithms. [Work was supported by the EC under the MAST-III project PROSIM, Contract No. MAS3-CT95-0008.]

9:45

2aUW6. A two-way parabolic equation for a fluid/elastic waveguide. Joseph F. Lingevitch and Michael D. Collins (Naval Res. Lab., Washington, DC 20375, jfl@abyss.nrl.navy.mil)

The parabolic equation (PE) method is applied to acoustic propagation in a fluid above an elastic layer. Two-way PEs have previously been developed for purely fluid or elastic waveguides [M. D. Collins, J. Acoust. Soc. Am. **93**, 1815–1825 (1993)]. These methods divide a range-dependent environment into a sequence of range-independent regions and apply the single scattering method to obtain the transmitted and reflected fields at each interface. Recently, these ideas have been extended to mixed media such as fluid/poro-acoustic waveguides. Improved Padé approximations for the interface conditions are useful in stabilizing the iteration formula for the transmitted and reflected fields [F. A. Milinazzo *et al.*, J. Acoust. Soc. Am. **101**, 760–766 (1997)]. In this paper, a fluid/elastic waveguide is examined and examples of the coupling between the fluid compressional wave and elastic waves at vertical interfaces are presented. [Work supported by ONR.]

9:50

2aUW7. Spatial coherence in range-dependent shallow water environments. Ilya Rozenfeld (Rensselaer Polytechnic Inst., Troy, NY 12180), William M. Carey (MIT, Cambridge, MA 02139), James F. Lynch (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), Peter Cable (BBN Systems and Technologies, New London, CT 06320), and William L. Siegmann (Rensselaer Polytechnic Inst., Troy, NY 12180)

In this presentation, effects of small random fluctuations on the spatial coherence of the sound field in shallow water with multilayered sediments will be examined. These fluctuations occur within the water volume and the sediment layers as well as at the layer interfaces. Most previous work has dealt with either range-independent or weakly range-dependent environments with random variabilities. However, strong range dependence often occurs in sound-speed profiles and at layer interfaces. For example, the region of the ACT III experimental series in the Straits of Korea shows range variability arising from sloping bathymetry and a coastal front. Consequently, spatial coherence for range-dependent waveguides with small random fluctuations will be treated. Numerical simulations of the coherence function will be presented. Results will be compared with coherence lengths of the field extracted from ACT III data.

9:55

2aUW8. Thin-sediment shear-induced effects on low-frequency broadband acoustic propagation in a shallow continental sea. Dag Tollefsen (Norwegian Defence Res. Establishment, Div. for Underwater Defence, P.O. Box 115, N-3191 Horten, Norway, dt@ffi.no)

Low-frequency acoustic broadband propagation loss data collected in areas of a shallow continental sea where the seabed is composed of hard substrates covered by thin deposits of sediment is presented. Data are

shown to exhibit several characteristics consistent with loss due to coupling to interface waves at the sediment–substrate interface; in instances of a physically thin sediment cover, loss is attributed to guided elastic waves in the sediment [S. J. Hughes *et al.*, J. Acoust. Soc. Am. **88**, 283–297 (1990)]. The interpretations are supported by numerical modeling of propagation loss using a recently developed wave number intergation code for horizontally layered fluid–solid media, and geoacoustic models consistent with geophysical data from the sites of acoustic experiments.

10:00

2aUW9. Elimination of branch cuts from the normal mode solution using gradient half-spaces. Evan K. Westwood and Robert A. Koch (Appl. Res. Labs., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029)

A method for eliminating the branch cuts and branch line integrals from the normal mode solution to the range-invariant acoustoelastic wave equation has been developed and implemented. In the usual normal mode formulation, evaluation of the vertical wave number in the ocean waveguide's lower half-space involves a square-root operation and gives rise to a branch point at the critical angle. When the Pekeris cut is chosen, energy steeper than the critical angle is represented by leaky modes, and lateral-wave energy near the critical angle is represented by the branch line integral. When a mode lies near the branch cut, the branch line integral can be significant at all ranges. Branch line integrals are cumbersome to compute, and, for range-dependent problems, cannot be included in adiabatic and coupled-mode algorithms. By inserting a (small) positive attenuation gradient in the lower half-space, the plane wave solution is replaced by a complex-valued Airy function solution, the branch point is eliminated, the Pekeris branch cut is replaced by a series of modes, and the leaky modes become bounded at infinite depth. Implementation and applications of this approach using the normal mode model ORCA are given. [Work supported by ONR 321OA.]

10:05

2aUW10. Improving a practical broadband adiabatic normal mode model by including untrapped modes. Robert A. Koch, Evan K. Westwood, Julienne E. LeMond, and David P. Knobles (Appl. Res. Labs., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029)

An adiabatic normal mode model that neglects untrapped mode contributions will give inaccurate transmission loss predictions for environments with bottom slopes when modes transition between being trapped and untrapped. For example, initially untrapped, but strongly excited, modes that subsequently become trapped away from the source may contribute significantly to water column fields. Results of Tindle and Zhang [Oceans '93 Proceedings, I-81] show that including untrapped modes in an adiabatic description significantly improves transmission loss predictions for the ASA benchmark wedge problem. A practical implementation of an adiabatic broadband propagation model for both trapped and untrapped modes will be described. Difficulties associated with the transition region between trapped and untrapped modes near the critical angle will be discussed, and the results of inserting a gradient in the lower half-space to solve the problem will be presented. [Work supported by ONR.]

10:10

2aUW11. Parabolic equation models for poroelastic transversely isotropic sediments. Andrew J. Fredricks, William L. Siegmann (Dept. of Math Sci., Rensselaer Polytechnic Inst., Troy, NY 12180), and Michael D. Collins (Naval Res. Lab., Washington, DC 20375)

Anisotropy in ocean sediments can have a significant effect on transmission loss. A parabolic equation (PE) model for problems involving transversely isotropic elastic sediments was recently developed [A. J. Fredricks *et al.*, J. Acoust. Soc. Am. **101**, 3182(A) (1997)]. Biot's theory of poroelasticity, which is appropriate for some sediments, is a generalization of elasticity that includes effects due to fluid-filled pores. Propagation models have been developed for poroelastic media, but only for the isotropic case. A poroelastic PE model is extended to handle transversely isotropic sediments. A description of the model will be presented along with examples to illustrate the effects of anisotropy. [Work supported by ONR.]

10:15

2aUW12. Inclusion of continuum effects in coupled-mode theory using leaky modes. David P. Knobles, Robert A. Koch, Evan K. Westwood, and Steven A. Stotts (Appl. Res. Labs., Univ. of Texas, Austin, TX 78713-8029)

A difficulty with coupled-mode algorithms for acoustic propagation in sloping, shallow-water regions is properly including the modal continuum. The disadvantage of the standard false-bottom approach is that a large number of modes are needed to represent the continuum, which makes the coupled-mode solution less practical. A leaky mode decomposition requires significantly fewer modes to represent the continuum. However, because the leaky modes are not bounded in the lower half-space, the overlap integrals involved in computing the coupling coefficients are undefined. In addition, the branch line integral, which is *not* included in the usual coupled-mode formalism, can become significant as modes undergo the transition between being trapped and being leaky. In this work, the approach of inserting a small attenuation gradient in the lower half-space is taken. The half-space gradient makes the mode functions have Airy-function solutions, eliminates the branch cut, replaces it by a series of modes, and makes the leaky modes well behaved at infinite depth. Using the differential form of the coupled-mode equations, overlap integrals can be computed analytically using well-known formulas for Airy functions. The accuracy and efficiency of the approach is evaluated using the ASA benchmark wedge problem as a test case. [Work supported by ONR.]

10:20

2aUW13. A search algorithm to predict the resonance frequency of a shallow-water soliton packet. Stanley A. Chin-Bing, David B. King, Alex Warn Varnas, and Robert A. Zingarelli (Naval Res. Lab., Stennis Space Center, MS 39529-5004)

Recently a number of researchers have performed acoustic simulations of shallow-water regions that contain large amplitude internal waves (solitons). Their results have confirmed earlier findings: (a) mode conversions, due to acoustic interactions with soliton packets, can produce a large loss in acoustic transmission; (b) this loss occurs within a narrow band of acoustic frequencies (about the resonance frequency); and, (c) the transmission loss is most prominent when there is strong coupling between the lower-order (water-borne) propagation modes and the higher-order, very lossy (bottom interacting) modes. Using this knowledge, development of a search algorithm has begun to predict the resonance frequency of a shallow-water soliton packet. In this proof-of-concept work, a shallow-water soliton model was used to generate replicas of the soliton fields in the Strait of Messina. The allowable acoustic mode conversions were calculated and correlated with the dominate spatial wave numbers of the soliton packet. This was used to predict the resonance frequency. The resonance frequency was later confirmed by making hundreds of acoustic runs. The search algorithm will be discussed and examples shown. [Work supported by ONR/NRL and by a Federal High Performance Computing DoD grant.]

10:25

2aUW14. Numerical model for low-frequency sound propagation in inhomogeneous waveguides. Alexander G. Voronovich (NOAA/ERL/ETL and Univ. of Colorado/CIRES, 325 Broadway, Boulder, CO 80303, agv@etl.noaa.gov)

Sound propagation in a shallow-water environment can result in the appearance of steep enough rays. Sufficiently accurate treatment of such situations with the help of the parabolic equation (PE) method can be complicated. On the other hand, propagation of low-frequency sound in inhomogeneous waveguides can be conveniently considered in terms of local modes. An algorithm for sound field calculation in the inhomoge-

neous waveguides was suggested recently [A. Voronovich, J. Comp. Acoust. **4**, 399–423 (1996)]. This algorithm is not based on parabolic approximation, it includes backpropagating field, and for 2-D situations is principally exact. Similar to the PE method it is also based on ''marching,'' however, in this case it proceeds in the backward direction. In contrast to other exact approaches which invoke piecewise constant (''staircase'') approximation of the inhomogeneous waveguide, this algorithm takes into account the mode interaction within each horizontal step. This allows one to increase the value of the horizontal step significantly making the algorithm very efficient. Generalization of this algorithm for the case of the uneven liquid bottom is considered. It is shown that due to sharp discontinuities at the bottom a bigger number of modes should be taken into account for sufficiently accurate calculations of the field in this case.

10:30

2aUW15. Broadband propagation over randomly varying, range-dependent elastic sediments. Michael Jaye (Rensselaer Polytechnic Inst., Troy, NY 12180), Xin Tang, Mohsen Badiey (Univ. of Delaware, Newark, DE 19716), and William L. Siegmann (Rensselaer Polytechnic Inst., Troy, NY 12180)

Acoustic experiments conducted over different tracks at the Atlantic Generating Station (AGS) site have shown significant transmission loss variability. These fluctuations cannot be accounted for entirely by bathymetric and water volume variations. Consequently, as suggested by previous studies, geoacoustic variations must be responsible for significant portions of the variability. We can take advantage of the relatively extensive core data that are available at the AGS site to model both the larger-scale range dependence and the smaller-scale variability. Uncertainties in the geoacoustic fields are modeled here by varying the vertical correlation length of the core profiles which changes the coefficients of representations by empirical orthogonal functions. The stochastic field representations are used for propagation modeling with both elastic and fluid sediments. Statistics of broadband signal transmission loss fluctuations are determined in terms of geoacoustic variabilities. Sensitivities of transmission loss predictions to frequency dependence of geoacoustic parameters are examined. Simulation statistics are compared with experimental data. [Work supported by ONR.]

10:35

2aUW16. The existence and coherence of ray bundles in a refractive ocean. Ivan P. Smirnov, Alexander I. Khil'ko (Inst. of Appl. Phys., Nizhny Novgorod, 46, Ulianov, Str., 603600, Russia), and Jerald W. Caruthers (Naval Res. Lab., Stennis Space Center, MS 39529)

Due to the existence of relatively smooth local extrema in the dependencies of ray-cycle lengths on initial path angles, different kinds of weakly diverging bundles (WDB) of rays can arise in refractive oceanic waveguides. As Brekhovskikh *et al.* have shown [Acoust. J. (in Russian) **36**, 5, 824–831 (1990)], such bundles transporting high-level acoustic intensity can be interesting with respect to these applications in ocean acoustic tomography (OAT). Conditions for the existence of WDB for piecewise linear approximations of sound velocity profiles are formulated in this work. Based on these results, the possibilities for the existence of WDB for different regions of the world's oceans are discussed. Important for tomographical application, the coherence of WDB is investigated under assumptions that the acoustic signals are emitted by noise sources with limited lengths of spatial coherence and the oceanic environment is randomly inhomogeneous in spatial coherence, as described by a Gaussian distribution. Numerically, it is shown that, because within a WDB ray parameters differ only slightly, coherence in WDB is maintained for propagation to long distances. In contrast are the rays outside the WDB. The optimal space/time filtering for OAT on the basis of the developed multiscale coherence approach is discussed.

10:40

2aUW17. Vertical noise coherence measurements in shallow water using Lagrangian drifters. Fancine Desharnais (Defence Res. Establishment Atlantic, P.O. Box 1012, Dartmouth, NS B2Y 3Z7, Canada, desharnais@drea.dnd.ca), Blair R. MacDonald, and Kenneth J. Mah (Seimac, Dartmouth, NS B3B 1W6, Canada)

The vertical coherence of an acoustic noise field in shallow water (at frequencies dominated by sea surface noise) can be used to infer certain ocean bottom properties such as the compressional sound speed of the upper sediment layer. As coherence is a normalized measurement, it is independent of background noise level, or wind speed/sea state, and remains a stable measurement over a wide range of environment conditions. A set of three Lagrangian ambient noise drifters (LANDs) were developed for vertical coherence measurements. The drifters (drogued at 15-m depth) follow the near-surface currents, and take hourly measurements of coherence from their two hydrophones located at 50-m depth. The hydrophone separation is 1 m, and the measurements are made over a usable frequency range of 100 Hz to 1 kHz. The drifters were deployed at Western Bank (Scotian Shelf, Canada) and drifted for up to 2.5 days. The sea conditions varied from calm to 3–4-m waves. The stability of the coherence data through the various sea states, and the impact of shipping noise on the measurements will be discussed.

10:45

2aUW18. Prediction of ambient noise in the ocean, the missing components. Douglas H. Cato (Defence Sci. and Technol. Organisation, P.O. Box 44, Pyrmont, NSW 2009, Australia, doug.cato@dsto.defence.gov.au)

The main components of ambient noise in the ocean were established by pioneers in ambient noise [V. O. Knudsen, R. S. Alford, and J. W. Emling, J. Marine Res. **7**, 410–429 (1948); G. M. Wenz, J. Acoust. Soc. Am. **34**, 1936–1956 (1962)] and prediction methods are generally based on the results of these studies. Most measurements were made in regions of high shipping densities where traffic noise usually obscured other components of ambient noise at low frequencies (below 200 Hz), so these do not appear in most prediction methods, even though their presence was noted in the early studies. Biological noise was also recognized as important, and widely studied, but is also not usually included. Studies of ambient noise near Australia, where shipping densities are generally lower, have shown the importance of low-frequency wind-dependent noise. Biological noise is also a major component in this part of the world, often being the dominant noise in tropical waters. Biological choruses are widespread and occur with diurnal regularity. These results are not inconsistent with measurements in other parts of the world. This paper discusses important components of ambient noise that are often missing from prediction methods.

10:50

2aUW19. Application of adaptive filter in influence extraction. S. Veerabhadraiah (Naval Sci. and Technol. Lab., Ministry of Defence, Govt. of India, Viyana Nagar, Visakhapatnam-530 027, India)

The very-low-frequency ocean ambient noise changes from place to place and time to time drastically due to various factors like thermal agitation, sea state, traffic, seismic factors, and biological activity, wind speed, etc. The surface and underwater mobiles generate an influence signal within the same frequency band of ambient noise but with extremely low magnitude. The influence signal gets buried in the high ocean ambients, yielding an extremely low signal-to-noise ratio, and are as such indistinguishable in the original time traces. In certain applications, perfect localization of such mobiles is extremely essential for extracting the influence signal buried in ocean ambients. This can be done using a self-optimizing adaptive filter known as a LMS (least mean square) filter. The filter automatically adjusts its parameters with the arrival of each new

ambient sample with a superior convergence rate at an appropriate step size. This technique, discussed in the paper, has been developed and successfully implemented to extract the desired signal from high ambients. Some sample graphical outputs depicting a combination of signals buried in ambient and extracted signal at the filter output. Necessary theory, a flowchart for implementing the LMS algorithm, and hardware realization of the same are also included in the paper.

10:55

2aUW20. Global autofocusing techniques for acoustic imaging. Peter T. Gough and Richard L. Lane (Dept. of Elec. and Electron. Eng., Univ. of Canterbury, Private Bag 4800, Christchurch, New Zealand, gough@elec.canterbury.ac.nz)

When images of acoustic fields are computed from measured data, the quality of the image is sometimes impaired by the acoustic wavelength limits or by turbulence in the media. However, more often, the image is impaired by random displacements in the position of the detecting array. Techniques exist to optimize the image on the basis of *a priori* knowledge. Since this knowledge is often statistical rather than deterministic, the image computed is the most probable image given the *a priori* knowledge. There can be no guarantees that what is computed is the exact image since there is an infinite combination of acoustic fields and tracks able to produce the same measured field. Using examples from some simulations of an existing synthetic aperture sonar, it is shown (by appealing to Bayesian statistics) that statistical information about the towfish behavior can be used to improve the quality of the image. Inherent in this technique is a cost function to be minimized and it is the precise nature of the cost function chosen that produces the most probable image. It is techniques such as this that hold out the prospect of SAS and passive towed array sonars without the need for on-board navigation units.

11:00

2aUW21. Up-to-date state and outlook for the intensity measurement method in underwater acoustics. Vladimir Shchurov (Lab. of Ocean Acoust. Noise, Pacific Oceanological Inst., Far Eastern Branch, Russian Acad. of Sci., 43 Baltiyskaya St., Vladivostok, 690041, Russia)

The acoustic intensity measurement method consisting of four components of the acoustic field [acoustic pressure $p(t)$ and three orthogonal components of the particle velocity vector $\mathbf{V}(t)\{V_x(t), V_y(t), V_z(t)\}$ simultaneous measurements] did not occupy a suitable place in underwater acoustics until now. Simultaneous measurement of four components of the acoustic field enables one to construct a point receiving system possessing direct characteristics in a wide frequency range (for example, from 10 to 100 Hz). By now unconventional results of investigations of underwater acoustic noises, reverberation, point source capacity, seismic noises, and underwater navigation were obtained. The intensity measurement method has given one a chance to research the acoustic field characteristics that have never been revealed during measurements of only acoustic pressure, i.e., characteristics connected with energy flux density vector. For example, a compensation of opposite energy fluxes of ambient noise and tone or signal similar to noise; horizontal energy flux of dynamic noise connected with propagational direction and the extent of wind near-surface roughness; splitting of ambient noise total field energy density into an isotropic component connected with the isotropic (diffuse) part of the field and an anisotropic one connected with the anisotropic (coherent) part of the field related to the energy transfer in the ocean. The isotropic component (possessing zero averaged flux) existence in the field of ambient noise allows for decreasing the threshold noise level for receiving systems measuring acoustic intensity, thus enables one to research a thin structure of the acoustic field of the noise and signal. Measurements of only acoustic pressure cannot give one such information. The acoustic intensity measurement method development will allow for constructing the most up-to-date acoustic devices for oceanologic processes dynamic investigation on the bases of ambient noise and sounding signal vector characteristic measurements.

TUESDAY MORNING, 23 JUNE 1998 GRAND BALLROOM III (W), 11:00 A.M. TO 12:00 NOON

Invited Paper

11:05

2aPLb1. Acoustics of outdoor surfaces. Keith Attenborough (Faculty of Technol., The Open Univ., Milton Keynes MK7 6AA, England)

While the development of absorbing materials for barrier surfaces is attracting considerable research interest, relatively little effort is being devoted to modifying ground surfaces for optimum ground effect. Indeed current schemes for predicting outdoor noise levels due to transportation and industry distinguish only between two types of ground; acoustically hard and acoustically soft. Ground effect phenomena are described with reference to relevant laboratory and outdoor data which indicate the influences of surface characteristics including porosity, small-scale roughness, elasticity, vegetation, extended reaction, and topography. Theories for the propagation of curved wavefronts near to porous ground and above rough ground predict the existence of surface waves. The relationship between these waves is discussed. The robustness of ground effects to meteorological influences is considered. Optimum characteristics for porous pavement with regard to propagation effects are described. Other possibilities for passive noise control reviewed include deployment of rough pavements and poroelastic materials, modifications to railway ballast, roadside cultivation, and landscaping. [Work supported by EPSRC and BBSRC (UK).]

2pPLa1. Trends in electromechanical transduction. Ilene Busch-Vishniac (Mech. Eng. Dept., Univ. of Texas, Austin, TX 78712 and Aero. and Mech. Eng. Dept., Boston Univ., Boston, MA 02215)

Electromechanical transducers (sensors and actuators) are devices which link electrical and mechanical energy domains. Ideal sensors are transducers in which the state of a system is monitored without being affected. Ideal actuators are transducers in which a system state is imposed, regardless of the load imposed. In recent years there has been growing attention on electromechanical transducers for a number of reasons: they are becoming more common in consumer items instead of being limited to laboratory equipment and industrial facilities; the demands placed on transducers, particularly with regard to size, speed, cost, and sensitivity, are becoming progressively harder to meet; the applications arenas for transducers are expanding to new domains; there is a push for miniaturization of sensors and actuators; more attention is being focused on actuators, as they are very difficult to design; and the time from discovery of new materials and techniques to the application in transducers is shrinking significantly. These trends, supported with reviews of research in the area, will be examined. Repercussions of these trends, current and in the near future, will also be discussed.

2pAAa1. Acoustics in the competition for the construction of ''La Fenice'' opera house. Maria Ida Biggi (Universita' Ca' Bonvicini, Venezia, Italy) and Roberto Pompoli (Dipartimento di Ingegneria-Via G. Saragat, 1, 44100 Ferrara, Italy)

In 1789, a group of nobles wished to build a new large theater in Venice. They announced a competition, in which 29 architects from all over Italy took part, presenting many different projects. Although the prize was given to one project, a different one was chosen to be executed. The author of the latter project was Giannantonio Selva and was the cause of much criticism, but it was appreciated for the results it obtained from the acoustic point of view. In his memoirs, Selva explained how he adapted the shape of the theater so that it became a semicircle with extensions on both sides and added that there were no precise theories regarding the building of a ''harmonic'' theater. He also appeared to be well informed on the debate about different curves to use in the hall. He suggested leaving an empty space under the orchestra pit, because ''it looks good.'' This paper deals with the description of the acoustical requirements in the competition for the construction of ''La Fenice'' and with the analysis of some of the projects presented taking into account the knowledge of room acoustics in the XVIII century.

1:25

2pAAa2. Preliminary project for the rebuilding of ''LA FENICE'' theater of Venice: Acoustic aspects. Mauro Strada (Istituto Architettura Universita' Venezia, 191 Santa Croce Tolentini 30135 Venezia, Italy) and Roberto Pompoli (Facolta' Ingegneria Universita' Ferrara, Via Saragat 1, 44100 Ferrara, Italy)

After a fire destroyed ''La Fenice'' Theater of Venice, the Town Council decided it should be rebuilt, being a place of memories for Venetians and people worldwide, committing to the Prefect, named Delegate Commissary, the management of the operation, compiling of a Regulated Contract until reconstruction is finished. He set up an expert workgroup for the drawing up of the Contract which is of main importance in the competition for judging the works. They decided to start the rebuilding of the theater as it was and where it was, preserving at least the internal and external aspects of the ''SaleApollinee'' halls, and the ''SalaGrande'' hall. They also decided to give freedom to the designers of the companies invited to the competition, concerning the stage aspects and all the facilities areas (halls for rehearsal, dressing-rooms, etc.). The problem has been the acoustic characteristics of the ''Sala Grande,'' which had to appear aesthetically as it was, nevertheless the materials were not going to be the same as before the fire, due to newer safety fireproof requirements. This article deals with all acoustic problems and the several stages of historical-critical deepening of the acoustics of the theater before the fire, brought into effect during the compiling of the Regulated Contract.

1:45

2pAAa3. The restoration of La Fenice in Venice: The consultant's viewpoint. Daniel E. Commins (commins acoust. workshop, 350 Fifth Ave., New York, NY 10118, comminsacoustics@compuserve.com)

Following the destruction by a fire of La Fenice in Venice, an extremely complex process was set in motion to attempt to rebuild the opera house as soon as possible. In this instance, acoustics is of utmost importance but it tends to be overshadowed by many other technical economical, and political requirements. Other major problems have surfaced, among which are the following: Very few opera houses, including La Fenice, are correctly documented from the point of view of acoustics; the leaders of such projects are not always aware of the impact of acoustics; the science of opera house acoustics is incomplete, to say the least. In the case of La Fenice, the decision was made to reconstruct it ''as was'' through a series of discussions with experts and users, and a well organized and efficient competition was set up. The present paper will attempt to analyze the strengths and weaknesses of this process, from the point of view of the ''acoustics'' referee.

Contributed Papers

2:05

2pAAa4. The acoustics of the Italian opera house, ''Teatro di San Carlo'' in Naples, Italy. Luigi Maffei, Gino Iannace, Carmine Ianniello, and Rosario Romano (DETEC–Univ. of Naples Federico II, Piazzale Tecchio 80, 80125 Naples, Italy, maffei@unina.it)

Teatro di San Carlo is reported to be the oldest existing European opera house. This horseshoe-shaped theater was opened on the 4th of November 1737, 41 years before the opening of La Scala in Milan and 51 years before the opening of La Fenice in Venice. Surprisingly, no objective acoustical data were found in the open literature for San Carlo. Therefore, the authors were stimulated in carrying out measurements of modern objective criteria in the above-mentioned opera house. As the theater hosts both symphonic/classical and opera concerts, two sets of measurements were carried out. The first one with the stage fitted for performing symphonic and classical music, and the second one with fitted scenery and the orchestra pit open, for performing opera concerts. Measurements in the unoccupied hall, yielded now classical, objective criteria (RT, EDT, C80, G, LE, and LF) at specific locations both on the main floor and in the boxes. The sound source was located along the longitudinal axis of the stage under the proscenium arch.

2:20

2pAAa5. Acoustics of the historical opera house of Bordeaux: Comparison between the results of objective and subjective surveys. Catherine Semidor and Aline Barlet (ERIAC, Ecole d'Architecture et de paysage de Bordeaux, Domaine de Raba, F 33405 Talence Cedex, France, catherine.semidor@bordeaux.archi.fr)

This paper deals with the relationships between objective and subjective results of an acoustic survey in the historical opera house of Bordeaux. The investigations were conducted with ordinary opera-goers during four performances of ''Traviata'' in order to have available statistical population answers. The results of an earlier experiment [C. Semidor, Proc. IOA **19**, Part 3, 29–38 (1997)] carried out in a dual-purpose hall with a test questionnaire built with simple words which explain the sensations of the listeners, have shown that the questions are correctly understood. The comparison of the ordinary listeners' answers with the objective results shows that the auditive sensations are fitting with the measured criteria obtained in the opera configuration with the opened pit and sceneries on the stage. For example, for the majority of people asked, the sound in this hall seems clear and coming directly from the stage (no surrounding by the sound sensation), and the sound attack impression is very clear, which is correlated by the weak values of reverberation time and EDT. In spite of comfort defects due to the age of the opera house, such as the lack of space between the seats, the architecture of the Grand Theatre of Bordeaux is very well appreciated.

2pAAa6. Acoustic conditions of the San Francisco War Memorial Opera House and its renovation. Dennis Paoletti, Kurt Graffy, Larry Tedford, and Red Wetherill (Paoletti Assoc., Inc., 40 Gold St., San Francisco, CA 94133)

The War Memorial Opera House is one of the most culturally significant performing arts venues in San Francisco. The San Francisco Opera organization (which includes the performers, designers, systems, and facilities) is known worldwide for the quality of its performances. The Loma Prieta earthquake which occurred just south of San Francisco in October 1989 was the impetus for the major renovation to the War Memorial Opera House currently in progress. This paper will report on the history of the San Francisco Opera House and the current renovation. It will also touch on some of the peripheral facilities and projects resulting from the renovation. Paoletti Associates has enjoyed a long-standing professional relationship with the San Francisco Opera organization, and the San Francisco War Memorial Board of Trustees, having been involved in a number of various studies for them over the past 20 years. They recognize the importance of acoustics, and they are quite concerned about the historical and cultural reputation of their performing arts facilities.

3:00

2pAAa7. A unique setting for an opera orchestra. Ewart A. Wetherill (Paoletti Assoc., Inc., 40 Gold St., San Francisco, CA 94133)

In 1995 the San Francisco Opera vacated the Opera House for one winter season and two summer seasons to allow for substantial renovation necessitated by damage caused during the 1989 earthquake. Rejecting the proposal of canceled opera seasons, the company tackled the more difficult option of utilizing the 4500 seat San Francisco Civic Auditorium augmented by two of San Francisco's older theaters. The cavernous and noisy Civic Auditorium, which is basically an arena with a large U-shaped balcony, presented a challenge in several dimensions. A complete stage, main floor seating, lighting, and backstage facilities had to be created. Lacking an orchestra pit, the opera designers placed the opera orchestra above dressing rooms, 16 ft above stage level and 60 ft behind the stage apron in a temporary orchestra enclosure. The entire undertaking is seen as a triumph of resourcefulness and willingness to face the challenge of severe physical limitations and budget constraints. Although complicated by an awkward plan configuration and limited overhead access, as well as conflicting rigging for lighting and scenery, the orchestra enclosure nevertheless evolved into a performance element that was both acoustically and visually appropriate. The development of the orchestra enclosure design is discussed in this paper.

3:15

2pAAa8. Virtual reflecting walls for improving the acoustics of defective halls. Jean-Paul Vian and Xavier Meynial (Acoust. Group, CSTB, 24 rue Joseph Fourier, F 38400 Saint-Martin d'Hères, France, vian@cstb.fr)

Many performing art centers and multipurpose halls with poor acoustics cannot be improved for economical reasons by architectural correction works or by mechanical moving devices. The principle of virtual acoustic wall [Guicking *et al.*, J. Acoust. Soc. Am. **78** (1985)] has been successfully applied to control the reflectivity and diffusivity of concert halls existing walls. Several independent active cells composed of a microphone, an electronic unit, and a loudspeaker form a virtual wall. By appropriately controlling the open loop gain in the cells of each virtual wall it is possible to create different sound fields fully coherent in space and time with the preexisting one. The first reflections can thus be reinforced and a natural reverberation enhancement effect is obtained by the acoustic exchange between the virtual walls. Computer sound simulation of three virtual walls in a concert hall was performed and experimental results, both objective and subjective, are shown for two concert halls in which a virtual wall system was installed.

3:30

2pAAa9. The next steps: Four examples of Artec's evolving room acoustics philosophy. Russell Johnson, Robert W. Wolff, Damian J. Doria, and Ashley Goodall (Artec Consultants, Inc., 114 W. 26 St., New York, NY 10001-6812, info@artec-usa.com)

This paper examines four Artec projects that have opened in 1997, and relates them to a room acoustics philosophy that has been evolving in Artec's designs since 1970. An illustrated discussion of the Winspear Centre (Edmonton, Alberta), the Living Arts Centre in Mississauga (Ontario), the Chan Centre (Vancouver, British Columbia), and the renovations to the stage acoustics at Music Hall, Cincinnati, highlights the importance of seat-count, complete freedom from exterior noise, room shaping, and a considerable amount of adjustability in order to achieve acoustical success in performing arts facilities.

3:45

2pAAa10. La Cité de la Musique in Paris. Daniel E. Commins (commins acoust. workshop, 350 Fifth Ave., New York, NY 10118, comminsacoustics@compuserve.com)

Fifteen years have been necessary to program, design, and build the Cité de la Musique in Paris. The author has been personally involved in all phases of the project and has assumed the principal acoustical responsibilities, with assistance from many acousticians. This music complex has two parts: the National Conservatory of Music and Dance, with some 250 music rooms, and the concert hall wing. The main concert hall, which has been in service for a few years, has a capacity of 900 to 1200 only, but it is designed in such a way that it can be used for various orchestral configurations: classical, in the round, central, etc. This means, of course, that acoustical reciprocity is a must: hearing conditions and musicality must be adequate for any pairs of points, in spite of the elliptical shape of the concert hall. The present paper will describe the means used to achieve a correct acoustical result in the concert hall and will give some insight into the characteristics of some of the other rooms.

2pAB1. An experimental study of the peripheral auditory mechanics in the goldfish (*Carassius auratus*) and oscar (*Astronotus ocellatus*). Mardi C. Hastings, James J. Finneran, and Corrie Derenburger (Ohio State Univ., Dept. of Mech. Eng., Columbus, OH 43210, hastings.6@osu.edu)

Dynamic mechanical responses of peripheral auditory organs in the goldfish (*Carassius auratus*), considered a hearing specialist because of its coupling via the Weberian ossicles between the swimbladder and inner ear, and the oscar (*Astronotus ocellatus*), an auditory nonspecialist, were measured *in vivo* using a noncontact, noninvasive ultrasonic system. Motion of the auditory organs was induced under water using pure tones at frequencies ranging from 12.5 to 3000 Hz. Measurements were made in both species with swimbladders intact and swimbladders deflated. Results from 23 goldfish and 38 oscars show that the swimbladder controls auditory bandwidth not only in hearing specialists, but also in nonspecialists which have no special coupling between the swimbladder and inner ear. Dual resonances routinely observed in the response of the anterior swimbladder, and motion of the Weberian ossicles transmitted to the saccular otolith at higher frequencies, contribute to the relatively broad auditory bandwidth of the goldfish. Although data were recorded only in the medial-lateral direction, they clearly indicate that displacement of the saccular otolith relative to its sensory epithelium in both the goldfish and oscar correlates with auditory thresholds for these animals reported in the literature. [Work supported by ONR Grant No. N00014-94-1-0337.]

2pAB2. A cohesive lumped parameter analysis of the mechanics of the goldfish peripheral auditory system. James J. Finneran (Biosciences Div. Naval Command, Control and Ocean Surveillance Ctr., RDT&E Div., 49620 Beluga Rd., San Diego, CA 92152-6266) and Mardi C. Hastings (Ohio State Univ., Columbus, OH 43210)

A mathematical analysis has been formulated to model the dynamic behavior of the goldfish peripheral auditory system, including the swimbladders, Weberian apparatus, and saccule. The two-chambered goldfish swimbladder is treated as a two degree-of-freedom mechanical system consisting of two coupled mass-spring-damper arrangements. The swimbladder is coupled to the Weberian ossicles using a phenomenological analysis of the anterior swimbladder tunica externa which permits both stretching and sliding. Analysis of the saccule features only a single degree-of-freedom, corresponding to the direction of orientation of the ciliary bundles. Inputs to the saccule consist of the transverse canal fluid motion and the motion of the animal's head (assumed to match the local acoustic particle motion). Mechanical properties required for the system equations were estimated from published literature and direct measurements. Results of the analysis compare favorably to experimental data for the motions of the swimbladders and Weberian ossicles. The results indivate that the Weberian apparatus has a significant impact on the hearing ability over a broad frequency range and that the saccule functions as a displacement sensor above approximately 300 Hz. [Work supported by ONR Grant No. N00014-94-1-0337 and the ASA Hunt Fellowship.]

2:15

2pAB3. Directional acoustic startle response in the goldfish. Thomas N. Lewis and Peter H. Rogers (The George W. Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0405)

Fish exhibit a characteristic Mauthner-initiated startle response to sudden acoustic stimuli. This escape response is thought to be triggered by predatory attacks since an acoustic wave is launched ahead of a striking predator. The nature of acoustic stimuli which elicit the startle response was examined in free-swimming goldfish (*Carassius auratus*). The results showed that a threshold level of acoustic acceleration (-30 dB *re*: 1 m/s^2), not pressure, was required to elicit a startle and that the threshold was invariant of bearing to the source. Near threshold, the fish turned in a random direction, but as the stimulus level increased, the fish was more likely to turn away from the source. The data indicated that the lateral component of the acoustic acceleration was the relevant parameter determining directionality. A proposed model uses the utricle to detect acoustic acceleration directly, the saccule to detect acoustic pressure indirectly, and logical wiring to perform the neural computation which explains the fish's behavioral performance.

2:35–2:50 Break

2:50

2pAB4. Detection of ultrasound and marine mammal echolocation clicks by the American shad (*Clupeidae*). David A. Mann (Tucker-Davis Technologies, Inc., 4550 N.W. 6th St., Gainesville, FL 32609), Zhongmin Lu, and Arthur N. Popper (Univ. of Maryland, College Park, MD 20742)

Clupeid fishes (herrings and shads) are among the main prey of echolocating cetaceans. Recent studies have shown that some clupeids are repelled by intense sounds from ultrasonic transducers. The hearing thresholds of a clupeid, the American shad (*Alosa sapidissima*) was determined using classical conditioning. Shad could detect sounds from 0.2 to 180 kHz, with two regions of best sensitivity, one from 0.2 to 0.8 kHz and another from 25 to 150 kHz. American shad were also able to detect simulated bottlenose dolphin (*Tursiops truncatus*) echolocation clicks with a threshold that suggests they could detect an echolocating dolphin at distances up to 187 m. These results have practical implications for the design of ultrasonic devices that could be used for repelling clupeids from power plant intakes and dams, as well as for the design of ultrasonic pingers that may reduce dolphin bycatch without affecting the catch of clupeids. [Work supported by NSF.]

3:10

2pAB5. Morphological responses of fish to low-frequency sound. Joseph A. Clark (CDNSWC, Code 734, Bethesda, MD 20084), Jane A. Young (CDNSWC, Bethesda, MD 20084), Amrit N. Bart, and Yonathan Zohar (COMB, Baltimore, MD 21202)

Results of an earlier study [Clark *et al.*, J. Acoust. Soc. Am. **100**, 2709(A) (1996)] suggested that low-frequency vibrations could have a positive effect on the growth rate of fingerlings grown in tanks. This talk describes a more extensive study with a larger sample of fish (640 Tlapia Nilotica grown in four control tanks and four treated tanks) for a longer period of time than the previous six week period. The control tanks were mildly acoustically quieted with foam rubber tank coatings that are normally applied to reduce heat conduction into the tanks. The treated tanks were excited continuously with shakers in the frequency range of 30–60 Hz for the duration of the test. Average weight and length versus time for fish in treated and control tanks were measured at 3 week intervals. Differences in the two groups and their possible causes are discussed.

3:30

2pAB6. Evening fish choruses near coral reef systems in the Great Barrier Reef, Australia. Robert D. McCauley (Dept. of Marine Biol., James Cook Univ., Townsville, Queensland 4811, Australia) and Douglas H. Cato (Defence Sci. Technol. Organisation, Pyrmont NSW 2009, Australia)

The nighttime ambient sea noise on and around coral reef systems in northern Australia is characterized by choruses produced by nocturnally active fishes. These choruses are produced year round, from dusk to dawn. Choruses are composed of many ''pops'' of between 5 and 28 ms length, with a decay envelope suggestive of a lightly damped swimbladder and with source levels calculated at 154–157 dB *re*: 1 μPa^2 at 1 m peak to peak. Sources are found mostly concentrated over 6–20 m water depth. Choruses have a mean spectral peak at 550 Hz (normal range 500–750 Hz) but may influence sea noise from 100 Hz to 3 kHz. The highest chorus levels occur just after dusk or in the early evening, reaching up to 35 dB above background levels. The recorded levels of choruses displayed distinct daily patterns, lunar patterns with higher levels around new moon periods, and seasonal patterns of highest level during the austral summer. Choruses occur over large spatial scales, with active sources heard at up to 15 km from reef systems and chorus influence on ambient sea noise extending considerably further. It is believed that nocturnal planktivorous fishes, such as those from the families Holocentridae and Priacanthidae, are responsible for choruses. 3:50

2pAB7. Mathematical model of echo-location of fish-eating flying bats. Anatoli Stulov (Dept. of Mech. and Appl. Math., Inst. of Cybernetics, Akadeemia tee 21, Tallinn, Estonia, EE0026)

The ability of flying bats *Vespertillionidae* to detect fish under the water surface using echo-location is surprised, because only one-thousandth of the acoustical pulse energy penetrates into water. Supposing the fish (air bubble) reflects the whole signal backwards, the bat must detect the echo-signal which is a million times less than the transmitted one. This fantastic level of the perception sensitivity of the flying bat lies on the bound of its ability. It seems incredible that the main method of getting food is provided for by the maximum effort of bat senses. The method of the bat echo-location is explained here in terms of the interaction of the frequency-modulated acoustical pulse with the air bubble under the water surface. It was shown that in the presence of the bubble the amplitude of the echo reflected by the water surface depends on the signal frequency. In the usual range of the echo-location, 50–100 kHz (the resonance frequency of the bubble lies near 1 kHz), there are at least four regions of frequency for which the amplitude of the signal reflected back to the bat varies up to 25%. Thus, the bat can detect fish in water easily.

TUESDAY AFTERNOON, 23 JUNE 1998 WEST BALLROOM B (S), 2:15 TO 5:35 P.M.

Session 2pAO

Acoustical Oceanography and Underwater Acoustics: Surf Zone Oceanography and Acoustics II

Grant B. Deane, Chair

Scripps Institute of Oceanography, Marine Physical Laboratory 0238, La Jolla, California 92093-0238

Invited Paper

2:15

2pAO1. The generation of ambient noise due to breaking surf. James H. Wilson (Dept. of Oceanogr., Naval Postgrad. School, Monterey, CA 93943, wilson@vsinc.com), Robert H. Bourke (Naval Postgrad. School, Monterey, CA 93943), and Josette P. Fabre (Neptune Sci., Inc., Slidell, LA 70458)

The past predominance for deep-water acoustic studies has dictated that little consideration be placed on the role of the surf zone as a source of ambient noise. Recent emphasis on propagation in coastal waters has increased the awareness of the importance of breaking surf to the noise field in littoral waters. Two recent studies, in Monterey Bay, CA, and at Duck, NC, have provided for the first time information on the source level density of surf-generated ambient noise. Inverse techniques were developed to infer the source level density from the total ambient noise field as measured at several offshore hydrophones. Source level spectra from 50–1000 Hz demonstrate a -5-dB/oct slope with absolute levels varying by 10–15 dB dependent on wave height and distance from the surf zone. Surf noise was found to contribute 80% (95%–99%) of the total offshore ambient noise during light (heavy) surf conditions. The inverse technique is highly dependent on accurate modeling of the transmission loss seaward from the surf zone, being predominantly a function of the geoacoustic properties of the sea bed. Additional comments will address breaker types and factors affecting breaker height and the noise due to waves breaking on the ice edge of the Greenland Sea.

2:35

2pAO2. Measurements of the space–time–frequency distribution of the noise in the surf zone. Richard M. Heitmeyer, Steven L. Means, Stephen C. Wales (Naval Res. Lab., Code 7121, Washington, DC 20375), Ellen S. Livingston (Office of Naval Res., Arlington, VA 22217), Jeffrey A. Schindall, and Marshall H. Orr (Naval Res. Lab., Washington, DC 20375)

The space–time–frequency distribution of the noise generated in the surf zone was measured in the SandyDuck'97 experiment during September and October 1997. The noise measurements were obtained on a 17-phone, 138-m, bottom-mounted, linear array located along a line perpendicular to the shore at a depth of one to three meters. Concurrent measurements of the location, size, and time evolution of the individual breaking waves directly above the array were made using a video camera mounted on a nearby tower. The measurements of the time history of the noise at individual phones along the array indicate that in regions of wave breaking, the noise contributions are broadband bursts, isolated in time with significant variations in level. A significant number of these broadband bursts exhibit a downward frequency sweep. Similarly, measurements of the time history of the noise observed along the array at selected frequencies show significant variations in both the range extent and the propagation speeds of the noise sources. The paper will present an interpretation of this variability in terms of the space–time distribution of the breaking waves obtained from the video measurements. [Work supported by ONR.]

2:50

2pAO3. SANDYDUCK97 angle-time-frequency measurements of breaking wave noise. Ellen S. Livingston (Code 321OA, Ocean Atmosphere and Space S&T Div., Office of Naval Res., 800 N. Quincy St., Arlington, VA 22217-5660, livinge@onr.navy.mil), Joal J. Newcomb (Naval Res. Lab., Stennis Space Center, MS 39529-5000), Richard Heitmeyer, Stephen C. Wales, and Steven L. Means (Naval Res. Lab., Washington, DC 20375-5350)

Low-frequency acoustic measurements (0 to 2400 Hz) were taken in October 1997 as part of the SANDYDUCK97 experiment. These measurements were made on a horizontal bottom-mounted line array deployed in the surf ''transition'' zone at about 500 m offshore. The array consisted of 64 elements oriented end fire to shore in 6 m of water. Video cameras, mounted on a shoreside tower, monitored the breaking wave events over the transition zone array and in the nearby surf zone during data collection periods. The beamformed array data provide an angle-time-frequency distribution of the breaking wave noise as detected in the transition zone. Comparisons will be made of the angle-time-frequency characteristics from noise fields generated during low-, medium-, and high-surf conditions, with particular attention to the differences between inshore and offshore characteristics. Results from a similar data set obtained during DUCK94 will be presented for comparison as well.

3:05

2pAO4. Characteristics of the low- and high-frequency ambient sound from breaking waves in the surf zone. Ali R. Kolaini (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, Coliseum Dr., University, MS 38677) and Jeffrey A. Nystuen (Univ. of Washington, Seattle, WA 98105)

An experiment was conducted along the Scripps Institution of Oceanography Pier to study the characteristics of the ambient sound in the surf zone. The role of the single large bubble's (order of a few centimeters) oscillations versus the collective oscillations of bubble clouds as possible mechanisms of generation of the low-frequency sound, especially the relatively broadband peak that appears around 20 Hz in the sound spectrum, is discussed. The frequency band at which ambient sound from breakers in the surf leaks out is identified. The acoustic attenuation which makes the surf zone extremely quiet above 2 kHz, and a possible method to use ambient sound to infer bubble size distribution in shallow water near the surf zone, are discussed. [Work supported by ONR.]

3:20

2pAO5. A theoretical investigation of the low-frequency sound generated by breaking waves. Mark R. Loewen and Cesar E. Farell (Dept. of Mech. and Industrial Eng., Univ. of Toronto, Toronto, ON M5S 3G8, Canada, loewen@mie.utoronto.ca)

The important influence of breaking waves on the dynamics of the upper ocean has motivated research into developing techniques for quantitatively measuring the effects of wave breaking in the field. Breaking waves are a major source of sea surface sound and breaking events produce sound at frequencies as low as 10 Hz. Collective bubble cloud oscillations have been shown to be the dominant source of the low-frequency sound. Laboratory experiments have shown that the low-frequency sound generated by breaking is correlated with the amount of wave energy dissipated and the volume of air entrained. Therefore it may be possible to use passive acoustic measurements in the field to obtain estimates of the volume of entrained air and energy dissipated by individual breaking events. Development of a model of the low-frequency sound generated by individual breaking waves is an important step in achieving this goal. A simplified model of the low-frequency sound generated by breaking has been developed based on the approach of Oguz [J. Acoust. Soc. Am. **95**(4), 1895–1912 (1994)]. The importance of the simplifying assumptions used in the model and the use of the model as an aid to interpreting field and laboratory measurements will be discussed.

3:35

2pAO6. Acoustic propagation in the ocean surf zone. Steven L. Means, Richard M. Heitmeyer, Stephen C. Wales, Thomas J. Hayward (Naval Res. Lab., Code 7121, Washington, DC 20375), Ellen S. Livingston (Office of Naval Res., Arlington, VA 22217), and Jeffrey A. Schindall (Naval Res. Lab., Washington, DC 20375)

Broadband acoustic propagation measurements were conducted during the SandyDuck'97 experiment to provide a means of interpreting noise data taken both within and outside of the surf zone. The source was located outside of the nominal surf zone region at a distance of 470 m from the shore in 6 m of water. The receivers were spaced at 6-m intervals 45 to 183 m offshore in 1 to 3 m of water. Both the source and the receivers were located along a line orthogonal to the shore. The cw line sets were transmitted to obtain a description of the temporal fluctuations in the narrowband propagation induced by the temporal variability of the medium, the surface, and the entrained bubble distribution, as a function of range and frequency. The cw pulses and biphase-modulated PR sequences were transmitted to obtain a description of the spatial and temporal variability of the multipath structure. Measurements show significant time variations even under low surf conditions. The measured results are interpreted through simulations obtained using a FEPE propagation model with near-concurrent estimates of the bathymetry and geoacoustic parameters derived by Fabre and Wilson [IEEE J. Ocean. Eng. **22**, 434–444 (1997)]. [Work supported by ONR.]

3:50–4:05 Break

4:05

2pAO7. Wind-generated acoustic spectral effects in the surf zone in the presence and absence of rainfall at Duck, North Carolina. John R. Proni (NOAA/Atlantic Oceanograph. and Meteorological Lab., Ocean Acoust. Div., 4301 Rickenbacker Cswy., Miami, FL 33149, proni@aoml.noaa.gov) and John C. Wilkerson (NOAA/Natl. Environ. Satellite Data and Information Service, Washington, DC 20746)

Observations of wind-induced effects upon concurrently measured rainfall-generated spectra in the surf zone off Duck, North Carolina were made in November, 1992. Rapid changes in wind speed from about 5 m/s to 14 m/s were accompanied by a frequency-dependent reduction in rain-

fall spectral level. The reduction initiated at about 50 kHz (the highest frequency recorded) and progressed to lower frequencies with time. When the wind burst diminished, spectral levels increased. Rainfall rate was monitored using conventional rain gauges so that rainfall rate change effects could be distinguished from wind change effects in the measured acoustical spectra. The general surf-noise spectrum level changes were also observed to be affected by wind speed changes.

4:20

2pAO8. Acoustic observations of suspended sediments in the Changjiang Estuary. Shuying Zhang (Shanghai Acoust. Lab., Acad. Sinica, 456 Xiao-Mu-Qiao Rd., Shanghai 200032, PROC)

An acoustic backscatter instrument of dual frequencies (0.5 and 1.5 MHz) was developed for suspended sediment measurements and for sediment transport studies. The instrument measures the vertical concentration profiles of suspended sediments with a temporal resolution of 1 s and a spatial (depth) resolution of 10 cm for 0.5 MHz or 2 cm for 1.5 MHz. The data of backscattered acoustic energy are sampled at a rate of 75 kHz for a 450-s burst each time, so each burst comprises 450 vertical profiles. Coincidentally, six calibration points for the water column are taken through water sampling. Further data processing for each burst, such as compensation for sound transmission losses, *in situ* calibration of acoustic scattering intensity to real concentration of suspended sediments, and ensemble averaging over adjustable time–depth sizes permits three-dimensional concentration profiles to be derived. To increase the accuracy of concentration measurement, a multisegment procedure to form an appropriate compensation and calibration curve is applied. Through observations at the Changjiang Estuary four patterns of vertical suspension profiles are identified at flood and ebb tides. In addition, lutoclines and interfacial waves within the near-bed high concentration suspensions are revealed.

4:35

2pAO9. Motivations for using a pulsed full spectrum Doppler to measure bedload and near-bottom suspended sediment transport. Peter Traykovski, James D. Irish, and James F. Lynch (AOP&E Dept., WHOI, Woods Hole, MA 02543, ptraykovski@whoi.edu)

Acoustic observations of bedform migration and suspended sediment transport at the New Jersey LEO-15 site revealed that bedload and near-bottom suspended load could be the dominant sediment transport mode over wave-formed ripples on a sandy bottom. Bedforms observed during storms using a rotary sidescan sonar were found to be wave orbital scale ripples which migrated in the onshore direction, forced by asymmetrical wave orbital velocities. Estimates of suspended sand transport were calculated from observations of acoustic backscattering and water velocity profiles. Suspended sand transport was also forced by asymmetrical wave velocities, and was found to occur primarily during the weaker offshore phase of wave motion. This net offshore suspended sediment transport was an order of magnitude less than the flux associated with onshore ripple migration. Thus it is hypothesized that ripple migration is most likely forced by unobserved bedload and near-bottom suspended transport. Spatially resolving bedload transport from the stationary bed is difficult since the motion occurs within a few grain diameters of the bed. Acoustic Doppler-based techniques, which are ideal for this type of measurement since the sediment velocity can be resolved from the stationary bed in the frequency domain, are being developed.

4:50

2pAO10. Changes in acoustic impedance of marine sediment covered with liquid pollutants. Henning Harms, Rainer Matuschek, and Volker Mellert (Dept. of Phys., Univ. of Oldenburg, D-26111 Oldenburg, Germany)

Acoustic properties of porous material are slightly changed by a coating layer, which is thin compared to the acoustic wavelength. These changes affect mainly the spherical wave reflection coefficient at grazing incidence. The phase change of a surface wave component is observed and enables the easy detection of the thin layer by measuring the interference of direct and guided surface waves. This method is investigated for screening observations in order to monitor liquid pollutants on marine sediment. Since sediment is usually not plain but more or less irregularly grooved, the coating by liquid pollutants will occur in patches. Laboratory experiments are carried out with rough surfaces of sediment to investigate the sensitivity of detecting an average change in impedance. The results are compared with a numerical model incorporating Biot theory [Tooms *et al.*, J. Acoust. Soc. Am. **93**, 171–181 (1998)], which was successfully applied to model experimental data of plain sediment (Harms *et al.*, 134th meeting of ASA). Since the rough surface produces a significant backscattering, the liquid patches are detectable in the backscattered signal as well. Experimental results of this contribution are presented and the possibility of using this method for monitoring purposes discussed. [Work supported by German Ministry of Technology BMFT.]

5:05

2pAO11. Scattering by two spheres: Theory and experiment. Irina Bjørnø and Leif Bjørnø (Dept. of Industrial Acoust., Tech. Univ. of Denmark, Bldg. 425, DK2800 Lyngby, Denmark)

Extensive studies of scattering of acoustical signals by targets of different regular shapes have formed a useful background for attempts to develop procedures for remote monitoring of suspended materials in marine environments as, for instance, measurements of characteristic parameters of suspended sediments. The scattering properties of single regular-shaped particles have been studied in depth by several authors in the past. However, single particle scattering cannot explain all features of scattering by suspended sediment. When the concentration of particles exceeds a certain limit, multiple particle scattering becomes important. As a first step in the investigation of mutual interactions between several particles, the acoustical scattering by two spheres has been studied theoretically and experimentally and the results are reported in this paper. The study has mainly been focused on three issues: (1) to develop a simplified theory for scattering by two elastical spheres; (2) to measure the scattering by two spheres in a water tank, and (3) to compare the theoretical/numerical results with the measured data. A number of factors influencing multiple scattering, including the geometrical distribution of particles, their shape, size, and material properties are taken into consideration in the studies to be reported. Broadband signals were used for the experimental studies.

5:20

2pAO12. Acoustic propagation affected by internal solitons in a coastal area. E. C. Shang, Y. Y. Wang, and L. Ostrovsky (Cooperative Inst. for Res. in Environ. Sci., Univ. of Colorado/NOAA/ETL, Boulder, CO 80303)

The NOAA/Environmental Technology Laboratory (ETL) conducted the ''Coastal Ocean Probe Experiment'' (COPE) in the Oregon coastal area (with water depth of 150 m) in September, 1995. Strong internal soliton activities have been observed. The isotherm records measured by FLIP demonstrate that the maximum amplitude of isotherm depression can reach ~30 m. Based on these internal soliton data, numerical simulation on acoustic propagation through solitons has been conducted. Some interesting features of the acoustic field are found: (1) The internal solitons can cause significant mode coupling, but there is no abnormal transmission loss (TL) appearing in the frequency range 50–1000 Hz. (2) Mode coupling strongly depends on frequency, mode number, and the direction of propagation. (3) The modal horizontal refraction (MHR) caused by the internal solitons is significant and offers additional useful information for acoustic monitoring of the internal soliton activities. [Work supported by NOAA.]

2pBV1. Optimal acoustic parameters for induced hyperthermia from focused MHz ultrasound: Phantom measurements with fluid flow and bubble activity. R. Glynn Holt and Ronald A. Roy (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, rgholt@bu.edu)

The effective coagulation of flowing blood by ultrasound, or acoustic hemostasis, is a complex process that encompasses several physical, biophysical, and biochemical facets. Motivated by this ultimate goal of efficient and predictable hemostasis, we have undertaken a series of laboratory experiments on a variety of phantoms insonified by 1-MHz focused ultrasound at MPa amplitudes. The goal of the present study is to quantify and characterize the physical response of a viscous, particulate-laden Newtonian flow to high-intensity focused ultrasound (HIFU). Experimental hyperthermia in a tissue/flow phantom as a function of acoustic parameters (pulse width, duty cycle, amplitude), flow parameters (volume flow rate, vessel size, flow geometry), and bubble content in the flow phantom is investigated. Spatiotemporally resolved temperature measurements in the flow and surrounding tissue phantom are reported. Time permitting, visualization of the modified flow due to acoustic streaming and radiation pressure will be undertaken to correlate flow events with the hyperthermia results. [Work supported by DARPA.]

2:25

2pBV2. Numerical simulations of tissue heating created by high-intensity focused ultrasound. Francesco P. Curra, Peter Kaczkowski, Pierre D. Mourad, Lawrence A. Crum (Univ. of Washington, Appl. Phys. Lab., 1013 NE 40th St., Seattle, WA 90105, pierre@apl.washington.edu), and Vera A. Khokhlova (Moscow State Univ., Moscow, Russia 119889)

Modeling of high-intensity focused ultrasound (HIFU) propagation and heating effects in tissue has usually been studied under the assumption of linear acoustics. Nevertheless, nonlinear propagation can lead to important differences in heat deposition depending on the degree of nonlinearity achieved in a HIFU field. To be presented are calculations of the spatial patterns of acoustic intensity (I) and heat generation [$H=-(\partial/\partial z+1/r\partial/\partial r)I$ for strongly nonlinear acoustic waves and $H=2\alpha I$ for weakly nonlinear acoustic waves, where α is acoustic absorption] associated with focused weakly and strongly nonlinear acoustic wave propagation in biological tissue. The propagation is modeled using a KZK equation method with special attention to correct modeling of shock generation and biologically relevant attenuation, as well as using initializing data based on existing designs of transducers for acoustic hemostasis. The heat generation term forces the ''bio-heat'' equation, which predicts the generation, movement, and dissipation of heat within biological tissue. The tissue model contains blood flow in an artery or vein and is perfused by a capillary bed. For this talk the differences in spatial patterns of acoustic intensity created by weakly and strongly nonlinear CW 1-Mhz acoustic wave propagation are shown. How those differences translate into differences in heat generation and therefore bioeffect within biological tissue are then demonstrated. [Work sponsored by DARPA.]

2:40

2pBV3. Occlusion of blood vessels using high-intensity focused ultrasound. Shahram Vaezy (Anesthesiology, Box 356540, Univ. of Washington, Seattle, WA 98195, adasi@u.washington.edu), Roy Martin, Peter Kaczkowski (Univ. of Washington, Seattle, WA 98195), George Keilman (Sonic Concepts, Woodinville, MA 98072), Steve Carter, Michael Caps, Pierre Mourad, and Lawrence Crum (Univ. of Washington, Seattle, WA 98195)

Vascular injury may result from both trauma and invasive medical procedures. High-intensity focused ultrasound (HIFU) was used to occlude surgically exposed blood vessels of anesthetized rabbits, as a mechanism of hemostasis applicable to vascular injury. A HIFU transducer, with a spherically curved aperture area of 6.34 cm^2, a focal length of 4 cm, and a frequency of 3.3 MHz, was used. The transducer was equipped with a conical housing filled with water, providing a coupling medium to the vessels. Femoral arteries and veins were occluded after a HIFU treatment of approximately 30–60 s, at a focal intensity of 3000 W/cm^2. The vessels were severed after the treatment to confirm complete occlusion. No bleeding was observed. Gross and microscopic examination of the vessels revealed two major mechanisms of occlusion, dissection of the vessel wall and shrinkage of the vessel. In the dissection mechanism, a flap of the inner wall of the vessel peeled as a result of the HIFU treatment and caused a blockage of the blood flow, while in the shrinkage mechanism a mechanical constriction of the vessel lumen caused the blockage. HIFU may provide a valuable method for hemostasis of injured vessels by treating a region of the blood vessel, proximal to the hemorrhaging site.

2:55

2pBV4. Occlusion of blood flow by high-intensity focused ultrasound. Ian Rivens, Ian Rowland, Gail ter Haar (Phys. Dept., Royal Marsden Hospital, Sutton, Surrey, UK, ian@icr.ac.uk), Mark Denbow, and Nicholas Fisk (Royal Postgraduate Med. School, Inst. of Obstetrics and Gynaecology, Queen Charlotte's and Chelsea Hospital, London, UK)

This work investigates the possiblity of occluding blood flow (*in vivo*) using high-intensity focused ultrasound surgery (FUS). Such an effect could be used, for example, in the noninvasive treatment of foetal dysfunctions. A high-power 1.7-MHz, 150-mm focal length, piezoelectric transducer was used to expose rat femoral vessels to a free field $I_-^{SP}=4660$ W cm^{-2} for 2 s under terminal

anaesthesia. Initially, eight separate exposures were used. Later experiments were aimed at determining an optimal single exposure to produce flow occlusion. Before and after exposure, magnetic resonance FISP 3-D angiograms (MRA) with submillimeter spatial resolution were acquired using a Siemens Vision MR System (1.5T) and extremity coil. In all animals, MRA showed reduced blood flow both in the treated region and distal to it. The results of single-dose optimization will be discussed. The ability to curtail blood flow using FUS allows the possibility of treating Foeto-Foetal Transfusion Syndrome by occluding the placental shunt vessels responsible for vascular inbalance in identical twins. Currently available interventional treatments (surgery or intrauterine laser therapy) have significant mortality and morbidity. The FUS has the advantage of being noninvasive. [Work was funded by the UK Medical Research Council.]

2pBV5. Measurements of sound speed in excised tissue over temperatures expected under high-intensity focused ultrasound conditions. Susannah H. Bloch, Michael R. Bailey, Lawrence A. Crum, Peter J. Kaczkowski (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105, peter@apl.washington.edu), George W. Keilman (Sonic Concepts, Inc., Woodinville, WA 98072), and Pierre D. Mourad (Univ. of Washington, Seattle, WA 98105)

Noninvasive monitoring of high-intensity focused ultrasound (HIFU) treatment by diagnostic ultrasound is currently limited by a poor understanding of the bioacoustic effects of tissue heating. Sound-speed measurement has been proposed as a means of noninvasive thermal mapping. The sound speed in most tissues changes monotonically but nonlinearly with temperature to around 60 °C. Above that temperature, at which the tissue proteins begin to denature, irreversible changes occur in the tissue and its corresponding acoustic properties. Sound-speed data around and above the range in which the tissue ''cooks'' is a challenge to obtain because of changes in tissue shape, compressibility, and overall dimensions associated with the cooking process. In this research, an apparatus to measure sound speed during a controlled temperature change was used to study the effects of temperature, thermal dose, and thermal dose rate on the speed of sound in various mammalian tissues. The apparatus, potential sources of error, and results will be presented, and implications for forward and inverse HIFU propagation modeling and acoustic remote sensing of HIFU-induced temperature changes will be discussed. 2pBV6. Role of cavitation during high intensity focused ultrasound treatment of prostate tissue. Narendra T. Sanghvi (Focus Surgery, Inc., 3940 Pendelton Way, Indianapolis, IN 46226)

The use of high intensity focused ultrasound (HIFU) has been well established to produce deep seated tissue necrosis using a short time ultrasound exposure. The scavenging system of the body replaces the necrosed tissue over time from the treated organ. However, in the case of benign prostatic hyperplasia (BPH) treatment, it is essential to remove treated tissue immediately after the treatment to offer improved urine flow rate and relief from the symptoms. Therefore, it was necessary to develop an ultrasound treatment system that not only provides thermal lesions that are deep in the tissue but also mechanical disintegration of urethra and surrounding tissue. Once the urethra is mechanically disintegrated, the necrosed tissue is sloughed with urine and provides an improved flow rate. The mechanical defect in tissue is produced using the cavitation process. The acoustic cavitation is produced by inserting a silastic catheter in the urethra. The catheter blocks the HIFU energy and produces standing waves which produce cavitation, and converts HIFU in a thermal dose larger than that produced by only absorption of acoustic energy by tissue. This method of treatment yields far greater results. The system is now being used in human BPH treatment.

2pBV7. Transrectal high-intensity ultrasound therapy of localized prostate cancer. Jean Y. Chapelon (INSERM U281, 151 Cours A. Thomas, Lyon, F69424, France, chapelon@lyon151.inserm.fr), Albert Gelet (E. Herriot Hospital, Lyon, F69434), and Emmanuel Blanc (Edap Technomed, Vaulx en Velin, F69120)

Prostate cancer is the most common cancer in men. The Ablatherm project has been developed in order to achieve a minimally invasive treatment of localized prostate cancer using transrectal high-intensity focused ultrasound (HIFU). The method uses a sharply focused wideband transducer operating in the frequency range 2.25–3.0 MHz to induce a localized thermal necrosis with a shot of 4.5-s exposure. This therapy transducer focused at 40 mm is coupled to a retractable 7.5-MHz biplane imaging transducer. A computer-controlled positioning device moves the probe in the rectum to ablate the volume defined with the image by repeating the shots every 5 s. For patient safety, the system includes a power monitoring circuitry combined with a real time A-mode ultrasound detection of the rectal wall. Since 1993, 44 patients have been treated in Lyon: A complete response was obtained in 26 and only 18 numerous advantages: It is minimally invasive requiring only a short hospital stay; it is repeatable unlike radiotherapy and additional treatment centered on insufficiently treated area can be performed. [Work supported by Technomed and Rhone Alpes Futur.]

2pBV8. Concept of biological focal field and its importance in tissue resection with high-intensity focused ultrasound. Zhi B. Wang, Feng Wu, Zhi L. Wang, and Chuan Liu (Inst. of Ultrasonic Eng. in Medicine, Chongqing Medical Univ., Box 153, 1 Medical College Rd., Chongqing 400046, PROC, chhifu@public.cq.sc.cn)

Many studies showed that *in vitro* the size and shape of the necrosed tissue volume generated by high-intensity focused ultrasound (HIFU) were dependent upon the transducer size and radius of curvature, operating frequency, input power, pulse duration, and delay time between each pulse. In this research the shape and size of necrosed tissue volume produced by HIFU with 1.6-MHz focused transducer were carefully checked and compared in rabbits and pigs. This volume was generated by a single exposure or focal planes. It was shown that with the same therapeutic parameters, HIFU can selectively necrose one region of liver *in vivo*. However, its shape and size differed between *in vitro* and *in vivo*. These changes implied that the necrosed tissue volume *in vivo* depended upon not only HIFU conditions, but also the structure, function, and movement of target tissue. In contrast with the physical focal region, necrosed tissue volume *in vivo* could also be termed the biological focal field of HIFU. Theoretically, it resembled more closely the living tissue damaged by HIFU. In order to avoid the side effects, it is important to set up the data about biological focal fields of different organs in tissue resection with HIFU.

4:40

2pBV9. Changes in ultrasonic images of tissue damaged by high-intensity focused ultrasound *in vivo*. Feng Wu, Zhi B. Wang, and Zhi L. Wang (Inst. of Ultrasonic Eng. in Medicine, Chongqing Medical Univ., Box 153, 1 Medical College Rd., Chongqing 400046, PROC, chhifu@public.cq.sc.cn)

In order to clarify the effects of high-intensity focused ultrasound (HIFU) on the liver *in vivo*, the morphological changes in a large animal model were detected by quantitative analysis of ultrasonic image. One region of the liver was selected as a target tissue by ultrasonic imaging. Then, using the method of focal planes, the target part of the liver was resected by ultrasound-monitored HIFU with a 1.6-MHz extracorporeal spherical-bowl transducer. Ultrasonic images of the liver at the selective region were acquired before, immediately, and consecutively after HIFU treatment. The bit difference of ultrasonic image at the selective damage of the liver *in vivo* before and after HIFU treatment was detected by a quantitative analysis system. It was observed immediately after focused extracorporeal pyrotherapy. Sharp changes in ultrasonic image were also detected by consecutive monitoring after treatment. It corresponded to the histological characteristics of the changes of the damaged tissue. These results suggest that as a method to detect necrosed tissue, the quantitative analysis of ultrasonic image may also be used as an indicator of morphological changes after HIFU treatment.

4:55

2pBV10. Ultrasound-positioned high-intensity focused ultrasound in the ablation of superficial bladder wall in miniswines. Zhi B. Wang, Feng Wu, Zhi L. Wang, and Chuan Liu (Inst. of Ultrasonic Eng. in Medicine, Chongqing Medical Univ., Box 153, 1 Medical College Rd., Chongqing 400046, PROC, chhifu@public.cq.sc.cn)

In order to simulate the ablation of a superficial bladder tumor, the effectiveness of ultrasound-positioned high-intensity focused ultrasound (HIFU) on the bladder wall was determined. One part of the bladder wall in 10 miniswines was selected as a damage region using ultrasonic imaging. Then, it was treated with a 1.6-MHz extracorporeal spherical-bowl transducer. Animals were killed immediately after treatment and the bladder wall and rectal tissue were examined macroscopically and histologically. As a result, brighter echoic regions at the selective damage of the bladder wall were detected by ultrasonic imaging immediately after treatment. These brighter echoes corresponded to the acute bladder wall damage which caused obvious necrosis on the superficial bladder wall. Also, histological analysis of the treated areas revealed epithelial denudation and irreversible changes of submucosal and superficial muscular layer under light and electron microscope. Two of the ten animals had microscopic hematuria. No macroscopic hematuria and rectal perforation occurred except for one case of a small burn on the rectal wall. It was concluded that as an extracorporeal approach HIFU can be used successfully to sonicate the selective region of the bladder wall in a large animal model *in vivo*.

5:10

2pBV11. Effects of high-intensity focused ultrasound on H_{22} liver tumor: An evaluation with different therapeutic programs. Feng Wu, Zhi B. Wang, and Zhi L. Wang (Inst. of Ultrasonic Eng. in Medicine, Chongqing Medical Univ., Box 153, 1 Medical College Rd., Chongqing 400046, PROC, chhifu@public.cq.sc.cn)

Most research shows that high-intensity focused ultrasound (HIFU) offers an extracorporeal approach to local removal of tumors. In order to choose the optimal conditions for clinical trials, this study was to evaluate the effects of different therapeutic programs of HIFU with 1200 W/cm^2 on H_{22} liver tumors. Seventy-three ICR tumor-bearing mice were divided into a control group and HIFU therapeutic groups. The therapy programs were defined by the numbers of pulses and pulse durations of HIFU with a 1.6-MHz focused transducer. The various parameters of tumor growth, x-ray, histology, electron microscopy, and mice nutritional state were used to assess the results of HIFU treatment. The data showed that HIFU had an inhibitory effect on H_{22} tumor growth in all therapeutic groups. With the same input power, the local effects of tumor removal were dependent upon the pulse durations and numbers of pulse. When the total number of pulses increased within a short time, the inhibitory effect was stronger. However, the nutritional state of animals in this group became worse. It implies that severe stress response and catabolism induced by an increase of HIFU pulse in a short time would occur.

2pEA1. Ultrasonic echo signals obtained in the outdoor environment. Michael J. Anderson, Jeffrey Luke, John Canning, and Dean B. Edwards (Dept. of Mech. Eng., Eng. Phys. Bldg. 324O, Moscow, ID 83844-0902)

Many, if not most, applications of ultrasonic transducers in air are for ranging systems used in a relatively structured environment. We describe the application of ultrasonic transducers to range sensing for a robotic autonomous vehicle that is intended to operate outdoors in a forested environment. Unlike the indoor environment, application of ultrasonic ranging outdoors involves a much more cluttered environment. The outdoor environment contains a large number of categories of objects and features, as well as a wide variation within each category. In this talk, a statistical summary of echoes obtained from features including ground contour, roughness elements, and obstacles common in the forest environment is presented. Information that can be extracted from the echo data that is useful to an autonomous controller is then discussed.

2:30

2pEA2. Modeling of electrostatic ultrasonic transducers with micro air-gap structure. Li-Feng Ge (Dept. of Phys., Anhui Univ., 3 feixi Rd., Helfei 230039, PROC)

A theoretical model developed by previous papers, i.e., the plate-on-air-spring model or short-tube model (or DK model) [L.-F. Ge, J. Acoust. Soc. Am. **100**, 2809 (1996), and Chin. Sci. Bull., Academia Sinica **42**, 22 (1997)], has been successfully extended to a generalized case, in which diaphragms of transducers are loaded also by in-plane tensile forces. Based on the dynamic analysis of such an electrostatic transducer, its diaphragm can be considered as a tensile thin plate supported by air-spring, or as a short tube enclosing air, terminated by a flexible tensile diaphragm and grooved backplate as a rigid wall. The physical model and mathematical formulation describing the transducer behavior has been further developed. A comparison between the tensile-plate-on-air-spring model (or TDK model) and the plate-under-tension model (may be termed TD model) [M. J. Anderson *et al.*, J. Acoust. Soc. Am. **97**, 262–272 (1995)] is discussed in the paper by an example of predicting the resonant frequencies of a U-grooved backplate transducer with $T=100$ N/m and $Vp=250$ V. The fundamental frequency is estimated by the new model at 349 kHz, corresponding pistonlike motion of the diaphragm, and second at 515 kHz, corresponding to the first bending vibration mode. The predictions are more consistent with the measurements reported. [Work supported by the Anhui Education Council Foundation.]

2pEA3. Control of particles in a standing wave field using ultrasonic vibration. Shinfuku Nomura, Kouichi Murakami, Yukinori Yoshikawa, and Junji Ochi (Ehime Univ., Dept. of Mech. Eng., 3, bunkyo-cho Matuyama, 790 Japan, nomu@en1.ehime-u.ac.jp)

In order to control the motion of micromachines by acoustic power, the behavior of particles falling in several liquids with a standing wave field was studied experimentally. A PZT transducer with a frequency of 28 kHz was fixed to the bottom of a cylinder. Several small tubes were inserted in this cylinder, and glass particles with a diameter of about 1.5–3.5 mm were dropped in these tubes, respectively. Since cavitation bubbles are observed by applying ultrasonic vibration to a liquid, cavitation intensity as estimated from the erosion loss of an aluminum sheet was measured to investigate the effect of cavitation generation on the radiation pressure. Cavitation intensity in degassed water was weaker than that in ion-exchanged water; however, the decrease in velocity of the glass particles by applying ultrasonic vibration exhibited the greatest deceleration in the degassed water. Ultrasonic power effectively acts on a particle as a radiation force when cavitation does not occur and there is almost no damping of the ultrasonic wave. When varying the tube diameter, as the ratio of the diameter of tube to the particle diameter increased, so did the deceleration. All particles were levitated by the ultrasonic radiation force in a ratio of more than 0.6.

2pEA4. Miniaturized ultrasonic sensor system for liquid analysis. Bernd Henning, Peter C. Daur, Alexander Wolf (Institut für Automation und Kommunikation e.V. Magdeburg, Steinfeldstrasse 3, D-39179 Magdeburg-Barleben, Germany, hen@ifak.fhg.de), Peter Hauptmann, and Alf Puettmer (Otto-von-Guericke Univ. IPE, Pf 4120, D-39106 Magdeburg, Germany)

At the moment, known commercial devices to measure the sound velocity in liquids are limited in their application because the relation between velocity and concentration of substances is often not clear, for instance, if it is a parabolic curve. Additionally, the temperature dependence shows similar behavior. This contribution will present an ultrasonic sensor system consisting of a miniaturized multisensor arrangement for the comprehensive acoustic characterization of liquid mixtures. The sensor is based on segmented cylindrical piezoceramics and measures velocity, impedance coefficient, attenuation coefficient, and temperature. If it is a known liquid mixture it is possible to use the measuring quantities to calculate the material properties acoustical impedance and absorption or the concentration of selected substances in complex liquids. The sensor system is able to adapt itself to different and changeable absorption conditions which is typical of industrial processes. The measuring chamber is optimized to investigate small volumes of liquid specimens. In this contribution the sensor design and the developed approach for the continuous and simultaneous measurement of acoustic properties of liquids will be described. Application examples of the sensor in the chemical and food industry will show the advantages and limits of our new sensor system.

2pEA5. The multicomponent composition of the low acoustic impedance matching layer for the ultrasonic transducer operating in the air. Tadeusz Gudra (Inst. of Telecommunication and Acoust., Wroclaw Univ. of Technol., Wybrzeze Wyspianskiego 27, 50-370 Wroclaw, Poland)

Piezoceramic transducers with matching layers are usually used to generate an ultrasonic wave in the air within the frequency range above 100 kHz. The paper presents a new material composition of low acoustic impedance named ITAKOM, whose acoustic characteristics makes it applicable as a matching medium between a piezoelectric transducer and a gas medium in a wide range of frequencies. Porosity is the common feature of all the lowest acoustic impedance materials. The results of the studies of different material compositions show that pore diameters and

their percentage in the composite volume have greater importance than the composite make-up and render possible the elaboration of a composite material whose parameters can be defined by the percentage interdependence of components. Due to the comparatively wide range of density and wave velocity materials of acoustic impedance ranging from $0.2-1\times10^6$ Pa·s/m can be produced. An example of an application of this material to construct the focusing ultrasonic transducer operating in the air at the frequency $f=1.3$ MHz in the setup of phase sensitive scanning acoustic microscopy as well as the results of object measurements are presented in the ultrasonic journal [Gudra *et al.*, Ultrasonics **34**, 711–719 (1996)].

3:30

2pEA6. High-intensity ultrasound for dewatering of slurries. Luis Elvira-Segura, German Rodriguez-Corral, Enrique Riera F. de Sarabia, and Juan A. Gallego-Juarez (Instituto de Acustica, CSIC, Serrano, 144, 28006 Madrid, Spain)

Dewatering is a process in which the water is removed from a product without changing its phase. Fine particle slurries are difficult to dewater and several processes such as filtration and centrifugation are conventionally applied. These processes, which are efficient to remove free water, are ineffective in removing water from interstitial spaces. High-intensity ultrasound can be used to assist conventional filtration processes in order to increase the rate of dewatering. Particularly, the application of ultrasonic energy has shown to be useful as a postfiltration process, once the free water has been removed. In this paper a new system is presented in which the combination of vacuum filtration and ultrasonic energy results in very efficient dewatering of very fine slurries constituted by particles sized between 0.1 and 10 μ. The system is based on the application of direct coupled ultrasonic energy to the cake formed on the surface of a ceramic vacuum filter by means of specially designed plate transducers. The obtained results demonstrate that the application of ultrasound significantly increases the interstitial water removal and, consequently, it diminishes the energy consumption of the whole process (dewatering and drying).

2pEA7. Parametric array in air: Distortion reduction by preprocessing. Thomas D. Kite (Dept. of Elec. and Comput. Eng., Univ. of Texas, Austin, TX 78712-1084, tom@vision.ece.utexas.edu), John T. Post (Univ. of Texas, Austin, TX 78713-8029), and Mark F. Hamilton (Univ. of Texas, Austin, TX 78712-1063)

In a parametric array, highly directional low-frequency sound is generated by the self-demodulation of an intense, amplitude-modulated high-frequency sound beam as a result of nonlinear propagation effects. The term ''audio spotlight'' was introduced by Yoneyama *et al.* [J. Acoust. Soc. Am. **73**, 1532 (1983)] for a parametric array in air used to generate directional audio frequency sound with an ultrasonic primary beam. Berktay's far-field solution [Berktay, J. Sound Vib. **2**, 435 (1965)] predicts a demodulated secondary waveform along the axis of the beam that is proportional to the second time derivative of the square of the modulation envelope. The secondary wave is therefore generated with high levels of harmonic distortion, even at moderate modulation indexes [Blackstock, J. Acoust. Soc. Am. **102**, 3106(A) (1997)]. Integrating the modulation signal twice and taking the square root removes this distortion; however, the resulting reduction in distortion due to taking the square root is severely limited by the bandwidth of the primary beam transducer. Here, the characteristics of the transducer are taken into account in developing an appropriate predistortion scheme to achieve high quality reproduction. Relationships between distortion, modulation index, secondary bandwidth, and secondary sound-pressure level are also discussed, and results of simulations are presented. [Work supported in part by ARL:UT IR&D.]

4:15

2pEA8. Acoustical imaging in air by a low-cost system working in the audio band. Andrea Trucco (DIBE–Univ. of Genoa, Via Opera Pia 11A, 16145 Genoa, Italy)

In order to generate a two-dimensional acoustic image of an aerial scene, a system working in the audio band and composed of low-cost conventional electroacoustic and computation devices has been developed and tested. Such a system uses a loudspeaker for the emission of acoustic pulses, eight microphones for the reception of backscattered waves, a generation/acquisition digital board, and a personal computer. As in medical echography, the adopted algorithm for the image formation is a wide-band coherent beamforming followed by a scan conversion in order to display the image in a Cartesian format (as a top view of the imaged scene). Robotic vision and remote measurement are potential applications of the system developed. Two major problems that were faced are the calibration of the microphones and the study of the best configuration in terms of pulse waveform and microphone placement. A simple calibration algorithm was achieved by comparing the obtained point spread function with the theoretical expectations, whereas the best configuration was obtained by taking into account the constraints imposed by the instrumentation and the application addressed. The obtained images are of good quality, also considering the low-cost instrumentation and the highly reverberant environment in which the experiments were performed.

4:30

2pEA9. Numerical analysis of high-intensity ultrasonic processing systems. Cleofe Campos-Pozuelo (Instituto de Acustica (CSIC) Serrano, 144 28006 Madrid, Spain), Bertrand Dubus (Institut d'Electronique et de Microelectronique du Nord, 59046 Lille Cedex, France), and Juan A. Gallego-Juarez (Instituto de Acustica (CSIC) Serrano, 144 28006 Madrid, Spain)

High-intensity applications of ultrasonic energy in industrial processing are based on the performance of the power transducers and their coupling with the processing chamber. In fact, the right distribution of the acoustic field inside the treatment chamber and the efficiency of the system transducer-chamber are determinant factors for the feasibility of the applications. Therefore, the knowledge of the influence of geometry and dimensions of the processing chamber as well as the effect of the excitation transducers on the pressure field distribution is essential for the development of practical systems. This paper deals with the finite element modeling of a high-intensity ultrasonic processing system which is composed of a flexural-plate transducer and a cylindrical tube with characteristic dimensions much longer than the wavelength. A three-dimensional numerical procedure has been developed for modeling the finite amplitude acoustic field. Fundamental and second harmonic pressure distribution are calculated for several chamber geometries and excitation conditions. It has been found that the efficiency of the system is dependent on the geometry and dimensions of the chamber as well as on the efficiency, dimensions, and vibration distribution of the exciting transducer. The results give a guideline for the design of practical processing systems.

4:45

2pEA10. A method of interpolating the diffractive information of the sphere-baffled microphone in the sound field of the spherical wave. Kimitoshi Fukudome (Dept. of Acoust. Design, Kyushu Inst. of Design, Fukuoka, 815 Japan)

The sphere-baffled microphone (SBM) has been used for estimating DOA of progressive plane waves and their extractions, but it is now planned to construct the diffractive information directory (DID) of the SBM with DOA entry and source_distance entry in the sound field of spherical wave. This paper deals with the interpolation methods of getting information associated with entries not appearing in DID. Numerical computation of the diffractive information is done for the 2-element SBM (right and left microphones at both ends of a diameter of 17.68 cm) at frequency points corresponding to the sampling frequency 22.05 kHz and 1024 point DFT. Two data sets of DOA interval of 6° [0,6,12, . . .] and [3,9,15, . . .] are used for interpolation and evaluation of errors. Interpo-

lations and their error evaluations are done in the regions of both the log magnitude versus frequency and the group delay versus frequency. Both the bilinear interpolation and cubic interpolation method result in significant interpolation errors up to 10 dB and 0.14 ms for the shadow region. Finally, a new method is presented with high accuracy of interpolation based on the landmarks-loci of the diffractive information.

5:00

2pEA11. A conceptual experiment of direct converting digital microphone. Yoshinobu Yasuno (Matsushita Commun. Industrial Co., Ltd., 600 Saedo, Tsuzukiku, Yokohama, 224 Japan) and Yasuhiro Riko (Riko Assoc. 1988-34, Kitahassaku, Midoriku, Yokohama, 226 Japan)

A transducer which directly converts signals from analog acoustic to digital electric is described. This consists of a subtracter, a sampling and holding circuit, a sigma-delta modulation circuit as a comparator, an accumulator, and a local digital-to-analog converter similar to a typical electric analog-to-digital converter. The subtracter is an electrostatic device which has a diaphragm, driving electrode, and detecting electrode. The driving electrode is divided into corresponding digital signal bits by the ratio of each area which enables one to drive the diaphragm digitally and is regarded as an electroacoustic digital-to-analog converter. The detecting electrode makes electric signals proportional to the displacement of the diaphragm driven by subtracting the incoming acoustic signal and electrically driven force. This is regarded as the subtracter. This detected signal is amplified and sampled-held and modulated by the sigma-delta procedure and generates subtracted signal to $+$ or -1 bit which is added to the accumulator memory by a very high-speed clock rate. The output of the accumulator is the digital signal output and is also given to the driving electrodes. A 4-bit conceptual device was developed for an experiment. Some results will be reported.

5:15

2pEA12. Acoustic simulation for a loudspeaker using FEM/BEM. Veijo Ikonen, Antti Suutala, and Seppo Pohjolainen (Tampere Univ. of Technol., Dept. of Math., P.O. Box 692, FIN-33101 Tampere, Finland, ikonen@alpha.cc.tut.fi)

Although the theory of acoustics is well known, computers and numerical methods have not been effectively utilized in the field. Formulating a sufficiently good physical model is often difficult. The wave equation for pressure can easily be derived, but the boundary conditions are not so obvious. The structure of the walls of an acoustic cavity and the behavior of surface materials can be quite complex. In addition, under the influence of an acoustic field the structures can start vibrating, and this vibration is then coupled to the acoustic field. Mathematically this leads to a system of two partial differential equations. This paper studies the problem of computing an internal acoustic field of a loudspeaker box. The acoustic properties of walls, made of MDF, are taken into account by using the impedance boundary condition. The coupling between the structure and the fluid is also considered. Both finite-element and boundary-element methods (FEM/BEM with SYSNOISE) are used for numerical computations and the results are compared with each other and with analytical solutions. When the wavelength is decreased, the element grid must be refined and the number of equations becomes very large. This is why partial differential equation models are more suitable in low frequencies.

5:30

2pEA13. Vibration characteristics of high frequency and complex vibration systems of 160 kHz to 1 MHz for ultrasonic wire bonding. Jiromaru Tsujino and Hiroyuki Yoshihara (Kanagawa Univ., Faculty of Eng., 3-27-1 Rokkakubashi, Yokohama, 221 Japan)

Vibration characteristics of high frequency and complex vibration systems of 160 kHz to 1 MHz for ultrasonic wire ball bonding are studied. High-frequency and complex vibrations have been shown to be very effective for ultrasonic wire bonding of IC, LSI, or various electronic devices. Required vibration displacement amplitude for successful bonding of a 600-kHz system is about 1/30 that of a conventional 60-kHz system. For installing a conventional ceramic capillary 1.8575 mm in diameter required for ball bonding, longitudinal to complex transverse vibration systems 5.5–7.0 mm in diameter are proposed. Vibration velocity distributions along longitudinal, transverse vibration systems and ceramic capillaries and vibration loci are measured by laser Doppler vibrometers. The ceramic capillaries are measured vibrating in transverse vibration modes with one, two, or three vibration nodes along them at 160 kHz to 1 MHz, and the conventional capillaries are revealed applicable in such high-frequency systems. The free edge of the capillary vibrates in elliptical or circular locus with the two longitudinal vibration systems driven simultaneously. Maximum vibration velocity at a capillary tip is over 0.5 m/s (peak-to-zero value) which is enough for bonding of thin wires successfully at high frequencies.

2pMU1. Composite materials for musical instruments: The maturity. Charles Besnainou (Lab. d'Acoustique Musicale, Univ. Pierre et Marie Curie, 4, place Jussieu-75252 Paris Cedex 05, France)

Nowadays, musical instruments made of composite materials allow comparison with good instruments made by craftsmen. These instruments result from 20 years of accumulated experiments carried out in laboratories. The first substitute of wood was a composite of wood: plywood. Over 70 years with this new material, honorable results were obtained for an industrial line of products: piano, harp, guitar, double bass. However, composite materials made of fibers and resin are designed to imitate the structure of wood. So a specific knowledge is needed. The first attempts were on bows because it seemed easy; good results were obtained with fiberglass. The next step was to replace the neck of an electric guitar. However, it was a long time before acoustic elements such as a soundboard

were designed. One needs first of all to develop a methodology to measure the mechanical parameters of wood: density, Young's modulus, and damping; and to cross over the mechanical results with the subjective choices of expert craftsmen. Of course, assimilated composite techniques are required. And then to learn, as in traditional apprenticeship, how to feel the quality of an instrument. Paradoxically, in terms of sound qualities, new materials need the same knowhow used by traditional instrument makers. Maturity means that the updated composite techniques are now very simple to be assimilated by craftsmen and manufacturers too; the prices of instruments are sufficiently low and the sound qualities have reached a good level. Some instruments, namely, the violin, lute, and guitar are demonstrated.

1:25

2pMU2. Nonlinear effects in a vibrating string (wire). Roger J. Hanson, H. Kent Macomber, and Michael P. Kassakatis (Dept. of Phys., Univ. of Northern Iowa, Cedar Falls, IA 50614, roger.hanson@uni.edu)

Many unusual effects are observed in vibrating strings or wires as a consequence of tensional changes and longitudinal motion which yield coupled nonlinear equations for transverse motion in orthogonal directions. For a wire driven sinusoidally in a transverse direction, notable effects observed at driving frequencies near a natural resonance include the generation of motion perpendicular to the plane of the driving force, sudden jumps in amplitude and phase, whirling motion, and hysteresis [R. J. Hanson, J. M. Anderson, and H. K. Macomber, J. Acoust. Soc. Am. **96**, 1549–1556 (1994)]. Further work demonstrates the generation of second, third, and higher harmonics with amplitudes sometimes comparable to the first. These harmonics, present in both the driving and perpendicular directions, contribute to a very complex total motion. All of the effects are very sensitive to asymmetries which produce slight differences in free vibration frequencies in two orthogonal directions. For the large amplitude free vibration of a plucked string, there are also significant consequences of the nonlinear effect of the tension changes. These effects for a plucked string will be related to several musical instruments. Phenomena for both the driven and plucked cases will be qualitatively demonstrated with video displays of the signals from optical motion detectors.

1:50

2pMU3. On the acoustics and psychology of piano touch and tone. Anders Askenfelt (Dept. of Speech, Music and Hearing, KTH, Box 70014, S-10044, Stockholm, Sweden), Alexander Galembo, and Lola L. Cuddy (Queen's Univ., Kingston, ON K7L 3N6, Canada)

By way of ''the touch,'' a pianist is able to achieve two degrees of freedom in the control of the key motion. Besides the final hammer velocity, the pianist can control, to some extent independently, the force history between the key and finger. By controlling the acceleration history of the key, while keeping the final hammer velocity constant, the pianist can vary the duration of the key and hammer motion and the forces between the interacting parts of the action. This will influence the intensity of vibrations in the hammer shank and of a noise precursor in the radiated sound. This report addresses the pianist's ability to change the touch parameters and to control them (at will) for musical purposes. The traditional controversy between physicists and some pianists raises a psychological question: ''Why do some pianists think they are able to control a timbre of the individual tone by touch?'' One hypothesis is that variations in touch change the perception of a tone for the pianist, but not for a listener, because for the pianist the tone perceived starts at finger–key contact, while for a listener it starts when the hammer hits the string.

2pMU4. Dynamic mechanical measurements on violin wood and audience evaluations of violin tone quality. Edwin R. Fitzgerald (Johns Hopkins Univ., 3400 N. Charles St., Baltimore, MD 21218), Carleen M. Hutchins, and Morton A. Hutchins (Catgut Acoust. Soc., Montclair, NJ 07042)

At the 125th Acoustical Society of America meeting in Ottawa, Canada, values of complex shear compliance ($J^* = J' - iJ''$), modulus ($G^* = 1/J^*$), and shear wave velocity and attenuation, measured over a continuous frequency range from 10 to 10 000 Hz at 20 °C and 50% RH, were described for samples of spruce and maple wood used in the construction of six violins. Four wood samples were measured for each violin, viz., samples of spruce and maple with and without cross grain. Relation of the violin wood dynamic mechanical properties to plate tuning of the violins also was discussed. Following these presentations, two members of the Ottawa Symphony orchestra each played two short pieces on each of the six violins, and the audience was asked for written comments on the tone quality of each violin. The evaluations display some variations as to the violin(s) with the best tone, but one of the six was rated as good or best tone by none, and the worst tone by many. The dynamic mechanical shear properties of this violin's wood differ in several respects from those of the other violins. Similar property differences for this wood relative to the others also exist in extensional moduli determined from flexural vibrations.

2pMU5. Vibrational modes of a tenor steel pan. Uwe J. Hansen (Phys. Dept., Indiana State Univ., Terre Haute, IN 47809, phhanse@scifac.indstate.edu) and Thomas D. Rossing (Northern Illinois Univ., DeKalb, IL 60115)

The tenor or lead pan has 28 or 29 notes covering the range of C_4 to E_6. In spite of its being the lead voice in a typical steel band, little research has been reported previously on its modes of vibration or its acoustical behavior. Using electronic TV holography, we have studied the modes of vibration of the various note areas in tenor pans by two different makers. Note areas generally have one or two overtone modes tuned harmonically to the fundamental [Rossing *et al.*, Phys. Today **49**(3), 24–29 (1996)]. Special attention has been paid to the strong acoustical and mechanical coupling between the note areas as they vibrate.

2pMU6. Observation of the brass player's lips in motion. R. Dean Ayers (Dept. of Phys. and Astron., California State Univ., Long Beach, 1250 Bellflower Blvd., Long Beach, CA 90840, rdayers@csulb.edu)

Mouthpieces with flat windows are used to examine the lip reed's motion during the steady parts of notes played on brass instruments. Magnified stroboscopic images show different parts of the upper lip moving

out of phase with each other. Sighting directly along the channel between the lips, one can observe a Rayleigh wave propagating downstream in the flesh of the upper lip. Downward crests of this disturbance reach maximum amplitude at the downstream end of the channel, where they provide most of the valving action on the air flow. The lower lip moves more as a lumped element, and mostly in the longitudinal direction. A computer model for this behavior will be complicated and may not show much improvement over the two-dimensional model of Adachi and Sato [J. Acoust. Soc. Am. **99**, 1200–1209 (1996)]. Of potentially greater value is a more accurate mental image for performers. Muscles controlling the embouchure just establish the boundary conditions for the motion of a thin, passive layer of flesh. This knowledge may help beginners to avoid such practices as jamming the mouthpiece against the lips and tensing muscles against each other unnecessarily.

3:15

2pMU7. Number of degrees of freedom of a lip-reed in brass-instrument playing. Xavier Boutillon (Dept. of Phys., Univ. of Michigan, Ann Arbor, MI 48109-1120)

A lip-reed is a double continuous system that potentially exhibits several degrees of freedom. Numerical simulations for sound synthesis as well as fitting a model with measurements naturally improve while increasing the number of degrees of freedom that are put into the model. However, this parameter is worth investigating as such. In a first approach, lips are coupled to a Helmholtz resonator whose resonance factor is actively reinforced, as described in Chen and Weinreich [''Nature of lip reed,'' J. Acoust. Soc. Am. **99**, 1227–1233 (1996)]. The dimensionality of the attractor or permanent regime of this nonlinear dynamical system is computed with embedding techniques of the corresponding time-series and information-based measurements [Gershenfeld *et al.*, *Time Series Prediction* (Addison-Wesley, Reading, MA, 1994)]. Preliminary results indicate a dimension of 1, 2 or 3 for different couplings between the lips and the resonator. The link with the number of freedom of the lip-reed will be discussed. [Work supported in part by CNRS and NSF.]

2pMU8. Annular time-domain acoustic source for horn acoustics. Joaquim B. Agullo and Ana Barjau (Dept. of Mech. Eng., Diagonal, 647, 08028 Barcelona, Spain, agullo@em.upc.es)

The time-domain description of horns is needed in time-domain simulations of acoustical systems such as wind instruments and is very helpful to understand their transient behavior. Unidimensional horn wave equations have been used as a first approximation. The Webster horn equation, however, is too unrealistic for horns with intense flare. The improved horn equation developed by Keefe *et al.* [*Proceedings of the SMAC-93* (1993), pp. 496–500] may be promising. A discretized approach that assumes the horn is made of cylindrical and conical elements with plane and spherical waves, respectively, has been widely used. More general alternatives based on the Kirchhoff integral are attractive because they can handle 2 and 3-D acoustic fields and lead to a surface discretization instead of volume discretization (as required in FEM). For axisymmetric horns, the use of an annular time-domain unit source, not implemented in commercial codes, dramatically reduces the number of elements. This paper presents the development of such a source and its application to time-domain horn acoustics. An example is presented for a cathenoidal horn and its results are compared to time-domain measurements.

3:45

2pMU9. Determining resonance frequency changes due to bore irregularities in woodwinds. Cornelis J. Nederveen (Acacialaan 20, 2641 AC Pijnacker, The Netherlands) and Jean-Pierre Dalmont (Université du Maine, 72017 Le Mans Cedex, France)

To determine tuning changes due to deviations from an ideal cylindrical or conical bore constituted by holes and by diameter variations, these deviations are modeled by local changes in compressibility and inertance. The magnitude of a compressibility change, being proportional to the volume change of a perturbation, is easily determined, but inertance changes pose more problems, since they may be less than proportional to the volume change. Determining these inertance changes is possible in various ways. An approximation (with a systematic error) is obtained by depicting the 3-D flow as stratified and integrating 2-D results obtained from Schwarz–Christoffel transformations, for which various accurate analytical and numerical solutions are available. Exact results can be obtained with finite difference methods: they are simple, have no systematic error, and only demand a large computing power. Results will be presented for correction impedances at hole junctions, hole ends with various flanges, and toroidal bends. A method of experimental verification and some results will be discussed.

4:00

2pMU10. Modeling in 3D of directional radiation of curved woodwind instruments. Rene E. Causse and Carole Lheureux (IRCAM, 1 place Igor Stravinsky, 75004 Paris, France)

In a previous presentation [Causse *et al.*, J. Acoust. Soc. Am. **100**(4), Pt. 2, 2812 (1996)], the directional pattern of some instruments of the woodwind family was modeled and compared. These instruments, oboe, clarinet, and flute, were chosen for their straight tube and for the fact that the simplification that the holes of the lattice are aligned and oriented in the same direction did not introduce big errors. A second class of instruments of this family are instruments with curved tubes, for example the bassoon, the bass clarinet, or the alto saxophone. The original model was modified to take into account the curves but also the real orientation of the holes. The far-field radiated pressure was calculated at a constant radius on a sphere enclosing the instrument. The main difficulty with this model is expressing the directivity of each opening (holes and bell) in the same coordinate system. In the cases where this leads to excessive calculation, some simplifications are proposed. Model results were compared with experimental measurements of actual instruments. Comparisons of the directional radiation between these instruments and also with straight ones will be presented. Implications for the perception of these instruments will be discussed.

2pNSa1. Reactions to aircraft noise. Truls Gjestland (SINTEF Telecom and Informatics, N-7034 Trondheim, Norway, truls.gjestland@informatics.sintef.no)

The data from three Norwegian surveys on reactions to aircraft noise have been reanalyzed. Data from more than 9000 respondents have been included. The response to a general annoyance question is compared to the response to questions on special effects concerning speech communication, sleep and rest disturbance, ambient noise, behavioral patterns, etc. The established dose–response relationships will form the basis for new Norwegian guidelines for assessing aircraft noise.

1:30

2pNSa2. The assessment of environmental noise—ISO 1996. Ian H. Flindell (Inst. of Sound and Vib. Res., Univ. of Southampton, UK) and Nicole D. Porter (Natl. Phys. Lab., Teddington, UK)

The concept of a grand ''general noise annoyance model'' which takes different noise sources and different situations into account by appropriate adjustments or correction factors is very attractive. On the other hand, it is well known that different people respond to different components of the overall situation (*acoustic features*) at different times, and that this selective attention process can be essentially unpredictable. In order to make progress in this field, it is essential that any new methods of assessment of environmental noise must take this inherent flexibility into account. This paper describes an input-process-outcome model which the authors have been working on as the underlying framework for the current revision of ISO 1996 ''Description and measurement of environmental noise.'' In essence, there are three possible outcomes of assessment (no impact, intermediate impact, and unacceptable impact) and three comparison processes (change in noise, new noise compared against existing background noise, and absolute criteria) which can be applied to the various inputs to determine the assessment outcome. The model allows sufficient flexibility to accommodate most existing national noise assessment procedures, reflects current scientific thinking, and provides a sound basis for choosing the best balance between the costs and benefits of noise control action.

1:55

2pNSa3. Loudness of combined noises derived from singular and concurrent community noises. Birgitta Berglund and Mats E. Nilsson (Inst. of Environ. Medicine, Karolinska Inst. and Dept. of Psych., Stockholm Univ., Stockholm, Sweden)

It seems logical to assume that the total loudness of combined noises should correspond to the arithmetic sum of the loudnesses of the singular noises as perceived within the combined noise. Although postulated by Powell in the mid 1970s, this hypothesis has not yet been empirically tested. In real life situations, a particular community noise is always perceived within a complex of environmental noises, and therefore, both its loudness and the annoyance it evokes will be associated with the noise immission rather than the noise emission from the singular source. Binary combinations of community noises were tested at up to seven levels of loudness and subjects estimated the loudness of combinations as well as the singular sounds with the aid of magnitude estimation. The loudness summation did not follow Powells arithmetic summation hypothesis. The loudness of singular noises differs when heard alone compared to when heard within the noise combination. As a consequence the type of interaction between loudness of community noises in real life situations (heard within) clearly has implications for the development of better models for total loudness as well as for total annoyance. Earlier models hvae relied on data produced from singular noise sources when heard alone.

2:20

2pNSa4. Psychological evaluation of sound environment with mixed sources. Sonoko Kuwano, Jiro Kaku, Tohru Kato, and Seiichiro Namba (Dept. of Environ. Psych., Osaka Univ., 1-16 Machikaneyama, Toyonaka, Osaka, 560 Japan)

In order to make the experimental situations closer to actual situations, experiments have been conducted in field conditions, where various sounds were audible. The results suggested that generally speaking, L_{Aeq} was a good measure for the evaluation of environmental noises. However, there were some cases where L_{Aeq} did not show good correspondence with subjective impressions. On the basis of the results of the field experiments, an experiment was conducted in a laboratory situation with precisely controlled stimuli in order to examine the applicability of L_{Aeq} to sound with mixed sources. Sounds which consisted of aircraft noise, road traffic noise, and train noise were used. Three events of each noise source were included in 15-min stimuli and the duration of road traffic noise was varied in three stimulus conditions. Subjects were asked to judge instantaneous loudness using the method of continuous judgment by category. After instantaneous judgment was over, overall impression of loudness of each sound source as well as the overall loudness of 15-min stimuli were judged. The following analyses was conducted; (1) comparison among three sound sources, (2) comparison among three experimental conditions, and (3) overall evaluation of sound environment with mixed sound sources.

2:45

2pNSa5. Reaction to combined sources of noise may depend on the respondents' interpretation of the questions. R. F. Soames Job (Dept. of Psych., Univ. of Sydney, NSW 2006, Australia, soamesj@psychvax.psych.su.oz.au)

Reaction to multiple sources of noise has proven difficult to explain. The unexpected results of assessment of total reaction to noise may not arise from inadequate integration within the subject nor from complexities of the perception of the noise. This abstract suggests that responses to questions regarding reaction to combined sources may reflect the subjects' interpretation of the relevant questions. Requests for reaction to the total noise load may be interpreted as requesting total reaction to the two sources, or average reaction to the two sources, or total or average reaction to the total noise environment. The consequences of such interpretations by the subjects are not easily predicted. Predictions would be influenced by: whether reaction is a unipolar negative scale versus a bipolar scale from negative to positive; whether the combined reaction is an average or a total; and whether the average or total should include consideration of the times for which each noise is not present. Finally, it should be noted that different subjects may interpret the same question in different ways in relation to these alternatives. Examples of the role of these variables are identified, and a set of models of reaction based on the various alternatives proposed.

3:10

2pNSa6. Combined qualitative and quantitative measurements to evaluate noises from combined sources. Brigitte Schulte-Fortkamp (Dept. of Phys., Oldenburg Univ., D-26111 Oldenburg, Germany, brigitte@aku.physik.uni-oldenburg.de)

Previous studies on assessing combined noises have shown the rating of environmental noises from combined sources as a very complex and difficult task. Disturbance and annoyance caused by the influence of noises require in their complexity an adequate procedure of evaluation. There are different theories to explain those rating results of an overall noise situation which is almost rated lower than the most annoying single source. If sounds are synergistic, the criteria and kinds of sources have to be found which are dominant for the person who assesses the noises. In traditional laboratory studies the context is faded out by the evaluation process, while the context effects in field studies play a decisive role and the evaluation of annoyance caused by noise allows the consideration of different factors in a situation where noises are combined. In a current socio- and psychoacoustical field study the process of assessing the noises and the noises as well are precisely described in interviews and acoustical diaries. In another combined procedure of qualitative-explorative and objective-standardized measurements in a laboratory setting specific noise components causing annoyance and disturbance have been identified. The special methodical procedure and results will be presented.

2pNSa7. Annoyance accumulation modeling in a community noise annoyance expert system. Dick Botteldooren (Dept. of Information Technol., Acoust. Group, Univ. of Gent, St. Pietersnieuwstraat 41, B9000 Gent, Belgium)

When the state of the sound environment in a region is monitored by tracing the percentage of people who are annoyed by noise, simulation models for community noise annoyance are needed. They allow, for example, the prediction of the impact of various noise control measures. Building such simulation tools is not an easy task because information is scarce and relations between quantities involved are uncertain. Therefore, an expert system was built that makes optimal use of the scarce information and combines as many expert opinions as possible. Consensus mechanisms, representation of uncertain data, and model uncertainty are key factors in this

model. Combination of annoyance caused by different sources is an important part of the system. Models proposed by various scientists are combined and compared to obtain the most likely global annoyance percentage. Both psychophysical and perceptual models can be applied at the same time. The probability approximation that is used for this task will be introduced. The results of this approach, which combines different opinions, will be shown for a number of example situations.

2pNSa8. Characterization of an urban area's acoustical comfort. Jacques Beaumont (ENTPE-DCGB/URA CNRS 1652, rue M. Audin, F 69518 Vaulx-en-Velin Cedex, France, jacques.beaumont@entpe.fr), Aline Barlet, Christophe Louwrse, and Catherine Semidor (ERIAC, Domaine de Raba, F 33405 Talence Cedex, France)

In this paper a global method to characterize acoustic comfort in urban areas is presented. This method takes into account the relationships between urban forms (shapes, sizes, and material surfaces), the opinions of town-users, and noise descriptors. These descriptors are deduced from a method based on time automatic detection threshold to classify four types of noise. This system allows the study of sound situation in a self-contained way over a long period (several hours). The influence of building design is estimated according to the visualization of the evolution of these descriptors in 2D and 3D maps all over the studied area. The first results show that noise levels fit well with the architectural characteristics of the buildings (facade irregularities, materials,...). To validate this method, experiments were conducted on a Bordeaux central district. The effects of an urban area's morphology on listeners' noise perception are analyzed from investigations carried out with people living or working in the tested site. The aim of this work is to develop a decision-assisting tool in the acoustic design of urban areas. Environmental considerations, such as noise, must be included in urban planning not only to avoid disturbance, but to provide better satisfaction in living in the city.

4:30

2pNSa9. Sound perception of the urban environment through an audio-visual approach. Stephanie Viollon, Catherine Lavandier (Universite de Cergy, IUT Dept. Genie civil, rue d'Eragny, Neuville sur Oise, 95 031 Cergy Pontoise Cedex, France, viollon@u-cergy.fr), and Carolyn Drake (Laboratoire de Psychologie Experimentale, 75 006 Paris, France)

Sound and visual environments of cities are usually studied separately without taking into consideration possible interactions between the two sensory modalities. The present research aims at developing an audio-visual approach for assessing the sound perception of the urban environment. It means an innovative approach which takes into account the influence of visual information on the sound judgment. In a preliminary *in situ* questionnaire, participants rated real-life urban environments along pairs of descriptive adjectives all related to the auditory modality. A Principle Components Factor Analysis revealed four perceptive factors characterizing the perception of the urban environment and also revealed two auditory variables which were the most influenced by the visual setting. Then, with a simulation experimental setting involving the creation of audio and visual artificial fields, a series of semantic differential tests was carried out. Listeners were required to rate the two auditory variables: appeasing–stressing and pleasant–unpleasant for eight sound urban environments and for four different visual settings. The results point out that judgments about the two sound variables are significantly influenced by the visual setting. Moreover, improvements in the experimental procedure suitable for testing audio–visual interactions in an urban context are discussed.

2pNSb1. The effects of exposure of intense free-field impulse noise on humans wearing hearing protection: Implications for new criteria. James H. Patterson, Jr. (U.S. Army Aeromedical Res. Lab., P.O. Box 620577, Fort Rucker, AL 36362-0577, jhpinal@snowhill.com) and Daniel L. Johnson (EG&G, MSI, P.O. Box 9100, Albuquerque, NM 87119-9100)

In a series of studies, human volunteers wearing earmuffs were exposed to high-intensity free-field impulse noise which simulated various military weapons noise. By detonating increasing amounts of explosive material, the exposure level was varied from one at which no effects were expected to a maximum level just below the threshold of injury to the lung and upper airway. The number of blasts was varied from 6 to 100. Temporary threshold shifts (TTS) measured 2 to 6 min after each exposure were used as the measure of effects on hearing. The highest level for each number of blasts at which 95% of the exposed population would not show a

significant TTS was used to establish the maximum safe exposure levels as measured in the open and under the earmuffs. These maximum safe exposure levels exceed the exposure limits used in the United States and other countries. Also, these results suggest that the number-intensity trading rule is more shallow than that used in most criteria. The exposures measured under the earmuff provide a good indication of the hazard. Implications of these results for impulse noise exposure criteria will be discussed.

1:30

2pNSb2. Hearing protectors and hazard from impulse noise: Melding method and models. G. Richard Price and Joel T. Kalb (US Army Res. Lab., APG, MD 21005-5425, dprice@arl.mil)

Studies agree that the protected ear tolerates surprising amounts of energy at very high levels; but with no theory to explain these results, practical application of such findings is like traversing an acoustic minefield. Our modeling of auditory hazard [G. R. Price and J. T. Kalb, J. Acoust. Soc. Am. **100**, 2674 (1996)] suggests the physical basis for the ear's resilience is a function of interaction between the hearing protector's effect on the waveform arriving at the ear and the ear's own complex responses to intense stimulation. We believe that the primary physical basis for hazard is mechanical stress at the level of the hair cell; hence assessment needs to take place in the time domain. Calculation begins either with the pressure history measured under a hearing protector or one derived from a free-field pressure and attenuation measures on the protector. The ear model includes an active middle ear muscle system, an amplitude-limited stapes displacement, and an algorithm for calculating hazard in the cochlea which integrates peak upward stresses at the level of the basilar membrane. In the end, the protected ear's apparent resilience is predictable and can be understood as part of a general theory of auditory hazard.

1:55

2pNSb3. Results of human studies with linear and nonlinear earplugs: Implications for exposure limits. Armand L. Dancer and Pascal J-F. Hamery (French-German Res. Inst. of Saint-Louis, 5 rue du General Cassagnou, BP 34, 68301 Saint-Louis Cedex, France, dancer@nucleus.fr)

Soldiers equipped with linear and nonlinear earplugs have been exposed to large impulses (weapon noises) and audiometric tests have been performed just before and after the exposures. In particular, new nonlinear perforated earplugs (allowing speech communication, detection and localization of acoustic sources) which have been developed at the French–German Research Institute of Saint-Louis are efficient for repeated exposures up to 187-dB peak when they are well fitted [Johnson and Patterson (1996) personal communication]. From various TTS studies it is concluded that: (i) the peak pressure attenuation (measured with a specially designed ATF) grossly underestimates the protection afforded by the earplugs when used in conjunction with the classical criteria for weapon noises (CHABA, MIL-STD, criterion of Pfander, criterion of Smmorenburg). The risk corresponding to an exposure to a slow rise-time impulse (i.e., under an earplug) is much lower than the risk corresponding to an exposure to an impulse of the same peak pressure with an instantaneous rise time, (ii) the L_{Aeq8} attenuation values based on objective insertion loss measurements (ATF) give in most exposure conditions a good evaluation of the auditory hazard, but in some other cases they still underestimate the efficiency of the hearing protectors.

2:20–2:25 Chair's Summary

2:25–2:35 Break

2:35

2pNSb4. Modeling the effect of a hearing protector on the waveform of intense impulses. G. Richard Price and Joel T. Kalb (US Army Res. Lab., APG, MD 21005-5425, jkalb@arl.mil)

Implicit in microphone-in-real-ear (MIRE) or real-ear-attenuation-at-threshold (REAT) tests with a hearing protector is the potentiality that such tests would establish its ability to ameliorate hazard. However, because the sound field under the protector is very different from the free field for which traditional DRCs customarily predict hazard, it is not clear how such measures should be used. The theoretically based mathematical model of auditory hazard we proposed by us as the basis for such assessments calculates motions of structures in the ear [Price and Kalb, J. Acoust. Soc. Am. **100**, 2674 (1996)]. Thus phase relationships in waveforms matter and the model must accurately couple them to the ear. Where only REAT data and free-field pressure measures are available, single path conduction through the protector is assumed and minimum-phase processing to calculate waveforms under protectors is used. Empirical tests with free-field impulses and an artificial head test fixture indicate that such an approximation is surprisingly good. With such calculated waveforms or MIRE measures, a Thevinin-equivalent source to drive the ear which allows the full calculation of auditory hazard with the model is created.

2:55

2pNSb5. A new nonlinear earplug for use in high-level impulse noise environment. Armand L. Dancer and Pascal J-F. Hamery (French-German Res. Inst. of Saint-Louis, 5 rue du Gener. Cassagnou, BP 34, 68301 Saint-Louis Cedex, France, dancer@nucleus.fr)

A nonlinear earplug allows speech communication, detection and localization of acoustic sources, and prevents hearing hazard from high-peak pressure impulses. Improved physical characteristics of a nonlinear earplug are explained: nonlinear attenuation starting with relatively small level (110 dB peak) and improvement of nonlinear attenuation for high levels. Such an earplug is especially designed against weapon noises (up to 190 dB peak). The study is based on experimental approach. Moreover, a theoretical model has been developed to explain the experimental results and to optimize the acoustic nonlinear filter dimensions and configuration. The nonlinearity of such a filter is due to one (or several) little hole(s), the acoustic impedance of which is essentially a viscous resistive one and depends on the particulate velocity in its center.

2pPAa1. Directional microphone array for measurement in an anechoic wind tunnel. Robin J. Alfredson and Alison K. Wilson (Monash Univ., Clayton, Vic, Australia)

An anechoic wind tunnel in which full-scale acoustic measurements may be conducted on automobiles at speeds up to 200 km/h has been constructed. The wind tunnel uses an open jet which is collected and returned in the closed-loop wind tunnel. This design allows for microphones to be positioned outside of the air flow typically some 4 to 5 m from the vehicle. Thus problems associated with extraneous wind noise on the microphones are largely eliminated but this has resulted in the need to develop microphone arrays which have directional characteristics in order to identify noise sources on the vehicle. A wide range of microphone configurations was examined recognizing the various constraints imposed by cost, data collection facilities, frequency range, and the geometry of the wind tunnel and vehicle. The design that produced an optimum solution was based on an arced array of 10 microphones. The output from each was summed having first been weighted. The array could be moved along the vehicle. Data will be presented indicating the characteristics of this and other arrays as well as the cost of construction.

2:35

2pPAa2. Phenomenological theory of the translational relaxation times in gases. Allan J. Zuckerwar (NASA Langley Res. Ctr., MS 236, Hampton, VA 23681-0001)

The classical equations governing the translational dispersion and absorption of sound in a gas yield a solution of such complexity as to obscure the relaxational character of the associated viscous and thermal transport processes. The approach taken here is to solve the secular equation by the method of Pade' approximation, which even to the relatively low order R_{11} yields a remarkably close approximation to the exact solution over a wide range of frequency/pressure ratios. As a result, translational relaxation can be ascribed the attributes of a conventional relaxation process such as relaxation times, relaxation strength, collision numbers, additivity relations, etc. To extend the theory to extremely high values of frequency/pressure ratio, a model is proposed to account for the noncontinuum behavior of the transport coefficients (viscosity and thermal conductivity) as the molecular mean free path approaches the acoustical half-wavelength. The theory shows good agreement with measurements in argon over the classical, Burnett, and transition regions as defined by Meyer and Sessler [E. Meyer and G. Sessler, Z. Phys. **149**, 15–39 (1957)].

2:50

2pPAa3. An automated apparatus for measuring sound speeds in hazardous gases. John J. Hurly (Natl. Inst. of Standards and Technol., Bldg. 221, Rm. A111, Gaithersburg, MD 20899)

Our laboratory has developed an automated apparatus for measuring the sound speed in hazardous gases such as those used in processing semiconductors. The sound speed is deduced from measurements of the acoustic resonance frequencies of a gas-filled, cylindrical cavity. After the cavity is calibrated with argon, the uncertainty in the sound speed is less than 0.01%. The $u(P,T)$ data span the temperature and pressure ranges 200–475 K and 100–1500 kPa. From the measured sound speeds we derive the ideal gas heat capacities from the zero-pressure intercepts with a typical uncertainty of only 0.1%. The virial equation of state is also deduced from $u(P,T)$ providing the temperature-dependent density virial coefficients. In comparisons with Burnett measurements, we find that the densities calculated with the derived virial equation of state have uncertainties of less than 0.1% in density. Some recent measurements in SF6, CF6, and C2F6 will be used to illustrate the systems capabilities. Work in progress on BCl3 will also be discussed.

2pPAa4. Ultrasonic flowmeter for the accurate metering of gases for semiconductor processing. Adam M. Calabrese (Natl. Inst. of Standards and Technol., Bldg. 220, Rm. A55, Gaithersburg, MD 20899, adam.calabrese@nist.gov) and Stuart A. Tison (Natl. Inst. of Standards and Technol., Gaithersburg, MD 20899)

Semiconductor production processes such as chemical vapor deposition rely upon accurate control of the flow rate (in the range of 1–1000 standard cm^3/min) of several ultrapure, yet highly toxic and/or reactive gases. Currently, thermal mass flow meters (TMFMs) are widely used in industry for these processes. Complications with the use of TMFMs arise because the flow must be divided (due to limited dynamic ranges) and calibration is normally performed with inert gases. In the present research, an ultrasonic Doppler shift flowmeter has been developed to measure gas flows. Measurements of the flow-induced phase shift of an acoustic plane wave propagating in an unobstructed tube, combined with the speed of sound of the gas, are used to determine the mean gas velocity. The combination of the mean gas velocity with measurements of the pressure and temperature allow calculation of the mass flow rate. The experimental system uses stainless steel tubes of diameter 0.05–0.1 cm, and frequencies near 100 kHz. No division of the flow is necessary. Prototype meters indicate that sensitivities on the order of 0.75°/standard cm^3/min are possible. Experimental data of two prototype systems using different geometries and receivers will be presented. [Work supported by NIST.]

2pPAa5. Ultrasonic methods for the on-line real-time characterization of mixing in multiphase systems. Leonard J. Bond and Hans Matthiesen (Univ. of Denver Res. Inst. and Dept. of Eng., 2050 E. Iliff Ave., Denver, CO 80208)

There is currently an increasing interest in developing ultrasonics to provide data that can be used for both process monitoring and control. These developments are being driven by the need to better understand the fluid dynamics and multiphase media interaction phenomena encountered. This is needed to give insights into the process and quantitative data for use in models. This paper will report results obtained through the analysis of dynamic B-scan and digital ultrasonic A-scan data, which are being used for the characterization of mixing in multiphase systems. Results obtained with a model system of sugar mixing into water, under a variety of conditions, will be presented. The insights that are given into the mixing process through the use of a B-scan system will be shown on video. The processes being used to extract data from (I) B-scan images and (II) rf (time-amplitude traces) measured with A-scan systems, to enable the implementation of a mixing index will be reported. Particular attention will focus on the issues of measurement scale and characterization of inhomogeneity. Data will be compared with theoretical model results for ultrasonic properties of homogeneous systems, in particular for suspensions, colloidal systems, and reactions including phase changes.

2pPAa6. Water jets and a self-focusing shock pulse source. Bruce J. P. Mortimer (School of Elec. Eng., Cape Technikon, P.O. Box 652, Cape Town 8000, South Africa) and Beric W. Skews (School of Mech. Eng., WITS Univ., South Africa)

The interaction of a liquid pressure pulse with a liquid–air boundary can produce surface deformation and water jet eruption if the incident pressures are high enough. This is important when analyzing damage mechanisms in lithotripsy and in our efforts to produce pulsed water jets [Mortimer and Skews, J. Acoust. Soc. Am. **100**, 3548–3553 (1996)]. High-pressure pulses can be generated by either using focusing lens refraction and convergent reflectors, or using self-focusing sources. In this work experimental results using an electromagnetic shock wave source (EMAS) and a new self-focusing source (FEMAS) as discussed. A high-speed digital camera was used to study the water jet production. It was found to consist of two regions; first a high-speed initial jet and second a slower cumulative jet due to the hydrodynamic flow initiated by the source. Results for the FEMAS show a contained cumulative jet as opposed to an unstable jet observed with the EMAS. These results indicate that the device concentrates its on-axis pressure and velocity, a result confirmed by our pressure measurements. However, the operation of the FEMAS was also found to be rather complex in behavior. [Work supported by the Foundation for Research Development.]

2pPAa7. Measuring longer tubular objects using acoustic pulse reflectometry. David B. Sharp and D. Murray Campbell (Dept. of Phys., JCMB, King's Bldg., Univ. of Edinburgh, Edinburgh, EH9 3JZ, UK, d.b.sharp@ed.ac.uk)

Acoustic pulse reflectometry is a noninvasive technique for measuring the internal dimensions of tubular objects. A sound pulse is produced using a loudspeaker and injected into the object under investigation via a source tube. The resultant object reflections are recorded by a microphone embedded in the wall of the source tube. Analysis of the reflections yields information about the bore profile of the object. At present, there is a restriction on the length of object that can be measured using the standard reflectometer. This restriction arises because after the object reflections pass the microphone they undergo further reflection at the loudspeaker. These source reflections return to the microphone as unwanted signal. Hence, there is only a finite time over which the object reflections can be accurately recorded which, in turn, limits the length of object that can be measured. In this paper, a method for removing the length restriction is described and preliminary results are presented. The method involves the cancellation of the incoming object reflections at the loudspeaker, thus preventing the formation of source reflections. [Work supported by EPSRC.]

2pPAa8. Temperature-scanning ultrasonic measurements in aqueous systems: What is new? Dmitri P. Kharakoz (Inst. of Theoretical and Exp. Biophys., RAS, 142292, Pushchino Moscow reg., Russia)

Ultrasonic measurements are the only high-precision approach to experimental studies of the mechanical part of free energy in liquids, the part directly related to the volume, pressure, and compressibility. During the last decade, a significant progress has been made in the studies of these parameters in aqueous solutions and dispersions of biomolecular materials. The following aspects are considered in this paper: (1) temperature dependence of volume and compressibility as a means to characterize hydration of solutes in water. Important information on the structure and dynamics of bound water can be obtained. (2) Single-frequency simultaneous measurements of sound velocity and absorption and the investigations of fast kinetics. A first-order phase-transition in lipid vesicles (aqueous dispersion) is considered as a process for which unique and very important kinetic information can be obtained by means of such measurements. (3) Sound velocity, compressibility, and volume as a means to characterize conformational states of macromolecules in aqueous solution. Temperature-induced phase transitions in macromolecules (proteins and other polymers). (4) A puzzle of the intrinsic compressibility and nonlinearity of native protein molecules. (5) The acoustic and calorimetric temperature-scanning measurements: A comparative aspect. [Work was supported in part by Russian Foundation for Basic Research, Grant No. 95-04-12226a.]

4:35

2pPAa9. Acoustic monitoring of the curing process in cement and concrete. Bernhard R. Tittmann, Hasson M. Tavossi (Penn State Univ., Dept. of Eng. Sci. and Mech.), and Frederic Cohen-Tenoudji (Univ. of Paris-7, Denis Diderot, Paris, France)

Acoustic wave velocity and attenuation measurements are used to monitor cement and concrete during hardening. The measured acoustic parameters can then be used to investigate the curing process. The goal of this work is to determine the time required for a given mixture of concrete to be hard enough for the removal of the molds, in order to speed up the construction process. Currently this removal time is unpredictable. In addition concrete, mortar, and cement, before hardening, can be considered as examples of granular materials. The shear, rigidity moduli, and acoustic wave velocity of these materials can differ from the values obtained by applying effective-medium theories and Biots theory. The complete description of the mechanical properties of these materials requires the consideration of discrete nature of the solid constituents and the effects of contacts between the grains. These effects are included in the theoretical description of the process. The methods of acoustic microscopy are also applied to investigate the surface and subsurface physical changes of cement during hardening. Theoretical and experimental results of this investigation will be presented.

4:50

2pPAa10. Model experiments on the evaluation of the cement bond with ultrasonic pulse-echo techniques. Wenxiao Qiao, Guangsheng Du, and Shihong Chi (Dept. of Petroleum Resource, Univ. of Petroleum, East China, Dongying, Shandong 257062, PROC)

Previous research shows that when the transducer is immersed in slurry, it is nearly impossible to determine the cement bond quality of the interface between the cement annulus and formation (Interface II) using the ultrasonic pulse-echo technique. Because strong reflection occurs at the interface between the slurry and casing, most of the portion of the pulse energy is reflected back. In this paper, methods of cement bond evaluation are studied in four different model experiments, in which the transducer is contacted closely to the casing. In these experiments, no matter whether the ultrasonic pulses are normally or obliquely incident to the casing, obvious signals corresponding to the Interface II are observed. Considering the practical implementation of the technique, a thin steel plate is inserted between the transducer and casing. The reflection signal can still be achieved. The model experiments indicate that the transducer-contact-casing system can eliminate the influence of the slurry, improve the ratio of signal-to-noise, evaluate the interface between the casing and cement (Interface I), and determine the cement bond quality of the Interface II if the Interface I is well bonded.

5:05

2pPAa11. Acoustic measurements of condensation/evaporation and crystal growth. Andi G. Petculescu and Larry A. Wilen (Dept. of Phys. and Astron., Ohio Univ., Athens, OH 45701, wilen@helios.phy.ohiou.edu)

Using a volume-modulation technique developed to study thermoacoustics, the complex compressibility of a liquid in coexistence with its vapor is measured. Such a system exhibits a distinctive behavior. At low frequencies, the inverse complex compressibility vanishes because the pressure remains at the equilibrium vapor pressure as the total volume is changed slowly. The volume change is accompanied by an exchange of molecules between the two phases. At higher frequencies, however, this exchange is too slow, and the pressure response approaches that which would be expected in the absence of the liquid phase. The presence of the liquid acts effectively as a high-pass filter whose time constant depends on the rate of condensation/evaporation. The application of this technique to the measurement of condensation coefficients of liquids will be discussed. The same technique can also be applied to solid/vapor systems where the results provide a measure of the crystal growth rate. A unique feature of this technique is that the crystal growth rate can be monitored continuously as a function of temperature. [Work supported by Ohio University Research and Sponsored Programs.]

2pPAa12. Anomalous excess noise in inhomogeneous elastic and piezoelectrical solids. Alexander M. Dykhne (Federal Sci. Ctr. ''Trinity,'' Troitsk, Moscow oblast', 142092, Russia)

The description of the macroscopic behavior of a microinhomogeneous material and the determination of its internal structure may be obtained from its response to external action. The parameters related to the second moments of the field are the simplest to determine. This is the work of deformation. Additional information about the material can be deduced from the higher moments of the respective field. These higher moments are most important in the case of a field with a highly nonuniform spatial dependence. For certain types of the heterogeneity geometry, some points of the elastic field concentration can exist where the field strength increases faster than a certain power function of the distance. The fourth moments of the field can diverge, which will lead to abnormally high excessive noise. The measurement of the excessive noise gives information about the structure of the material. A simple method for determining the high distribution moments of a field is based on measurements of the excessive noise arising from the fluctuations in material constants such as elasticity moduli. This is related to, for example, the deformation of a solid under a fixed external load or the eigenfrequencies of elastic vibrations. In the case of piezoelectrical materials, the excess noise may originate from both elastic and electrical external fields. Their measurement gives more information about the internal structure of the material.

5:35

2pPAa13. Acoustic pulse diagnostics of relaxation media. German A. Maksimov and Vladimir A. Larichev (Moscow Eng. Phys. Inst., Kashirskoe sh. 31, Moscow, 115409, Russia, maximov@dpt39.mephi.ru)

The investigation of propagation of acoustic fields in different media is an important source of information about nonideal properties of these media. For study of small-amplitude acoustic waves, the most essential of the nonideal properties are the dissipative–dispersive properties, which are characterized by the frequency dependence of the absorption factor and the phase velocity. These properties can be described in terms of relaxation processes, which arise in the field of acoustic waves. Conventional ways to determine the relaxation times spectrum (RTS) parameters are acoustic spectroscopic measurements of temperature–frequency dependence of absorption and phase velocity of sound in the medium. Currently, such problems can be solved by applying the pulse methods of measurements. In the report the possibilities of acoustic pulse diagnostics of relaxation media are discussed. Parameters of media (such as five moments of RTS) are defined which can be determined experimentally by methods of pulse acoustic diagnostics. The criteria for a pulse excitation source and its registration distances are obtained which provide the most efficient pulse acoustic diagnostics. The comparison of developed approach with the first experiments is fulfilled.

2pPAb1. Optical detection of leaky-Rayleigh waves at air–solid interfaces. Laszlo Adler, Christophe Mattei (Adler Consultants, Inc., 1275 Kinnear Rd., Columbus, OH 43212), Michel de Billy, and Gerard Quentin (Univ. Paris 6 and 7, CNRS U.R.A. 17, Paris Cedex 05, France)

Due to the difficulties associated with ultrasonic generation and detection in air in the megahertz region, air-coupled nondestructive evaluation has only recently been explored. In this work, a shear transducer is mounted directly over the edge of a solid specimen so that it can generate a bulk mode in the interior of the solid as well as a Rayleigh wave along the surface. A recently developed optical heterodyne interferometer proved to be sensitive to the leaky-Rayleigh wave in air more than a centimeter away from the solid surface. Results of velocity and attenuation measurements of leaky-Rayleigh waves for several solids will be presented. The technique can also be applied to plates to measure leaky-Lamb velocity and attenuation in air. This method can be used for low optical reflectivity solid surfaces: Thus it can be extended for noncontact nondestructive evaluation applications.

2:35

2pPAb2. Theoretical and experimental study of surface waves on solid–fluid interfaces when the fluid sound velocity is larger than the shear wave velocity in the solid. F. Padilla, M. de Billy, and G. Quentin (Groupe de Physique des Solides, Tour 23, Univ. Paris 7, Denis Diderot, 2 place Jussieu, 75251 Paris Cedex 05, France, Unit assoc. au CNRS n 17, padilla@gps.jussieu.fr)

Two surface waves can propagate on a solid–fluid interface: the Rayleigh and the Stoneley waves. The problem is well known when the fluid sound velocity cF is lower than the velocities in the solid (cS and cL). The Scholte–Stoneley dispersion equation has been studied when cF is greater than the shear wave velocity cS. The numerical results obtained for PVC–water and Plexiglas®–water show that there might exist two surface waves whose velocities are lower than cS. The two corresponding roots of the dispersion equation tend to the Rayleigh root of the solid–vacuum interface as the density of the fluid tends to zero. The structure of the two waves has been studied using the formalism of the evanescent plane waves. They are theoretically propagating without attenuation along the interface and exponentially decaying along the direction normal to the interface inside both media. These two waves have been experimentally observed. They exponentially decay along the direction normal to the interface inside both media. The experimental arrival times are in very good agreement with the theoretical ones.

2:50

2pPAb3. A modal reduction technique for the finite element formulation of Biot's poroelasticity equations in acoustics applied to multilayered structures. Franck C. Sgard (LASH, DGCB URA CNRS 1652, ENTPE-Rue Maurice Audin, 69518 Vaulx-en-Velin Cedex, France, Franck.Sgard@entpe.fr), Noureddine Atalla, and Raymond Panneton (GAUS, Univ. de Sherbrooke, QC J1K 2R1, Canada)

Lately, the authors have presented a general technique, referred to as *selective modal analysis* allowing for a reduction of setup time, computer storage, and solution time of large finite element models involving poroelastic structures. This method uses a dual basis associated with the skeleton *in vacuo* and the fluid phase in the rigid skeleton limit, respectively. A compact system in terms of modal unknowns is obtained by projecting the coupled system over the dual basis. This technique has been previously tested in the case of the determination of surface impedances and quadratic velocities of single porous materials excited both mechanically and acoustically. It is proposed in this talk to investigate the efficiency of the *selective modal analysis* technique in the case of multilayered structures made up from a combination of elastic, poroelastic, and acoustic media under various boundary and loading conditions. The theory behind the technique will be recalled together with numerical examples illustrating its performance.

3:05

2pPAb4. Sound propagation in gas-filled rigid-framed porous media: General theory and new experimental and numerical data. Denis Lafarge, Michel Henry (LAUM, UMR CNRS 6613, 72085 Le Mans, France), Mouaouia Firdaouss, and Jean-Luc Guermond (LIMSI, UPR CNRS 3251, BP 133, 91403 Orsay, France)

The acoustic properties of gas-filled porous media have been the subject of extensive theoretical and experimental work. However, even in the simplest case of rigid-framed materials, most of the theoretical developments found in the acoustical literature remain largely empiric or semi-phenomenologic. This is due to the complicated microstructure of porous materials in general. Starting with first principles and using a simple two-scale analysis, a general formulation of the problem of (linear) long-wavelength sound propagation in gas-filled media is provided in terms of two independent permeabilities. One of these—the viscous dynamic permeability—is well known. Its thermal analog, the thermal dynamic permeability, is new in the acoustical context. It can be related to a notion of ''mean survival time'' in diffusion-controlled reactions. The exact connection between the microgeometry and the frequency-dependent dynamic permeabilities is obtained in terms of independent geometrical distribution functions. Useful analogies with the dispersion of electric and magnetic permeabilities are noted. New experimental and numerical data demonstrate the usefulness of the scaling functions proposed by Wilson *et al.* and Pride *et al.* Different limitations of the general modeling and the mentioned scaling functions are also noted.

3:20

2pPAb5. Nonlinear propagation of laser-generated acoustical pulses in granulated media. Konstantin Naugolnykh (CIRES, Univ. of Colorado/Environ. Technol. Lab., Boulder, CO 80303), Igor Esipov, Konstantin Matveev (N. Andreev Acoust. Inst., Moscow 117 036, Russia), and Viktor Zosimov (Appl. Acoust. Inst., Dubna 141 980, Russia)

Laser generation of high-intensity broad frequency band acoustical pulses in different fluids and their propagation in water-saturated cobalt-manganese crust (CMC) samples are investigated. Acoustic pulses of amplitude up to 3 MPa and duration about 1 s are generated in water, oil, and benzene by the action of CO_2 on a laser pulse. The propagation of the short acoustic pulses through the water-saturated CMC samples is considered. The complexity of the CMC structure leads to specific nonlinear acoustical features of the process—nonlinear distortion of the acoustic pulse and amplitude-dependent attenuation. Abnormal sound attenuation in the high-frequency band is observed with low-energy probing sound pulses. This effect could be connected with the sound energy capture and its localization as oscillating modes of the structure. This effect vanishes with increasing intensity of the probing pulses, apparently due to the changes in crust structure. At the same time, specific nonlinear distortion of the sound pulse takes place—increasing of the acoustic pulse amplitude leads to decreasing of the negative phase of the passed acoustic pulse. [Work supported in part by Russian Fund for Fundamental Research.]

3:35

2pPAb6. High-resolution spectroscopy of the Lamb modes of a plate near normal incidence. G. Durinck, W. Thys (Katholieke Universiteit Leuven Campus Kortrijk, Interdisciplinair Res. Center, 8500 Kortrijk, Belgium), J. L. Izbicky, and P. Rembert (Universite du Havre, 76610 Le Havre, France)

Using a high-resolution digital oscilloscope and advanced datahandling plate modes near normal incidence, other than those identified by Lamb, were studied. This search was led by the complex roots of the dispersion relation for a plate in water. Solutions with a complex wave number component in the propagation direction indeed reveal near normal incidence the existence of plate modes no one has ever observed to our knowledge. In this paper experimental results are presented at the cutoff frequencies of the S1 and S2 modes of a 1.5-mm-thick aluminum plate, and at the cutoff frequencies of the A1 and A2 modes of a 1.5-mm-thick glass plate. The extra resonance predicted by the theory is resolved by looking at the time history of the radiating plate. This is done either by displacing the time window far into the free emission regime or by displacing the receiving transducer in the propagation direction.

3:50

2pPAb7. Electric-field influence on Lamb and SH wave properties in $LiNBO_3$ plates. B. D. Zaitsev, S. G. Joshi, and I. E. Kuznetsova (Inst. of Radio Eng. and Electron. of RAS, Saratov Branch, Zelyonaya str., 38 410019 Saratov, Russia)

Presently, acoustic devices using an electrically controlled time delay are highly promising. They include acoustic phase shifters, amplitude and phase modulators, and transversal filters with electrically controlled amplitude-frequency characteristics. Lithium niobate is one of the most promising materials with the anisotropic nonlinear electroacoustic interaction studied for bulk (BAW) and surface (SAW) acoustic waves. This paper is devoted to the theoretical investigation of electrically controlled characteristics of acoustic waves in plates of lithium niobate. The main crystallographic cuts and various thicknesses of plate under the action of different orientations of an external electric field have been investigated. It was confirmed that the dependence of velocity on an electric-field intensity has a complex nature as well as for SAW and BAW. Therefore, even and odd portions of analyzed dependencies have been introduced and studied separately. It was found that mentioned portions are functions not only of wave propagation direction and electric-field orientation but of plate thickness. It allows the changing of the nature of velocity dependence on electric-field intensity from a quadratic law to a linear one. Another advantage is the possibility of providing a significant electric-field intensity by using low voltage due to thin thickness of plate.

4:05

2pPAb8. Effects of sound and vibrations on tensions and deformations of a stratificated plate. Florian-Paul I. Simion (Dept. of Theoret. Mech., Univ. Politehnica of Bucharest, 313 Splaiul Independentei, 77206, Bucharest) and Gabriela-Cristina D. Simion (Univ. Politehnica of Bucharest, 313 Splaiul Independentei, 77206, Bucharest, simion@freddy.cib.pub.ro)

Effects due to sound and vibrations phenomena in bodies are multiple and more complex than those in the case of sound propagation in air. In the present paper deformations and tensions are analyzed in the case of a plate with eight layers and a solicitation in flexion. Our plate is subjected to a uniform pressure. Let us consider a Cartesian frame $(O, \mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3)$ for our multilayer plate from composite material. Axis $\mathbf{x}_3$ is normal to the medium surface of the plate. This plate is composed of eight unidirectional layers and the angles between fibers of a layer and axis $(O|\mathbf{x}_1)$ have the following values: 0, $\pi/2$, 0, $\pi/2$, $\pi/2$, 0, $\pi/2$, 0. Matrix of rigidities for a layer is determined in a rectangular base $(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3)$ in case $\mathbf{x}_1$ parallel to the direction of fibers. A formula of medium deformated surface, arrow in the middle of plate and flexion deformation is determined. Particular application efforts in each layer are computed and their graphs are plotted.

2pPP1. Development of active and passive processes in gerbil cochlea. David M. Mills and Edwin W. Rubel (Dept. of Otolaryngol., Head & Neck Surgery, Univ. of Washington, Seattle, WA 98195)

Distortion product otoacoustic emissions were monitored in neonatal gerbils during furosemide intoxication, to examine the ontogeny of different mechanisms underlying cochlear responses to acoustic stimuli. Results indicate: (1) Above 2 kHz, active processes were functional at adult levels at all ages. (2) In the youngest animals (14 days) the maximum frequency seen for the active response was 16 kHz, while in adults it was 40 kHz. This limitation on the active frequency response is believed to be due to the underlying passive cochlear mechanical response, and is consistent with the known place code shift. (3) The length of the active amplification zone at the extreme base decreased from 1.2 mm at 15–19 days to 0.6 mm at maturity. (4) At midfrequencies, there was an increase in net active gain from 15 to 19 days, then a subsequent decrease to reach a uniform 25-dB gain across frequency by maturity. Overall, these results are consistent with an increase in the rate of gain (dB/mm) from 15 to 19 days as the endocochlear potential increases to mature levels, followed by a decrease in the length of the active amplification zone throughout the cochlea with maturity. [Work supported by NIH DC00395.]

1:35

2pPP2. Development of human cochlear function. Carolina Abdala (House Ear Inst., 2100 W. 3rd St., Los Angeles, CA 90057)

The time course for functional development of the human cochlea is not clear. The advent of otoacoustic emissions (OAE) methodology has made it possible to noninvasively probe cochlear function in humans. Distortion product OAE isosuppression tuning curves indirectly reflect cochlear frequency selectivity. They are generated by presenting a third suppressor tone simultaneously with the stimulating tones f1 and f2 and increasing the level of the suppressor until a criterion amount of suppression is achieved. When the suppressor level required to achieve criterion reduction in DPOAE amplitude is plotted as a function of frequency, a DPOAE suppression tuning curve (STC) can be generated. DPOAE (2f1−f2) STCs have been generated in adults and neonates to investigate development of cochlear tuning in humans [Abdala *et al.* (1996); Abdala and Sininger (1996)]. Results of these studies suggest that the human cochlea is resolving frequency in an adultlike fashion by term birth. Other findings also support this contention [Bargones and Burns (1988); Eggermont *et al.* (1996)]. However, results of a recent study conducted with very premature neonates [Abdala (1997)] suggest that STC width and growth of suppression is not adultlike in premature neonates. These results may be indicative of cochelear immaturity just prior to term birth.

2:05

2pPP3. Evidence of prenatal hormonal effects on the auditory system. Dennis McFadden (Dept. of Psych. and Inst. for Neurosci., Mezes Hall 330, Univ. of Texas, Austin, TX 78712, mcfadden@psy.utexas.edu)

There are marked sex differences in a number of behavioral and physiological measures of the auditory system. Evidence is accumulating that some of these sex differences exist at birth and are attributable to the magnitude of prenatal exposure to androgenic hormones, such as testosterone. A generalization emerging from this evidence is that greater prenatal androgen exposures lead to greater masculinization of these auditory responses. At this point, little is known about the modes of action of androgens on developing cochelear structures, but because the degree of masculinization of otoacoustic emissions (OAEs) appears to parallel the degree of masculinization of other brain structures and behaviors, OAEs appear to have the potential to be a valuable, noninvasive window onto the processes of prenatal development and sexual differentiation. Examples of this potential will be discussed. [Work supported by NIDCD.]

2:35–2:45 Break

2:45

2pPP4. Human auditory system maturation: A neurophysiological comparison between normal-hearing children and children who use a cochlear implant. Curtis W. Ponton, Manuel Don, Betty Kwong, Michael D. Waring (House Ear Inst., 2100 West Third St., Los Angeles, CA 90057), and Jos J. Eggermont (Univ. of Calgary, Calgary, AB T2N 1N4, Canada)

Auditory-evoked responses provide detailed, objective measures of maturational change in the central auditory system from the level of the brainstem to the cortex. Auditory-evoked responses can reflect activity originating from three pathways: the lemniscal and nonlemniscal pathways as well as from a modality nonspecific pathway originating in the reticular activating system (RAS) and its associated thalamic nuclei. Maturational time courses for these pathways were derived from evoked response data recorded from 156 normal-hearing subjects ranging from 5–20 years of age. Analyses of these data indicate that each pathway may have a unique developmental sequence. For normal-hearing children, the lemniscal pathway appears to follow a longer developmental time course than either the nonlemniscal or RAS pathways. For children with implants, the developmental sequences for these pathways are differentially affected depending on onset and duration of deafness. Specifically, maturation of the lemniscal pathway is delayed by an amount that approximates the period of deafness, whereas maturation of the RAS pathway may be related to the age at onset of deafness.

3:15

2pPP5. Psychoacoustic development in humans and the effects of otitis media on psychoacoustic development. Joseph W. Hall III and John H. Grose (Div. of Otolaryngol./Head & Neck Surgery, 610 Burnett-Womack CB#7070, Univ. of North Carolina, Chapel Hill, NC 27599-7070, jwh@med.unc.edu)

Psychoacoustic measures of auditory development in children with normal hearing and fluctuating conductive hearing losses reveal several general trends. First, processing efficiency is usually reduced in young children: they require higher SNRs and are less sensitive to AM. However, underlying mechanisms may be mature: derived measures of frequency selectivity, TMTF time constants, across-frequency processing (CMR and the processing of multiple modulations), and binaural processing (MLD for broadband maskers and sensitivity to off-midline stimuli) are adultlike by age 5. Nevertheless, key differences remain: across-frequency processing in children is less tolerant of asynchronies than in adults and, for narrow-band maskers, young children have poor binaural masking release, a result which is not due simply to perceptual similarities between signal and masker. A second general trend is that deficits in function due to early conductive hearing loss are not permanent, although the duration of abnormal performance appears to be strongly associated with the specific function being measured. Basic measures of CMR recover by approximately six months but the processing of multiple modulations takes longer. The MLD may take several years to recover. Interpretations of these findings in terms of CNS strategies for analyzing peripheral information will be presented. [Work supported by NIH NIDCD.]

2pPP6. Excessive auditory backward masking and its potential remediation in children with specific language impairment. Beverly A. Wright (Audiol. and Hearing Sci. Prog., 2299 N. Campus Dr., Northwestern Univ., Evanston, IL 60208-3550, b-wright@nwu.edu)

Approximately 5% of children who are otherwise unimpaired have marked difficulties perceiving and producing spoken language. This disorder is typically labeled specific language impairment. Recent psychoacoustic tests indicate that children with specific language impairment have excessive auditory backward masking, as demonstrated by their extreme difficulties detecting brief tonal signals followed by longer noise maskers. These results are consistent with the hypothesis that specific language impairment results from an auditory perceptual deficit that makes difficult the discrimination of brief, rapidly presented sounds, including phonemes in speech. Subsequent studies using adults with normal hearing and language skills indicate that the interference from a backward masker can be reduced with practice. This learning generalizes from trained to untrained backward-masking conditions and appears to result from improvements in temporal rather than spectral processing. Taken together, these data imply that training in auditory backward-masking conditions may be a useful intervention for children with specific language impairment. 2pPP7. Frontiers and backwaters of research on the biological bases of hearing development. Edwin W. Rubel (Bloedel Hearing Res. Ctr., Box 357923, Univ. of Washington, Seattle, WA 98195, rubel@u.washington.edu)

The goal of this talk will be to summarize recent advances and current challenges in research on the biological bases of hearing development. Three areas will be focused on: functional and structural changes in the cochlea during the early stages of hearing development; the biological bases of critical periods for inner ear and brain development; and the influence of experience on structure and function of central auditory pathways. In each area the dramatic advances in the amount and quality of descriptive information that has emerged over the past decade will be considered. These data provide a firm foundation on which to test hypotheses regarding the mechanisms that govern development. The contributions that the tools of modern cellular and molecular biology can bring toward providing new answers to questions of developmental mechanisms will be discussed.

Session 2pSA

Structural Acoustics and Vibration: Memorial Session for Manfred Heckl

Kenneth A. Cunefare, Chair
G. W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia 30332-0405

Chair's Introduction—2:15

2pSA1. Active control of curve squeal caused by trains. Maria A. Heckl (Dept. of Mathematics, Keele Univ., Staffordshire ST5 5BG, UK)

Squeal noise is generated by a feedback mechanism. It occurs if two bodies are in contact and move relative to each other so that dry friction acts in the contact area. This can lead to an unstable oscillation driven by the feedback between the friction force and the relative velocity of the bodies. Sound is radiated from one or both oscillating bodies. Some well-known types of noise are generated by this phenomenon, for example squeal and the sound of a bowed string. Curve squeal (the noise produced by the wheels of a train that travels fast around a tight bend) is considered in this paper. The frequency spectrum of curve squeal is dominated by one or a few sharp peaks which correspond to certain bending resonances of the free wheel. Squeal noise can be controlled and even suppressed by a secondary feedback system, consisting of a sensor (to pick up the wheel oscillation or the squeal noise), filter, phase-shifter, amplifier, and transducer (to apply the control signal). This type of control amounts to the stabilization of an originally unstable wheel oscillation and is a special form of active control. A mathematical model for this secondary feedback method will be presented. Numerical results for its effectiveness will be shown.

2:35

2pSA2. Realization of the Cremer admittance of silencer linings with passive absorber elements. Friedel P. Mechel (Landhausstr. 12, D-71120 Grafenau, Germany)

L. Cremer has shown that the maximum attenuation in a lined duct is obtained when the solution of the characteristic equation lies in the first branch point of that equation. This condition specifies a surface admittance of the lining, the Cremer admittance. Much effort was undertaken in the Institute of Professor Cremer, later directed by Manfred Heckl, to realize this admittance. It will be shown how a computer program can find the material and dimension parameters of a lining with Cremer admittance, after a suitable principal construction was conceived (e.g., multilayer porous absorber, or Helmholtz resonators, etc.). The potentials and the principal limitations of a lining with a Cremer admittance will become visible.

2:50

2pSA3. The influence of barrier edge treatments. Michael Möser (Inst. für Technische Akustik, Einsteinufer 25, 10587 Berlin, Germany)

The paper deals with the reduction of the sound field in the shadow region behind barriers by means of an attached body at the edge of the screen. The reflecting attributes of the barriers hatpiece are described by a locally reacting impedance. The considerations start with a repetition on the diffraction at ideal soft and hard bodies to demonstrate the governing principle of tangential power transport parallel to their surface: The impedance must be chosen in such a way that the tangential intensity near the edge is lowered, such turning the incoming power to ''undangerous'' directions. Subsequently, the differences due to finite impedances are discussed. The physical principles are demonstrated in a computer animation of the sound fields for the different cases. Theoretical computations give considerable improvement of the level reduction in the shadow zone for not too small angles of diffraction. They are compared with measurement results and practical applications are discussed.

3:05

2pSA4. Induced damping in Heckl's beam experiment. D. Feit and M. Strasberg (Code 7052 and 702, respectively, David Taylor Model Basin, NSWC, 9500 MacArthur Blvd., West Bethesda, MD 20817-5700)

In 1961, Heckl described an experiment showing that the loss factor of a beam in flexural vibration was increased considerably by the attachment of a large number of small cantilevered strips along the span of the beam, their lengths varying so that their frequencies of antiresonance extended over the first five modal resonance frequencies of the beam [J. Acoust. Soc. Am. **33**, 640–651 (1961)]. The increase in loss factor occurred even though the total strip mass was much smaller than the beam mass. More recently, an approximate theoretical estimate of the loss factor of Heckl's beam with attached strips, using a simple expression for induced dissipation based on ''fuzzy'' substructure concepts was presented [J. Acoust. Soc. Am. **99**, 335–344 (1996)]. This estimate agreed well with Heckl's measurements at some frequencies, but disagreed at others for unknown reasons. In an attempt to understand the cause of the partial disagreement, new calculations have been performed using a finite-element model of the beam and strips, the loss factor being estimated from resonance bandwidths in steady-state frequency response and transient decay rate.

3:20

2pSA5. Waveguide absorbers for structural damping. Eric Ungar (Acentech, Inc., 33 Moulton St., Cambridge, MA 02138)

For a series of experimental measurements, Manfred Heckl attached strips of damping tape extending outward from the plate edges to increase the plate's damping. He understood that vibrations induced in the tapes would extract vibrational energy from the plates, but did not explore their effects in detail. The present paper presents an analysis of the damping effects that attached wave-bearing systems can produce and illustrates realizations of waveguide absorbers in the shapes of tapered rods and beams. It also presents related experimental data and describes the general potential of waveguide absorbers.

3:50

2pSA6. Heckls influence on SEA development. Richard H. Lyon (RH Lyon Corp, 691 Concord Ave., Cambridge, MA 02138)

Manfred Heckl was at Bolt Beranek and Newman Inc. in the early 1960s during the development of the basic SEA ideas and applications. As various concepts, formulas, and experimental results emerged, he constantly showed how those results related to the earlier work of Westphal, Cremer, and others. Four areas are particularly fresh in my mind—the use of transmissibility notions for connected plates, the use of reciprocity to calculate SEA results, the modal density of cylindrical structures, and the edge damping of plate structures. In every case, Manfred was able to bring fresh insights to the discussions. Although his name is not on many SEA papers, his contributions and influence were strong and are not forgotten.

4:05

2pSA7. The estimation and control of rolling noise from trains. Paul Remington (BBN Technologies, 10 Moulton St., Cambridge, MA 02138)

Throughout his career Manfred Heckl contributed significantly to the body of knowledge that helped to clarify the mechanisms governing the generation of rolling noise from trains. During a brief period at the Technical University in Berlin this author had the opportunity to collaborate with Prof. Heckl and to learn from his insights and expertise in this field. Here an important mechanism for the generation of noise from trains, the interaction force in the zone of contact between wheel and rail produced by the small scale roughness on their running surfaces, will be examined. Analytical techniques for predicting the interaction forces that include the effects of load and wheel and rail profile will be described. The implications for controlling the noise at the source will be examined and the noise reduction achieveable will be estimated using measured wheel and rail roughness data. [Work was supported by the European Rail Research Institute, Utrecht, The Netherlands.]

4:20

2pSA8. The multipole method: Contributions of Manfred Heckl and new developments for high-frequency acoustic scattering. Martin Ochmann (Technische Fachhochschule Berlin, Fachbereich Mathematik und Physik, Luxemburger Strasse 10, D-13353 Berlin, Germany)

In 1988, Cremer and Wang suggested spherical field synthesis (one-point multipole method) for calculating sound radiation from nonspherical bodies. Then, Heckl derived a close connection between Cremer's method and the Helmholtz integral equation. Also, he recommended the use of several multipole locations for applying the method to nonconvex radiators (multipoint multipole method). From these ideas, the multipole method has since been extended in several directions. Recent research results were obtained by investigating the high-frequency scattering from a nonconvex structure. This structure consists of a sphere where the positive octant is cut out. The region of the missing octant is called a ''cat's-eye,'' since it acts like a three-dimensional reflector. Hence, depending on the angles of incidence, multiple reflections can occur. The surface may be rigid or characterized by a local absorbing surface impedance. A boundary element model of this structure consists of nearly 8000 elements for accurate consideration of large values of ka. The results of the multipole method are compared with a newly developed iterative solver of the Helmholtz integral equation for high-frequency scattering. Both methods agree well. However, it is shown that commonly used approximations at high frequencies fail, e.g., the plane wave approximation, if multiple scattering occurs.

4:35

2pSA9. Acoustics teaching and Manfred Heckl. Thomas D. Rossing (Phys. Dept., Northern Illinois Univ., DeKalb, IL 60115, rossing@physics.niu.edu)

If allowed to have only a dozen acoustics books in my library, one of them would certainly be *Structure-Borne Sound* by Cremer, Heckl, and Ungar. This book, which is the epitome of clarity, could only be written by skilled acousticians who are also great teachers. Although the entire book is the result of a close collaboration between these master teachers, the Foreword tells us that the chapters on Damping, Impedance, and Radiation were written by Manfred Heckl. He also animated several of the figures from the chapter on Radiation for a classroom video he created. His lively lectures, often punctuated with thoughtful demonstrations of acoustical phenomena, serve as examples to teachers of acoustics around the world.

4:50

2pSA10. The use of tuned absorbers in minimizing sound power from vibrating structures. Gary H. Koopman, Eric Constans, and Ashok Belegundu (Ctr. for Acoust. and Vib., Penn State Univ., 157 Hammond Bldg., University Park, PA 16801)

This paper presents a methodology for designing quiet shell structures through the use of multiple tuned resonators. Thin shell structures are targeted for noise reduction because of their ubiquity in industry. They are used to cover and protect noisy devices, such as gearboxes and electrical transformers, and are also used to keep dirt and other contaminants away from moving parts, as in the case of automotive valve covers. The method combines a finite element method vibration prediction code, a boundary element method sound power prediction code, and a combined stochastic/gradient-based optimization algorithm for optimizing the locations and parameters (stiffness, mass, and damping) of the tuned absorbers. A design example has been optimized: a thin shell covering a motor/gearbox/brake combination. It is demonstrated that the addition of a small amount of weight (130 g, or 1.6% of the weight of the shell) can produce substantial reductions in sound power (13 dB in the targeted a $\frac{1}{3}$-octave band centered at 125 Hz).

5:05

2pSA11. Recollections of Professor Manfred Heckl. Gideon Maidanik (Carderock Div., Naval Surface Warfare Ctr., David Taylor Model Basin, Code 7030, 9500 MacArthur Blvd., West Bethesda, MD 20817-5700)

Professor Manfred Heckl was one of the scientific giants in the area of acoustics. He combined theory and experiment so well that both were made simple and transparent. I met Manfred at BBN in 1960. I realized he was one of those individuals that you could approach even when the question was not properly formulated. He helped and taught you how to formulate the question and directed you to the answer. He was an exceptional mentor and generous colleague. When he left BBN to return to Germany to assist in establishing Muller-BBN and to be groomed to succeed Cremer's professorship in Berlin, I lost a major impetus in my early development in acoustics. We tried to maintain close professional contacts, but his personal touch was missed and the efforts were not successful. Periodically, we did have face-to-face professional contacts and these were immensely enjoyable and beneficial, but the day-to-day influence was gone and I was poorer for it. Early in our relationship at BBN we became friends and we remained so to the end. I had many opportunities to test this friendship and it withstood intact the passage of time. It is this friendship that I will cherish forever.

5:20

2pSA12. Concentrated lateral excitation of structures. Bjorn A. T. Petersson (Dept. AAETS, Loughborough Univ., Loughborough, Leicestershire LE11 3TU, England)

Supplementing a recent study, aimed at clarifying theoretical requirements regarding models for prediction and design of transmission characteristics for built-up structures [Petersson and Heckl (1996)], vibration transmission relating to lateral force and moment excitation has been investigated for plates and beams of arbitrary depths. Through the associated mobilities, the power transmission and the cross-coupling between lateral translational and lateral rotational components of excitation and motion are studied and the influence of the volumetric nearfield is examined. Complete descriptions are developed for the two associated point-cross mobility elements. From the theoretical results it can be concluded that reciprocity with respect to the point-cross mobility elements is strictly only valid in the hypothetical case of point excitation. The numerical results demonstrate, however, that reciprocity can be invoked in an approximate sense also for realistic excitation conditions. It is shown that a reducttion of a lateral force excitation, remote from the neutral layer, to a combined force and moment excitation at the neutral layer is not applicable except for very small Helmholtz numbers. It is also concluded that the volumetric nearfield affects all mobility elements. Finally, some manageable estimation procedures for the mobilities will be proposed.

5:35

2pSA13. Measurement of multicomponent point mobilities on thick plates and deep beams. Christ A. F. de Jong (TNO Inst. of Appl. Phys., P.O. Box 155, 2600 AD Delft, The Netherlands)

The accuracy of power-based prediction methods for sound and vibration transmission in built-up structures, such as statistical energy analysis, is crucially dependent on the estimation of the input power as well as the power transmitted at junctions. These transmissions are governed by multi-component mobilities. When the excitation area is small compared with the structural thickness, the mobilities are strongly influenced by the volumetric near fields. Recent theoretical studies of concentrated excitation of plates and beams of arbitrary thicknesses [Petersson and Heckl, JSV 196(3) (1996) and Petersson ICA'98] have lead to some manageable estimation procedures for the mobility components. This paper describes a series of dedicated laboratory experiments undertaken to validate the estimation procedures. The mobility components are extracted from measured frequency response functions via an inverse method. The experimental procedure and the difficulties encountered are described. The results are compared with the estimated mobilities.

Session 2pSC

Speech Communication: Prosody, Production, and Voice (Poster Session)

Stefanie Shattuck-Hufnagel, Chair
Speech Communication Group, Research Laboratory, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, Massachusetts 02139

Contributed Papers

All posters will be on display from 1:00 p.m. to 5:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 5:00 p.m. To allow for extended viewing time, posters will remain on display until 1:00 p.m. on Wednesday, 24 June. A cash bar will be set-up near the poster area during the Social Hour on Tuesday, 23 June, from 6:15 p.m. to 7:30 p.m.

2pSC1. The domain of phrase-final lengthening in English. Stefanie Shattuck-Hufnagel and Alice Turk (Dept. of Linguist., Adam Ferguson Bldg., Univ. of Edinburgh, Edinburgh EH8 9LL, Scotland, turk@ling.ed.ac.uk)

Intonational phrase final lengthening is well established for the final syllable rhyme in English [Klatt (1976), Wightman (1992), Campbell and Isard (1991)]; there is some evidence for lengthening extending further leftward [Langeveld (1997) for Dutch, Berkowitz (1993) for Hebrew], and for post-boundary lengthening of the initial consonant of a new prosodic constituent [Fougeron and Keating (1997), Fougeron (1997), Gow and Gordon (1995), and A. Cooper (1991)]. It is asked whether boundary-related duration lengthening extends further in both directions from a prosodic constituent boundary, using prosodically disambiguated sentence pairs like ''Please say 'Thomasburg or Terraceville and Watertown will play' '' and ''Please say 'Michigan or Madison and Vatican will play,' '' in which pitch-accent and main-word-stress-related lengthening can be distinguished from boundary-related lengthening. Results will be presented for 40 sentence pairs produced by four speakers (normal and reiterant forms) for individual time segments measured across the full extent of each target phrase. Preliminary results from a single speaker suggest that preboundary lengthening can extend leftward to the primary stress of a polysyllabic word. [Work supported by EPSRC.]

2pSC2. Ambiguity in prominence perception in spoken utterances of American English. Laura C. Dilley and Stefanie Shattuck-Hufnagel (Speech Commun. Group, RLE, 36-511, MIT, 77 Massachusetts Ave., Cambridge, MA 02139)

For most words of English in most spoken contexts, the location of the main stress syllable is clear. However, for words in which (a) the main lexical stress is not obvious from the phoneme string alone (e.g., main-stress-ambiguous words like ''digest'' and ''increase,'' and certain proper names), and (b) the possible positions for the main stress consist of adjacent full-vowel syllables, an ambiguity in the location of the prominence and, consequently, in the identity of the lexical item (for main-stress-ambiguous words) is observed when these words occur in contexts with certain $F0$ configurations extending across the adjacent full-vowel syllables (e.g., a rise followed by a peak, or a peak followed by a fall; $F0$ peaks frequently dissociate from lexically stressed syllables [Ladd (1996)]). In these cases, the syllable affiliation of the main lexical stress is unclear; either the peak or movement (rise or fall) in the $F0$ contour can be heard as the prominence. This suggests that listeners interpret $F0$/syllable alignment in light of their language knowledge and a set of perceptual proclivities [Handel (1989)]. When the language fails to specify enough information or two perceptual proclivities are in conflict, perceptual ambiguity can result.

2pSC3. Intonation of noun phrases in Unangan (Eastern Aleut). Alice Taff (Dept. of Linguist., Box 354340, Univ. of Washington, Seattle, WA 98195-4340) and Jacob Wegelin (Univ. of Washington, Seattle, WA 98195-4322)

This paper reports on the intonation patterns of Unangan. The effect of syntactic structure on intonation was investigated. Data for this study are taken from recordings of 12 fluent speakers each providing around 20 sentences in Unangan elicited by English stimuli. Numerical results of entire pitch tracks generated on the Kay CSL 4300B were subjected to statistical analysis. Exploratory plots of batches of sentences were produced using a smoother. When utterances are grouped by speaker, Unangan words have been shown to have an intonation contour whereby each word attains a maximum in its first half, ending lower than it starts. The combination of highs at each word beginning with the downtrending of sentences creates the overall sentence shape of a cascade, each word a step in the falls [Taff and Wegelin, UCLAWPP (1997)]. Building on that study, this investigation looks at plots of same sentences compared across speakers finding that in the possessor/possessed construction (e.g., cormorant's neck) the second word in the phrase is higher in pitch than the first, contrary to the lowering of each successive word described above. Results indicate that intonation in this language is closely related to its syntax. [Work supported by NSF.]

2pSC4. Vowel devoicing and the loss of lexical accent in Tokyo Japanese. Mafuyu Kitahara (Dept. of Linguist., Indiana Univ., Bloomington, IN 47405)

The fundamental frequency of words with devoiced syllables was measured in order to see how the conflict between devoicing and the pitch accent is resolved in Tokyo Japanese. Previous studies found that the pitch after the devoiced accented syllable is elevated in order to compensate for the loss of the accent. Earlier results [M. Kitahara, J. Acoust. Soc. Am. **101**, 3195 (1997)] show that the pitch elevation occurs only when there is no phrasal high tone before the devoiced region. The present study further eliminates the possibility of accent shifting by controlling the moraic structure of target words. They contain one or two devoiceable syllables and a moraic nasal in front of the devoiceable region. Four speakers of Tokyo Japanese pronounced target words embedded in a carrier phrase. If

the accent shifts away from the devoiced syllable, pitch elevation should not occur because the accent is realized somewhere else. Preliminary analysis of the data shows that the accent on the devoiced syllable is not shifted but simply lost under these conditions because the moraic nasal cannot bear an accent in Tokyo Japanese. This result is discussed in connection with intra- and interspeaker variations of the accentual pattern.

2pSC5. The effect of stress on duration in Aleut. Lorna Rozelle (Dept. of Linguist., Box 354340, Univ. of Washington, Seattle, WA 98195, rozelle@u.washington.edu)

Although duration is often one of the physical correlates of stress, it has been claimed [A. Berinstein, UCLAWPP 47 (1979)] that languages with contrastive vowel length do not use duration as a correlate of stress. This study addresses three questions about the phonetic correlates of stress in Aleut, a language with contrastive vowel length. Is duration a correlate of stress in Aleut? If so, does the change in duration caused by stress neutralize the phonemic contrast between short and long vowels? Finally, does stress assignment precede or follow the optional deletion of the final syllable? Data from four native speakers of Pribilof Aleut were analyzed. Vowel duration was measured from the spectrographs produced by a Kay CSL 4300B speech analysis system. Vowels were categorized as stressed or unstressed according to the Aleut stress rule [A. Taff, MA thesis, University of Washington, 1992] and as long or short according to the words dictionary entry. Statistical analysis shows that duration is a correlate of stress, counter to Berinstein's claim. However, despite the change in duration wrought by stress, contrastive ratios between short and long vowels are maintained. In addition, stress is assigned before final syllable deletion.

2pSC6. Temporal structuring of acoustic segments in speech communication. Rodmonga K. Potapova (Dept. of Appl. and Exp. Linguist., Moscow Linguist. Univ., Ostozenca 38, 199837, Moscow, Russia, mglu@online.ru)

The following problems were studied on the domain of the temporal structuring of speech utterance: the determination of algorithms of synthesis of the rhythmic patterns of the utterance, the problem which is often referred to as preprogramming of the temporal organization of the speech signal being part of a more general problem of synthesis (generation) of prosodic patterns of the utterance; the determination of signals used in the information exchange between linguistic and neuro-physiological levels of speech analysis and synthesis; the rules determining the conversion of transformation of the rhythmic patterns of the utterance into real-time intervals between articulatory positions and movements. The character of a durational correlation which has been revealed in this experiment (with the use of the special correlation coefficient ρ and the test of the H_0-hypothesis) made it possible to define three types of temporal correlation: microcorrelation (for subsound and sound levels), mesocorrelation (for syllabic level), and macrocorrelation (for the level of phrase rhythmic structures—phonetic words). The integral temporal organization of speech utterance is determined on the one hand by a lower level effect—coarticulation, and on the other hand by a higher level effect—the rhythmic patterns of a phrase.

2pSC7. Influence of functional and acoustic parameters of intonation contours on prosody lateralization. Marc D. Pell (McGill Univ., School of Commun. Sci. and Disord., 1266 Pine Ave. West, Montreal, QC H3G 1A8, Canada, czbm@musica.mcgill.ca)

The perception of prosody by adults with unilateral right- (RHD) and left-hemisphere (LHD) damage and subjects without brain injury was assessed through six tasks that varied functional (i.e., linguistic/emotional) and acoustic attributes of a common set of stimuli. Three tasks measured the ability to detect prominence cues in short utterances (focus perception) and three tasks examined the perception of emotional-prosodic features by the same listeners (emotion perception). Within each condition, an initial task tested recognition of each ''type'' of prosody when all naturally occurring acoustic features (but no semantic features) signalled the target response (baseline). Two additional tasks assessed how changes in (a) duration and (b) fundamental frequency parameters of the stimuli influenced performance on the baseline task within each condition. Results indicated that, irrespective of the availability of specific acoustic parameters, recognition of prosody by both RHD and LHD patients was highly influenced by functional attributes of the stimuli (i.e., LHD patients were selectively impaired in detecting linguistic prominence whereas both groups were impaired in deriving the emotional tone). Brain-damaged patients also displayed irregularities when individual acoustic properties of the stimuli were manipulated, indicating that both functional and acoustic attributes of prosody may be determinants of prosody lateralization.

2pSC8. Syntactic ambiguities and their resolution in prosody: Observations in Japanese, Korean, Mongolian, and Turkish. Shigeru Sato, Young-Sook Choi, and Kei Yoshimoto (Grad. School of Intl. Cultural Studies, Tohoku Univ., Sendai, 980-77 Japan, satos@intcul.tohoku.ac.jp)

Acoustic measurement was made of utterances of syntactically ambiguous sentences in Tokyo and Sendai Japanese, Seoul and Kyongsang Korean, Mongolian, and Turkish to observe prosodic strategies for disambiguation. Materials were sentences of the types ADV-VP1-NP-VP2 and ADJ-NP1-NP2-VP, where the former is ambiguous in terms of adverbial modification, ADV modifying either VP1 or VP2, and the latter creates ambiguity for the adjective ADJ modifying either NP1 or NP1+NP2. For these constructions, the four languages show identical constituent structures, and accordingly create same ambiguities. After defining the syntactic depth of a boundary, $F0$ of the phrase before and after the boundary, and duration of the syllable and pause before the boundary were measured. The results for differentiating the syntactic depth: (1) Tokyo Japanese and Kyongsang Korean make use of $F0$ rise after the boundary, (2) Seoul Korean lengthens the duration, (3) Turkish uses $F0$ rise before the boundary followed by a pause, and (4) pause is the indication for Sendai Japanese and Mongolian.

2pSC9. The effects of discourse focus and lexical accent on the prosodic phrasing in Japanese. Young-Sook Choi, Shigeru Sato, and Kei Yoshimoto (Grad. School of Intl. Cultural Studies, Tohoku Univ., Sendai, 980-77 Japan, yschoi@insc.tohoku.ac.jp)

Measurement of $F0$ was made of utterances of Japanese sentences to observe behavior of intonation contours with varied focus assignment and lexical accent specifications. Materials were 80 sentences of right-branching structures of the type NP1-NP2(-NP3)-VP, where 16 have two three-mora NP's and 64 three NP's, including all the permutations of NP's, each with one of the four lexical accent types. The utterances were generated in question–answer discourse contexts so that in a sentence, one NP was always focused. The results are: (1) focus assignment has no significant effect on NP1, (2) NP2 and NP3 are significantly higher when focused than when not focused, and (3) focused/unfocused NP2 preceded by unaccented NP1 is significantly higher than those preceded by accented NP1, and so is NP3 preceded by NP2 with the same conditions. These suggest that focus assignment on NP2/NP3 requires rephrasing there, that

a lexical accent of an NP narrows the pitch range of the following phrase, and that the prosodic status of focus assignment is lower than that of the lexical accent.

2pSC10. Effects of prosodic structure on consonant weakening. Lisa M. Lavoie (Dept. of Linguistics, Cornell Univ., Morrill Hall, Ithaca, NY 14853, LML1@cornell.edu)

While the effects of lexical stress are most obvious on vowels, consonants also show evidence of prosodic structure. In English, stress conditions the flapping of alveolar stops and Turk [''Effects of Position in Syllable and Stress on Consonant Articulation,'' Ph.D. dissertation, Cornell University, 1993] has shown that labial stops also shorten in the flapping environment. This study investigates the strength of intervocalic consonants as a function of word stress, position-in-word, and speech rate. Two stress pairs of closely matched disyllabic words (one for word-initial, one for word-medial) were recorded for 16 English consonants at three rates of speech. Words for [v] are as follows, with the stressed syllable capitalized: VENdor, veNEER; SEver, seVERE. Results for fricatives will be reported, including the following tendencies for fricatives which are the onset to an unstressed syllable: voiced fricatives are more fully voiced, some fricatives are shorter, more formant structure is evident in the noise, and transitions to the following vowel may be longer. Findings for each speech rate will be compared to determine how the rate may impact consonant behavior. Each correlate will be evaluated with respect the hypothesis that consonants in unstressed syllables are more vowellike.

2pSC11. Intergestural coordination adjacent to multiple prosodic boundaries. Dani Byrd (Haskins Lab., 270 Crown St., New Haven, CT 06511-6695)

Recent work has demonstrated that progressively larger prosodic boundaries result in increasing amounts of lengthening for consonant gestures both preceding and following the boundary. This experiment extends these findings by considering kinematic data collected with a magnetometer to determine if: (1) vowel gestures demonstrate lengthening patterns comparable to those of consonant gestures due to adjacent prosodic boundaries, and (2) the relative timing or intergestural coordination between consonant and vowel gestures is affected by adjacent boundaries. Eighty tokens were recorded for each of three speakers using magnetometry for a / . . . amə(#)mi . . . / sequence with five differing boundary conditions: (1) no boundary, (2) a simple word boundary, (3) a boundary between elements in a list, (4) a vocative name boundary, and (5) an utterance boundary. Durations of the bilabial closings and openings, duration of the vocalic tongue raising movement from [a] to [i], and temporal latencies between the pre- and post-boundary [m]'s and the [i] articulation were determined. All subjects demonstrated lengthening of the vocalic tongue raising for larger boundaries, although they differed in whether the lengthening was more pre- and post-boundary. Furthermore, two subjects had no systematic changes in relative /#CV/ timing, but one subject showed relatively later vocalic peak velocities for larger boundary conditions. [Work supported by NIH.]

2pSC12. Nontraditional acoustic features of focus. H. Timothy Bunnell, Stephen R. Hoskins, and Debra Yarrington (The duPont Hospital for Children and Univ. of Delaware, 1600 Rockland Rd., Wilmington, DE 19803)

Natural productions of the sentence ''Bob bought Bogg's box'' in which focus was varied over each of the four words of the sentence were altered to produce prosodic cue neutralized versions. The alterations were applied singly and in all possible combinations to form eight experimental versions of each original sentence (the original and seven cue-neutralized versions). The original sentences as spoken by eight talkers and their cue-neutralized versions were presented to listeners with the task of identifying the focused item in the sentence. Results indicated that (a) overall, *F*0 cues were more important than either amplitude or duration cues in signaling focus, (b) the importance of amplitude and duration cues was greatly enhanced when *F*0 cues were neutralized, and (c) in many cases, identification of focus remained above chance after all three acoustic features were neutralized. The present study reports analyses of the residual acoustic features which continue to convey focus when amplitude, duration, and *F*0 are neutralized. [Work supported by NIDRR and the Nemours Research programs.]

2pSC13. Baby word rhythm preferences of Japanese infants. Akiko Hayashi (Faculty of Education, Tokyo Gakugei Univ., 4-1-1, Nukui-Kita, Koganei-Shi, 184 Japan, hayashi@u-gakugei.ac.jp), Kyoko Yoshioka (Tokyo Gakugei Univ., Koganei-Shi, 184 Japan), and Reiko Mazuka (Duke Univ., Durham, NC 27708-0085)

For infants acquiring English, many studies have shown that the dominant stress pattern of the language (viz., strong–weak syllable sequence) plays a critical role in perception, segmentation, and early speech production. Questionnaires to Japanese mothers revealed that many words they use in child-directed speech take the form of XsX or XsXs (X=regular mora; s=special morae). It was hypothesized that this sequence might count as a dominant rhythmic pattern for Japanese infants. Using a head-turn listening preference paradigm, 8–10-month-old Japanese infants were found to show a preference in listening to lists of pseudowords that conform to the XsX pattern when compared to another list of words with three regular morae (XXX). Four- to six-month-old infants showed no such preference. An additional experiment eliminated the possibility that the result of the first experiment was simply based on the presence or absence of special morae in the lists. The results will be discussed in relation to the increasing body of English data to examine how infants might learn to take advantage of language-specific rhythmic patterns in language development.

2pSC14. The relationship between spectral properties and perceptual evaluation of hypernasality in children with cleft palate—vowel /i/. Ryuta Kataoka, David Zajac, Robert Mayo, Donald Warren (UNC Craniofacial Ctr., Univ. of North Carolina, Chapel Hill, NC 27599-7450), and Kaoru Okabe (Coretex Corp., Tokyo, 192 Japan)

The purpose of this study was to examine the relationship between spectral characteristics and the perceptual evaluation of hypernasality in speakers with cleft palate. Speech samples from 32 cleft palate patients (average age 9.3 years) and 5 normal subjects (average age 9.4 years) were used in this study. The isolated vowel /i/ produced by each subject was filtered using 16 one-third octave bandpass filters from 200 Hz to 6.3 kHz to obtain a 1/3 octave spectrum. These spectra were normalized using the total power level of the 16 1/3 octave bands. Three sophisticated listeners rated the speech samples using a six-point equal-appearing interval scale. Average spectra obtained from the hypernasal and the normal groups were compared. Spectral characteristics of hypernasality in the vowel /i/ were identified as a rise in power level between the first formant (*F*1) and the second formant (*F*2) and a rise in power level of *F*1. Multiple regression analysis revealed a high correlation ($r=0.81$) between the averaged perceptual scores and four levels of 1/3 octave bands: the band containing *F*1, the first, the second, and the fourth bands from *F*1. [Work supported by NIDR Grant Nos. DE07105 and DE06957.]

2pSC15. Effects of levodopa on finger and articulatory movements in Parkinson's disease. Michele Gentil and Pierre Pollak (INSERM, CHU Clinique Neurologique BP 217, Grenoble 38043 Cedex 9, France, michele.gentil@ujf-grenoble.fr)

Efficacy of levodopa therapy on finger and articulatory movements in Parkinson's disease was studied. The production of isometric force was estimated in both conditions, without and with levodopa in 14 patients with a diagnosis of idiopathic Parkinson's disease (the mean duration of symptoms was 9 years). Forces generated by the upper and lower lips, tongue, and right and left forefingers in the presence of visual feedback were measured by means of force transducers. Moreover motor disability of patients was assessed in each condition. Fourteen control subjects also participated in this study. The beneficial effect of levodopa on finger motor disorders of patients was observed as indicated by better motor scores and improved production of finger forces. In contrast, the production of articulatory forces of patients was either not improved or aggravated by levodopa therapy. These results suggest that cerebral nondopaminergic lesions are probably responsible for the impairments of parkinsonian speech.

2pSC16. Stop-consonant production by dysarthric speakers: Use of models to interpret acoustic data. Kelly L. Poort (Res. Lab. of Electron. and Dept. of EECS, MIT, 50 Vassar St., Cambridge, MA 02139)

Acoustic measurements have been made on stop consonants produced by several normal and dysarthric speakers. The acoustic data were previously recorded by H. P. Chang and H. Chen at MIT. In the present study, various aspects of production following release of the oral closure were quantified through the use of acoustic measures such as spectra and durations of noise bursts and aspiration noise, as well as shifts in frequencies of spectral prominences. Through comparison of these measurements from the normal and dysarthric speech, and based upon models of stop-consonant production, inferences were drawn regarding articulator placement, rate of articulator release, tongue-body movements, and vocal-fold state. The dysarthric speakers deviated from normals particularly with respect to alveolar constriction location, rate of release, and tongue-body movement into the following vowel. For example, the lowest front-cavity resonance in the burst spectrum of an alveolar stop is normally in the range 3500–5500 Hz. For three of eight dysarthric speakers, the range was lowered to 1500–2800 Hz, indicating either placement of the tongue tip further back on the palate or formation of the constriction with the tongue body in a location similar to that of a velar stop. [Work supported in part by NIH Grant DC00075.]

2pSC17. Formant trajectory characteristics in persons with Parkinson, cerebellar, and upper motor neuron disease. Gary Weismer and Jill Wildermuth (Dept. of Communicative Disord. and Waisman Ctr., Univ. of Wisconsin-Madison, 1500 Highland Ave., Madison, WI 53705)

Vocalic nuclei appear to have a good deal of importance in understanding the speech motor control deficit in dysarthria. Research in our laboratory over the past ten years has shown that the slope of formant transitions and the size of the acoustic vowel space are both predictive of the speech intelligibility deficit associated with amyotrophic lateral sclerosis (ALS). Moreover, certain aspects of formant trajectories, such as transition duration and transition extent, seem to provide useful inferences about the articulatory disorder in ALS and in Parkinson disease (PD). In the present study the investigation of vocalic nucleus production in persons with dysarthria is broadened, by reporting on formant trajectory characteristics of persons with Parkinson, cerebellar, and upper motor neuron disease due to stroke. The hypothesis of pathology-specific trajectory characteristics is evaluated, and some methodological considerations concerning the parametrization of formant trajectories are discussed. [Work supported by NIDCD DC00319.]

2pSC18. The effects of utterance length on temporal control in aphasia. Shari R. Baum (School of Commun. Sci. and Disord., McGill Univ., 1266 Pine Ave. W., Montral, QC H3G 1A8, Canada, insr@musicb.mcgill.ca)

By comparing the same syllables produced in a variety of utterance-length conditions, the present investigation examined the hypothesis that fluent aphasics exhibit a shorter-than-normal speech planning domain, whereas nonfluent aphasic patients exhibit impaired speech timing at all levels. Subjects included nonfluent aphasics, fluent aphasics, RHD controls, and normal controls. The base stimuli were 10 monosyllabic nouns from which 10 bisyllabic words were derived. Each of the 20 words also appeared medially in the context of a short (4–6 syllable) and a long (8–10 syllable) sentence. Productions were elicited two times each and recorded for acoustic analysis. Durations of the target monosyllable as a proportion of whole utterance durations were computed. Preliminary analyses revealed that normal speakers produced target syllables with shorter durations in 2-syllable relative to 1-syllable words in both long and short utterances. Target syllables were shorter in the long sentences, as expected. A similar pattern was found for the other speaker gruops, but the magnitude of the differences was larger in the fluent and nonfluent aphasic patients productions. Moreover, the nonfluent speakers' proportional durations were aberrant due to abnormally long sentence durations. Results are discussed in rlation to theories of temporal control in brain-damaged patients. [Work supported by MRC.]

2pSC19. Source modeling of severely pathological voices. Bruce R. Gerratt, Jody Kreiman, Norma Antonanzas-Barroso, Brian Gabelman (Div. of Head/Neck Surgery, UCLA School of Medicine, 31-24 Rehab. Ctr., Los Angeles, CA 90095-1794), and Abeer Alwan (UCLA, Los Angeles, CA 90095)

Previous studies using a simplified LF source model [Qi and Bi, J. Acoust. Soc. Am. **96**, 1182–1185 (1994)] to describe pathological voice sources indicated that model fit to the return phase is particularly poor. To examine the perceptual importance of differences in how the return phase is modeled, various functions were fitted to the source waveforms that had been obtained by inverse filtering. Voices were then resynthesized using these different source functions, and the resulting signals were compared perceptually to the original natural voice and to versions synthesized with LF modeled sources. The perceptual importance of changes in closing phase modeling for these severely pathological voices will be discussed, as will the range of functions necessary to obtain perceptually satisfactory synthesis of severely deviant voice sources. [Research supported by NIH.]

2pSC20. Speaking rate-induced acoustic variability in Parkinson's disease. Kris Tjaden (Dept. of Commun. Disord., San Diego State Univ., 5500 Campanile Dr., San Diego, CA 92182-1518, Tjaden@mail.sdsu.edu)

The idea that speech consists of overlapping gestures that slide with respect to one another suggests that measurable kinematic, and hence, acoustic differences should characterize utterances produced with varying degrees of gesture overlap. [Saltzman and Munhall, Ecolog. Psych. **1**, 333–382 (1989)]. Further research suggests that a simple acoustic model of overlapping gestures [Weismer *et al.*, J. Phon. **23**, 149–164 (1995)] accounts for some of the spectral and temporal variability in speech produced by individuals with apraxia of speech. One implication is that articulatory deficits associated with motor speech disorders can be modeled, in part, as disruptions in gesture overlap. The extent to which a model of overlapping gestures accounts for acoustic variability in other motor speech disorders is largely unknown. The present study explored the extent to which a simple acoustic model of overlapping gestures accounted for speaking-rate induced variability in *F*2 trajectories produced in target words by individuals with Parkinson's disease (PD), young adults, and older adults. *F*2 onset frequency was used as an acoustic measure of

overlapping consonantal and vocalic gestures; *F*2 onset frequency also was used to predict across-repetition temporal variability in *F*2 trajectories.

2pSC21. A comparative study of speech motor programming in stutterers and nonstutterers. N. Aravind Kumar and S. R. Savithri (Speech and Hearing, All India Inst. of Speech and Hearing, Mysore 570 006, India)

The present study was undertaken to verify the credibility of theories that attribute the locus of stuttering aetiology to be a central speech planning dysfunction. Ten stutterers and ten nonstutterers participated in this study which utilized a choice reaction time paradigm to determine the effects of three independent variables, viz., word length, phonetic complexity, and linguistic complexity on dependent variable-speech reaction time (SRT). By varying the response complexity in this manner it was intended to manipulate the response preparation in a way that if stuttering depends on a premotor programming, then the response complexity would adversely affect response preparation time and this effect of ''complexity'' would be greater for stutterers (with aberrant speech programming) than for nonstutterers. The results obtained supported the above and significant differences were elicited in both within and across group conditions. However, some peculiar ''effects,'' viz., ''paradoxical complexity effect'' and ''motor ceiling effect'' were also evidenced and are subsequently discussed. The results of the study suggest that the stutterers may be endowed with inefficient motor programming capabilities that are aggravated by increased production demands especially under time stress conditions.

2pSC22. Modeling of articulatory dynamics using cascaded first-order systems. Yorinobu Sonoda and Kohichi Ogata (Faculty of Eng., Kumamoto Univ., 2-39-1 Kurokami, Kumamoto, 860 Japan, ogata@eecs.kumamoto-u.ac.jp)

This paper proposes modeling of articulatory dynamics using cascaded first-order systems. The model, which consists of simple first-order components, can be a good approximation for the behavior of a complex system. In the paper, the approach to modeling the articulator movements was performed on several articulatory organs: tongue, jaw, etc. Parameters describing the model were obtained from observed articulatory data in such a way that time patterns of impulse response of the model were approximated to velocity ones of movements. Good approximations were obtained on time patterns of articulation for vowels and consonants. Therefore, successive movement patterns for continuous speech including consonants were approximated by combining several models with high accuracy. By modeling articulatory dynamics for vowels and consonants based on articulatory measured data, complex articulatory patterns in a form of [-V C V-] were synthesized and the time instant of input commands for articulation of vowels and consonants were estimated in a connected speech sound including consonants. [Work supported by SCAT.]

2pSC23. Testing a normalization procedure for articulatory recovery. Richard S. McGowan (Sensimetrics Corp., 26 Landsdowne St., Cambridge, MA 02139)

In order to recover articulatory movement from human speech in the analysis-by-synthesis procedure used in a current project it is necessary to adapt, or normalize, the anatomy of the vocal tract of an articulatory synthesizer. A normalization procedure was tested in which the vocal tract length and the functions determining the conversion of midsagittal distance to cross-sectional area were adjusted until there was an acoustic match between the synthesizer and the human over a selected set of utterances. Testing of the normalization procedure was performed using vowel data on two subjects from the Wisconsin x-ray microbeam data set to find how many utterances with known midsagittal shape and acoustic information were necessary so that the adjusted synthesizer vocal tract was able to predict output of novel utterances. Another part of the normalization procedure is to find a mapping between the settings of the articulators of the synthesizer and the corresponding midsagittal shapes of the human vocal tract. Neural networks were trained to map from the settings of the articulatory synthesizer to the positions of pellets over limited sets of vowels. The ability of these networks to generalize was tested with novel vowels. [Work supported by grant DC-01247 from the NIH.]

2pSC24. A task-dynamic approach to gestural anticipation in speech: A hybrid recurrent network. Elliot Saltzman (Haskins Labs., 270 Crown St., New Haven, CT 06511, saltzman@haskins.yale.edu) and Suvobrata Mitra (Univ. of Connecticut, Storrs, CT 06269)

Recent simulations of the anticipatory timing of speech gestures within the *task-dynamic* model of gestural patterning are described. To accomplish this, a sequential neural network architecture is used in a simplified dynamical system in which the network's outputs define the activations of gestures within a set of vocal tract constrictions (''tract variables'') whose dynamics are second order. These activations act only to insert target values into the tract-variable dynamics; the stiffness and damping coefficients are fixed. The forward dynamics, from current tract-variable state and target inputs to the next tract-variable state, are then modeled by a second recurrent network whose outputs are fed back to the sequential network. In this manner the simulated articulatory timing patterns are sensitive both to the intended linguistic sequence and to the articulatory dynamics themselves. Simulations will be described suggesting that anticipatory gestural timing is defined along a simple implemented continuum between rigid time-locking and unrestricted lookahead behavior. Temporally elastic anticipatory behavior such as that reported for French lip protrusion falls naturally within this continuum. These results provide an elegant account of interspeaker and interlanguage differences in anticipatory gestural timing. [Work supported by NIH.]

2pSC25. An interactive construction system of three-dimensional vocal tract shapes from tomogram. Tohru Yokoyama, Nobuhiro Miki, and Yoshihiko Ogawa (Faculty of Eng., Hokkaido Univ., Sapporo, 060 Japan, yokoyama@kairo3.hudk.hokudai.ac.jp)

A new interactive system is developed to construct the 3-D vocal tract shape from tomogram, for the purpose of understanding the relationship between the speech production process and the geometrical figure of the human vocal tract. The shaded 3-D vocal tract shape can be seen with this system from any direction, by construction from a set of 2-D images measured by, for example, MRI or x-ray CT, and basic geometrical information is obtained for estimating the area function and transfer function, or creating the mesh model for 3-D FEM. For constructing a 3-D vocal tract shape, the following three operations are conducted for the system. First, the 3-D locations of the tomogram images are interactively determined. Second, the contours of the air tract in the images are extracted after several image processings. Third, the wire frame model of the vocal tract, including a branching case, is constructed computationally from the extracted contours. The system is developed using the C++ language as an object-oriented programming language, Motif toolkit as GUI, and PEX as 3-D graphic libraries. The proposed system provides a convenient tool for speech research on the X-Window environment.

2pSC26. Palate shape effects on characteristic vowel tongue postures. Mark K. Tiede (ATR Human Information Processing Res. Labs., 2-2 Hikaridai, Seika-cho, Soraku-gun, Kyoto, 619-02 Japan, tiede@hip.atr.co.jp)

In this work MRI vocal tract data obtained during sustained vowel production is used to investigate the interaction between individual speaker differences in hard palate shape and the compensatory adjustments to tongue posture needed to tune language-specific vowel formant resonances. PCA techniques developed in previous work [Tiede and Ye-

hia, J. Acoust. Soc. Am. **100**, 2658(A) (1996)] were used to characterize three-dimensional tongue and palate shapes for vowel inventories of five Japanese and five American English subjects. Parametrized shapes for individual speakers were compared to a normalized mean tract shape pooled across subjects for each language. Preliminary results show that the axis of tongue body displacement is associated with oral cavity depth (OCD, measured from the teeth to the rear pharyngeal wall): Shorter OCD subjects showed greater vertical /a/ versus /i/ differences, and longer OCD subjects used more of a horizontal component. Systematic effects of palate vault shape on tongue constriction location have also been observed. These results are consistent with the speaker-specific articulatory (''A'' space) adaptations suggested in previous work [Honda *et al.*, Proc. ICSLP96, 784–787 (1996)].

2pSC27. Characteristics of phonation offset and onset in normal adults and children. Laura L. Koenig (Long Island Univ., Brooklyn, NY)

A major goal of research into the dynamics of vocal fold vibration is to specify the physical requirements for self-sustained oscillation, i.e., phonation. In recent years, theoretical and modeling studies have sought to define the necessary conditions for initiating phonation in laryngeal models of varying complexity, focusing especially on requisite pressure levels (the phonation threshold pressure), structural configurations (glottal width and the glottal convergence angle), and their interrelations. Conditions surrounding phonation offset have received somewhat less attention but are generally understood to involve different scale values of the same set of variables. This paper investigates voicing behavior around abduction for /h/ in normal English-speaking adults and 5-year-olds. Recordings consist of intraoral air pressure and oral airflow collected using a Rothenberg mask. DFT analyses of airflow signals from speakers whose /h/Us had voicing interruptions reveal that spectral changes accompanying phonation offset differ from those seen at phonation onset. Speakers show various individual patterns but the difference is typically most evident in the amplitude and bandwidth of the first harmonic. These results add to the empirical literature indicating that initiation and cessation of voicing do not occur under identical conditions. [Work supported by NIH.]

2pSC28. Speaker identification using noncontemporary speech samples. Harry Hollien and Reva Schwartz (Inst. for Adv. Study of the Commun. Processes, 50 Dauer Hall, Univ. of Florida, Gainesville, FL 32611)

There are two noncontemporary elements important to speaker identification. In one, listeners are asked to make identifications at various latencies after hearing the speaker (time of identification is noncontemporary) or, in the second, samples of the speaker's voice are obtained at markedly different times (noncontemporary samples). It has been found that memory for voice decays over time in the first case; hence it has been assumed that the noncontemporary samples pose just as difficult a challenge. AN aural–perceptual speaker identification project was carried out to test this second relationship. Noncontemporary samples, with latencies of 4, 8, and 32 weeks, and then 6 and 20 years, were studied. It was found that mean correct identification was initially reduced by 15% and this level was sustained for up to 6 years. It was only after 20 years that levels dropped significantly (to 33%). It is concluded that listener's efficiency in identifying noncontemporary speech will show only modest decay over time and, hence, its use ordinarily should have only a minimal effect on the speaker identification process.

2pSC29. Perception of intoxication effects on speech. Harry Hollien and Gea DeJong (Inst. for Adv. Study of the Commun. Processes, 50 Dauer Hall, Univ. of Florida, Gainesville, FL 32611)

Can speakers, especially actors, effectively mimic the speech of intoxicated individuals and can they volitionally reduce speech degradation resulting from this behavioral state? Auditors were tasked to determine if actors sounded more inebriated when simulating it than when they actually were intoxicated and if they sounded less intoxicated (than they were) when attempting to sound sober. Young, healthy actors, chosen on the basis of a large number of selection criteria were required to produce several types of utterances: (1) during a learning phase, (2) when sober, (3) at three simulated levels of intoxication, (4) during actual, and parallel, levels of controlled intoxication, and (5) at the highest level of intoxication but when attempting to sound sober. Two (counterbalanced, ABX) aural–perceptual procedures were carried out with 40 listeners. It was found that these auditors rated the speakers as being more intoxicated when sober, but simulating drunkenness, 88% more often than when actually intoxicated. They also were judged as sounding less inebriated (than they were), when attempting to sound sober, 61% of the time. The bases for these relationships will be discussed.

2pSC30. Perceptually motivated modeling of noise in pathological voices. Brian Gabelman, Jody Kreiman, Bruce R. Gerratt, Norma Antonanzas-Barroso (Div. of Head/Neck Surgery, UCLA School of Medicine, 31-24 Rehab. Ctr., Los Angeles, CA 90095-1794), and Abeer Alwan (UCLA, Los Angeles, CA 90095)

Research investigating the correlation of acoustic measures of noise and the perception of pathological voice quality has consistently demonstrated a moderate association. However, this correlational approach cannot address basic questions concerning their cause and effect relationship, such as how carefully noise must be modeled to preserve the perceived pathological vocal quality, and what particular aspects of the noise are necessary to preserve natural vocal quality. To address these questions, an analysis by synthesis approach was applied to a large sample of natural pathological vowels varying in severity of pathology. Several synthetic versions of each voice were created using an LF source model and a formant synthesizer. Amplitude and spectral characteristics of the noise were varied as necessary. Stimuli were compared perceptually to the original voice and to each other. A discussion will focus on the procedures necessary to adequately model noise in voices with severe vocal pathology, and on the perceptual importance of differences in how vocal noise is synthesized. [Research supported by NIH.]

2pSC31. A perceptual and acoustic study of the imitated voice. Kirk P. H. Sullivan (Dept. Ling., Umeå Univ., S-901 87 Umeå, Sweden) and Frank Schlichting (Hamburg Univ., D-20144 Hamburg, Germany)

The belief that an individual can discriminate between different voices from memory is central to the concept of the voice line-up, the aural analogue of the police identification parade, and its application in the legal sphere. This paper examines the impact professional and amateur imitations have on the accuracy of the technique and whether differences in impact can be explained by an examination of vowel space, timing, and $F0$ values. Three groups of experimental participants heard a series of different voice line-ups. They were instructed to indicate which voice of each series was the voice they had been asked to identify. Not all of the series contained the voice to be identified. Group one was presented line-ups containing a high-quality professional imitation. This resulted in a significant degree of confusion between the voice to be identified and the imitation. Group two was presented the same series of line-ups but the professional imitation was exchanged for an amateur one. Group three was presented the same line-ups, but containing another amateur imitation. The amateur imitators failed to cause confusion with the voice they were imitating, yet succeeded, to different degrees, in disguising their natural voices such that their own identity was protected.

2pSC32. Acoustic analysis of the effects of alcohol on the human voice. Orla M. Cooney, Kevin G. McGuigan, Peter J. P. Murphy (Dept. of Phys., Royal College of Surgeons in Ireland, St. Stephens Green, Dublin 2, Ireland, kmcguigan@rcsi), and Ronan M. Conroy (Royal College of Surgeons in Ireland, Dublin 2, Ireland)

Experiments to determine the physical effects of alcohol on the human voice are reported. Recordings of sustained phonations and prescribed texts were taken from 12 volunteers at various stages of alcohol consumption, to determine whether a significant change in voice frequencies occurs when alcohol has been consumed. No association between the fundamental frequency of a sustained phonation and level of alcohol consumption is observed (regression coefficient = 0.146, t ratio = 0.28, $df = 71$, $p = 0.781$). Similar results for the higher formant frequencies are also observed. The effect of alcohol on duration of speech is also investigated. Prescribed-text, sentence duration is found to increase at the rate of 6.4% (standard error = 0.5%, $p < 0.0001$) per ml of alcohol consumed per kilogram of body weight. There is no evidence that the sex of the speaker is related to the effect of alcohol on sentence duration. Acoustic analysis of fixed-text voice recordings is therefore not a suitable method of determining whether a person is alcoholically intoxicated. [This research was supported by the Research Committee of the Royal College of Surgeons in Ireland.]

2pSC33. The use of random spliced speech for the recognition of familiar voices. Ricardo M. Figueiredo (Dept. of Legal Medicine, UNICAMP, CX. POSTAL 6153, CEP 13084, Campinas, Brazil, ricfig@turing.unicamp.br)

Various techniques for experimental speech signal manipulation to test recognition of familiar voices have been used, but random spliced speech (RSS) has not been tried. This procedure, which consists of randomly recombining digitally segmented speech signals, offers the advantage of more natural-sounding speech and decreased risk of creating artifacts interfering with perception. Although intelligibility is also destroyed by this technique, RSS preserves the spectral cues related to voice quality, as well as *F*0 level and range. In the present experiment, various 3.5 s RSS samples of 11 males were presented to 34 listeners, each familiar with only one of the voices. In a recognition task with forced yes/no responses, the index of correct identification was well above chance. An analysis of misindentifications revealed that proximity of *F*0 means led to more errors than did similarity of long term average spectra. Since speakers with *F*0 mean less than 2.8 semitones apart were frequently confused, it seems that in such an experimental situation the listeners may be forced to rely on isolated cues, such as *F*0; this may explain the high number of false identifications, even though the number of false rejections is practically nonexistent.

2pSPa1. Reconstruction and projection of interior sound fields using a spherical measurement array. Earl G. Williams (Naval Res. Lab., Code 7137, Washington, DC 20375)

A spherical surface populated with microphones is placed within an aircraft fuselage or automotive cabin, and the sound field is determined throughout the interior of the source. This hypothetical experiment is the goal of the measurement system which will be discussed. The output from this spherical antenna is processed using mathematical and signal processing techniques to solve both a forward (projection) and an inverse (reconstruction) problem when no sources are within the array. The forward projection provides the field inside the measurement surface. The field outside is computed by solving an inverse problem providing a reconstruction of pressure and velocity in a spherical region up to the external enclosing boundaries. The accuracy of a proposed measurement system for both the forward and inverse modes of operation will be discussed. This discussion includes number of sensors and sensor placement schemes, and, most importantly, the effect of ambient noise and SNR on the projections and reconstructions, including the maximum reconstruction distances from the measurement sphere which can be obtained. [Work supported by ONR and NASA.]

2:50

2pSPa2. Multichannel acoustical measurement for sound field mapping. Svend Gade (Brüel & Kjær Skodsborgvej 307, DK-2850 Nærum, Denmark, sgade@bk.dk) and Jørgen Hald (Brüel & Kjær, DK-2850 Nærum, Denmark, jhald@bk.dk)

A newly developed sound field mapping method, which uses time-domain holography, is useful for localization, quantification, and ranking of sound generating regions on engines and gearboxes under run-up (i.e., nonstationary) conditions. The technique, which is called nonstationary STSF, requires simultaneous measurement of time histories on a planar surface covering the sound source. Thus subarray scanning as used with the cross-spectral STSF technique cannot be applied and a two-dimensional microphone array with half wavelength microphone separation must be used. Consequences of the need for a full size fixed array system is that it is not feasible for measurements to cover a whole vehicle, except at low frequencies, and for engine measurements a large number of microphone measurement channels is needed to cover a frequency range up to 3 kHz. The technique maps all sound field descriptors

in the near field, but not only as a function of physical location but also as a function of time for transient events. Nonstationary STSF allows source attenuation simulations similar to the cross-spectral STSF technique to be performed. The development of TDH is part of the Brite–Euram project PIANO, dealing with new pass-by noise optimization methods for quiet and economic heavy road vehicles.

2pSPa3. Signal processing for sound capture. Daniel V. Rabinkin, Richard J. Renomeron, Atul Sharma, and James L. Flanagan (CAIP Ctr., Rutgers Univ., 96 Frelinghuysen Rd., Piscataway, NJ 08854-8088)

High-quality electret microphones and single-chip processors are economical enough to be used in large numbers. This latitude opens opportunities for dynamic source location and sound capture with spatial selectivity in three dimensions. This report discusses algorithms for matched-filter processing of microphone arrays and for coordinate tracking of moving talkers. A prototype conferencing system is demonstrated in which the automatic source locator steers both a video camera and a beam-forming microphone array to capture image and audio from a moving talker. [Components of this research are supported by NSF Contract 397-26740 and DARPA Contract DABT63-93-C0037, the New Jersey Commission on Science and Technology, and the corporate members of the Rutgers Center for Computer Aids for Industrial Productivity (CAIP).]

2pSPa4. Modeling in-vehicle engine noise. Filip Deblauwe, Patrick Van de Ponseele, and Geert Lowet (LMS Intl., Interleuvenlaan 68, B-3001 Leuven, Belgium, fdb@lms.be)

Transfer path analysis is accepted as a tool to model or troubleshoot the lower engine orders for in-vehicle noise. The contribution of each force input that is coherent with the engine can be evaluated both for amplitude as well as phase. This allows ranking the individual paths and allows identifying paths that interact (cancel effects). The ability to listen to these contributions, also called partial pressures, is needed for the sound quality evaluation of engine noise, and the next logical step in transfer path analysis. Steady-state applications of time domain transfer path analysis have been reported, but primarily the study of pseudostationary sounds such as engine run-ups was desired. In this document, different methods will be discussed that could enable this type of work. The new developed synthesized order substitution method is presented. This method enables an engine sound engineer to listen to the sound due to a single or a set of noise transfer paths, for a reasonable computation effort.

2pSPa5. Localization of acoustic emissions in aerospace structures. Paul J. Wells, Arthur Stephens (Adv. Information Processing Dept., Br. Aerosp. Sowerby Res. Ctr., FPC267, PO Box 5, Filton, Bristol BS12 7QW, UK), and Andy Ibbotson (Br. Aerosp. Airbus, Filton, Bristol, UK)

Health Usage and Monitoring Systems (HUMS) offer the potential to revolutionize the civil aircraft industry's approach to routine scheduled inspections. Developments in acoustic emission measurements allow the direct detection and localization of fatigue damage in complex primary aircraft structures. This information has been used to successfully guide inspections and to locate damage in regions inaccessible to conventional NDT methods. The use of such a system in flight will lead to inspection costs being reduced significantly and will promote confidence in the structural integrity of next generation civil aircraft. This paper will examine the question of the optimum positioning of sensors for a given sample using methods such as genetic algorithms and simulated annealing. The use of dimensional reduction projection techniques is also discussed. In an aerospace structure the propagation of sound will not be isotropic because of the variation in the thickness of the structure. This anisotropy will limit the accuracy of localization unless accounted for. The magnitude of this effect is determined empirically for an aircraft wing panel, and a method for calibrating acoustic emission measurements to minimize the effect of this anisotropy is suggested.

2pSPa6. Imaging of supersonic surface fields on a cylindrical shell. Charles N. Corrado, Jr., Daniel T. DiPerna, and Matthew Conti (Eng. Tech. Ctr., 240 Oral School Rd., Mystic, CT 06355-1208)

Conventional imaging techniques represent a radiating body as a distribution of equivalent monopole sources. This paper presents a more rigorous approach for imaging the supersonic components of both surface pressure and normal velocity produced by scattering or radiation from a nominally cylindrical body. The technique employs the Helmholtz integral equation to relate monopole and dipole strengths. A modal expansion of the surface pressure on a baffled cylinder forms the basis for determining an array-weighting function used to estimate the surface fields. The technique makes use of acoustic pressure data measured in a horizontal plane at ranges where the evanescent field is insignificant. No far-field constraints are imposed in the derivation of the method, allowing the measurements to be conducted within the geometric near-field of the body. When the array is located in the far field, this method is shown to yield similar array-weighting functions to a method derived by Williams [E. G. Williams, J. Acoust. Soc. Am. **99**, 2022 (1996)]. Mid-frequency, $2 \leqslant ka \leqslant 20$, scattering and radiation data from measurements of a ribbed cylindrical shell are used to illustrate the technique. The intensity images reveal membrane wave and rib scattering processes in both the time and frequency domains. [Work supported by NSWC and ONR.]

2pSPa7. Holographic reconstruction of active sources in a three-dimensional enclosure. Yang-Hann Kim, Young-Key Kim (Ctr. for Noise and Vib. Control, Dept. of Mech. Eng., Korea Adv. Inst. of Sci. and Technol., Taejon, 305-701, Korea), Byeongsik Ko, and Kangho Ko (Daewoo Motor Co., 199 Chongchon-dong, Pupyong-gu, Inchon, 403-714, Korea)

This study proposes a method to identify active sources. The theory itself does not limit the application of the proposed method, but the main aim has been focused on finding the location of active noise sources and their strengths in an enclosure. The acoustic holography method can be applied to identify active sources, primary sources if one prefers to call them. However, it will depict all sources including imaginary sources, which one may call secondary sources, which are due to reflections on the walls of enclosure. In this study, an attempt has been made to distinguish these two different types of sources. First, boundaries are modeled by the inhomogeneous Robin boundary condition. It makes it possible to represent the boundaries as the combination of general ideal sources and passive boundaries; the ideal sources imply the primary sources, while the

passive boundaries control the secondary sources. Second, this general boundary condition is combined with the holography method to reconstruct the strength of ideal sources. A technique for estimating surface admittance of passive boundaries is also proposed for a three-dimensional sound field by generalizing that for a duct.

5:20

2pSPa8. Estimation of far-field pressures from geometric near-field measurements. Daniel T. DiPerna, Charles N. Corrado, Jr. (Eng. Technol. Ctr., 240 Oral School Rd., Mystic, CT 06355-1208, ccorrado@atinc.com), and David C. Warwick (Naval Surface Warfare Ctr., West Bethesda, MD 20817-5700)

Measurements of radiated noise are often made in the geometric near field of a cylindrical radiator to take advantage of high signal-to-noise ratios. At these ranges the far-field beam patterns are not fully established and the corresponding sound pressure levels cannot be determined via a simple range correction. In this paper, three methods of estimating the far field given measurements primarily made in a horizontal plane are presented. All three methods employ propagator matrices to relate surface field quantities to the near- and far-field pressures. The pressures measured over a segment of the receive array are multiplied by a weighting vector determined from the propagator matrices to minimize the mean square error between the actual and estimated far field. One method represents the surface field as a distribution of monopole sources of unknown strength. This method also employs an image source field representation to attenuate surface bounce contributions. The second method represents the surface field in terms of cylindrical harmonics with unknown modal coefficients employed at discretized axial positions along the cylinder. The third method is formulated using unknown modal coefficients derived from a substitution of the spherical harmonic expression of the free-space Green's function in the Helmholtz integral equation.

2pSPa9. Feasibility of using imperfect microphone arrays in noise source location. Tarun Bhatt, J. Richard Houghton, and Corinne M. Darvennes (Dept. of Mech. Eng., Tennessee Technolog. Univ., Cookeville, TN 38505, tarun@bigfoot.com)

Microphone arrays are being used in many applications such as noise source location, sound intensity measurement, or acoustic holography. For the purpose of source location using the unwrapped phase method, it is important to use phase-matched microphones. The paper studies the feasibility of replacing phase-matched microphones with an array of unmatched microphones and of finding faulty microphones within the array. For this purpose, two sets of tests were performed. With the first set, the microphone characteristics were measured. An electronic circuit provided time delays, i.e., phase information, between the microphones, and narrow and wideband source signals supplied frequency responses for all the microphones. With the second set of tests, optimization techniques and neural network methods were used to locate a noise source with (1) a matched microphone array, (2) an unmatched array, and (3) an array containing faulty microphones. Comparison of the data from the various microphone arrays is presented in this paper. The feasibility of using unmatched arrays with optimization and/or neural network methods is discussed. It is also demonstrated that a microphone with a significant signal-to-noise ratio and/or a large phase error can be pinpointed within the microphone array.

5:50

2pSPa10. Superdirectivity design for a sphere-buffled microphone array. Kazuhiko Kawahara and Kimitoshi Fukudome (Dept. of Acoust. Design, Kyushu Inst. of Design, 4-9-1 Shiobaru Minami-ku, Fukuoka City, 815-8540 Japan, kawahara@kyushu-id.ac.jp)

For the signal extraction from a diffuse sound field, the superdirecitonal microphone array seems to be more stable and more effective than the noise canceling microphone array system. In this research, for the sphere-baffled microphone array (SBM), the superdirectivity characteristic was designed by the frequency domain beamforming method and the complex least mean square algorithm. The frequency domain beamforming is a method for a broadband beamforming. There is a possibility of improvement of the directivity frequency characteristic. The SBM is an array which was embedded 36 elements on the rigid diffractive sphere of 8.84 cm radius. An advantage of SBM is its isotropy. When the directivity characteristic was fixed for a definite direction, only the shift coefficent can be used to change the mainlobe direction. This idea can be easily generalized into the three-dimensional mainlobe control. In a typical design calculation, for the beamwidth of -3 dB, 30° was achieved at the frequency 2 kHz. This characteristic is comparable to that of a larger size microphone, which is called a shotgun microphone.

6:05

2pSPa11. Beamforming for broadband constant beamwidth through FIR filter and DSP implementation. Yuanliang Ma, Baosong Zhang (Inst. of Acoust. Eng., Northwestern Polytechnical Univ., Xi'an 710072, PROC, ylma@nwpu.edu.cn), and Didier Vray (Creatis, INSA de Lyon, France)

The paper presents a method to design a beamformer for broadband constant beamwidth. This is important in sonar systems for sea bottom observation and classification applications. For a given frequency band, a number of frequency points are chosen to represent the response. For each frequency point, a beamforming weighting vector can be deduced to satisfy a given beamwidth requirement by existing methods, for example, Chebyshev shielding coefficients can be deduced for a linear array. For a broadband array of N elements, a $N*M$ matrix can be obtained if M frequency points are chosen. Each row of the matrix represents a frequency response of an array element, which can be satistied by a FIR filter designed by model-reference adaptive techniques. The sum of outputs from a bank of N FIR filters provides a beamformed output and so it is very handy to be implemented by DSP hardware. A design example shows that the results are satisfactory.

2pSPb1. FFT beamforming with cylindrical arrays: Application to the Toroidal Volume Search Sonar. Christian P. deMoustier and Timothy C. Gallaudet (Marine Physical Lab., Scripps Inst. of Oceanogr., 9500 Gilman Dr., La Jolla, CA, 92093-0205)

FFT beamforming is typically applied to arrays of coplanar and equally spaced elements. For curved arrays, conventional delay and sum beamforming should be the norm because the elements are not coplanar and the projection of their position on a tangent plane yields unevenly spaced elements. However, with appropriate phase correction coefficients, FFT beamforming can be applied to the elements contained in a 90° sector of a cylindrical array if beams formed within $\pm 35°$ about broadside are kept. Within this sector results are essentially identical to those obtained via conventional beamforming but the FFT technique is more efficient computationally and better suited to real-time applications. The error bounds associated with FFT beamforming on cylindrical arrays are discussed and we present applications of the technique to data collected with the Toroidal Volume Search Sonar by the Coastal System Station, Panama City, FL. [Work sponsored by ONR-NRL (Contract No. N00014-96-1-G913).]

2pSPb2. Acoustic source estimation based on physical modeling and optimization algorithm. Aggelos J. Amditis, K. S. Nikita, and Nikoloas K. Uzunoglu (Dept. of Elec. and Comput. Eng., Natl. Tech. Univ. of Athens, 15773 Zografou Cambus, 9 Iroon Polytechniou St., Zografou, Athens, Greece)

The propagation of acoustic waves in the sea is analyzed by employing a horizontally stratified model for the sea medium with an arbitrary number of layers. Through this physical model, the acoustic field distribution, originating from an elementary source at an arbitrary location point inside the sea medium, is calculated by implementing a Green's function approach. The proposed optimization algorithm is based on the minimization of the quadratic error function between estimated source signal values and signal values corresponding to known acoustic sources for the frequency content of the measured signal. Initial source estimation is based on the measured signal and the transfer function obtained by the above described propagation model. The minimization of the error function with respect to the model parameters described is carried out independently for each signal, corresponding to a known source, by employing the downhill-simplex minimization method. The measured signal is positively recognized as one corresponding to a known acoustic source if the minimization procedure results in an error value less than a predefined limit.

2:55

2pSPb3. Robust Kalman-based time-varying DOA estimation of impulsive noise. Han-Su Kim and Koeng-Mo Sung (School of Elec. Eng., Seoul Natl. Univ., Seoul 151-742, South Korea)

This paper presents the robust Kalman-based method which is modified with a Huber function for estimating time-varying DOA (direction of arrival) under an impulsive noise environment. The Kalman-based algorithm can estimate the proper parameter in the additive white Gaussian noise. But it is well known that the performance of the Kalman algorithm degrades seriously when the input or the estimation error contain impulsive noise (burst outliers) which can arise frequently in many practical applications. The proposed algorithm has the robustness over the impulsive noise by putting bounds to the derivative of its cost function with respect to the estimation error, using Huber function. It is known in the theory of robust estimation that if the influence function is bounded, the estimator is robust. Simulations show that the performance of the proposed algorithm is less vulnerable to the impulsive noise than the conventional Kalman algorithm.

3:15

2pSPb4. A universal parallel sonar signal processing system. Lifu You and Enfang Sang (Dept. of Underwater Acoust. Eng., Harbin Eng. Univ., Harbin 150001, PROC, euipc@public.hr.hl.cn)

A modern signal processing algorithm has been widely used in the sonar system, which has improved the sonar system features, but has also given the sonar signal processing system more compute burden in the meantime. Parallel signal processing technology is a solution. A universal parallel signal processing module is designed, which is based on the VME bus, so it is convenient to get a more powerful processing system. This module is comprised of four TMS320C40 digital signal processors. As examples, some basic sonar signal processing algorithms such as FFT, beamforming, etc. have been implemented using this system. The efficiency and speedup are given in this paper. This parallel signal processing system is suitable for many kinds of sonar systems.

3:35

2pSPb5. Maximum likelihood track-before-detect matched-field beamforming with SWELLEX data. Kerem Harmancı, Joseph Tabrikian, and Jeffrey L. Krolik (Dept. of Elec. and Comput. Eng., Duke Univ., Durham, NC 27708-0291)

Moving source localization methods are seriously limited at low signal-to-noise ratios because the signal energy becomes spatially spread over long observation times. In this paper, the integration time available to matched-field beamformers is extended by incorporating *a priori* statistical knowledge of the source dynamics. This is accomplished by first showing that the well-known minimum variance beamformer output power is essentially the log-likelihood function with respect to source location under a model consisting of a single target in an unknown but structured noise field. This likelihood function for a single frame of data may be combined with the conditional distribution of the current target position given its previous location to obtain a maximum-likelihood (ML) track-before-detect processor. In cases where the sample covariance matrix is ill-conditioned, derivation of a constrained ML estimate assuming known diffuse noise level is given. Results are presented using vertical hydrophone array data for an underwater acoustic source off the coast of southern California. Comparisons with conventional MV matched-field beamforming demonstrate that incorporating source dynamics into the processor improves its ability to maintain the target track even in the presence of interference.

2pUW1. The effects of bandwidth, dispersion, and correlation length scale on shallow-water reverberation. Kevin D. LePage (SACLANT Undersea Res. Ctr., Viale San Bartolomeo 400, 19138 La Spezia, Italy)

The ensemble average of the short-time average of the monostatic reverberation power expected in a shallow-water waveguide is obtained explicitly in the parameters of modal phase speed, slowness, dispersion, and source bandwidth under the assumption of a Gaussian source envelope and a two-dimensional Gaussian spatial scatterer correlation function. Results show that in the limiting case of very narrow bandwidths, resonant scattering is expected, yielding lower backscattered levels, and significant propagation structure is superimposed on the backscatterer time series, consistent with the two way TL to the scattering patch at the center frequency. In the limit of patch size small compared to the correlation length scale, higher backscattered levels, consistent with the scattering strength of the individual scatterers themselves, are expected, and the superimposed propagation structure is reduced due to the spatial decorrelation of the patches interrogated by the individual modes. Expressions for the time varying vertical coherence are also obtained in this framework.

2:25

2pUW2. High-frequency acoustic scattering from thermally generated turbulence. John Oeschger (Coastal Systems Station, Naval Surface Warfare Ctr., Dahlgren Div., Panama City, FL 32407-7001, oeschger_john@ccmail.nscs.navy.mil)

The results of a laboratory experiment are presented for the case of high-frequency broadband multistatic acoustic scatter from a thermally generated buoyant plume. The dominant scattering mechanism is changes in the relative compressibility, which is related to the temperature difference from ambient. Far-field weak scattering theory is used to describe the scattering process. This results in a simple relationship between the complex acoustic scatter and the one-component, three-dimensional Fourier transform of the temperature field measured at the scattering producing Fourier component K, defined as the Bragg wave number. This wave number is the magnitude of the difference wave vector between the scattered and incident wave vectors. Theory predicts for measurements made in the same scattering direction that spectral estimates for overlapping Bragg wave numbers be identical. Utilizing data collected from simultaneous multiple bistatic configurations with parallel Bragg wave vectors yields a more fully resolved spectral estimate of the scattering producing temperature field. A time series of the spectral estimate of the turbulent temperature field is shown for a three-channel bistatic common Bragg direction measurement. The results indicate agreement between the spectral estimates in the regions of overlapping Bragg wave numbers, validating the theoretical description. The time series also shows strong, yet highly variable nulls in the wave-number spectrum of the turbulence. [Work supported by ONR.]

2:30

2pUW3. Range spread measurement of underwater scatterers and channels using active sonar probing signals and a cross-correlation process. James J. Kisenwether and Dennis W. Ricker (Autonomous Control and Intelligent Systems Div., Appl. Res. Lab., Penn State Univ., State College, PA 16804)

A method for measuring range spread of underwater scatterers and channels based on the cross-correlation processing of the tones of a multicomponent waveform has been developed. The correlation terms which comprise the measure are samples of the time-frequency correlation functions (TFCF) of scatterers and channels. The measure has been used to characterize the time-frequency spread and represents the signal coherence. This paper will provide a review of two frequency correlation function representations and their characterization using the aggregate coherence measure, termed correlation mass. The sensitivity of this measure as a function of waveform parameters, scatterer structure, and measurement platform motion will be defined and its robustness on a multiping basis assessed. It will be shown that this measure can be decomposed into correlated components resulting from interaction with a scatterer and a channel. Essentially the composite correlation is obtained by sampling the product of the scatterer and channel TFCF's. Data from in-water experiments and digital sonar simulations will be presented which validates the linear systems model of the composite scattering process. [Work supported by ONR.]

2:35

2pUW4. Target size measurements via specular echo spectrum. Jerome Mathieu, Patrick Schweitzer, Etienne Tisserand, Serge Weber (L.I.E.N. (Electron. Instrumentation Lab. of Nancy), Univ. Henri Poincare-Nancy 1, BP 239, 54506 Vandoeuvre-les-Nancy Cedex, France, mathieu@lien.u-nancy.fr), and Serge Gauthier (G.E.M.C.E.A., 54500 Vandoeuvre-les-Nancy, France)

Ultrasound principles actually used to determine experimentally the size A of solid targets are based on measurement of scattering attenuation. The principal limit of this method comes from the difficulties in identifying excess attenuation due to scattering. This paper presents a new method to determine the size A of a target by means of specular echo spectrum. When an immerged (in water) target is insonified with a very brief ultrasound pulse, the backscattered echo contains two parts temporally distinguishable. The first part is the specular echo. The specular echo target spectrum St depends on the form function F and A, but also of the measuring chain response. So this method includes a gauging step which consist to calculate the spectrum Sb of a block's echo. It is also showed that Sb/St (which is noted Fmes) is proportional to F in the bandwidth measuring chain B. The comparison of Fmes and F gives the bandwidth B in

terms of KA, where K is a known wave number. Thus A is deduced by comparing Fmes and F. The most interesting advantage of this method is its independence towards attenuation. Some results are presented.

2:40

2pUW5. The extraction of a target scattering response from measurements made in a range-dependent shallow-water environment. Angie Sarkissian (Naval Res. Lab., Washington, DC 20375-5350, angie@aqua.nrl.navy.mil)

The free-field scattering response of a target may be extracted from measurements made over long ranges in a range-independent shallow-water environment by the use of vertical array of sources and vertical array of receivers. The procedure requires the generation of a low-order shallow-water mode by the source array and the extraction from the received echo at the receiver array of a low-order shallow-water mode. The algorithm is generalized to range-dependent environments where additional complications exist due to the mode coupling produced by the range dependence in the shallow-water environment, which exists in addition to the mode coupling produced by the scatterer. Results of numerical simulations are presented for a ribbed cylindrical shell with hemispherical end caps. The target scattering response is computed using the finite elements and infinite elements method, and the propagation is computed using the parabolic equations method. [Work supported by ONR.]

2:45

2pUW6. Formalism for boundary scattering in waveguides. David H. Berman (Dept. of Phys. and Astron., Univ. of Iowa, Iowa City, IA 52242, david-berman@uiowa.edu)

A natural scheme for discussing scattering in a waveguide with rough boundaries involves propagating waves from a source to the rough boundaries, followed by some form of interaction with the boundaries, followed by propagating from the boundaries to a receiver. The interaction with the boundaries is often described by a scattering amplitude whose relationship to the scattering amplitude for the same boundary located in a half-space is not entirely clear. The present work shows what this relationship is and what propagator should be used to carry the waves to and from the boundaries. These results are based on a systematic multiple-scattering analysis and provide non *ad hoc* expressions for both the scattering and the propagation parts of the problem. As an illustration, the problem of computing reverberation time histories is discussed, a problem beyond the realm of parabolic equation methods which are sometimes used to treat multiple scattering.

2:50

2pUW7. Backscattering by layered media: Modeling and comparison with data. Laurent Guillon (Lab. d'Acoust. de l'Univ. du Maine, UMR CNRS 6613, Ave. Olivier-Messiaen, BP 535, 72017 Le Mans Cedex, France, lguillon@ifremer.fr) and Xavier Lurton (Lab. d'Acoust. Sous-Marine, IFREMER, Plouzané, France)

Deep-water multibeam echosounders provide bathymetry data and acoustical images, the latter being sometimes difficult to interpret. Indeed, due to the size of the wavelength used (about 10 cm), the wave's penetration into the seafloor is not negligible and the internal geological structure of the seafloor must be taken into account in the acoustical modeling. A model for backscattering by layered media is proposed here for trying to explain the acoustical response of such geological configurations. It is based on the concept of ''equivalent input backscattering strength'' through a multilayered stratified lossy medium. Each fluid layer may feature a continuous variation in acoustical parameters (sound velocity, density, and attenuation) and generates volume backscattering. The backscattering strengths provided by the sediment finite volume and by an underlying basement are affected by various effects inside the upper layer stack : refraction, attenuation, and interferences. Synthesizing the classical approaches of backscattering (interface and volume) and transmission in layered media, this model allows one to discuss the various components and effects featured in the resultant backscattering strength. It is finally compared to acoustical data recorded in areas where some ground truth is available.

2:55

2pUW8. Measurement at low ultrasonic frequencies of absorption due to suspended particulate matter. Niven R. Brown, Timothy G. Leighton (Inst. of Sound and Vib. Res., Univ. of Southampton, Southampton SO17 1BJ, UK, nrb@isvr.soton.ac.uk), Simon D. Richards, and Tony D. Heathershaw (Defence Evaluation and Res. Agency, UK)

The visco-thermal absorption of sound by suspended particulate matter can be reliably measured using a reverberation technique. This absorption may have an adverse effect on the performance of sonars operating at low ultrasonic frequencies in coastal waters where suspensions are often present in significant concentrations. A series of experiments has been performed to study the viscous absorption by suspensions in the frequency range of 50–150 kHz by taking the difference in reverberation times of a volume of water with and without particles. Measured attenuation agrees reasonably well with that predicted by theory for concentrations above 0.5 g/l. A number of interesting phenomena have also been observed which are related to the measurement system and the turbulent flow required to keep the particulate suspended. For accurate measurement, losses at the container walls must be minimized. Although there are small losses at the surface by transmission, along with losses due to absorption in the acoustic boundary layer, the presence of bubbles and dissolved gas, and turbulence, the relative measurement gives a good assessment of the absorption by the particles. These effects are discussed and results for particulate absorption are presented.

3:00

2pUW9. Turbidity in future high-frequency sonar performance models. Simon D. Richards (Defence Evaluation and Res. Agency, UK), Niven R. Brown, and Timothy G. Leighton (Univ. of Southampton, Southampton, UK)

Current sonar performance models are incapable of accurately predicting the performance of high-frequency sonars in highly variable turbid coastal waters. There is therefore a requirement for improved models incorporating the additional effects in such environments. Turbid coastal waters are characterized by relatively high levels of suspended particulate matter, the presence of which leads to increased attenuation through viscous absorption and scattering, leading to a significant reduction in the detection range of high-frequency active sonars at moderate concentrations. The additional attenuation mechanisms have been incorporated into a propagation-loss model and the effect on detection range has been investigated. The additional attenuation processes are influenced by the ambient temperature, pressure, and salinity, and the effects of these parameters on the total attenuation in seawater containing suspended mineral particles has also been investigated. The results presented demonstrate that the effects of suspended particulate matter should be included in future high-frequency sonar performance prediction models in turbid environments. Temperature is found to be an important factor influencing the attenuation, and the local temperature should therefore be used in performance calculations. [Published with the permission of the Controller of Her Britannic Majesty's Stationery Office.]

3:05

2pUW10. Spectral diffusion of seismo-acoustic waves in shallow water. Robert I. Odom (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105) and Valerie I. Peyton (Yale Univ., P.O. Box 208109, New Haven, CT 06511)

The propagation of seismo-acoustic waves in a strongly forward scattering medium is modeled as an energy diffusion process satisfying a convection-diffusion equation in slowness space [Odom and Mercer, Geophys. J. Int. **127**, 111–124 (1996)]. No energy propagates with a slowness greater than the Stoneley/Scholte wave slowness, and therefore must sat-

isfy a zero flux boundary condition at the maximum slowness. At a slowness equal to 1/(minimum shear speed), energy is lost by radiation to shear waves, and for finite frequencies satisfies a mixed boundary condition in slowness space. Maupin [Geophys. J. Int. **126**, 762–780 (1996)] has recently shown how the branch line integral for the elastic continuum can be written as a dyad, which does not suffer from common problems with other formulations employing leaky modes. Maupin's dyadic representation for the elastic wave continuum is employed to derive the proper mixed boundary condition and illustrate its effect on the diffusion of seismo-acoustic wave energy in a shallow water waveguide. [Work supported by ONR.]

3:10

2pUW11. Experimental verification of the deformed cylinder scattering model and its application for the calculation of backscattering from fish. Kouichi Sawada (Natl. Res. Inst. of Fisheries Eng., Ebidai, Hsaki, Kashima, Japan), Zhen Ye (Natl. Central Univ., Chung-li, Taiwan, R.O.C.), and Masahiko Furusawa (Tokyo Univ. of Fisheries, 4-5-7 Konan, Minato, Tokyo, Japan)

The dorsal aspect target strength pattern of straight cylinders made of polystyrene (EPS) are measured and compared with the deformed cylinder scattering model (DCM) proposed by Ye [Zhen Ye, J. Acoust. Soc. Am. **102**, 877–884 (1997)] in the range of the tilt angle from $-50°$ to $50°$. Both experiments and the theory agreed very well for the wide range of tilt angle. The deformed cylinder model is also applied to predict the target strength pattern of Ayu (*Plecoglossus altivelis*) which is a river fish with an open swimbladder. The dorsal target strength of Ayu is measured by keeping it in alive condition. Then its swimbladder's shape is observed using a soft x-ray system and digitized. Digitized data is used for the calculation on the basis of the deformed cylinder model and also the shape of the swimbladder is reproduced carving a rectangular solid of EPS by hand. The measured TS pattern of alive Ayu, the physical EPS model of swimbladder, and the DCM calculation agreed very well. Expanded polystyrene is a useful material to verify the scattering theory of the gas model and can become an artificial fish model with a swimbladder. Scattering from a complicated shape as a fish is predictable using DCM.

3:15

2pUW12. Comparison between subcritical penetration models and *in situ* data. Alain Maguer, Eric Pouliquen, Edoardo Bovio, Warren L. J. Fox, and Henrik Schmidt (NATO SACLANT Undersea Res. Ctr., Viale S. Bartolomeo 400, 19138 La Spezia, Italy)

This paper presents the recent results of a study whose overall objectives are to determine the mechanism(s) contributing to anomalous high-frequency sound penetration into sediments, and to quantify the results for use in sonar performance prediction for the detection of buried objects. To date, several mechanisms have been hypothesized in order to explain this phenomenon, the most frequently mentioned being: (a) the existence of a Biot slow wave in the sediment, (b) surface roughness, and (c) scattering of the evanescent wave by volume inhomogeneities within the sediment. *In situ* acoustic measurements were performed on a sandy bottom whose geoacoustic properties were carefully identified. A parametric array mounted on a tower moving on a rail was used to insonify hydrophones located above and below the sediment interface. An extensive data set covering a wide range of grazing angles (both above and below the estimated critical angle) and frequencies (2–50 kHz) was acquired and processed. The results are compared to models for the three mechanisms stated in an attempt to explain the anomalously high sound-pressure levels measured. Dependence on frequency, depth into the sediment, and grazing angle is explored.

3:20

2pUW13. Subcritical penetration into a viscoelastic solid due to interface roughness: Laboratory experiment and perturbation theory model. Garfield R. Mellema, Terry E. Ewart, and Kevin L. Williams (Appl. Phys. Lab., College of Ocean and Fishery Sci., and Dept. of Elec. Eng., Univ. of Washington, Seattle, WA 98105, mellema@apl.washington.edu)

The propagation of acoustic energy into sub-bottom sediments at grazing angles below the compressional critical angle has been well documented and various mechanisms to explain this propagation have been proposed. Due to the complexity of the *in-situ* environment the propagated energy might not be the result of a single mechanism, but a sum of a combination of several mechanisms. In order to better consider the validity of one of the more prominent mechanisms, rough surface scattering, a simplified laboratory environment has been constructed in which to make measurements of penetration due to interface roughness. In this environment, the sediment has been replaced by a homogenous viscoelastic solid. To preserve the uniformity of the solid, both the transmitter and the receiver are located in the water column, where their radiation patterns are well characterized. Use of an automated positioning and measurement system and a large interface area ensures that the series of measurements are both repeatable and statistically meaningful. A perturbation theory model has been constructed for comparison with the measurements. In the experiment its accuracy is evaluated as the surface roughness is increased through the limit of perturbation theory. [Work supported by ONR.]

2pUW14. Aspects of a damped surface wave in the Fourier diamond spaces. New surface wave analysis method (SWAM). Loïc Martinez, Jean Duclos, and Alain Tinel (LAUE, Pl. R. Schuman, BP 4006, 76610 Le Havre Cedex, France)

A damped surface wave (complex wave number $K=K'+jK''$) is described by its space-frequency representation $S(x,\omega)=\exp(jK(\omega)x)$. The wave-number-frequency representation $Ksi(k,\omega)$ is the spatial Fourier transform of $S(x,\omega)$. A Ksi-cut versus k is a k-Breit Wigner form (square modulus maximum for $k=K'$,K'' half-width). A Ksi-cut versus ω is then shown to be an ω-Breit Wigner form (square modulus maximum for $\omega=\Omega'$, with an Ω'' half-width). New interesting properties are found: the phase velocity is $C_p=\Omega'/K'$ and the group velocity is $C_g=\Omega''/K''$. The wave-number-time representation $N(k,t)$ is the inverse frequency Fourier transform of $Ksi(k,\omega)$. $N(k,t)$ is then shown to be $N(k,t)=\exp(j\Omega(k)t)$. The space-time representation $s(x,t)$ is obtained by inverse frequency (respectively, wave number) Fourier transform of $S(x,\omega)$ [respectively of $N(k,t)$]. The four spaces s, S, Ksi, and N are the four Fourier diamond spaces. Used on $s(x,t)$ experimental datas, the two cuts properties are the basis of the surface wave analysis methods (SWAM). Those methods identify the complex K (respectively, Ω) using k-ARMA (respectively ω-ARMA) models. Using SWAM on a cylindrical shell, the A-wave is experimentaly fully characterized. The agreement with theoretical results is excellent.

3:30

2pUW15. Aspects of cylindrical shell resonances in the Fourier diamond spaces. Use of surface wave analysis methods (SWAM) on experimental or numerical datas. Loïc Martinez, Jean Duclos, and Alain Tinel (LAUE, Pl. R. Schuman, BP 4006, 76610 Le Havre Cedex, France)

For an attenuated surface wave (wave number $K=K'+jK''$), the resonant space-frequency $S(x,\omega)$ representation of a cylindrical shell is performed versus the angular position x. In this space, the MIIR properties are demonstrated. The resonant wave number-frequency representation $Ksi(k,\omega)$ is then obtained by spatial Fourier transform of $S(x,\omega)$. This two-dimensional second space clearly separates clockwise and anticlockwise propagating waves. The first ones are observed in the positive k

values of *Ksi*, and the second ones in the negative *k* values of *Ksi*. The modulus of *Ksi* is maximum each time that the resonant condition is encountered [ω so that $K'(\omega)$ is integer]. As new results, the k cut of Ksi reveals the Sommerfeld Watson aspect of the problem and SWAM identify the complex *K*. On an ω cut of *Ksi*, SWAM identify the RST aspect of the target (and a little more): complex frequency resonances $\Omega = \Omega' + j\Omega''$ for real modes *n*. SWAM is performed on experimental datas and on numerical form functions. The agreement with theoretical results obtained by RST is very good.

3:35

2pUW16. New experimental characterization of a resonance: Identification of the mode number using the Argand diagram and the GTD approach. Serge Derible, Jean-Marc Conoir, Jean-Louis Izbicki, and Pascal Rembert (LAUE, Universite du Havre, Pl. R. Schuman, 76610 Le Havre, France)

Until now, the mode n of vibration of an immersed cylindrical shell, associated to the reemission of a peripheral wave, using an incident quasi-monochromatic plane wave is performed by carrying out the method of isolation and identification of resonance. The new method proposed here involves only the FFT of the whole pressure signal backscattered at normal incidence by the shell, normalized using the FFT of the incident wideband signal. At a resonance frequency, corresponding to an unknown value of n, the background phase φ_{exp} is measured from the Argand diagram of the scattered pressure. It corresponds to the argument of the pressure at the resonance frequency. The geometrical theory of diffraction allows us to connect the background phase φ_{GTD} to the mode number n. This mode is then deduced by minimizing the difference between φ_{exp} and φ_{GTD}. Experiments are carried out for *A* and S_0 resonances. Then, with a single backscattered signal, it is possible to obtain the frequency, the width, and the mode of the resonance.

3:40

2pUW17. Scholte wave dispersion by rippled liquid/solid interface topography. Jacques R. Chamuel (Sonoquest Adv. Ultrason. Res., P.O. Box 81153, Wellesley Hills, MA 02181-0001)

The effect of sand ripples on seismoacoustic waves is not yet understood. Quantitative results are presented characterizing the dispersion of Scholte waves propagating along a rippled surface of an immersed ''soft'' solid half-space. One model has a sinusoidal profile with a ratio of corrugation amplitude to wavelength of 0.25. The observed Bragg frequency components of broadband transient received waveforms are shifted by 180° as the receiver is displaced one cycle along the corrugation, however, the other frequency components are delayed by a smaller amount following the dispersion characteristics. Scholte and Rayleigh wave experimental dispersion graphs obtained from ''soft'' solid models are compared with replotted scaled numerical results on Rayleigh wave dispersion along a ''hard'' corrugated solid half-space [Glass *et al.*, ''Propagation of Rayleigh surface waves across a large-amplitude grating,'' Phys. Rev. B **24**, 6843–6861 (1981)]. The findings reveal that a rippled ''soft'' liquid/solid interface can decrease the velocity by more than 70% of high-frequency Scholte wave components propagating normal to the ripples. The accuracy of acoustic inversion and detection of buried objects depends on predicting the effect of seafloor topography. [Work supported by ONR.]

3:45

2pUW18. Scatterer depth estimation using broadband active matched field processing. Brian K. Jennison (Loyola College, Dept. of Elec. Eng., 4501 N. Charles St., Baltimore, MD 21210-2699), C. Allan Boyles, and Kevin J. McCann (Johns Hopkins Univ., Laurel, MD 20723-6099)

The reduction of false alarms caused by boundary reverberation is one of the major challenges confronting active acoustic systems used for anti-submarine warfare. Scatterer depth serves as a powerful discriminant for distinguishing false target echoes reflecting from the surface or the bottom from actual targets located within the water column. Active matched field processing provides a technique for estimating the scatterer depth by comparing the measured acoustic data with a series of modeled replicas generated assuming different scatterer depths. This paper considers active matched field processing to estimate the depth of a scatterer (range is assumed known from the delay time of the echo) using a single receive hydrophone. Since matched field processing is sensitive to environmental mismatch, the search space is expanded to include both the scatterer depth and the unknown environmental parameters. Simulated annealing is used to efficiently search the parameter space for the optimal solution. A novel cost function, based solely on multipath arrival times rather than the relative multipath amplitudes, is introduced to make the search robust to uncertainties in scatter characteristics. Simulation results demonstrate the effectiveness of the technique to accurately estimate scatterer depth with limited environmental data.

3:50

2pUW19. The detection of cylindrical objects of low acoustic contrast buried in the seabed. Ruthven C. Evans and Timothy G. Leighton (Inst. of Sound and Vib. Res., Univ. of Southampton, Highfield, Southampton SO17 1BJ, UK, ecpr@isvr.soton.ac.uk)

It is anticipated that the next generation of submarine fiber-optic telecommunications cables will be invisible to present-day detection systems. In cooperation with Cable and Wireless (Marine) Ltd., research has been conducted into the remote detection of buried objects of low acoustic contrast, with particular emphasis given to the detection of buried cables. Specifically, this has concerned the design of a detection system that can reliably discriminate a small diameter (cm scale), cylindrical target buried to a depth of up to 1 m below the seabed from a range of 1 m above. A purpose-built, laboratory-scale, automated sensing system comprising a bistatic arrangement of adjustable, focused transducers is described. This apparatus has been used successfully in the high-resolution imaging of a range of buried objects, proving an acoustic detection system to be a feasible solution. Recent experimental investigations have focused on two areas: Waveform optimization techniques, to maximize seabed penetration and target interaction, and matched filtering and clutter reduction techniques, to optimize the detection system to the acoustic signature of a particular buried object. Results are presented.

3:55

2pUW20. Characteristic of a semiburied object in shallow water. Shi-e Yang and Xiukun Li (Dept. of Underwater Acoust. Eng., Harbin Eng. Univ., 150001 Harbin, PROC)

The impulse reflection of a semiburied object is strongly complicated due to a multipath channel effect in a shallow-water environment, and usually also mixed with unavoidable bottom reverberation. An efficient method of signal processing in order to obtain necessary characteristics of the object, which can be used for object identification, is discussed, and several experimental examples are given.

2pPLb1. Representation of complex spectra in the peripheral auditory system. Eric D. Young, Barbara M. Calhoun, Jane Yu (Dept. Biomed. Eng. Ctr. Hearing Sci., Johns Hopkins Univ., 720 Rutland Ave., Baltimore, MD 21205, eyoung@bme.jhu.edu), and Israel Nelken (Hebrew Univ.—Hadassah Med. School, Jerusalem, Israel)

The representation of acoustic stimuli in the auditory periphery is tonotopic; frequency is mapped onto a place in the array of auditory neurons and the stimulus energy at each frequency is represented by the activity of neurons at the corresponding place in the neural array. Despite this generality, the details of the process can be complex, in part due to nonlinearities in neural processing. In the dorsal cochlear nucleus (DCN), for example, neurons give the same response to an energy peak in the spectrum as they do to an energy notch. Because of the nonlinearities, it may not be possible to predict the responses to arbitrary spectral shapes from responses to tones. In the DCN, a physiological model which accounts for the nonlinearities has been developed, but this method is not generalizable. A method for characterizing receptive fields for broadband stimuli has been developed based on the presentation of ensembles of stimuli with random spectral shapes; a neuron's sensitivity to a particular frequency is obtained from the correlation between the neuron's rate and the stimulus energy at that frequency. Because this method uses complex stimuli, it should better predict responses to complex stimuli of similar bandwidths. [Work supported by NIDCD.]

3aPLa1. How listeners find the right words. Anne Cutler (MPI for Psycholinguistics, P.O. Box 310, 6500 AH Nijmegen, The Netherlands)

Languages contain tens of thousands of words, but these are constructed from a tiny handful of phonetic elements. Consequently, words resemble one another, or can be embedded within one another, acoustics not withstanding. The past few years of psycholinguistic research have seen repeated confirmation that the process of spoken-word recognition by human listeners involves activation of multiple word candidates consistent with the input, and that these candidate words actively compete with one another. Current models of the word-recognition process are computationally explicit and can accurately reproduce the experimental results, as will be demonstrated by simulations with the SHORTLIST model, operating on a realistic vocabulary of 26 000 words. Activation and competition, however, do not exhaust the range of procedures which human listeners can call upon to find words in speech. My colleagues and I have recently established that listeners are sensitive, at an early, prelexical stage of speech processing, to constraints on what could potentially be a word of the language. Furthermore, cross-linguistic comparisons—of English, French, Japanese, and Sesotho—suggest that these constraints are not tailored to the characteristics of a particular vocabulary, but are universal.

3aAAa1. Sound transmission through permeable double-leaf membranes. Kimihiro Sakagami (Environ. Acoust. Lab., Faculty of Eng., Kobe Univ., Rokko, Nada, Kobe, 657 Japan), Masakazu Kiyama (Kobe Univ., Kobe, 657 Japan), Toru Uyama, and Masayuki Morimoto (Kobe Univ., Kobe, 657 Japan)

Double-leaf membranes with a permeable interior leaf are one of the typical constructions in membrane-structure buildings. A theory to predict the sound-pressure reflected by, and transmitted through, this type of double-leaf membrane was established by taking into account the coupled motion of the membranes and surrounding sound field [K. Sakagami, M. Kiyama, and M. Morimoto, J. Acoust. Soc. Am. **100**, 2735(A) (1996)]. In this same paper, the theory was experimentally validated. That work focused on absorption characteristics since the lack of absorption is one of the main acoustical problems in this type of building. The present paper investigates the sound transmission through a structure of this type in order to gain insight into its sound insulation performance which, in many cases, needs to be improved. The effects of the parameters of the double-leaf membrane on its transmissibility are demonstrated and discussed through numerical examples: The characteristics drastically change with the permeability of the interior leaf. The effect of the interior permeable leaf's mass is slight, whereas that of the exterior impermeable leaf is significant, particularly at mid-high frequencies. The effect of an absorbent layer in the cavity is also examined.

9:40

3aAAa2. Prediction of noise transmission through commercial profiled metal cladding systems. Y. W. Lam (Dept. of Acoust. Audio Eng., Univ. of Salford, Salford M5 4WT, UK)

Lightweight profiled metal cladding systems generally have poor acoustic insulation characteristics, and traditional theories for evaluating noise transmission through building elements are usually not applicable to double-skin profiled systems because of their orthotropic nature. Based on extensive experimental observations, a new method for predicting the sound reduction index (SRI) of commercial double-skin cladding systems is proposed. The method combines existing theory for orthotropic flat plates with finite element analysis to account for the pronounced ''dips'' in the SRI at midfrequencies, which are caused by the resonances of the profile geometry. The predicted SRI was shown to compare well with measurements on 15 cladding systems used in the experimental work. The method was further extended to cover commercial double-skin cladding constructions. Analytical equations were formulated to account for the orthotropic nature of the cladding sheets, the sound bridging through fixing supports, and the sound reduction through the in-fill insulation. Comparisons of predictions against sound reduction measurements were made on a wide range of commercial cladding products. Good agreement between predictions and measurements was found.

10:00

3aAAa3. European prediction models for building acoustics. Eddy Gerretsen (TNO Inst. of Appl. Phys., P.O. Box 155, NL-2600 AD Delft, The Netherlands, gerretsen@tpd.tno.nl)

About 8 years ago work started in the European standardization organization (CEN) to create prediction models for several acoustic aspects in building: airborne sound transmission, impact sound transmission, facade sound transmission, facade sound radiation, and the noise caused by technical equipment. The main aim is to provide the link between the acoustic performance of products and elements, as measured by standardized laboratory measurement methods, and the performance in the realized buildings. So far the prediction models for the first four aspects are (almost) finished. The work on the part concerning equipment noise has yet to start, handicapped as it is by a lack of available knowledge in this area. The chosen approach for the models on airborne and impact sound transmission applies separate independent transmission paths between rooms, which can be shown to be a first-order estimation of a SEA approach. For these models a new quantity has been introduced to characterize the structure-borne sound transmission at junctions of building elements. Further work is focusing on the description of measurement methods to determine this quantity and on verification of the models in order to indicate more precisely their reliability in predicting the acoustic performance of buildings.

10:20

3aAAa4. Structure-borne transmission in lightweight buildings. Robert J. M. Craik (Dept. of Bldg. Eng. and Surveying, Heriot-Watt Univ., Riccarton, Edinburgh EH14 4AS, UK)

The move away from mass as a means of reducing sound transmission in buildings has led to the development of lightweight buildings. High levels of sound insulation are achieved by introducing discontinuities while retaining structural integrity. This paper will examine structure-borne sound transmission in lightweight framed buildings. For sound transmission through a wall or floor it is the coupling between the frame and the lightweight panels which must be considered. The coupling can be classified as either a line connection or a point connection. Each of these cases will be examined and the theories for sound transmission compared with experimental results. Flanking transmission must also be considered and models for the coupling between the structural elements will also be examined. These models are different from traditional buildings as many of the elements behave as beams rather than as plates. The structure is therefore a collection of beams and plates rather than just plates. Some of the transmission paths for transmission between adjacent rooms will be examined both for the case where all walls and floors are lightweight constructions and for the case where there is a mixed construction with traditional walls but lightweight floors.

10:40

3aAAa5. Flanking paths between walls and lightweight wood frame floors using statistical energy analysis. T. R. T. Nightingale (Inst. for Res. in Construction, Natl. Res. Council Canada, Ottawa, ON K1A 0R6, Canada), and J. A. Steel (Heriot Watt Univ., Riccarton, Edingurgh EH14 4AS, Scotland)

Previous work has examined flanking paths from a floor/ceiling assembly to a load-bearing wall (where the floor joists were oriented normal to the supporting wall). It was shown that beams at the joint (plates and joist header) must be considered when predicting transmission at this type of joint. The dominant flanking path was from the floor deck to the supporting wall which reduced the apparent sound insulation from FSTC 59 to 53. The path from the upper to the lower wall was insignificant. This paper presents the results of a similar study that examined flanking paths from a nominally identical floor/ceiling assembly to a non-load-bearing wall (where the joists were parallel to the joint axis). Measured velocity level differences and apparent sound insulation are compared to the load-bearing wall configuration. Flanking paths involving a non-load-bearing wall are shown to have no appreciable impact. Joint models are presented using both standard wave methods and dynamic stiffness methods. The joint models are incorporated into a statistical energy analysis model of the system. Measured and predicted results for the two joint configurations are compared and show good agreement between 100–3150 Hz.

11:00

3aAAa6. The use of semianalytical calculation models to verify SEA predictions of flanking transmission in building structures. Ivan Bosmans and Gerrit Vermeir (Lab. of Bldg. Phys., Katholieke Univ. Leuven, Celestijnenlaan 131, B-3001 Heverlee, Belgium, ivan.bosmans@bwk.kuleuven.ac.be)

The prediction of structure-borne sound transmission between coupled plates represents a key aspect when studying sound transmission in buildings, since vibrational energy flow between walls and floors leads to the existence of flanking paths. The resulting flanking transmission can be assessed theoretically using statistical energy analysis (SEA). In this method, the coupling between plates is usually estimated based on the wave approach for the corresponding semi-infinite plates. For a specific type of junction, one might consider verifying the predictive performance of SEA experimentally on an isolated plate junction. However, possible discrepancies between measured and predicted data can result either from the failure of the calculation model for the semi-infinite plates, or by the violation of the basic SEA assumptions. In this paper, a semianalytical calculation model based on a modal summation approach for finite-sized plates is proposed to determine the source of the prediction error. For this purpose, calculations are performed for two ensembles of similar corner junctions with randomly distributed dimensions. The analysis emphasizes the influence of the model overlap factor on the accuracy of SEA. [Research funded by the Flemish Institute for the promotion of Scientific Technological Research in Industry (IWT).]

Architectural Acoustics and Noise: Impact of Trains on Performance Halls

George P. Wilson, Chair
Wilson Ihrig and Associates, Inc., 5776 Broadway, Oakland, California 94618

Invited Papers

11:25

3aAAb1. Owner/builder perspective of the impact of trains on performance halls for Benaroya Hall, Seattle. Andrew Clapham, Project Manager (Seattle Symphony, 305 Harrison St., Seattle, WA 98109-4645)

The Seattle Symphony began planning for a new concert hall in early 1987 at a location near their existing venue, the Seattle Opera House. During funding negotiations with The City of Seattle in 1992, the City made it clear that they wished to have the new facility located in their downtown core area. They offered a site that had many added challenges. These included being in the flight path of Sea-Tac International Airport; being alongside the Metro transit tunnel which is to accommodate light rail; being located in the heart of a very active city; and finally being located directly above the twin track railroad tunnel that runs north to south through the city center. In order to achieve the desired acoustical quality for the 2 500-seat main auditorium and 540-seat recital hall, not only for performances, but also for digital recording, a number of innovative design and construction techniques were required. These ranged from a massive foundation slab above the tunnel, to construction of a vibration isolated building within a building, which is supported on natural rubber isolation bearings. The challenges of designing and constructing this unique building will be presented.

11:45

3aAAb2. Vibration isolation design for Benaroya Hall. George P. Wilson (Wilson, Ihrig & Assoc., Inc., 5776 Broadway, Oakland, CA 94618)

Location of the new Seattle Concert Hall, Benaroya Hall, directly over an existing Burlington Northern railroad tunnel required development of a very effective vibration and noise isolation system. The first step in the design was to measure the ground-borne vibration and noise levels from trains via boreholes at the site and in the basement levels of nearby buildings located over the tunnel. From the measured vibration, the expected sound level in the performance space was projected for comparison with the criterion established for acceptable level and inaudibility. This comparison determined the amount and frequency range for the reduction required. The degree of reduction of structure-borne noise required determined that the design required two parts, a massive foundation mat for coupling loss and an isolation system with 4-5 Hz effective natural frequency and full reduction over a wide frequency range. Achieving the needed attenuation required a structure with very high mechanical impedance and isolators which provide a low acoustical impedance over a broad frequency range, leading to the use of heavy concrete structure and natural rubber isolation bearings. Details of the design parameters and materials are presented along with results from measurements with the completed isolation system and partially completed hall.

12:05

3aAAb3. Structural design for vibration isolation at Benaroya Hall. Brian H. Glover (Skilling Ward Magnusson Barkshire, 1301 Fifth Ave., Ste. 3200, Seattle, WA 98101-2699)

Vibration and noise isolation criteria, together with an urban site for the Seattle Symphony Hall, created unusual constraints for its structural design. A massive concrete mat foundation bridges and isolates the railroad tunnel running diagonally under the site. Two garage levels and an isolation level further separate the Auditorium from the tunnel, while 30 ft of unexcavated soil remain between the Auditorium and an adjacent underground transit station. Heavy concrete construction is used extensively to add mass for isolation. Concrete topping was added to the Auditorium roof for isolation, and double concrete walls surround the Auditorium. Exterior precast concrete cladding adds further mass and isolation. To speed construction time, the Auditorium balconies, including the inner walls which were cast to odd geometric shapes, are precast concrete. The Auditorium structure is isolated from the surrounding structure by an uninterrupted, 7-in.-wide joint, creating a ''box within a box'' The only structural connections to the Auditorium inner box are two types of special, natural rubber isolation bearings at its base. One bearing type takes gravity loads. The other type, initially prestressed, takes lateral loads. The need for bearing access under the base of the Auditorium created unusually shaped transfer girders.

3aAAb4. Controlling subway noise in the LG Arts Center—Sangnam Hall. D. Stanton Korista and Ahmad Abdelrazaq (Skidmore, Owings & Merrill LLP, 224 South Michigan Ave., Ste. 1000, Chicago, IL 60604)

The LG Arts Center in Seoul, Korea is a multifunction facility including a Hall intended for a variety of performances including western drama and dance, chamber music, traditional Korean folklore plays, opera, oration, and digital recordings. The 1050 seat Hall is designed to guard against both airborne and groundborne noise. Airborne noise is controlled by enclosing the stage house and the audience chamber with 200-mm airspace double walls. Horizontal and vertical acoustical joints at the Hall structure interface with the main building and control groundborne noise generated by the subway trains in a tunnel adjacent to the site. The subway tunnel and the foundation structure of the building are in the same rock strata and the groundborne noise is transmitted as structure-borne noise to the Hall through the lower-level parking structures. Without isolation the noise from the subway would have intrusive effects on the multifunctional use of the performance hall and stage area. Vibration isolation rubber bearings are provided in the interface design to reduce the noise to acceptable levels in the noise critical space. The impact of the proposed isolation bearing pads on the building design and their acoustical benefits are discussed.

12:40

3aAAb5. Train and rail transit noise in cinemas and theaters: Case studies. M. Asselineau (Peutz & Assoc., 103 Bd Magenta, F75010 Paris, France)

Train and subway noise unfortunately often turns out to be part of the show in theaters and cinemas of large cities, as the history of rail lines construction, or simply the urban planning, brought them close together. This paper aims to submit and discuss a few case studies, involving both rehabilitation and new construction projects, that feature cinema and performance facilities located near underground and suburban lines, main lines, or even high-speed lines. Those case studies, which range from real success to total failure, outline the architectural and technical context of the situation and discuss the sound and vibration levels measurements, as well as the technical solutions that were applied to the construction. It turns out that in rehabilitation projects, while the client may be willing to improve the acoustics, structural limitations can often be encountered, while in new projects there often is a need to convince the client of the importance of vibration control.

3aAB1. Three-dimensional computer modeling of biosonar emission in the common dolphin. James L. Aroyan (Elo TouchSystems, Inc., 41752 Christy St., Fremont, CA)

Several delphinid species are known to possess a highly sophisticated and adaptable biosonar system, yet the exact acoustic mechanisms involved in signal generation, emission, and reception remain poorly understood. Recently, a novel computational approach was utilized in an investigation of the acoustical mechanisms of dolphin biosonar. Three-dimensional acoustic simulation techniques and a new method for mapping acoustic tissue properties from x-ray computed tomographic data were applied to models of the forehead and lower jaw tissues of the common dolphin, *Delphinus delphis.* This approach proved highly effective in studying the detailed processes of biosonar emission and reception in this animal. The results of the investigation which concern the emission

system of this dolphin will be presented. These results include: (1) the common dolphin's skull plays the predominant role in beam formation; (2) the melon contributes significantly to narrowing of the emitted beams; (3) the melon behaves as a waveguide and a lens in the biosonar signal emission process; (4) the results of both inverse simulation and forward extrapolation programs suggest that the biosonar signal source tissues lie within a small volume of the soft tissues of the right nasal passageway.

3aAB2. Acoustic pathways of hearing in the bottlenose dolphin, *Tursiops truncatus*. Whitlow W. L. Au (Hawaii Inst. of Marine Biol., P.O. Box 1106, Kailua, HI 96734), Bertel Mohl (Univ. of Aarhus, Aarhus, Denmark), Paul E. Nachtigall (Hawaii Inst. of Marine Biol., Kailua, HI 96734), Jeffrey L. Pawloski, and James L. Aroyan (Elo TouchSystems, Inc., Fremont, CA)

The acoustic pathways for the reception of sound in the Atlantic bottlenose dolphin were studied by measuring auditory brain-stem-evoked potential responses as a specially designed suction cup hydrophone was placed at different areas of the animal's head. The dolphin was trained to come out of the water and beach on a rubber mat. Evoked responses were recorded differentially with suction cup surface electrodes placed between the parietal (noninverting) just posterior to the blowhole and mastoid (inverting). A transient signal was used as the stimulus and the amplitude of the stimulus was lowered in fixed dB steps until the evoked response reached a specific level close to the threshold level. The results indicate that the most sensitive portion of the lower jaw is slightly forward of the pan-bone and about 3/4 of the way toward the front of the lower jaw and along certain spots on the bottom midline of the lower jaw. The relative sensitivity of different areas of the lower jaw was also determined. The measurement results will be compared with results from calculations based on numerically solving the three-dimensional wave equation for wave propagation into the lower jaw of the dolphin. [Work supported in part by ONR, Grant No. N0001496WX30364.]

10:05

3aAB3. Effect of low-frequency seismic exploration signals on the cetaceans of the Gulf of Mexico. Shannon Rankin and William E. Evans (Marine Acoust. Lab, Texas A&M Univ., 5007 Ave. U, Galveston, TX 77550)

The increasing use of seismic exploration has created a need to understand effects that intense low-frequency sounds have on the distribution, abundance, and behavior of cetaceans. The goal of this study is to determine possible effects of seismic exploration on cetaceans in the northern Gulf of Mexico. Low-frequency sounds originating from seismic exploration were compared with the presence/absence of cetaceans as determined by acoustic and visual methods of detection. The recordings were collected via a towed passive hydrophone array during seasonal GulfCet research cruises from 1992–1997. The study area consisted of 14 north–south transects ranging from the 100–2000 m isobath in the northern Gulf of Mexico. For odontocetes, with the exception of sperm whales, no relationship between presence of low- and medium-frequency seismic noise was found on a relatively large spatial scale of hundreds of kilometers. For mysticetes, results were inconclusive due to small sample size. These findings suggest that the repetitive signals generated by seismic exploration may not have a negative impact on the large-scale distribution or overall abundance of delphinids in the Gulf of Mexico. However, additional studies have indicated possible negative impacts on aspects of communication and orientation of behavior in sperm whales (*Physeter macrocephalus*).

10:25

3aAB4. An onboard acoustic data logger to record biosonar of free-ranging bottlenose dolphins. Douglas P. Nowacek, Peter L. Tyack (Dept. of Biol., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543), Randall S. Wells (Chicago Zoological Society, c/o Mote Marine Lab., Sarasota, FL 34236), and Mark P. Johnson (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

An acoustic data logger has been developed which utilizes a two-channel DAT recorder housed in aluminum and attached to the dorsal fin. The recorder has a flat frequency response from 10 Hz to 14 kHz, and each tape can store 120 min. The first suction-cup hydrophone (sensitivity −205 dB) was placed 10 cm posterior of the blowhole, and the second 20 cm below the lateral base of the dorsal fin. The anterior ''high-frequency'' hydrophone, designed to record echolocation signals, has unity gain and a one-pole 10-kHz high-pass filter. The ''ambient'' hydrophone located at the base of the dorsal fin has +18-dB gain and a one-pole 1-kHz high-pass filter. To obtain echolocation recordings the ''high-frequency'' hydrophone was filtered through a simple demodulator in one of the deployments. The package includes VHF radio transmitters for tracking the animal and recovering the package after it releases via corrosible magnesium links. The package was attached to temporarily restrained animals which, after release, were followed to record behavioral data while the recorder logged acoustic activity. During the two successful deployments to date the logger recorded animal vocalizations, surfacing events, the sounds of passing boats, and hydrodynamic sounds produced by the animal's fluke strokes. 3aAB5. Results of underwater ambient noise measurements in three large tank exhibits at the Monterey Bay Aquarium. Daniel M. O'Neal and Steven R. Baker (Phys. Dept., Naval Postgrad. School, Monterey, CA 93943-5000)

Measurements have been made of the underwater ambient noise in three large tank exhibits at the Monterey Bay Aquarium: the Kelp Forest Exhibit (335 000 gal), the Monterey Bay Habitats Exhibit (350 000 gal), and the Outer Bay Waters Exhibit (1.4 million gal). A single, calibrated, Navy-type DT-276 was used. The hydrophone output voltage was preamplified and recorded using a 16-bit digital audio tape recorder with a sampling rate of 48 kHz. Measurements were made with various mechanical equipment (motors, fans, pumps, sprinklers, wave machine) turned on and off. On one occasion, the noise was measured in the largest tank, the Outer Bay Waters Exhibit, during a power shutdown. For comparison, measurements were also made at several locations and depths in the inner Monterey Bay. The results of one-third octave band and narrow-band analyses will be presented. Comparisons will be made between the aquarium and bay results and standard deep water ambient noise spectral density curves.

11:20

3aAB6. Identification of dolphin schools by bioacoustical unique features. Konstantin Kebkal (State Oceanarium of Ukraine, 9, Epronovskaya, 335024 Sevastopol, Ukraine, kostia@hotmail.com; kostya@fb10.tu-berlin.d400.de), Rudolf Bannasch (Technische Universitat Berlin, FG Bionik & Evolutionstechnik, Ackerstr. 71-76, D-13355 Berlin, Germany), and Valeriy Kulagin (State Oceanarium of Ukraine, 9, Epronovskaya, 335024 Sevastopol, Ukraine)

Long-term acoustical observations conducted on bottle-nosed dolphins (Tursiups truncatus ponticus) in the State Oceanarium of Ukraine as well as in the open sea revealed the existence of school specific acoustic features. It was found that each dolphin school uses a unique set of whistle contours in conjunction with a preferable frequency band and certain time characteristics. If the latter two characteristics somewhat vary according to particular surrounding and behavioral situations, the composition of normalized whistle contours stays stable. Each single whistle can be described by a set of polynomial coefficients characterizing its shape. Referring to the whole set of whistles emitted, a diagram of signal preferences can be built. Several samples will be presented to demonstrate that such diagrams represent acoustical portraits unique for every dolphin school. Based on those analyses, the development of a system for passive auto-

matic monitoring of dolphin abundance and migration activity is in progress. The system should consist of radio-acoustical buoys placed in the sea to record signals and to transmit them to a coastal station and an automatic signal analyzer in conjunction with an expert-system capable of determining whether the respective signals belong to a school registered earlier, or a new one.

11:40

3aAB7. Matched-field processing of baleen whale vocalizations using calibrated environmental models. Aaron M. Thode, Gerald L. D'Spain, and William A. Kuperman (Marine Physical Lab., Scripps Inst. of Oceanogr., Univ. of California at San Diego, La Jolla, CA 92093-0205)

During the 1997 Marine Mammal Vocalization (MMV) experiment conducted by the Scripps Marine Physical Laboratory last September, J15 source tows were conducted in a highly range-dependent environment northwest of San Nicolas Island in the Southern California Bight region. The tows consisted of eight radial tracks ranging from 1 to 6 nautical miles from the research platform FLIP, along all cardinal directions. Among the signals broadcast were low-frequency combs (18–110 Hz), middle-frequency combs (50–200 Hz), FM downsweeps (900 to 50 Hz over 9 s), and an Eastern Pacific type A blue whale recorded during the 1996 MMV experiment. Multiple CTD casts were also taken, and a bathymetric database was obtained from the National Oceanographic Service. All these data are used to calibrate matched-field processing environmental models, which are subsequently applied to find the location in 3D space of a series of blue whale vocalizations. [Work sponsored by ONR.]

12:00

3aAB8. Feasibility of monitoring bowhead whales with a vertical line array. Kevin D. Heaney and Peter N. Mikhalevsky (Sci. Applications Intl. Corp., 10260 Campus Pt. Dr., San Diego, CA 92121)

As part of the ACOUS trans-Arctic acoustic propagation experiment, a vertical line array will be deployed off Pt. Barrow, Alaska in the summer of 1998. The array will be cabled to shore and will be capable of real-time recording of acoustic frequencies from 20 to 500 Hz. This array will provide scientists the opportunity to record bowhead whale songs in real time from hydrophones spanning the water column. Currently, the bowhead whale census is taken during the spring migration from the edge of ice leads. The feasibility of doing a Fall census, when the sea is relatively free of ice, will be presented. Recordings of bowhead whale songs, and simulations of localization using the vertical array will be presented. Using varying bathymetry and sono-buoys, to add to the horizontal resolution of the array, 3D localization of vocalizing whales should be possible.

12:20

3aAB9. Observations of the movements of humpback whales about an operating seismic survey vessel near Exmouth, Western Australia. Robert D. McCauley (Ctr. for Marine Sci. Technol., Curtin Univ. Technol., P.O. Box U 1987, Perth 6854, Western Australia), Micheline-Nicole Jenner, Curt Jenner (Ctr. for Whale Res., Broome 6725, Western Australia), and Douglas H. Cato (Defence Sci. Technol. Organisation, Prymont, NSW 2009, Australia)

As part of a project investigating the interaction of air-gun noise and marine animals, monitoring of migrating humpback whales traversing the track of a seismic vessel was conducted in October 1996. Four separate pods traveling SW in 100–120 m of water were followed as they approached a seismic vessel traveling on an east/west heading and operating a 2678 cui air-gun array every 8 s. The response of pods was to change course at 3–6 km from the vessel so as to pass in front of or behind it. In one instance a single animal was observed moving slowly at 4.2 km NNW of the vessel, then to suddenly accelerate to 10–12 kn on a SW course across the vessel's bow at a closest range of 1.5 km. It then swam S at 5–10 kn until it was 4 km from the vessel. During the period of rapid swimming the animal stayed close to the surface with the tail flukes often breaking the water, maintaining a 40-s blow interval. The animal then swam steadily SW, eventually stopping and commencing singing on encountering a pod of two animals at 15 km from the still operating seismic vessel. [Work supported by the Energy Research and Development Corporation, Australian Petroleum Production and Exploration Association, and WMC Petroleum.]

3aAO1. Applications of two frequency insonification techniques to oceanic bubble sizing. Andy D. Phelps, Matt D. Simpson, and Timothy G. Leighton (Inst. of Sound and Vib. Res., Univ. of Southampton, Southampton SO17 1BJ, UK, ap@isvr.soton.ac.uk)

This work presents the results from using a combination frequency acoustic technique to measure the near-surface bubble population in both the open sea and surf zone. The benefits of using a combination frequency technique are that the collected data are more accurate and less prone to ambiguities than linear backscatter measurements. The technique monitors the appearance of sum-and-difference signals generated by the nonlinear interaction of two sound fields: one high-frequency signal scattering geometrically from the bubble surface and the other used to excite the bubble into resonant pulsation. The work details the calibration of the apparatus necessary to relate the measured heights of the sum-and-difference terms to actual numbers of bubbles, and describes the experimental procedure for the collection of the oceanic data. The collected data are verified using simultaneous measurements of the dispersive sound speed and attenuation, which can be compared with estimates calculated from the measured bubble population. The results from a number of trials are presented, with both time-averaged and time-variant measures of the local population demonstrated. [Work supported by the Natural Environment Research Council.]

8:45

3aAO2. Possibilities for small-scale emission tomography of bubble plumes in shallow water. Ivan P. Smirnov, Alexander I. Khil'ko (Inst. of Appl. Phys., Nizhny Novgorod, 46, Ulianov, Str., 603600, Russia), Paul A. Elmore, and Jerald W. Caruthers (Naval Res. Lab., Stennis Space Center, MS 39529)

Bubble plumes, created at the sea surface by breaking waves, emit sound in a broad range of frequencies. Based on the spatial and temporal characteristics of the emitted sound, emission tomographic reconstruction of the noise source distribution and evolution may be possible. It is shown that the space/time variables needed for the reconstruction process can be estimated from the coherence function of the radiated noise. The effectiveness of the reconstruction procedure when noise is present is estimated theoretically by the following physical model: (1) the location and time of bubble creation is assumed to be random and statistically independent, (2) the spatial distribution of the noise in the cloud, the spatial structure of the cloud, and the coherence function of the noise are described by a Gaussian distribution, (3) the sizes of the sources are much smaller than the size of the acoustic fields, and (4) the observation distance is much greater than the size of the sources. The requirements for the reconstruction process and the possible limitations of the method are discussed.

9:00

3aAO3. Monitoring air–sea exchange using ambient sound. Jeffrey A. Nystuen (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, nystuen@apl.washington.edu)

Wave breaking and precipitation are important processes contributing to the exchange of momentum, heat, water, and gas at the air–sea interface. These processes are also principal generators of high-frequency (over 1 kHz) underwater ambient sound. Furthermore, the bubbles generated by the breaking waves and raindrop splashes can be stirred downward into the ocean mixed layer forming an effective sound absorption layer. When present this layer modifies the ambient sound field, and can thus be detected using passive acoustics. Using the passive sound field as the exploratory tool, more conventional measurements of salinity, temperature, bubbles, wind, and surface waves will be examined. Anomalies in near-surface salinity are explained by acoustically derived rainfall and wind-speed measurements. Acoustically derived rainfall measurements suggest that rain affects the surface wave field. Enhanced injection of bubbles into the mixed layer by rain in the presence of high wind is indicated by changes to the shape of the underwater sound spectrum. [Work supported by ONR Ocean Acoustics and NSF.]

9:15

3aAO4. Wave scattering and propagation in bubbly liquids. Zhen Ye (Dept. of Phys., Natl. Central Univ., Chung-li, Taiwan, ROC) and Alberto Alvarez (Natl. Central Univ., Chung-li, Taiwan, ROC)

Acoustic wave propagation through bubbly liquids can be modified significantly by its scattering by the bubbles. The effects may be conveniently studied either by diagram methods when the number of bubbles is large, or by numerical simulation when the number is not so large. In this paper, numerical simulation on the acoustic scattering and propagation in a bubbly mixture is reported, with comparison to the effective medium theories. The analysis shows possible Anderson localization of acoustics waves. It is found that collective modes in bubble clouds are possible when the bubble volume fraction reaches a certain value. [Work supported by NSC of ROC and Spanish Ministry of Education.]

9:30

3aAO5. Rough surfaces characterization using a time-reversal mirror. Philippe Roux, Mathias Fink (Lab. Ondes et Acoustique, ESPCI, 10 rue Vauquelin, 75005 Paris, France), and James H. Rose (Iowa State Univ., Ames, IA 50011)

A new method is described for determining the rms height and autocorrelation function of rough surfaces using measurements made with an acoustic time-reversal mirror (TRM). First, the TRM insonifies the surface and the backscattered wave is recorded and time-reversed. Second, the TRM is displaced parallel to the surface and, at each displacement the previously recorded time-reversal wave is rebroadcast. For zero displacement the time-reversed wave is matched to the surface and the original incident pulse is recovered (upon reflection of the rebroadcast wave). However, with increasing displacement the signal ceases to resemble the incident pulse. The decorrelation of the signal allows one to characterize the surface. Measurements are reported for a number of periodic and random rough surfaces.

9:45

3aAO6. The Aharonov–Bohm effect revisited by an acoustic time-reversal mirror. Philippe Roux, Julien De Rosny, and Mathias Fink (Lab. Ondes et Acoustique, ESPCI, 10 rue Vauquelin, 75005 Paris, France)

The violation of time-reversal invariance for acoustic waves to achieve a new way of characterizing a vorticity field with a double acoustic time-reversal mirror (TRM) is taken advantage of. In particular, it is shown experimentally that the double TRM works as a vorticity amplifier. In the case of a vorticity filament, the sound-vorticity interaction is interpreted as the acoustical analog of the Aharonov–Bohm effect. Numerical experiments simulate the acoustical Aharonov–Bohm effect by propagating a plane wave which is scattered by a heterogeneous motionless medium.

10:00

3aAO7. Real-time characterization of unstationary flows using a time-reversal mirror. Agnes Maurel, Julien De Rosny, Sebastien Manneville, Philippe Roux, and Mathias Fink (Lab. Ondes et Acoustique, ESPCI, 10 rue Vauquelin, 75005 Paris, France)

Violation of time-reversal invariance for acoustic waves is a new method for characterizing a vorticity field with a double acoustic time-reversal mirror (TRM). Experiments show that the double TRM works as a vorticity amplifier and, even in the case of small vorticity field, provides the characteristics of the flow. Moreover, the TRM works in real-time and allows one to measure the vorticity field at a 20-Hz frequency rate. The case of a Von Karman vortex street is studied experimentally.

10:15

3aAO8. Results from cross-correlation measurement of estuarine current velocity. Roger W. Bland and Daniel G. Neuman (Dept. of Phys. and Astron., San Francisco State Univ., San Francisco, CA 94132)

A technique for accurate measurement of the average water velocity in estuarine environments has been developed. The technique is based on measuring the travel time of 200-kHz ultrasonic signals. A high degree of precision has been obtained using a cross-correlation technique, and long, detailed time series have been recorded. However, in some geometries the precision is degraded by multipath interference. Measurements of current speed in California's Sacramento-San Joaquin River Delta system will be discussed, with particular reference to the effects of multipath interference. Data were collected throughout a large flood in Dec. 1996–Jan. 1997. An analysis of the variation of the strength of the ultrasonic signal has been carried out to determine the attenuation of the signal due to the load of suspended sediment, and the results will be presented. The current-velocity time series recorded in the San Francisco Bay also show wave trains from boat wakes. These wakes will be discussed.

3aBV1. Mechanisms for biological effects of ultrasound. Edwin L. Carstensen (Dept. of Elec. Eng. and Rochester Ctr. for Biomed. Ultrasound, Univ. of Rochester, Rochester, NY 14627)

At least three physical processes have the potential to produce therapeutic benefits through ultrasound exposure. These include heating, cavitation, and a related group of second-order mechanical effects that involve radiation forces and streaming on a macroscopic or microscopic scale. In most applications of ultrasound in physical therapy, deep heating is the postulated rationale for its use. Hyperthermia as an adjunct to cancer therapy requires sophisticated control of ultrasonic heating. At higher levels, ultrasound can be used to destroy precisely selected tissues obviating the need for surgical intervention. In this application, nonlinear propagation can be used to selectively increase the absorption parameters of the target tissues. At low amplitudes the response of bubbles is dominated by the acoustic pressure. At a critical acoustic pressure, however, the inertia of the surrounding medium becomes controlling. At this threshold acoustic pressure a 10% or 20% increase in acoustic pressure leads to an increase in the collapse pressure in the bubble by orders of magnitude. Radiation forces can be detected by auditory and tactile sensors. Macroscopic acoustic streaming may alter transport across biological membranes and microscopic streaming exerts stresses on the membranes and the cytoplasmic and nuclear contents of cells.

8:30

3aBV2. Toxin and gene transfer into cells by extracorporeal shock waves. M. Delius (Inst. for Surgical Res., Univ. of Munich, Klinikum Grosshadern, 81366 Munich, Germany) and U. Lauer (Univ. of Tübingen, 72076 Tübingen, Germany)

Shock wave application to cells *in vitro* causes a transient increase of the permeability of the cell membrane which does not lead to cell death. It was hypothesized that shock waves might be a new method of transferring therapeutic agents directly into cells. To test this, biological effects resulting from the acoustical transfer of proteins and nucleic acids into cells were examined. Protein transfer was examined with the ribosome inactivating proteins gelonin and saporin which inhibit the cellular protein synthesis. Dose response curves were established with three tumor cell lines in the presence and absence of shock waves. Compared to the controls, shock waves enhanced the action of gelonin and saporin from 300 to 40 000 fold. *In vivo* experiments with an animal tumor model established that acoustic transfer of these agents into cells also occurred *in vivo*. Gene transfer by shock waves was examined in a number of cell lines by plasmid vectors carrying standard reporter genes. Transfer succeeded in many cases yet the transduction efficiency was lower than with other established methods of gene transfer. In summary shock wave permeabilization is a new method for tumour therapy and gene transfer.

8:55

3aBV3. Ultrasound-induced transcutaneous transport for drug delivery and diagnostics. Joseph Kost (Dept. of Chemical Eng., Ben-Gurion Univ., Beer-Sheva, 84105, Israel, kost@mit.edu), Samir Mitragotri, and Robert Langer (MIT, Cambridge, MA 02139)

In spite of major research and development efforts in transdermal systems and the many advantages of the transdermal route, impermeability of the human skin is still a major problem that limits the usefulness of the transdermal drug delivery approach. Application of ultrasound induces temporary structural changes in the skin resulting in enhanced transdermal transport of molecules (sonophoresis). Experimental findings suggest that among all the ultrasound-related phenomena evaluated, cavitation plays the dominant role in sonophoresis, suggesting that application of low-frequency ultrasound should enhance transdermal transport more effectively. It was found that at the low ultrasound frequencies high molecular weight molecules including insulin, interferon, and erythropoietin can be transported through the skin. Recently it was shown that the enhanced skin permeability during sonophoresis also facilitates outward diffusion of glucose present in the interstitial fluids beneath the skin. The *in vitro* as well as *in vivo* experiments show that the amounts of glucose extracted by sonophoresis are proportional to the blood glucose concentrations. Furthermore, the amount of glucose extracted by ultrasound can be measured and used to predict temporal changes in the blood glucose levels. These results demonstrate the feasibility of developing a noninvasive method of drug delivery and diagnostics using ultrasound.

9:20–9:35 Break

9:35

3aBV4. Ultrasound for the mediation of a therapeutic agent through the blood–brain barrier. Leonard J. Bond (Univ. of Denver Res. Inst., 2050 E. Iliff Ave., Denver, CO 80208) and Lawrence Ng (Univ. of Colorado Health Sci. Ctr., Denver, CO 80262)

There is a critical need to develop safe, noninvasive, nonchemical methods to enhance the delivery of nonlipophilic neuropharmaceuticals to the brain. A novel method for mediating nonlipophilic drug transport across the blood–brain barrier (BBB) will be presented. Preliminary data were obtained using a unit operating at 1.6 MHz with ultrasound coupled through water and an attenuating layer onto an *in vitro* cell-culture model of the BBB. The effects of different intensities on permeation rate and cell integrity were investigated. Various microscopic techniques were used to determine cell condition and viability. At low intensities no effects were seen. At intermediate intensities enhanced permeation up to levels of a factor of 3 increase were measured. At the highest intensity substantial cell disruption was observed. Preliminary observations regarding the mechanism for the interaction of ultrasound with the BBB will be presented. Work is in progress to determine the conditions for effective trans-cranial delivery of ultrasound using phantoms constructed to model *in vivo* brain. By promoting transport of nonlipophilic drugs across the BBB, this approach has the potential to safely and effectively treat a wide range of brain and central nervous system disorders.

9:50

3aBV5. Mechanistic studies of ultrasonically enhanced transdermal drug delivery. J. M. Farrell (Harvard-MIT Div. for Health Sci. and Technol., Boston, MA 02139), S. Mitragotri, S. Theis, J. Kost, and R. Langer (MIT, Boston, MA 02139)

The transdermal route of drug delivery offers a noninvasive and painless alternative to more traditional routes such as injections. However, its applicability is limited to only a handful of drugs due to the low permeability of the skin. It has been demonstrated that low-frequency ultrasound significantly enhances transdermal transport of a variety of drugs (sonophoresis). There is strong experimental evidence to suggest that cavitation plays a key role in this enhancement, although it is not clear which cavitational effects are primarily responsible for the transport. Cavitation can affect transdermal transport in at least two ways: It can induce changes in skin structure, creating pathways or channels for molecules to diffuse across and/or it can induce convective transport across the skin. An experimental system has been developed to assess contributions due to each of these phenomena individually. Although the data are insufficient to eliminate a role for convective processes, these experiments clearly indicate that stuctural changes in the skin play an important, and probably primary, role in enhanced transport.

Invited Paper

10:05

3aBV6. Enhancement of ultrasound-mediated transfection with cavitation micronuclei. James F. Greenleaf (Dept. of Physiol. and Biophys., Mayo Clinic and Foundation, Rochester, MN 55905, jfg@mayo.edu) and Mark E. Bolander (Mayo Clinic and Foundation, Rochester, MN 55905)

Many methods are available for transferring foreign genes into mammalian cells (transfection). The advantages of ultrasound-mediated transfection are that it can be controlled in both space, by focusing, and time, by exposure. It was tested whether ultrasound-mediated gene transfection in cultured immortalized human chondrocytes would be enhanced using artificial cavitation nuclei in the form of Albunex®. Here 1.0 MHz ultrasound transmitted through the bottoms of six-well culture plates containing media with green fluorescent protein reporter gene plasmids at a concentration of 40 μg/ml and Albunex® at 50×10^6 bubbles/ml produced a peak transfection efficiency of about 50% of the living cells when exposure was 4×10^5 P spatial average peak pressure (SAPP) for 20 mins. Using these parameters, transfection efficiency increased linearly with ultrasound exposure pressure with a transfection threshold observed at a SAPP of 10^5 P. Adding fresh Albunex® at 50×10^6 bubbles/ml prior to sequential one second 3.2 or 4.0×10^5 P exposures increased transfection efficiency by 15% for each of three consecutive exposures. Efficient *in vitro* and perhaps *in vivo* transfection appears possible with ultrasound providing both temporal and spatial control over the transfection process.

10:30

3aBV7. Defects of bilayers generated by ultrasound. M. S. Malghani, Jie Yang, and Junru Wu (Dept. of Phys., Univ. of Vermont, Burlington, VT 05405)

Transdermal drug delivery is handicapped by the low skin permeability caused by highly ordered structure of lipid bilayers in the outer human skin layer. It has been reported that ultrasound can increase the permeability of human skin [S. Mitragotri, D. Blankschtein, and R. Langer, Science **269**, 850–853 (1995)]. The enhancement was attributed to acoustic cavitation but the underlying physical mechanism is not fully understood. As a model, dipalmitoylphosphatidylcholine (DPPC) lipid bilayers are insonicated by ultrasound of two submegahertz frequencies (168 and 707 kHz). The free-field spatial peak pressure amplitudes of both are measured to be 6×10^5 Pa. Bilayer defects, which have average diameters of tens to hundreds of nanometers and can be detected by an atomic force microscope, are generated within less than 0.5 min. The number of the defects grows with time. The defect growth rate at the 168-kHz frequency is about 3.5 times that at the 707-kHz frequency.

Session 3aEA

Engineering Acoustics: Electroacoustics and Standards

George S. K. Wong, Chair
Institute for National Measurement Standards, National Research Council, Montreal Road, Ottawa, ON K1A 0R6, Canada

Invited Papers

8:00

3aEA1. Selected topics in electroacoustical calibrations, measurements, and standards. Victor Nedzelnitsky (Natl. Inst. of Standards and Technol., Sound Bldg. 233, Rm. A147, Gaithersburg, MD 20899-0001, vnedzel@nist.gov)

Modern instruments including multichannel dynamic signal analyzers capable of FFT and other signal processing, as well as improved concepts for applying these instruments to particular electroacoustical measurement and standardization issues, are essential tools in modern electroacoustical metrology. The overall uncertainty of a measurement, and its suitability for its intended purpose, may involve components of uncertainty that are individually and collectively difficult to evaluate. In such instances, the capacity to perform the same measurement in different ways can be especially valuable. Different measurements exploiting differences in source signals, signal processing implementations, and apparatus can provide valuable insight and can support the validity of measurement results and interpretations. Examples selected from recent and ongoing work at NIST include calibration or characterization of microphones and microphone arrays in a free field, examination of imperfections in anechoic chambers, and measurement of effects of instabilities and nonlinearities in electroacoustical systems. Recent ANSI (American National Standards Institute) and IEC (International Electrotechnical Commission) standardization work involving the coherence function method for examining nonlinearities in the electroacoustical performance of hearing aids has elicited comments proposing an alternative method involving the Hilbert transform. Some significant advantages and disadvantages of these methods are discussed.

8:15

3aEA2. Progress in silicon microphones. Gerhard M. Sessler (Univ. of Technol., Merckstrasse 25, D-64283 Darmstadt, Germany, ses@uet.th-darmstadt.de)

Recently, several advances have been made in the design, technology, and performance of silicon microphones. New or significantly modified transducers are: (1) condenser microphones consisting of a single chip processed with sacrificial-layer technology to form the electrode-air gap system; (2) condenser microphones with small parasitic capacitance to decrease the load on the sensor output; (3) optical-waveguide microphones utilizing novel waveguide designs and operating with intensity modulation, which, to date, has not been used in acoustic silicon sensors. Also, attention has been given to various types of ultrasonic silicon microphones for airborne sound. Of importance in all implementations is the equivalent noise level, which is, in some microphone-preamplifier systems, sufficiently low for certain applications, but still higher than for conventional microphones. The present state of the art with respect to transducer design and performance will be discussed.

8:30

3aEA3. Design and properties of face to face couplers for microphone comparison calibration. Erling Frederiksen (Bruel and Kjaer, Skodsborgvej 307, 2850 Naerum, Denmark. erlingfred@bk.dk)

This paper describes the design and properties of microphone comparison calibration couplers. In 1988 Bruel and Kjaer introduced a sound level calibrator with a built-in reference microphone which, via a feed-back system, controls the sound pressure in its coupler cavity. This was a significant step in the direction of more stable calibrators. The same calibrator presented another new principle. The microphone to be calibrated and the reference are placed face to face in such a short distance that their diaphragms see essentially the same sound pressure which is produced by a rotational symmetrical source. This mounting was found to improve the accuracy and to increase the upper frequency limit of the new calibrator by more than five times in comparison with previous calibrator configurations. Today IEC-TC29 prepares an international standard for comparison calibration of working standard microphones. The method of this standard uses the special symmetrical mounting of the source and the microphones. The paper describes results obtained with some experimental couplers which are made in this connection in order to analyze the calibration accuracy and optimize the frequency range. The couplers are mainly intended for comparison of sensitivity magnitude but may also be used for comparison of phase response characteristics.

8:45

3aEA4. Controlled environment for reciprocity calibration of condenser microphones. George S. K. Wong and Lixue Wu (Acoust. Standards, Inst. for Natl. Measurement Standards, Natl. Res. Council, Ottawa, ON K1A 0R6, Canada)

For precision reciprocity calibration of condenser microphones it is necessary to operate the calibration apparatus under a controlled environment such that fluctuations in pressure, temperature, and relative humidity are reduced to a minimum. The design, implementation, and performance of a highly stable environmental chamber for calibration of microphones and instruments is discussed. For reciprocity microphone calibrations, the system enables resolution of better than 0.001 dB.

9:00

3aEA5. Procedures for the precision of sound power determination by S. I. scanning method. Hideki Tachibana (Inst. of Industrial Sci., Univ. of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo, 106 Japan) and Hideo Suzuki (Ontec R&D Co., Ltd., Yokohama, 226 Japan)

As the third international standard of ISO 9614 series (Acoustics—Determination of sound power levels of noise sources using sound intensity), the precision method by scanning is now being drafted by ISO/TC43/SC1/WG25. It will be Part 3 (Precision method for measurement by scanning), following Part 1 (Measurement at discrete points: precision, engineering and survey classes) and Part 2 (Measurement by scanning: engineering and survey classes). In this paper, the outline of the draft and discussions are introduced by focusing on the measurement accuracy, the methods for checking the adequacy of the measurement sound field (field indicators), and practical procedures.

9:15

3aEA6. Experimental study on the accuracy of sound power determination of S. I. scanning method. Hiroo Yano (Chiba Inst. of Technol., 2-17-1 Tsudanuma, Narashino-shi, Chiba, 275 Japan), Hideki Tachibana (Univ. of Tokyo, Tokyo, 106 Japan), and Hideo Suzuki (Ontec R&D Co., Ltd., Yokohama, 226 Japan)

In ISO/TC43/SC1/WG25, the precision method of sound power determination by sound intensity scanning method is being drafted as the third standard of ISO 9614 series. For this drafting work, some experimental studies were performed on the measurement accuracy, the methods for checking the measurement sound field (field indicators), and practical procedures of signal processing during the scanning. The sound power determination was made for artificial sound sources (a reference source and a sound source system consisted of two loudspeakers) and actual noise sources (a vacuum cleaner and an air compressor) by changing such measurement conditions as the scanning density, the scanning speed, and the strength of the extraneous noise. From the experimental results, the validities of the specifications in the draft are examined.

9:30

3aEA7. Electroacoustics and standards. Gunnar Rasmussen (G.R.A.S. Sound & Vib. aps., Skelstedet 10B, 2950 Vedbæk, Denmark)

Standardization within electroacoustics has been of great importance for the development of sound measuring instrumentation. The sound level meters are used to build up a homogeneous database, which in turn is used as a foundation for the measurement standards. Based on the database, regulation and legislation of noise exposure, noise control, product labeling, etc., may take place. The development of standards for sound level meters, measurement microphones, and calibration techniques has led to big improvements. The development of standards for intensity instrumentation and measurements will hopefully lead to similar improvements in developing the instrumentation and practical use in the daily work of the practitioners. The revision of the standards is important. They should hopefully lead to improvements for the manufacturer and for the users. The revisions should take into account the technical development and the expanded use of instrumentation in the acoustical and mechanical field. The ability to measure small changes in emitted intensity by critical sources is important for research in noise control. The measurement of sound-pressure level in the outdoor environment is not well treated in the standards, although it is an area where the legislation is most restrictive regarding noise exposure, because it influences the largest parts of the population. Examples and proposals will be given.

3aEA8. The study of long-term sensitivity changes in backplate electret type condenser microphones. Kenzo Miura (Matsushita Commun. Eng. Co., Ltd., 4-3-1 Tsunashimahigashi, Kohoku-ku, Yokohama, 223 Japan) and Yoshinobu Yasuno (Matsushita Commun. Industrial Co., Ltd., 600 Saedo-cho, Tsuzuki-ku, Yokohama, 224 Japan)

The estimation of the lifetime of a usual electret condenser microphone (ECM) using an electret foil as a diaphragm has already been reported by authors. On the other hand, backplate electret type condenser microphones (BECMs) used for mobile telephones, recently, and the backplate that is laminated with electret foil has been examined and studied concerning the estimation of sensitivity changes over a long time span. Heat acceleration tests for electret foil on the backplate were taken, and from the results, the surface charge decay of backplate electret was estimated. As the thickness of the diaphragm in a BECM is thinner than the usual ECM, sensitivity increasing because of looseness of diaphragm tension was expected to become larger than the usual ECM. Therefore, heat acceleration tests for the diaphragm only were taken and estimates of the levels of sensitivity increasing by the looseness of the results. The charge decay characteristics on the electret surface and the characteristics of tension looseness in the diaphragm had both results taken together. The long-term sensitivity changes of BECMs were estimated and compared with the sensitivity of BECM samples that were left for about 10 years at room temperature.

3aEA9. Measurement of microphone random-incidence and pressure-field responses and determination of their uncertainties. Johan Gramtorp and Erling Frederiksen (Bruel & Kjaer, 2850 Naerum, Denmark, jgramtorp@bk.dk)

For many applications it is important to know the frequency response of the measurement microphone. In an earlier paper the determination of the free-field response and the uncertainties of the responses based on actuator calibration for $\frac{1}{2}''$ microphones was discussed [J. Gramtorp and E. Frederiksen, J. Acoust. Soc. Am. **100**, 2672 (1996)]. This paper continues by discussing the determination of the pressure-field and random-incidence responses and the determination of their uncertainties. The pressure-field responses are based on estimated pressure-field corrections obtained using the pressure-field reciprocity technique and electrostatic actuator calibration. The random-incidence responses are based on a large number of free-field measurements with different angles of incidence increased in small steps, and calculated according to IEC 1183, combined with electrostatic actuator calibration. From most manufacturers no infor-

mation on the uncertainties is available, but a complete set of uncertainty values for pressure-field and random-incidence corrections and responses for the new Bruel & Kjaer Falcon Range microphones will be presented and discussed.

10:30

3aEA10. Measuring system for the derivation of thermal loudspeaker parameters. Gottfried K. Behler and Armin Bernhard (Inst. for Tech. Acoust., RWTH Aachen, Templergraben 55, D-52056 Aachen, Germany, gkb@akustik.rwth-aachen.de)

Loudspeakers used in high-power applications are stressed by mechanical and thermal load. Both can be the reason for damage and should be controlled. Whereas the mechanical situation can be derived from the input voltage and the total impedance, which can be measured easily, it is rather difficult to calculate for the actual voice coil (VC) temperature under working conditions. It is possible to derive the VC temperature from the input voltage using linear mathematics if the thermal equivalent circuitry of the loudspeaker including the cabinet is known. Former papers have discussed the thermal equivalent circuitry of the loudspeaker without taking the cabinet into account. In the presented paper an equivalent circuit is presented, which can be used for loudspeakers in different cabinets and a measuring method is shown, that enables long-term measurements on loudspeaker systems with constant input power using a PC-based regulator. The main problem is to calculate the voice coil temperature from the measured impedance data. The solution of this problem is presented. At least the thermal parameters of the equivalent circuit are calculated from the measured data using curve fitting. Different loudspeakers and setups have been tested. The results will be presented.

3aMU1. Studies in bowing point friction in bowed strings. Robert. T. Schumacher (Dept. of Phys., Carnegie Mellon Univ., Pittsburgh, PA 15213)

By using force transducers at the terminations of a violin E string, one may reconstruct the force and velocity at the bowing point that produces those termination forces [R. T. Schumacher and S. Garoff, Institute of Acoustics, Proceedings, Vol. 19: Part 5, 43–48 (1997) (ISMA'97)]. That information, combined with examination of the ''friction track'' [R. T. Schumacher and S. Garoff, CAS J. **3**(2), 9–16 (1996)] allows the possibility of determining the frictional properties of the rosin-mediated bow–string interaction. The reconstruction of the force, $f(t)$, and velocity, $v(t)$, allows determination of the force–velocity relation $F(v)$. That reconstruction is a delicate operation requiring careful measurement of the reflection functions of the transverse waves at the terminations. Use of simulations aids in determining the limitations of the reconstructions. Knowledge of $F(v)$, combined with examination of the friction track, variation of the chemical constituents of the rosin, and chemical preparation of the string surface, as well as measurements of the rosin's physical properties, such as softening temperature and x-ray structural examination, will eventually establish the physical basis for the alternating adhesion–lubrication properties of the rosin that produce the slip-stick string oscillation.

9:40

3aMU2. Modal analysis of violins and cellos. Thomas D. Rossing, Mark Roberts, Eric Bynum, and Laura Nickerson (Phys. Dept., Northern Illinois Univ., DeKalb, IL 60115)

Normal modes of bowed string instruments are determined by the coupled motion of the top plate, back plate, enclosed air, ribs, neck, fingerboard, etc. Normal mode testing has traditionally been done using sinusoidal excitation, either mechanical or acoustical, although modal testing with impact excitation is a fast, convenient way to determine the normal modes of an instrument. Holographic interferometry provides the greatest detail about mode shapes, but the best understanding of the normal modes of an instrument results from application of more than one testing method. The normal modes in a cello are found to be quite similar to the corresponding modes of a violin, although they may appear in a different order in frequency. Modal frequencies in one cello were found to occur at 0.29 to 0.43 times the corresponding mode frequencies in a violin.

10:05

3aMU3. A normal-mode-based model of violin radiation. George Bissinger (Phys. Dept., E. Carolina Univ., Greenville, NC 27858, bissingerg@mail.ecu.edu)

A simple physical vibration–radiation model based entirely on experimental modal analysis can successfully predict the spatially averaged radiative properties of a bridge-excited violin measured with a rotating microphone array. The energy transfer from bridge excitation to acoustic radiation is modeled using (a) the measured transfer mobility $Y(\omega)$ to characterize energy transfer from the bridge to the corpus, and (b) the radiation efficiency R_{eff}, calculated from a boundary element program for each normal mode to characterize the energy transfer from the corpus to the air. This model provides string-specific radiation predictions and allows one to make quick estimates of the averaged acoustical effects of violin adjustments or modifications which would be expected to change $Y(\omega)$ but not R_{eff}, e.g., bridge trimming. Extensions of the model and future applications and directions for its application will be discussed.

10:30

3aMU4. Influence of the weight of mutes on tones of a violin family. Kenshi Kishi (Dept. of Electro-Commun., The Univ. of Electro-Commun., 1-5-1, Chofugaoka, Chofushi, Tokyo, 182 Japan, kkishi@peacock.ee.uec.ac.jp)

The phrase ''con sordino'' is used for the score of a violin family to indicate the use of a mute. The mute is used to reduce the volume of the violin tones and change their tone quality. This paper examines the influence of the weight of mutes on tones of a violin using the spectral envelopes of the violin tones. Violins with and without mutes were played by a skilled player in an anechoic chamber to produce tone samples which were then recorded on a DAT recorder. Using the tone samples, the time variances of the fundamentals and spectral envelopes obtained by FFT analyses were examined. The force transfer function of a cello bridge with mutes installed, which is used for convenience, was measured. From these examinations and analyses, we made the following observations: (1) the higher the order of harmonics, the lower their relative sound pressure levels compared with that of the fundamental and (2) the level differences between the peaks and dips of the spectral envelopes are reduced as the weight of a mute is increased.

10:55–11:05 Break

11:05

3aMU5. Anomalous low frequencies from a bowed violin string. Roger J. Hanson (Phys. Dept., Univ. of Northern Iowa, Cedar Falls, IA 50614, roger.hanson@uni.edu) and Frederick W. Halgedahl (Univ. of Northern Iowa, Cedar Falls, IA)

With a bow force greater than the Schelleng maximum and careful bow control, it is possible on a violin to produce sounds of definite pitch ranging from approximately a musical third to as much as two octaves below the normal pitch. [Hanson *et al.*, CAS J., **2**, Series II, 1–7 (1994)]. The pitch is in agreement with the fundamental frequency of the observed harmonic series. The fundamental itself is very weak if the sounds are produced on the open violin G string. These anomalous low frequencies (ALF) occur when the bow force is great enough to prevent the Helmholtz kink from triggering the normal release of the string from the bow hair. The bow serves as a quasitermination point of the string so that there are pronounced bow-nut and bow-bridge reflections yielding at the bow a very complex waveform, some portion of which triggers the slipping of the string. The ALF can also be produced on a bowed monochord where the motion at several points is detected optically, and the sound is generated from the resulting signal. Some musical applications of the effect will be discussed.

11:30

3aMU6. Acoustical aspects of chamber music for strings. Juergen Meyer (Physikalisch-Technische Bundesanstalt, D-38116 Braunschweig, Germany, juergen.meyer@ptb.de)

Playing string quartet music under different room acoustics conditions demands adaptation of the playing technique, particularly of the articulation. If not damped by the bow, violin tones have a 60-dB decay time of about 0.5 s in the highest part of the range, increasing to about 1 s for the lowest tones; in the lower stringed instruments, decay times are as much as 3 s. When damped by the bow, the decay times can be shortened to about 0.1 s. Attack times of staccato violin tones are of the order of 30–50 ms; smoothed attacks may be prolonged up to 200 ms. The temporal structure of a fast staccato tone sequence (14 tones per second) is mainly characterized by breaks in the overtones of the order of 25 ms, whereas the fundamentals seem to be blended together or slurred. These values correspond with typical acoustical criteria of historical and contemporary chamber music halls. To determine the reaction of musicians to the boundary conditions as well as the listeners' impressions, a test was performed by playing the same programs of short and different music examples during only 3 h in three halls having different room acoustic properties.

3aMU7. Radiation mechanisms of a violin with known modal characteristics. Lily M. Wang and Courtney B. Burroughs (Grad. Prog. in Acoust., Penn State Univ., P.O. Box 30, State College, PA 16804)

Multiplanar near-field acoustic holography (NAH) involves reconstructing the surrounding radiated sound field from measurements of the complex pressure on at least four intersecting planes enclosing a source [L. M. Wang and C. B. Burroughs, J. Acoust. Soc. Am. **100**, 2654(A) (1996)]. After a brief review of the multiplanar NAH technique, results from applying the algorithm to a bowed violin (Hutchins' SUS295) are shown for each open string. An open-frame mechanical bowing apparatus, which has been previously described, is used to excite the violin [L. M. Wang and C. B. Burroughs, J. Acoust. Soc. Am. **99**, 2502(A) (1996)]. Areas of significant radiation on the violin structure are identified. Measurements are also compared to results from modal analyses previously performed on the same instrument. [Work supported by NSF Graduate Fellowship, Bell Laboratories GRPW Grant, and AAUW Selected Professions Dissertation Fellowship.]

12:10

3aMU8. Behavior of real violin strings, mechanically bowed. Norman C. Pickering and Michael P. Kerr (J. D'Addario and Co., Inc., Farmingdale, NY)

Traditional methods of evaluating various types of strings for bowed instruments have relied almost exclusively on subjective impressions of expert players. In the real world, busy professionals rarely have enough time or objectivity to provide string designers and manufacturers with precise information. Furthermore, such opinions are affected by factors unrelated to the stings themselves, and are subject to change in ways that are often difficult to relate to the design details of the product being tested. The use of a well-designed bowing machine makes it possible to amass quantities of data on specific strings, enabling string makers to discover the characteristics that are favored by professional artists. Data is obtained for strings having cores of gut, synthetic polymers, monofilament, and stranded steel. By varying bow force, velocity, and distance from the bridge an envelope of usable combinations is accurately determined. Time for development of Helmholtz waveform partial by partial, average frequency variation as well as cycle-by-cycle period variation, and overall spectral distribution can all be determined with good repeatability. Driving strings magnetically instead of by bowing permits frequency determination of individual partials, an indication of string flexibility or lack of it. This work has led to new string designs, incorporating new materials and manufacturing processes.

3aNSa1. A new way of reducing self-sustained flow noise. Reni A. Henry, Anas Sakout, Alex L. Coiret (Lab. L.E.P.T.A.B., La Rochelle Univ., avenue Marillac, 17042 La Rochelle Cedex 1, France), and Aziz Hamdouni (Poitiers Univ., 86960 Futuroscope Cedex, France)

Vortex shedding from shear layers may be driven by the resulting acoustical field. In order to achieve noise reduction, the feedback loop is broken down with the help of auxiliary secondary flows that are created by means of minor geometrical modifications. Experiments have been conducted on a flow through two close orifice plates in a cylindrical duct: they have brought forward the possibility of reaching stable paths of flow bifurcations where an important noise reduction is obtained in a large range of flow rates. By creating a suitable interaction between the main shear layer of the confined jet and thin auxiliary shear layers, noise reduction takes place in a range of 20–40 dB. The latest result is the following: due to the stability of the flow bifurcation path that can be reached, such a level of noise reduction is maintained in a large range of flow conditions. Moreover, by choosing an adequate path, noise reduction takes place for flow conditions where intense tones would be present if these flow conditions were to be reached through conventional means. It may be emphasized that such methods are costless, compared to some sophisticated active control methods.

9:50

3aNSa2. A new approach to low-frequency room noise criteria. Robert D. Hellweg, Jr. and Hsien-sheng (Jason) Pei (Digital Equipment Corp., PKO2-1/J60, 129 Parker St., Maynard, MA 01754, hellweg@mail.dec.com)

There are three different and conflicting room criteria methods that are widely used by consultants today: room criterion (RC), balanced noise criterion (NCB), and noise criteria (NC). The RC procedure is documented in ANSI S12.2-1995 ''Criteria for evaluating room noise'' and the ''1995 ASHRAE Applications Handbook;'' the NCB procedure in ANSI S12.2; and the NC ''tangency'' method in the ''1991 ASHRAE Applications Handbook.'' There are significant differences in the three criteria, especially for low frequencies, which can impact the costs both of new designs and of remedial actions to existing facilities. In order to promote a resolution to these differences, NOISE-CON96 and NOISE-CON97 held special technical sessions on room noise criteria. Based on our analysis of published research and on experiences dealing with other noise sources, the authors suggest an approach to resolve the low-frequency differences: (1) establish basic room criterion curves for noises without abnormal temporal or spectral characteristics, and (2) apply correction factors to the measured data to account for abnormal features before comparison to the basic criterion. This paper presents details of the suggested approach, the status of revisions to ANSI S12.2 and to the ASHRAE handbook, and other ongoing research.

10:20

3aNSa3. Parameters involved in low-frequency noise annoyance. Ulf Landstrom (Natl. Inst. for Working Life, Box 7654, S-907 12 Sweden)

Noise annoyance and related adverse responses evoked during exposures in low-frequency environments are effected by a number of separate and interacting parameters. Laboratory as well as field studies have shown that in most cases the correlations between annoyance and noise levels or linear values are very weak. For descriptions of the fundamental correlations between low-frequency noise exposure, annoyance, and related adverse effects, deeper knowledge about the different interacting factors is needed. One consequence of this deficient knowledge of the critical factors for low-frequency noise annoyance is that well-founded methods for the evaluation of annoyance and related adverse effects are still missing. Noise control, building and rebuilding of new acceptable environments, or other types of measures against the low-frequency noise problems cannot be based only on evaluations of the dBA or other simple rating alternatives. For adequate evaluations and measures, deeper knowledge about interacting factors, e.g., tones, frequency character, bandwidth, exposure time, fluctuations, perception, masking and type of work, is needed. The present paper is a summary of the results and conclusions that could be drawn from studies directed upon some of the most important parameters involved in low-frequency noise annoyance.

Contributed Paper

10:50

3aNSa4. The effects of age on annoyance caused by low-frequency noise. Rukhsana Adams and Bridget M. Shield (School of Eng. Systems and Design, South Bank Univ., London SE1 0AA, UK, shieldbm@sbu.ac.uk)

A laboratory study into the response of subjects to noises of varying intensity and frequency content has been carried out. Eighty subjects ranging in age from approximately 20 to 70 yr were asked to rate sounds according to annoyance. The hearing levels of the subjects were tested using pure-tone audiometry. The annoyance ratings have been analyzed to investigate relationships between annoyance and spectral shape, and also to determine whether the annoyance responses are related to age or hearing acuity. Preliminary results suggest that there is a strong relationship between age and response to low-frequency sound, subjects over the age of 45 finding sounds with high levels of noise below 200 Hz significantly more annoying than younger subjects. However, the annoyance ratings of the older subjects do not appear to be related to hearing levels, suggesting that the response may be due to some other factor such as the association of the noise.

9:20

3aNSb1. The investigation of a towed trailer test for passenger tire coast-by noise measurement. James K. Thompson (Automated Anal. Corp., 2805 South Industrial, Ste. 100, Ann Arbor, MI 48104, jthompso@autoa.com) and Thomas A. Williams (Hankook Tire, 3535 Forest Lake Dr., Uniontown, OH 44685)

It is difficult to quantify the portion of coasting vehicle noise that is due to tire-pavement interaction alone. There are often contributions from aerodynamic noise of the vehicle, transmission whine, noise from suspension components, and other miscellaneous sources. The towed-trailer method used in the revised SAE J-57 standard has been shown to be an effective means of isolating tire-pavement noise for truck tires. This paper reports the results of a test program conducted by SAE Tire Noise Standards Committee to evaluate the feasibility of towed-trailer coast-by testing of passenger and light truck tires. The results of tests conducted in April 1996 at the Ohio Transportation Research Center are described and they indicate that accurate measurements are possible for towed-trailer testing of passenger tires. It is shown that a key aspect of performing such a test is reducing the noise of the tow vehicle and that sufficient reduction is possible even for quiet test tires. During the period of this work, the ISO/TC 31/WG 3 working group developed a draft trailer test method for evaluating tire noise. This test procedure was also evaluated. The results show the proposed test method to be highly accurate for tire noise evaluation.

9:40

3aNSb2. Assessment of tire/pavement interaction noise under vehicle passby test conditions using sound intensity measurement methods. Paul R. Donavan, Richard F. Schumacher, and Jeffrey R. Stott (Noise and Vib. Ctr., 483-324-101, General Motors Proving Ground, Milford, MI 48380)

Over the past several years, sound intensity measurement methods have become an increasing valuable tool in isolating tire/pavement interaction noise when a vehicle is tested under full throttle acceleration conditions such as the ISO 362 R15 procedure. Several investigations have been conducted and reported which demonstrate the relationship between ''on-board'' sound intensity measured close to a tire contact patch and the sound pressure level measured by a stationary microphone 7.5 m away from the line of travel of the vehicle. Using these relationships, the contribution of tire/pavement noise can be assessed relative to other noise sources associated with a vehicle under acceleration as measured at 7.5 m. In this application, it has been determined that some tires can produce significantly higher noise levels under the torque of acceleration than under cruise conditions. Sound intensity has also been used to separate sound propagation from sound generation effects in the assessment of test surfaces such as those specified by SAE and ISO. This paper reviews the various applications of sound intensity in the assessment of tire/pavement interaction noise issues related to vehicle passby noise, the implication of recent findings on noise reduction strategies, and the potential for standardization of sound intensity techniques.

10:00

3aNSb3. The influence of belt and tread band stiffness on the tire noise generation mechanisms. Wolfgang Kropp, Krister Larsson, and Stephane Barrelet (Dept. of Appl. Acoust., Chalmers Univ. of Technol., S-41296 Gothenburg, Sweden, wk@Ta.chalmers.se)

A brief introduction to a theoretical model is presented which describes a smooth tire rolling on a rough road surface. The model is limited to a two-dimensional contact between tire and road. It includes the vibration properties of the tire, the nonlinear contact, and the sound radiation. It is also taking into account the influence of the acoustic properties of the road surface. The model is applied to determine the sound radiated due to the tire vibrations and the local deformations of the tread band. A parameter study is presented which shows the influence of the bending stiffness of the belt and the stiffness of the tread band on the noise generation and radiation mechanisms. The study also considers the influence of the surface roughness of the road. In this way it is possible to quantify which part of the roughness spectrum is leading to sound generation via tire vibration and which part of the roughness spectrum is involved in the local deformation of the tread band.

10:20

3aNSb4. Identification of sources of tire/pavement interaction noise. Richard J. Ruhala and Courtney B. Burroughs (Grad. Prog. in Acoust., Penn State Univ., State College, PA 16804)

Although most highway noise is due to radiation from rolling tires, the dominant sources of tire/pavement interaction noise remain largely unknown. In this study, near-field acoustical holography (NAH) is used to visualize the acoustic field of a rolling tire on outdoor pavement surfaces. Since NAH measurements are conducted in the near field, areas of maximum radiation from the tire may be localized with a much finer resolution than with conventional measurements. Planar NAH is used to scan planes along the side, front, and rear planes of the tire. A scanning mechanism will be attached to an automobile trailer for measurements of tire noise under realistic conditions and procedure as developed in earlier results [R. J. Ruhala and C. B. Burroughs, SAE 972047 (1997)]. Several types of tires are evaluated, including blank tire, tire with even spaced transverse grooves, tire with only circumferential grooves, and a production passenger car tire. The tires are tested on both smooth and rough pavements, and at several speeds. The results will provide further insight into the sources and mechanisms of tire/pavement interaction noise. [Work supported by Goodyear, DOT, and GM.]

10:40

3aNSb5. Effects of the acoustical characteristics of road pavements on long-range sound propagation. Michel C. Bérengier (L.C.P.C. - Ctr. de Nantes, BP 19, 44340 Bouguenais, France), Jean-François Hamet (I.N.R.E.T.S. 25, 69675 Bron cedex, France), and Yves Pichaud (L.C.P.C.-Ctr. de Nantes, 44340 Bouguenais, France)

For many people in industrial countries, traffic noise is considered as one of the most important elements of discomfort. In the past 15 years, the only protections for the neighboring populations against road traffic noise were road barriers. For a short time, the modification of the road pavement can partly contribute to decrease this nuisance. Recent research on the acoustical performances of road pavements have been carried out, and, a first ranking in the close proximity of the road has been established using a standardized method. From these first results, it is possible to predict the road traffic noise far from the road taking into account the acoustical characteristics of various pavements. This prediction procedure requires the theoretical knowledge of all the physical phenomena occurring along the propagation path. This is the reason why the model used for calculation integrates ground effects over mixed surfaces and atmospherical parameters such as vertical sound-speed gradients. The pavement effect is introduced in the model through the sound power spectrum of the tire/road noise source located a few centimeters above the road surface. The predicted results are advantageously compared to *in-situ* measurements carried out over some hundred meters.

10:55

3aNSb6. Acoustic modeling of road vehicles for traffic noise prediction: Determination of the sources heights. Jean-François Hamet, Marie-Agnès Pallas (I.N.R.E.T.S. 25, av. François Mitterand, case 24, 69675 Bron cedex, France), David Gaulin, and Michel C. Bérengier (L.C.P.C.-Ctr. de Nantes, 44340 Bouguenais, France)

For traffic noise predictions road vehicles can be modeled by point sources. When dealing with the evaluation of noise barrier's efficiency or of far-field noise, the knowledge of the sources heights is of primary importance. Their determination can be obtained from two different methods. The first one deals with an inverse fitting procedure performed on experimental excess attenuation results between two receivers 7.50 m apart. Knowing the noise frequency spectrum at the reference microphone and the pavement and close ground impedances, it becomes possible to adjust the source height by minimizing the prediction/measurement differ-

ence. By this procedure, the equivalent noise source is found very close to the surface. Otherwise, sources heights can be obtained directly using microphone arrays. These measuring techniques are now commonly used to localize sound sources of railway vehicles. Their application to road vehicles appears to be more recent. For the present case dealing with the determination of the source height only, a simple vertical array can be implemented. Preliminary measurements made on a light vehicle confirm that the acoustic radiation due to the various sources (including engine noise) comes practically entirely from the car underbody, i.e., from a zone close to the ground.

11:10

3aNSb7. Modeling of tangential contact forces. Krister Larsson, Stephane Barrelet, and Wolfgang Kropp (Dept. of Appl. Acoust., Chalmers Univ. of Technol., S-412 96 Gothenburg, Sweden, kl@ta.chalmers.se)

The main noise source from vehicles at speeds greater than 50 km/h is the tires. To reduce traffic noise it is therefore necessary to understand the noise generation mechanisms in the contact between tire and road. The paper presents an improvement of an earlier developed acoustic rolling model concerning a smooth tire rolling on a rough surface. This model consists of three steps. First, the radial contact forces between road and tire are calculated. These forces give the vibrations of the tire, which finally give the sound radiation from the tire. A method to include the tangential forces into the rolling model is the topic of this paper. To do this, the influence of the tread blocks on the force transmission from the road to the belt of the tire has to be known. A FEM-model of one tread block is made in order to determine its dynamical properties. A simplified model of the block is established, by only taking into account the two lowest modes in the frequency range of interest (i.e., up to 3 kHz). This simplified model is included in the existing contact model to give the response of the tire due to tangential or radial excitations.

11:25

3aNSb8. Computational and subjective procedures for the assessment of sounds with weak tonal components. Wolfgang Ellermeier (Inst. of Psychol., Univ. of Regensburg, Regensburg, Germany) and Matthias Vormann (C.v.O Univ., Oldenburg, Germany)

A discrete tone is defined as ''prominent'' if the level of the tone exceeds the level of the noise contained in its critical band by 6 dB. Tonal or narrow-band noise components of tire sounds often fall short of this level, but are nevertheless rated as prominent by test drivers. Tonality is closely related to the sensation of pitch strength, which depends upon the sensation level, bandwidth, duration, and frequency of the tonal components present. In order to compare a number of computational procedures for calculating the tonality of sounds, a broad range of tire noises, synthesized tire sounds, and artificial tone–noise mixtures in which the level and bandwidth of the tonal components was varied, were subjectively assessed using (a) a paired-comparison technique, and (b) categorical judgments collected from about 60 listeners. They were objectively assessed by tone-to-noise and prominence-ratio measurements, and by a new method based on a model of pitch sensation which accounts for the temporal and frequency resolution as well as for masking properties of the human ear. The advantages and limits of the different methods will be compared and discussed. Especially for weak narrow-band components, the pitch model seems to be superior to the other methods used to quantify the degree of tonality.

3aNSc1. Instrumentation for the measurement of occupational noise exposure: Past, present, and future. Theodore J. Kuemmel (Quest Technologies, Inc., 510 S. Worthington St., Oconomowoc, WI 53066)

The instruments used to measure occupational noise exposure have all evolved from the basic sound level meter. Variation of the sound fields and the dynamics of the measurement environment raised questions about the validity and accuracy of occupational noise exposure measurements. Measurement practice and instrumentation have evolved significantly to overcome the limitations inherent in the measurement of sound levels. Modern microprocessor based instruments which automatically compute noise exposures have dramatically improved the validity and accuracy of occupational noise exposure measurements. Today many of the measurements of occupational noise exposure can be reliably replicated. This paper addresses the challenges faced when attempting to assess occupational noise exposure, and their influence on the development of occupational noise exposure measurement instrumentation. The influence of technology, regulation, and standards on instrument development is also addressed.

9:35

3aNSc2. Occupational noise measurement standard: ANSI S12-19. Richard Goodwin (Acoust. Systems, Inc., P.O. Box 146, Vandalia, OH 45377, asi898-3198@worldnet.att.net)

This standard provides procedures for the measurement of occupational noise exposure from all types of noise; e.g., continuous, fluctuating, intermittent, and/or impulse/impact. Measurements may be reported as sound level with corresponding duration, time-weighted average sound level, and/or noise dose. This standard provides for the measurement of the noise exposure of individuals and can be extended to represent groups performing similar activities. It can also be used to measure the noise exposure from a given job or activity. This standard does not provide procedures for the measurement of occupational noise exposures attributable to the rise of earphones or telephone receivers. This standard presents recommended practices for utilizing instrumentation such as a sound level meter, noise dosimeter, integrating sound level meter, and acoustical calibrators. Guidelines are provided for measurement conditions such as the acoustical environment, measurement activities, and operational variations. The parameters surrounding the noise and its impact on the selection of instrumentation is presented. Specific guidelines for using a sound level meter, a noise dosimeter, and an integrating sound level meter are presented. Guidelines for documentation and reporting of the measurement of occupational noise exposure are specified.

9:50

3aNSc3. What are we still doing wrong in assessing occupational noise exposure? Daniel L. Johnson (Larson-Davis, Inc., 1681 West 820 North, Provo, Utah 84601)

Sound level meters/dosimeters and measurement/prediction procedures have improved greatly over the last 20 years. Instrumentation nowadays can be expected to assess the energy of impulsive noise properly, provide a time history of the noise exposure, and have a sufficient dynamic range. Nevertheless, some improvements are still needed. These improvements are to (1) rework the SLM standards so the measurement envelope for all instruments, regardless of type, can be specified to be the same; (2) provide better methodology for determining when infrasound and ultrasound need to be measured; (3) provide a mechanism for properly assessing intermittent exposures, including the inclusion of effective quiet; and (4) finally, as a visionary dream, provide long-term measurement of occupational/nonoccupational noise exposure coupled with environmental factors as well as health factors such as blood pressure and hearing threshold levels. The need for and the details of each of these improvements will be discussed.

10:05

3aNSc4. Types and frequencies of abnormal sound levels when using noise dosimeters to establish worker TWAs. Larry H. Royster (Dept. of Mech. Eng., North Carolina State Univ., Raleigh, NC 27695-7910) and Julia D. Royster (Environ. Noise Consultants, Inc., Raleigh, NC 27622-0698, effective_hcps@compuserve.com)

The potential contamination of noise dosimetry noise exposure findings as impacted by the following types of artifacts was investigated: thumping of the microphone, moving the microphone around during the sample, hollering directly into the microphone, effects of body reflections, and blowing directly at the microphone. The findings from this investigation support the assumption that contamination of noise dosimetry daily noise exposure results is not of significant concern, at least when using a 5-dB exchange rate (OSHA). In addition, the detailed histogram records obtained from conducting noise dosimetry noise exposure surveys at five large industrial facilities were reviewed. Of the over 28 000 histogram samples reviewed, less than 14 samples indicated potential contamination from unusual noise sources. In summary, the results of this study confirm what the authors have observed over many years of conducting industrial noise exposure studies using noise dosimetry: contamination of noise dosimetry findings is not a significant issue (at least when a 5-dB exchange rate is utilized).

10:20

3aNSc5. Sound exposure profiling: A noise exposure assessment alternative. Lee D. Hager (James, Anderson & Assoc., Inc., P.O. Box 23113, Lansing, MI 48909, lee_hager@compuserve.com)

Assessment of worker sound exposure based on incremental task sound levels has a history dating back to the earliest days of recognition of noise as a hearing hazard. Sound exposure profiling (SEP) uses current technology to compile task-based sound measurements to model long-term risk of exposure to hazardous noise. SEP is an alternative to full-shift dosimeter techniques for sound exposure assessment. The methodology offers the advantage of providing additional information about noise sources and how worker interaction with noise sources results in long-term risk of exposure. SEP has been adopted by several major corporations as their corporate strategy for assessment of worker noise exposure, and is supported in ANSI S12.19-1996, ''Measurement of Occupational Noise Exposure.'' This paper will described SEP and its application in industry.

10:35

3aNSc6. Unusual jobs require unusual methods for noise exposure measurement. John P. Barry (U.S. Dept. of Labor—OSHA, 3535 Market St., Philadelphia, PA 19104, john.barry@internetmci.com)

With the diversity of the American workplace, the one size fits all approach cannot accommodate every occupational noise exposure measurement challenge. This is precisely why ANSI Standard S12.19-1996, ''Measurement of Occupational Noise Exposure,'' permits different measurement criteria and a variety of instrumentation and methodologies. The Occupational Safety and Health Administration (OSHA) and the Mine Safety and Health Administration (MSHA) use employee-worn noise dosimeters almost exclusively to document alleged violations of the occupational noise standards. However, employers and consultants may use any method that properly identifies those employees who need to be included in a hearing conservation program and that relates the noise exposure with the risk of occupational hearing loss and the effectiveness of hearing protection devices. Some environmental and

operational hearing loss and the effectiveness of hearing protection devices. Some environmental and operational problems that affect occupational noise measurement are temperature, humidity, rain, wind, radio, magnetic and microwave interference, intrinsic safety, and the presence of hazardous materials. To illustrate effective handling of these measurement problems, the methodologies used in the occupational noise exposure assessment of operating municipal departments will be discussed.

11:05

3aNSc7. Investigation of intermittency in the noise exposure pattern of longwall coal miners. J. Alton Burks and Roy C. Bartholomae (Pittsburgh Res. Lab., Nat. Inst. for Occupational Safety and Health, P.O. Box 18070, Pittsburgh, PA 15236, aib5@cdc.gov)

It is generally recognized that intermittent exposures to noise are less hazardous than continuous exposures with the same energy. This effect has been accounted for in the USA with the use of a 5-dB exchange rate, instead of the 3-dB rate associated with the equal energy principle. However, the appropriateness of the 5-dB exchange rate for assessing the risk of noise exposures in mining has never been examined closely. The authors have previously reported the results of a worker noise exposure survey conducted at six longwall coal mines [R. C. Bartholomae and J. A. Burks, Proceedings: NOISE-CON '94, 1017–1022 (1994)]; the time-resolved dosimeter data from that study were reanalyzed to determine if the noise exposure pattern of longwall miners can be categorized as intermittent. For this purpose *effective quiet* is defined to be a period of time in which the sound level is less than 75 dBA [W. Melnick, J. Acoust. Soc. Am. **90**, 147–154 (1991)] for 10 s or longer [K. D. Kryter, *The Effects of Noise of Man* (1985), p. 273]. It is found that the miners experience an average of 125 periods of effective quiet and an average total quiet time of 1.7 h on a daily basis.

11:20

3aNSc8. Hearing hazard evaluation and hearing conservation in a very reverberant indoor firing range. Felix Z. Sachs (U.S. Army Ctr. for Health Promotion and Preventive Medicine, 5158 Blackhawk Rd., APG, MD 21010-5422, felix_sachs@chppm-ccmail.apgea.army.mil)

OSHA and Army regulations differentiate steady from impulse noise exposure, but the boundary is fuzzy. A 300-m research indoor firing range produced 10-s reverberation times resulting in noise exposures straddling this boundary. Worker exposure was assessed as both steady and impulsive under both OSHA and Army criteria. The highest peak level was 164.9 dBP, the maximum ''slow'' level was 133 dBA. Hearing protector calculations for steady noise used the NIOSH ''assumed protection values'' method. Army noise criteria use 3-dB exchange between level and time. Any parallel filter analyzer could measure the time-averaged octave band levels. OSHA uses 5-dB exchange rate, a rare feature on parallel filter analyzers. Administrative controls were most stringent for the Army steady noise method and least restrictive for the MIL-STD-1474 impulse noise method. For OSHA steady noise, allowable rounds per day depended on the number of shots fired per burst due to the 5-dB exchange rate. [The opinions or assertions contained herein are the views of the author and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense.]

11:35

3aNSc9. Noise from sandblasting. Tonnes Ognedal and Rune Harbak (Sinus AS, Sandvigaa 24, N-4007 Stavanger, Norway)

With respect to the increased focus on the working environment, a project has been carried out in order to investigate the noise exposure for personnel working with sandblasting and UHP-water blasting. For sandblasting, three different aspects that influence the noise exposure have been evaluated: (a) Noise from the nozzle and the blasting object, (b) noise generated by the air supply in the masks/helmets, and (c) sound attenuation of the masks and helmets. Normal A-weighted noise levels outside the protective gear are between 110 and 120 dB while sandblasting. The noise level inside the mask and the inner hood will vary from 95–105 dB from the sandblasting. The noise generated by the air supply can be as high 90–100 dB inside the inner hood. Thus the total average noise exposure for the personnel (without earplugs) is 97–107 dB with today's most common equipment in Norway. Noise from UHP-water blasting can also reach levels up to 110–120 dB, depending on the blasting object and the acoustic environment. Normal working gear gives less protection to the ear than the sandblasting gear. Both the sandblasting and the UHP water blasting may create loss of hearing to the workers.

11:50

3aNSc10. Occupational noise and solvent exposure in the printing industry. Rande Ferris and Beno Groothoff (DTIR, Queensland Govt., Brisbane, Australia 4030, rande.ferris@dtir.qld.gov.au)

The study examined the effects on hearing from occupational noise and solvent exposure in the printing industry and was conducted by measuring a selection of workers' daily noise dose, sampling personal solvent exposures and audiometric testing before and after shifts for the detection of a hearing threshold shift. Audiometric test results were inconclusive due to the inadequate testing areas provided at each workplace. Personal monitoring confirmed that where solvent exposure occurs, high noise levels are usually also present. Fifty-three percent of the noise dose level measurements exceeded the statutory limit $L_{\mathrm{Aeq,8h}}$ of 85 dB and a further 9% exceeded the limit of 140 dB (L_{in}). Twenty-two percent of the analyzed solvent exposure samples revealed benzene, with 5% exceeding the worksafe exposure standard of 16 mg/m^3. The lack of essential information contained in Material Safety Data Sheets (MSDSs) for substances used in the printing industry was highlighted. Accurate MSDSs are required to assist employers in discharging their obligation to provide correct information about hazardous substances to employees under the Workplace Health and Safety Act of 1995, as well as the hazards associated with those substances. Better information is required in an MSDS, from manufacturers and suppliers, as to the specific properties and health hazards of a hazardous substance.

3aPAa1. Under which conditions is sonochemistry able to give information about the so-called extreme conditions prevailing inside the collapsing bubbles? Jacques Reisse, Kristin Bartik, and Nicolas Segebarth (Univ. Libre de Bruxelles, Chimie Organique, CP 165, 50, ave. F. D. Roosevelt, 1050 Bruxelles, Belgium)

Sonochemistry is able to give information about the extreme conditions prevailing inside collapsing bubbles. However, this information is obtained only when the experimental data correspond to primary chemical steps taking place in the gas phase inside the bubbles. This is unfortunately often not the case: The experimental data correspond, in the majority of cases, to secondary reactions taking place either in a shell around the collapsing bubble or in the bulk liquid. The short introductory talk to the sonochemistry session will be devoted to trying to answer the following questions: How must reactions, able to give relevant information about the so-called extreme conditions inside the bubbles, be selected? What is the actual reaction zone inside the bubble and what are the temperature limits for this zone? Is it certain that the ''active zone'' for sonochemistry is always the same as the ''active zone'' for sonoluminescence? Why does sonochemistry involve radicals instead of ions?

8:20

3aPAa2. Sonochemical preparation of protein microspheres. Kenneth S. Suslick, Kenneth J. Kolbeck, Gregory S. Kufner, and Gregory W. Szewczyk (Dept. of Chemistry, Univ. of Illinois, 601 S. Goodwin Ave., Urbana, IL 61801)

Aqueous suspensions of protein microspheres with Gaussian-like size distributions in the micron size range can be produced with high-intensity ultrasound by the sonochemical oxidation of cysteines to form interprotein disulfide cross links. The microspheres can be synthesized containing a core of aqueous or organic liquids (i.e., microcapsules) or air (i.e., microbubbles such as Albunex). The micron sized spheres are contained by a 60-nm layer of protein (approximately ten protein molecules.) The small diameter (less than 5 μm) of the microspheres permits the microspheres to circulate through the bloodstream, while sonochemically linking native protein to form microspheres prevents the expected *l* immune response. To date, we have synthesized microspheres that can be monitored with *in vivo* imaging techniques (MRI and x-ray) as well as microscopy. The distribution and circulation lifetime in the bloodstream has been altered by modifying the properties of the microsphere. These microspheres have many potential biomedical applications such as drug delivery vehicles, blood substitutes, and radiological imaging agents.

8:40

3aPAa3. Sonochemistry of aqueous solutions: EPR and spin trapping studies of radical intermediates. Peter Riesz and Vladimir Misik (Natl. Cancer Inst., NIH, Bethesda, MD 20892-1002)

The primary free radical species produced in the sonolysis of aqueous argon-saturated solutions (i.e., H, OH, and O_2-) and in N_2-containing aqueous solutions (H, OH, O_2-, NO) can be identified by electron paramagnetic resonance (EPR) combined with spin trapping. The EPR experiments using cadmium(2+) ions as hydrated electron scavengers show that no detectable level of hydrated electrons is formed in the sonolysis of argon-saturated water at neutral *p*H. The temperature dependence of the semi-classical treatment of the kinetic isotope effect for H and D formation by O–H and O–D bond scission in 1:1 H_2O–D_2O mixtures was used to estimate the effective temperatures (2000–4000 K using phenyl *t*-butyl nitrone spin traps) in collapsing cavitation bubbles. At low concentrations of nonvolatile solutes (e.g., acetate ions, amino acids, and sugars) only radicals formed by H-abstraction were observed. At high concentrations, pyrolysis radicals such as methyl radicals from acetate, amino acids, and sugars could also be spin trapped. For volatile organic solutes, the effect of the vapor pressure of the solute on the effective value of gamma (the ratio of C_p/C_v) in the cavitation bubble is the major determinant of radical yields.

9:00

3aPAa4. Sonoluminescence and sonochemistry in aqueous solutions containing surface active solutes. Franz Grieser, Muthupandian Ashokkumar, and Katrina Barbour (AMPC, School of Chemistry, Univ. of Melbourne, Parkville, 3052 Australia)

The ultrasound induced reduction of gold chloride in aqueous alcohol solutions has been measured and compared with the extent of sonoluminescence (SL) quenching observed in the same solutions, as a function of alcohol concentration. Both ultrasound initiated phenomena were found to be directly related to the Gibbs surface excess concentration of the alcohol at the gas/water interface. The SL quenching occurs in two distinct surface excess regimes. The first region accounts for about 90% quenching of the SL signal. The second quenching region extends over a broader surface excess range and the profile matches the extent of enhancement in the reduction of gold chloride. When the nonvolatile surfactant sodium dodecylsulfate (SDS) was used instead of alcohol, the trends in the SL signal and in the sonochemical reduction process were quite different. At low concentrations (<2 mM) of SDS, the SL signal was enhanced over that obtained from water without surfactant. At higher SDS concentrations, the SL signal declined and leveled off to about 80% of the water signal at about 10 mM. In contrast, the reduction of gold chloride increased to about 8 mM SDS and then remained constant above this value. Possible mechanisms that explain the results will be presented.

9:20–9:40 Break

9:40

3aPAa5. Sonochemical reactor optimization using computational acoustics techniques. Jean-Louis Y. Migeot (LMS Numerical Technologies, 70 Interleuvenlaan, 3001 Leuven, Belgium)

The designer of a sonochemical reactor is confronted by a complex problem characterized by a large number of design parameters: reactor shape and dimensions, number, positions and power of ultrasound sources, frequency, solvant, temperature, etc.? A wide parametric study cannot be conducted experimentally due to time and cost constraints and a numerical model seems the only viable approach. Such a model must reflect the inherent complexity of the system and at the same time be simple enough to provide relevant results in a reasonable amount of time. This paper proposes an iterative modeling methodology based on the following steps: (1) a finite-element model of the fluid in the reactor, (2) a relationship between local acoustic pressure and gas fraction released by cavitation, and (3) equivalent acoustic properties for the cavitating medium. After a few iterations, this model leads to two main results: (1) the pressure field in the reactor and (2) the cavitation zone and the distribution of gas fraction in this cavitation zone. One can further postprocess the pressure field to predict the streaming forces on the fluid and therefore predict the flow pattern using classical CFD techniques.

10:00

3aPAa6. Sonochemistry—A demonstration lecture. Timothy J. Mason (Sonochemistry Ctr., School of NES, Coventry Univ., Coventry CV1 5FB, UK)

The potential uses of sonochemistry for the processing and chemical industries of the future have been established already in the chemical laboratory. The driving force for this technology is acoustic cavitation and a deeper understanding of this phenomenon will be required to help sonochemistry achieve more widespread acceptance and implementation in industry. For this reason a coordinated research effort is needed involving not only chemists but engineers, physicists, and mathematicians. In the past interaction between these disciplines has been limited due to the different scientific circles in which they move, but a few conferences, including this one, have sought to bring such disciplines together to promote cooperation. This presentation incorporates a series of demonstrations which illustrate the types of physical and chemical effects of cavitation and ultrasound which interest the chemist. These will include degassing, the generation of free radicals, the effects of cavitation near a surface, the dispersion of solids, emulsification, and particle manipulation in an acoustic field. Hopefully these will serve not only as an introduction to sonochemistry for those whose main discipline is not chemistry, but also as a focus for the powerful effects of cavitation which need deeper coordinated exploration.

10:20

3aPAa7. The effects of organic compound doping in single-bubble sonoluminescence. Muthupandian Ashokkumar, Franz Grieser (AMPC, School of Chemistry, Univ. of Melbourne, Vic 3052, Australia), William B. McNamara, Kenneth S. Suslick (Univ. of Illinois—Urbana, IL 61801), Thomas J. Matula, C. Allen Frensley, and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

Controlled experiments have been conducted to ascertain the effects of doping with organic compounds on single-bubble sonoluminescence (SBSL) in water. Previous experiments with multi-bubble sonoluminescence (MBSL) indicate that millimolar additions of alcohols quench the sonoluminescence intensity [Ashokkumar *et al.*, J. Phys. Chem. (in press)]. For a given concentration of alcohol, the degree of quenching apparently depends on the hydrophobicity of the alcohols. Similar results are observed in SBSL, using Ethanol, 1-Propanol, and 1-Butanol [intensity quenching measurements of 1-Butanol agrees with those of Weninger *et al.*, J. Phys. Chem. **99** (1995)]. Spectra and radius-time measurements are obtained for these systems. Further experiments with weak organic acids and bases, which change their neutrality with *p*H, are also being conducted. The results and possible interpretations will be discussed. [This research supported by DOE, NSF, and the ARC.]

10:35

3aPAa8. An interpretation of the MBSL temperatures deduced from metal atom emission. Lawrence S. Bernstein (Spectral Sci., Inc., 99 South Bedford St., Burlington, MA 01803, larry@spectral.com)

Recent MBSL observations [McNamara *et al.*, Univ. of Illinois (private communication)] of metal atom emission from a variety of metal carbonyls seeded into Ar display similar peak emission temperatures of approximately 5000 K. Additionally, metal ion emission lines have not been detected. These observations can be interpreted to mean that the peak emission temperature is also the peak collapse temperature. The same conclusion was previously reported based on the same 5000 K temperature observed for C2 MBSL. However, it was argued [Bernstein *et al.*, J. Phys. Chem. **100**, 6612 (1996)] that the chemistry giving rise to C2 emission

turns on and off in a narrow temperature window around 5000 K. Thus it was concluded that C2 emission is not a useful thermometer for higher collapse temperatures which may be attained in MBSL. It is argued that a similar situation exists for the metal atom emission chemistry. Detailed calculations based on a coupled chemical–hydrodynamic collapse model support this hypothesis. The lack of observed metal atom ion lines is attributed to the absence of sufficiently strong lines in the observational spectral window of the experiments.

3aPAb1. Development of solid state nonlinearity. M. A. Breazeale (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

The nonlinear acoustics of solids developed from the nonlinear acoustics of fluids. Originally, the problem was to undo correctly the Hooke's Law assumption without losing nonlinear terms. At present, one problem is to find a use for nonlinear acoustics of solids. The first problem has been solved; the second one is an ongoing one. It is the reason for special sessions. To develop geological exploration based on nonlinear acoustics, at first it was thought that nonlinear acoustics of crystalline solids would do. Now it is known that other nonlinearities must be considered. The purpose of the present paper is to show how solid state nonlinear acoustics developed, how nonlinear acoustics of crystals requires only one nonlinear term, and to give evidence of the fact that the subject needs to be expanded.

8:05

3aPAb2. Acoustic nonlinearities in earth solids. Lev A. Ostrovsky (Univ. of Colorado, CIRES/NOAA Environ. Technol. Lab., 325 Broadway, R/E/ET1, Boulder, CO 80303, lostrovsky@etl.noaa.gov) and Paul Johnson (Los Alamos Natl. Lab., Los Alamos, NM 87545)

Nonlinear elastic response in earth solids is a robust and representative physical characteristic. In this lecture the evidence leading to this conclusion is presented by providing an overview of theoretical and experimental developments in the domain. Illustrated measurements include those of nonlinear response in rock from a variety of dynamical wave experiments. The evidence leads to a pattern of unifying behavior. Nonlinear elasticity in earth solids is large relative to most materials; hysteresis and ''discrete'' memory play an important role in nonlinear properties of earth solids; nonlinear response is evident over a large frequency interval (dc to several MHz at least); and nonlinear response is significant, as is commonly appreciated, at large static and dynamic strain levels, but also at small strains where this behavior and the manifestations of this behavior are commonly disregarded. Recently, the methodology for extracting the nonlinear coefficients for a material have been proposed. Some theoretical models of structural nonlinearity of solid media and of wave propagation in such media are also described.

8:25

3aPAb3. Model equations for nonlinear surface waves. M. F. Hamilton (Dept. of Mech. Eng., Univ. of Texas, Austin, TX 78712-1063), Yu. A. Il'inskii, and E. A. Zabolotskaya (MacroSonix Corp., Richmond, VA 23228)

The theoretical framework developed originally for modeling nonlinear Rayleigh waves in isotropic elastic half-spaces [Zabolotskaya, J. Acoust. Soc. Am. **91**, 2569 (1992); see also Knight *et al.*, *ibid.* **102**, 1402 (1997)] has been extended to encompass a broad class of nonlinear surface wave problems. The theory is based on Hamiltonian mechanics, in which spatial Fourier amplitudes are used as generalized coordinates, and coupled spectral equations are obtained for the harmonic amplitudes in the wave. The nonlinearity coefficient matrices are expressed explicitly in terms of the second- and third-order elastic moduli of the materials. Solutions of the equations describe harmonic generation, waveform distortion, and shock formation not only at the interface but also in the interior of the solid. Cylindrical spreading and beam diffraction may be taken into account, as can transient effects in pulses. Model equations, and simulations of nonlinear surface waves in real materials, shall be presented for Rayleigh, Stoneley, Scholte, and Lamb waves, and surface waves in crystals and piezoelectric materials. The validity of the theory has been demonstrated via quantitative agreement with measurements of laser-generated Rayleigh wave pulses with shocks in fused quartz [Lomonosov *et al.*, J. Acoust. Soc. Am. **101**, 3080(A) (1997)]. [Work supported by NSF and ONR.]

8:45

3aPAb4. Principles and applications of nonlinear acoustic nondestructive testing. Alexander M. Sutin and Dimitri M. Donskoy (Stevens Inst. of Technol., Davidson Lab., 711 Hudson St., Hoboken, NJ 07030)

Nonlinear acoustic techniques have recently been introduced as a new tool for nondestructive inspection and evaluation of fatigued, defective, and fractured materials. Various defects such as cracks, debonding, fatigue, etc., lead to anomalously high levels of nonlinearity as compared with flawless structures. One of the acoustic manifestations of such nonlinearity is the modulation of ultrasound by vibration. This effect is explained by using a model of the defect as contact between two rough surfaces. The vibration varies the contact area modulating the ultrasonic probing wave passing through the defect. A theoretical model considering interaction of different modes of vibrations and probing waves is discussed. Two methods employing the nonlinear interaction of ultrasound and vibration were developed, namely vibro-modulation (VM) and impact-modulation (IM) methods. The VM method employs forced harmonic vibration of the tested structure, while the IM method uses impact excitation of the structures natural modes of vibration. The crack detection tests were carried out for different objects made out of steel, plastic, glass, concrete, and carbon. These nonlinear techniques demonstrated certain advantages as compared with the conventional linear acoustic technique, specifically high sensitivity and applicability to highly inhomogeneous structures. [First author was supported in part by RFBR, Grant No. 96-05-64459.]

3aPAb5. Measurements of surface-wave harmonic generation in nonpiezoelectric materials. Donna C. Hurley (Natl. Inst. of Standards and Technol., Div. 853, 325 Broadway, Boulder, CO 80303, hurley@boulder.nist.gov)

Methods for exciting surface waves suitable for harmonic generation experiments in nonpiezoelectric materials have been investigated. Such methods are needed for improved characterization of engineered surfaces. Unlike conventional ultrasonic techniques, nonlinear experiments require the ability to produce finite-amplitude, spectrally pure surface waves. Comb structures were selected from the methods evaluated, because they appear to offer the greatest potential for harmonic generation experiments on arbitrary substrates. The out-of-plane component of the surface waves was measured using a Michelson interferometer. The apparatus enabled direct measurement of absolute displacements with a spatial resolution of approximately 50 μm. Using this combination of excitation and detection techniques, the evolution of narrowband surface waves in the 1–10 MHz range was studied. Displacement amplitudes as large as 35 nm at a fundamental frequency of 10 MHz were observed. The spatial behavior of the fundamental and second-harmonic displacements indicated that, for correct interpretation, it was necessary to account for diffraction and other geometrical effects. Quantitative results will be presented for a variety of experimental configurations, including different substrates and comb shapes. Experimental results will also be compared to predictions of available theories for nonlinear surface wave propagation.

9:20–9:30 Break

9:30

3aPAb6. Pulsed nonlinear surface acoustic waves in crystals. R. E. Kumon, M. F. Hamilton (Dept. of Mech. Eng., The Univ. of Texas at Austin, Austin, TX 78712-1063), Yu. A. Il'inskii, E. A. Zabolotskaya (MacroSonix Corp., Richmond, VA 23228), P. Hess (Inst. of Physical Chemistry, Univ. of Heidelberg, 69120 Heidelberg, Germany), A. M. Lomonosov, and V. G. Mikhalevich (General Phys. Inst., Russian Acad. of Sci., 117942 Moscow, Russia)

A theoretical model developed recently for the propagation of nonlinear surface acoustic waves in crystals [Hamilton *et al.*, *Nonlinear Acoustics in Perspective*, edited by R. J. Wei (Nanjing U.P., Nanjing, 1996), pp. 64–69] is used to investigate transient effects associated with pulses. The present work extends an earlier theoretical investigation of pulsed nonlinear Rayleigh waves in isotropic solids [Knight *et al.*, J. Acoust. Soc. Am. **96**, 3322(A) (1994)]. The latter was verified via comparison with measurements of laser-generated nonlinear Rayleigh waves with shocks in fused quartz [Lomonosov *et al.*, J. Acoust. Soc. Am. **101**, 3080(A) (1997)]. Here simulations of waveform distortion and shock formation are presented for pulses in real crystals, including Si, KCl, and Ni, and for a variety of surface cuts and propagation directions. The second- and third-order elastic moduli in the nonlinearity matrix are taken from measurements reported in the literature. Attention is focused on waveforms corresponding to recent measurements of laser-generated nonlinear surface waves propagating in Si along the $\langle 112 \rangle$ direction in the (111) plane [Lomonosov and Hess, *Nonlinear Acoustics in Perspective* (Nanjing U.P., Nanjing, 1996), pp. 106–111]. Preliminary comparisons of theory with measurements obtained in related experiments are in good agreement. [Work supported by ONR and the RFBR Foundation.]

9:45

3aPAb7. Rayleigh wave solitons in layered media. Robert I. Odom (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

The problem of weakly dispersive long waves in a thin nonlinear solid layer over a linear isotropic solid half-space is formulated as a nonlinear thin plate problem with one free surface and one surface bonded to the underlying linear isotropic half-space. If terms cubic in the displacement gradient are retained in the nonsymmetric Piola–Kirchoff stress tensor, a multiple-scale perturbation analysis of the equations of motion leads to the Benjamin–Ono equation $u_t + \alpha u u_x + \beta \mathscr{H}[u_{xx}] = 0$, where u is a particle displacement, $\mathscr{H}[\cdot]$ indicates the Hilbert transform, and α and β are constants that depend on the material properties of the layer and half-space. The Benjamin–Ono equation admits soliton solutions, and can be solved by the inverse scattering transform. This work may provide a mathematical model for small amplitude nonlinear seismic waves propagating in a thin sediment layer over a much harder basement. It may also have application to surface acoustic wave (SAW) device physics.

10:00

3aPAb8. Nondestructive flaw detection in a solid medium using nonlinear acoustic effects. C. M. Song, K. I. Jung, and S. W. Yoon (Acoust. Res. Lab., Dept. of Phys., Sung Kyun Kwan Univ., Suwon, 440-746, Rep. of Korea, swyoon@yurim.skku.ac.kr)

In a solid material it is very difficult to find tiny defects or cracks with the conventional linear acoustic techniques as nondestructive evaluation methods. When defects exist in a material, nonlinear acoustic responses become dominant in a propagating medium and can make it possible to detect such defects. As an application of such nonlinear acoustics, a nonlinear acoustic modulation technique for nondestructive flaw detection described in previous work [Kim *et al.*, J. Acoust. Soc. Am. **101**, 3029 (1997)] was applied to several different sample materials to confirm its

feasibility. The second harmonic measurements can easily indicate existence of tiny defects or cracks in the samples. The time-delay measurements of the modulated sum and difference frequency signals can accurately locate defects in aluminum, steel, and brass solid rods, respectively.

10:15

3aPAb9. Slow nonlinear dynamics in rock. R. A. Guyer (Dept. of Phys. and Astron., Univ. of Massachusetts, Amherst, MA 01003), K. R. McCall (Univ. of Nevada, Reno, NV 89557), and K. E-A. Van Den Abeele (Los Alamos Natl. Lab., Los Alamos, NM 87545)

Recent experiments on the elastic response of Berea sandstone show that nonlinear excitation of a resonant bar is accompanied by a slow dynamics, a dynamics involving time scales many orders of magnitude longer than the excitation period, $2\pi/\omega$. A lumped-element description of a resonant bar is developed. A complementary phenomenological theory of slow nonlinear dynamics is postulated. This phenomenological theory is used in the lumped-element description to explain the experiments. The results illustrate the possibility of experimental exploration of slow nonlinear dynamics using the acoustic analogue of a NMR experiment. [Work partially supported by OBES, Engineering and Geosciences Grant No. W7405-ENG-36, the National Science Foundation Grant No. EAR-9528965, and the Institute of Geophysics and Planetary Physics at Los Alamos National Laboratory.]

10:30

3aPAb10. Nonlinear behavior in rock: Experiments show two distinct behaviors. James A. TenCate, Koen E. A. VanDenAbeele,[a] and Thomas J. Shankland[b] (Los Alamos Natl. Lab., Los Alamos, NM 87545)

The compliant features of rocks—cracks, pores, and the fluids filling them—give rise to a variety of nonlinear elastic effects. As a means of achieving large dynamic strains, longitudinal resonance experiments on thin bars of sandstones were performed. Resonance curves were obtained by measuring acceleration at the end of the bar while sweeping frequency at a fixed drive level. As drive levels increased, resonance curves showed peak bending toward lower frequencies (softening modulus). Two very distinct nonlinear behaviors were observed for several different rock samples. At moderate strain amplitudes ($\approx 10^{-6}$), the effects of nonlinearity became quite pronounced: rapid peak shifting and resonance curve shape changes were accompanied by slow dynamics—shapes of the nonlinear resonance curves depend on sweep direction and rate [Geophys. Res. Lett. **23**, 3019–3022]. However, even at lower strain amplitudes, nonlinearity remains. Small frequency shifts are observed, even down to the measurement noise of our apparatus. The exact nature of the transition between the two nonlinear behaviors (e.g., effects of temperature or composition) and an explanation for the nonlinearity at very low strain levels are being pursued. [Work supported through the Office of Basic Energy Sciences—Geosciences of the Department of Energy.] [a]Currently at Laboratorium Bouwfysica, K.U. Leuven, Belgium. Psychological and Physiological Acoustics: Auditory Attention I

Donna L. Neff, Cochair
Boys Town National Research Hospital, 555 North 30th Street, Omaha, Nebraska 68131

Ervin R. Hafter, Cochair
Department of Psychology, University of California, 3210 Tolman Hall, #1650, Berkeley, California 94720

Chair's Introduction—9:15

Invited Papers

9:20

3aPP1. Shared attention to simultaneous stimulation. Ervin R. Hafter, Anne-Marie Bonnel, and Erick Gallun (Dept. of Psych., Univ. of California, Berkeley, CA 94720, hafter@socrates.berkeley.edu)

Shared attention is studied using a dual task, where observers respond independently to two simultaneously presented signals. Cost is defined by a loss in performance relative to one signal tested alone. Standard stimuli are followed by signals that can be either incremental or decremental changes in level, frequency, or spatial location, relative to the standard. In a ''detection'' paradigm, the subject says ''change'' for signals of either polarity, but in an ''identification'' paradigm where all trials present signals, the subject responds with the polarities. Comparing results with fixed standards to those with a standard that roves from trial to trial shows that a major determinant of the cost of shared attention is the type of memory used in the task. Fixed standards, which show reliance on absolute memory, yield relatively high performance, but there is a cost of shared attention. Conversely, with roved standards, where absolute memory cannot be used, performance is relatively low and there is no cost. Thus a dissociation is found in which the additional process used in the context-coding mode is costly for attention but not performance. [Research supported by the Natl. Inst. of Health (NIDCD 07787), USA, Univ. of California, USA, and CNRS, France.]

9:45

3aPP2. Cross-modal links between auditory and visual attention. Charles Spence (Dept. of Psych., Oxford Univ., South Parks Rd., Oxford OX1 3UD, England, charles.spence@psy.ox.ac.uk) and Jon Driver (Univ. College London, London WC1E 6BT, England)

Using the orthogonal spatial-cuing paradigm, it has been shown that people make elevation discriminations concerning target sounds more rapidly and accurately when auditory targets are presented at covertly attended azimuths location [C. Spence and J. Driver, J. Exp. Psychol. Hum. Percept. Perform. **20**, 555–574 (1994)]. These shifts of auditory spatial attention could either be elicited endogenously, by informative cues that predicted the likely target location, or exogenously by peripherally presenting spatially uninformative auditory cues. More recently, extensive cross-modal links between audition and vision in the control of both exogenous and endogenous orienting have been reported, such that, for example, a shift of auditory attention typically leads to a shift of visual attention to the same location [C. Spence and J. Driver, J. Exp. Psychol. Hum. Percept. Perform. **22**, 1005–1030 (1996)]. Participants in all previous behavioral studies of crossmodal attention had their eyes and head in spatial alignment. New data is reported showing a partial remapping of audiovisual space when the eyes and head are misaligned (i.e., when people look out of the corner of their eyes). This remapping ensures that attention is oriented to the correct distal location, irrespective of receptor misalignment. [Work supported by MRC (UK).]

10:10

3aPP3. Auditory objects of attention. C. J. Darwin and R. W. Hukin (Exp. Psych., Univ. of Sussex, Brighton BN1 9QG, UK, cjd@biols.susx.ac.uk)

Although interaural time differences (ITDs) are the dominant cue for the lateralization of complex sounds, they are remarkably weak at grouping together simultaneous sounds. Experiments are reviewed which explore the relationship between this observation and auditory attention. A small difference in ITD between two sentences spoken in the same voice is sufficient to allow a listener to say which of two target words occurred in the attended sentence, even when the two sentences are resynthesised to have the same fundamental frequency. By contrast, a large difference in ITD does not allow a listener to exclude a single harmonic from a target steady-state vowel within an attended sentence. The results can be explained by assuming that listeners are not able to attend directly to frequency components that share a common ITD. Rather, listeners attend to the direction of auditory objects, whose frequency composition is determined by grouping cues such as onset time and harmonicity, and whose lateral position is determined from the lateralization cues of the component frequencies. [Work supported by UK MRC.]

10:35–10:50 Break

10:50

3aPP4. Perceiving talking faces: Insights into attention. Dominic W. Massaro (Dept. of Psych., Univ. of California, Santa Cruz, CA 95064)

Perceivers naturally integrate auditory and visual information in the perception of speech and emotion. Although both modalities contribute to perception, instructions and intention appear to modulate the impact of these modalities. Although there is some influence of the to-be-ignored modality, perceivers can attenuate its influence so that some degree of control is possible. The fuzzy logical model of perception provides a good account of performance under the different instruction conditions. For the estimation of the free parameters corresponding to the parameters that correspond to the evaluation of the auditory and visual sources, the FLMP assumed different parameter values in the different instruction conditions. Different parameter values were sufficient to capture the results. Intention can thus be accounted for in terms of information with no qualitative changes in information processing. Within the framework of the FLMP, the fundamental pattern recognition algorithm does not change. Bearing out this assumption, intention can enhance or attenuate the information contribution of sources that are available, but intention does not seem capable of enforcing another type of pattern recognition algorithm. Future research using expanded factorial designs should be able to provide a more definitive understanding of the role of intention and attentional set in pattern recognition. [Work supported by NIDCD.]

11:15

3aPP5. Electrophysiological studies of auditory spatial attention. Steven A. Hillyard and Wolfgang A. Teder-Salejarvi (Dept. of Neurosci., U.C. San Diego, La Jolla, CA 92093, shillyard@ucsd.edu)

Recordings of event-related potentials (ERPs) from the scalp can track the processing of auditory signals through the afferent pathways from brainstem to cortex. ERP components elicited in auditory cortex during the time range 50–200 ms are highly sensitive to selective attention, with attended sounds eliciting greater amplitudes than unattended sounds. Using combined ERP and behavioral measures, the allocation of auditory attention was studied in a free-field array of seven or eight speakers. Brief noise bursts were presented in a random, fast-paced sequence from all the speakers, and subjects were required to attend to the sounds at one location while ignoring the others. Both behavioral detection responses and ERP amplitudes were highest for stimuli at the attended location, with a progressive falloff for responses to increasingly distant sound sources. These data revealed the shape of spatial tuning curves for auditory attention in free-field and support gradient models of attentional allocation. An analysis of ERP waveforms indicated that spatial selectivity is established by consecutive stages of progressive fine-tuning over the time range 50–350 ms poststimulus. Session 3aSA

Structural Acoustics and Vibration: Damping and Absorption

Jean R. Nicolas, Chair
Department Genie Mecanique, Universite de Sherbrooke, Uds 2500 Boulevard de l'Université, Sherbrooke, QC J1K 2R1, Canada

Contributed Papers

8:00

3aSA1. An algorithm for calculation of material loss factors using single degree of freedom method and digital data measured by FFT analyzer. Toshiyuki Maeda (Dept. of Mech. Eng., Nishinippon Inst. of Technol., 1633, Aratsu, Kanda, Miyako, Fukuoka, 800-03 Japan, t.maeda@nishitech,ac,ip)

The half-power band-width method that is conventionally used to calculate material loss factors cooperated with one single degree of freedom method using data of each resonance response of a material bring out estimation errors caused by approximation of resonance frequency due to discrete frequency when data are measured with FFT analyzer. The proposed new algorithm is able to determine the actual resonance frequency, and its amplitude directly from digital data and loss factors without approximation.

8:15

3aSA2. Dynamic and acoustic properties of beams of composite material. Shiva Sander Tavallaey (MWL, Dept. of Vehicle Eng., KTH, 100 44 Stockholm, Sweden)

Modern engineering techniques require the use of more sophisticated and optimized structural design. One way towards this aim is the use of materials which in some way optimize their inherent properties. A concept which suits this purpose very well is composite/sandwich material. Sandwich/composite materials find numerous applications where high strength and low weight are important criteria. The dynamic behavior of a sandwich beam with different boundary conditions has been investigated. Measurements have been carried out. Free-free and clamped-clamped boundary conditions were included. Modal analysis has been used to estimate resonance frequencies and modal parameters. Further, acoustical parameters of a composite plate are measured. An analytical model for prediction of wave propagation constants in sandwich/composite structure is presented. Measured and predicted results are compared.

8:30

3aSA3. Full-spectrum-based acoustic spectroscopy for determining elastic and damping constants in forced-free bars. Qiushuang Guo and David A. Brown (Dept. of Elec. and Comput. Eng., and Ctr. for Marine Sci. and Technol., Univ. of Massachusetts—Dartmouth, N. Dartmouth, MA 02747)

Elastic moduli and damping have been previously determined by measuring the resonant frequencies and quality factor of a virtually free–free bar. The development of a complete analytical solution to the longitudinal wave equation including damping effects for a bar freely supported, driven at one end, and under the influence of transducer mass and stiffness at both ends was previously reported on [Qiushuang Guo and David Brown, ''Effects of transducer mass on resonance frequency and quality factor of free-free bar,'' J. Acoust. Soc. Am. **101**, 3062 (1997)]. The analytical solution to the torsional and flexural waves in a bar including damping effects will be reported on here. When the entire spectrum of data is used, a more accurate determination of elastic moduli and internal damping coefficient is obtained. [Work supported by the University of Massachusetts—Dartmouth.]

8:45

3aSA4. Numerical method using filter banks for vibroacoustic analysis in the medium frequency domain. Sylvie Gorog and Philippe Micheau (Université de Sherbrooke, Sherbrooke, QC J1K 2R1, Canada)

Efficient numerical tools are needed to predict the vibroacoustic response of a viscoelastic structure in the medium frequency range. The presented method is formulated within the framework of nonuniform modulated filter banks, a signal processing tool. The structure is described using a variational approach. The method consists of dividing the frequency domain of interest into several subdomains and hence solving a time domain equation of motion for each subdomain. The complete displacement field is then reconstructed from the different time domain solutions. This time-frequency computations rely on the design of analysis and synthesis filter banks. Flexural vibrations of plates *in vacuo* are studied to illustrate the numerical efficiency of the method. According to the variational approach that is used, results show that the proposed method allows the computation of the solution in frequency domains where classical modal methods and direct methods are limited from a numerical point of view. This numerical tool is of great interest for the study of structures having frequency-dependent properties.

9:00

3aSA5. Improvement of damping via analysis of viscoelastic composites. Ibrahima Sow, Jean Nicolas, and Toan Vu-Khanh (Dept. Genie Mecanique, Universite de Sherbrooke, UdS 2500 Blvd. de l'Universite Sherbrooke, QC J1K 2R1, Canada)

High damping materials allow vibration and noise to be suppressed or at least reduced. Unfortunately, materials with high loss tangents also exhibit low modulus of elasticity. A new composite damping material is investigated, which consists of specially designed fibers embedded in a viscoelastic matrix. This new approach not only enhances damping through improvement of matrix loss tangent by the addition of elastomer, but also through selection of adequate ply orientation, ply stacking, geometry of fibers, and fraction of fibers. Theoretical analysis of the viscoelastic properties of this composite is presented in order to identify the optimum material with high stiffness and high loss tangent according to all parameters. To address validation theoretical developments are compared to experimental results.

9:15

3aSA6. Characteristics for vibration damping of the concrete included secondary subject. Noboru Ishikawa and Hidemaro Shimoda (Inst. of Technol., Shimizu Corp., 3-4-17 Etchujima Koto-ku, Tokyo, 135 Japan)

A concrete structural material with damping performance for vibration has been investigated. It is proposed that in order to reduce the sound propagation in the solid material, the concrete material disperses many

small cells in which many easy moving particles are included. It is expected that the vibration energy which is applied to the material is absorbed by the impaction and friction of the particles alternatively and between particles and cell's wall. The preliminary experiment to confirm the capability of the high damping material on the basis of this concept has been carried out. It was shown that damping performance of the specimen depended on the size, the density, and the volume fraction of the particles by the impact vibration testing for the coupon-sized test specimen. The effect of the easy moving particles for reduction of the sound propagation in the solid was confirmed by the sound propagation testing for the middle-sized panel specimen.

9:30

3aSA7. Finite-element modeling of the vibroacoustic behavior of poroelastic materials. Hamid Bouhioui and Murray Hodgson (UBC, Dept. of Mech. Eng., 2324 Main mall, Vancouver, BC V6T 1Z4, Canada, bouhioui@mech.ubc.ca)

Porous materials are widely used nowadays as part of the insulation systems in the automotive industry or as effective sound absorbers in other areas, such as architecture. Their complex dynamic behavior is due to the various interaction phenomena within the elastic porous material. Such materials have been effectively modeled thanks to the original work of Biot. In the work reported here, the classical Biot theory for elastic porous materials is used for the development of a new three-dimensional finite element. While the finite-element development remains classical, a new numerical implementation is proposed. This new approach allows very fast computation times compared to the approaches existing in the literature. The finite element developed is general and suitable for any type of finite-size, extended-reaction porous material, with any boundary conditions. Comparisons are made using solutions found in the literature, along with a fine analysis of different aspects of the vibroacoustic behavior of porous materials.

9:45

3aSA8. Modeling of porous material added damping on a vibrating plate. Nicolas Dauchez, Sohbi Sahraoui (Laboratoire d'acoustique, Université du Maine, UMR CNRS 6613, Av O. Messiaen, 72085 Le Mans Cedex 9, France, dauchez@laum.univ-lemans.fr), and Noureddine Atalla (Université de Sherbrooke, Sherbrooke, QC J1K 2R1, Canada)

Porous materials like plastic foam are well known for their ability to absorb sound. When bonded onto a vibrating structure they may add damping. Their damping performance is investigated here. The generic configuration is a free aluminum plate (28 cm$\times$22 cm$\times$1 mm) mechanically excited (20–500 Hz), damped by a 1- to 5-cm-thick foam layer. The analysis of porous material behavior, based on Biot–Allard theory [J.-F. Allard (Chapman and Hall, 1993)] shows that damping is mainly related to the frame viscoelasticity. A formulation of an equivalent plate, substituting the porous layer by a monophasic viscoelastic material, is presented. This formulation gives behavior indicators, like amount of added stiffness and damping. It also accelerates the computation of the structure vibration, compared with a 3-D finite element code, including poroviscoelastic elements [R. Panneton and N. Atalla, J. Acoust. Soc. Am. **100**, 346–354 (1996)]. Good agreement is found with both the complete discretized formulation and experimental results. Maximum damping available from biphasic phenomena, like air flow induced by the layer flexure, is also evaluated and compared with structural damping. This shows that more sophisticated mounting conditions should be used to take advantage of the biphasic property.

10:00

3aSA9. On the use of assumed spatial distributions for the vibration analysis of built-up plate structures. Ross A. Fulford and Bjorn A. T. Petersson (Loughborough Univ., Loughborough, Leicestershire LE11 3TU, UK)

For the vibratory analysis of built-up structures, traditional pointlike connections cannot be applied where the interface is large and the wavelength small. Instead, the spatially distributed wave field has to be accounted for whereby the interface has to be considered as either a surface or, for a one-dimensional contact, a line. To analyze such, the traditional approach is to rely upon numerical methods such as the finite element method. These approaches are often cumbersome, however, in that they reveal little about the physics of the systems. As an alternative, this paper considers the development of a method whereby the spatially distributed properties of a line contact can, with the salient physics retained, be included in simplified mathematical models. The basis of the method is to describe the spatial properties with respect to Fourier components and hypothesize that the first order, i.e., uniform, component is most influential. Via an assumed uniform force distribution, the approach is applied, with some promise, to the problem of predicting the vibratory power transmission between a box and a plate.

10:15

3aSA10. Statistical analysis of boundary sound absorption in a panel-cavity system. K. S. Sum and J. Pan (Dept. of Mech. and Mater. Eng., Univ. of Western Australia, Nedlands, Western Australia 6907)

Sound absorption due to acoustic-structural coupling has a significant effect on the acoustical behavior of an enclosed sound field in vibroacoustic systems. In the high-frequency range, this absorption is related to the average behavior of acoustic and structural modes and a statistical description (e.g., statistical energy analysis) of the coupling and its effect on the sound field response is well known. In both the low- and medium-frequency ranges, acoustic-structural coupling of low-order modes tends to dominate and there are large variations in acoustical behavior between acoustic modes. Therefore accurate modal description of the sound field boundary conditions is now important. However, in the medium-frequency range, the complicated boundary conditions are difficult to describe due to the presence of a large number of dominant acoustic and/or structural modes. Thus acoustic-structural coupling is not well understood and the physical interpretation of sound absorption in this frequency range is not clear. The aim of this paper is to obtain some physical insights in the behavior of sound absorption due to acoustic-structural coupling at medium frequencies. The coupling is statistically analyzed for a panel-cavity system and its physical relationship to the boundary sound absorption is illustrated.

10:30

3aSA11. Sound transmission through multilayer structures with isotropic elastic porous materials. Noureddine Atalla, Raymond Panneton, Michel Tournour, and Celse K. Amedin (G.A.U.S., Dépt. Génie Mécanique, Univ. de Sherbrooke, Sherbrooke, QC, Canada)

This paper discusses the prediction of transmission loss through multilayer structures with porous materials. First, a brief review of recent formulations for multilayer structures with poroelastic materials is presented. Second, the transmission loss problem is described and formulated using a coupled finite element and boundary element procedure. Issues such as poroelastic-elastic coupling, poroelastic-fluid coupling, and radiation from a poroelastic material will be addressed. The developed model is validated through numerical examples. Its advantages and limitations are discussed. Finally, typical results showing the vibroacoustic effects of several parameters such as the multilayer configuration, the types of porous materials, and the mounting conditions are presented. 9:20

3aSC1. Bilingual exposure and some consequences on native-language recognition processes at four months. Laura Bosch (Dept. Psicologia Basica, Universitat de Barcelona, Passeig de la Vall d'Hebron, 171, 08035 Barcelona, Spain)

Evidence of language-specific influences on infants' speech perception presupposes the existence of a basic level of native-language representation. Findings from a language discrimination task, indicating that two-month-old infants perform successfully only when one of the two languages is the native one, but not when both are unfamiliar languages, have been interpreted as evidence that a primary representation of the structure of the native language has been reached, and is probably based on the prosodic/rhythmic properties of the input language (Mehler *et al.*, 1996). The capacity to discriminate languages seems also to be dependent on their prosodic distance. Recent research in this laboratory has addressed the issue of language discrimination for a prosodically close pair of Romance languages, i.e., Spanish and Catalan. While four-month-old infants from monolingual environments seem able to recognize their native language, either Spanish or Catalan, infants from bilingual families did not show a preference for either language. In a second series of experiments, infants from bilingual environments were tested with the same procedure, this time selecting one of their familiar languages to be contrasted with a completely unfamiliar one (English and also Italian). When compared to infants from monolingual families, they showed slower orientation latencies toward the familiar language.

9:45

3aSC2. Effects of language experience on speech perception. Patricia K. Kuhl (Dept. of Speech and Hearing Sci., Univ. of Washington, Seattle, WA 98195)

Language experience during the first year of life has a dramatic effect on infants' perception and production of speech. In this presentation, (a) studies of cross-language effects of language experience on consonant and vowel perception, (b) studies of the effects of speech experience on infants' vowel production, and (c) infant Mismatched Negativity (MMN) responses for speech will be used to show that language experience causes infants to ignore physical differences between speech stimuli that are irrelevant in their native language. A theory is offered to explain how early language experience alters speech perception. The theory holds that listening to native-language speech causes infants to develop ''perceptual maps'' of the incoming speech information. These maps functionally alter the perceived distances between physical stimuli. [Work supported by NIH.]

10:10

3aSC3. The development of phonetic perception in the first year of life. Linda Polka (School of Commun. Sci. and Disord., McGill Univ., Montreal, QC H3G 1A8, Canada, cztg@musica.mcgill.ca)

There is considerable evidence that language-specific influences on speech perception begin early in life with attunement to different aspects of language structure emerging at different ages in the first year. With respect to segmental units, cross-language research has focused on the perception of syllables differing in a single consonant. This talk will focus on research investigating developmental patterns in cross-language vowel perception in the first year of life. A series of experiments exploring vowel perception in English-learning and German-learning infants as well as English-speaking and German-speaking adults will be presented. The results provide further insights into the emergence of language-specific influences and also reveal language-universal perceptual biases that infants bring to the task of vowel perception. Implications of these findings with respect to the early development of phonetic perception and vocal production will be addressed. [Work supported by NSERC.]

10:35–10:45 Break

10:45

3aSC4. Developing sensitivity to native language sound patterns. Peter W. Jusczyk (Depts. of Psych. and Cognit. Sci., Johns Hopkins Univ., Baltimore, MD 21218, jusczyk@jhu.edu)

During the second half of their first year, English-learning infants begin to show sensitivity to the structure and organization of native language sound patterns. In particular, they give evidence of recognizing the phonetic, phonotactic, and prosodic characteristics of native language words. Moreover, their sensitivity to these features of native language sound organization appears to play a critical role in infants' ability to segment words from fluent speech. Evidence for the use of this language-specific information in word

segmentation by infants will be presented. In particular, we will focus on changes in the development of word segmentation abilities between 7.5 and 10.5 months of age. In addition, findings will be considered that suggest infants' representations of the sound patterns of words are detailed both in terms of the phonetic properties and indexical features that they include. [Work supported by NICHD and NIMH.]

11:10

3aSC5. Updates on becoming a native listener. Janet F. Werker, Judith E. Pegg, Rushen Shi, and Christine Stager (Dept. of Psych., Univ. of British Columbia, 2136 West Mall, Vancouver, BC V6T 1Z4, Canada)

Infants' sensitivity to the sound structure of the native language becomes finely honed during the first year. New studies confirm and extend this fact in the domains of phonetic, metrical, and grammatical processing. First, infants were tested on their ability to discriminate phonetic, but nonmeaningful differences in the native language. Although most 6- to 8-month olds discriminated [d] versus [t], 10- to 12-month olds did not. Thus, by 10–12 months, infants listen to only those phonetic differences that distinguish acceptable native-language syllabic shapes. Next, English-learning infants' discrimination of single syllable words such as ''clone'' from their WS counterparts, e.g., ''cologne'' was examined. Testing infants from the newborn period through the first year of life revealed that this ability is not robustly evident until around 10 months. Finally, the authors asked whether infants are sensitive to the acoustic and phonological cues distinguishing content from function words. Using lists of content versus function words excised from infant-directed utterances, it was found that both neonates and 6-month olds distinguished these broad grammatical categories. These studies confirm and extend our understanding of initial biases and listening experiences on infant speech processing. A critical question the authors are now addressing is how these changes in speech perception prepare the child for language learning.

11:35

3aSC6. Rapid gains in the speed and efficiency of word recognition by infants in the second year. Anne Fernald, John P. Pinto, and Daniel Swingley (Dept. of Psych., Stanford Univ., Stanford, CA 94305-2031)

Toward the end of the second year, during the period of rapid development in productive vocabulary known as the ''vocabulary explosion,'' infants also make dramatic gains in the speed and efficiency with which they are able to recognize familiar words in fluent speech. Here several studies using an on-line measure of speech processing by infants from 15 to 24 months of age are presented. In this research, an auditory-visual matching procedure, in which infants looked at two familiar pictures while hearing a target word that matched one of the pictures, was used. Monitoring infants' eye movements from the onset of the target word, word recognition was assessed by measuring infants' latency to look to the matching picture in response to the spoken word. These studies show that by the end of the second year, children are progressing toward the highly efficient performance of adults, using incomplete acoustic information to make rapid and accurate decisions about the identity of spoken words. [Work supported by NIMH.]

3aUW1. Measuring parameters that control acoustic propagation in granular sediments near the seafloor. Robert D. Stoll (Lamont-Doherty Earth Observatory of Columbia Univ., Palisades, NY 10964, stoll@ldeo.columbia.edu)

Propagation of acoustic waves in granular sediments near the water-sediment interface is controlled by a number of parameters such as fluid and grain compressibility, permeability, and the compressibility and shear stiffness of the skeletal frame in a water environment. A new experimental technique for evaluating several of these properties is described wherein a cylindrical, water-saturated sample is subjected to vertical, steady-state fluid flow. By controlling the hydraulic gradient, any desired vertical, effective

stress may be generated and acoustic measurements then made across the diameter. When the effective stress is reduced to zero, acoustic measurements yield the compressibility of the grains, whereas at nonzero effective stress levels, it is possible to assess the effects of depth of embedment which causes changes in the compressibility and stiffness of the frame. Finally, by measuring the flow rate at each gradient, a direct evaluation of permeability is made. Preliminary measurements agree with most historical evaluations of these parameters suggesting that some recent work which challenges the traditional values is in error. 3aUW2. Matched-field inversion using the down hill simplex algorithm. Martin Musil (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC V8W 2Y2, Canada), John M. Ozard (Defence Res. Establishment Atlantic, Victoria, BC V9A 7N2, Canada), and Michael J. Wilmut (Royal Military College, Kingston, ON K7K 7B4, Canada)

In recent years inversion techniques have been proposed to effectively and efficiently determine geophysical parameters. The focus of this matched-field inversion (MFI) study is to determine the geoacoustic and geometric parameters for a North-East Pacific shallow water data set. MFI correlates modeled data, called replicas, with the measured data and uses a search algorithm to find model values which maximize the correlation function. In our MFI the parabolic equation (PE) is used to compute the replicas to account for mode coupling in the range-dependent environment. The first stage of the optimization algorithm employs a random search to determine $N+1$ parameter sets with the best correlations, where N is the number of parameters being determined. Next the $N+1$ sets are the input to the downhill simplex algorithm. The algorithm is shown to perform well for simulated vertical line array data for search parameter ranges representative of the environment in the shallow North-East Pacific Ocean. The inversion technique was then applied to measured data obtained in the North-East Pacific on the continental shelf using towed CW and broadband sources and a vertical array of hydrophones. The geometric parameters of the experiment and dominant geoacoustic parameters were successfully recovered.

3aUW3. Numerical analysis on inversed bottom geoacoustic models for predicting a shallow-water acoustic field. Guoliang Jin and Renhe Zhang (Shanghai Acoust. Lab., Academia Sinica, Shanghai 200032, PROC)

The bottom reflection coefficient as a function of the grazing angle is calculated for a liquid bottom with depth-dependent sound velocity, density, and attenuation. The bottom geoacoustic parameters of a simplified model, which describes only the depth dependence of sound velocity and treats the density and attenuation as the depth independent, are derived from the bottom reflection coefficients by the least-squares fit. The inversion accuracy in reproducing an acoustic field in the water column is tested by the performance of matched field processing, the sound propagation losses, modal group velocities, and modal eigenvalues for numerical examples. In general, the test results are good for single frequencies, but degrade for broader frequency bands. The possible distortion of the depth dependence of sound velocity from the inversion under the simplified model is discussed.

3aUW4. A multifrequency inversion method for geoacoustic parameters. Renhe Zhang, Fenghua Li, and Wenyu Luo (Natl. Lab. of Acoust., Inst. of Acoust., Chinese Acad. of Sci., Beijing 100080, PROC, zrh@public.east.cn.net)

The effects of the bottom parameters on the sound field are discussed theoretically and two characteristic angles relevant with geoacoustic parameters are put forward. Based on the theoretical analysis of the characteristic angles, a multifrequency inversion scheme is given as follows: High-frequency and far-field data are used to invert the upper bottom parameters first, and then low-frequency and near-field data are used to invert the lower bottom parameters. Simulated geoacoustic inversions based on simulated annealing method and the beam-displacement ray-mode (BDRM) sound propagation model are applied to the test cases from the 1997 Geoacoustic Inversion Workshop. The simulated inversions show that the inversion results of multi-frequency inversions are more accurate and reliable than those of the single-frequency inversions. The multi-frequency inversion scheme is also applied to the experimental data from '96 China–US Far Yellow Sea Experiment. [Work supported by NSF of China and ONR of USA.]

3aUW5. Geoacoustic parameter inversion from waveform structure. Fenghua Li and Renhe Zhang (Natl. Lab. of Acoust., Inst. of Acoust., Chinese Acad. of Sci., Beijing 100080, PROC, zrh@public.east.cn.net)

Based on the beam-displacement ray-mode (BDRM) sound propagation model, the effect of the bottom reflection coefficient on the pulsed waveform structure in shallow water with a thermocline is discussed. Simulated numerical calculations show that in shallow water with a thermocline, the bottom reflection amplitude and the bottom reflection phase can be inverted by the envelope of the pulsed waveform and the pulsed waveform structure, respectively, when the source and/or the receiver are above the thermocline. Using the experimental data from '96 China–US Far Yellow Sea Experiment, inversions for bottom reflection amplitude and reflection phase are performed. The waveform correlation between the experimental waveform and the inversion waveform is about 0.88 while the envelope correlation between them is about 0.95. The inversion of the experimental data shows that the inversion for the bottom reflection coefficient is effective and the inversion results are stable when the source and/or the receiver are above the thermocline. [Work supported by NSF of China and ONR of USA.]

3aUW6. Geophysical measurements on sediment cores and geoacoustic modeling. Philip P. Thomson, John I. Dunlop (Dept. of Appl. Phys., UNSW, Sydney 2052, Australia), and Frank Neissen (Alfred Wegner Inst., Bremerhaven, D-27568, Germany)

Geophysical measurements on marine sediments cores have considerable interest and importance in underwater acoustics and marine geophysics. A series of studies on geoacoustic properties of marine sediments have been conducted and modeled on the samples from Australian continental shelves by the technique developed by UNSW. More works were carried out on cores from North Atlantic ocean basins at the Alfred Wegner Institute in Germany by using a multisensor core logger (MSCL). MSCL is a logging device which enables a number of geophysical measurements such as p-wave velocity, gamma ray attenuation, and magnet susceptibility on marine sediment cores encased in cylindrical plastic core liners. A pair of compressional wave transducers at 250 kHz is used to measure dilatational velocity and a gamma ray source and detector are used to measure attenuation in the cores. A comparative study of physical properties measured by a MSCL system and UNSW technique has been applied to a wide range of frequencies and modeled with modified Biot–Stoll theory.

8:30

3aUW7. Building an acoustic library for categorizing bottom substrate type. John Hedgepeth, Colleen Sullivan (BioSonics, Inc., 4027 Leary Way NW, Seattle, WA 98107, jhedgepeth@biosonicsinc.com), Robert Sullivan (Parametrix, Inc., Seattle, WA), and Patrick Schneider (Instituto de Ciencias del Mar, Barcelona, Spain)

A hypothesis to categorize bottom substrate type is that information about the bottom sediments is encoded in the echo signal. Bottom typing means that to decode this information, however, for data verification, the user of automated typing programs should establish libraries where data acquisition of acoustic data is accompanied by physical core samples of the bottom. Separate verification should be done for different types of bottoms (e.g., %rocks, %sand, %silt, and %clay). Data from 126 observations of sediments in the vicinity of Commencement Bay near Tacoma, WA was used to establish libraries and to test the capability of the Visual Bottom Typer software to categorize correctly. Four different algorithms were used: division of the first bottom echo, ratio of the first and second bottom echo, cumulative intensity of the first bottom echo, and fractal dimension of the first bottom echo. The echo signal parameters depended not only on the type of bottom sampled but also on the equipment parameters. Two different frequencies and two different beam widths were compared. Verification results were valid for particular combinations of equipment parameters.

3aUW8. A measuring method for shear wave velocity of marine sediment using radiation impedance. Masao Kimura (Dept. of Ocean Eng., Tokai Univ., 3-20-1 Orido, Shimizu, Shizuoka, 424 Japan, mkimura@scc.u-tokai.ac.jp)

Radiation impedance of a circular vibrating plate on the surface of viscoelastic medium such as marine sediment varies with the viscoelastic properties of the medium. Therefore it is possible to predict the viscoelastic properties using the characteristics of the radiation impedance. It was demonstrated that the shear wave velocity of viscoelastic media can be determined using the value of the frequency at which the imaginary part of radiation impedance becomes zero, and the measured results of shear wave velocities for dry and wet sands were shown. In this study, the radiation impedance is measured for some kinds of marine sediment models. Then, the values of shear wave velocities obtained from the measurements of the radiation impedance, and the measured values using a bimorph type piezoelectic transducer, are compared. Moreover, the effect of the size of the radius of the circular vibrating plate on the measured values of shear wave velocities are considered.

8:38

3aUW9. Measurements of high-frequency acoustic scattering from seabed vegetation. Anthony P. Lyons and Eric Pouliquen (SACLANT Undersea Res. Ctr., APO AE 09613-5000, lyons@saclantc.nato.int)

Knowledge of the acoustic properties of seabed vegetation is required for accurate seafloor characterization in many shallow-water sites. As the study and modeling of acoustic scattering from seabed vegetation have been very limited to date, characteristics such as the dependence of scattering strength on grazing angle or frequency are still largely unknown. In order to quantify these properties, acoustic scattering experiments were conducted in beds of *Posidonia Oceanica* at several sites near the islands of Elba and Sardinia, Italy and in Saros Bay, Turkey with side-scan, single beam, and parametric transducers. Normal incidence broadband measurements were made at both the primary (40 kHz) and secondary (8 kHz) frequencies of a parametric sonar. Oblique incidence measurements were made with linear sources at frequencies from 29 to 385 kHz and with coverage over a large range of grazing angles. Results of these measurements are presented in terms of scattering strength versus grazing angle as well as scattered amplitude statistics. The mean scattering strength of the posidonia beds was found to be quite high (≈ -22 dB) and also to be fairly constant over most of the range of grazing angles, indicative of a volume scattering mechanism. Ultimately this effort will aid in the development of theoretical models of acoustic backscatter in seagrass covered sites.

8:42

3aUW10. Use of Scholte waves to determine the shear wave velocity structure in marine sediments. Sayuri Kawashima and Masao Kimura (Dept. of Ocean Eng., Tokai Univ., 3-20-1 Orido, Shimizu, Shizuoka, 424 Japan, 60oid001@scc.u-tokai.ac.jp)

Scholte waves propagating in marine sediments exhibit velocity dispersion, if the shear wave velocity of the sediment under the seabed surface depends on the depth. Therefore, it is possible to obtain the shear wave velocity profile of marine sediment, using velocity dispersion characteristics of Scholte waves. In this study, *in situ* experiments of Scholte waves in marine sediments are conducted off the coast of Shizuoka. A weight-drop system, lifting a weight and releasing it, was used as the source. Propagated signals are detected by gimbaled geophones. Group velocity dispersion characteristics are obtained from the recorded signals using the multiple filter method. Next, the depth dependence of shear wave velocity is obtained from the group velocity dispersion curves of Scholte waves using an inversion method. Furthermore, the estimated depth dependence of shear wave velocity is investigated.

8:46

3aUW11. Simplex simulated annealing: A hybrid approach to geoacoustic inversion. Mark R. Fallat and Stan E. Dosso (School of Ocean Sci., Univ. of Victoria, Victoria, BC V8W 3P6, Canada)

The problem of matched-field inversion of acoustic fields for ocean-bottom geoacoustic properties has received considerable attention in recent years. In order to avoid the large number of local minima typical of multidimensional geoacoustic parameter spaces, many inversions apply global optimization methods, such as simulated annealing (SA), to minimize the mismatch between measured and modeled fields. However, the random manner in which SA searches the parameter space can be quite inefficient, particularly near convergence and/or in cases where the minima represent narrow valleys not aligned with the parameter axes. In addition, standard SA has no memory, so a good solution may be discarded at the early stages and never revisited. In order to improve the efficiency and effectiveness of SA, a local inversion component based on the downhill simplex method within a global approach to geoacoustic inversion has been incorporated. The simplex method is sensitive to local gradients, and provides efficient perturbations at all stages which are independent of the coordinate axes. Also, the simplex of models carried through the inversion retains good models and provides a memory for the algorithm. The hybrid approach of simplex simulated annealing will be described and illustrated for geoacoustic inversion. [For Underwater Acoustics Best Student Paper Award.]

3aUW12. Frequency dependence of acoustic response due to randomness and uncertainties in physical properties of porous media. Yongke Mu, Mohsen Badiey, and Alexander H.-D. Cheng (Univ. of Delaware, Newark, DE 19716)

Models of acoustic waves in porous media are complicated because of the multiple physical parameters involved. The physical structure of these parameters can be random, and the accuracy toward their direct measurement or indirect estimate is generally uncertain. In order to better understand the extent by which different parameters can affect the interaction between the acoustic waves and the porous media, these randomness and uncertainty issues need to be addressed. In this paper, the investigation is based on the Biot model. First, the model is improved based on effects arising from the statistical distribution of pore/grain size. Next, effects of

randomness in sediment stratigraphy are examined. Also, we take into consideration the uncertainty resulting from data scarcity. Numerical tools used include propagator matrix, PE, and Monte Carlo simulation. From the variation of different parameters a different result is found. But frequency is found to always play an important role. For example, at lower frequencies the effects of pore/grain size can be neglected, but at higher frequencies they have significant impact. The material frequency response for the microscopic and macroscopic randomness is examined here. The results offer a better understanding of the interaction between the acoustic waves and the porous media.

3aUW13. Inversion of explosive shallow-water transmission loss data to obtain acoustic seabed models. Marshall V. Hall (DSTO Maritime Operations Div., P.O. Box 44, Pyrmont, NSW 2009, Australia, marshall.hall@dsto.defence.gov.au)

Acoustic transmission losses (TL) measured with explosive charges along a track in shallow water have been analyzed at frequencies in octave steps starting from 16 Hz. The results have been inverted to obtain the acoustic properties of the seabed, which is modeled as a uniform half-space. There are five unknown parameters: sound and shear speeds (C_p and C_s), sound and shear absorption coefficients (A_p and A_s), and density. The number of unknowns is reduced to three by using a regression equation for density in terms of C_p, while A_s is set to its maximum physical value. By holding C_s fixed for subsets of the process, the number of unknowns is reduced to two (C_p and A_p). For a given seabed, the theoretical TL is computed as a function of range using TL models valid for stratified media. The rms residual between the measured and theoretical TL is computed over rectangles in the C_p–A_p plane. The position at which the rms residual is a minimum is noted, and expressed as a function of C_s. Criteria for selecting the optimum result are discussed. The half-space properties contain useful information, but since they vary with frequency, they do not describe the actual seabed.

3aUW14. The development of the multibeam echosounder: An historical account. Ståle Vilming (Norwegian Univ. of Sci. and Tech., Fac. of Elec. Eng. and Telecom., Trondheim, N-7034, Norway, vilming@tele.ntnu.no)

The first paper on narrow-beam echosounding was published in 1960. Since then, the advantages of the principle of multibeam swath bathymetry for seabed mapping has been recognized by many institutions working in the field of area mapping underwater. We intend to review the development the multibeam echosounder has undergone from the ''beginning'' until the present in order to better understand the challenges facing the field today. It can safely be said that the field of area mapping has diversified into many directions since the 1960s. At that time most of the development was related to the mechanical and electronic system components, whereas present research focuses on: better algorithms for more precise mapping, seabed classification, image processing, acoustical modeling of the backscattering process from seafloor and volume, and high-resolution methods for direction finding of plane waves. Multibeam echosounding thus encompasses many scientific disciplines, and we consider it important to summarize the state of the art in these disciplines as far as they are related to seabed characterization. This could help scientists to better understand the requirements for further research.

9:02

3aUW15. A comparison of Hankel transform algorithms' performance in shallow-water waveguides and their effect on the determination of seabottom plane-wave reflection coefficients. Ben Cox and Phillip Joseph (Inst. of Sound and Vib. Res., Univ. of Southampton, Southampton SO17 1BJ, UK, btc@isvr.soton.ac.uk)

Complex acoustic pressure data as a function of range may be decomposed into its constituent wave-number components by taking the Hankel transform. This paper investigates the accuracy of a number of discrete Hankel transform algorithms applied to computer simulated pressure data in a shallow water channel for a variety of seabed bottom types. The results are compared against the exact solution and the most accurate algorithm identified for shallow-water applications. The differing behavior of these algorithms is illustrated by their use in the Hankel transform method proposed by Frisk *et al.* [J. Acoust. Soc. Am. **68**, 602–612 (1980)] for the determination of seabottom plane-wave reflection coefficients. The results from computer simulations and scale model tank experiments are compared.

9:06

3aUW16. Comparison of the performance of global optimization methods with perturbative methods in the estimation of ocean bottom properties from multifrequency data. Subramaniam D. Rajan (Sci. Solutions, Inc., 18 Clinton Dr., Hollis, NH 03049)

During 1988 a series of acoustic propagation experiments was conducted in the Hudson Canyon area off the coast of New Jersey. It included synthetic aperture experiments in which a source transmitting multiple tones was towed toward/away from a vertical array of receivers. By this means, a two-dimensional structure of the acoustic field was obtained at eight different frequencies. This data set is used to estimate the bottom acoustic properties using global optimization approaches such as simulated annealing and genetic algorithm and to compare their performance with that of perturbative methods, which because of their simplicity have some advantages over the global methods.

9:10

3aUW17. Performance evaluation of horizontal and vertical vector sensor arrays in shallow water environments. Peter Gerstoft (Marine Physical Lab., UCSD, La Jolla, CA 92093-0704) and Joo Thiam Goh (DSO Natl. Labs., 118230 Singapore)

In planning an experiment it is essential to have as diverse information as possible in order to obtain a good estimate of the relevant parameters. Traditionally, the inversion for waveguide parameters as well as the source location is done exclusively using pressure measurements. Recently, it has been suggested by Nehorai and Paldi [IEEE Trans. Signal Process. **42**, 2481–2491 (1994)] that arrays of vector sensors (sensors that measure both pressure and velocities) could be used. Experiments have also been conducted in deep water by D'Spain *et al.* [IEEE Oceans (1992)]. In a realistic shallow-water environment the use of either vector or pressure sensors on a linear horizontal/vertical array with amplitude-only or complex-valued data at a number of discrete frequencies are discussed. Based on developed maximum-likelihood functions, the performance for the above type of data will be classified using either a global or a deterministic approach. For the deterministic approach, the Cramer Rao lower bound (CRLB), based on derivatives of the likelihood function, is used. For the global approach the *a posteriori* distributions are examined. These are based on Monte Carlo integration of the likelihood function. [Work supported by DSO National Laboratories, Singapore.]

9:14

3aUW18. Range-dependent environmental mismatch in matched-field tomography (MFT). Ronald T. Kessel (School of Earth and Ocean Sci., Univ. of Victoria, P.O. Box 3055, Victoria, BC V8W 3P6, Canada)

The goal of MFT is to determine unknown geoacoustic properties of the ocean by fitting a model to data recorded when the source–receiver configuration is known. The best-fit model presumably gives the best estimate of the actual geoacoustic properties along the propagation path. But the best-fit model, like the family of trials from which it is drawn, is necessarily constrained and idealistic. For simplicity, the horizontal variation of the sediments and bathymetry might have been ignored, and all trials might have had the same number of sediment layers, fixed arbitrarily perhaps, with each trial simply assigning different geoacoustic properties to those layers. If the best-fit model does not match the actual environment in these and other respects, then in what way does its properties represent those of the actual environment? When is the best-fit narrowly functional, fitting one data set well enough, but failing given other source–receiver configurations or frequency bands? These fundamental questions are addressed using the adiabatic theory of mode propagation, following a general perturbative approach to mismatch in any geoacoustic parameter in weakly range-dependent environments. Systematic and random mismatch are considered, and the implications for MFT are explored.

9:18

3aUW19. Application of coordinate rotation to inversion for sediment parameters. John S. Perkins, Michael D. Collins, and Laurie T. Fialkowski (Naval Res. Lab., Washington, DC 20375)

A global optimization technique (e.g., simulated annealing), combined with an accurate acoustic simulation capability, provides the means to invert measured acoustic data for unknown environmental parameters (e.g., sediment properties). Two problems are often encountered: (1) Which parameters are actually important to the solution? and (2) What are the parameter couplings? These problems can be regarded as difficulties in navigating through a multidimensional landscape to find the global minimum of the cost function (the error between the measured data and the simulated acoustic field corresponding to a given set of parameter values). A coordinate rotation technique based on the eigenvectors of the covariance matrix of the gradient of the cost function has been developed [M. D. Collins and L. Fishman, J. Acoust. Soc. Am. **98**, 1637–1644 (1995)]. In applying this technique to low-frequency (<200 Hz) SWellEX-96 data involving a drifting source of known position and a 32-element vertical receiver, a 12-parameter representation of the sediment structure and properties leads to a frequency-dependent parameter hierarchy and parameter couplings. The resulting environmental inversions are compared with previous characterizations and are used in matched-field processing to locate the source at other times during the experiment. [Work supported by ONR.]

3aUW20. Offshore geoacoustic inversions using sounds from land vehicle activity. Gerald L. D'Spain, William A. Kuperman, LeRoy M. Dorman, Lewis P. Berger, and William S. Hodgkiss (Marine Physical Lab., Scripps Inst. of Oceanogr., La Jolla, CA 92093-0704)

Land-based vehicle activity can be clearly detected and tracked by underwater acoustic sensors located outside the surf zone. This capability has been demonstrated with nearshore seismoacoustic data collected during the Marine Physical Lab's Adaptive Beach Monitoring (ABM) program. The purpose of this paper is to demonstrate how the sounds from these land vehicles can be used to perform inversions for the offshore geoacoustic properties, somewhat akin to the use of Vibroseis in geophysical exploration. The event of interest here is where four tracked vehicles traveled down the beach at a speed of 10 m/s, creating signal beam levels that exceeded background levels by 35 dB in the 30- to 70-Hz band. The signal-to-background noise ratio in single element spectra also is sufficiently high that these vehicles can be used as sources of opportunity. The datum for the inversions is the strong frequency dependence of the phase velocity of the arrivals in this frequency band. Forward modeling is performed with a parabolic equation (PE) code written by Mike Collins. Results are compared to those obtained from the offshore arrivals of broadband detonations conducted on the beach. [Work supported by ONR, Code 32.]

3aUW21. The multiple scattering interactions of cobbles and pebbles lying on the ocean floor. C. Feuillade and R. W. Meredith (Naval Res. Lab., Stennis Space Center, MS 39529-5004)

A new model for predicting the sonar target strengths of ensembles of rocks lying on the ocean floor has recently been presented. The model represents rocks by either rigid movable spheres or elastic spheres of variable size, density, and numerical/geometrical configuration. When the rocks are densely packed, and therefore in close proximity to each other, it is important to consider the contribution that multiple scattering interactions make to the collective scattering response. To investigate this question, a T-supermatrix formalism, a self-consistent procedure which includes all orders of multiple scattering [see Lim and Hackman, J. Acoust. Soc. Am. **91**, 613–638 (1992)], has been developed to describe the radiatively coupled ensemble. The method allows the coherently summed scattered pressure field in any direction to be determined, as well as the total power scattered by the system. Application to rocks of cobble and pebble size classes indicates that the effect of multiple interactions is dependent upon the acoustic frequency, the rock spacing relative to the radius, and the grazing angle. The results obtained provide a basis for estimating the relative importance of these interactions in determining target strength. [This work was supported by ONR/NRL.]

3aPLb1. Stochastic effects in ocean acoustics. Advances in theory and experiment. Barry J. Uscinski (Dept. of Appl. Mathematics and Theoretical Phys., Univ. of Cambridge, Cambridge, UK)

As the need to operate in the kilohertz range increased in the 1960s, existing approaches to ocean acoustics, based on sound-speed profiles and ray-tracing, became quite inadequate. The raggedness of acoustic transmissions, previously regarded simply as noise, was so pronounced at the higher frequencies that the stochastic properties themselves became an urgent area of research. Several major ocean transmission trials were carried out to obtain fluctuation data. The trial at Cobb Seamount produced results that could not be explained by existing random-wave propagation theory. The research that followed led to significant advances in several areas. New propagation theory emerged based on the parabolic equations for the acoustic field moments. In particular it was the construction of analytical solutions of the equation for the fourth moment that provided the first satisfactory explanation of the Cobb intensity fluctuation spectra. Advances in numerical simulation methods and capability have allowed pictures of the full stochastic acoustic field in an ocean transmission trial to be produced. These have not only confirmed experimental variances and cross correlations but have also revealed the spatial structure of the field, including interesing features such as the elongated sound ribbons that arise in some cases.

Meeting of Accredited Standards Committee S2 on Mechanical Vibration and Shock

to be held jointly with the

U.S. Technical Advisory Group (TAG) Meeting for ISO/TC 108 Mechanical Vibration and Shock (and Subcommittees ISO/TC 108/SC1, SC2, SC3, SC5, and SC6)

D. J. Evans, Chair S2 and Chair of the U.S. Technical Advisory Group (TAG) for ISO/TC 108, Mechanical Vibration and Shock
National Institute of Standards and Technology (NIST), Acoustics, Mass and Vibrations Group, Building 233, Room A147, Gaithersburg, Maryland 20899

Accredited Standards Committee S2 on Mechanical Vibration and Shock. Working group chairs will present reports of their recent progress on writing and processing various shock and vibration standards. There will be a report on the interface of S2 activities with those of ISO/TC 108 (the Technical Advisory Group for ISO/TC 108 consists of members of S2, S3, and other persons not necessarily members of those committees), including plans for 1998 meetings of ISO/TC 108 and/or its Subcommittees.

SCOPE OF S2: Standards, specifications, methods of measurement and test, and terminology in the fields of mechanical vibration and shock, and condition monitoring and diagnostics of machines, but excluding those aspects which pertain to biological safety, tolerance and comfort.

3pPL1. Marine mammal ears: An anatomical perspective on underwater hearing. Darlene R. Ketten (Biol. Dept., WHOI, Woods Hole, MA 02543 and Dept. of Otolaryngol., Harvard Med. School, Boston, MA 02114, dketten@whoi.edu)

Analyzing structure and function in specialized ears can produce new insights into fundamental hearing mechanisms and lead to technological advances. Research into dolphin echolocation is a classic example. Recently, however, concerns over anthropogenic sounds in the oceans pushed us to develop a broader knowledge of marine mammal hearing, and, in the last five years, hearing research on marine mammals expanded considerably. The resulting data on their hearing, ear anatomy, and vocalizations suggest that marine mammal ears are more diverse and complex than previously expected, with acoustic capabilities spanning infra to ultrasonic ranges. Seals are amphibious hearers with middle and inner ears similar to land carnivores, while the ears of whales are strikingly different and are adapted exclusively to hearing underwater. Consistent with high sound speeds in water, specialized fats, not air-filled canals, conduct sound to the ear, and both middle and inner ears are located well outside the skull. Vestibular components are reduced, consistent with cervical fusion related to hydrodynamic body shapes; but their cochlear components, particularly the auditory fibers, are hypertrophied. Neural hypertrophy may be adaptive for high background noise, but may also be related to exceptional signal processing mechanisms in both infra and ultrasonic whales.

3pAA1. Concert hall research: Balancing complexity and practicality. John Bradley (Inst. for Res. in Construction, Natl. Res. Council, Montreal Rd., Ottawa, ON K1A 0R6, Canada)

An approach that has carefully balanced complexity and practicality has led to several new developments in concert hall research. These new developments are reviewed and their practical implications are explored. The two separate dimensions of spatial impression, apparent source width and listener envelopment, are each related to different physical parameters. The relationship between these acoustical parameters and the design of halls will be explored. For example, listener envelopment is related to the relatively late arriving lateral sound energy. Measurements in a number of halls will be used to explore how this and other acoustical measures of spatial impression are related to hall design. This same new understanding of spatial impression can also further enhance our understanding of sound fields under balconies and help us to design improved electroacoustic enhancement systems. Spatial impression is also influenced by sound level and especially by lower frequency levels. The importance of levels and the balance between high- and low-frequency levels has often been neglected. New work relating the perception of bass and treble sound to different factors will be reviewed. Previous studies and new analyses will be used to explore how hall design can influence perceptions of tonal balance in concert halls.

3pAO1. An intermediate-range sonar for fish detection. David Farmer, Mark Trevorrow (Inst. of Ocean Sci., 9860 W. Saanich Rd., Sidney, BC V8L 4B2, Canada, dmf@ios.bc.ca), and Bjarke Pederson (LIC Eng., D-2900 Hellerup, Denmark)

A primary challenge in acoustic fish stock assessment is the limited sampling volume of vertically oriented sonars. While long-range imaging with powerful shore-based systems has demonstrated interesting possibilities, practical and environmental constraints motivate an intermediate technology with the goal of mapping fish distributions to ranges of a few km. This work describes a 40-element 12-kHz array deployed both for subsurface towing and also for mounting on the sea floor with motor drive allowing azimuthal rotation. Field tests in the towed configuration have been carried out in the Strait of Georgia, with the array maintained on the sound channel axis at a depth of 40 m. While there was some sensitivity to towing depth, fish could be detected out to the 7-km sampling limit at the same time as fishing activity showed the presence of migrating sockeye salmon. Sea floor deployment in a shallow coastal area demonstrated the sonar's ability to track herring and provides experience in the use of a rotating mount for sector imaging of fish schools. Based on experience gained with this implementation, both the potential applications and limitations of this approach for intermediate range fish detection are identified.

3pAO2. Shallow-water salmon and herring detection using 100-kHz sidescan sonars. Mark V. Trevorrow, David M. Farmer (Inst. of Ocean Sci., 9860 W. Saanich Rd., Sidney, BC V8L 4B2, Canada), and Bjarke Pedersen (LIC Eng. A/S, Hellerup, Denmark)

Acoustic results of fish detection using fixed 100-kHz sidescan sonar installations in the Fraser River (British Columbia) and in the Oresund (near Copenhagen, Denmark) are reviewed. Looking transverse to the river flow, echo traces due to migratory salmon were observed at ranges up to 250 m in water 6 to 13 m deep. The salmon trajectories were readily identified and counted against the background of reverberation from the river surface and bottom sediments. Similarly in the Oresund, long-term monitoring detected migrating herring schools above background reverberation at ranges up to 500 m in water 10 to 13 m deep. In both cases, occasional strong backscatter interference from vessel wakes and wind-induced surface bubble layers was observed. In the Oresund, changes in acoustic propagation conditions due to bottom inflow of more saline oceanic water drastically reduced fish detectability. For salmon in the river, acoustic multipaths due to boundary reflections were distinguishable from direct echoes at ranges up to 150 m. The general problems of shallow-water boundary reverberation and multipath reflection focusing will be reviewed, with discussion on how to compensate for these waveguide effects.

2:05

3pAO3. Multibeam sonar image processing and three-dimensional analysis of fish schools. Chafiaa Hamitouche, Valerie Fracasso, and Carla Scalabrin (ENST-Bretagne, Technopole de Brest-Iroise, B.P. 832, 29285, Brest Cedex, France)

Digital data from a high-resolution multibeam sonar were processed to provide 3-D fish school descriptors. The multibeam sonar operates at a carrier frequency of 455 kHz, with 60 beams of 1.5° each, allowing an observation angle of 90°. The envelope of the signal is sampled every 5 cm. The usual operating range is 100 m with a ping rate of 7 pings/s. This huge amount of data provides larger biovolume samples with higher data resolution than standard fisheries research vertical echosounders used until now to describe fish school structure [C. Scalabrin *et al.*, ICES J. Mar. Sci. **53**, 181–188 (1996)]. Furthermore, the use of a multibeam sonar allows construction of 3-D images of fish schools. Data were processed by specially designed image algorithms in order to account for anisotropy in the range and vessel movement direction planes. Three-dimensional analyses such as smoothing, segmentation, visualization of the segmented volume, and its quantification were performed. Three-dimensional patterns description tools (invariant with respect to translation, rotation, and scaling) were studied. These tools might lead to the classification of the detected structures using pattern recognition methods.

3pAO4. Near-resonance scattering from schooling fish. R. W. Nero, C. H. Thompson, C. Feuillade, and R. H. Love (Naval Res. Lab., Stennis Space Center, MS 39529-5004)

Most fish have air-filled swimbladders which provide some buoyancy to aid in swimming. These swimbladders resonate like damped air bubbles and are very efficient scatterers. A mathematical formalism has recently been developed to describe near-resonance backscattering from schooling fish. [C. Feuillade, R. W. Nero, and R. H. Love, J. Acoust. Soc. Am. **99**, 196–208 (1996)]. This model predicts that coupled resonance and interference effects will occur when fish are closely spaced. These effects cause the frequency response of a tightly packed school to differ significantly from that of a single fish. As fish spacings increase beyond several body lengths, these effects rapidly diminish. When this model was developed, only one small set of data was available for comparison to model predictions; these data gave indications that the model was valid [Holliday, J. Acoust. Soc. Am. **51**, 1322–1332 (1972)]. Experiments off the west coast of the United States and in the Gulf of Mexico have recently been conducted on several different species of schooling fish in order to confirm the validity of the model and determine its robustness. Measurements on numerous schools confirm that scattering from schooling fish is accurately represented by the model. [Work supported by ONR/NRL.]

3pAO5. Sound scattering from a few scatterers: Application to swimbladder fish. Zhen Ye and Alberto Alvarez (Dept. of Phys., Natl. Central Univ., Chung-li, Taiwan, ROC)

This paper presents a general method for describing sound scattering by an ensemble of a few scatterers. A scheme is developed for calculating the effective scattering function of such an ensemble, including all orders of multiple scattering between targets. The method is then applied to low-frequency sound scattering by small fish schools. It is shown that in the backscattering, certain regular patterns in scattering appear as a result of interference rather than multiple scattering, when the fish form an ordered structure. The interference peaks are due to in-phase scattering, and can be explained by the Bragg reflection mechanism. Such regular interference patterns are gradually degraded, as the random deviation in each individual fish location from its mean position increases. For a completely random distribution of fish, the model recovers the results from the random-phase approximation. For the forward-scattering case, it lacks either the regular or the noisy interference. The scattering strength seems rather smooth, and may be well approximated by the incoherent summation of forward-scattering function of each individual fish. The scattering by partially or perfectly ordered fish schools is hardly distinguishable from that by totally random distributions of fish in the forward direction. 3pBV1. Chemopotential by low-level ultrasound. George H. Harrison and Elizabeth K. Balcer-Kubiczek (Radiation Res. Div., Univ. of Maryland, 655 W. Baltimore St., 6-015BRB, Baltimore, MD 21201, gharriso@umabnet.ab.umd.edu)

Recent laboratory studies have identified a new approach to cancer therapy: the potential of drug action by ultrasound. Both standard chemotherapeutic cytotoxins and relatively nontoxic compounds related to those used in photodynamic tumor therapy are being investigated. Common to most reported investigations has been the use of continuous wave ultrasound at spatial peak, temporal average intensities exceeding 0.5 W/cm^2, implying the likelihood of temperature elevation in insonated tissue, and usually involving cytotoxicity from the action of ultrasound alone. On the other hand, for potentiation of chemotherapy using tone-burst or pulsed ultrasound at spatial average, time average intensities less than 0.3 W/cm^2 has been demonstrated [G. H. Harrison, E. K. Balcer-Kubiczek, and P. L. Gutierrez, Ultrasound Med. Biol. **22**, 355–362 (1996)]. Chemopotentiation data will be presented for several biological test systems with emphasis on human prostate tumor cell lines. Mechanistic evidence will be analyzed; fluid streaming and shear stress are likely important determinants of chemopotentiation and the cell membrane can be expected to be an important site in this process. Ultrasound-induced modification of drug resistance may have important apoptotic links. These factors suggest the importance of treatment-induced differential expression of membrane-related genes.

1:25

3pBV2. Sonochemistry of sonodynamic therapy. Peter Riesz and Vladimir Misik (Radiation Biol. Branch, Natl. Cancer Inst., N.I.H., Bethesda, MD 20892)

Sonodynamic therapy is a promising modality for cancer treatment based on the synergistic effect of cell killing by a combination of drugs (sonosensitizers) and ultrasound. The effectiveness of sonodynamic therapy was demonstrated in cell studies and in tumor-bearing animals. The mechanism of drug-dependent sonosensitization is unknown, but it seems likely that various mechanisms operate for different classes of sonosensitizers. Ultrasound-mediated sonodynamic activation of porphyrins is particularly poorly understood and hypotheses ranging from singlet oxygen production to peroxyl radical formation have been advanced. Evidence has been obtained against some of the arguments which were proposed in favor of the singlet oxygen hypothesis and the requirement of extracellular localization of gallium porphyrin ATX-70 molecules for sonosensitization in HL-525 cells has been established. Short-lived toxic intermediates produced from sonosensitizers by ultrasound are implicated in the mechanism of sonodynamic activation of some sensitizers. EPR spectroscopy was used to identify proposed intermediates in the activation of certain sonosensitizers (e.g., *N*,*N*-dimethylformamide, DMSO) by ultrasound. Certain water-soluble azo compounds, which are stable at hyperthermia temperatures and can be decomposed by ultrasound to give peroxyl radicals capable of initiating peroxidation of lipids and damaging other cellular sites, appear to be promising sonosensitizers.

1:50

3pBV3. Gene activation and gene delivery with ultrasound. Evan C. Unger (Dept. of Radiol., The Univ. of Arizona, Tucson, AZ 85724-5067, eunger@vms.ccit.arizona.edu), Thomas McCreery, Robert Sweitzer, DeKang Shen, GuanLi Wu, and Veronica Caldwell (ImaRx Pharmaceutical Corp., Tucson, AZ 85719)

Transfection experiments were performed *in vitro* in cell culture and *in vivo* in fish and mice using cationic liposomes with several different reporter genes. The effect of continuous-wave 1-MHz ultrasound on cell viability, cell permeability, and gene expression was assessed. RT-PCR was used to monitor gene expression of cell repair genes in insonated cells. Acoustically active halocarbon-containing liposomes were prepared for gene delivery. Ultrasound increased cell permeability and gene expression following liposomal transfection. RT-PCR showed upregulation of repair of a number of cell repair genes after ultrasound exposure. The acoustically active gene delivery vehicles provided highly efficient transfection both with and without ultrasound *in vitro* and *in vivo*. Following IV administration of halocarbon-containing liposomes/gene complexes, preferential gene expression was observed in the insonated tissue. Ultrasound has potentially useful applications for targeting and enhancing gene therapy.

2:15

3pBV4. Ultrasound activation of new drugs for killing cancer cells. Katsuro Tachibana and Toshiki Uchida (First Dept. of Internal Medicine, Fukuoka Univ. School of Medicine, 7-45-1 Nanakuma, Jonan, Fukuoka, 814-80 Japan)

The study of the destructive action of ultrasound in conjunction with drugs upon cancer has become an exciting area. New substances that are chemically activated by low level ultrasound energy have recently been discovered [Tachibana *et al.*, Lancet **349**, 325 (1997)]. Three nontoxic red stains frequently used for cosmetics and food, Rose Bengal, Eosin Y, and Erythrosine B were evaluated if cytotoxic effects can be induced by ultrasound energy *in vitro*. Gastric and leukemic cancer cell line suspensions were exposed to ultrasound (1 MHz) with or without the drugs. The survival rate of the cells was measured immediately after treatment. The temperature increase was less than 2 °C. Treatment with ultrasound plus drugs resulted in a significant reduction of the survival rate compared to ultrasound alone. Whereas the drug alone showed no change in survival rate. Although the mechanism is unclear, it is postulated that ultrasound energy, possibly cavitation, activated these drugs. Further experiments should be carried out to evaluate its use in the clinical situation. The three stains could be applied as new booster agents for treatment of cancer by ultrasound.

Contributed Paper

2:40

3pBV5. Control of ultrasound-mediated reversible membrane permeabilization for targeted drug delivery. Mark R. Prausnitz, Keyvan Keyhani, Aimee Parsons (School of Chemical Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0100), and Thomas N. Lewis (Georgia Inst. of Technol., Atlanta, GA 30332-0405)

Ultrasound-mediated permeabilization of cell membranes is a potentially useful method to noninvasively enhance delivery of therapeutic compounds into targeted cells. Unlike previous studies concerned only with cell death, in this study the effects of ultrasound exposure parameters on reversible membrane permeabilization of prostate cancer cells were determined. Cells were suspended in a solution containing a membrane-impermeant marker (calcein) and exposed to 24-kHz ultrasound. Viability and molecular uptake were quantified using flow cytometry. Average uptake increased with incident ultrasound pressure above a threshold and reached a plateau (20%–25% of external calcein concentration); increased with total exposure time; was weakly dependent on pulse length (3.3 ms to 1.0 s) with a small maximum at 10–33 ms and a sharp decline at 1.0 ms; and was independent of duty cycle (0.5%–50%). The fraction of viable cells decreased continuously with increasing pressure, decreased as uptake increased for most other examined condition was approximately 25% for maximum uptake under optimal conditions. Uptake decreased approximately exponentially with the time at which calcein was added to the cell suspension after exposure, with a time constant of about 1 min. The membrane disruptions allows uptake of albumin (MW=66 000) but not R-phycoerythrin (MW=240 000).

3pEA1. Efficiency and electromechanical resonance in magnetostrictive transducers. Frederick Calkins and Alison Flatau (Iowa State Univ., Dept. of Aerosp. Eng. and Eng. Mech., 2019 Black Eng., Ames, IA 50011)

Analysis of the transduction phenomenon of a Tonpilz Terfenol-D magnetostrictive transducer is presented. Transducer efficiency is discussed from electroacoustic and scalar energy perspectives. Equations are presented for identifying the frequency of most efficient transducer operation based on electroacoustic theory [F. V. Hunt, in *Electroacoustics: The Analysis of Transduction, and Its Historical Background* (Acoustical Society of America, New York, 1982)]. Experimental results are presented that show this analysis to be accurate. However, two nonintuitive results are observed: most efficient transducer operation occurs at a frequency above mechanical resonance; and changes in operating conditions which result in an increase in transducer efficiency cause the frequency of highest efficiency to increase even further above the frequency of mechanical

resonance. This motivated a comparison with a scalar energy analysis for development of a better, or at least more intuitive, understanding of the mechanisms which might explain this result. Energy analysis aids in recognizing the distinction between the transducer's mechanical and electromechanical resonances and that the magnitude of achievable efficiency will be enhanced by separation of electromechanical and mechanical resonances. Coupling the energy and electroacoustic analyses, one arrives at persuasive arguments for explaining the experimental observations regarding magnetostrictive transducer efficiency.

1:15

3pEA2. A study of 1-3 piezocomposites high drive limits. Thomas R. Howarth (Naval Res. Lab., Washington, DC, howarth@nrl.navy.mil), David Van Tol, Charles Allen, and Jack Hughes (Penn State Univ., State College, PA)

A preliminary study of the electrical drive limits of 1-3 piezocomposites has been completed. Two injection molded 1-3 piezocomposite samples were designed, fabricated, and procured from Material Systems, Inc. of Littleton, MA. Each of the composites had a 25% volume fraction of piezoceramic, a hard epoxylike matrix, a silver epoxy electrode pattern, 6-mm thickness, 100×100-mm total cross-sectional area with an active cross-section of 20×20 mm. One of the samples featured type II (PZT-5H) piezoceramic while the other featured type I (PZT-4). Each of the transducers was fitted with thermocouples to monitor temperature effects. Transducer efficiency, voltage response (TVR), current response (TCR), and power responses (TPR) were measured over the frequency range of 25 Hz–500 kHz in 200-Hz steps where the transducer thickness resonance frequency was approximately 240 kHz. This presentation shall outline the sample fabrication, the tests, and the final results. Photographs will be shown on the units upon failure. A comparison between the 1-3 piezocomposite materials limits shall be made with traditional piezoceramics. [Work supported by Dr. Kam Ng of ONR 334.]

1:30

3pEA3. The development of affordable constant beamwidth transducers using injection molded 1-3 piezoelectric composite. Kim C. Benjamin, A. L. Van Buren, and Sheridan Petrie (Naval Undersea Warfare Ctr., Newport, RI 02481)

The design, fabrication, and acoustic calibration results for a new class of constant beamwidth transducers (CBTs) is presented. This experimental study extends previously reported work by Van Buren *et al.* [J. Acoust. Soc. Am. **73** (1983)] in which a CBT was constructed using hundreds of individual end-capped PZT ceramic cylinders. Each ceramic element assembly was wrapped in corprene to provide mechanical isolation from the massive metal housing and to provide a pressure release boundary condition. This presentation describes a new design approach which employs injection molded piezocomposite which is curved to form a spherical cap. Design equations will be presented which allow one to dimension the active spherical section for a given application. Of key importance to a successful CBT design is the proper implementation of velocity amplitude shading. The current approach uses an area shading technique that is achieved through selective electroplating of copper. The design, construction, and measured results for three different geometries, including a 0.76-m (30″) diameter unit will be discussed.

1:45

3pEA4. Lamb wave generation in composite plates with a thin linear array of piezoelectric elements. Thierry Demol, Pierrick Blanquet, Emmanuel Moulin, and Christophe Delebarre (I.E.M.N. (UMR CNRS 9929), Dept. O.A.E., U.V.H.C., Le Mont Houy, B.P. 311, 59304 Valenciennes Cedex, France, demol@univ-valenciennes.fr)

Since Lamb waves are very efficient in the nondestructive testing of composite plates, new transducers are developed nowadays. They may be movable, stuck onto the surface, or integrated into the plates (''smart structures''). In order to detect defaults with few transducers, a multi-element linear array transducer has been developed to generate single-mode Lamb waves able to propagate over long distances. Movable prototypes were designed in order to evaluate their ability to generate the appropriate waves. Then, composite plates have been equipped with the same kind of transducers consisting of several thin PZT plates. High response levels have been obtained using a unidirectional composite with propagation along the fiber direction. Results for cross-ply laminates were inferior but still acceptable. The main result obtained during this experimental work was the understanding of the generation process for this kind of transducer. Unlike comb transducers, each element generates a separate wave and suitable time delays or spacing between the elements can improve the global response in accordance with linear rules. Furthermore, the delays are easily determined from the responses of each element. This behavior is very interesting as default detection is possible using the properties of the generation process.

2:00

3pEA5. Built-in transducer design for Lamb wave generation in composite structures. Pierrick Blanquet, Thierry Demol, Emmanuel Moulin, and Christophe Delebarre (I.E.M.N. (UMR CNRS 9929), Dept. O.A.E., U.V.H.C., Le Mont Houy, B.P. 311, 59304 Valenciennes Cedex, France, lamb@univ-valenciennes.fr)

Conventional ultrasonic inspection of large composite structures is very time consuming due to the necessity of surface scanning. Because they can propagate over long distances, Lamb waves are an attractive solution to this problem. Two methods are available for the generation of Lamb waves in composite plates. The first method, and the most useful one, consists of using bonded transducers. The second solution is to use a built-in transducer. In both cases, the transducers must be designed to generate efficiently the signal and choose the mode of propagation. In the following, a method to design a built-in transducer will be discussed. First, the case of a unidirectional composite plate is considered. An analytical method is developed, then the results are compared with those obtained using finite element analysis. In the case of a square element transducer embedded in the composite plate, the computed results are compared with experimental data. Then, the method is extended to the case of a multilayered plate. An analysis is performed to determine the optimal design of a built-in multi-element transducer.

2:15

3pEA6. Optimization of the piezoelectric circular bimorph. Andrzej Dobrucki (Wroclaw Inst. of Technol., Inst. of Telecom. and Acoust., Wybrzeze Wyspianskiego 27, 50-370 Wroclaw, Poland)

The combined finite-element and boundary-integral method was applied for modeling of vibration and sound radiation of piezoelectric circular bimorphs. The bimorph consists of two circular piezoelectric disks, which are separated by a metal plate. When an electric voltage is supplied to the bimorph, a bending moment develops which actuates the transducer to transversal deflection. During the design process of the transducer the following limitations must be taken into account: (1) piezoelectric material and thickness of the disks are usually predetermined, (2) the outer diameter of the transducer, i.e., of the metal plate is given. The influence of the metal plate material and its thickness on the frequency response of the transducer is discussed. Young's modulus, Poisson's ratio, density, and the loss factor characterize the properties of the materials. The influence of the ratio of a piezoelectric disk's diameter to metal plate diameter is also discussed. Another important property which was considered during the

optimization process, is the mounting of the transducer, i.e., applied boundary conditions. As an example, the design of a small transducer is presented. The results of calculations are in good accordance with the result of the measurement of realized construction.

2:30

3pEA7. Research on inhomogeneous 1-3 PZT/polymer composite transducer. DaLun Xu (Dept. of Modern Appl. Phys., TsingHua Univ. Beijing, 100084, PROC) and TieYing Zhou (TsingHua Univ., Beijing, 100084, PROC)

An improved equal stress physical model [W. A. Smith and A. Shaulov, Ultrasonics Symposium, 642–647 (1985)] for the inhomogeneous 1-3 PZT/polymer composite material is presented. This model calculates the properties that determine the thickness-mode oscillations in thin plates. Based on this model, together with the constitutive relations for polymer and PZT, expressions are derived for the effective material parameters such as electromechanical coupling constant, acoustic impedance, etc., in terms of the properties of constituents. A relation between the vibration amplitude of the transducer's surface and the volume fraction of the piezoceramic is also deduced. The distribution of the vibration of the transducer's surface, hence the distribution of the acoustic field, can be precisely controlled by adjusting the distribution of the volume fraction of the PZT phase in the transducer. To test our model experimentally, a number of special transducers were made. The measurements of the acoustic field that is produced by the transducers are in good agreement with the theory. The research provides guidelines for the transducer engineer to design inhomogeneous 1-3 PZT/polymer composite transducer, such as transducers of Gauss type, Bessel type, or other special types.

2:45

3pEA8. The ring-type all-fiber Fabry–Perot interferometer hydrophone system. Donglin Li (Harbin Eng. Univ., Dept. of Underwater Acoust. Eng., Harbin 15001, PROC)

In the paper the theory of the ring-type all-fiber Fabry–Perot interferometer hydrophone is given. Such a hydrophone system has been constructed. Experimental results have shown the system has a free-field open-circuit voltage sensitivity level of about -130 dB *re*: 1 V/μPa.

3pED1. Nonlinear effects in the paraxial region of diffracting sound beams radiated by cylindrical sources. Svetlana V. Babenkova, Vera A. Khokhlova (Dept. of Acoust., Phys. Faculty, Moscow State Univ., Moscow 119899, Russia, vera@na.phys.msu.su), and Steven G. Kargl (Univ. of Washington, Seattle, WA 98105)

Intense cylindrical sources are widely used in underwater acoustics and medical ultrasound; however, nonlinear-diffraction phenomena in acoustic fields of this geometry are not studied yet as well as the fields produced by unfocused and weakly focused circular piston sources. The present work is based on a special analytical method that has been developed recently [M. F. Hamilton, V. A. Khokhlova, and O. V. Rudenko, J. Acoust. Soc. Am. **101**, 1298–1308 (1997)] to model nonlinear and diffraction effects near the axis of an acoustic beam radiated by apodized circular source. This method combines the advantages of the parabolic approximation with nonlinear geometrical acoustics, and it permits an exact solution of the nonlinear problem. The approach is extended to acoustic waves radiated by a finite-length cylinder. A system of nonlinear coupled equations describing waveform distortion in the paraxial region of the beam is derived from the modified KZ equation. Analytical solutions are obtained in the time and frequency domains for an initially sinusoidal wave radiated by the cylinder with Gaussian shading of the amplitude along the axis. Nonlinear waveform distortion, shock formation distance, harmonic propagation curves, directivity pattern, and effect of steering are investigated for various parameters of the source. [Work supported by ONR, RFBR, and CRDF.]

3pED2. Sentential prosodic contour facilitates adults' short-term memory for nonsense syllable strings. Diana L. Schenck (Dept. of Psych., and Cornell Phonet. Lab., Dept. of Modern Lang., Cornell Univ., Ithaca, NY 14853, dls14@cornell.edu)

Recent linguistic theories propose that prosodic contour functions to facilitate encoding, processing, and storing of information in the speech signal. To date, most evidence for these theories comes from studies of infant perception and processing of prosodic speech. The present study employed a short-term memory CV nonsense syllable recall task in order to attempt to replicate with adults the findings for infants that have supported these theories. Ten adult subjects listened to nonsense CVs in two sets, one presented with sentential prosodic contour, the other presented in list form, and recalled as many syllables, in order, from each string as they could. Results were significant at the $p<0.05$ level and supported the hypothesis that subjects would better recall those syllable strings presented in prosodic contour, as the number of errors was fewer for the prosodic set than for the list set. Small familiarity/order of presentation effects and individual differences were found for all subjects. These results suggest that (1) adults use processing and coding strategies similar to those employed by infants in response to linguistic stimuli; and (2) sentential prosody does, in fact, facilitate short-term memory for these stimuli, possibly by enhancing the perceptual saliency of the linguistic input.

3pED3. Design and development of PC-IMAT: Teaching strategies for acoustical oceanography, part II. Lee Anne Hurley, Kevin M. Thomas, Murray S. Korman (Dept. of Phys., U.S. Naval Acad., Annapolis, MD 21402), John W. Schuler (Navy Personnel Res. and Development Ctr., Brooks AFB, TX 78235), and Eleanor Holmes (Integrated Performance Decisions, Arlington, VA 22202)

The PC-IMAT (Personalized Curriculum for Interactive Multisensor Analysis Training) project is proving to be a flexible and effectively evolving computer-based training/educational platform needed to help tackle ASW and other tasks which require extensive analysis, classification, and interpretational skills. Midshipman taking SP411 (Underwater Acoustics and Sonar) are currently using PC-IMAT [J. Acoust. Soc. Am. **101**, 3096A (1997)] to help investigate effective instructional strategies which convey understanding of a complex multivariate domain (like ray trace or propagation loss models). Classroom demonstration lectures and out-of-class projects allow students to successfully interact with experimental apparatus and make actual measurements (e.g., Fourier analysis, detection theory, beam pattern functions, sound speed versus temperature, computer ray tracing, reflection and transmission at an interface, and target strength versus angle of a scale model sub). However, a link between textbook theories, the actual physics experiments, and the real world setting of tactical sonar has been missing. Usage of PC-IMAT on actual submarine training exercises shows the limitations and enhancements of tactical maneuvering when sonar systems are subject to complex surroundings. The research and development of ''scientific visualization'' on PC-IMAT should ultimately incorporate a strong link between both learning environments. [Work supported by ONR.]

3pED4. Sonic gas analyzers. Matthew V. Golden, Robert M. Keolian, and Steven L. Garrett (Grad. Prog. in Acoust., Penn State Univ., P.O. Box 30, State College, PA 16804, golden@sabine.acs.psu.edu)

Whistles were used to determine the presence of hydrogen and/or methane in mines before 1900 in Germany. Since early in the 20th century, the measurement of gas thermal conductivity using a hot wire technique has been the method of choice for nonspecific detection of ''contaminating'' gases in air. At that time, the choice of thermal conductivity detectors was motivated by the popularity of the Wheatstone Bridge circuit for precision measurement [P. E. Palmer and E. R. Weaver, ''Thermal-conductivity method for the analysis of gases,'' Tech. Papers of the Bureau of Standards, No. 249, Vol. 18, Jan. 7 (1924)]. At the present time, the precision-to-cost ratio for frequency/time measurements exceeds that for voltage/current measurement by more than an order of magnitude. This presentation will examine the advantages which an electronic measurement of sound speed using inexpensive components and novel resonator geometries can bring to the detection of gaseous contaminants in air. Prototype sensor/electronics results will be presented. A discussion of temperature compensation techniques as well as the sensitivity to changes in pressure and humidity will be included. [Work supported by ONR.]

3pED5. Use of pseudo-random codes in pulse compression. Paul Shoning and Antal Sarkady (Dept. of Elec. Eng., U.S. Naval Acad., Annapolis, MD 21402)

Pseudo-random, or pseudo-noise (PN), codes are numeric sequences which appear random to the uninitiated observer yet are easily predictable to those who know the generation algorithm. Traditionally, PN codes have been generated by a hand wired sequence of binary shift registers, but are now created using programmable logic chips wired from user defined netlists. A properly implemented logic chip can generate PN codes of maximum length $L=2^n-1$ where n is the number of shift register segments. The code's period is limited only by the number of shift registers available. Bipolar PN codes have a normalized autocorrelation function that is unity at zero shift and $1/L$ at all other shifts. Thus PN codes can be used to amplitude modulate (AM) the ''main bang'' of an active RADAR or SONAR system. This modulation produces compression which vastly improves the range resolution and the sensitivity of the system. The properties of PN codes and their use in a simulated active SONAR system will be demonstrated using MATLAB programs.

Noise and Architectural Acoustics: Progress Report and Discussion on the Continuing Activity on ASA's Role in Noise and Its Control

David Lubman, Cochair
14301 Middletown Lane, Westminster, California 92683

T. James duBois, Cochair
9424 Crystal View Drive, Tujunga, California 91042

Chair's Introduction—2:15

A meeting is being sponsored by the Technical Committees on Noise and Architectural Acoustics to review current progress and invite further discussion on activity to increase the role of the ASA in noise, noise control and related architectural acoustics issues. This outreach effort has included activity on increasing public awareness about noise and noise control, on public hearing screening testing and development of self-testing techniques, on seminars on industrial noise, on meeting room acoustic environments and, currently of special interest, on classroom acoustics. Discussions about these and/or new related activity, including encouraging joint activity in these areas with other professional organizations will be encouraged.

3pPAa1. Hydrodynamical perturbation effects in multiple-bubble sonoluminescence. Alex Robinson, David W. Kuhns, Anatol M. Brodsky, and Lloyd W. Burgess (Dept. of Chemistry, Univ. of Washington, Seattle, WA 98195-1700)

This presentation will describe the observation of new dynamical effects in multibubble sonoluminescence (MBSL). The experiments show a specific time-dependent nonmonotonic response of MBSL in aqueous and organic solutions to hydrodynamical perturbations caused by sudden pressure changes. Through a fast pressure jump, the bubble field is forced into an excited metastable state, subsequently relaxing over a period of seconds to minutes. The period and intensity of the system excitation is highly dependent upon physical parameters and small concentrations of surface active species. By monitoring the system via sonoluminescence intensity, low level quantitation of alcohols and earth metals in water as well as percent concentrations of water in alcohols has been performed. [Work supported by the Center for Process Analytical Chemistry.]

1:15

3pPAa2. Dependence of multibubble sonoluminescence intensity on the sound field in a sonochemical reactor. Hideto Mitome, Teruyuki Kozuka, Toru Tuziuti (Natl. Industrial Res. Inst. of Nagoya, AIST, 1 Hitare-cho, Kita-ku, Nagoya, 462 Japan, mitome@nirin.go.jp), and Liming Wang (Japan Small Business Corp., Tokyo, 105 Japan)

Since sonochemical reaction is related to the generation of acoustic cavitation bubbles, sonoluminescence induced by the collapse of bubbles can be a measure to specify the reaction field. The present paper discusses dependence of multibubble sonoluminescence intensity on the sound field in a sonochemical reactor to specify the cavitation field quantitatively. Deionized and distilled water was filled in a square reactor cell $50\times50\times140$ mm, which was settled in a temperature-controlled water bath, and was irradiated by cw ultrasound changing the frequency from 20 to 250 kHz for various values of water depth and temperature. The intensity of sonoluminescence was measured by a photomultiplier tube with a converging lens ensuring all the sonoluminescing position was detectable. The experimental results show that the luminescence intensity is very sensitive to the water depth. A change as small as 1 mm alters the vibration mode in the cell. The intensity is also strongly dependent on the amount of dissolved air and temperature. Correlation between the luminescence intensity and the harmonics in the ultrasonic waveform generated by nonlinear vibration of bubbles is shown. 3pPAa3. Problems of ultrasonic energy transferring into liquid-phase load. Oleg V. Abramov, Vladimir O. Abramov, Vitaly N. Bulgakov, and Oleg M. Gradov (Lab. of Ultrasound, N. S. Kurnakov Inst., Leninsky prosp. 31, Moscow 117907, Russia, abramov@ionchran.msk.ru)

The rational circuits of construction and modes of operations for a system: electric generator, electroacoustic transducer, sonotrode system, irradiator, and liquid phase are considered from the point of view of transferring vibrations of maximum power into the load. The analysis has shown that for realization of vibration transfer of the greatest possible acoustic power created by the electroacoustic transducer, it is necessary to use the sonotrode system with developed surface. It can be realized by using an irradiator of the tubular form, in which the longitudinal fluctuations are transformed into radial ones. Calculations of tubular type sonotrode systems, based on use of the analytical approaches and of computer modeling, are conducted. A number of sonotrode systems that transform longitudinal vibrations into ones, extending in a radial direction in relation to axes' tubular irradiator, is made and tested. For improving the technological efficiency of the device, the tubular irradiator form was optimized to increase the number of the cavitational bubbles beneficially worked in the liquid and intensity of hydroacoustic streaming. So, for increasing the number of the cavitational bubbles on the external surface of the tubular irradiator at the high-amplitude zones for the longitudinal vibrations, the cross lugs are formed. The stand for valuation of acoustic capacity, entered in liquid load, is assembled, and experimental research at the choice of optimum modes of ultrasonic processing of liquids with various physical properties (viscosity, surface tension, density) is conducted.

3pPAa4. Enhancement of ultrasonic cavitation yield by a bifrequency irradiation and its frequency effect. Ruo Feng, Channgping Zhu, Huamao Li, and Zhouhua Chen (State Key Lab. of Modern Acoust., Nanjing Univ., Nanjing, 210093, PROC)

The ultrasonic cavitation yield given by a combining orthogonal irradiation at frequencies of 28 kHz and around 1 MHz is studied experimentally by using electric detection method. It is shown that the cavitation yield produced by the bifrequency irradiation is much larger than the sum of the yields produced separately by the two irradiations. For instance, when the intensity of 28-kHz ultrasound is fixed but that of 0.87-MHz ultrasound changes in the range of 4–7 w/cm^2, the cavitation yield of the combining irradiation is equal to 1.9–3.4 times of the sum of the yields given separately by the two irradiations. The ultrasound beams of 28 kHz combined separately with 1.0 and 1.7 MHz are also used. The results show that the enhancement of cavitation yield by bifrequency irradiation is notably dependent on the used frequencies. When the intensity of 0.87-, 1.0-, and 1.7-MHz ultrasound is taken 6.5 w/cm^2, the combining irradiation

gives 4.4, 3.2, and 1.8 times the cavitation yield of 28-kHz irradiation, respectively, which is similar to that obtained previously by using single-frequency ultrasound irradiation. The authors would like to acknowledge Professor T. J. Mason for his valuable suggestion.

3pPAa5. Two-phase theory of acoustic wave propagation in magnetic liquids. Tomasz Hornowski (Inst. of Acoust., Adam Mickiewicz Univ., Matejki 48/49, 60-769 Poznań, Poland, hornaku@phys.amu.edu.pl), Mariusz Kaczmarek (Inst. of Fundamental Technolog. Res., Mielżyńskiego 27/29, 61-725 Poznań, Poland), Mikołaj Łabowski, and Andrzej Skumiel (Inst. of Acoust., Adam Mickiewicz Univ., Matejki 48/49, 60-769 Poznań, Poland)

A new theoretical approach to ultrasonic wave propagation in magnetic liquids is proposed on the basis of a two-phase model in which the solid phase (magnetic particles coagulating to clusters forming a rigid skeleton) and the liquid phase (carrier liquid) are described by separate sets of equations for the balance of mass, momentum, and angular momentum. Interaction between clusters is described by components of the stress and strain tensors in the solid phase whereas interaction between the clusters and the liquid is accounted for as Stokes, Basset, and added mass forces and the respective angular momenta. Expressions are derived for the velocity and attenuation as functions of the wave frequency and the angle between the propagation direction of the ultrasonic wave and the magnetic field. Moreover, the expressions obtained are checked experimentally for several ultrasonic wave frequencies *versus* the strength and direction of the magnetic field under various conditions. [Work supported by KBN Research Grant No. 2PO3B 07912.]

2:15

3pPAa6. Sonofluorescence image in an analogous sonochemical reactor. Huamao Li, Andong Xie, Fan Zhong, Huijun Wan, Lijun Liu (Sci. Res. Managerial Office, Ji'an Teachers' College, Ji'an, 343009, PROC), and Ruo Feng (Nanjing Univ., 210093, PROC)

According to the sonofluorescence principle of ultrasonic cavitation oxidation suggested by the authors [Huamao Li *et al.*, Acta Acust. **22** (1997)], the cavitation field distribution images in both analogous symmetrical and nonsymmetrical sonochemical reactors filled with aqueous Luminol–KOH alkaline solution have been taken when using an ultrasound with an operating frequency of 1.45 MHz and an ultrasonic electric power of 25 W. The images seem to show that the ultrasonic cavitation field in the analogous symmetrical sonochemical reactor appear symmetrical with uniform distribution, and the ultrasonic cavitation fields in the analogous nonsymmetrical sonochemical reactors appear nonsymmetrical with nonuniform distribution, but the nonsymmetrical cavitation field distribution can be guided along some curved way. The authors think that the sonofluorescence image method can be available for use in a sonochemical reactor designed for getting uniform or positioning cavitation field. [Work supported by the Natural Science Foundation of Jiangxi province and the Science Foundation of Ji'an Teachers' College.]

3pPAb1. Interaction of counterpropagating acoustic waves in materials with nonlinear dissipation and in hysteretic media. Hélène Bailliet, Vitalyi Gusev, Pierrick Lotton, and Michel Bruneau (Lab. d'Acoustique, IAM–UMR 6613, Univ. du Maine, av. O. Messiaen, 72085 Le Mans Cedex, France, helene@laum.univ-lemans.fr)

Current interest in the interaction of sound waves traveling in opposite directions is due to progress in thermoacoustics (where the acoustic resonator is a part of the refrigerator) and achievements in diagnostics of solids via the evaluation of standing waves in rods. In the present analysis, the second-order nonlinear processes are described by the equation $\partial^2 V_+/\partial t^2 - c_0^2(\partial^2 V_+/\partial x^2) = -(\partial/\partial t)\{(\partial/\partial x)[(\epsilon-1)V_-^2+V_+^2] + RV_+|V_+| - h[V_-^A+V_-\mathrm{sgn}(\partial V_-/\partial t)](\partial V_-/\partial x)\}$. Here $V_\pm = v_+(\mu x, t-x/c_0) \pm v_-(\mu x, t+x/c_0)$, $\mu \ll 1$, $v_\pm$ are particles velocities, and superscript A denotes amplitude of a periodic wave. Elastic nonlinearity [the first group of terms on the right-hand side (rhs)] does not provide effective interaction of ''$\pm$'' waves. Nonlinear dissipation (the term proportional to R on the rhs) is responsible for the additional attenuation of the ''$-$'' wave induced by the ''$+$'' wave. The chosen form of dissipative nonlinearity is typical of gas-filled porous structures used in thermoacoustics. Hysteretic nonlinearity typical of micro-inhomogeneous materials (the last group of terms on the rhs) leads to amplification of the weak ''$-$'' wave in the field of the strong ''$+$'' wave. Predicted stimulated backscattering of sound in hysteretic media can influence the operation of parametric underground antennas. [Work supported by DGA.]

1:15

3pPAb2. Pseudo-Rayleigh and pseudo-Scholte surface acoustic solitons. Vitalyi Gusev (Lab. d'Acoustique, Univ. du Maine, av. O. Messiaen, 72085 Le Mans, France), Christ Glorieux, and Jan Thoen (Lab. Akoest. Therm. Fys., Katholieke Univ., Leuven, Celestijnenlaan 200D, B 3001 Leuven, Belgium)

Soliton solutions for the equation $s^2(\partial v/\partial x) = \alpha(\partial/\partial\tau)v^2 + \beta(\partial/\partial\tau) \times (H[v])^2 - D(\partial^2/\partial\tau^2)H[v]$, describing wave propagation on a fluid–solid interface covered by elastically linear film, have been found analytically. In this equation x is a ''slow'' spatial coordinate, τ is a ''fast'' time, α and β are nondimensional nonlinear parameters, S is the wave velocity in the absence of a film, and H denotes the Hilbert transform with respect to τ. This equation generalizes the recently proposed model for nonlinear Rayleigh waves [J. K. Hunter, Contemporary Math. **100**, 185–202 (1989)] and the equation derived for Scholte waves [Gusev *et al.*, IEEE UFFC (1998)], where $D=0$, by accounting for linear variation of the wave velocity with frequency $D \equiv \partial s_p/\partial\omega(\omega=0+0)$. Velocity dispersion $s_p = s_p(\omega)$ $[s \equiv s_p(0)]$ is due to interface loading by an acoustically thin

film and described by the last term in the right-hand side of the equation. The problem of the nonlinear surface/interface wave amplitude distribution in the interior of the medium is also addressed.

1:30

3pPAb3. Nonlinear acoustics of solids: History and modern trends. Vladimir A. Krasilnikov (Dept. of Phys., Moscow State Univ., Moscow, 119899 Russia, snk@snk.phys.msu.su)

The author had the pleasure to be involved in the pioneering experiments on the nonlinear acoustic wave propagation in crystals and metals (1960). It was found that even for small wave amplitudes acoustic harmonics generation took place for longitudinal waves. The results obtained were interpreted from the point of view of Hooke's law nonlinearity due to nonparabolic interaction potential taking into account accumulation effects in nondispersive media. Besides that, transversal acoustic waves under some external effects like pressure, heating, etc., also demonstrated nonlinear behavior despite that it was forbidden in a framework of crystal lattice theory. It was accounted for by the development of structural disturbations in a material and seemed to be the first attempt to demonstrate the importance of acoustic nonlinear nondestructive testing of different materials. It was shown later that some construction materials and rocks have much higher nonlinear parameter values than those for crystals and metals. The paper will also present an historical review of recent developments in other areas of nonlinear acoustics in solids: measurements of nonlinear acoustic parameters, surface acoustic waves nonlinearity, ''clapping'' nonlinearity, defective solids and rocks, etc.

1:45

3pPAb4. Measurement of third-order elasticity in isotropic solids. Z. W. Qian (Natl. Lab. of Acoust., Inst. of Acoust., Acad. Sinica, Beijing 100080, PROC, qzw@canna.ioa.ac.cn) and Wenhua Jiang (Nanjing Univ., Nanjing 210093, PROC)

The responsibility of second-order harmonics to the SV incidence was investigated in an isotropic solid such as aluminum, and each sample to be measured was designed as a semicircular disk of which the cross section is a semicircular polygon in order to provide many incidental angles for measuring. The displacements of both the linear and second-order waves were observed in the area near the center of the semicircle, where the surface is stress free. According to the theory proposed by one of the authors (Qian), the third-order elastic constants can be obtained acoustically by the inverse techniques.

2:00

3pPAb5. Nonlinear acoustics of zero-volume nonbonds and cracks. Igor Yu. Solodov (Dept. of Phys., Moscow State Univ., Moscow, 119899 Russia, snk@snk.phys.msu.su)

The results of experimental investigation of nonlinear acoustic phenomena for surface (SAW) and bulk waves (BAW) in materials with nonbonded interfaces and closed cracks are reported. Several mechanisms of acoustic nonlinearity specific for such materials were found and analyzed. In a propagation mode SAW harmonics generation and wave interaction effects revealed two to three orders of magnitude increase in nonlinear parameter values for a nonbonded interface. Unconventional higher harmonics ratio was measured and manifested in a distinctive nonlinear SAW waveform distortion. Efficient generation of harmonics forbidden in homogeneous isotropic solids was observed for shear BAW in the presence of nonbonds and cracks. Peculiar rectification effects were found for SAW propagation and BAW reflection at an interface and shown to result in both acoustic broadening and creeping of a nonbonded area. Extremely high efficiency was measured for nonlinear BAW–SAW transformations accompanying combined three-wave interactions at a nonbonded interface. In a reflection mode such an interface demonstrated a unique feature of nonlinear reflection with inverse spectral distribution of the harmonic amplitudes. Some prospective applications of the effects observed were demonstrated in signal processing, tribology, and nonlinear NDE of zero-volume nonbonds and closed cracks.

Session 3pPAc

Physical Acoustics: Memorial Session for Isadore Rudnick

Richard Stern, Cochair
Applied Research Laboratory, Pennsylvania State University, P.O. Box 30, State College, Pennsylvania 16804-0030

Robert M. Keolian, Cochair
Applied Research Laboratory, Pennsylvania State University, P.O. Box 30, State College, Pennsylvania 16804-0030

Isadore Rudnick was born on May 8, 1917 and passed away in Los Angeles on August 22, 1997. He was considered America's foremost acoustical physicist during the second half of the twentieth century, having made seminal contributions to both classical and quantum acoustics and having trained scores of graduate students and several postdoctoral fellows. He received his Ph.D. in Physics at the University of California, Los Angeles (UCLA) and, after work at Duke University and Penn State, he returned to UCLA where he was a professor of Physics for the past 39 years. He held visiting academic appointments in Paris, Haifa, Rome, Tokyo, Copenhagen, and Nanjing. Professor Rudnick was a member of the National Academy of Science and the Governing Board of the American Institute of Physics and received the prestigious Fritz London Award for his research in Low Temperature Physics from the International Union of Pure and Applied Physics. He was a recipient of the Acoustical Society's Biennial Award (1948), its first Silver Medal in Physical Acoustics (1975), and the Gold Medal (1982). He served as the Society's vice president (1962) and president (1969).

Friends, family, colleagues and former students will present reminisces, photos, video clips, and jokes that we hope will remind attendees at this special session of how fortunate we all were to have benefited from the life of this great and wise gentleman and scientist. Attendees will have the opportunity to make informal comments at the conclusion of the scheduled presentations.

3pSA1. Vector fields and quadratic maps. Huw G. Davies and Konstantinos Karagiosis (Dept. of Mech. Eng., Univ. of New Brunswick, Fredericton, NB E3B 5A3, Canada)

Vector fields describing responses of nonlinear systems are often investigated by sampling on a suitable Poincaré section. For example, period-1 limit cycles yield one fixed point, period-2 two points, and so on. More information could be obtained if the full return map on the section rather than just the fixed points were known. Such a map can be obtained numerically from transient analysis of the system. Instead, an analytic approximation of the map is discussed here, in the general quadratic form $x_i(t)=a_{ij}(t)x_j(0)+b_{ijk}(t)x_j(0)x_k(0)$. $x_i(t)$ are perturbations away from the limit cycle, $t=0$ being chosen on the Poincaré section. This equation with $t=T$, the fundamental period, is the required map. $a_{ij}(T)$ is the Floquet monodromy matrix. Differential equations for a_{ij} and b_{ijk} are obtained from a Taylor expansion of the system equations and solved recursively. The three-dimensional Rössler attractor which is known to yield a smooth, one-dimensional unimodal map is used as an example. [Work supported by NSERC.]

1:20

3pSA2. Experimental and theoretical analysis of the nonlinear dynamics and acoustics of a rattling plate. Karen J. Fegelman and Karl Grosh (Dept. of Mech. Eng. and Appl. Mech., Univ. of Michigan, 2350 Hayward St., Ann Arbor, MI 48109-2125)

Rattle has become an important issue in the motive and aerospace industries. Design for the prevention and reduction of rattle noise requires that the underlying mechanisms be understood and powerful, flexible numerical tools be developed. In this paper, the focus is on the former, developing a basic theoretical and experimental foundation for determining the vibroacoustic behavior arising from the nonlinear dynamics associated with the rattle process. In order to understand the fundamental mechanics of rattle, a model problem was formulated involving a hinged plate rattling against a stiff contact point excited by base motion. The plate was modeled as a flexible beam and the resulting equations of motion were solved explicitly. It was found that the calculated accelerations at the tip of the beam quantitatively agree with those measured from an experimental test stand. In addition, the predicted and measured sound pressure levels (SPL) at various points were found to agree qualitatively. Finally, the closed form flexible body solutions were analyzed with regard to stability to predict transitions from periodic to chaotic rattling behavior. In particular, the sensitivity of the transition region to chaos on the base motion amplitude and frequency are investigated experimentally and theoretically.

1:40

3pSA3. Effects of disorder and nonlinearity on the propagation of classical waves. Olivier Richoux, Claude Depollier, Jean Hardy, and Abderrahmane Brezini (Inst. d'Acoustique Mécanique, UMR CNRS 6613, Univ. du Maine, 72085 Le Mans Cedex 9, France, bal@laum.univ.-lemans.fr)

The interplay between the effects of disorder and nonlinearity on the propagation of classical waves is examined by means of an analytical model and numerical simulations. A quasi-one-dimensional string is loaded by N masses, each one fixed to a spring. Disorder is introduced onto the system by considering masses and/or lattice spacing as random variables. Nonlinearity is assumed to arise from the dynamical potential associated to each spring. The wave propagation is formulated in terms of the transfer matrix. The Lyapunov exponent is computed for various system size, yielding the spectrum and the localization length. The numerical simulations have been performed for the linear ordered case which serves as support. The purely disorder linear system offers a direct realization for the observation of the classical Anderson localization. Disorder in mass perturbs the allowed band from the upper edge in contrast to the disorder in position from both edges, the latter appears more efficient in inducing the Anderson localization. The nonlinear system in presence of both order and disorder exhibits bandwidths greater than their respective similar linear case. These findings suggests strongly that nonlinear waves are robust enough to propagate through the system even in the presence of disorder.

2:00

3pSA4. Nonlinear vibroacoustical free oscillation method for crack detection and evaluation. Leonid M. Gelman and Sergey V. Gorpinich (Dept. of Nondestructive Testing, Natl. Tech. Univ. of Ukraine, 37, Peremogy pr, Kiev, 252056, Ukraine, ania@gelman.pp.kiev.ua)

For detection and evaluation of cracks, the vibroacoustical method of free oscillations, based on nonlinear dynamics of a tested object, is widely used. However, in spite of wide practical application, the theoretical basis of this method is insufficiently investigated. The theoretical research of the decrement of the damped nonlinear free oscillations is given in the presence of a crack in a tested object. New generalizations of the decrement for nonlinear oscillations are proposed and investigated. New analytical expressions between the decrement and relative size of a crack, factors of damping, and the natural frequency of a tested object without a crack are received, on the basis of which a new testing feature is proposed and investigated. The cases of small and large damping are considered. The results obtained allow one to explain the phenomena that appeared at the method usage. [Work supported in part by the John D. and Catherine T. MacArthur Foundation.]

2:20

3pSA5. Nonlinear dynamic behavior of a piezoelectric 1-3 composite. Thomas J. Royston (Dept. of Mech. Eng., Univ. of Illinois, Chicago, IL 60607-7022, troyston@uic.edu) and Brian H. Houston (Naval Res. Lab., Washington, DC 20375-5000)

The nonlinear vibratory behavior of a smart material component, a 1-3 piezoceramic composite, is characterized theoretically and experimentally. The developed theoretical model for the electroelastic behavior of the 1-3 composite follows conventional assumptions made by prior investigators but includes higher-order electrical, mechanical, and electromechanical terms in the constitutive equations for the embedded PZT-5 phase. Dynamic experimental measurements of the 1-3's mechanical response to harmonic electrical excitation over a range of excitation frequencies and mechanical loading conditions quantify the level of higher harmonic content (harmonic distortion) in the device and illustrate the dependence of this on the mechanical coupling conditions of the component to its surrounding. While this study focuses on a particular piezoelectric device, the techniques developed are applicable to the wide range of smart materials and structures which exhibit significant nonlinearity, including those based on piezoelectric, electrostrictive, magnetostrictive, and electrorheological technologies, to name a few. [Work supported by ASEE/NRL Summer Faculty Program.]

2:40

3pSA6. Theoretical bases of the vibroacoustical nonlinear forced oscillation diagnostics method. Nadezhda I. Bouraou (Dept. of Orientation and Navigation, Natl. Tech. Univ. of Ukraine, 37, Peremogy pr., Kiev, 252056, Ukraine), Leonid M. Gelman, and Nataliya Yu. Ossokina (Natl. Tech. Univ. of Ukraine, Kiev, 252056, Ukraine)

A new passive vibroacoustical forced oscillation diagnostics method, based on nonlinear dynamics of tested objects, is considered. The method uses nonstationary vibration excitation with changed frequency. For the first time, theoretical research of the nonlinear oscillation system is given with mentioned excitation and the presence of the crack in the tested object. New analytical expressions between the estimates of spectral density of signals, radiated at tested object forced oscillations, and the relative size of the crack, duration of diagnostics, and speed of frequency excitation changing are received. On the basis of mentioned expressions, testing data are proposed and investigated. Comparison with the case of stationary excitation is given.

3pSP1. Using acoustic impulses to detect buried objects. Charles G. Don, David E. Lawrence, and Andrew J. Rogers (Dept. of Phys., Monash Univ., Vic 3168, Australia)

A detector of nonmetallic buried objects, such as land mines, has been developed using acoustic impulses with a peak energy around 1 kHz. The initial proposal was to compare the difference in signals from two microphones spaced equally on either side of the sound source held a few centimeters above the ground. Ideally, over a uniform surface the difference signal is zero, however, when one microphone is over an object an additional reflected pulse remains after subtraction. In practice, this pulse is small and often obscured by noise. Better results have been obtained if data from a single microphone is subtracted from a ''reference'' waveform. Some problems which have to be overcome are optimizing the alignment of the two pulse trains and deciding whether or not to normalize the signals prior to subtraction. If care is not exercised, either process may distort or mask the required object reflection. This small reflected signal can be further enhanced, compared to the background noise, by correlating with an appropriate known waveform. Mention will also be made of the effects of different media and surface contours.

1:20

3pSP2. Automatic noise source recognition. Didier Dufournet, Philippe Jouenne, and Adam Rozwadowski (01dB, Inc., 1583 E. Genesee Street, P.O. Box 796, Skaneateles, NY 13152)

MADRAS is an acoustic monitoring system that features the automatic recognition of noise sources. It is based on a tree classifier able to use different classification techniques like signal processing, morphology, fractional analysis, and neural networking. A very high accuracy of recognition is achieved due to the optimization of the choice of real-time technique applied and to the intrinsic performance of each algorithm. MADRAS can learn the characteristics of new sources and also use a database of previously processed cases and typical events. The paper presents the results of multiple source recognition in a complex acoustic environment. Implemented on a real time PC-based measuring analyzer called Symphonie, MADRAS has been able to distinguish all noise sources. Acquired data may then be processed to obtain the energy contribution of each source and a list of the frequency of each appearance. Simulations may be viewed and modified.

1:40

3pSP3. A novel octave graphic equalizer. Marija F. Hribsek and Dejan V. Tosic (Faculty of Elec. Eng., Bul. Revolucije 73, 11000 Belgrade, Yugoslavia)

An octave constant Q graphic equalizer using a new class of active bandpass filters is presented. It covers all 11 standard octaves in a frequency range from 16 Hz to 20 kHz. The level in each octave can be changed within ± 20 dB with respect to the reference level which corresponds to the zero dB gain of the equalizer. The advantages of the proposed bandpass biquads are the use of only one operational amplifier per octave, a very small resistors spread ratio, and equal values of the resistors in all octaves. The computer simulation has been used to verify the design of the novel circuit. The new design has been compared to the existing solutions reported in the literature. The comparison shows excellent agreement with the published results. The effects of the finite gain and bandwidth of the real operational amplifier have also been investigated. The proposed new equalizer shows to be robust against these amplifier imperfections.

2:00

3pSP4. Tomographic scanning acoustic microscope system. Daesik Ko, Daekun Song, and Kyesuk Jun (24, mok-dong, chung-ku, Taejon, 301-729, South Korea)

In this paper, a new type of acoustic microscope system using the tomographic image processing technique of STAM (scanning tomographic acoustic microscope) and operation principles of the transmission-mode and detection technique of SAM (scanning acoustic microscope system) is proposed. Since SAM and scanning laser acoustic microscope system (SLAM) used in the past were operated at the reflection mode, these systems could not obtain high-resolution tomographic images. Although STAM could process tomographic images, due to the detection-using laser, problems such as complex detection hardware, alignment, and low S/N ratio occur. If the tomographic image processing technique is used for ultrasonic microscope systems, the axial resolution can be enhanced and it can help and work together with the existing systems to detect cracks that are difficult to find in the reflection mode. These experimental results will be used for various ultrasonic microscope tomographic image processing and ultrasonic measurements.

2:20

3pSP5. Motion compensated high-frequency synthetic aperture sonar. James T. Christoff (Coastal Systems Station, Dahlgren Div. Naval Surface Warfare Ctr., Code R21, Panama City, FL 32407-7001, christoff_jim@ccmail.ncsc.navy.mil)

The Coastal Systems Station has recently completed a set of sea tests using a high-frequency synthetic aperture sonar (HFSAS) mounted on a towed underwater vehicle. The processed results from these tests demonstrate that 2.5-cm resolution can be achieved in shallow water from a small physical array. This system had a Doppler unit to control the ping rate, but had no inertial navigation system and depended entirely upon acoustic backscatter from the seabed to correct for vehicle deviations in the line of sight. In these sea tests the dual overlapped phase center technique [Sheriff, Symposium on Autonomous Underwater Vehicle Technology, pp. 236–245, 1992] was used as the motion compensation algorithm. The tests were conducted over a target field in the Gulf of Mexico that contained a variety of targets, both small sphere and minelike targets. This paper will present results from the HFSAS in the form of a point response function and an acoustic image. The HFSAS achieved between 2.5- and 3-cm resolution on the smallest sphere and produced excellent images of the remaining targets out to a range of approximately 70 m. [Work supported by ONR.]

3pSP6. A study of extracting characteristic parameters of a tubular target. Renqian Wang and Yingchun Li (Dept. of Electron., Peking Univ., Beijing 100871, PROC)

An inverse problem of sound scattered by a tubular target is studied for extracting its characteristic parameters. A geometrical acoustic method is used to describe the scattered field of the tubular target. A physical model is suggested: the backscattering of a tube shell is simplified into reflection of a plane wave on layered media under conditions: $ka \gg 1$, $c/c2 \gg h/b$, here a, b, and h are outer radius, inner radius, and thickness of the tube shell, respectively, and c and $c2$ are sound velocity of the external medium of the tube shell and (longitudinal wave) sound velocity of the tube shell. Reconstruction formulas of the characteristic parameters of the tubular target are given. The characteristic parameters of an elastic tube shell, such as a metallic tube shell, a metallic tube covered with sound-absorbing materials, a bone tube of a pig, and soft tube shell such as a blood vessel, and a trachea of a pig, are reconstructed by using computer simulation and experiments. The theoretical results obtained by this method are supported by experiments.

WEDNESDAY AFTERNOON, 24 JUNE 1998 METROPOLITAN BALLROOM (S), 1:00 TO 3:00 P.M.

Session 3pUW

Underwater Acoustics and Acoustical Oceanography: Bottom Geoacoustic Characterization and Inversion II (Précis Poster Session)

Subramaniam D. Rajan, Chair
Scientific Solutions, 5907 106th Avenue, Northeast, Kirkland, Washington 98033

In this session, an oral summary of each paper will be presented followed by a poster session. All posters will be on display, and all contributors will be at their posters, from 2:00 p.m. to 3:00 p.m. To allow for extended viewing, posters will remain on display until 5:30 p.m.

3pUW1. Head wave data inversion for geoacoustic parameters of the ocean bottom off Vancouver Island. Mark C. A. Laidlaw, Oleg A. Godin, and N. Ross Chapman (SEOS, Univ. of Victoria, P.O. Box 1700, Victoria, BC V8W 2Y2, Canada)

As a part of the Pacific Shelf-93 experiment, small explosive charges were used as underwater sound sources on the continental shelf off Vancouver Island. Broadband acoustic signals received by a vertical line array show the rich structure of precursors arriving prior to the direct water wave. Kinematic properties of the precursors are found to be consistent with those of head waves with different numbers of reflections at the ocean surface and bottom. Power spectra of the precursors reveal complicated interference structure, including deep nulls at relatively low frequencies. Positions of the nulls in the frequency domain and their depth dependence are shown to be sensitive to the variation of compressional wave speed in the bottom. A combination of beamforming, spectral analysis, and travel-time considerations is applied to separate and identify individual head wave arrivals in the sequence of precursor signals. Range- and depth-dependence of the travel times for individual head waves are inverted to determine compressional wave speeds in two distinct subbottom layers and to estimate the thickness of the sediment layers. The frequency- and range-dependence of the head waves amplitudes are analyzed to estimate the compressional wave attenuation. [Work supported by NSERC.]

1:12

3pUW2. Acoustic propagation in gassy sediments. Michael D. Richardson, Warren T. Wood (Marine Geosciences Div., Naval Res. Lab., Stennis Space Center, MS 39529, mike.richardson@nrlssc.navy.mil), Aubrey L. Anderson (Texas A&M Univ., College Station, TX 77843), and Roy H. Wilkens (Hawaii Inst. of Geophys. and Planetology, Univ. of Hawaii at Manoa, Honolulu, HI 96822)

Measurements of values of sediment physical properties, bubble volume, and bubble size distribution are used to predict sound speed and attenuation in the fine-grained, gassy sediments of Eckernförde Bay, Baltic Sea. The predicted results are compared to *in situ* and laboratory measurements of sound speed and attenuation over the frequency range of 5–400 kHz. Dispersion of sound speed is used to determine the upper limit of methane bubble resonance near 20 kHz. These data combined with bubble size distribution measured using CT scans of sediments held under ambient conditions yield an estimate of effective bubble size of 0.3–5.0-mm equivalent radii. Histograms of bubble size distribution are then used to predict frequency-dependent sound speed and attenuation based on the model of Anderson and Hampton [J. Acoust. Soc. Am. **67**, 1865–1903 (1980)]. Given the highly variable spatial distribution of bubble volume and size, the agreement between theory and measurement is remarkably good.

1:19

3pUW3. An optimization technique applied to the recovery of acoustic impedance profiles. Marcelo Magalhaes and Roberto Tenenbaum (Acoust. and Vib. Lab., Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil)

A method based on a global optimization technique is used to solve the inverse (identification) problem of one-dimensional wave propagation in transversely infinite inhomogenous media. The scheme consists of minimizing a cost function given by the square distance (according to the Euclidean norm) between a measured and a synthetic signal, the latter produced by an arbitrary impedance profile. This cost function imposes several difficulties, since the model for the synthetic signal causes it to be polynomial whose degree is at least equal to the number of layers in which the profile is discretized. The optimization method used is a secant one, which, instead of making use of information about the second derivatives of the cost function, which is too time consuming, generates sucessive approximations of its Hessian matrix, based on information gathered as the procedure progresses. Moreover, in order to guarantee that the method follows a descent direction, that is, the cost function is always reduced, a BFGS (Broyden–Fletcher–Goldfarb–Shanno) updating rule is used, together with a Wolfe line search procedure. Results are shown for some continuous as well as stratified media, showing that the method works well with both smooth and nonsmooth profiles.

1:26

3pUW4. Sequential versus iterative methods for recovering acoustical impedance profiles of inhomogeneous media. Roberto Tenenbaum and Marcelo Magalhaes (Acoust. and Vib. Lab., Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil)

Optimization methods for identification of nonhomogeneous media are known to be very time consuming. On the other hand, sequential methods (layer stripping methods) are computationally very efficient and rather unstable under noisy data. In this work, some recent optimization techniques are applied to recover the impedance profile from the reflected data. A careful approach has to be used though, since the cost function is highly nonlinear and its evaluation is quite costly in a computational point of view. The optimization method chosen is a secant one, which, instead of using information about the second derivatives of the cost function, generates successive approximations of its Hessian matrix, based on information gathered as the procedure progresses. The sequential method lies in a new algorithm for computing the reflection response of a truly layered media for an arbitrary input, which can easily be inverted. The results of both methods are compared for some synthetic echoes. The behavior of the methods for random and zero-average noise added to the response is studied. The advantage of using each of the methods as a function of the signal-to-noise ratio is then discussed.

1:33

3pUW5. An experiment on inversion of sound profile through ray modeling. Yuanliang Ma, Xiaoquan Jiang, Yuanhai Sheng (Inst. of Acoust. Eng., Northwestern Polytechnical Univ., Xi'an 710072, PROC, ylma@nwpu.edu.cn), Shixing Yang, and Qingzuo Cheng (CSSC, PROC)

An experiment was conducted in a lake of 150-m depth. A very short hydrophone array (3-m long or 1/50 of the water depth) was used for data acqisition, which consists of 13 hydrophones with 25-cm spacing. Receiving signals are modeled as sums of eigenrays determined mainly by the sound profile, while the sound profile is expressed by six measured samples at different depths in addition to a known sound speed at the bottom. The inversion is based on a simulated annealing algorithm off-line using a 486/100 microcomputer and completed within 2 min. The resultant rms error of sound profile is about 1.6 m/s in comparison with the measured data. An important feature of this approach is that instead of matching the measured to the modeled data vector, arriving structure expressed by the DOA angles and relative time delays are matched for the inversion. To estimate the arriving structure, high-resolution spectrum analysis techniques such as OWSF and MUSIC are adopted. The experiment has shown that inversion of the sound profile can be successfully achieved through ray modeling and using a very short vertical array.

1:40

3pUW6. Waveguide characterization estimation in shallow water using a vertical array. Dejun Jiang (Inst. of Acoust., Academia Sinica, Beijing 100080, PROC)

Waveguide characterization estimation in shallow water using the complex mode approximation of an acoustic field is presented. The advantages of the method are that (1) the dependence on the environmental parameters will obviously decrease. (2) The waveguide characterization parameters (k_m, β_m) can be obtained at the same time, even when the fine structure in the bottom medium, such as the number and thickness of layers, the velocity of compressive and shear wave, and attenuation, is less known or unknown. (3) It can extract the bottom reflection coefficient $V(k)$. Numerical examples illustrate that (1) the accuracy of k_m is at least 10^{-5}, the related error of β_m is mostly less than 20%, and the smaller the mode number, the smaller the related error is. (2) The reflection coefficient in the bottom at low grazing angle can be obtained using a vertical array where the total number of samples is $N=18$ and the length $L=90$ m. The experimental data of 500 Hz are emphatically discussed here. The results for an $f=500$-Hz-wide impulse acoustic signal source which is located at $z_s=11$ m and $r_s=21$ km show that the extracted accuracy of k_m is between 10^{-4} and 10^{-5} and the related error of β_m is between 9% and 26%.

1:47

3pUW7. The error analysis of inverse algorithms for reconstructing the acoustical parameter profile of layered media. Jun-xuan Lin and Qing-hua Bao (Dept. of Phys., Ocean Univ. of Qingdao, Qingdao 266003, PROC)

Reconstructing the parameter profile of layered media is studied with the telemeter of tiny structure in hydrology, oil exploration, and the position selection of petroleum platform in the ocean. It is a much studied topic in the field of ocean acoustics. An inverse scattering experiment of thermocline was completed by us in 1992. The inverse results by the sample iteration algorithm and DC algorithm agreed well with the data measuring by the CTD instrument. It is still an open question. Further discussion in the aspect of reliability is presented in this paper. Generally speaking, inverse errors are caused by: (1) the inverse algorithm itself, (2) signal processing for the stability of computation, and (3) the improper problem. The result of a model inverse experiment shows that the errors caused by the algorithm itself and signal processings are not so critical if the improper problem was not paying enough attention.

4aPLa1. Fuzzier but simpler analytic models for physical acoustics and structural acoustics. Allan D. Pierce (Dept. of Aero. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02315, jones@bu.edu)

Acousticians have long been forced to analyze physical systems for which they apparently do not have enough information to make detailed analytical or computational predictions. One could say that their knowledge of such systems is ''fuzzy.'' Alternately, the means of measuring the details or of describing such a system may be in principle possible, but the answers one really desires, those which one can ''deal with,'' are of seemingly far less complexity than the modeled system in all its detail. The trick, of course, is to hypothesize a small number of simple and relevant descriptors of the system and to build a predictive model that uses only these descriptors. The rich and venerable literature of acoustics abounds with successful attempts in this vein, and a few such, taken from diverse subfields such as physical acoustics, architectural acoustics, underwater acoustics, and structural acoustics, are briefly reviewed in this talk. New problems and new questions lead to new searches for appropriate descriptors and for simple models which employ these descriptors. Theoretical tools which help to fill in the gaps caused by the incompleteness of these descriptors are general conservation principles and Jayne's theory of maximum-likelihood based on Shannon's uncertainty function.

Architectural Acoustics: Case Study on the New Tokyo Performing Arts Center

Leo L. Beranek, Chair
975 Memorial Drive, Suite 804, Cambridge, Massachusetts 02138-5755

Chair's Introduction—7:45

Invited Papers

7:50

4aAA1. Japan's new National Performing Arts Center. Takahiko Yanagisawa (TAK Associated Architects, Inc., 1-7 Kanda Nishiki-cho, Chiyoda-ku, Tokyo, 101 Japan)

Japan's first National Performing Arts Center, a ''theater city,'' was opened in the Shinjuku district of Tokyo in the fall of 1997. The center is composed of the New National Theatre, which was the winning design in an international architectural competition in 1986, and Tokyo Opera City and covers a total area of 11 acres. The New National Theatre includes an opera house, a drama theater, and an experimental theater, while Tokyo Opera City comprises a concert hall, a skyscraper, and shops. The center promises to become the focal point of theatrical and musical activity in Japan. The architectural goal was to create spaces which would fully engage the human senses, becoming a ''sanctuary of memorable experiences.'' Special focus was placed on the enhancement of the live sound produced by the human voice as well as instrumental sound. The acoustical consultant and associated laboratory were intimately involved from the beginning, and it was therefore possible to integrate their ideas into the design at an early stage. The team also conducted measurements of many of the world's finest halls. Each of the halls boasts its own distinct character, and they are acclaimed by musicians, audiences, and critics alike.

8:05

4aAA2. Acoustical design of the opera house of the New National Theater, Tokyo, Japan. Leo L. Beranek (975 Memorial Dr., Ste. 804, Cambridge, MA 02138), Takayuki Hidaka, and Sadahiro Masuda (TAK Associated Architects, Inc., Tokyo, 101 Japan)

The New National Theater (NNT) project containing three halls started with an open international design competition in 1986 and ended with a grand opening October 10, 1997. The architect is Takahiko Yanagisawa. The opera house, the core of the NNT facility, has a seating capacity of 1810, a volume of 14 500 m^3, and a reverberation time with full audience of 1.5 s (stage curtain open).

Various model experiments, using a CAD model, 1:10 scale model, and full-sized materials samples, were conducted over a 7-year period. As a result, the main floor has an almost rectangular shape, three-layered balconies have a modest fan shape, and the balcony fronts at each level create a rectangular shape. The overhang of each balcony is minimized to take visibility requirements into consideration. The unique design has a large curved reflector in front of the proscenium and over the orchestra pit and curved reflecting surfaces at the fronts of each of the side balconies to reflect the singer's voices uniformly from a large portion of the tremendous stage. The balcony fronts, the side walls, and the ceiling also augment the reflections from those surfaces. The unoccupied values are: EDT=1.6 s, $C_{80}(3)$=2.4 dB, $[I-IACC_{E3}]$=0.66m and bass ratio=1.1.

8:55

4aAA3. Acoustical design of the medium theater of the New National Theater, Tokyo, Japan. Leo L. Beranek (975 Memorial Dr., Ste. 804, Cambridge, MA 02138), Takayuki Hidaka, and Sadahiro Masuda (TAK Associated Architects, Inc., Tokyo, 101 Japan)

The medium theater is mainly intended for the performances of musicals, dramas, dances, and small-size operas. It features use of two types of stage arrangement: a proscenium type with modest fan plan (1038 seats with V=7150 m^3 and occupied RT=1.0 s), and an open stage type with wide fan plan (1010 seats with V=9250 m^3 and occupied RT=1.3 s). The stage types are changeable from one to the other by operation of a movable floor, which is the front half of the main floor, and of slidable side walls. To cope with a wide variety of performing types, two stage types, two scenery lofts, and extensive lighting and loudspeaker requirements, minimal effective initial reflecting surfaces to enhance raw voice were studied through experiments and studies with CAD models and 10:1 scale model tests. The rear wall is a combination of a Schroeder QRD diffuser and absorbing material to eliminate echo. Satisfactory sound strength without amplification is possible only because of the short depth of the hall.

9:10–9:20 Break

9:20

4aAA4. Acoustical design of the Tokyo Opera City (TOC) Concert Hall. Takayuki Hidaka (Takenaka R & D Inst., 1-5-1 Otsuka, Inzai, Chiba, 270-13 Japan), Leo L. Beranek (Cambridge, MA 02138), Sadahiro Masuda, Noriko Nishihara, and Toshiyuki Okano (Takenaka R & D Inst., Chiba, 270-13 Japan)

The TOC Concert Hall, called ''Takemitsu Memorial'' in honor of the late composer Toru Takemitsu, was opened September 10, 1997. With a seating capacity of 1636 and a volume of 15 300 m^3, the hall is sized to cover the musical range from recitals to orchestral concerts. The plan is rectangular in shape but, by request of the architect Takahiko Yanagisawa, the ceiling is a distorted pyramid, with its peak nearer the stage than the rear of the wall. This unique shape had to be analyzed using a CAD model and a 1:10 scale model so that all interior surfaces would be adjusted in shape and absorption to yield optimum values for RT, EDT, $IACC_{E3}$, surface diffusion, initial time delay gap, and loudness [Beranek, *Concert and Opera Halls* (ASA, New York, 1996)]. To provide a better ensemble condition for the musicians on stage and to provide early reflections to several other regions, a square canopy, almost 10 m on a side, is suspended above the stage. The pyramidal ceiling has diffusing elements added to simulate coffers. Schroeder QRDs on the ceiling surface facing the orchestra are used to control echo and to add sound diffusion. With audience, RT=1.95 s, G=6.4 dB, and $[1-IACC_{E3}]$=0.72.

10:10

4aAA5. Relation of acoustical parameters with and without audiences in concert halls and a simple method for simulating the occupied state. Takayuki Hidaka (Takenaka R & D Inst., 1-5-1 Otsuka, Inzai, Chiba, 270-13 Japan), Leo L. Beranek (Cambridge, MA 02138), and Noriko Nishihara (Takenaka R & D Inst., Chiba, 270-13 Japan)

Six acoustical parameters, RT, EDT, C_{80}, D, G, and $IACC_{E3}$, were measured with and without audiences at six concert and opera halls. The range in volume was 3576 to 15 300 m^3. The upholstering of the chairs ranged from light to heavy. Comparisons were made of these parameters before and after addition of the audience. The conclusions are: (1) Predictions of the occupied reverberation times were found inaccurate when the measured unoccupied values were adjusted by using unoccupied versus occupied data for the chairs obtained in a reverberation chamber. If diffuse sound conditions are assumed, it would be possible to predict EDT, C_{80}, D, and G from the occupied RT values whether measured or calculated as above. Such predictions are also inaccurate. (2) Plots of the six parameters, i.e., unoccupied versus occupied values, are nearly straight lines with correlations generally in excess of 0.9. These high correlations permit the use of empirical equations to predict these parameters for occupied halls from measurements made in unoccupied halls. (3) It was also found that $IACC_{E3}$ is almost the same whether measured with or without audience. This supports a previous report that $IACC_{E3}$, for unoccupied halls, is of importance in assessing their subjective quality when occupied [Hidaka *et al.*, J. Acoust. Soc. Am. 989–1007 (1995)]. This paper also reports on the successful use of a cloth covering over unoccupied seats to simulate occupied conditions.

10:30

4aAA6. Objective and subjective measurement of 15 opera houses in Europe and the USA. Takayuki Hidaka (Takenaka R & D Inst., 1-5-1 Otsuka, Inzai, Chiba, 270-13 Japan) and Leo L. Beranek (Cambridge, MA 02138)

Acoustical measurements were executed at 15 major opera houses in eight countries under unoccupied conditions. The objective parameters determined are RT, EDT, C_{80}, D, G, $IACC_{E3}$, and $IACC_A$, which are common attributes needed for concert hall evaluation. The measured unoccupied RT's range from 1.26 to 2.15s and occupied RTs, usually predicted using the empirical equations of the preceding presentation, range from 1.19 to 1.74 s. The range of the other six parameters are also examined. In particular, $[1-IACC_{E3}]$ has a range from 0.39 to 0.72, which is similar to that for concert halls [Hidaka *et al.*, J. Acoust. Soc. Am. 998–1007 (1995)]. Questionnaires have been returned from about 20 opera conductors which enable the authors to present subjective evaluations of the halls. Finally, the subjective evaluations are compared with the objective data.

Session 4aAB

Animal Bioacoustics: Temporal Patterns and Rhythm

Christopher W. Clark, Chair
Section of Neurobiology and Behavior, Bioacoustic Research Program, Cornell University, Ithaca, New York 14850

Invited Papers

8:30

4aAB1. It's all a matter of timing: Temporal mechanisms for production and encoding of acoustic signals. Andrew H. Bass and Deana A. Bodnar (Neurobiology and Behavior, Cornell Univ., Mudd Hall, Ithaca, NY 14853, ahb3@cornell.edu)

Studies of acoustic communication in teleost fish have identified basic principles underlying both the motor control of acoustic signaling and the sensory encoding of the physical attributes of those signals. Parental male midshipman fish excavate denlike nests under rocky shelters in the intertidal and subtidal zones along the western coast of the United States and Canada. Nesting males generate long duration, multi-harmonic signals with a sinusoidallike appearance that are known as ''hums.'' Observations of courtship behavior together with phonotaxis experiments support the hypothesis that the hum functions as a mate call. Early studies showed that a rhythmically active, pacemaker-motoneuron circuit in the hindbrain establishes the temporal features of hums [Bass and Baker, J. Neurobiol. **21**, 1155 (1990)]. Recent studies suggest that temporal coding in the auditory midbrain contributes to the segregation of, and discrimination between, concurrent acoustic signals which form acoustic beats like those generated by the overlapping hums of nesting male midshipman during the breeding season [Bodnar and Bass, J. Neurosci. **17**, 7553 (1997)]. Hence, the rhythmic timing of action potentials is important for both acoustic signaling and reception. [Work supported by NIH and NSF.]

8:55

4aAB2. Temporal rhythms in the signals of insects. T. G. Forrest (Dept. of Biol., Univ. of North Carolina at Asheville, Asheville, NC 28804, tforrest@unca.edu)

The signals generated by acoustic insects exhibit temporal patterns on several time scales. Annual or seasonal rhythms provide information about temporal changes in insect population size. Knowledge of such changes might be useful in ecological monitoring programs. Circadian or daily rhythms commonly seen in insect signaling are generated by endogenous ''clocks'' that are reset by environmental cues. Understanding these daily patterns is also important for monitoring insect populations. Within insect populations, the signals of neighbors sometimes show temporal patterns of synchrony or alternation with timing on the order of seconds. The phase relationships among individuals are maintained by acoustic resetting, whereby an individual's temporal rhythm will change depending on the phase that neighboring signals are received. On still smaller time scales, temporal patterns of insect songs are diverse and generally differ among species. These small-scale patterns are often essential components of mating signals and are used in mate recognition and mate choice.

9:20

4aAB3. Stochastic resonance in the amphibian auditory system? It's just a matter of time. P. M. Narins (Dept. of Physiological Sci., UCLA, 405 Hilgard Ave., Los Angeles, CA 90095)

Noise has traditionally been a factor to minimize or eliminate for optimum performance of a communication system. Recently, it has been proposed that in some cases, noise may *benefit* information transfer and that its existence in sensory systems may be an adaptation to *enhance* detection of weak signals. One possible mechanism that could take advantage of noise to enhance signal transmission is a physical phenomenon known as *stochastic resonance* (SR). In order to study such effects in auditory neurons, use was made of the ability of amphibians to function over a range of ambient temperatures, and thus over a range of internal noise levels. The goal of the present study was to determine the effect of temperature (and internal noise) on information transmission in the frog. To this end, core temperature shifts were induced experimentally and the resulting changes in signal-to-noise ratio (S/N) were quantified. Although our results do not demonstrate SR in the sense that the S/N passes through a maximum at a particular internal noise intensity, we do demonstrate the profound influence of the internal noise on the S/N derived from the neural spike trains. Moreover, recent field and behavioral data will be presented and interpreted in the framework of stochastic resonance. [Work supported by NIH Grant DC-00222 to PMN.]

9:45–10:00 Break

10:00

4aAB4. Whale voices from the deep: Temporal patterns and signal structures as adaptations for living in an acoustic medium. Christopher W. Clark (Section of Neurobiology and Behavior, Bioacoustics Res. Prog., Cornell Univ., Ithaca, NY 14850, cwc2@cornell.edu)

Whales produce long, rhythmic patterns of sounds and some sounds travel many hundreds of miles underwater. Species can be distinguished by temporal features, but there has been a history of infatuation with melodic qualities as the primary features of measurement. Temporal rates and time-bandwidth products are generally related to bathymetry and transmission properties, suggesting that signal features are adapted for communication and navigation. Pelagic species such as blue and fin whales rely on signals in the 10–30-Hz band, presumably to take advantage of the excellent low-frequency propagation properties of the deep ocean, with 10–200-s patterns of sound delivery. Examples will be presented illustrating the remarkable cadence of signal delivery and that animals retain a rhythm after minutes of silence. Shallow water species produce mid-frequency signals (50–1000 Hz) with temporal patterns on the order of seconds. These species with faster rhythms have greater signal variability covering a greater frequency range. At what level is this relationship between temporal pattern and spectral bandwidth indicative of adaptation to optimize for communication and navigation? Is temporal pattern a retained, conservative feature and spectral variability more of an embellishment by individuals to adjust to local conditions?

Contributed Paper

10:25

4aAB5. Time pattern of Sperm whale codas recorded in the Mediterranean Sea 1985–1996. G. Pavan (Centro Interdisciplinare di Bioacustica e Ricerche Ambientali, Università degli Studi di Pavia, Via Taramelli 24, 27100 Pavia, Italy), T. Hayward (Naval Res. Lab., Washington, DC 20375), J. F. Borsani, M. Priano, M. Manghi, and C. Fossati (Università degli Studi di Pavia, Via Taramelli 24, 27100 Pavia, Italy)

Sperm whales, *Physeter macrocephalus*(*catodon*), emit short click sequences, called codas, with regular time patterns [Watkins and Schevill, J. Acoust. Soc. Am. **62**, 1485 (1977)]. Since codas recorded in different geographical areas have different and stable patterns, they possibly serve to convey regional information. More than 120 codas were recorded in the Central Mediterranean Sea in the years 1985–1996 by several research groups using a number of different detection instruments, including stationary and towed hydrophones, military sonobuoys and passive sonars. All of the recorded codas share the same time pattern 3+1 (///-/) with an overall duration ranging from 456 to 1280 ms and an average value of 910 ms. Even if the coda duration varies, the click pattern remains significantly stable. In the present work, the repetition rate and time pattern of Mediterranean codas are characterized, also taking into consideration their possible biological and geographical role. [Work supported by the Italian Ministry of the Environment, Inspectorate for Sea Protection, and by the Italian Navy. Work of the second author supported by ONR Base funding at NRL.]

Chair's Introduction—9:15

Invited Paper

9:20

4aAO1. Acoustic scattering models of zooplankton from several major anatomical groups—theory and experiment. Timothy K. Stanton, Dezhang Chu (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543, tstanton@whoi.edu), and Peter H. Wiebe (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

In order to estimate zooplankton abundance with active acoustics methods, it is crucial to understand the acoustic scattering properties of the zooplankton. The major challenges in formulating scattering models include the facts that there are no exact solutions for these complex bounded bodies and that the boundary conditions are difficult to determine due to animal size and heterogeneities. A series of laboratory scattering measurements and associated model development has been conducted involving zooplankton from three major anatomical groups: (1) fluidlike (euphausiids), (2) elastic shelled (marine snails, both benthic and pelagic), and (3) gas-bearing (siphonophores). The measurements include backscatter versus acoustic frequency (part or all of the range 24 kHz to 1 MHz) and angle of orientation (up to one-degree precision). Dominant acoustic scattering mechanisms are identified through both

spectral and time-domain (pulse compression) analyses and scattering models are developed accordingly. Data and modeling results from the past several years are reviewed and the following new results are presented: (1) a new formulation for predicting scattering at end-on incidence by euphausiids and (2) observations and modeling of a strong peak in scattering levels of the shelled bodies in the upper Rayleigh scattering region. 4aAO2. Covariance Mean Variance Classification (CMVC) techniques: Application to the acoustic classification of zooplankton. Linda V. Martin Traykovski (Dept. of Biol., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543, lmartin@whoi.edu), Timothy K. Stanton, Peter H. Wiebe, and James F. Lynch (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

Accurate acoustic classification of zooplankton species has the potential to significantly improve estimates of zooplankton biomass made from ocean acoustic backscatter measurements. Theoretical models have been developed for three zooplankton scattering classes (hard elastic shelled, e.g., pteropods; fluidlike, e.g., euphausiids; gas bearing, e.g., siphonophores), providing a sound basis for a model-based classification approach. The Covariance Mean Variance Classification (CMVC) techniques classify broadband echoes from individual zooplankton based on comparisons of observed echo spectra to model space realizations. Three different CMVC algorithms were developed: the Integrated Score Classifier, the Pairwise Score Classifier, and the Bayesian Probability Classifier; these classifiers assign observations to a class based on similarities in covariance, mean, and variance, while accounting for model space ambiguity and validity. The CMVC techniques were applied to several hundred broadband (~350–750 kHz) echoes acquired from 24 different zooplankton to invert for scatterer class. All three classification algorithms had a high rate of success with high-quality, low SNR data. The CMVC approach was also applied to several thousand echoes from fluidlike zooplankton to invert for angle of orientation using both theoretical and empirical model spaces; excellent success rates were achieved with the empirical model spaces.

4aAO3. A DWBA-based representation of the extinction cross section of weakly scattering objects: Application to zooplankton. Dezhang Chu (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543) and Zhen Ye (Natl. Central Univ., Chung-li, Taiwan, ROC)

Because of the weakly scattering nature of the marine organisms, the Distorted Wave Born Approximation (DWBA) has been successfully used in modeling the acoustic backscattering by zooplankton [Stanton *et al.*, J. Acoust. Soc. Am. **94**, 3463–3472 (1993); Wiebe *et al.*, IEEE J. Ocean. Eng. (in press)]. However, in the cases where the scattering-induced attenuation is noticeable, the previously used DWBA-based solutions fail to predict the attenuation since they ignore the imaginary part of the scattering form function and result in a zero extinction cross section. In this paper, a revised DWBA-based approximation is presented to include the imaginary part of the scattering form function. In deriving the revised solution, phase compensation based on ray paths is used. The solutions are compared with the exact solutions, and the agreements between the approximate solution and the exact ones are reasonably good. The results from this study can be applied to bioacoustic applications where the attenuations due to scattering or/and multiple scattering by zooplankton are significant.

4aAO4. An *in situ* target strength model for Atlantic redfish. Stephane Gauthier and George A. Rose (Fisheries Conservation Chair, Memorial Univ., P.O. Box 4920, St. John's, NF A1C 5R3, Canada, sgauthie@caribou.ifmt.nf.ca)

An *in situ* target strength (TS) model for Atlantic redfish is proposed based on a series of acoustic-trawl experiments conducted at the outer edge of the Green and Grand Banks in Newfoundland waters (NAFO div. 3Ps) in July 1996 and January 1997. Acoustic data were collected using a SIMRAD EK500 echosounder with a hull-mounted 38-kHz split beam transducer and a deep-tow system with a 38-kHz dual beam transducer that can be towed down to 400-m depth. Bottom and midwater trawling sets were performed to account for fish species composition and length distributions. Study sites were selected on the basis of low variance in individual fish size and the absence of other fish species. The model tests the dependence of TS on diel migratory behavior, TS methodology (split and dual beam), distance from transducer, fish density and size, and the presence and relative abundance of zooplanktonic organisms (krill).

4aAO5. Sensitivity of acoustic scattering models to fish morphometry. J. Michael Jech and John K. Horne (Cooperative Inst. for Limnology and Ecosystems Res., 2205 Commonwealth Blvd., Ann Arbor, MI 48105, jech@glerl.noaa.gov)

Current efforst to model fish backscatter (e.g., Kirchoff ray-mode model [C. S. Clay and J. K. Horne, J. Acoust. Soc. Am. **96**, 1661–1668 (1994)] use digitized images of fish anatomy for a more realistic representation of swimbladder shape, volume, and aspect. However, the degree of image resolution necessary for acoustic characterization and improved predictions, and the variability associated with resolution has not been quantified. Does a more accurate and higher resolution image result in improved correlation between theory and empirical measurements? Backscatter amplitudes display strong relationships with carrier frequency, swimbladder shape, and swimbladder aspect at rather high frequencies. Are predictions of these relationships influenced by image resolution? X-ray images of Atlantic cod (*Gadus morhua*) and brook trout (*Salvelinus fontinalis*) were digitized at fine resolution, and sensitivity analyses were performed to quantify the effect of varying image resolution on predicted backscatter as a function of carrier frequency and swimbladder shape and aspect. Quantifying image resolution is a step towards determining morphometric effects on backscatter variability and estimating fish abundance using multi-frequency data and the inverse approach. [Work supported by ONR.]

4aAO6. Quantifying intraspecies variation in acoustic backscatter models. John K. Horne and J. Michael Jech (Cooperative Inst. for Limnology and Ecosystems Res., 2205 Commonwealth Ave., Ann Arbor, MI 48105, horne@glerl.noaa.gov)

Fisheries researches are increasing the use of frequency-, length-, and aspect-dependent backscatter models in population abundance estimates of fish and zooplankton. Model predictions are often based on measurements from a single or a limited number of organisms. The resulting model parameters are used to predict backscatter for organisms of any length in the population. At rather high frequencies (i.e., length/wavelength ratios of 1 to 20), choice of carrier frequency, swimbladder shape, and swimbladder aspect influence amplitudes of returned echoes. Morphological differences among individuals will therefore determine the variance observed in amplitudes of echo ensembles. To quantify variance in predicted backscatter within species as a function of carrier frequency, fish length, and swimbladder aspect, we combined data from digitized x rays with Kirchhoff ray-mode backscattering models of brook trout (*Salvelinus fontinalis*) and Atlantic code (*Gadus morhua*). Quantifying backscatter variances within and between species allow us to examine the applicability of multi-frequency data and the inverse approach to estimate fish length abundances. [Work supported by ONR.]

4aAO7. Estimation of the target strength of juvenile salmonids at any aspect. Thomas J. Carlson (USCE—Waterways Experiment Station, CENPP-PE-E, P.O. Box 2946, Portland, OR 97206-2946)

Many tasks, such as assessment of the state of stocks and observation of migrant behavior, elemental for recovery of Columbia River basin salmonid stocks, are currently performed using active acoustic methods. Detectability models are required to configure acquisition systems, design elements of studies, and process and analyze data. Accurate and precise estimates of juvenile salmonid target strength are necessary input to detectability models. The target strength at 420 kHz of 87 juvenile salmonids was measured within the length range of 45 to 300 mm. The fish were rotated through pitch, roll, and yaw planes. Forty target strength measurements were obtained for each degree of rotation in each plane for each fish. Mean target strengths were computed for 1° and 5° increments of rotation. The mean target strength estimates for each 5° increment of rotation for all fish were fit to the equation $\sigma/\lambda^2 = a(L/\lambda)^b$. Estimates of mean target strength for regions of the sphere encompassing the fish between the planes of rotation were estimated by interpolation to complete a description of the target strength of juvenile salmon at any aspect.

11:25

4aAO8. Target strength measurements of walleye pollock (*Theragra chalcogramma*). Jimmie J. Traynor (Natl. Marine Fisheries Service, NOAA, Seattle, WA, jimt@afsc.noaa.gov)

The results of recent target strength measurements of walleye pollock from the North Pacific are presented. The measurements, made with a lowered transducer system are compared with historical results. The system allows the transducer to be moved closer to the target fish thus reducing the well-known bias of *in situ* target strength measurements due to range-dependent noise thresholds. Results using a conventional system with the transducer mounted on the research vessel and this system are discussed. The AFSC currently uses a target strength-to-length relationship [TS=20 log(L)−66.0, L, length in centimeters] to scale echo integration information to estimates of fish density. The appropriateness of this practice is discussed in light of the recent target strength measurements. Caveats regarding the limitations of *in situ* target strength measurement techniques are presented and suggestions for appropriate conditions for such measurements are provided.

11:40

4aAO9. Three-dimensional acoustic measurements of zooplankton swimming behavior in the Red Sea. Duncan E. McGehee (Tracor Appl. Sci., 4669 Murphy Canyon Rd., San Diego, CA 92123, dmcgehee@galileo.tracor.com), Amatzia Genin (H. Steinitz Marine Biol. Lab., 88103 Eilat, Israel), and Jules S. Jaffe (Scripps Inst. of Oceanogr., La Jolla, CA 92093-0238)

Three-dimensional swimming trajectories of several hundred thousand individual zooplankters were measured using the 445-kHz acoustical imaging system FishTV during a three night moored deployment in the Gulf of Eilat, Israel. The sonar examined a 5-m^3 volume at 27 m depth, in water 300-m deep. The image rate was 4 images/s. Targets were tracked from image to image using an automatic three-dimensional tracking algorithm. Over 14 000 targets remained in view for over 5 s, and their trajectories were used in subsequent analysis. Data from net tows indicated that most targets were euphausiids. The horizontal speeds of targets −75 dB and below were highly correlated with flow measurements from an S4 current meter. These targets also exhibited strong vertical motions, apparently due to internal waves. Estimated mean flow was subtracted from each trajectory to compute the swimming speeds of the animals themselves. These were generally much lower than the mean flow. During the night, variance in the vertical component of the flow-removed tracks was much greater than variance in the horizontal. However, the variance became more isotropic as dawn approached. A hop-and-sink foraging behavior offers one possible explanation for this.

4aBVa1. Specific characteristics of ultrasound contrast agents. Nico De Jong and Peter Frinking (Erasmus Univ., Rm. Ee 2302, P.O. Box 1738, 3000 DR Rotterdam, The Netherlands)

Ultrasound contrast agents possess acoustical characteristics which differ from the surrounding medium. Specific signatures of the agent, consisting of free or encapsulated gas bubbles, will improve the discrimination between the blood containing the agent and the tissue. One of the specific signatures is the initiation of a volume pulsation when the ultrasound wave hits a free or encapsulated gas bubble. Depending on the magnitude of the ultrasound wave the pulsation will be linear to the applied pressure or nonlinear to the applied pressure. Nonlinear vibration can be split into stationary (harmonic) and transient (power) scattering. Besides the nonlinear vibration (harmonics), specific characteristics include enhanced scattering as a function of the acoustic amplitude, transient scattering which is very useful for measuring flow, LOC (loss of correlation) imaging, and the persistence as a function of ambient parameters like pressure and temperature. Recently, a 2-D echomachine has been adapted for imaging of the nonlinear vibration of contrast agents and further developments in both hardware and software will be advantageous for the many specific characteristics of these agents.

9:35

4aBVa2. Nonlinear properties of microbubbles and applications to medical ultrasound imaging. Volkmar Uhlendorf, Thomas Fritzsch, Michael Reinhardt, and Frank-Detlef Scholle (Res. Labs. of Schering AG, 13342 Berlin, Germany, volkmar.uhlendorf@schering.de)

Gas bubbles smaller than 10 μm dissolve within milliseconds even in gas-saturated liquids, but coatings, etc. can prevent dissolution. These stabilized microbubbles serve as transpulmonary contrast agents. When only their linear properties are employed, physical laws limit the diagnostic potential to detection in large diameter vessels. Nonlinear acoustic properties of contrast agents permit very important additional applications. Nonlinearity arises from bubble pulsations, shell properties, finite amplitude waves, and electronic hardware. The first two sources can dominate, allowing new diagnostic imaging modes sufficiently sensitive to detect isolated microbubbles *in vivo*. Harmonic imaging modes detect 2nd harmonics of the transmit frequency, mainly from microbubbles. Acoustic Emission modes destroy bubble shells by one pulse of moderate amplitude. Consequently, the free bubbles respond strongly to this and other pulses before dissolving. Observed lifetimes of 1–20 ms are enough for harmonic or conventional Doppler detection. Typically, bubbles are replenished too slowly to get similar signal intensity for more than one frame at normal rates. Optimal pulse timing should allow new microbubbles to move close to the beam axis before the next pulse arrives. Applications may be counting methods, flow tagging, and quantification of tissue perfusion, possibly combined with single-shot three-dimensional acquisition and HI modes.

9:55

4aBVa3. Harmonic imaging for microbubble contrast agent detection. P. N. Burns (Imaging Res., Sunnybrook Health Sci. Ctr. S660, 2075 Bayview Ave., Toronto, ON M4N 3M5, Canada, burns@srcl.sunnybrook.utoronto.ca), C. T. Chin, D. Hope Simpson (Medical Biophys., Univ. of Toronto), and J. Powers (ATL Ultrasound, Bothell, WA 98041-3003)

The detection of microbubble contrast agents in the vessels of the microcirculation is currently limited by the relatively low concentrations attainable without causing acoustic attenuation, set against the high clutter signal imposed by surrounding soft tissue. By inducing nonlinear resonant oscillation in a population of microbubbles in transit in the circulation, echoes at the second harmonic can be detected preferentially, thus segmenting the blood signal from that due to tissue. Real-time harmonic imaging and Doppler have been implemented using a clinical array imaging system, and it is shown that with bubble agents it can detect flow in 40 μm vessels of the kidney. At higher incident peak pressures (above about 0.5 Mpa at about 3 MHz), some microbubble contrast agents are irreversibly disrupted by ultrasound. They then produce transient echoes which are high in amplitude and rich in harmonics. Furthermore, transient echoes can be obtained repeatedly over a period of milliseconds, allowing correlation imaging. Such ''transient Doppler'' imaging can demonstrate microcirculatory blood in the capillaries of the moving myocardium, a new development with significant clinical potential. [Work supported by Medical Research Council of Canada.]

4aBVa4. Acoustic characterization of contrast agents for medical ultrasound imaging. Lars Hoff (Dept. of Telecommunications, The Norwegian Univ. of Sci. and Technol., N-7034 Trondheim, Norway, hoff@tele.ntnu.no) and Per C. Sontum (Nycomed Imaging AS, N-0401 Oslo, Norway)

Nycomed's ultrasound contrast agent *NC100100* has been investigated by *in vitro* acoustic measurements. Acoustic attenuation spectra were used to determine resonance frequencies of the particles. The spectra were correlated with size distributions, and it was found that the shell-encapsulated gas bubbles can be described as viscoelastic particles with bulk modulus 700 kPa. When exposed to hydrostatic overpressures mimicking those found *in vivo* during the systolic heart cycle, the resonance frequency increased, as expected by the particles' increased stiffness. This effect was reversible: After the pressure was released, the particles went back to giving the original attenuation spectrum. This shows that the particles are not destroyed or otherwise changed by the pressure. Acoustic backscatter measured as a function of distance through a contrast agent was used to estimate the backscatter efficiency of the particles, that is, the ratio between scattered and absorbed ultrasound. Results from these measurements agree with theoretical estimates based on the attenuation spectra. Measurements on *NC100100* were compared with earlier results from measurements on *Albunex*® and measurements on an experimental polymer-encapsulated contrast agent, showing how different shell materials cause differences in particle stability and stiffness.

4aBVa5. Nonlinear response of microbubbles to pulsed diagnostic ultrasound. Sascha Hilgenfeldt, Detlef Lohse (Fachbereich Physik, Univ. of Marburg, Renthof 6, D-35032 Marburg, Germany), and Michael Zomack (Schering AG, Berlin, Germany)

The sound radiation from micrometer-size bubbles driven by short ultrasound pulses emitted by diagnostic ultrasonography devices is investigated. The frequency spectrum is analyzed in order to predict useful parameter ranges for the application of the second harmonic method.

11:00

4aBVa6. Acoustical nonlinearity parameter of liquids with microbubbles. X. F. Gong, S. G. Ye, D. Zhang (Inst. Acoust., State Key Lab. Modern Acoust., Nanjing Univ., Nanjing, 210093, PROC), S. S. Feng, R. Q. Zhang, R. T. Wang (Acad. Sinica, PROC), Z. Z. Xu, L. M. Liu (Shanghai Zhong Shan Hospital, China), and K. L. Ha (Pukyoung Natl. Univ., Pusan, Korea)

The gas bubbles in liquid are the strong scatters of the sound propagation in such liquid. A liquid containing microbubbles is used as an effective ultrasound contrast agent in medical diagnosis to improve the

contrast of the ultrasonic image. However, the existence of bubbles in liquid may enhance its nonlinearity parameter. In our previous paper, the preliminary results of some ultrasound contrast agents were reported and their large values of the nonlinearity parameter were obtained. This paper is devoted to an experimental demonstration of the influence of microbubbles on the nonlinearity parameter B/A values. These include measuring the dependence of B/A values of Echovist 300 on time. Results show that B/A values decrease with time (from 2678 to 16 over 45 min). B/A values of human blood with a different portion of Echovist were also studied. Larger B/A values are obtained with more Echovist. B/A values of a kind aqua, such as 76% Injectio Meglumini Diatrizoatis Composita (MDC), were studied before and after sonication with different bubble contents. Results indicate that the values of nonlinearity parameter depend on the presence of microbubbles obviously. Some explanation of this effect is discussed. [Work supported by NSF of China.]

11:15

4aBVa7. Bubble dynamics of ultrasound contrast agents. Michalakis A. Averkiou, Matthew F. Bruce, and Jeffry E. Powers (ATL Ultrasound, P.O. Box 30003, Bothell, WA 98041)

The bubble dynamics involved with microbubble contrast agents under insonification is investigated. The acoustic field of an ATL HDI-3000 diagnostic ultrasound system in a contrast specific harmonic imaging mode is reviewed first, and its major features that are related with microbubble behavior are discussed. Issues relating to sound attenuation, mechanical index, and bubble destruction are addressed. The nonlinear oscillatory behavior of contrast microbubbles is modeled with the Gilmore equation. The acoustic pressure field of a short pulse utilized in harmonic imaging is measured with a hydrophone and used as the driving pressure of the Gilmore model. Radius-time $[R(t)]$ and bubble wall velocity-time $[U(t)]$ curves are shown. Frequency domain analysis of $U(t)$ indicates transient resonance characteristics in both the fundamental and second harmonic components that are somewhat different from what one would expect with a continuous-wave steady-state response. The times for complete solution of microbubbles in water are calculated and correlated to observations seen in ultrasound images with contrast agents. Radio frequency (rf) data of scattered pulses from contrast agent microbubbles in an *in-vitro* experiment were collected with a phased array. This data is used to support and explain the contrast microbubble behavior.

11:30

4aBVa8. Estimation of contrast agent concentration using spectrum analysis. Cheri X. Deng (Riverside Res. Inst., 330 W 42nd St., New York, NY 10036, cheri@rrinyc.org), Frederic L. Lizzi (Riverside Res. Inst., New York, NY 10036), Ronald H. Silverman, and D. Jackson Coleman (Cornell Univ. Medical College, New York, NY 10021)

A theoretical scattering model was formulated to calculate the calibrated power spectrum of ultrasound contrast agents. The analysis incorporates the scattering coefficient from an encapsulated contrast agent bubble and includes the effects of realistic focused beams. The results relate specific spectral features to the characteristics of contrast agents, including their concentration and size distribution. Analytical calculations and experimental studies were conducted to analyze the calibrated power spectra of backscatter data using Albunex® and Aerosomes™ over frequency bands employed in typical medical ultrasound (3–12 MHz) and very-high-frequency ultrasound (VHFU, 15–50 MHz). The results showed that contrast agent concentration can be estimated from the spectral features such as the spectral slope and intercept values, which are measured using linear regression analysis. These studies also demonstrated the feasibility of employing contrast agent with VHFU, using wide-band transducers with center frequencies near 40 MHz. The VHFU scans of *in vivo* rabbit eyes showed the time history of contrast agent activity and revealed increased backscatter (as much as 8 dB) within subsegments of the ciliary body. Estimation of contrast agent concentration as a function of time promises to provide key information about perfusion in a contrast agent perfused organ.

11:45

4aBVa9. Detection and estimation of microbubble size distribution in blood. Klaus V. Jenderka, Georg Dietrich, Ulrich Cobet (Inst. of Medical Phys. and Biophys., Medical Faculty, Martin Luther Univ., D-06097 Halle, Germany), and Petr Urbanek (HP-medica, Bahnhofstrasse 30, D-86150 Augsburg, Germany)

The characterization of the microbubble size distribution in blood is of great practical interest for the design and the use of heart–lung machines and for clinical research. Another application is the continuous estimation of size distribution of ultrasound contrast agents. The measurement system is based on a 2-MHz pulse Doppler device and a special transducer, designed to connect to a 3/8-in. tube. The computer controlled system consists of two simultaneously working channels. The system is self-calibrating. The amplitude of a reference echo from a reflector behind the tube is used for the compensation of different acoustical properties of the tube. The minimal size of detectable gas bubbles and also the resolution of the size distribution is 1 μm in diameter. The detected size distribution will be measured continuously and saved every 5 s. Therefore it is possible to study the time course of the number and the size of gas bubbles, for example, during a heart operation. Showing the effectiveness of an arterial blood filter is done by measurements before and after the filter. Examples of the size distribution of contrast agents in different suspensions versus time after injection will be presented.

4aBVb1. Ultrasonic phased array design for reduced crosstalk. John Dodson and Karl Grosh (Dept. of Mech. Eng. and Appl. Mech., Univ. of Michigan, Ann Arbor, MI 48109-2125)

In recent years, therapeutic ultrasound has received increased attention as a treatment modality for cancer therapy (hyperthermia) and heart arrythmia (ablation surgery). Ultrasonic phased arrays offer the benefit of noninvasive treatment with the flexibility of variable focus and beam steering. In designing and building these arrays, electromechanical isolation is extremely important as interelement crosstalk will degrade array performance. However, manufacturability and cost, constraints which may conflict with the goal of reduced crosstalk, must also be a consideration. Efficient numerical methods present a useful design tool for array design and allow the investigation of structural acoustic phenomena in general. In this paper, a two-dimensional finite-element model for an ultrasonic phased array in contact with the human body is used to study array design. The effects of material selection and geometry for matching layer(s) and interelement structural matrix are examined for their impact on radiation pattern, power input to the fluid domain, and deleterious effect on the electromechanical behavior of the transducers. Finally, design guidelines are formulated and, if possible, compared to experimental results.

9:30

4aBVb2. A new method of ultrasonic hydrophone calibration using KZK wave modeling. Hendrik J. Bleeker (ATL Ultrasound, 22100 Bothell Everett Hwy., P.O. Box 3003, Bothell, WA 98041) and Peter A. Lewin (Drexel Univ., Philadelphia, PA 19104)

Most commercially available ultrasonic transducers exhibit finite amplitude distortion in water during hydrophone measurements needed to comply with regulatory requirements. The frequencies observed due to finite amplitude distortion can easily exceed ten times the transducer center frequency and 100 MHz. Typically, hydrophone calibrations are supplied only up to 15 or 20 MHz and do not exhibit a flat response. The frequency response above 15 MHz should be known to accurately represent the acoustic information, especially for high-frequency transducers ranging between 7.5 and 15 MHz. A new hydrophone calibration technique has successfully predicted the frequency response of hydrophones up to 100 MHz. A circular source transducer was first characterized and then modeled using the KZK wave propagation model. This model accounts for diffraction, absorption, and nonlinearity. The transducer frequency response was measured with a hydrophone and compared to the simulation. This difference characterized the frequency response of the hydrophone and was used to estimate the hydrophone calibration. The estimated calibration at 20 MHz was checked and provided good agreement with the manufacturer calibration supplied. Acoustic measurement accuracy will be improved if the hydrophone frequency response is deconvolved from the actual acoustic transducer response.

9:45

4aBVb3. High-frequency backscatter measurements of bovine tissues with unfocused and focused transducers. Subha Maruvada and Kirk K. Shung (Grad. Prog. in Acoust. and Bioengineering Prog., Penn State Univ., State College, PA 16801, sxm104@psu.edu)

In order to improve resolution of ultrasonic imaging, high-frequency scanners which are employed in the range 20–50 MHz are needed. As a result, it is critical to obtain data on ultrasonic scattering and attenuation in this frequency range. At these high frequencies, it is not feasible to make scattering measurements with unfocused transducers, therefore focused transducers are needed. Using the standard substitution method to calculate the backscatter coefficient, as is used with unfocused transducers, yields erroneous results for focused transducers. The assumption that the reflected echo from a perfect reflector in the far field can be calculated as though the transducer acts like a point source does not hold for focused transducers. Therefore a method is presented for focused transducers where the flat reflector is substituted by a particulate reference medium whose backscatter coefficient is well known and documented. Unfocused transducers in the range 10–20 MHz will be used in comparison with focused transducers to measure backscatter. For 15–35 MHz, focused transducers will be used. Results for the backscatter coefficient will be presented for various bovine tissues.

10:00

4aBVb4. The acoustic properties of microcalcifications in the context of breast ultrasound. Martin E. Anderson (Dept. of Biomed. Eng., Duke Univ., Durham, NC 27708), Mary S. C. Soo (Duke Univ. Medical Ctr., Durham, NC 27708), and Gregg E. Trahey (Duke Univ., Durham, NC 27708)

Breast microcalcifications are small crystals of calcium phosphates which are important diagnostic indicators under mammography. Despite continuing advances in the resolution and sensitivity of modern scanners, the role of ultrasound in the breast clinic is limited by the inability of current ultrasound practice to visualize microcalcifications reliably. While mammography is currently the gold standard for their detection, approximately 70% of breast biopsies prompted by the presentation of microcalcifications result in negative biopsy. The improved visualization of microcalcifications under ultrasound could provide additional diagnostic information in these cases, potentially reducing the number of negative biopsies. A review is presented of the theoretical and empirical results to date of this group's studies of the acoustic properties of microcalcifications as characterized through the application of classical theoretical models, including the Faran model, and through clinical studies of suspected *in vivo* microcalcifications and breast tissue backscatter. The similarities found between theoretical and clinical results strongly suggest that microcalcifications have elastic scattering properties. The findings are presented in an analysis of the relative impact of phase aberration, spatial resolution, and tissue backscatter on the visualization of microcalcifications with ultrasound. [Work supported by NIH Grant No. RO1-CA43334.]

10:15

4aBVb5. Acousto-mechanical imaging for cancer detection. Armen Sarvazyan (Artann Labs., 22 Landsdowne Rd., East Brunswick, NJ 08816)

One of the hot areas of ultrasonic medical diagnostics is elasticity imaging (EI). Recently, an alternative method of imaging tissue structures in terms of their elasticity, the method of mechanical imaging (MI), has emerged. The essence of MI is the solution to an inverse problem using the data of stress patterns on the surface of tissue compressed by a force sensor array [A. P. Sarvazyan, Proc. Tenth IEEE Symposium ''Computer based medical systems,'' Maribor, Slovenia, 120–125 (1997)]. A prototype of the device for mechanical imaging of the prostate has been developed and feasibility of MI technology has been proven in recent clinical studies. The present paper describes a modality of medical imaging, acousto-mechanical imaging (AMI) comprising features of both EI and MI. The data on the stress pattern measured by the force sensor array of MI complement the strain data obtained by ultrasonic EI device. An embodiment of the AMI device comprises a force-sensing array made of sound transparent film inserted between an ultrasonic scanner probe and the tissue. Synergy of combining these two complementary methods results in the fact that for certain applications the AMI technology has a diagnostic potential much superior to that of EI and MI separately.

10:30–10:45 Break

10:45

4aBVb6. Shear wave excitation in a rubberlike medium by focused shock pulse. Yury A. Pishchal'nikov, Valery G. Andreev, Oleg V. Rudenko, Oleg A. Sapozhnikov (Dept. of Acoust., Phys. Faculty, Moscow State Univ., Moscow 119899, Russia, yura@naexp.phys.msu.su), and Armen P. Sarvazyan (Artann Labs., East Brunswick, NJ 08816)

Ultrasonic excitation of shear waves is important for elasticity imaging of biological tissue. In the shear wave elasticity imaging shear strain is remotely induced in tissue by the radiation force of focused modulated ultrasound. Previous study has shown that tone bursts of millisecond duration at megahertz frequencies with intensities and exposures typical for diagnostic ultrasound may induce bulk radiation force of the order of 0.01 N/cm^3 and shear displacements of the order of 10 μ. In this work, new nonlinear mechanisms are discussed that provide detectable shear displacements by means of single submicrosecond pulses. Two new possibilities are discussed. Significantly enhanced radiation force and greater shear displacement can be produced in tissue by single acoustic videopulse with nonzero momentum. Another possibility is based on the enhanced nonlinear absorption which occurs after the shock is formed in the temporal profile of the pulse. Nonlinear mathematical models describing the process of generation of shear waves using single pulses are developed. Experimentally, single focused pulses are excited by high-power laser radiation inside an optoacoustic cell. Shear displacements are detected in a sample of gel using optical scattering. Results of modeling and experiments are in good agreement. [Work supported by CRDF and RFBR.]

11:00

4aBVb7. A virtual source method for evaluating ultrasound propagation through tissues mapped from medical images. Jie Sun and Kullervo Hynynen (Div. of MRI, Dept. of Radiology, Brigham and Women's Hospital, Harvard Med. School, 221 Longwood Ave., Boston, MA 02115)

A numerical model which uses digitized layer interfaces was developed for calculating multilayer ultrasound propagation, reflection, and refraction. This model was used to project the acoustic field from a spherical phased array (diameter 10 cm, F number 1, frequency 1 MHz) into multilayer tissues, and was verified by performing phantom measurements. A section on each layer interface in the propagation path was used as a virtual source. Digitized profiles of the tissue layer interfaces of arbitrary shapes can be obtained from MRI, CT, or ultrasound. The phase delay for each element of the phased array was first calculated, and then applied to each element for phase correction. With no phase correction, the focus of the array was shifted and defocused. By using the phased array, the shifted focal point was corrected and the side lobes were reduced. The effects of the array element size (number) were investigated for a deep sonication where the layer thickness information was obtained from a series of MRI scans of a volunteer. For this particular array, it is shown that the element size of 0.39 cm^2 is small enough to produce a near-optimum focus. [Work supported by NCI Grant No. CA 46627.]

4aBVb8. An A-mode ultrasound technique for tracking the advance of coagulation front in laser irradiated tissue. Zhigang Sun, Hao Ying, Brent Bell, Massoud Motamedi (Biomed. Eng. Ctr., The Univ. of Texas Medical Branch, Galveston, TX 77555-0456), and Jialiang Lu (The Univ. of Houston, Houston, TX 77204)

This communication presents an A-mode ultrasound technique for automatically determining the advance of coagulation damage front in laser irradiated tissue. The basic assumption underlying our technique is that the waveform of the echo signal scattered from a tissue region undergoing coagulation should be changing more rapidly than tissue regions where no coagulation is taking place. In this technique, we first track rf echo signals scattered from many small tissue regions during heating by computing the cross-correlation coefficient between two consecutively acquired echo signals. We then use the resulting coefficients as a measure of waveform change to determine the position of coagulation front via an automatic procedure. To test our technique, we carried out ten *in-vitro* experiments in which pig liver samples were irradiated using an Nd:YAG laser with fluence in the range of 32.4–112.0 W/cm^2 for 290 s. A 10-MHz broadband single-element spherical focused ultrasound transducer was used to detect the thermal coagulation front. The mean-square difference between ultrasonically and histologically determined coagulation depths was 1.0 mm, whereas the mean coagulation depth was 7.2 mm. This good agreement between ultrasonically and histologically determined results shows the potential of our technique for monitoring coagulative tissue damage during thermal therapy.

11:30

4aBVb9. Two-dimensional nonlinear propagation of pulsed ultrasound through a tissue-like material. Ibrahim M. Hallaj, Steven G. Kargl (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105), Ronald A. Roy, and Robin O. Cleveland (Boston Univ., Boston, MA 02215)

During a lithotripsy operation or ultrasound surgery, high-intensity acoustic waves propagate through tissue. Damage and thermal dose delivered to the target site and to tissue neighboring the target site is of significant interest in such operations. Results of a study of the propagation of intense ultrasonic pulses through a tissuelike material are presented. Two-dimensional simulations showing the effects of nonlinearity in inhomogeneous absorbing materials are used to calculate the acoustic pressure field, from which input is obtained for a bioheat equation calculation. Results show the mean and peak acoustic pressures within a target volume as a function of time, and the thermal dose delivered to a target volume due to a pulsed source in the range of frequencies used for ultrasound surgery. The degradation of the focusing ability of an ultrasonic array in nonlinear inhomogeneous media is illustrated, and conclusions regarding therapeutic ultrasound are made. 4aEA1. Sensor engineering at the microscale. Thomas B. Gabrielson (Appl. Res. Lab., Penn State Univ., P. O. Box 30, State College, PA 16804, tbg3@psu.edu)

Modern techniques for microfabrication have led to visions of significant new sensor applications. However, the translation of devices from centimeter scales to micrometer scales can cause effects that are unimportant at the larger scales to dominate the behavior at the smaller scales. When sensor structures approach material grain sizes or ferroelectric or ferromagnetic domain sizes, design philosophies need to be adjusted; when clearances are very small, viscous and thermal effects can dominate the dynamic response. While microfabrication has made dimensional downscaling of several orders of magnitude possible, intuition and ''engineering practice'' developed on the macroscale may lead to unsound devices on the microscale. Successful miniaturization of devices and structures depends on an understanding of the changing roles of various forces, energies, and interactions on the appropriate scales. Even with this level of understanding, optimum performance may not be achieved by simple shrinking of a macroscale device. Nowhere is this more evident than in biological organisms where markedly different solutions to sensing, searching, navigation, locomotion, and thermal regulation are used by organisms of different sizes.

9:45

4aEA2. Area averaging sensors for vibro-acoustic control. Brian H. Houston and Robert D. Corsaro (Naval Res. Lab., Code 7130, Washington, DC 20375)

NRL has been conducting acoustic control research for underwater and in-air sound and vibration applications. In many of these studies, the success of the control system depends substantially on the ability of the sensors to measure the physical quantities of interest accurately while ignoring extraneous contributions. For example, the sensors developed for use in the Acoustic Boundary Control (ABC) research were required to monitor accurately the normal component of the average acoustic field on the tile surface, while being insensitive to transverse and high wave number components. The extremely low noise figures required in this study forced the development of special-purpose acoustic pressure and velocity sensors which now are finding use in other applications, including vibration isolation mounts.

4aEA3. Sound power emission measurement and control on a 300-t hydraulic press. Fabrizio Bronuzzi, Caterina Cigna, Mario Patrucco (Dip. Georisorse e Territorio, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129 Torino, Italy, patrucco@vdiget.polito.it), and Maurizio Sassone (''E. Sassone'' s.r.l., Monale (AT) Italy)

The paper summarizes the results of research work carried out to evaluate properly the noise emission characteristics of a 300-t hydraulic press in a complex noise propagation environment. On the basis of the collected data, some control measures were designed, and the results are discussed. As well known, noise is widely affected by the acoustical environment the sound propagates through, and an effective description of the source emission properties is required for the control design. Traditional measurement techniques are not the best for this purpose, because the information on acoustic pressure depends on the environment. To overcome this problem, the emitted acoustic power was then evaluated by means of acoustic intensity measurements; in such a way it is possible to qualify real and complex sound sources, locating the contribution of single parts that participate in sound generation. Resulting maps describing the contribution of every single part, an effective individuation of improvement strategies was possible, since the priorities for intervention were available. A new campaign of sound intensity measurements confirmed the expected control measures' results, and the direct measurements of the operators' exposure confirmed the success of the intervention.

10:25

4aEA4. Active control of sound transmission through an industrial sound encapsulation. Paul Sas, Wouter Dehandschutter, Rene Boonen, and Antonio Vecchio (Dept. of Mech. Eng., Div. PMA, Katholieke Universiteit Leuven, Celestijnenlaan 300B, B-3001 Heverlee, Belgium, wouter.dehandschutter@mech.kuleuven.ac.be)

In this paper, an active control system is developed to enhance the sound transmission loss of a sound encapsulation at low frequencies. The sound encapsulation is used to shield a noise source, such as an air compressor. The control systems comprise two control loudspeakers and two error microphones. The Filtered-X LMS adaptive feedforward control algorithm is used to drive the signals at the error microphones to a minimum. The reference signal for the control algorithm is taken from the noise source, i.e., the tacho signal of the compressor. This study deals with the optimization of the location of control sources and error sensors in view of the achieved control performance. From this perspective it is important to note that minimizing the sound-pressure level at the error microphones, which are constrained to be located inside the sound encapsulation, does not necessarily reduce the acoustic intensity measured in the

far field of the encapsulation (or at least, not to the same degree). Relevant issues which are considered are: the coupling of control sources with the acoustic modes of the enclosure, changes to the interior sound field due to active control, etc.

10:40

4aEA5. Structural vibration mode imaging using photorefractive holography. K. L. Telschow and V. A. Deason (Idaho Natl. Eng. and Environ. Lab., Lockheed Martin Idaho Technologies Co., MS 2209, Idaho Falls, ID 83415-2209, telsch@inel.gov)

Photorefractive processing of optical interference offers a noncontacting optical method for vibration detection that forms an optical ''lock-in'' amplifier. Multiwave mixing with synchronous detection allows measurement of both the vibration amplitude and phase of a vibrating surface directly as a function of the excitation frequency. Narrow bandwidth detection with flat frequency response can be achieved at frequencies above the photorefractive response ($\sim$100 Hz). A minimum detectable displacement amplitude of a few picometers has been demonstrated for a point measurement, with the possibility of further improvement. The method can also be configured to provide full-field imaging of resonant vibrational modes of materials with various microstructures and shapes. Both specularly and diffusely reflecting surfaces can be accommodated. Results will be presented showing the noncontacting imaging capabilities for vibrational spectral analysis of structures and characterization of material properties that these sensors provide for smart systems. [Work suported by the U.S. Department of Energy.]

10:55

4aEA6. Piezoelectric resonant sensor for sound velocity of liquids. Helmut Nowotny (Institut für Theoretische Physik, Vienna Univ. of Technol., Wiedner Hauptstr. 8/136, A-1040 Wien, Austria), Ewald Benes, Branka Devcic-Kuhar, Martin Gröschl, Dagmar Harrer, Rudolf Thalhammer, and Felix Trampler (Institut für Allgemeine Physik, Vienna Univ. of Technol., Wiedner Hauptstr. 8/134, A-1040 Wien, Austria, benes@iap.tuwien.ac.at)

The sensor consists of two circular piezoelectric plates with the liquid in between. Each piezoelectric plate is a bulk resonator with two electrodes driven in thickness extensional modes. The two resonator plates are electrically connected in parallel and the total admittance is measured in the vicinity of two quasiharmonic series resonance frequencies by a PC-controlled electric admittance measurement system. The extensional thickness mode purity was checked directly by corresponding mode pattern measurements using a laser speckle vibration amplitude measurement system. The sensor element is mounted in a thermostated aluminum housing to avoid temperature effects and to obtain the sound velocity of the liquid at a defined temperature. Two quasiharmonic resonance frequencies are used to allow the elimination of the unknown density of the liquid. The sound velocity is calculated out of a rigorous one-dimensional theoretical model of the three-layer sensor arrangement. In addition to the determination of the sound velocity of the liquid, the mass density of the liquid can be obtained from the same primary measurements. However, at present the accuracy of the density value is one order of magnitude lower than that of the velocity (typically 0.1% for water, acetone, glycerin).

11:10

4aEA7. Transient behavior of acoustic gyrometers. Philippa Dupire and Michel Bruneau (Lab. d'Acoustique, IAM—UMR 6613, Univ. du Maine, av. O. Messiaen, 72085 Le Mans Cedex, France, amb@laum.univ-lemans.fr)

Acoustic gyrometry was developed during the past 15 years as a new miniaturized or low-cost technology. The operation of acoustic gyrometers employs acoustic fields inside fluid-filled resonant cavities to determine angular velocities. Until now, research efforts and design methodology have concentrated both on trapezoidal miniaturized gyros (etched on silicon chips) as well as on cylindrical gyros designed using classical techniques. These approaches are restricted to the frequency domain, which involves only the steady Coriolis effect. Nowadays, the need for a time domain solution for inertial effects on acoustic fields clearly arises when dealing with applications involving strong variations of the rotation rates. This paper aims at providing such advances in ''inertial-acoustic'' theory and modeling. The discussion covers cylindrical gyros because the presence of an unsteady rotational velocity gradient (with respect to the radial coordinate) of a gas in a cylindrical cavity adds one of the most important features both in the basic physics underlying ''inertial-acoustic'' transient processes and in the behavior of the gyros. In conclusion, only some new requirements, which have to be taken into account in the design of acoustic gyros, will be addressed as a discussion of the transient behavior in detail is beyond the scope of this paper. 4aMU1. Spectral versus harmonic information for timbre: Pilot and experimental results. Einar Mencl (Haskins Labs., 270 Crown St., New Haven, CT 06511, einar@tom.haskins.yale.edu)

This work summarizes results from six experiments on steady-state timbre perception. The primary variable of interest was the physical similarity of tones within each trial: tones were either similar by virtue of their spectral envelope (i.e., they shared resonance characteristics) or their harmonic envelope (i.e., they shared overtone characteristics). These two continua were chosen as candidates for basic perceptual dimensions because (1) they each contain specific types of information about the sound source/event, and (2) a cursory computational analysis suggests that very different processes are needed to extract information about resonances versus overtones from the auditory input. It was reasoned that if different subsystems subserve the processing of timbre along each of these two dimensions, then performance on perceptual tasks would dissociate under appropriate experimental manipulations. These included

(1) attentional focus and response type (timbre similarity judgment, pitch direction judgment, or pitch contour judgment), (2) perceptual priming, and (3) auditory masking. Results demonstrate that in general both dimensions of similarity can support perceptual priming, but also show specific dissociations which inform the understanding of steady-state timbre perception. [Portions of this research were supported by NSF Grant No. DBS-9222358 to Jamshed Bharucha.]

8:25

4aMU2. Macrotimbre: Contribution of attack, steady state, and verbal attributes. Gregory J. Sandell (Parmly Hearing Inst., Loyola Univ., 6525 N. Sheridan, Chicago, IL 60626, sandell@sparky.parmly.luc.edu)

The timbre attributes of a source that are contained across variations in pitch, dynamic, and articulation can be referred to as its ''macrotimbre.'' The timbre of a musical instrument changes across pitch, and thus learning its macrotimbre can be dependent upon the ability to make comparisons among individual pitches. Using 20 pitches shared by two easily confused instruments ($C4$ to $G5$, oboe and English horn), listeners performed better at categorizing novel notes (from a pitch range different from those heard in training) when training facilitated comparison of notes (versus isolated presentations) [Sandell and Chronopoulos, Proc. Third ESCOM Conf., Uppsala, Sweden, 222–227 (1997)]. This indicated that information contained across pitches was useful in generalizing timbre knowledge to previously unheard notes. The present study used (1) multiple versions of the tones (natural, shortened, attack + synthetic steady-state, synthetic steady-state alone), (2) a sorting task under conditions where comparisons were facilitated or hindered, and (3) ratings of verbal attributes (nasal, breathy, muffled, etc.) to isolate the relevant across-pitch timbre properties, and appraise the relative contributions of the attack and steady state.

8:50

4aMU3. Methods for measurement and manipulation of timbral physical correlates. James W. Beauchamp (School of Music and Dept. of Elec. and Comput. Eng., Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801)

Multidimensional scaling calculations based on the results of listening tests comparing musical sounds almost always identify one perceptual dimension which is strongly correlated with a measure of the spectral centroid, whereas other dimensions are less obviously correlated to particular physical parameters. Some parameters which have been suggested as good correlates are attack time, spectral flux, and spectral irregularity [J. Krimphoff *et al.*, J. Phys. IV (C5), 625–628 (1994)]. Also, spectral rolloff, preattack noise, general noisiness, and inharmonicity have been proposed as important factors. Based on time-variant spectral analysis with custom software [J. Beauchamp, Audio Eng. Soc. Preprint No. 3479], these parameters and others can be quantified and manipulated, leading to various applications. For example, synthesis using simplified parameter contours provides stimuli for discrimination testing to reveal listeners' sensitivities to these parameters. Measurement of spectral differences can be correlated to discrimination results. Equalization of parameters common to two instrument sounds allows listeners to focus on those timbral aspects which are different. Finally, hybrid musical sounds created by interchanging parameter contours between instruments can shed light on timbral perception.

9:15–9:30 Break

9:30

4aMU4. Perceptual independence of excitor and resonator properties in percussive instrument sounds. Stephen McAdams (Inst. de Recherche et de Coordination Acoustique/Musique (IRCAM), 1 place Igor Stravinsky, F-75004 Paris, France), Koei Kudo, and Holle Kirchner (IRCAM, F-75004 Paris, France)

The perceptual independence of various sensory dimensions has been studied using a speeded classification paradigm developed by Garner. In this paradigm the speed of classification of items varied along one dimension is compared to the same classification when random variation along a second dimension is present. Perceptual interaction is inferred when performance in the latter is slower or worse compared to the former. Such interactions have been shown for simple dimensions such as pitch, loudness, and a spectral dimension of timbre. The present study tested the independence of complex dimensions with overlapping spectral and temporal characteristics. One dimension consisted of the hardness of a percussion mallet (excitor property) and the other of either xylophone bar density or tympani size (resonator properties). These complex source-related dimensions show evidence of interaction in both performance scores and reaction times. A greater independence is found when unrelated variation is introduced along a third dimension (striking force), although performance scores decrease globally. The results are discussed in terms of previously reported interactions among simple dimensions and interactions among complex source properties.

9:55

4aMU5. The effect of amplitude and centroid trajectories on the timbre of percussive and nonpercussive orchestral instruments. John M. Hajda (Prog. in Systematic Musicology, Dept. of Ethnomusicology, UCLA, Box 951657, Los Angeles, CA 90095-1657)

This study explores the salient acoustical attributes of the associative aspects of Western orchestral instrument timbres. Association refers to a subject's ability to connect or link a stimulus with its intended comparison; this occurs in tasks such as identification, matching, or categorization. Unlike most previous research in instrument association, this study considers both continuant (nonpercussive) and impulse (percussive) classes of instruments. Certain acoustical transformations, such as the partitioning of a signal into attack, steady state, and decay, are not possible for both classes. Findings which have been made regarding the salience of signal segments must be questioned in terms of their application to a more general and inclusive theory of musical timbre. Previous perceptual and timbre synthesis research has demonstrated the importance of global rms amplitude and spectral centroid (the

amplitude-weighted mean frequency). Here, both amplitude and centroid are considered in terms of individual trajectories. The evolutions of and relationships between these trajectories are markedly distinct for continuant and impulse classes of instruments. The perceptual significance of these trajectories is measured through the experimental control of their magnitude and direction. A convergence method is employed to ascertain the necessary and sufficient conditions for instrument association.

10:20

4aMU6. Computer identification of wind instruments using cepstral coefficients. Judith C. Brown (Phys. Dept., Wellesley College, Wellesley, MA 02181, brown@media.mit.edu)

Earlier results on computer recognition of the oboe and saxophone [J. C. Brown, J. Acoust. Soc. Am. **101**, 3167(A) (1997); ''Musical instrument identification using cepstral coefficients as features'' submitted to J. Acoust. Soc. Am.] have been extended to include the clarinet and the flute. Approximately 30 samples of duration 2–10 s of each of the four instrument types comprise the test set. The training set consists of longer segments of approximately 1 min duration. Eighteen mel-based cepstral coefficients were calculated for each of the sounds. The training data were summarized by a cluster analysis with Gaussian probability density functions formed from the mean and variance for each of the clusters. The probability of belonging to each of the four classes was then calculated for the test sounds, and a Bayes decision rule was invoked to assign them to one of the classes. Results indicate that this is a very promising method for automatic recognition of musical instruments.

4aNS1. Effect of the flat panel resonance on the absorption characteristics of a microperforated-panel absorber. Ke Liu (Inst. of Acoust., Academia Sinica., P.O. Box 2712, Beijing 100080, PROC), Fenglei Jiao (Beijng Inst. of Light Industry, Beijing 100037, PROC), and Hui Ding (Beijing Municipal Inst. of Labour Protection, Beijing 100054, PROC)

The flat panel resonance can affect the absorption characteristics of a microperforated-panel absorber. This effect was not considered in the existing theory. In this paper, the method of measuring the no-hole flat panel resonance is applied to analyze this effect. The sample is a stainless steel microperforated panel, with the diameter of perforations $d=0.2$ mm, the separation of holes $b=2.5$ mm, the thickness of panel $t=0.2$ mm, and the thickness of cavity behind the microperforated-panel $D=95$ mm. Theoretically, its resonance frequency is 508 Hz, and the maximum absorption coefficient is 0.9. However, the experimental result shows that there are two absorption peaks at 280 and 680 Hz, respectively. Two resonance peaks also appear as a sample of a no-hole flat panel is measured. When the thickness of cavity is changed, the result is still similar. Moreover, when sound intensity is enhanced, two resonance peaks also exist, and move towards low frequency. Therefore, it is possible that the absorption frequency band can be widened, or the absorption coefficient within absorption frequency band can be enlarged, by using the resonance frequency of different materials. [Work supported by the National Natural Science Foundation of China.]

9:00

4aNS2. Prediction system for rotor–stator interaction noise generation, propagation, and optimization of acoustic liners. Yadong Lu (Inst. of Acoust., Acad. of Sci., P.O. Box 2712, Beijing, 100080, PROC), Zongan Hu, and Jiya Cui (Beijing Univ. of Aeronautics and Astronautics, Beijing, 100083, PROC)

Based upon the acoustic mode matches between the source modes and propagating modes, this paper applies the flexible tolerance optimization method to optimize the acoustic parameters (impedance), geometric structure parameters, such as open area ratio, cavity depth, and hole diameter, and operating condition parameters, such as blade passing frequency. The optimum values of the design variables are determined when the in-duct sound suppression approaches the maximum. It can be derived from the optimum results that the emphasis of the engineering optimization design of the perforated plate honeycomb structure should be placed on the optimum choice of the open area ratio and cavity depth. Some other referential criteria for the engineering design of the multi-linings are also provided. Thus, the theoretical prediction system for rotor–stator interaction noise generation and in-duct propagation and optimization of acoustic liners has been developed in this paper. By means of this prediction system, the acoustically multi-sectioned treatments can be theoretically designed for the suppression of rotor–stator interaction noise with discrete frequency, in advance of the beginning of the practical engineering design of acoustic liners.

9:15

4aNS3. The Wiener–Hopf technique and scattering of acoustic waves in ducts. Fredrik Albertson (MWL, Dept. of Vehicle Eng., Royal Inst. of Technol., 100 44 Stockholm, Sweden, fal@fkt.kth.se)

The reactive silencer is the standard product for attenuating noise in ducts with flue gases. A model problem is solved for such a silencer by calculating the scattering of acoustic waves at sharp edges in a two-dimensional waveguide. In this waveguide the walls are considered acoustically hard and to ensure the existence of a unique solution an edge condition is applied. An exact analytical solution is found using the Wiener–Hopf technique, which relies heavily on the Fourier transform with assumptions on regularity of the solution. Control methods are employed to check the theory and the accuracy of the numerical results. One of the control methods is derived from the energy conservation principle. Symmetries, so-called reciprocity relations, are found for the reflection and transmission matrices and are first used to check the analytic calculation and later to reduce the numerical work. A quasistationary model is also used for control purposes. It is valid for low frequencies and checks the phase of the transmission and reflection coefficients, while the energy method only covers the corresponding absolute values. Physical results as the behavior of the reflection and transmission coefficients are also presented. These coefficients are analyzed as functions of both frequency and geometry.

9:30

4aNS4. Acoustic response of a thin poroelastic plate. Kirill V. Horoshenkov (Dept. of Civil and Environ. Eng., Univ. of Bradford, Bradford BD7 1DP, England) and Kimihiro Sakagami (Kobe Univ., Rokko, Nada, Kobe, 657 Japan)

The expression for the viscosity correction function in the Attenborough model for the acoustic properties of rigid frame porous media is modified to account for the viscothermal effects in the oscillatory flow in the vibrating frame. The Helmholtz integral equation formulation is used to produce the solution for the sound field reflected from an infinite, thin, porous, elastic plate. The effect of an air cavity behind the plate is considered. A parametric study is performed to predict the effect of variations in the microscopic parameters of the poroelastic plate.

9:45–10:00 Break

10:00

4aNS5. A nondestructive method for measuring the airflow resistance of locally reacting jet engine nacelle components. T. R. T. Nightingale (Inst. for Res. in Construction, Natl. Res. Council Canada, Ottawa, ON K1A 0R6, Canada) and Brandon Tinianow (Johns Manville Tech. Ctr., Littleton, CO 80127)

As a noise control measure to reduce inlet fan noise of jet engines, the nacelles are often equipped with a locally reacting absorber formed by a thin resistive wire mesh placed over a honeycomb structure. Historically there has been a problem to measure, in nondestructive fashion, the airflow resistance of repaired or refurbished nacelle parts for the purpose of demonstrating OEM compliance. ASTM-C522 is the traditional airflow resistance test method and is destructive, requiring a sample be cut from the specimen and fit into an apparatus where the flow velocity due to a constant pressure drop can be measured. This paper presents the theory and practical considerations of a nondestructive test method to measure the airflow resistance using an ASTM-E1050 impedance tube placed against the wire mesh of the complete specimen. Transfer matrix theory is used to describe the combined impedance of the wire mesh and air cavity. It is shown that at the air cavity resonance frequency the measured system impedance will be that of the wire mesh with the real part being the airflow resistance. Airflow resistance estimates obtained using the presented method and the ASTM-C522 test method are shown to be in excellent agreement.

10:15

4aNS6. A measurement of sound power lever of noise source—Vibration velocity method. Weicheng Yang (Res. Inst. of Household Elec. Appliance of China, No. 6 Yuetan Beixiaojie, Beijing 100037, PROC) and Wuzhi Qiao (Beijing Inst. of Light Industry, Beijing 100037, PROC)

Sometimes it is necessary to measure on-line the noise of some products, such as the household electrical appliances and their parts (motors, compressors, and contacts). Nowadays, several measurements (sound intensity measurement and vibration flow measurement) have been applied, but are not good enough. In this paper, another on-line measurement of sound power lever of noise source vibration, velocity measurement, is proposed. This measurement has two advantages, viz., without the influence of the surrounding area and with less measuring time. After the theoretical analysis and the experiment to the small-type compressor of the refrigerator in a semi-anechoic chamber, the sound-radiating efficiency curve is attained. Based on the vibration velocity measurement, the sound power lever of the compressor is predicated through this curve. The error of the predicated result is less than 2 dB, compared with that of the standard ISO 3745.

10:30

4aNS7. The limit of absorbing characteristics of folded resonators silencers and ways of its realization. Roudolf Starobinski (Lab. Acoustique, Univ. Le Maine, B.P. 535, 72017 Le Mans, France) and Jean Kergomard (Univ. Le Maine, 72017 Le Mans, France)

The folded resonance silencer is a version of 1/4-wave resonator having a very compact shape. They are usually used for suppressing of narrow-band and discrete frequency noise. The sets of resonators tuned to adjacent frequencies can be successfully used for a wide frequency band as well. The general theorems governing the behavior of these resonators are represented in this report. The limits of the muffling characteristics of the resonators and the ways of its realization are investigated on their base. It is shown that the potential muffling ability of a folded linear resonator is 1.2 dB less than for a Helmholtz resonator. However, taking into consideration the possibility of increasing the neck's cross-sectional area, they are more effective at high sound levels because of the higher quality factors. It is shown also that with the help of coupling folded resonators the resonance effects can be created in the frequency band wider than two octaves. These peculiarities make the use of the folded resonators very interesting in noise control systems.

4aPAa1. Hugh Guthrie Flynn, 1912–1997. David T. Blackstock (Appl. Res. Labs. and Dept. of Mech. Eng., Univ. of Texas, Austin, TX 78712-1063, dtb@mail.utexas.edu)

Hugh Flynn spent most of his first three decades in Columbus, Ohio. During the 1930s he was a newspaper crime reporter and also studied physics at Ohio State University. After graduating from Ohio State in 1939, he took a job with the Navy's Bureau of Ordnance and was a Naval officer during WWII. While working for the NAS Committee on Undersea Warfare after the war, he met F. V. Hunt, who encouraged him to study acoustics at Harvard. There Hugh became interested in cavitation, the beginning of a lifelong love affair with bubbles. After his doctoral degree in 1956, he stayed on as one of Hunt's postdocs. The year 1960 was a propitious one. He married Prudence Turgeon and joined the faculty of the new Electrical Engineering Department at the University of Rochester. He spent the rest of his life in Rochester, where he solidified his international reputation as a respected authority on cavitation and fathered three children, Kitty, Molly, and Nathaniel. Despite retiring as Professor Emeritus in 1978, he stayed active in research for the rest of his life. His projects during retirement included bubble phenomena in medical ultrasonics and nuclear fusion from cavitation.

9:40

4aPAa2. Sonically induced growth of gas bubbles by diffusion. Anthony I. Eller (Sci. Applications Intl. Corp., 1710 Goodridge Dr., McLean, VA 22102, eller@osg.saic.com)

Small gas bubbles that might normally dissolve and disappear may instead grow if set into pulsations of sufficient amplitude by an applied sound field. The mechanism involved is a fundamental asymmetry related to the spherical geometry of the conditions which favors diffusion of gas into the bubble during its expanded state over diffusion out of the bubble during a contracted state. Values of the threshold acoustic pressure for growth were computed by a theory that accounts for spherical bubble dynamics as well as convection terms in the diffusion equation and shows general agreement with measured counterparts. Rates of bubble growth for above-threshold conditions can be unexpectedly high if nonspherically symmetric acoustic streaming occurs. A closely related phenomenon—the onset of nonspherical bubble vibration—occurs within the same general range of acoustic pressures observed for bubble growth and will also be described.

4aPAa3. Reminiscences on bubble dynamics and cavitation. M. Strasberg (Code 702, David Taylor Model Basin, NSWC, 9500 Macarthur Blvd., West Bethesda, MD 20817-5700)

A review of various topics in cavitation and bubble dynamics discussed with Hugh Flynn, most of them still containing unsolved details. Among these are rectified diffusion of gas into pulsating bubbles and the effect of surface films; thermal rectified diffusion and the associated temperature rise; parametric shape oscillations of bubbles and the failure to observe resonances; the threshold conditions for cavitation, the cause for the persistence of the required nuclei, and the effect of a temporary static pressure increase on the nuclei; the dynamics of an individual cavity growing and collapsing in a compressible liquid and the associated internal pressure and radiated sound; and the cavitation noise radiated by cavitating propellers.

10:20

4aPAa4. Physics of acoustic cavitation in liquids: H. G. Flynn's review 35 years later. A. Prosperetti (Dept. of Mech. Eng., The Johns Hopkins Univ., Baltimore, MD 21218)

In 1964 Hugh G. Flynn published in Vol. I, Part B of the series *Physical Acoustics*, edited by W. P. Mason (Academic Press), a long review article by the title ''Physics of Acoustic Cavitation in Liquids.'' This was the first comprehensive review of the topic and has had a enormous influence on the field, serving as an introduction to cavitation and bubble dynamics for at least two generations of researchers (including the present author). A summary of that work will be presented in the light of subsequent developments and the present understanding of the cavitation phenomena. [Work supported by NASA.]

10:40

4aPAa5. Cavitation terminology. Wesley L. Nyborg (Phys. Dept., Univ. of Vermont, Burlington, VT 05405)

Among the important contributions Flynn made to the subject of acoustic cavitation was his introduction of concepts and language which have greatly helped our thinking and our communications. In 1964, he defined two acceleration functions and used them for classifying the behavior of gas-filled cavities in a sound field. The more violent kind of behavior, involving ''collapse,'' occurs when one of the functions, the inertial function, dominates at a critical time during cavity contraction. This type of cavitation was initially called ''transient,'' partly because the collapse events are of short duration, and partly because the cavities themselves are often short-lived, disappearing through fragmentation and dissolution after collapse events. The other class of cavitation is called ''stable,'' and represented oscillatory motion which might be complicated but which persists indefinitely. This classification has become very helpful in discussing cavitation phenomena and is widely used in the literature. In recent years, however, the term ''inertial'' has come into use, replacing ''transient,'' for cavitation in which Flynn's inertial function dominates. Examples will be discussed in which Flynn's classification is applied to experimental situations.

4aPAa6. Influence of nonradial experimental conditions on the acoustic scattering behavior of a single cavitation bubble. Torsten Niederdraenk (Institut für Technische Akustik, RWTH Aachen, 52056 Aachen, Germany, tni@akustik.rwth-aachen.de)

The dynamic behavior of a single cavitation bubble in a sound field can be evaluated using the acoustic scattering technique. A high-frequency image sound is scattered by the bubble, which pulsates in the primary driving sound field. The scattered sound contains information about the bubble oscillation. The shape of the bubble radius can be observed by evaluating the amplitudes of the scattered sound or by determination of frequency shifts caused by the motion of the bubble wall. If the wavelength of the high-frequency image sound and the bubble size are of the same order, or if the boundary and excitation conditions in the experimental setup do not fulfill the demand of a spatially independent primary driving field, the bubble is exposed to nonradial driving conditions. Modes of bubble oscillation may develop that can be decomposed into spherical harmonic components of different order. These modes affect the acoustic scattering behavior, because sound emissions of the nonradial contributions of bubble oscillation are characterized by different directivities. Moreover, the amplitudes of sound emitted by higher-order spherical harmonics depend more strongly on the receivers' distance to the bubble.

4aPAa7. Susceptibility of silicon wafers to acoustic microcavitation damage. Sameer I. Madanshetty and Jogesh B. Chandran (Mech. and Nuclear Eng., Kansas State Univ., 339 Durland Hall, Manhattan, KS 66506-5106)

Acoustic methods are being increasingly used in semiconductor processing. Given the increase in circuit densities being implemented on semiconductor chips the requirements for particulate contamination tolerance are becoming more stringent. The semiconductor industries roadmapped specifications for 1998, 0.25 μm feature size require control of all particulate contaminants larger than 0.08 μm. Fine cleaning of post CMP wafers is currently being done by using the megasonics process. The cleaning effectiveness depends on the strength of the acoustic fields used. In using high-intensity, high-frequency acoustic fields it is crucial to ensure that the surface of the silicon wafer does not suffer any damage due to cavitation. This paper assesses the damage potential of semiconductor wafers to acoustic microcavitation. Acoustic microcavitation is brought about by low megahertz acoustic fields giving rise to micron size bubbles that live a few microseconds. In exposing a surface to continuous waves one could obtain cavitation effects in an average, overall sense; the details of nucleation, evolution of inertial events, however, get glossed over. Both, pulsed and cw insonification were studied. Experimental measurements of the thresholds for cavitation damage of semiconductor wafers will be presented.

11:45

4aPAa8. Study of the correlations between the cavitation noise power and bubble volume rate in an acoustic cavitation bubble field. Stéphane Labouret, Jacques Frohly, Nathalie Poulain, Roger Torguet, and Francis Haine (IEMN-DOAE, Université de Valenciennes, B.P. 311, Le Mont Houy, 59 300 Valenciennes Cedex, France, labouret@univ-valenciennes.fr)

The effects of ultrasound cavitation depend on both the insonification conditions and the liquid characteristics, by means of their influence on the bubble cloud. For this reason, the study of the cavitation bubble field is of interest. The implemented hyperfrequency method allows the monitoring of the bubble volume rate, called void rate a, during the insonification, versus acoustic pressure or dissolved air concentration in water. On the other hand, the oscillating behavior of bubbles found expression in a characteristic acoustic spectrum. The cavitation noise power, defined as the integral of the cavitation acoustic spectrum, permits the estimation of the importance of the dynamic activity of the bubble field. The aim of this paper is to set the relations between the void rate evolution and the cavitation noise power. The evolutions of the cavitation noise power versus the void rate will be examined in two situations, whether the void rate evolution is due to the acoustic pressure variation or to a change of the dissolved air content in water. A link between the cavitation noise power and the increased speed of the void rate will be set.

4aPAb1. Acoustical helicoidal waves and Laguerre–Gaussian beams: Applications to scattering and to angular momentum transport. Brian T. Hefner and Philip L. Marston (Dept. of Phys., Washington State Univ., Pullman, WA 99164-2814)

Traveling waves having helicoidal wavefronts are cylindrically symmetric except for an azimuthal angular dependence of $\exp(im\phi - i\omega t)$, where m is an integer. The amplitude vanishes at the screw-phase dislocation [J. F. Nye and M. V. Berry, Proc. R. Soc. London Ser. A **336**, 165–190 (1974)] on the z propagation axis. Examples of paraxial helicoidal waves are the Laguerre–Gaussian beam solutions of the parabolic wave equation. Some potentially useful properties of acoustical helicoidal waves are analyzed. Just as for linearly polarized optical Laguerre–Gaussian beams [L. Allen *et al.*, Phys. Rev. A **45**, 8185–8189 (1992)], the ratio of the axial angular momentum flux to the acoustical beam power is found to be m/ω so that axial radiation torques are generated when the acoustical energy is absorbed. Helicoidal waves are predicted to backscatter in a way which reveals the axisymmetry of the scatterer when combined with a helicoidal mode-selective detector. Some strategies for acoustical helicoidal wave generation and detection will also be described. [Work supported by the Office of Naval Research.]

4aPAb2. Vibrations of a film with arrays of point masses. Takato Handa, Andy Piacsek, and Roger Yu (Dept. of Phys., Central Washington Univ., Ellensburg, WA 98926)

As a result of the Bloch theory, the eigenstates of an electron in a strictly periodic potential are extended and the eigenenergy levels form allowed energy bands separated by forbidden gaps. Very recently there has been a great deal of excitement in the physics community concerning the extension of the idea to electromagnetic and acoustic waves. The three-dimensional (3-D) photonic band material with a periodically varying dielectric constant has been found. The frequency band structure of a rectangle thin film with arrays of point masses on it interests us. It is assumed that the film is supported by a frame so that at the boundaries, the vibration vanishes. By taking advantage of this zero-boundary condition, a double sine wave expansion was used to transform the 2-D wave equation into a matrix equation. Up to 12 000 eigenvalues and eigenfunctions can be obtained accurately. A number of point mass configurations (or arrangements) were studied and their frequency structure provides rich insight into the physics of the system. In this report, the calculated frequency band structure of the system and the wave functions will be discussed.

9:50

4aPAb3. Absorbing boundary conditions for acoustic waves and Huygens principle. Gérard Mangiante (Lab. Mécanique d'Acoust., Ctr. Natl. Recherche Sci., 31 Chemin Joseph-Aiguier, 13402 Marseille Cedex 20, France, mangiante@lma.cnrs-mrs.fr) and Sylvestre Charles (Schlumberger Geco-Prakla, Inversion Methods, Houston, TX 77077)

When numerically simulating acoustic wave propagation, artificial boundaries must be introduced into the model to limit the area of computation. To eliminate the spurious reflections produced by these artificial boundaries, absorbing boundary conditions are needed. Such boundary conditions are usually approximated according to two main strategies: paraxial wave equation and the use of viscous media. This paper describes a new approach of the boundary conditions problem using Jessel's formulation of Huygens principle [Jessel (1991), Mangiante (1994), Charles (1996)]. A suitable distribution of Huygens secondary sources was arranged in a transition zone surrounding the model, and adjusted to produce destructive interference to cancel the wave field outside this transition zone. Perfect absorption can be theoretically obtained and can be numerically illustrated. However, due to practical difficulties, only an approximation of this solution has been derived for a finite difference scheme. This approximation consists in splitting the history of the wave field within user defined time windows. The main difficulties are related either to the space and time behavior of the Green functions, or to the solution of the wave equation problem via a finite difference scheme.

10:05

4aPAb4. Diffraction by a hard half-plane: Useful and simple frequency forms to an exact time-domain solution. Djamel Ouis (Eng. Acoust., P.O. Box 118, S-22100, Lund, Sweden, djamel.ouis@kstr.lth.se)

The general case of diffraction of a spherical wave by a hard half-plane is considered. The calculations are based on Biot and Tolstoy's exact and explicit form of the solution to the diffraction problem by a hard wedge. This solution is given in the time domain but its Fourier transform is not available. It is the aim of this paper to present some useful and simple approximations for the early time diffracted field which when transformed into the frequency domain is shown to be satisfactory in comparison to numerical integration. This could give some valuable contributions to calculations on scattering by noise barriers and the like. The results of some experiments are also presented.

10:35

4aPAb5. A discussion on nonradiating sources. Ricardo E. Musafir (Acoust. & Vib. Lab/Dept. of Mech. Eng. and Hydraulics Dept., Univ. Federal do Rio de Janeiro-CP 68503, 21945-970, RJ, Brazil, rem@serv.com.ufrj.br)

The fact that a given source sound field can be generated by more than one source distribution is quite well known but is frequently given an overexaggerated importance. This paper discusses the structure of sources of silence, the name given by Doak [Proc. I.O.A., 10-2, 693–700 (1988)] to the reactive part of a source distribution, i.e., to the part with no far field and which is responsible for the ambiguity. It is shown that, since all ambiguities can always be traced back to the impossibility of distinction between the sound fields of a point monopole and of an isotropic point quadrupole, a simple criteria can be established for identifying a general source distribution as active or reactive. The particular case of the velocity field due to a point dipole (i.e., to a point force) in an homogeneous medium at rest is worked out in detail, since it contains a source of silence (associated with the vorticity at the source point) which is frequently mis-

handled. The concepts presented are applied to aeroacoustic wave equations, to discuss optimization of the choice of dependent variable as well as some case of identification of nonradiating sources found in the literature.

10:50

4aPAb6. To lend an ear to the dimensionality of space. Jean Hardy (Lab. acoustique, Univ. Le Mans BP535 72017 Le Mans CNRS UMR 6613, France)

Since the laws of physics are essentially based on our feeling of the real word, it seems natural to consider the problem of the space dimensionality. The usual conception of the space follows from the vision and leads to the conviction that dimensionality of the real word is 3; a similar approach but using the ears is done in this work. An acoustical source emits an impulse in a homogeneous and isotropic N-dimensional space. The Green's function obtained shows that odd and even dimensionalities have different behaviors. For odd dimensionalities the Green's function is a combination of a step, a delta function and its derivatives; the step function is responsible for reverberation, the other gives the structure of the impulse front which travels at the wave velocity. The even dimensionality uses the half derivatives for expressing propagation, the wave propagation is subject to reverberation which decreases with the time, the wave velocity is not well defined, and the signal transmission and consequently the communication are difficult if not impossible. An explicit demonstration with 1, 2, 3, 4, and 5 dimensions can be done using musical and speech samples.

11:05

4aPAb7. Resolution of the convected Helmholtz's equation by integral equations. M. Beldi (France Acoust., Res. and Development Dept., 11, rue du 8 Mai 1945, 60350 Berneuil sur Aisne, France) and F. S. Monastir (Univ. of Center, 5000 Monastir, Tunisia)

Using the free-field convected Green's function, the integral formulation for the acoustic velocity potential and its normal derivatives associated with Helmholtz's equation in a uniform flow is established. An original development for the calculation of the Cauchy principal value in the singular integrals is presented. As far as the finite part in the hypersingular integral is concerned, a new transformation of the convected double-layer potential normal derivative is proposed. The result of this transformation avoids the explicit calculation of the finite part. Moreover, it generalizes the famous works [M. P. Stallybrass, J. Math. Mech. **16**, 247–1286 (1967)] [A. W. Maue, Zeit. für Phys. **126**, 601 (1949)] on the resolution of the Helmholtz's equation, by integral equations, in a fluid with null velocity. This new variational method by integral equations can easily be coupled with the variational formulation for studying the convection and refraction effects of the acoustic waves in a nonuniform flow [M. Beldi, Third International Conference on Theoretical and Computational Acoustics, Newark (14–18 Aug. 1997)]. The numerical results shows the importance of these effects.

11:20

4aPAb8. Enhanced ray theory. Nikolai E. Maltsev (Instrumar Ltd., P.O. Box 13246, Stn 'A' 39 Pippy Pl., St. John's, NF A1B 4A5, Canada)

The numerical implementation of standard ray theory faces two intrinsic difficulties, the infinite value of the field at caustics and the nonlinear boundary value problem for computation of eigenrays—rays which connect source and receiver. In an earlier work [N. E. Maltsev, J. Math. Phys. **35**, 1387–1389 (1994)], a nontraditional approach was developed to treat the caustics problem. This report describes a procedure of embedding a nonlinear boundary value problem for eigenrays into the space of a higher number of dimensions, where it becomes an initial value problem for a new system of equations, differential equations for eigenrays. These two enhancements of the ray theory produce a regular method of computation of the field anywhere in the media, including shadows, for harmonic and pulse sources with all physical attributes of rays, such as arrival times and angles.

11:35

4aPAb9. Experimental study on the vortex-shedding sound from a yawed circular cylinder. Jong-Soo Choi and Hoon-Bin Hong (Dept. of Aerosp. Eng., Chungnam Nat'l Univ., 220 Kung-Dong, Taejon, Korea)

For a cylinder in a uniform flow stream, sound is generated by the fluctuating pressure on the surface of a cylinder due to the vortex shedding behind the cylinder. It is known that the major parameters in predicting the acoustic pressure at the far field are the flow velocity, the correlation length, and the fluctuating lift coefficient. In this experimental study, the correlation length of the wake is measured with hot-wire sensors and compared to the one obtained with pressure sensors on the cylinder surface. A new measurement technique for the unsteady lift estimation by using a pressure sensor rotating circumferentially is used to show reasonably good results. The surface pressure and the radiated sound are also measured simultaneously for different yaw angles and showed that the reduced normal velocity component to the cylinder axis reduces the unsteady lift fluctuation which results in lowered sound-pressure level. However, experimental result shows that ''the cosine law'' which uses the normal velocity component as a characteristic velocity for noise generation from a yawed cylinder needs to be carefully reviewed.

National Center for Physical Acoustics, University of Mississippi, Coliseum Drive, University, Mississippi 38677

Contributed Papers

All posters will be on display from 9:15 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 9:15 a.m. to 10:45 a.m. and contributors of even-numbered papers will be at their posters from 10:45 a.m. to 12:00 noon. To allow for extended viewing time, posters will remain on display until 12:00 noon on Friday, 26 June.

4aPAc1. Theory on mass transport generated by ultrasonic Lamb waves. Gonghuan Du, Zhemin Zhu, Xiaoliang Zhao (Inst. of Acoust. and State Key Lab of Modern Acoust., Nanjing Univ., Nanjing 210093, PROC), and Junru Wu (Univ. of Vermont, Burlington, VT 05405)

It was reported that acoustic streaming generated by a Lamb-wave sensor (LWS) can be used to pump fluids and transport solids in a small-scale system [Appl. Phys. Lett. **59** (1991)]. The speed, observed by attracting small polystyrene spheres suspended in water, is proportional to the square of the wave amplitude and is about 100 μm/s for 6.5-nm surface displacement of the plate. In this paper, a fairly practical model, i.e., a thin isotropic plate in contact with a viscous liquid layer on its side, is presented. Based on the rigorous propagation theory of Lamb waves and Nyborg's [Phys. Acoust. B **2**, 265–295] and Bradley's [J. Acoust. Soc. Am. **100**, 1399–1408 (1996)] theories of acoustic streaming, the first-order ultrasonic field in the viscous liquid layer and the second-order mass-transport velocity distribution of the liquid are calculated. Comparison between our theoretical values of the Ao-mode Lamb wave and Moroney *et al.*'s experimental result is given. It shows good agreement. [Work supported by NSF of China.]

4aPAc2. Photoacoustic study of the electron–hole transport in a piezoelectric semiconductor. Weimin Gao, Viltali Gusev, Christ Glorieux, Kris Van Rostyne, Ward Van Looy, Jan Thoen (Lab. Akoestiek en Thermische Fysica, Dept. Natuurkunde, Katholieke Universiteit Leuven, Celestijnenlaan 200D, B-3001 Leuven, Belgium), and Gustaaf Borghs (IMEC, B-3001 Leuven, Belgium)

In a piezoelectric semiconductor acoustic waves can be excited via the inverse piezoelectric effect. This excitation process is the result of a screening of the applied electric field by the expanding space distribution of electrons and holes which are generated by pulsed laser radiation. The time and space characteristics of the electron–hole transport in this process are contained in the corresponding acoustic signals. The piezoelectric direct-gap semiconductors cadmium sulfur selenide and gallium arsenide are investigated experimentally at room temperature. A pulsed nanosecond UV excimer laser is used to excite electrons and holes on these samples. The generated longitudinal acoustic waves are detected by a laser interferometer. The obtained acoustic pulses of cadmium sulfur selenide show that both the expansion of the screened region in space and the electron–hole plasma expansion are supersonic at the time scale of laser action. The observations in this optoacoustic experiment indicate that the fast carrier transport is governed by photon recycling, i.e., the reabsorption of photons released by radiative recombination of electron–hole pairs. Experiments for gallium arsenide are in progress and will also be reported.

4aPAc3. Ultrasonic investigation of glass transition dynamics of polyurethane systems. Pierre-Yves Baillif, J. Mohamed Tabellout, and Jacques Emery (Gr. ultrason, UMR 6515 Chimie et Phys., des Materiaux Polymeres, Univ. du Maine, Av. O. Messiaen, 72035 Le Mans Cedex, France, ultrason@aviion.univ-lemans.fr)

Ultrasonic technique is an interesting tool to probe high-frequency dynamic properties of materials by determination of the mechanical modulus. Associated with other methods (rheology, DLS, etc.), it allows the investigation of molecular dynamics associated with sol–gel and glass transitions in polymers on a wide frequency range. Polypropylene glycol triol crosslinked with diisocyanate is a good model system for this purpose in polymer networks. By varying the amount of diisocyanate, stable systems are formed which correspond to different stages of polyurethane gel formation. Three triols with different molar masses (260, 700, and 6000 g/mole) are used as precursors in order to apprehend the influence of the macromolecular chain size on the systems dynamics. The temperature dependence of the ultrasonic absorption and velocity shows a relaxation process, the so-called alpha-relaxation associated with the glass transition. The influence of the stoichiometric ratio $r=[\mathrm{NCO}]/[\mathrm{OH}]$ on this transition is much less important in a large molecular mass precursor system, indicating that entanglement effects become predominant. The ultrasonic relaxation times associated with those obtained by other techniques are represented in an Arrhenius diagram and follow the same William–Landel–Ferry (WLF) law, showing the different systems dynamics' similarity. The WLF parameters seem, in that case, to have a character of universality.

4aPAc4. Longitudinal structural relaxation of glass-forming epoxy oligomer. Mami Matsukawa (Dept. of Electron., Doshisha Univ., Kyotanabe, Kyoto, 610-03 Japan) and Norikazu Ohtori (Niigata Univ., Niigata, 950-21 Japan)

The glass transition process of a common epoxy oligomer (diglycidyl ether of bisphenol A) has been characterized by Brillouin scattering (GHz range) and ultrasonic pulse spectroscopy (MHz range). As the temperature decreases, longitudinal wave velocity rapidly increased. It showed a large frequency dispersion at temperatures higher than the thermodynamical glass transition temperature (T_g). At T_g, velocity changes showed a clear kink. Wave attenuation also showed a peak of the main (alfa) relaxation at temperatures higher than T_g. The peak temperature shifted to lower temperatures in the MHz range, following the VFT type relaxation behavior, which is very common in the main relaxation. The velocities, however, still showed a clear frequency dispersion at temperatures lower than T_g. Because the main relaxation usually results from a large-scale conformational rearrangement of the polymer chain backbone, the effect of this relaxation seems to be neglected at these temperatures. Taking into ac-

count the frequency changes of attenuation peak widths, the effect of other subrelaxations at lower temperatures is discussed. These results are not in contradiction with the acoust-optic dispersion measurements of this oligomer [Kruger *et al.*, Phase Transition (to be published)].

4aPAc5. Hot-spot model of single-bubble sonoluminescence. Kyuichi Yasui (Dept. of Phys., Waseda Univ., 3-4-1 Ohkubo, Shinjuku, Tokyo, Japan)

The hot-spot model of single-bubble sonoluminescence (SBSL) is studied. The temperature is assumed to be spatially uniform inside the bubble except at the thermal boundary layer near the bubble wall even at the strong collapse based on the theoretical results by Kwak *et al.* [Phys. Rev. Lett. **77**, 4454 (1996)]. The effect of the kinetic energy of gases inside the bubble is taken into account, which heats up the whole bubble when gases stop their motions at the end of the strong collapse. A bubble in water containing air is assumed to consist mainly of argon based on the hypothesis by D. Lohse [D. Lohse *et al.*, Phys. Rev. Lett. **78**, 1359 (1997)]. Numerical calculations under an SBSL condition reveal that the kinetic energy of gases heats up the whole bubble considerably. It is also clarified that vapor molecules (H_2O) undergo chemical reactions in the heated interior of the bubble at the collapse and that chemical reactions decrease the temperature inside the bubble considerably. It is suggested that SBSL originates in quasithermal radiation from the whole bubble rather than a local point (the bubble center) heated by a converging spherical shock wave widely suggested in the previous theories of SBSL.

4aPAc6. Nonlinear reflection of acoustic waves at the dissipative isotropic solid–solid interfaces. W. H. Jiang, J. J. Chen, and Y. A. Shui (Inst. of Acoust. and State Key Lab. of Modern Acoust., Nanjing Univ., Nanjing 210093, PROC, whjiang@nju.edu.cn)

The nonlinear reflection at the solid–solid interfaces is investigated under the condition that a SV wave is incident from a nondissipative solid medium to a dissipative solid medium. The amplitude of the freely propagating reflected second harmonic SV wave is calculated. Comparing with previous calculation without consideration of dissipation, it is observed that the peaks of the reflected second harmonic SV wave in the vicinity of critical angles for refractive P and SV waves become smooth and the influence of nonlinear properties of the refractive medium on the amplitude of the reflected second harmonic wave is more notable. A experiment is carried out for glass–copper or rock interface. The SV wave of 8 MHz is incident from glass in which the attenuation of the acoustic wave is negligible upon glass–copper or rock interface. The reflected second harmonic SV wave is detected by a transducer with the working frequency of 16 MHz. The amplitudes of the second harmonic wave at the different incident angles are measured. The resultant angular dependence is in basic agreement with the calculation. [Work supported by NSF of China.]

4aPAc7. Estimation of forward-propagated ultrasonic fields in layered fluid media. K. L. Ha, M. J. Kim (Dept. of Phys., Pukyong Natl. Univ., 599-1 Daeyon-dong, Nam-gu, Pusan 608-737, Korea), W. Y. Zhang, S. G. Ye, and X. F. Gong (Inst. of Acoust., Nanjing Univ., Nanjing 210093, PROC)

The forward propagation of two-dimensional ultrasonic fields through layered fluid media was investigated theoretically by the angular spectrum method combined with the Rayleigh–Sommerfeld diffraction theory and experimentally by measurement of the fields using a precise scanning system with a needle-point hydrophone. Two types of transmitting transducers, one of which is a plane and the other of which is a concave type with the same frequency and the same aperture, were used. In theoretical analysis fields of incidence on a boundary of layer were calculated by the Rayleigh–Sommerfeld diffraction theory and those of transmission throughout the boundary were obtained by applying the angular spectrum method to the fields of incidence and considering the spatial-frequency-dependent transmission coefficients on each boundary. The optimum angular range and the spatial sampling interval could be obtained by supposing the virtual boundaries in the homogeneous medium of water and its appropriateness was confirmed experimentally. It was shown that the forward-propagated fields which could be estimated theoretically agreed reasonably with the measured data in two kinds of simple layered media with one or two boundaries.

4aPAc8. High temporal resolution of the acoustic transients associated with optical cavitation in water using a large area piezoelectric transducer. David C. Emmony and Robin D. Alcock (Dept. of Phys., Loughborough Univ., Loughborough, Leicestershire LE11 3TU, UK, d.c.emmony@lboro.ac.uk)

A PVDF piezoelectric transducer has been used to study the shock wave associated with a laser generated cavitation bubble in water. The measurements depend upon the accurate recording of the voltage developed in a large (3 mm) diameter but thin (9* m) piezoelectric film transducer placed close to a Nd YAG laser-generated cavity in water. The spherical shock transients excite the film over the duration of the passage of the wave through the transducer, and an invertion algorithm of the voltage trace gives the pressure profile along a radius. Pressure profiles due to initial breakdown and first collapse are in excellent agreement with those obtained using full field high-speed optical interferometry of the laser–liquid interaction.

4aPAc9. Particle interactions in coupled phase theory for sound propagation in concentrated emulsions. J. M. Evans and K. Attenborough (Faculty of Technol., The Open Univ., Milton Keynes MK7 6AA, UK, j.m.evans@open.ac.uk)

Theoretical studies of the acoustically induced interphase heat transfer in concentrated emulsions are reviewed. Interactions between the thermal fields around the particles influence the heat transfer and hence the complex wave number of propagating sound. Two modeling approaches are discussed: a hydrodynamic treatment and thermal wave scattering. These methods are used to calculate the interphase heat transfer at high concentrations. Modified heat transfer terms including the effect of particle interactions are obtained, which may be used in coupled phase theory. Predictions of the complex wave number using a revised coupled phase model [J. M. Evans and K. Attenborough, J. Acoust. Soc. Am. **102**, 278–282 (1997)] are compared with experimental data on ultrasound propagation in oil in water emulsions. The comparisons show the nondimensional frequency and volume fraction regions where interactions have a significant effect on the wave number.

4aPAc10. Particle trajectories in a drifting resonance field separation device. Bernhard Handl, Martin Gröschl, Felix Trampler, Ewald Benes (Institut für Allgemeine Physik, Vienna Univ. of Technol., Wiedner Hauptstr. 8/134, A-1040 Wien, Austria, benes@iap.tuwien.ac.at), Steven Woodside, and James Piret (Univ. of British Columbia, Vancouver, BC V6T 1Z3, Canada)

Drifting resonance field (DRF), a new method for the separation of particle/fluid suspensions is introduced. Unlike particle filters using ultrasound-induced coagulation, the DRF method only utilizes the primary acoustic radiation force to achieve the separation effect. This is done by cyclically switching the driving frequency of the DRF resonator between consecutive resonances, causing a directed motion of the particles and thus concentrating the particles in a certain region of the separation volume. Trajectories of polystyrene spheres (approximately 12 microns in diameter) suspended in distilled water have been measured in a prototype DRF resonator, varying the number of the utilized resonance frequencies and the acoustic power input. The measured particle trajectories are compared to computer simulations based on the same process parameters as used in the experimental setup, showing a high correspondence between experi-

mental and simulated data. Both experiments and simulations prove the high potential of the DRF method for separation technology. A promising field of application is the up-scaling of acoustic cell retention systems recently introduced in animal cell culture, potentially yielding higher flow-through rates. The presented results are a valuable basis for design and process parameter optimization of future DRF separation devices.

4aPAc11. Methods of processing laser Doppler anemometry signals to extract sound field information. John S. Cullen, David B. Hann, Clive A. Greated, and D. Murray Campbell (Dept. of Phys. and Astron., Univ. of Edinburgh, The Kings' Bldg., Mayfield Rd., Edinburgh EH9 3JZ, UK)

For several years laser Doppler anemometry (LDA) has been used to measure mean flow rates in gaseous and liquid flows. It is only recently that LDA has been developed as a technique for recording instantaneous particle velocities, enabling nonintrusive measurements to be made in sound fields. The paper describes a typical experimental setup and discusses various methods of digitally processing the LDA photodetector signals to extract the required velocity information. Particular emphasis is placed on the zero counting and Hilbert transformation techniques. The problem of signal dropout is also addressed. LDA measurements of acoustic particle velocity amplitudes are compared with acoustic velocity amplitudes deduced from probe microphone and impedance measurements. It is found that LDA measurements could be made not only in monofrequency sound fields but also in more complex sound fields containing a fundamental component and additional harmonics. Theoretical and practical limitations of the techniques are investigated and used to assess the viability of applying them to studies in the bores and mouthpieces of brass instruments.

4aPAc12. Approach to characterize the sound field of pulse-excited ultrasonic sensors using a Laser-Doppler vibrometer. Bernd Henning, Stefan Prange, Mark Schuart, and Karsten Dierks (Institut für Automation und Kommunikation e.V. Magdeburg, Steinfeldstrasse 3, D-39179 Magdeburg-Barleben, Germany)

A new efficient approach to make visible sound fields in front of acoustic sensors in liquids will be presented. The goal is to investigate the sound field characteristic of real manufactured acoustic transmitters particularly by discontinuous excitation like pulse, burst, and other. Another point is the analysis of the influence of materials and sensor design on the final acoustic behavior. In comparison to the Schlieren technique it is possible to use moderate excitation of transmitters (only a few volts) and more variable signal shapes too. The experimental setup consists of a Laser Doppler vibrometer and a high-resolution three-dimensional positioning system. The control of the positioning system as well as the data acquisition and processing will be fully automatic realized by a personal computer. A software tool archives the data and calculates the complex sound field characteristic in dependence on time or place. The result is an interesting animation representing the real sound field characteristic of acoustic sensors. The advantages and limits of the approach and developed experimental setup will be described. Some examples will show the sound fields in front of cylindrical focusing transmitters. The influence of different excitation signal shapes on the final sound field will be discussed.

4aPAc13. Simulation of ultrasound propagation in a thermally turbulent fluid using Gaussian beam summation and Fourier modes superposition techniques. Christian Lhuillier, David Fiorina, Jean-Luc Berton (Commissariat a l'Energie Atomique, Cadarache, DER/SSAE/LSMR, F-13108 Saint-Paul-lez-Durance cedex, France, ssaelsmr@macadam.cea.fr), and Daniel Juve (UMR CNRS 5509, Ecole Centrale de Lyon, F-69131 Ecully, France)

The CEA (French atomic agency) develops ultrasonic devices for the control and the inspection of Fast Breeder Reactors. The ultrasonic pulses propagate in a liquid which may be turbulent. To predict or interpret the effects of a homogeneous isotropic thermal turbulence, a numerical model has been implemented. Independent realizations of random thermal field are generated by superposition of random Fourier modes. For each realization the complex pressure field is calculated by the Gaussian beam summation method. Statistics over the set of realizations provide an estimation of the variance of time of flight and intensity fluctuations. Simulations have been performed with a point source. When the level of fluctuations is small, the model yields results which are in a good agreement with the analytical solutions given by Chernov and Rytov. When the level of fluctuations grows, it predicts correct evolutions. Multiple eigenrays are well predicted and calculations in time domain with a pulsed source show multiple transmitted signals or modifications in the signal shape.

4aPAc14. Lattice Boltzmann methods in acoustics. James M. Buick, D. Murray Campbell, and Clive A. Greated (Dept. of Phys. and Astron., Univ. of Edinburgh, Rm. 4201 J.C.M.B., The Kings' Bldg., Mayfield Rd., Edinburgh EH9 3JZ, UK)

The lattice Boltzmann model is a recently developed technique for the numerical simulation of fluid motion. It has been successfully applied to a variety of incompressible fluid phenomena and has been shown to be an efficient simulation tool which is ideally suited for implementation on massively parallel computers. Here the application of the lattice Boltzmann model is considered to simulate acoustical processes in which the fluid can, to a first approximation, be considered to be incompressible. The validity and limitations of this approach are considered and the results of simulations performed on the Cray T3D at Edinburgh University are presented. These include sound propagation in tubes, modeling of air flow in the mouthpiece of brass instruments, and the simulation of acoustic streaming in tubes and around cylinders. In each case the fluid velocity, density, and pressure are found at each grid point and each time-step of the simulation, allowing flow patterns and density changes to be observed. The results of the simulations are compared to the predictions of theory and/or experimental observations and suggest that the lattice Boltzmann method can be used as a numerical tool to give insight into complex acoustical situations.

4aPAc15. Acoustical characteristics of the noise radiated from supersonic multijets. Yoshikuni Umeda and Ryuji Ishii (Div. of Aeronautical and Astronautics, Dept. of Eng. Sci., Kyoto Univ., Yoshida Hon-Machi, Sakyo-ku, Kyoto, 606 Japan)

The acoustical characteristics of the noise radiated from combined jets exhausted from one main nozzle and 1, 2, 4, or 8 subnozzles which were placed asymmetrically or symmetrically to the main nozzle were investigated experimentally. The diameter d of the main nozzle was 5 mm and that of subnozzle a/d was 0.2 or 0.6, where a is the diameter of the subnozzle. The center-to-center spacing b of the main and subnozzles was fixed to 5 mm (b/d=1.0). In this experiment, the pressure ratio R of the jets was varied from 2.00 to 6.33. From the frequency characteristics of the screech tone, it is found that in almost all cases, two oscillation modes appear, but when eight subjets with a/d=0.6 were used, the screech tone disappeared completely. Although the total cross-sectional area of the multiple nozzles was larger than that of a single jet, it is found that the sound-pressure level radiated from multijets becomes the same or lower than that from the single jet. [Work supported by the Ministry of Education and Culture of Japan, Grant No. C2-09650187.]

4aPAc16. Acoustic parameters of high functional plastics. I. Measurement of acoustic velocities (wave propagation velocities). Masahide Gakumazawa and Minoru Akiyama (Dept. of Systems Eng., Shibaura Inst. of Technol., 307 Fukasaku, Ohmiya-shi, Saitama, 330 Japan)

Recently, high functional plastics (so-called engineering plastics) which improved the weak point of conventional plastics have been used in the industry. The acoustic parameters of these engineering plastics in the high frequency have been sparsely reported in the literature using a variety of experimental techniques. In this study the acoustic velocities (wave propagation velocities) of engineering plastics are measured using the scanning acoustic microscopy in the range from 50 to 200 MH, and the velocities were compared with the velocities reported in the literature in the lower frequencies.

8:00

4aPP1. Effects of stimulus level and background noise on vowel representations in the auditory brain stem of cats. Bradford J. May (Dept. of Otolaryngol.—HNS, Johns Hopkins Univ., Baltimore, MD 21205) and Murray B. Sachs (Johns Hopkins Univ., Baltimore, MD 21205)

Effects of stimulus level and background noise on vowel representations in the ventral cochlear nucleus (VCN) were investigated by recording single-unit discharge rates in anesthetized cats. The quality of vowel encoding by populations of neurons can be evaluated by plotting vowel-driven rates as a function of each unit's best frequency (BF, the most sensitive frequency); the resulting rate profiles are assumed to show good representations of formant structure if there are high driven rates at BFs near formant frequencies and low rates at BFs near spectral troughs. Among the VCN unit types recorded in the present study, chopper units exhibited the most detectable formant-to-trough rate differences across vowel levels and in background noise. By contrast, primarylike units produced vowel representations that reflected the limited dynamic range of auditory-nerve fibers [May *et al.*, Aud. Neurosci. **3**, 135–162 (1996)]. Primarylike units with low spontaneous rates (SR$<$18 sp/s) showed better representations than high SR primarylike units, but failed to respond at low vowel levels. These results suggest that peripheral representations of speech sounds are sharpened by patterns of auditory nerve convergence in the cochlear nucleus. [Work supported by NIDCD Grant No. DC00109.]

4aPP2. The role of the auditory periphery in the categorization of stop consonants. Robert I. Damper (Dept. ECS, Univ. of Southampton, Southampton SO17 1BJ, UK, rid@ecs.soton,.ac.uk)

A proper understanding of speech perception requires an understanding of the staged restructuring of information that occurs as an acoustic stimulus is transformed by the auditory system into a phonetic percept. It is now firmly established that a physiologically faithful computer simulation of peripheral processing feeding into a trainable artificial neural network (ANN) is capable of reproducing the important aspects of the categorization of initial stop consonants into voiced and unvoiced classes. Correct behavior is found to be insensitive to the ANN architecture and a precise training scheme used, suggesting that such categorization is very basic to the repertoire of auditory processing strategies. Unlike a human or animal listener, a computational model can be easily manipulated and interrogated to discover the underlying basis of category formation. In particular, the physiological-based simulation of the auditory periphery can be dramatically simplified and the effect on categorization observed. It is found that proper modeling of frequency scaling and neural adaptation are essential to correct simulation of the well-known shift of phoneme boundary with place of articulation for stop consonants. The role of the auditory periphery in this case seems to be to emphasize the region of first formant information around the time of voicing onset.

8:30

4aPP3. Integrating monaural and binaural spectral information. Michael A. Akeroyd, Quentin Summerfield, and John R. Foster (MRC Inst. of Hearing Res., University Park, Nottingham NG7 2RD, UK, michael@ihr.mrc.ac.uk)

When speech is presented at a different lateral position to an interfering noise, analyses of both intensity and interaural differences can recover parts of the speech spectrum. It would thus be advantageous if listeners could integrate these two types of information. Their ability to do so using two-formant vowel-like stimuli was tested. A diotic white noise was modified by either increasing the intensity of two 1-ERB-wide bands by 6 dB (''monaural'' condition), by interaurally decorrelating those two bands (''binaural'' condition), or by increasing one band's intensity but interaurally decorrelating the other (''mixed'' condition). Four center frequencies were used—250, 650, 950, and 1850 Hz—and combined in pairs to create four vowels: 250–950, 250–1850, 650–950, and 650–1850. Both bands must be detected to distinguish these stimuli. Identification performance was significantly above chance in all conditions but best in the monaural condition. It was as good in the mixed condition as in the binaural condition. Performance in the mixed condition was better than predicted form performance when only a single band was presented, and thus it could not be due to listening to the bands individually. These results indicate that listeners can integrate monaural and binaural evidence of speech spectra.

8:45

4aPP4. Gap detection threshold in ears with and without spontaneous otoacoustic emissions (SOAEs). Jacek Smurzynski and Rudolf Probst (Dept. of Otorhinolaryngology, Univ. of Basel, Kantonsspital, CH-4031 Basel, Switzerland, smurzynski@ubaclu.unibas.ch)

Gap detection was measured for two groups of normally hearing young adults using broadband (0.1–12 kHz) noise stimuli presented monaurally through an insert earphone. Group I consisted of subjects who exhibited both strong SOAEs and click-evoked otoacoustic emissions (CEOAEs). Group II included individuals with no SOAEs in either ear and CEOAE levels that were $<$50th percentile of a laboratory normative da-

tabase. An adaptive 2IFC procedure was used to determine the hearing threshold of the noise stimulus for each ear tested. Next, an adaptive 2IFC gap detection task was performed for the stimuli presented at either 10-, 20-, 30-, or 50-dB sensation level (SL). At the stimulus level of 10 dB SL, the ears in group I exhibited greater intersubject variability and higher mean gap detection thresholds than those in group II. The results at higher SLs did not show any differences between the two groups and were consistent with the data in the literature. A short gap in the broadband stimulus presented near the hearing threshold is masked by SOAEs and strong CEOAEs that are evoked by the stimulus. [Work supported by Swiss National Science Foundation.]

4aPP5. Modulation masking in a speech recognition task for normal-hearing and hearing-impaired subjects. Rene van der Horst (Dept. of Clinical and Experimental Audiol., Univ. of Amsterdam, Meibergdreef 9, Amsterdam, 1105 AZ, The Netherlands, r.vanderhorst@amc.uva.nl)

The effect of masking in the modulation domain was determined in a consonant recognition task. It is known from psychoacoustical experiments [T. Houtgast, J. Acoust. Soc. Am. **85**, 1676–1680 (1989)] that modulation detection can be masked by another modulation. An experiment was designed that tries to verify whether detection of the modulations in a speech signal is essential for speech recognition. The goal of this experiment was to determine whether stochastic modulations can mask the modulations in a speech signal and disturb speech recognition as effectively as filtering out speech modulations [R. Drullman *et al.*, J. Acoust. Soc. Am. **95**, 1053–1064 (1994)]. The masker used was a stochastic narrow-band signal with minimal inherent fluctuations. The masker signal was, in every critical band, multiplied with the speech modulations. Several masking conditions were created with different bandwidths and center frequencies. The center frequencies were all lying in the region of modulation frequencies which are important for speech (4–20 Hz). Normal-hearing subjects and subjects with sensorineural hearing loss participated in the experiment. The confusion matrices were analyzed by means of multidimensional scaling techniques. The results of the two groups of subjects will be compared with the results obtained with a psychoacoustic model.

4aPP6. A mathematical model of consonant perception by cochlear implant users with the SPEAK strategy. Mario A. Svirsky and Ted A. Meyer (Dept. of Otolaryngol., Indiana Univ. School of Med., 702 Barnhill Dr., RR-044, Indianapolis, IN 46202)

The traditional approach to determine which psychophysical variables are important for speech perception by cochlear implant (CI) users has been to perform correlational analyses. However, the finding of a statistically significant correlation between psychophysical and speech perception variables does not explain the actual mechanisms CI users employ to identify speech sounds. A mathematical modeling approach is proposed that does provide a detailed description of how CI users identify speech sounds based on the acoustic information they receive. To use the proposed approach, it must be hypothesized what the relevant psychophysical dimensions are for a given stimulation strategy. In this study, it is hypothesized that users of the SPEAK stimulation strategy use three types of cues to identify consonants: first, the average cochlear locations stimulated in response to the first three formants; second, the silent gap duration (if present); and third, the ratio between total energy above and below 1000 Hz. Based on a subject's performance along these psychophysical dimensions, the model outputs a predicted consonant confusion matrix. Preliminary comparisons between model predictions and actual data indicate that the model was able to predict which pairs of consonant sounds would be most frequently confused by CI users. 4aPP7. Categorical loudness perception in normal and hearing impaired subjects. Vishakha W. Rawool (Commun. Disord. and Special Education, Bloomsburg Univ., Bloomsburg, PA 17815)

This study compared categorical loudness perception in three subject groups: young (22–24 years) normal, older (43–60 years) normal, and older (60–80 years) hearing impaired (thresholds between 50 and 70 dB SPL at the test frequencies). Eleven subjects were included in each group. The subjects were asked to judge the loudness of warbled tones (2 and 4 kHz) presented at various sound-pressure levels in the following categories: not audible, very soft, soft, comfortable, loud, and very loud. The sound-pressure levels were calibrated for each individual ear. The multivariate analyses of variance was performed on the very soft, soft, comfortable, and loud variable. Average SPLs obtained in each category were used for the analyses. The results showed significant differences in the young normal and the hearing impaired groups in loudness perception across the four categories. No significant differences were apparent in the young normal and older normal groups. The older normal and the older hearing impaired groups differed across all the loudness categories except for the ''loud'' category where no significant differences were apparent. [Work supported by a Bloomsburg University grant for Research and Disciplinary Projects.]

10:00

4aPP8. Across-channel sensitivity to temporal asynchrony in cochlear implantees. Robert P. Carlyon (MRC Appl. Psych. Unit, 15 Chaucer Rd., Cambridge CB2 2EF, UK), Luc Geurts, and Jan Wouters (Univ. of Leuven, Leuven, Belgium)

Five post-lingually deafened users of the LAURAflex cochlear implant detected temporal asynchronies between two 400-ms, 100-Hz trains of 40-μs biphasic pulses, applied to two ''target'' electrode pairs. The pulses in the signal stimulus of each 2IFC trial were delayed by between 0.3 and 4.8 ms on either the basal or apical target, relative to those on the other target. The pulses in the standard stimuli were nearly synchronous, containing a 0.1 ms-delay to the electrode whose pulses were not delayed in the signal. All listeners performed substantially above chance over a wide range of delays. Four were more sensitive to basal delays than to apical delays; one showed the opposite trend. Presenting a ''masking'' 1000-Hz pulse train to electrode(s) between the two targets did not substantially affect the results. This finding, combined with the wide (6–10 mm) separation between the targets suggests that performance was not mediated by neurons responding to both target electrodes. Rather, it is argued that they represent a genuine sensitivity to differences in timing between discrete auditory channels.

10:15

4aPP9. The effect of fast-acting compression on psychoacoustic jnd's. Brent W. Edwards (ReSound Corp., 220 Saginaw Dr., Redwood City, CA 94063)

Fast-acting compression is used in hearing aids to compensate for loudness recruitment in patients with sensorineural hearing loss. Intensity difference limens are independent of the slope of the loudness function and it has been argued that compression normalizes loudness perception in hearing-impaired individuals at the expense of their intensity discrimination performance. Similar arguments have been made with regard to the effect of fast-acting compression on envelopes: Compression reduces the magnitude of envelope fluctuations and thus impairs the near-normal temporal processing capabilities of hearing-impaired individuals. The exact consequences of compression on these perceptual abilities are not clear, however, due to the level- and depth-dependent thresholds of intensity and modulation discrimination tasks, respectively. The effect of fast-acting compression will be quantified in terms of these psychophysical tasks and the results will be related to the speech recognition performance of hearing-impaired individuals.

10:30

4aPP10. Spectro-temporal modulation transfer and speech intelligibility for multiband amplitude compression. Joost M. Festen (Dept. of Otolaryngol., Univ. Hospital VU, P.O. Box 7057, 1007 MB Amsterdam, The Netherlands, jm.festen@azvu.nl)

For ears with sensorineural hearing loss the growth of loudness with stimulus level is often larger than in normal ears. This phenomenon is called recruitment. To restore normal loudness perception and to fit speech in the limited dynamic range of an impaired ear many modern hearing aids apply some form of multiband amplitude compression. However, within the cochlea nonlinearity and frequency selectivity are closely linked and therefore recruitment often goes together with reduced frequency selectivity. While compression may correct the recruitment, it does not improve the frequency selectivity. The opposite is even more correct; multichannel compression reduces the spectro-temporal variations in speech. Therefore in terms of speech intelligibility, the net effect of compression is difficult to predict. In an experiment speech intelligibility after multiband compression in quiet and in noise for 16 hearing-impaired listeners was measured. For each individual listener the speech spectrum was shaped and presented monaurally halfway in the ear's dynamic range in all conditions. Results show a decrease in intelligibility with both increasing compression ratio and increasing number of channels. These results can be fitted with a single curve when intelligibility is plotted as a function of the transfer of phase-locked modulations in time and frequenc.

4aSA1. Resonators attached to a structure—a SEA canon. R. H. Lyon (RH Lyon Corp, 691 Concord Ave., Cambridge, MA 02138-0799, rhlyon@lyoncorp.com)

One of the earliest problems analyzed using SEA ideas was a plate structure connected to a single resonator. Then structure-to-structure problems replaced the single resonator with a multiplicity of resonators as a model for the second structure. Because of the desire to relate the problem to those involving real structural connections—to beams, plates, and sound fields—the resonators became models for the natural modes of the structure and the resonators lost their identity. Fuzzy structure models have emphasized the resonators themselves, with passing attention to actual structural arrangements that they apply to. Of particular interest to SEA, however, is the relationship between modal density and ''mass density,'' and the relative strengths of internal and coupling damping, particularly as they relate to the transient response of the system. This presentation will discuss these matters.

9:55

4aSA2. Rudimentary statistical energy analysis and structural fuzzies. G. Maidanik (David Taylor Res. Ctr., Bethesda, MD 20084) and J. Dickey (Johns Hopkins Univ., Baltimore, MD 21218)

Structural fuzzies (Sfs) is a dynamic complex that is attached to a primary structure in order to provide a higher degree of dissipation. The dissipation is with respect to the power that is injected into the driven primary structure. It is argued that care needs to be exercised in the definition of the loss factor that is associated with this dissipation. This definition is examined and discussed; then, the role of the Sfs is analyzed in terms of a rudimentary statistical energy analysis (SEA). It is shown that the effectiveness of the dissipation is enhanced if the coupling of the Sfs to the primary structure is strong enough to approximate equipartitioning of modal energies, if the modal density in the Sfs either approximates or exceeds that in the primary structure and, finally, if the inherent loss factor in the Sfs is sufficiently higher than that in the primary structure. The definitions of strong enough coupling, modal densities, and inherent loss factors will be given. Examples of Sfs will be cited and discussed.

10:30

4aSA3. Spatial distribution of energy in SEA acoustic volumes. Evan B. Davis (Boeing Commercial Airplane Group, P.O. Box 3707 M/S 67-ML, Seattle, WA 98124-2207, evan.b.davis@boeing.com)

Statistical energy analysis (SEA) methods predict the space average energy in acoustic volumes. The predicted SEA acoustic energy levels are converted to SPL levels using the assumption that the sound field is diffuse. The SEA prediction methods estimate a single, space averaged value for the acoustic energy in the enclosure, whereas the theory of diffuse sound fields in enclosures predicts a nonuniform energy distribution in the enclosure. The energy levels and SPLs increase near the boundaries of the enclosure. The theory of diffuse sound fields can therefore be applied to generate an estimate of the spatial distribution of sound energy from the predicted spatial average. The sound field distributions are based on the Waterhouse corrections for reverberation rooms [Waterhouse, J. Acoust. Soc. Am. **27**, 247–258 (1955)]. The use of the Waterhouse correction in

the interpretation of SEA predictions is most useful in acoustic volumes which are relatively small in relation to the acoustic wavelengths of interest. Enclosures which have dimensions on the same order as the acoustic wavelengths are commonly encountered in transportation systems such as automobiles and airplanes.

10:55

4aSA4. Fuzzy structure, initial problem. Poincare theorem. Samuil A. Rybak (N. N. Andreyev Acoust. Inst., Shvernik Str. 4, Moscow 117036, Russia)

A system consisting of a master structure—an oscillator, coupled with a number of oscillators, distributed in some frequency range—is considered. The master oscillator is initiated by a delta-function pulse, and damping is neglected. The energy flows from the master structure to the fuzzy system, the amplitude of its oscillations falls exponentially, and the amplitudes of fuzzy system oscillators are exponentially growing. This means that asymptotically the master structure becomes silent and the fuzzy oscillators have the maximum of their amplitudes. After the time T, depending on the full number of degrees of freedom, the picture almost fully returns back. But the time T becomes infinite when the number of oscillators is infinite (when their distribution is continual, for example). If at an arbitrary time one changes the signs of the velocities of the full system of oscillators, the phase trajectory turns back strongly the same way, because the system is conservative. The path tracing of the pole, which is originating in the integral describing the influence of the fuzzy system of oscillators on the master oscillator, is the same as usual, but the sign of the index of the exponential attenuation changes and the system goes to the initial state, with amplitude growing exponentially. [Work was partially supported by the Russian Foundation of Basic Research.]

THURSDAY MORNING, 25 JUNE 1998 GRAND BALLROOM I (W), 7:45 TO 10:45 A.M.

Session 4aSC

Speech Communication: Speech Perception Theories and Models (Poster Session)

Paul Iverson, Chair
House Ear Institute, 2100 West Third Street, Los Angeles, California 90057

Contributed Papers

All posters will be on display from 7:45 a.m. to 10:45 a.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 7:45 a.m. to 9:15 a.m. and contributors of even-numbered papers will be at their posters from 9:15 a.m. to 10:45 a.m. To allow for extended viewing time, posters will remain on display until 7:30 p.m. A cash bar will be set up in the poster area from 5:00 p.m. to 7:30 p.m. preceding the banquet.

4aSC1. Testing two information taxonomies in Spanish. Guillermo Andrés Toledo (Dépt. de langues et linguistique, Faculté des lettres, Univ. Laval, Cité Univ., Québec, QC G1K 7P4, Canada, ucineacad@sminter.cam.ar)

Two information taxonomies, i.e., in the first experiment, New/Given distinction and, in the second experiment, three cognitive categories of the mental representation of referents: activation, semiactivation, inactivation differences [W. Chafe, in Tomlin *Coherence and Grounding in Discourse* (John Benjamins, Amsterdam, 1987), pp. 21–51 and K. Lambrecht, *Information Structure and Sentence Form* (Cambridge U.P., Great Britain, 1994), pp. 1–1161 have been explored in Argentinian Spanish. In the first experiment, semispontaneous materials were recorded from communicative interactions between three male speakers, one female speaker, and the listener. Brand-New plus New (Inferrable) versus Given (Textually Evoked) items were selected for acoustic analysis. In the second experiment, activation, semiactivation, and inactivation states encoded in semispontaneous discourses were taken from interactions between three male speakers and the listener. In both experiments, tonal prominences were studied through intonational contours on pairs of contrasted items: natural values and data transformed through logarithmic z-score normalization. Results in the first experiment indicated a relevant tonal encoding in new items. Findings in the second experiment have shown higher prominences correlated with inactive states, lower prominences with active and semiactive states.

4aSC2. Perception of speech gestures. René Carré (ENST, Dept. Signal, 46 rue Barrault, 75634 Paris Cedex 13, France) and Pierre L. Divenyi (Exp. Audiol. Res., V. A. Med. Ctr., Martinez, CA 94553)

Perception of a synthetic French /aya/ sequence, generated by coproduction of two simultaneous gestures (tongue constriction and lip rounding), was tested in a series of experiments. The tokens consisted of eight different degrees of gesture reduction in which the target /y/ was not reached. The /ay/ trajectory in the plane $F1$–$F2$ was not rectilinear (it pointed first to /i/ before reaching /y/), having to do with the fact that the acoustic effect caused by lip rounding (lowering $F2$) becomes manifest later than the effect due to constriction (lowering $F1$ and raising $F2$). The /aya/ transition is, therefore, an appropriate stimulus to study the role of the linearity of trajectories in speech perception. Results show that unless /y/ is present as a steady-state vowel for at least 30 ms, the lip rounding gesture is ignored and the percept is /aia/. Thus the results strongly suggest

that formant trajectories are perceived as time averages through a mechanism that calculates the direction of transition toward an (unreached) target from a running average of the direction of the formant trajectory. These findings point to the importance of the trajectory direction in vowel reduction and of the time dimension in phonetic distinctions. [Work supported by NATO.]

4aSC3. Coarticulation in CV syllables: A locus equation and EPG perspective. Marija Tabain (Speech, Hearing and Lang. Res. Ctr., Dept. of Linguist., Macquarie Univ., Sydney, Australia 2109)

Stop, nasal, and fricative consonants of Australian English were paired with a wide variety of vowel monophthongs to form CV syllables which were placed in a carrier phrase. The EPG and acoustic data were obtained from four female speakers producing these phrases. Locus equations [Lindblom, Acoust. Soc. Am. **35**, 1773–1781 (1963)] were generated from the acoustic data, and coarticulation indices [Farnetani, *Speech Production and Speech Modelling*, edited by Marchal and Hardcastle (1990), pp. 93–130] were calculated from the EPG data. The coarticulation indices were compared with the slope values from the locus equations [Krull, PERILUS **10**, 87–108 (1989)] in order to determine the degree of coarticulatory resistance for a given consonant phoneme as measured in the articulatory and acoustic domains. Results suggest that the greatest degree of coarticulation is shown in the labial and velar consonants, and less in the apico-alveolar consonants. The least degree of coarticulation is shown by the lamino-postalveolar consonants /S Z/. These results agree with data from Australian Aboriginal languages and with results presented by Recasens for Catalan [J. Phon. **12**, 61–73 (1984); **19**, 177–192 (1991)].

4aSC4. A model for dependences in phonetic categorization. Roel Smits (Dept. of Phonet. and Linguist., Univ. College London, 4 Stephenson Way, London NW1 2HE, UK)

A quantitative model for human categorization behavior is proposed which can be applied to four-alternative forced-choice categorization data involving two binary classifications. A number of processing dependences between the two classifications are explicitly formulated, such as the dependence of the location, orientation, and steepness of the class boundary for one classification on the outcome of the other classification. The significance of various types of dependences can be tested statistically. Analyses of two data sets from the literature [Repp *et al.*, J. Exp. Psych: Human Percept. Perform. **4**, 621–637 (1978); Whalen, Percept. Psychophys. **46**, 284–292 (1989)] show that interesting dependences in human speech recognition can be uncovered using the model.

4aSC5. Familiarity and pronounceability of nouns and names. Aimée M. Surprenant (Dept. of Psychol. Sci., Purdue Univ., West Lafayette, IN 47907-1364, aimee@psych.purdue.edu), Susan L. Hura (Lucent Technologies, Holmdel, NJ 07733), Mary P. Harper, Leah H. Jamieson, Stephen A. Hockema, Tsung-Hsiang Hsueh, Michael T. Johnson, Pramila N. Srinivasan, Scott M. Thede, Christopher M. White, Glenis Long, and Ayasakanta Rout (Purdue Univ., West Lafayette, IN 47907-1353)

Proper names have several properties that create problems for speech recognition systems: the number of names is large and ever changing, names can be borrowed directly from other languages and may not conform to usual pronunciation rules, and the variety of pronunciations for names can be high. Because the set of proper names is so dynamic and machines are notoriously poor at phoneme recognition, a promising approach to designing a name recognition system is to incorporate statistical aspects of proper names (e.g., frequency, familiarity). Unfortunately, there exists relatively little data on the distribution of names. Ratings of familiarity and pronounceability were obtained for a randomly chosen sample of 199 surnames (from 80 987 entries in the Purdue phonebook) and 199 nouns (from Kucera–Francis). The ratings for nouns versus names are substantially different: nouns were rated as more familiar and easier to pronounce than surnames. Frequency and familiarity were more closely related in the proper name pool than the word pool, although the correlations were modest. Ratings of familiarity and pronounceability were highly related for both groups. The value of using frequency and the ratings of familiarity and pronounceability for predicting variations in actual pronunciations of words and names will be discussed.

4aSC6. Ranking the pitches of concurrent vowels. D. Dwayne Paschall (Texas Tech Univ. Health Sci. Ctr., Box 42073, Lubbock, TX 79409) and Peter F. Assmann (Univ. of Texas at Dallas, Richardson, TX 75083-0688)

When two vowels are presented simultaneously, listeners can label them more accurately if their fundamental frequencies differ, and under some conditions they can report which vowel has the higher pitch. In this study the interaction of fundamental frequency and binaural cues on judgments of the relative pitches of concurrent vowel pairs is examined. On each trial listeners were told which vowels were presented and were asked to indicate which vowel was on the higher pitch. The first vowel had an F_0 of 140 Hz and the second vowel was either 1, 2, 4, or 8 semitones lower or higher than the first. When the fundamental frequency difference was small (1 semitone), the ability to rank the pitches of the two vowels was near chance level, and dichotic presentation provided little advantage over monaural presentation. With monaural presentation performance improved gradually with increasing F_0 difference, reaching a maximum near 80% correct at $+8$ semitones. When the stimuli were presented dichotically there was a dramatic improvement between 1 and 2 semitones and performance was near 100% with larger F_0 differences of 4 and 8 semitones. The interaction of F_0 differences and binaural cues places important constraints on models of concurrent vowel segregation.

4aSC7. Selection of a tonotopic scale for vowels. Terrance M. Nearey (Dept. of Linguist., Univ. of Alberta, Edmonton, AB T6G 2E7, Canada)

Various distinct tonotopic scales (e.g., log frequency, ERB, Bark) have been used for the representation of fundamental and formant frequency data for vowels. In previous work in our laboratories [T. Nearey, Proc. ICSLP92, 583–586 (1992)], generalized linear modeling was used to assess the relative appropriateness of these scales on both production measurement and vowel categorization data on each scale using several alternative vowel normalization schemes. That work focused on F_0 and F_1 and used the classic data of Peterson and Barney [G. Peterson and H. Barney, J. Acoust. Soc. Am. **24**, 175–184 (1952)]. Analysis of that data suggested that the log scale as provided somewhat better fits to the data with less evidence of violations of modeling assumptions. However, results in modeling perceptual data (from Canadian English listeners) were less clear. The present study will extend the scope of the earlier work by examining more data and expanding the statistical modeling framework. The production analyses will be augmented using an additional large production data set for another dialect of American English [J. Hillenbrand *et al.*, J. Acoust. Soc. Am. **97**, 3099–3111 (1995)]. The perceptual analyses will be augmented using additional perceptual data sets collected in our laboratories.

4aSC8. An exemplar-based account of emergent phonetic categories. Francisco Lacerda (Stockholm Univ., Inst. of Linguist., 106 91 Stockholm, Sweden)

This paper describes how an exemplar-based model can be used to study the early stages of language acquisition and phonetic category formation. The paper discusses in particular how a (conceptually) very simple model, inspired by Edelmans notion of Neural Darwinism, may account for the emergence of phonetic categories arising from the interaction between ambient language input and limited memory-representation resources. It presents an explicit attempt to demonstrate how phonetic

categorization may emerge ''spontaneously'' from exposure to natural infant-directed speech data. The results suggest that phonetic categories may emerge if the auditory input is statistically correlated with one (or several) other sensory inputs. The perceptual-magnet effect is also discussed in the light of the present model. According to the model, the perceptual-magnet effect can be seen as a consequence of distributed memory representations. [Work supported by The Bank of Sweden Tercentenary Foundation, grant 94-0435.]

4aSC9. Effect of spectral distance on vowel height perception. Patrick C. M. Wong and Randy L. Diehl (Dept. of Psych., Univ. of Texas at Austin, Austin, TX 78712, pcmwong@ccwf.cc.utexas.edu)

Perceived vowel height has been reported to vary inversely with the distance (in Bark) between the first formant frequency ($F0$) and the fundamental frequency ($F0$) [H. Traunmueller, J. Acoust. Soc. Am. **69**, 1465–1475 (1981)]. However, in a study using back vowels, Fahey *et al.* [J. Acoust. Soc. Am. **99**, 2350–2357 (1996)] found that phonetic quality was not only determined by the $F1-F0$ distance, but also by the tonotopic distances between *any* adjacent spectral peaks (e.g., $F3-F2$, $F2-F1$, and $F1-F0$), with greater weight accorded to smaller distances. The present study further tested this possibility by using front vowels. Listeners identified three sets of synthetic vowels varying orthogonally in $F1$ and $F0$ and ranging from /i/–/ɪ/, /ɪ/–/ɛ/, or /ɛ/–/æ/. The results allowed this possibility to be rejected. Furthermore, they supported the study of Hoemeke and Diehl [J. Acoust. Soc. Am. **96**, 661–674 (1994)] that $F1-F0$ was the best predictor of perceived vowel height for the phonological distinction [+/−high] (i.e., the /ɪ/–/ɛ/ distinction), while $F1$ alone was the best predictor for the two other vowel set distinctions. [Work supported by NIDCD.]

4aSC10. Syllable as the segmentation unit in perceiving spoken Chinese. Chin-Hsing Tseng (Dept. of Special Education, Natl. Kaohsiung Normal Univ., Kaohsiung, Taiwan)

How spoken Chinese is segmented by native speakers has been addressed by the author in recent years. Evidence has accumulated to support the view that the syllable is the level at which speakers segment their spoken language. Earlier studies found that Mandarin–Chinese phonemes were detected faster in real syllables than in nonexistent syllables, that they were faster for level-tone and falling-tone syllables than for rising-tone or dipping-tone syllables, and that structural complexity had no effect on phoneme detection. These effects have preempted phoneme and word as the segmentation unit in real-time processing. This study was designed to investigate the role of stress foot in segmentation, to discover the locus of the tone effect, and to replicate the tone and complexity effects with Taiwanese speech materials. Stress assignment and phoneme detection tasks were employed as the experimental paradigms. The results indicated that stress assignment in Mandarin is not consistent enough to warrant a stress-foot segmentation procedure, that the tone effect originates from syllable duration variations, and that earlier effects were replicated with Taiwanese.

4aSC11. Phonological boundaries and the spectral center of gravity. Michelle R. Molis, Randy L. Diehl, and Adam Jacks (Dept. of Psychol., Univ. of Texas, Austin, TX 78712, molis@mail.utexas.edu)

A critical limit of 3–3.5 Bark has been reported for the ''spectral center of gravity'' effect between the second and third formants ($F2$ and $F3$) and is assumed to correspond to a perceptually natural boundary [A. K. Syrdal and H. S. Gopal, J. Acoust. Soc. Am. **79**, 1086–1100 (1986)]. This hypothesis was tested for both the [+/−back] and [+/−coronal] distinctions in English vowels. Subjects identified two sets of three-formant synthetic vowels which varied orthogonally in $F2$ and $F3$ and ranged between /ʊ/–/ɪ/ ([+/−back]) or /ɝ/–/ʊ/ ([+/−coronal]). For the /ʊ/–/ɪ/ distinction, a boundary shift was observed solely as a function of $F2$, ruling out an invariant $F3-F2$ boundary. For the /ɝ/–/ʊ/ series, both $F2$ and $F3$ influenced boundary location. There was a relatively stable $F3-F2$ boundary for the mean identification responses in this case, but it occurred at less than the predicted 3–3.5 Bark difference. Follow-up results will also be presented. [Work supported by NIDCD.]

4aSC12. An exemplar-based model of silent-center syllable perception. Stephen Winters and Keith Johnson (Dept. of Linguist., Ohio State Univ., 222 Oxley, 1712 Neil Ave., Columbus, OH 43202)

Rakerd and Verbrugge [J. Memory Lang. **26**, 558–563 (1987)] suggested that the perception of silent-center syllables—CVC syllables with the middle 60% of the vowel edited out and replaced with silence—had to involve some form of speaker normalization. Crucial to their argument was their subjects' ability to perceive cross-gender hybrids of such syllables. Rakerd and Verbrugge reasoned that even modest accuracy in perceiving these hybrids entailed some sort of normalization of the disparate acoustic qualities of male and female voices in order to derive one perceptual whole. Rakerd and Verbrugge's study has been replicated in order to test the ability of a computationally implemented exemplar model to perceive silent-center syllables. Exemplar-based modeling utilizes no ''speaker normalization'' as such, but, nonetheless, the model in this study approximated the performance of human subjects in perceiving silent-center syllables correctly. The model's performance on the important ''hybrid'' case was almost identical to subjects' responses. These results suggest that the human ability to perceive silent-center syllables does not necessarily entail some process of speaker normalization in speech recognition. [This material is based upon work supported under a National Science Foundation Graduate Fellowship and NIDCD Grant No. R29-DC01645-06.]

4aSC13. The time course of learning: Neurophysiologic changes during speech training. Kelly L. Tremblay, Nina Kraus, Therese McGee, and Steve Zecker (Dept. of Commun. Sci. and Disord., Northwestern Univ., 2299 North Campus Dr., Evanston, IL 80208)

The ability of normal-hearing adults to identify and discriminate novel speech sounds improves with training. Neurophysiological changes associated with this improvement include increased duration and area, as well as shortened onset latency, of the mismatch negativity (MMN) [N. Kraus *et al.*, J. Cog. Neurosci. **7**, 25–32 (1995); K. Tremblay *et al.*, J. Acoust. Soc. Am. **102**, 1–12 (1997)]. The MMN is a passively elicited, preattentive, auditory event-related potential that reflects auditory discrimination and echoic memory [R. Naatanen *et al.*, Acta Psychol. **42**, 313–329 (1978)]. To date, little is known about the time course of neurophysiological change and the manifestation of learning. The present study examined the time course of perceptual learning and its relation to changes in the MMN with the expectation that cortically evoked potentials could provide insight into the biological processes underlying perceptual learning and serve as a clinical tool for evaluating change during efforts of (re)habilitation in the communicatively impaired. Specifically, it was found that neurophysiological change is apparent in the MMN preceding behavioral improvement. This suggests that auditory training alters the neural activity that provides the necessary coding of the speech stimuli and those changes are later integrated into functional behavior.

4aSC14. Context effects in the auditory identification of Spanish fricatives /f/ and /θ/: Hyper and Hypospeech. Sergio Feijóo, Santiago Fernández, and Ramón Balsa (Dpto. Física Aplicada, Fac. de Física, 15706, Santiago, Spain, fasergio@uscmail.usc.es)

Twenty-eight subjects heard 40 Spanish words in which the initial fricative was /f/ or /θ/, combined with vowels /e/ and /u/. Ten words were used for each particular combination (2 fricatives$\times$2 vowels $\times$10 words). Two forms of speech (Hypo and Hyperspeech) and four conditions were considered: (1) Isolated fricative segment; (2) fricative segment + 51.2 ms of the following vowel; (3) fricative + whole following vowel; (4) whole word. The statistical analysis showed that, despite their differences in production and acoustic characteristics, isolated fricative segments were equally recognized in Hypo and Hyperspeech (cond. 1). Including the vowel (conditions 2 and 3) significantly improved recognition of both fricatives for both forms of speech, except for the combination /f/+/e/: While fricative identification improves slightly in Hyperspeech, in Hypospeech, recognition decreases with respect to cond. (1). For this particular combination, an acceptable recognition rate is only achieved in the whole word condition for both forms of speech. The results indicate that: (a) Clear speech is not necessarily more intelligible than hypospeech; and (b) The role of vocalic context in the recognition of /f/ and /θ/ is similar for both forms of speech.

4aSC15. Evidence of independent verbal processors for the same stimulus: Insights from dichotic verbal transformations. James A. Bashford, Jr. and Richard M. Warren (Dept. of Psych., Univ. of Wisconsin, Milwaukee, WI 53201, bashford@csd.uwm.edu)

A clearly enunciated word heard repeating without change undergoes illusory verbal transformations (VTs) to different words or syllables. Surprisingly, when a repeating word is delivered dichotically with an interaural asynchrony of half its duration, the separate lateralized images of the word are heard to undergo independent VTs (e.g., ''commence'' heard at one ear while ''tress'' is heard at the other) [see Warren and Ackroff, Nature **259**, 475–477 (1976)]. The present study eliminates a peripheral explanation attributing such independent changes to lateral asymmetries in repetition effects upon the lower auditory pathways, which might provide conflicting acoustic-phonetic information to a single verbal processor. A dichotic alternation paradigm, in which successive statements of a repeating word were presented to opposite ears (e.g., ''flame'' presented left, then ''flame'' presented right . . .) was also found to produce independent VTs. However, when higher amplitude noise was presented to the ear opposite the alternating speech signal, contralateral induction [Warren and Bashford, Percept. Psychophys. **20**, 380–386 (1976)] produced diffuse medial localization of the otherwise lateralized signals, and despite monaural verbal stimulation, VTs were linked across ears. This and other evidence to be discussed demonstrate independent preattentive verbal processors for spatially distinct sources. [Work supported by NIH.]

4aSC16. Inducing a ''perceptual magnet''-like effect in a nonspeech modality. Fatima Husain and Frank H. Guenther (Dept. of Cognit. and Neural Systems, Boston Univ., 677 Beacon St., Boston, MA 02215, fhusain@cns.bu.edu)

Kuhl and colleagues have described a ''perceptual magnet effect'' in which subjects show a decreased ability to discriminate between vowel-like stimuli when these stimuli fall near a prototypical vowel from their native language. Guenther and Gjaja [J. Acoust. Soc. Am. **100**, 1111–1121 (1996)] proposed that the effect results from experience-based map formation in auditory brain regions. Because this model attributes the effect to neural mechanisms that have been identified in cortical areas subserving different sensory modalities, it predicts that it should be possible to induce magnet effects in nonspeech modalities. To test this, adult subjects' discrimination sensitivities to narrow-band noise stimuli were tested before and after training sessions meant to approximate an infant's exposure to speech sounds. Training consisted of a categorization task that preferentially exposed subjects to stimuli from a small frequency range meant to correspond to a prototypical vowel. Sensitivity tests after training revealed that subjects had become worse at discriminating sounds within this ''prototype'' range as compared to a ''nonprototype'' range that was absent during training. This suggests that the magnet effect may not depend on phonetic processing and may reflect neural mechanisms common to different sensory modalities. [Supported by NIDCD and the Sloan Foundation.]

4aSC17. Interarticulator phasing and locus equations. Anders Lofqvist (Haskins Labs., 270 Crown St., New Haven, CT 06511, lofquist@haskins.yale.edu)

A locus equation plots the frequency of the second formant at vowel onset against the target frequency of the same formant for the vowel in a consonant–vowel sequence. The slope of the equation has been assumed to reflect the degree of coarticulation between the consonant and the vowel, with higher slopes associated with more coarticulation. This study examined the articulatory basis for this assumption, using VCV sequences where the consonant was a bilabial stop /p, b/ and the vowels one of /i, a, u/. Articulatory movements were recorded using a magnetometer system. Four subjects participated and produced ten repetitions of each sequence. One articulatory measure was the temporal phasing between the onset of the lip closing movement and the onset of the tongue body movement from the first to the second vowel. Another was the magnitude of the tongue movement from the onset of the second vowel to the tongue position for the vowel, averaged across four receivers placed on the tongue. When compared with the corresponding locus equation slopes, neither measure showed support for the assumption that the slope serves as an index of the degree of coarticulation between the consonant and the vowel. [Work supported by NIH.]

4aSC18. Latency of MEG M100 response indexes first formant frequency. Krishna K. Govindarajan (MIT, Cambridge, MA 02139), Colin Phillips (Univ. of Delaware, Newark, DE 19716), David Poeppel, Timothy P. L. Roberts (UCSF, San Francisco, CA 94143), and Alec Marantz (MIT, Cambridge, MA 02139)

Magnetoencephalography recordings from the auditory cortex of subjects listening to synthetic vowels show a close correlation between the timing of the evoked M100 response and the first formant frequency ($F1$). These results are consistent with evoked magnetic field latencies elicited by tone stimuli, which show 100 to 300-Hz tones associated with latencies up to 30 ms longer than 500 to 3000-Hz tones. In experiment 1, three-formant vowels /u,a,i/ were presented at two fundamental frequencies ($F0=100$ Hz, 200 Hz). The M100 latency was a function of the vowel identity and not $F0$: M100 was significantly shorter for /a/ than /u/, consistent with the spectral center of gravity being at a higher frequency for /a/. In experiment 2, single-formant vowels (/u/:$F1=330$ Hz, /a/:$F1=720$ Hz) were covaried with two $F0$ values. M100 latencies were shorter for /a/ (high $F1$) than for /u/ (low $F1$), at both fundamentals. In experiment 3, subjects listened to pure-tone complexes with frequencies and amplitudes matching the $F0$ and $F1$ energy peaks of the stimuli in experiment 2. M100 latencies showed the same pattern: latency covaried with the energy

peak corresponding to $F1$, suggesting that the sensitivity to the energy in the $F1$ range is not speech-specific. Finally, an experiment involving two-formant, amplitude-varying vowels will be presented.

4aSC19. Perceptual magnet effect in corner vowels. Robert Allen Fox and Lynn Carahaly (Dept. of Speech and Hearing Sci., Ohio State Univ., Columbus, OH 43210)

In previous studies of speech perception, Kuhl and colleagues have provided evidence that the category goodness of a vowel influences the perception of that particular vowel—the perceptual magnet effect. These data indicate that listeners demonstrate poor discrimination of vowel tokens when they are close to the prototype vowel but good discrimination when the vowel is close to a nonprototypic vowel. However, data will be provided from experiments conducted in this laboratory using an MDS paradigm on the /i/–/ɪ/ distinction that indicate this effect is eliminated or severely curtailed when all tokens are good exemplars of the /i/ category ($>75\%$) and the nonprototypic exemplars are not near a phoneme boundary. In addition, given the almost exclusive reliance in the literature on the /i/–/ɪ/ vowel pair, additional data will be provided on the magnet effect in the /u/–/ʊ/ and /ʌ/–/ɑ/. Similar to /i/, extreme tokens of both /ɑ/ and /u/ that are distant from the prototype, but not in the direction of another vowel category (and thus near a phoneme boundary). The results will be discussed in terms of whether the effect is linguistic (phonetic) or auditory in nature.

4aSC20. Surveying auditory space using vowel formant data. Matthew J. Makashay and Keith Johnson (Dept. of Linguist., Ohio State Univ., 222 Oxley Hall, 1712 Neil Ave., Columbus, OH 43210, makashay@ling.ohio-state.edu)

Recent research has suggested that vowel category learning and the perceptual magnet effect are the natural consequences of auditory neural map formation [F. H. Guenther and M. N. Gjaja, J. Acoust. Soc. Am. **100**, 1111–1121 (1996)]. As these effects are language specific, the organization of the perceptual map crucially is dependent on the input received during learning. Guenther and Gjaja implemented a working model of a self-organizing neural map to show that, given input from Gaussian distributions around vowel category centers, unsupervised training leads to a warping of the perceptual space toward the category centers. This work replicates Guenther and Gjaja's results and provides a more realistic test of the model by using real vowel formant data instead of idealized distributions. Single and multiple male talker vowel data were used to train auditory neural maps. Single-talker simulations resulted in map organization similar to Guenther and Gjaja's results. However, no clear vowel category clusters emerged in the multiple-talker simulations. [Work supported by NSF Graduate Fellowship and NIH FIRST Award R29-DC01645-06.]

4aSC21. Relation between discrimination and identification of English vowels. Diane Kewley-Port and Amy T. Neel (Dept. of Speech and Hearing Sci., Indiana Univ., Bloomington, IN 47405)

Although resolution for formant frequency is considerably better than needed for vowel identification in English, adjacent vowels in the $F1$-by-$F2$ plane may not be equally discriminable. Kuhl has reported better discrimination for poor vowel exemplars than good exemplars (''perceptual magnet effect'') for a few vowels in high stimulus uncertainty tasks. The purpose of this experiment was to determine the relation between discrimination thresholds and the judgment of vowels as good, confusable, or non-English. A large $F1$-by-$F2$ vowel space (190 tokens) encompassing five English front vowels was synthesized in equal bark steps. Based on an identification task with goodness ratings, two vowels representing each goodness category were selected for the discrimination task. Eight listeners participated in a minimal uncertainty discrimination task to estimate thresholds for $F1$ and $F2$. Analysis of variance of the 12 thresholds (converted to Δ Barks) found that thresholds for non-English vowels were significantly poorer than the other two categories, whereas thresholds for good and confusable vowels were similar. These results are not consistent with the perceptual magnet effect. Vowels within areas of the $F1$-by-$F2$ space judged as good exemplars are not discriminated more poorly than those in confusable areas. [Work supported by NIH-NIDCD-02229.]

4aSC22. The effect of vowel prototypicality and extremity on discrimination sensitivity. Satsuki Nakai (Univ. of Edinburgh, Edinburgh EH8 9LL, UK, satsuki@ling.ed.ac.uk)

The present study examines the effect of vowel extremity and prototypicality on discrimination sensitivity. Kuhl [1991] has shown that listeners are not as capable of distinguishing other variations of /i/ from a prototypical /i/ (the stimulus with the highest goodness rating, henceforth P) as from a nonprototypical /i/ (a stimulus with a low goodness rating). However, considering evidence suggesting that discrimination sensitivity grows poorer towards the exterior of the vowel space [Schouten and van Hessen, 1992], it is unclear whether it is vowel prototypicality or extremity that correlates with low discrimination sensitivity, for P is the most extreme among the stimuli used in the discrimination task in Kuhl [1991]. In order to investigate the above issue, discrimination curves were obtained from native speakers of Japanese and Greek in the corner of the vowel space where Japanese /u/ and Greek /u/ are located. As Japanese /u/ is not cardinal, the effect of vowel prototypicality and extremity on discrimination sensitivity could be observed separately on Japanese subjects' discrimination curves. The results indicate that both vowel prototypicality and extremity contribute to low discrimination sensitivity, and that the extremity of P correlates with the magnitude of its effect on discrimination sensitivity.

4aSC23. Phonetic categories: Internal category structure and processing speed. Joanne L. Miller (Dept. of Psych., Northeastern Univ., Boston, MA 02115), Peter D. Elimas (Brown Univ., Providence, RI 02912), and Ethan Cox (Univ. of Arizona, Tucson, AZ 85721)

Phonetic categories have a graded internal structure, with some members perceived as better exemplars than others. In a project focusing on voiceless stop consonants, the relation between this structure and processing speed has been examined. Speech continua were constructed in which the voice-onset-time (VOT) value of a word-initial consonant systematically changed from very short to very long. Unspeeded identification tests confirmed that stimuli with very short VOT values are perceived as voiced, whereas those with longer VOT values are perceived as voiceless. Category-goodness rating tests further confirmed that only stimuli within a limit range along each continuum are perceived as good exemplars of the voiceless category; stimuli with shorter or longer VOT values are perceived as poorer exemplars. Initial results from an ongoing experiment involving speeded identification indicate that (1) compared to the best exemplars of the voiceless category, identification of poor exemplars in the voiced–voiceless boundary region is relatively slow, but (2) across a wide range of values, poor exemplars with VOT values longer than the best exemplars are identified as quickly as the best exemplars themselves. These initial findings indicate that internal category structure is not necessarily reflected in processing speed. [Work supported by NIH.]

4aSC24. The effect of speaking style alterations on locus equation stability. Harvey M. Sussman, Eileen Dalston, and Sam Gumpert (Dept. of Commun. Sci. and Disord., Univ. of Texas, Austin, TX 78712, sussman@mail.utexas.edu)

Locus equations, as a phonetic descriptor of stop place of production, have been systematically investigated across speakers, gender, languages, perturbation conditions, syllable position, and manner class. As locus equation slope is thought to directly reflect the extent of anticipatory coarticulation of the vowel on the prevocalic consonant, changes in coarticulation as brought about by altered speaking styles can effectively alter locus equation descriptors of stop place. This study attempted to assess the stability of locus equations within each speaker as citation-style hyperarticulation was compared relative to spontaneous, hypoarticulated output. Twenty speakers, ten male and ten female served as subjects. Traditional citation-style locus equations were generated from productions of CV /t/ words printed on lists with initial /bdg/ followed by ten medial vowel contexts. Locus equations were also derived from spontaneous speech output which was generated by rapid reading of discourse-like passages constructed to resemble normal conversational speech, but with numerous lexical items beginning with /bdg/ in many vowel contexts. Spectral analysis was performed with the Kay Elemetrics CSL system. Comparisons of slopes, y intercepts, R^2, and standard error of estimates across the two speaking conditions will be presented and discussed.

4aSC25. Modeling the perception of features in the identification of English consonants. Tobey L. Doeleman (Dept. of Linguist., Cornell Phonet. Lab., Cornell Univ., Ithaca, NY 14853)

The perception of voicing, place, and manner was investigated in a series of gating experiments in which subjects identified eight English consonants in six different duration conditions [T. L. Doeleman, J. Acoust. Soc. Am. **101**, 3111(A) (1997)]. Subjects heard either all eight stimuli or two mutually exclusive subsets such that certain feature information was given (e.g., manner given in sets [p, t, b, d] and [f, s, v, z]). Although all subjects listened to the same 48 stimuli, identification significantly improved for subjects given place information (i.e., sets of labials and alveolars). The results are modeled using a spreading-activation connectionist model, the Integration-Competition model [Spivey-Knowlton (1996)]. In this model, the phoneme and feature representations compete with one another such that featural distinctions correspond to different weights assigned to the connection between feature and phoneme layers. The target phoneme has high activation from all featural arrays, resulting in the highest activation in the phoneme array. The increase in identification scores across duration conditions is modeled by the increase in activation of the target phoneme with successive time steps. The model also predicts observed consonant confusion patterns in that distracter phonemes sharing more features with the target phoneme will have higher activation levels.

4aSC26. Additive effects of phonetic distinctions in word learning. Joseph V. Pater (Dept. of Linguist., Univ. of Alberta, Edmonton, AB T6G 2E7, Canada, joe.pater@ualberta.ca), Christine L. Stager, and Janet F. Werker (Univ. of British Columbia, Vancouver, BC V6T 1Z4, Canada)

While infants have been demonstrated to be sensitive to a wide variety of phonetic contrasts when tested in speech discrimination tasks [Eimas *et al.* (1971) et seq.], recent work [Stager and Werker (1997)] has shown that following habituation to a word–object pairing, infants of 14 months fail to notice when the place of articulation of the initial consonant is switched [b/d]. Using the same procedure, the present study has found that infants do not respond to a change in voicing [b/p]. They do, however, notice a switch between dissimilar words [lɪf/nim]. One interpretation of these findings is that 14-month-olds do not encode either place or voice distinctions in lexical representations, so that words differing in only these features are treated as identical. To test this hypothesis, the effect of combining featural contrasts is currently being investigated by examining whether infants do respond to a change in both place and voice [d/p]. If there is such an additive effect, the contrasts must be represented. This would entail that an explanation for the failure to distinguish words differing in only a single feature should invoke processing factors, rather than representational ones.

4aSC27. Vowel perception by children and adults: Based on steady states or transitions? Joan E. Sussman, Jason Steinberg, and Julie Fenwick (Dept. of Communicative Disord. and Sci., State Univ. of New York at Buffalo, 122 Park Hall, Buffalo, NY 14260, jsussman@acsu.buffalo.edu)

The current investigation studied whether children, aged 4–5 years, and adults identified vowels on the basis of steady-state or transitional formant frequencies. Four types of synthetic tokens, created with a female voice, served as stimuli: (1) steady-state centers—220-ms formant frequencies for the vowels [i] and [ae]. (2) vowelless tokens with transitions appropriate for [bib] and [baeb], (3) ''congruent'' tokens that combined the first two types of stimuli into [bib] and [baeb], and (4) ''conflicting'' tokens that combined the transitions from [bib] with the vowel in [baeb] and vice versa. Results showed that children identified vowels most accurately in steady-state centers and congruent stimuli (96%) and used steady-state cues in 87% of conflicting tokens for vowel identification. Adults were equally accurate for vowelless, steady-state, and congruent tokens (99%) and used steady-state and transition cues for vowel identification. Findings do not support Nittrouer's Developmental Weighting Shift Hypothesis, but findings for adults do lend some support to the Dynamic Specification theory of Strange and colleagues. [Work supported by a Research Development Fund award from the Research Foundation at the University at Buffalo and by the Center for Hearing and Deafness at UB.]

4aSC28. Lexical competition in spoken word recognition by younger and older adults: A comparison of the rime cognate, neighborhood, and cohort. Mitchell S. Sommers (Dept. of Psych., Washington Univ., Campus Box 1125, St. Louis, MO 63130) and Shigeaki Amano (NTT Basic Res. Labs., 3-1 Morinosato-Wakamiya, Atsugi, Kanagawa, 243-01 Japan)

A central issue in research on spoken word recognition has been to specify the lexical candidates that are initially activated and compete during lexical discrimination. Amano [J. Mem. Lang. (submitted)] has recently proposed a new candidate set, the rime cognate (RC), which suggests that the set of potential lexical candidates consists of all items containing the same phoneme sequence as the rime (vowel nucleus plus coda) of that word. The present study was designed to compare the ability of the RC and two other sets, the neighborhood and cohort, to account for spoken word recognition in both younger and older adults. Density measures derived from the neighborhood were significantly correlated with identification scores for younger and older subjects. In contrast, RC density metrics were significantly correlated with identification scores only for older adults. Both neighborhood and RC density measures accounted for a greater percentage of the variance in spoken word recognition for older than for younger listeners. Metrics derived from the cohort were not significantly correlated with identification scores for either younger or older adults. The implications of these findings for several current models of spoken word recognition are discussed. [Work supported by the Brookdale foundation.]

4aSC29. Integration of auditory and visual speech information. Michael D. Hall, Paula M. T. Smeele, and Patricia K. Kuhl (Dept. of Speech and Hearing Sci., Univ. of Washington, Seattle, WA 98195, mdhall@u.washington.edu)

The influence of visual information on auditory speech perception can be observed under conditions where the two sources of information are discrepant [McGurk and MacDonald (1976)]. Recent studies from our laboratory [Hall *et al.* (1996)] focused on one such condition, where a face producing /b/ is combined with a dubbed auditory /g/ token, resulting in the frequent auditory perception of /bg/. These studies used auditory tokens that varied in quality, and have suggested that the probability of auditory consonant identification as /g/ was sufficient to predict the probability of /bg/ responses. The current study extended this approach to the converse conditions, where an auditory /b/ was dubbed on a visual /g/ production, which typically results in the frequent auditory perception of /d/ or /th/. Additionally, similarity ratings were collected for sets of auditory /g/ and /b/ stimuli, as well as for both types of auditory-visual conditions (/g/+/b/ and /b/+/g/). Multidimensional scaling (MDS) of these ratings was used to determine whether auditory category structure predicts MDS solutions for combined auditory and visual information. Implications of the results for the nature of auditory-visual speech integration will be discussed. [Work supported by NICHD.]

4aSC30. Speech-sound perception in normal and learning-disabled children: Effect of lengthened CV transition duration. Ann R. Bradlow, Nina Kraus, Trent Nicol, Therese McGee, Jenna Cunningham (Auditory Neurosci. Lab., Northwestern Univ., 2299 N. Campus Dr., Evanston, IL 60208, abradlow@nwu.edu), and Thomas D. Carrell (Univ. of Nebraska–Lincoln, Lincoln, NE 68538)

Previous research has established that many children with learning problems exhibit perceptual deficits in response to certain auditory stimuli, such as stop consonants in CV context. In order to investigate the precise acoustic features of stop consonants that pose perceptual difficulties for these children, discrimination thresholds were compared for normal and learning-disabled children along two separate synthetic /da/–/ga/ continua that differed only in the duration of the formant transitions. Results showed that simply lengthening the formant transition duration from 40 to 80 ms did not result in improved discrimination thresholds for the learning-disabled children. Similarly, an electrophysiologic response that is known to reflect the brain's preconscious ability to detect a change from one auditory stimulus to another indicated diminished responses in these children to /da/ versus /ga/, regardless of transition duration. This finding suggests that the brevity of the CV formant transitions is not the sole acoustic basis for the observed perceptual deficits. Furthermore, signal processing techniques aimed at enhancing perception of stop consonants likely need to consider other acoustic features, such as relative amplitude and frequency characteristics, instead of (or in addition to) CV transition duration. [Work supported by NIH R01 DC 01510.]

4aSC31. Listener variability and multiple perception processes. Stephanie Lindemann (Program in Linguist., Univ. of Michigan, 213 W. Mosley St., Apt. 6, Ann Arbor, MI 48103, lindeman@umich.edu)

The relationship between the perception of individual phonemes and the perception of words is investigated to determine if these are similar tasks for listeners. Since listeners may be able to use top-down processes in full words, it is argued that, at least for some, the task of identifying isolated phonemes may be very different from the task of identifying a full word. Because greater variability in performance is expected from non-native speakers, 15 native speakers of Sudanese Arabic (as well as a control group of 12 native speakers of American English) were tested on identification of American English phonemes in word context and the same instance of these phonemes extracted from the words. The overall agreement between corresponding items on the two tests was significantly better than chance, but scores of individual subjects varied substantially, with phoneme-word test agreement falling below chance for many subjects. Additionally, not all non-native subjects performed better on the full word task, suggesting that they do not all use higher-level information. It is therefore argued that studies of phoneme-level perception are more relevant to some listeners' word perception than to others'.

4aSC32. Effects of affective tone of voice on spoken word recognition. Lynne C. Nygaard, Jennifer S. Queen, and S. Alexandra Burt (Dept. of Psych., Emory Univ., Atlanta, GA 30322)

Traditionally, the study of emotional tone of voice has been considered separately from the study of formal linguistic aspects of spoken language. Research has typically focused either on how listeners detect emotion in an individual's voice, or on how listeners extract abstract linguistic content. The present study was designed to investigate how these two sources of information interact. In two experiments, listeners were presented with homophones that had one affective (happy or sad) and one neutral meaning and with nonhomophones that had either a happy, sad, or neutral meaning. Within each experiment, words were spoken in a tone of voice that was either congruent, incongruent, or neutral with respect to affective meaning. In the first experiment, naming latencies were collected to determine if tone of voice affects the speed of lexical processing. In the second experiment, transcription accuracy was assessed to determine if tone of voice affects the selection of word meaning. The results suggest that emotional tone of voice was used to resolve lexical ambiguity, but did not appear to affect specifically the time course of lexical access. The implications of these results for current theories of spoken word recognition will be discussed. [Work supported by NIH.]

4aSC33. On the perception of qualitative and phonetic similarities among voices. Robert E. Remez, Jennifer L. Van Dyk (Dept. of Psych., Barnard College, 3009 Broadway, New York, NY 10027-6598), Jennifer M. Fellowes (Columbia Univ. College of Physicians and Surgeons, New York, NY 10032), and Philip E. Rubin (Haskins Labs., New Haven, CT 06511)

A perceiver who learns to recognize an individual talker becomes familiar with attributes of the talker's voice that are present in any utterance regardless of the linguistic message. Customary accounts of individual identification by ear presume that such durable personal aspects of an individual's speech are graded qualities (e.g., vocal pitch and pitch range; melodious, breathy, or raspy timbre; etc.) independent of the acoustic properties that evoke segmental phonetic contrasts. Alternatively, some classic and recent studies alike suggest that familiarity includes attention to attributes of dialect and idiolect conveyed in the articulation of consonants and vowels. These linguistic phonetic properties of speech are effective for recognizing a talker when voice quality is eliminated as a source of information. The present investigation sought direct evidence of attention to qualitative and phonetic attributes of speech. Natural samples and sine wave replicas of sentences spoken by five male and five female talkers were used in a similarity tournament with adult listeners. The results establish the differential perceptual resolution of qualitative and phonetic attributes in the perception and recognition of talkers. [Work supported by NIDCD and NICHD.]

4aSC34. Perception of American English /r/ and /l/ by Mandarin speakers: Influences of phonetic identification and category goodness. Feng-Ming Tsao, Michael Hall, Richard Eyraud, and Patricia K. Kuhl (Dept. of Speech and Hearing Sci., Univ. of Washington, Seattle, WA 98195)

Studies in speech perception show a perceptual magnet effect for listeners which is characterized by shrunken perceptual distances near excellent exemplars of phonetic categories and stretched distances near poor exemplars. This study extended this work by examining the influence of Mandarin speakers' phonetic identification and category goodness on their perception of American English /r/ and /l/. Eighteen /ra/ and /la/ tokens were used that varied *F*2 and *F*3 frequencies. Listeners identified stimuli as Mandarin /u/, /m/, or /l/, provided goodness ratings for them, and rated the similarity of all stimulus pairs. Multidimensional scaling analyses of similarity ratings exhibited that the perceptual ''map'' for Mandarin speakers differs substantially from that of American speakers [Iverson and Kuhl, J. Acoust. Soc. Am. (1996)] listening to the same stimuli. The results indicate that (1) Mandarin speakers perceived /u/ and /l/ in the space, (2) perceptual distance was shrunk near the best exemplars of phonetic categories and stretched near the category boundary, (3) variations of *F*2 were more important than *F*3, and (4) individual differences in /l/ identification corresponded to a degree of shrinking near the best exemplars of the /l/ category. Results indicate that listeners use their native-language representations in the perception of a non-native language.

4aSC35. Non-native listeners' representations of within-word structure. Takashi Otake (Dokkyo Univ. and Max-Planck Inst. for Psycholinguistics, Wundtlaan 1, 6525 XD, Nijmegen, The Netherlands, otake@dokkyo.ac.jp), Kiyoko Yoneyama (The Ohio State Univ., Columbus, OH 43210-1298), and Hideki Maki (Salem-Teikyo Univ., Salem, WV 25426-0500)

Human listeners may form conscious representations of potential within-word structure in which lexicon is represented by some phonological units. An earlier study examining monolingual speakers of Japanese and English with native inputs suggests that levels of representation by Japanese speakers may be involved with richer knowledge of word-internal structure, while English speakers are sensitive to syllables [Otake *et al.*, Proceedings of EUROSPEECH 95 **3**, 1703–1706 (1995)]. The present study investigated how monolingual speakers of English learning Japanese could form conscious representations of potential within-word structure in Japanese. Three groups of subjects (*N*: 36, 33, and 40 for three different levels) were presented with 150 Japanese spoken words and asked to mark on a written transcript of each word the second natural division point from the onset in the word. The statistical analysis showed that all groups exploited syllables to represent Japanese words irrespective of Japanese proficiency. These results suggest that the exploitation of phonological unit to represent within-word structure in foreign inputs may be the same as the one in the native input as proposed by our recent pilot work (Otake and Yamamoto, 134th Meeting of the ASA **101**). [Work supported by Fulbright senior research grant and TAF.]

4aSC36. The discovery of natural classes by non-native listeners. John Kingston and Elliott Moreton (Linguist. Dept., South College 226, Univ. of Massachusetts, Amherst, MA 01003)

Using natural disyllabic stimuli, English speakers were trained to sort one, two, or three pairs of German nonlow rounded vowels into two categories, then a new pair was added and their ability to sort it into the same categories was tested. Each pair contrasted in [high], [tense], and [back]. Category membership was determined by only one of these features. Three-pair training provided enough information to tell which one; two-pair narrowed it down to two possibilities; one-pair left it open. Listeners in three experiments using different pairs of test vowels sorted the test vowels significantly better as the number of training pairs increased. This suggests they were inducing feature-based natural classes. The rival exemplar model of Nosofsky [J. Exp. Psych.: Gen. **115**, 39–57 (1986)] would say that while more pairs bring more phonetic variety, they also exemplify more robustly the dimensions along which the categories differ phonetically, and thereby shift attentional weight to those dimensions. Similar experiments will pit these two hypotheses against one another with training pairs which contrast only in the feature that defines the sort categories. If listeners are using feature-based natural classes, their performance should not improve with more training pairs; if they are using exemplars, it should. [Work supported by NIH.]

Signal Processing in Acoustics, Engineering Acoustics, Architectural Acoustics and Education in Acoustics: Acoustics in Multimedia—Systems Issues I

Daniel R. Raichel, Chair
Department of Mechanical Engineering, Steinman Hall, The City College of The City University of New York, New York, New York 10031

Invited Papers

8:00

4aSP1. *The Journal of the Acoustical Society of America* and other technical journals of the future—a new multimedia format? Daniel R. Raichel (Dept. of Mech. Eng., Steinman Hall, The City College of The City Univ. of New York, New York, NY 10031)

The *Journal of the Acoustical Society of America (JASA)* is now available in two formats—the traditional printed issue and the CD-ROM. However, CD-ROMs are in the early process of being displaced by the newer, more powerful DVDs which feature a capacity of approximately 2.8 GB per disk side rather than the 650 MB standard for each CD-ROM. CD-ROMs, however, will not immediately be rendered obsolete by the use of a current DVD player since the latter is backward compatible for CD-ROM playback. However, even in the CD-ROM format, a technical journal can take on new aspects of multimedia, which were hitherto unavailable or impracticable in printed media. The greatly enhanced capacity of the DVD disk provides even greater opportunities for extended expositions. Animation scenes, photographs, extended databases which would not have otherwise been included in a printed article, dynamic plots, sound effects, virtual reality scenes which permit one to ''visit'' laboratory sites or ''witness'' the topical phenomena, and even computer programs and entire reproductions of cited references can be incorporated in an article slated for publication on the new multimedia disks or on future storage devices.

8:25

4aSP2. Mediacoustics, a software package on CD for teaching acoustics using multimedia techniques. Michael Wahlrab (01dB, Inc., P.O. Box 796, Skaneateles, NY 13152)

Mediacoustics uses multimedia techniques on CD for teaching acoustics. It is divided into four study areas: basic physics, noise and man, room acoustics, and noise control. Sound clips, text, pictures, photos, and video animation illustrate each module. The index and chapters may be edited. Individual text passages may be annotated and an included acoustical dictionary provides definitions of common terms and formulas. Any contemporary multimedia computer equipped with a sound card and amplified loudspeaker can be used to access Mediacoustics and its hundreds of video clips.

8:50

4aSP3. Animations created in *Mathematica* for acoustics education. Victor W. Sparrow (Grad. Prog. in Acoust., Penn State Univ., University Park, PA 16802) and Daniel A. Russell (Kettering Univ., Flint, MI 48504)

One of the unifying assumptions in acoustics and vibrations is that waves and structures move and vibrate. In teaching these topics it makes sense to show students exactly HOW things move. For the last several years the authors have been using the symbolic manipulation program *Mathematica* [Wolfram Research, Inc., Champaign, IL] to produce brief animations for teaching acoustics. World Wide Web sites have been created for easy access to the animations by all students. The present paper will explain how the animations are created and will demonstrate several including one and two degrees of freedom oscillators, a piston in a tube, reflected waves, doppler effect, elastic waves, circular membranes, and circular plates. The current animations are relatively simple constructions to keep the file sizes to a minimum. However, improved animations containing substantially enhanced graphics will be possible with Internet 2.

4aSP4. A software teacher for acoustical measurements. Ila Tokola, Matti Karjalainen, and Martti Rahkila (Helsinki Univ. of Technol., Lab. of Acoust. and Audio Signal Processing, P.O. Box 3000, FIN-02015, Helsinki, Finland)

The huge development in computer technology has made it tempting to use computers in acoustics education. QuickSig, an object-oriented Common Lisp based signal processing environment has been used for acoustical measurements. It provides an excellent means to present graphics and handle signals, and it is easy to program for educational purposes as well. A Simple Loudspeaker Measurement Program is a Computer Based Education (CBE) application for self-studying of acoustical measurements. The application deals with free-field measurements of loudspeakers and related theory. The measurements are actually made with the program and genuine results are achieved each time. The software teacher interactively helps the student to obtain results that make sense and monitors the progress with multiple-choice questions. The results can also be

saved for post-processing. The main difference between this application and on-line help systems in measurement packages is that the teacher emphasizes learning of acoustical measurements, not the measurement software itself! On the other hand, with this application, the students do real measurements, including the loudspeaker and microphone setup in an anechoic chamber, unlike most self-study CBE applications. Furthermore, the application can be used also by engineers, technicians, etc. for assisted measurements.

4aSP5. Design and development of PC-IMAT. John W. Schuler (Naval Personnel Res. and Development Ctr., Armstrong Lab., Brooks AFB, TX 78235) and Murray S. Korman (U.S. Naval Acad., Annapolis, MD 21402)

NPRDC has been tasked to provide empirical evidence of effective instructional strategies for the acquisition of conceptual knowledge under the project name PC-IMAT (Personalized Curriculum for Interactive Multisensor Analysis Training). The domain to be investigated and demonstrated includes those concepts required for the successful planning and execution of antisubmarine warfare (ASW), specifically, the conceptual knowledge underlying the prediction of sound transmission paths and detection ranges. Navy-standard models which are used in fleet SONAR prediction systems are available to support the learners' conceptual understanding of the elements of the oceanographic environment which affect acoustic propagation. To date, these models are employed in a microcomputer based, stand-alone delivery architecture in both a linear interactive courseware (ICW) format and in modules suitable for independent exploratory learning. Midshipmen taking SP411 (Underwater Acoustics and Sonar) are currently using PC-IMAT to help investigate what are the effective instructional strategies which convey understanding of a complex multivariate domain (like ray trace or propagation loss models). Research on ''scientific visualization'' (to enhance comprehension and retention) and student feedback will also be used to help develop and evaluate other training materials including beamforming, reverberation, target motion analysis, and scattering. [Work supported by ONR.]

4aSP6. Construction of a HATS and its HRTF measurement for 3-D sound. Kyeong Ok Kang, Dong-Gyu Kang, Min-Soo Hahn (Elec. and Telecom. Res. Inst., P.O. Box 106, Yusong Post Office, Taejon, 305-600, Korea, kokang@audio.etri.re.kr), Mun-Jae Jho (Korea Res. Inst. of Standards and Sci., Taejon, Korea), and Dae-Kwon Jeong (Korea Aviation Univ., Koyang, Korea)

Based on the anthropometric data on the head and torso dimensions in Korean male adults, a head and torso simulator (HATS) was constructed. Data, which have no counterparts in the Korean standards, were used with ANSI S3.36-1985. Measuring microphones can be positioned at the eardrum or at the ear canal entrance according to measuring purposes. Head related transfer functions (HRTFs) for the HATS, i.e., binaural impulse responses, were measured at 710 points on a spherical surface of radius 1.55 m using a burst maximum length sequence (MLS) signal of 65 535 samples in an anechoic chamber. The measurement system consists of one part to generate the MLS signal and to drive a Boss 101A loudspeaker and another part to record the output signal of a microphone in the HATS and consequently to measure the impulse response. Also measured were the impulse responses of the driving loudspeaker and some headphones for 3-D sound reproduction in order to get the exact HRTF of the HATS-alone. The impulse-version HRTFs at the sampling frequency of 44.1 kHz, which have filter lengths of 512 points with minimum phase characteristics and can be used for 3-D sound, were finally obtained through a post-processing procedure.

10:15

4aSP7. Measuring and modeling the effect of source distance in head-related transfer functions. Jyri Huopaniemi and Klaus A. J. Riederer (Helsinki Univ. of Technol., Lab. of Acoust. and Audio Signal Processing, P.O. Box 3000, FIN-02015, Helsinki, Finland)

Efficient modeling of human spatial hearing by digital filter approximations of head-related transfer functions (HRTFs) is the key technology in 3-D sound processing. It is well known that the HRTF bears the major static localization cues, the interaural time difference (ITD), and the interaural level difference (ILD) that are functions of frequency and the incident angle of arrival. The effect of source distance has, however, often been neglected in HRTF models. In this paper, a method for efficient distance-dependent HRTF modeling is presented, which is based on both theoretical and empirical data. HRTF measurements on eight human subjects and one dummy head were carried out at two source distances, 2 and 0.65 m. It has been argued in the literature that the distance changes mainly affect the ILD, whereas the ITD remains approximately constant. Based on this finding, which was also supported by the measurements performed in this study, a filter structure that models the ILD change as a function of distance was derived. The results of this study are applicable to many near-field listening applications.

9:20

4aUW1. The penetrable wedge as a three-dimensional benchmark. Grant B. Deane (Scripps Inst. of Oceanogr., La Jolla, CA 92003)

In 1989, members of the Acoustical Society of America developed a suite of range-dependent benchmark geometries, allowing the underwater acoustics community to compare the performance of analytical and numerical solutions to two-dimensional propagation problems. These benchmarks were successful in providing the acoustics community with a set of standards, and continue to be useful as reference geometries. Over the past decade, there have been significant advances in analytical and numerical solutions to three-dimensional propagation problems, and establishing three-dimensional benchmarks is a timely development. A useful benchmark must eliminate the undesired complications of a real-word environment but retain the essential physics of the problem while being tractable to a variety of modelers. A geometry which satisfies these constraints is the ocean wedge with a penetrable basement. The three-dimensional Green's function for the penetrable wedge has already been studied by a number of investigators, and measured with scale-model tank experiments. The state of modeling and measurement for the wedge will be discussed in the context of its usefulness as a three-dimensional benchmark.

9:40

4aUW2. Three-dimensional propagation effects: Modeling, observations, and suggested benchmark cases. Kevin B. Smith (Dept. of Phys., Naval Postgrad. School, Monterey, CA 93943, kevin@physics.nps.navy.mil)

Over the past several years, many acoustic propagation models have been adapted to compute the influence of azimuthal coupling. These so-called three-dimensional (3-D) models should provide more accurate predictions of the acoustic field in 3-D variable environments than previous 2-D$\times$N models. However, such advanced 3-D propagation models are generally slower than their 2-D $\times$N predecessors. It is, therefore, important to understand the significance of the difference between 3-D and 2-D$\times$N and when such effects should be considered. Furthermore, as of this date, no formal set of benchmark cases and solutions has been defined to test the accuracy of the various 3-D models currently being used. This paper will provide a general overview of 3-D propagation models and how they can be used to assess the significance of azimuthal coupling in ocean acoustics. Specific examples of such influences will be provided from a 3-D parabolic equation model and compared to results from the corresponding 2-D$\times$N version. Of particular interest will be the pseudo-3-D effects predicted by 2-D$\times$N calculations and the ability to distinguish true 3-D effects in experimental data. Finally, several environmental scenarios will be suggested as possible benchmark cases for future studies. [Work sponsored by ONR Code 321OA.]

10:00

4aUW3. Experimental measurements of three-dimensional underwater sound propagation over a variable bathymetry. Stewart A. L. Glegg, Joseph M. Riley, and Antony LaVigne (Ctr. for Acoust. and Vib., Dept. of Ocean Eng., Florida Atlantic Univ., Boca Raton, FL 33431)

There appear to be very few experimental measurements of the three-dimensional features of sound fields in the ocean, especially in shallow water where bottom interactions can have a dominant effect. One of the reasons for this lack of experimental data can be attributed to the difficulty in designing an experiment to identify three-dimensional propagation effects. Bathymetric refraction occurs, for the most part, on a very large scale and so to differentiate between local variability of the propagation and refraction by a bathymetric feature, measurements have to be carried out simultaneously over a large area. This is easier to achieve in the laboratory environment where repeatability of the experimental results is not an issue. This paper will describe a series of laboratory scale experiments which were carried out to identify the major features of underwater sound propagation over a realistic three-dimensional bathymetry. The model used is based on the bathymetry of the Santa Lucia Escarpment, but is not unlike bathymetry found in other coastal regions in different water depths if the correct scaling is used. A number of three-dimensional sound maps will be shown of the field from a point source. [Work supported by ONR.]

10:20

4aUW4. Three-dimensional sound propagation modeling of the Santa Lucia escarpment data. Michael B. Porter (Marine Physical Lab., Code 0205, 8602 La Jolla Shores Dr., La Jolla, CA 92037, porter@mpl.ucsd.edu)

The KRAKEN normal-mode program includes options for both $N\times 2$-D and full 3-D modeling. The latter is implemented using Gaussian beams to treat the horizontal refraction of modes. Since the model allows for mixed acoustoelastic problems, 3-D sound propagation can be simulated over ocean bottoms supporting shear waves. To study its accuracy, the model is applied to several 3-D scenarios, including both a simple wedge and a topographically complicated case based on the Santa Lucia escarpment off the coast of California. The results are compared to the laboratory scale data presented by Glegg *et al.* in this session.

10:35–10:40 Break

10:40

4aUW5. Benchmarking two three-dimensional parabolic equation methods. Frederic B. Sturm (Lab. M.N.C., I.S.I.T.V, Université de Toulon, France), John A. Fawcett, and Finn B. Jensen (SACLANT Undersea Res. Ctr., 19138 La Spezia, Italy)

Results of acoustic propagation modeling using two different three-dimensional parabolic equation methods are presented. One model [J. Fawcett, J. Acoust. Soc. Am. **93**, 2627–2632 (1993)] uses standard splitting and operator approximations while the other method [F. Sturm, M. Pélissier, and D. Fattaccioli, *Proc. of the Third European Conference on Underwater Acoustics*, 243–248 (1996)] does not split the azimuthal operator and maps the bathymetry into an equivalent flat bottom problem. Examples of propagation over wedge and corrugated bathymetries are considered for different frequencies. Both point-source and modal initial fields are used. The three-dimensional solutions exhibit interesting three-dimensional refractive effects. The convergence of the solutions with respect to azimuthal discretization is also discussed.

10:55

4aUW6. Parabolic equation modeling with the split-step Fourier algorithm in four dimensions. F. D. Tappert (Appl. Marine Phys., Univ. of Miami, RSMAS, Miami, FL 33149, ftappert@rsmas.miami.edu)

Fully range-dependent 3-D (with coupled azimuths) single-frequency PE/SSF models have existed for many years, and 2-D (vertical plane at fixed bearing) wide-angle broadband PE/SSF models have existed for even longer. By combining these, a 4-D (three space dimensions plus time) PE/SSF model has been developed that runs on a desktop computer. This model is exactly reciprocal if ocean currents are omitted, and is exactly energy conserving if absorption is omitted. Examples of model predictions, projected onto two dimensions, are displayed for shallow water propagation. In a situation where ray chaos due to variable bathymetry is strong, plots of intensity as a function of travel time and bearing at fixed depth and range are especially interesting. [Work supported by ONR.]

11:10

4aUW7. Three-dimensional ocean acoustics: Techniques and examples. Michael D. Collins, Joseph F. Lingevitch, and Gregory J. Orris (Naval Res. Lab., Washington, DC 20375, collins@ram.nrl.navy.mil)

The method of matched asymptotics can be used to solve scattering problems involving a compact object in a waveguide [M. D. Collins and M. F. Werby, J. Acoust. Soc. Am. **85**, 1895–1902 (1989)]. This approach involves different asymptotic limits in different regions. In the inner region near the object, the Green's function can be approximated by either the free-space or half-space Green's function depending on the vertical location of the object. The inner problem is therefore the free-space or half-space scattering problem. The outer solution satisfies the three-dimensional parabolic equation. When horizontal variations in the waveguide are sufficiently gradual, the solution is asymptotic to a specular point source for $ka=O(1)$. This approximation can be improved by including a vertical dipole correction. The three-dimensional parabolic equation has been applied to free-space scattering problems by solving the exterior problem for the scattered field directly [M. F. Levy and A. A. Zaporozhets, J. Acoust. Soc. Am. **103**, 735–741 (1998)]. This approach is also useful for some waveguide scattering problems. [Work supported by ONR.]

11:25

4aUW8. Limitations on adiabatic normal modes in range-varying environments. Peter C. Mignerey (Acoust. Div. 7120, Naval Res. Lab., Washington, DC 20375-5350, mignerey@nrl.navy.mil)

Curvilinear coordinates are used to extend adiabatic normal modes to weak range-dependent environments including those with sloping bottoms. Reciprocal vertical wave numbers of a reference mode provide the coordinate scale factors. This approach is valid for negligible horizontal derivatives of intermodal vertical-wave number ratios. Large gradients in the bottom impedance make these ratios large, implying significant mode coupling in oceanic regions spanning both soft and hard terrains. Additionally, a large number of eigenvalues are needed to compute adiabatic normal-mode solutions for high-resolution acoustic fields. The direct solution of eigenvalue problems on a fine grid is often prohibitive. Alternatively, the eigenvalues may be interpolated to the fine grid. This approach usually requires extrapolation toward edges across which the horizontal wave number becomes imaginary at mode cutoff. One choice for an interpolation function is the integrated reciprocal vertical wave number. This function, proportional to water depth, is smooth and real throughout the cutoff region, while causing the horizontal wave number to vanish along the cutoff line. [Work supported by the Office of Naval Research and partially by DOD High Performance Computing facilities at NRL.]

4aUW9. Three-dimensional acoustic effects due to ocean currents. Oleg A. Godin (School of Earth and Ocean Sci., Univ. of Victoria, P.O. Box 1700, Victoria, BC V8W 2Y2, Canada, ogodin@uvic.ca)

In the presence of currents, vertically stratified fluids become acoustically anisotropic in the horizontal plane and the group and phase velocities of the acoustic normal mode are generally not parallel. In this paper, the resulting 3-D effects and their implications for acoustic monitoring of ocean currents are discussed in terms of the normal modes. The sensitivity of various acoustic quantities to the vertical and in-plane and out-of-plane horizontal components of the flow velocity is estimated. Despite anisotropy, there is no azimuth coupling at long-range sound propagation in a stratified moving medium. When a waveguide varies in the horizontal plane, the 3-D effects due to current-induced anisotropy and horizontal refraction are superimposed. The relative importance of these two phenomena in shallow- and deep-water scenarios is analyzed by considering horizontal (modal) rays in the presence of currents. For the purposes of numerical simulations, a parabolic approximation is considered for sound in a moving fluid. A new parabolic equation is proposed for efficient numerical modeling of the 3-D acoustic effects in the ocean with currents. [Work supported by NSERC.]

4aUW10. Three-dimensional solutions to range-dependent problems in shallow water by a pseudo-spectral method. Altan Turgut and Stephen N. Wolf (Naval Res. Lab., Acoust. Div., Washington, DC 20375)

A pseudo-spectral method is used to solve the acoustic and elastic wave equations in the time domain. The application of such a computation and memory-intensive method to shallow-water propagation and scattering problems is discussed. Three-dimensional solutions are given for two

different shallow-water related problems: pulse propagation through solitary internal waves and pulse scattering from bottom inhomogeneities. The size of a typical computational domain for both problems is about (30 wavelength)^3. However, for the propagation problem, distances up to several hundred wavelengths have been achieved by moving the computational domain with the wavefront. The accuracy of the pseudo-spectral method has been checked with analytical solutions to simpler problems. Two-dimensional results of moving-domain approach are compared to those of single-domain and good agreement is observed. The existing method is expected to confirm the accuracy of the approximate solutions such as PE in a complicated range-dependent environment. [Work supported by ONR.]

THURSDAY MORNING, 25 JUNE 1998 GRAND BALLROOM III (W), 11:00 A.M. TO 12:00 NOON

Session 4aPLb

Plenary Lecture

Donna L. Neff, Chair

4aPLb1. Psychoacoustics of cochlear hearing impairment and the design of hearing aids. Brian C. J. Moore (Dept. of Experimental Psych., Univ. of Cambridge, Downing St., Cambridge CB2 3EB, England, bcjm@cus.cam.ac.uk)

Cochlear hearing impairment is usually associated with damage to the hair cells within the cochlea. When the damage is restricted to the outer hair cells (OHCs), the main consequence is disruption of the ''active'' mechanism which normally enhances the response of the basilar membrane to weak sounds and which sharpens the tuning (frequency selectivity) of the basilar membrane. Psychoacoustically, damage to OHCs results in loss of sensitivity (elevated absolute thresholds), loudness recruitment, and reduced frequency selectivity. Damage to the inner hair cells (IHCs) causes basilar membrane vibrations to be transduced less effectively, so absolute thresholds are elevated, but does not result in altered frequency selectivity or loudness recruitment. Sometimes, IHCs and/or neurons may be completely inoperative at certain places within the cochlea, giving rise to ''dead regions.'' Such regions can strongly influence the perception of pitch and loudness. Current hearing aids can partially compensate for the effects of loudness recruitment by using compression amplification, but there is much controversy about the ''best'' form of compression. The deleterious effects of reduced frequency selectivity on speech intelligibility in noise can be alleviated by various methods for improving the speech-to-noise ratio, although so far only directional microphones have given clear benefits.

Meeting of the Standards Committee Plenary Group

ORGANIZATION OF STANDARDS COMMITTEE PLENARY GROUP MEETING

S1 Acoustics—U.S. Technical Advisory Group (TAG) for IEC/TC 29 Electroacoustics and ISO/TC 43 Acoustics

S3 Bioacoustics—U.S. Technical Advisory Group (TAG) for ISO/TC 43 Acoustics, IEC/TC 29 Electroacoustics, and ISO/TC 108/SC4 Human Exposure to Mechanical Vibration and Shock

S12 Noise—U.S. Technical Advisory Group (TAG) for ISO/TC 43/SC1 Noise and ISO/TC 94/SC12 Hearing Protection

The meeting of the Standards Committee Plenary Group will precede the meetings of the Accredited Standards Committees S1, S3, and S12, to take place in the following sequence on the same day: S12—9:30 a.m. to 11:30 a.m., St. Helens Room; S3—2:00 p.m. to 3:15 p.m., St. Helens Room; S1—3:30 p.m. to 4:45 p.m., St. Helens Room.

Discussion at the Standards Committee Plenary Group meeting will consist of national items relevant to all S Committees, plus a review of the international standardization (U.S. TAG) activities including reports on recent meetings and planning for forthcoming meetings.

Members of S2 on Mechanical Vibration and Shock (and U.S. TAG for ISO/TC 108 and five of its Subcommittees, SC1, SC2, SC3, SC5, and SC6) are also encouraged to attend the Standards Committee Plenary Group meeting, even though the S2 meeting will take place one day earlier, on Wednesday, 24 June 1998 at 9:00 a.m.

The U.S. Technical Advisory Group (TAG) Chairs for the various international Technical Committees and Subcommittees under ISO and IEC, which are parallel to S1, S2, S3, and S12 are as follows:

U.S. TAG Chair/Vice Chair	TC or SC	U.S. TAG
ISO		
P. D. Schomer, Chair H. E. von Gierke, Vice Chair	ISO/TC 43 Acoustics	S1 and S3
P. D. Schomer, Chair H. E. von Gierke, Vice Chair	ISO/TC 43/SC1 Noise	S12
E. H. Berger, Chair	ISO/TC 94/SC12 Hearing Protection	S12
J. Erdreich, Chair H. E. von Gierke, Vice Chair	ISO/TC 108/SC4 Human Exposure to Mechanical Vibration and Shock	S3
D. J. Evans, Chair	ISO/TC 108 Mechanical Vibration and Shock	S2
R. H. Mehta, Chair K. Won, Vice Chair	ISO/TC 108/SC1 Balancing, including Balancing Machines	S2
A. F. Kilcullen, Chair	ISO/TC 108/SC2 Measurement and Evaluation of Mechanical Vibration and Shock as Applied to Machines, Vehicles and Structures	S2
B. E. Douglas, Chair	ISO/TC 108/SC3 Use and Calibration of Vibration and Shock Measuring Instruments	S2
D. J. Vendittis, Chair	ISO/TC 108/SC5 Condition Monitoring and Diagnostics of Machines	S2
G. Booth, Chair	ISO/TC 108/SC6 Vibration and Shock Generating Equipment	S2
IEC		
V. Nedzelnitsky, U. S. TA	IEC/TC 29 Electroacoustics	S1 and S3

Meeting of Accredited Standards Committee S12 on Noise

P. D. Schomer, Chair S12, and Chair U. S. Technical Advisory Group (TAG) for ISO/TC 43/SC1, Noise
U. S. CERL, P.O. Box 9005, Champaign, Illinois 61826-9005

B. M. Brooks, Vice Chair, S12
Brooks Acoustics Corporation, P.O. Box 3322, Vernon, Connecticut 06066

H. E. von Gierke, Vice Chair, U.S. Technical Advisory Group (TAG) for ISO/TC 43/SC1, Noise
1325 Meadow Lane, Yellow Springs, Ohio 45387

E. H. Berger, Chair, U. S. Technical Advisory Group (TAG) for ISO/TC 94/SC12, Hearing Protection
E-A-R/Aearo Company, 7911 Zionsville Road, Indianapolis, Indiana 46268-1657

Accredited Standards Committee S12 on Noise. Working group chairs will report on their progress for the production of noise standards.

SCOPE OF S12: Standards, specifications and terminology in the field of acoustical noise pertaining to methods of measurement, evaluation and control; including biological safety, tolerance and comfort and physical acoustics as related to environmental and occupational noise.

Session 4pAAa

Architectural Acoustics: Case Study on the New Tokyo International Forum

J. Christopher Jaffe, Chair
Jaffe Holden Scarbrough Acoustics, Inc., 114A Washington Street, Norwalk, Connecticut 06854

Chair's Introduction—1:00

Invited Papers

1:15

4pAAa1. Role of the acoustic advisors in the design of the Tokyo International Forum. Teruji Yamamoto (Toho Univ., Funabashi, Japan), Hideki Tachibana (Univ. of Tokyo, Japan), and Christopher Jaffe (Jaffe Holden Scarbrough Acoust., Inc., 114A Washington St., Norwalk, CT 06854)

The Tokyo Municipal Government appointed two acoustical advisors to review the acoustic design criteria developed for the Tokyo International Forum, Dr. Teruji Yamamoto and Dr. Hideki Tachibana. This paper describes the role of acoustic advisors on such a large project and show how they were able to assist the design team throughout the design and construction of the complex. Items to be covered include: process of design competition, acoustic requirements, process of acoustical design, outline of construction; and acoustical check during and after construction.

1:45

4pAAa2. Room acoustic designs for the Tokyo International Forum. Christopher Jaffe, Mark Holden, Russell Cooper (Jaffe Holden Scarbrough Acoust., Inc., 114 A Washington St., Norwalk, CT 06854, dcoppola@jhsacoustics.com), T. Kobayashi, and F. Kawakami (Yamaha Acoust. Res. Labs., Hamamatsu, Japan)

The room acoustic design of the Tokyo International Forum centered around the four performance halls: the convention center, the atrium, and the large multi-use meeting/dining halls. This paper will describe the program use of each space and the acoustic criteria developed to meet these requirements. Major emphasis will be placed on Hall A, a 5000-seat congress hall that was to be used to unamplified symphonic concerts and operas as well as highly amplified Broadway musicals and rock concerts, and Hall B, a 1500-seat classical music hall and piccolo opera house that also would be used for conferences and popular entertainment. A unique architectural

feature of Hall B is the first design and installation of a Concert Hall Shaper, a device that enables a proscenium theatre with a stagehouse to be converted to a single acoustic volume for events such as symphony concerts requiring a longer reverberation time. Hall C, an extremely flexible space for fashion shows, summit meetings, and large receptions, and Hall D, another versatile space for theater, recitals, and live television productions, will also be described.

2:15–2:25 Break

2:25

4pAAa3. Sound and vibration control for the Tokyo International Forum. Fukushi Kawakami, Tetsu Kobayashi (Yamaha Acoust. Res. Labs., Hamamatsu, Japan), Christopher Jaffe, Mark Holden, and Russell Cooper (Jaffe Holden Scarbrough Acoust., Inc., Norwalk, CT 06854)

The acousticians for the Tokyo International Forum were faced with a number of very severe noise and vibration problems related to the siting of the complex in the center of downtown Tokyo, the placement of the performance halls next to one another, and the location of a portion of the mechanical equipment on the roof. In addition, subway lines ran parallel to three of the boundaries of the structure, another line ran under the building, and the main tracks of Japan Rail ran above ground alongside the major atrium. This paper will discuss the noise criteria set for the performance rooms and other noise sensitive spaces, the noise and vibration measurements taken to determine the severity of the train-related conditions, predictions of other noise and vibration sources, and the solutions developed by the design team to meet the criteria required by the program. Among the solutions are a secant wall surrounding the foundation, box in box construction for the four performance halls, blocking mass installations at key locations throughout the steel skeleton of the complex, and isolation joints and sound locks between the performance rooms.

2:55

4pAAa4. Design of sound reinforcement and acoustic field control systems for the Tokyo International Forum. Christopher Jaffe, Mark Holden, Paul Scarbrough, David Robb (Jaffe Holden Scarbrough Acoust., Inc., 114A Washington St., Norwalk, CT 06854, dcoppola@jhsacoustics.com), Yasushi Shimizu, Shinjirou Yamashita, and Fukushi Kawakami (Yamaha Acoust. Res. Labs., Hamamatsu, Japan)

The extremely varied program use of the four performance halls at the Tokyo International Forum provided the electroacoustic designers with a number of extremely challenging problems. This paper describes the events that were to take place in all of the rooms, the designs selected to accommodate these programs, and the coordination of the design of the electroacoustic systems with the room acousticians, the architects, and the theater consultants. Of special interest is the design of the sound systems for Hall A, the 5000 seat symphony/congress hall which was to be used for opera and symphony performances without employing close-in microphone amplification techniques, and Hall D, which was to be used for live theater and recitals as well as television productions. The final portion of the paper will discuss the sound contractor's role in completing such an immense project and in particular the relationship that contractors have with designers and owners in Japan.

3:25–3:55 Discussion

Contributed Papers

All posters will be on display from 1:00 p.m. to 5:30 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 3:15 p.m. and contributors of even-numbered papers will be at their posters from 3:15 p.m. to 5:30 p.m.

4pAAb1. Early sound distribution in auditorium. Jiqing Wang and Guorong Jiang (Inst. Acoust., Tongji Univ., 1239 Sipin Rd., Shanghai 200092, PROC)

It is known that the strength of the audience area of a hall is largely dependent on the early sound, i.e., the direct sound and the first reflections. They are varied not only with reverberation time, but also with the geometry of the room, the absorption arrangement of the room, and the location of the source and(or) the receiver. Results from digital simulation and field measurements in halls show that the attenuation rate of early sound with the distance between the source and the receiver is much larger than ordinary predictions. It is more rational in complying with the subjective judgment. Therefore it should not be ignored in the acoustical design of a hall.

4pAAb2. The late reverberation time as a new criteria for the evaluation of hall acoustics. V. J. Stauskis (Vilnius Gediminas Tech. Univ., Saulėtekio al. 11, 2040 LT Vilnius, Lithuania)

Investigations show that the field decay after-35 dB has its reverberation values, which differ considerably from the values of the standard reverberation time. The experiment was carried out in a rectangular hall measuring $13.6\times10.7\times7.0$ m. The sound absorption coefficients of all planes in the hall were small (0.02–0.05). One hundred seventy semi-upholstered chairs were used for the experiment. When the chairs were placed in the hall, the decrease in the field of a nonfiltered signal was sudden and pronounced, while in the interval from 1500–4000 ms it was slow. The experiments with the filtered signal showed that, at any frequencies, there existed both the initial sudden and the late slow decrease in the sound field energy. The higher the frequency, the longer the interval of the slow decrease in the sound field. When approximating the decrease from -35 to -40 dB, the reverberation time was 15 s at 250 Hz and 4000 Hz. When approximating the decrease from -45 to -50 dB, the reverberation time was as long as 20–21 s within the frequency range of 500 to -2000 Hz.

4pAAb3. Study on acoustic index variations due to small changes in an observation point. Katsuaki Sekiguchi (College of Sci. and Technol., Nihon Univ., Suragadai, Kanda, Chiyoda-ku, Tokyo, 101 Japan, sekiguch@arch.cst.nihon-u.ac.jp) and Toshiki Hanyu (Junior College of Nihon Univ., Narashinodai, Funabashi, Chiba, 274 Japan)

Acoustic index variations due to small changes in an observation point in a concert hall were studied. Three kinds of methods were used in order to measure the acoustic indexes: (1) one point measurement using a single channel microphone; (2) binaural measurement using a dummy head microphone; and (3) the regular tetrahedron peak point method using a 4-channel microphone system. The acoustic index variations in each of the methods were analyzed. In addition, subjective experiments were performed in order to evaluate the effects of the variations. Compared to these measurements, problems with the acoustic indexes which were analyzed by each of the methods were found. One point measurement may incorrectly evaluate a concert hall.

4pAAb4. Effects of the spatial information of a sound field on listener envelopment. Toshiki Hanyu (Junior College of Nihon Univ., Narashinodai, Funabashi, Chiba, 274 Japan, hanyu@arch.jcn.nihon-u.ac.jp) and Sho Kimura (Nihon Univ., Surugadai, Kanda, Chiyoda-ku, Tokyo, 101 Japan)

The spatial information of sound fields in various kinds of concert halls as virtual sound-source distributions and short-term directional diffusion factors were measured. It is clear that the spatial information in a concert hall is characterized by how the reflections surround a listener. Accordingly, the relationship between the spatial information and listener envelopment was studied. First, subjective experiments were performed using a simulated sound field in an anechoic room in order to study the effects of lateral energy ratios on listener envelopment. As a result, the lateral energy ratios were not sufficient to evaluate listener envelopment. The research demonstrates that listener envelopment is not only related to

late arriving reflections but also to early reflections. In addition, listener envelopment is related to the spatial distributions of the reflections that surround a listener. Furthermore, the implications for concert hall design were discussed.

4pAAb5. An evaluation method of concert hall acoustics. Y. Hirasawa (Faith, Inc., Form-Gokomachi 583, Gokomachi-Ebisugawa, Kyoto, 604 Japan) and Z. Maekawa (Environ. Acoust. Lab., Oyodonaka, 4-13-11, Osaka, 531 Japan, nd7j-mekw@asahi-net.or.jp)

A lot of objective physical parameters for acoustic evaluation of a concert hall have been proposed. However, no one can believe that they provide a perfect method for designing a concert hall. There is a problem with the measuring method of physical parameters, i.e., almost all acoustical measurements in a hall use an omni-directional loudspeaker, which is not similar to most musical instruments. Also, no parameter specifies tone-color or sonority of music performance. These are important factors in evaluating concert hall acoustics. The remaining problems must be considered as follows: (1) The position of sources on a stage changes tone-color and generating sound power. (2) The directivity of sources gives different effects on room acoustics at the same position on the same stage. (3) Each musical instrument has its own important frequency range. What instrument shall be selected properly and what execution of the instrument shall be adopted for evaluation? (4) What is a suitable program of music for evaluation of hall acoustics? Some examples of the problems upon sources and its performance with using real musical instruments, and the remaining problems for evaluations of the concert hall will be presented.

4pAAb6. Acoustical behavior of churches: Gothic-Mudejar churches. Juan J. Sendra, Teófilo Zamarreño, and J. Navarro (School of Architecture of Seville, Avda Reina Mercedes s/n, 41012 Sevilla, Spain)

Traditionally, a particularly good acoustic behavior has been assigned to Christian churches. But this statement, which is not true at all, has led to important errors in church rehabilitation works, more so in those that implicate changes of use, such as auditoriums or theatrical halls, which is the case of many churches in Spain. This research group has worked in acoustical analysis for more than ten years, and has participated in many cases of church rehabilitation, among which is acoustical behavior. We are talking about a type of church very common in the south of Spain, Gothic-Mudejar churches. They are churches with these common characteristics: relatively little volume, plants with three naves, and wooden ceilings. With this work, significant conclusions drawn from the acoustical analysis of ten churches of Seville that respond to this type are presented. Their characteristics are quite homogeneous, so it is possible to get conclusions about the acoustical conditions of this ecclesiastical type.

4pAAb7. Acoustical design of Sumida Triphony Hall. Toshiko Fukuchi and Hideo Nakamura (Nagata Acoust., Inc., Minami-Shinjuku-Hoshino Bldg., 8F, 5-23-13 Sendagaya Shibuya-ku, Tokyo, 151-0051 Japan, fukuchi@nagata.co.jp)

The Sumida Triphony Hall was opened near Kinshityo JR station, located in the eastern part of Tokyo, in October 1997. The building contains two concert halls, the Main Hall, with 1801 seats, as the home of the New Japan Philharmonic, and the Recital Hall, with 252 seats. The Main Hall has a rectangular shape with the sloped ceiling rising at 12.5 degrees toward the back of the hall in parallel to the main floor and with two balconies around the main audience area. The reflecting panels were hung over the stage to help the ensemble for players. The shape was basically checked with the technique of computer simulation and the detail of the ceiling and the wall was studied by use of a 1/10th-scale model. An organ with 66 stops was installed at the front of the hall. The Recital Hall is a typical ''shoebox'' hall. In order to attenuate the vibration caused by railroad tracks, the vibration isolating barriers were embedded around a part of the outer walls of the building, and also the vibration insulating structure was adopted at the Main Hall partly and the Recital Hall entirely. The outline of acoustical design will be reported.

4pAAb8. Subjective assessment of the uneven distribution of reflections within a concert hall. Eugenio Collados (Dept. of Phys., Univ. of Santiago, Santiago, Chile, ecollado@lauca.usach.cl)

Most physical variables other than RT are known to vary significantly within a concert hall. Namely, early to late energy ratio, lateral energy fraction, and sound strength. Less well known are the subjective correlates to the above variations. A series of experiments were carried out in order to assess the number and meaning of subjective dimensions throughout a single hall. Testing environments were both an anechoic chamber array and an actual hall with artificial sources, where subjects were asked to judge classical music samples. In both cases the standard spatial distribution was modified by the addition of discrete reflections while keeping level and RT constant. At least four subjective dimensions were found, as many as found in hall-to-hall comparisons. Up to 59% of variance was related to the spatial image of the source. After comparing results between the anechoic chamber and the actual hall, the visual impression seems to partially compensate for the variations due to distance. These results raise some doubts on the validity of listening tests performed without a visual stimulus. It is also suggested that these effects should be considered in designing halls with active systems.

4pAAb9. A neural network analysis of concert hall acoustics. Fergus R. Fricke and Young G. Han (Architectural and Design Sci. Dept., Univ. of Sydney, Sydney, NSW 2006, Australia)

A neural network analysis using data from 51 concert halls was undertaken. The analysis related the acoustic quality of halls, as judged by musicians, to ten hall parameters: volume, surface area, number of seats, length, width, height, mean rake angle of seats, a surface diffusion index, stage height, and extent of stage shell/enclosure. The surface diffusion index and the extent of the stage shell were determined by a group of architects who made judgments on the basis of photographs and drawings of the halls. The results of the analysis are tentative and difficult to generalize, as there are so many inputs and so many possible combinations of parameters, and the effect of a particular factor is, in some cases, neither linear nor monotonic. The results are applied to a particular hall, the concert hall of the Sydney Opera House, where changes are being contemplated. There are some unexpected results which, at this stage, give food for thought rather than the basis for action, as there are obvious limitations to this work, such as extraneous factors influencing judgments of acoustic quality, surface diffusion estimation, and extent of the stage shell and the limited number inputs used to describe the halls.

4pAAb10. Directional dependence of the change of auditory source width by very short time-delay reflections. Masayuki Morimoto and Mariko Watanabe (Environ. Acoust. Lab., Faculty of Eng., Kobe Univ., Nada, Kobe, 657 Japan, mrmt@kobe-u.ac.jp)

Barron [J. Sound Vib. **15**, 475–494 (1971)] showed that spatial impression (SI) corresponding to auditory source width (ASW) decreases when the time delay of reflections relative to the direct sound is shorter than 10 ms. This paper investigates the effect of the direction of lateral reflections on the decrease of ASW. The music motif used in this investigation was a 6.5-s section of the 4th movement of Mozart's Jupiter Symphony (No. 41), which was the same motif as Barron used. The sound fields used as stimuli consisted of a direct sound and two discrete reflections with a 1-ms interval between them. The time-delay of the first reflection relative to the direct sound was 2, 4, or 8 ms. The directions of the

reflections were ±18°, ±45°, or ±72°. The experimental results demonstrate that the decrease of ASW depends on the direction of the reflections. As the reflections arrive from a more frontal direction, ASW decreases more sharply relative to the delay time.

4pAAb11. Reverberation time in Serbian Orthodox worship spaces. Miomir Mijic (Faculty of Elec. Eng., Bul. Revolvcije 73, Belgrade, Serbia)

Seven years ago, at the ASA Meeting in November 1990, this author presented some preliminary results of acoustical research realized in the Serbian Orthodox worship spaces. At that time the results for only seven churches were included in the paper. This research has been continued until now and nearly 60 churches were analyzed, different in volume, age, and the architectural style. Such a large number of measurements allow some more general conclusions about acoustical characteristics of orthodox worship spaces. Reverberation times obtained in realized measurements show the important influence of several specific factors such as strong orthodox rules in church interior design and volume shapes. These factors are influenced by traditional architectural styles accepted as unalterable even in the contemporary architectural design. Some differences in the frequency characteristic of the reverberation time according to different historical periods were also discovered.

4pAAb12. An experiment to identify preference groups among concert hall listeners. M. Miklin Halstead, Johan L. Nielsen, and A. Harold Marshall (Acoust. Res. Ctr., The Univ. of Auckland, Private Bag 92019, Auckland, New Zealand, mm.halstead@auckland.ac.nz)

The task of specifying the acoustical behavior of a concert hall depends upon knowing the preferred subjective acoustical characteristics for the intended program material. Several studies have suggested that the listening population might be divided into groups with respect to their preferred acoustic, with different weightings applied to different subjective factors in each. Our project endeavors to identify and describe these groups, and to make their composition an integral part of hall design. This paper describes a subjective experiment designed to identify and measure individual listening preferences in a simulated concert hall setting, and presents the experiments first results. Following from these results, an attempt is made to place tested individuals into preference groups. The applicability of the experiment is considered in terms of the quality of hall simulation and of the impact of the simulator and experimental design on the listeners discrimination.

4pAAb13. On spatial variability of room acoustics measures. Johan L. Nielsen, M. Miklin Halstead, and A. Harold Marshall (Acoust. Res. Ctr., The Univ. of Auckland, New Zealand, j.nielsen@auckland.ac.nz)

The use of high-energy measurement signals combined with digital multichannel recording and postprocessing leads to a highly efficient collection of impulse responses in concert halls. During measurements in two similar concert halls, the Christchurch Town Hall, New Zealand, and the Hong Kong Cultural Centre (both described in companion papers), responses were collected in all seats in some areas and in different positions in some single seats, in addition to the usual sampling of all areas. An omnidirectional loudspeaker source was used, and the measurements were repeated in several source positions. The distribution of various parameters in these areas are compared to the results for the whole hall. Based on this comparison the use of mean and standard deviation as measures of location and spread for the parameters is discussed, and the variation of parameters with varying source locations is demonstrated. Approaches toward the reduction of parameter sensitivity to insignificant details in the early sound field are briefly discussed and illustrated using the measured data.

4pAAb14. Acoustical design of the Queensland Conservatorium of Music. Keiji Oguchi, Yasuhisa Toyota, and Minoru Nagata (Nagata Acoust., Inc., Minami-Shinjuku-Hoshino Bldg., 8F, 5-23-13 Sendagaya Shibuya-ku, Tokyo, 151-0051 Japan, oguchi@nagata.co.jp)

The auditorium of the Queensland Conservatorium of Music was planned for both classical music concerts and lyric performances in the newly constructed conservatorium in the Southbank of Brisbane, Australia. The retractable orchestra shell is moved forward to the proscenium on the stage, and forms a shoebox style concert space with 643 seats. Small doors are installed on the orchestra shell for acoustical fine tuning in the stage space. Absorptive materials appear when the doors are opened. In lyric performances, the orchestra shell is retracted backward. The frontal area of the stage floor is sunk as an orchestra pit. The reverberation time becomes short, from 2.0 to 1.6 s, with retracting the orchestra shell, and varies by 0.3 s with acoustic curtains on the audience side walls for both concert and lyric use. The acoustical design and characteristics of the auditorium and players' preference on the acoustical tuning elements are reported in this paper.

4pAAb15. Estimation and analysis of acoustic parameters of ancient churches for concert performances. Tiziana Ottonello, Enrico Dassori (IATU—Univ. of Genoa, Via Opera Pia, 16145 Genova, Italy), and Andrea Trucco (DIBE—Univ. of Genoa, Via Opera Pia 11A, 16145 Genova, Italy)

This paper presents a study on the propagation of musical sound, where occasionally concert performances are held. The five selected churches were built in Genoa between the eleventh and the seventeenth century. The analysis was aimed at the computing of acoustic parameters (e.g., reverberation time, early decay time, initial decay gap, speech trasmission index, definition index), based on structural modeling and computer simulation (RAMSETE software) as well as experimental texts. Analysis of results showed that romanic churches generally provide better acoustic characteristics. Furthermore, acoustic not standing modifications (e.g., absorbing panels, curtains) were designed in order to make the observed acoustic parameters comparable with those observed in a typical concert hall. This work was developed in the framework of a project aimed at creating new music halls using the existing old buildings, generally dedicated to other aims.

4pAAb16. Acoustic behavior of a tense-structure. Alessandro Cocchi and Lamberto Tronchin (DIENCA–CIARM Viale Risorgimento, 2, 40136 Bologna, Italy, tronchin@ciarm.ing.unibo.it)

During the design of a concert hall, the acoustical behavior of the sound field is often investigated by using numerical models. In the case of a restoration of the hall, or during the design of the orchestra chamber, acoustic measurements of impulse responses in the hall give precious information on the sound fields, e.g., RT, clarity, and so on. By using numerical simulation, it is then possible to verify the efficiency of the acoustic solution. Much commercial software is available, all of them following the geometric assumptions, as the Eikonal equation, while the diffraction and diffusion of sound are not usually taken into account, and all of them require the absorption coefficient of the walls. The tense-structure, on the other hand, is not so easy to model, owing to the peculiar characteristics, i.e., modal behavior and impossibility to measure the absorption of the membrane. In this paper, the design of an acoustic intervention in a tense-structure is shown. A procedure to find out the ''equivalent absorption'' of the membrane is shown. The results of such a model are compared with the experimental measures.

4pAAb17. Variations in the surface textures of choral reflectors. Elizabeth J. Lee and Campbell J. Yule (Acoust. Res. Ctr., Univ. of Auckland, New Zealand, elee@ccul.auckland.ac.nz)

The commission to design a portable choral reflector seemed a simple process of finding a balance between acoustical and structural requirements. Initial inquiries, however, found a lack of information on the acoustical effect of different surface textures normally used. An experiment was developed to assess both the subjective and objective performance of varying degrees of surface roughness. Eight possible surfaces were chosen and applied to standardized panels. The impulse response of each panel was measured in an anechoic room using a maximum length sequence signal. Early results indicate significant differences in the reflected energy and frequency response of the respective panels. An attempt to obtain a subjective evaluation of the reflections by convolving choral and solo voice recordings with the impulse response of the panels will be reported. A prototype choral reflector based on this work will be described. [The support of the Acoustics Research Centre for this project is acknowledged.]

4pAAb18. Acoustical design of Harmony Hall Fukui. Akira Ono, Suzuyo Yokose, and Katsuji Naniwa (Nagata Acoust., Inc., Minami-Shinjuku-Hoshino Bldg., 8F, 5-23-13 Sendagaya Shibuya-ku, Tokyo, 151-0051 Japan, ono@nagata.co.jp)

Construction of Harmony Hall Fukui, which was sponsored by the Fukui prefecture government, was completed on September 3, 1997. The facility contained a large hall, a small hall, and administrative offices. In the central area of the facility is an administrative room, rehearsal rooms, and machinery space. The two halls are situated at the east and west ends of the facility. This architectural zoning brings advantages and savings for effective sound insulation and noise control of the ventilation system. The large hall seats 1456 people and is a concert hall in the shoebox style. The room shape was studied by computer simulation techniques during the design stage, and the details of the wall and ceiling were studied by use of 1/10th scale model experiments before the construction work started. The small hall seats 610 people in an extremely intimate setting. The seating surrounds the stage, and even the height of the balcony seating is staggered to create what may be termed a ''mini-arena'' style. The unique layout heightens the audience's feeling of proximity to the stage. Acoustical design and acoustical characteristics will be presented at the meeting.

4pAAb19. Effects of the modulated delay-time interval of the single reflection on subjective preference. Junko Atagi, Yoichi Ando (Grad. School of Sci. and Technol., Kobe Univ., Rokkodai, Nada, Kobe, 657 Japan, 962t001n@kobe-u.ac.jp), and Yasutaka Ueda (Hazama Corp., Karima, Tsukuba, 305 Japan)

In the past, experimental results of the sound-pressure level (SPL) were obtained which showed that the indoor sound field is regarded as a time-variant system due to an air current. Using the time-variant model represented by the direct sound and the varying delay time of single reflection, an experiment was performed on an effect on subjective preference. This experiment was focused on the effect of the modulation interval (Δ) of the delay time of the single reflection. The delay time of reflection (Δt_1) was adjusted to the most preferred delay time of reflection which was obtained by the experiments for the time-invariant sound field. In the case of fast tempo music, where the minimum value of the effective duration of the autocorrelation function is $\tau_{e_{\min}} = 43$ ms, the scale value of subjective preference is higher in a time-variant sound field than a time-invariant one. On the other hand, in the case of slow tempo music, $\tau_{e_{\min}} = 127$ ms, such an effect could not be found. It is suggested that a time-variant sound field might have a positive effect on subjective preference in the performance of a fast tempo music.

4pAAb20. Individual differences of subjective preference for sound fields with a different preferred delay time of reflection. Souichiro Kuroki, Ippei Yamamoto (Faculty of Eng., Kagoshima Univ., 1-21-40, Korimoto, Kagoshima, 890-0065 Japan), Hiroyuki Sakai, and Yoichi Ando (Kobe Univ., Rokkodai, Nada, Kobe, 657-8501 Japan)

The purpose of this study is to clarify the relationship between the individual preferred delay time of reflection and the effective duration of the autocorrelation function (ACF) of sound source. Subjective preference tests were conducted by varying the delay time of reflection (Δt_1) which is one of the four objective parameters related to subjective preference of sound fields. In this paper, five dry sources of instrumental music with different effective duration are used. In addition to the global preference with a number of subjects, individual-preference-scale values also were obtained by the method of paired-comparison tests. An attempt is made here whether or not individual differences in subjective preference may be explained by the categorical classification of musical experience, sex, and age of subjects.

4pAAc1. Modeling of acoustic parameters and speech intelligibility in long enclosures. Lening Yang and Bridget M. Shield (School of Eng. Systems and Design, South Bank Univ., London SE1 0AA, UK, shieldbm@sbu.ac.uk)

Ray tracing computer models have been developed for the prediction of the sound field and speech intelligibility in long enclosures of any cross-sectional shape. The models for enclosures of circular and rectangular cross section are particularly suitable for the prediction of speech intelligibility in underground railway stations. The model for use in long enclosures of rectangular cross section has been validated using data measured in a real underground station in Hong Kong. Measurements of acoustics parameters including sound propagation, early decay time, clarity index C50, and center time D50 were made along the length of the platform, with a single source towards one end of the platform. The model correctly predicts the acoustic parameters, the predictions being particularly accurate at midfrequencies. In addition the speech transmission index is accurately predicted at all frequencies, especially in the far field of the source.

4:25

4pAAc2. Relationship between speech transmission index and easiness of speech perception in reverberatory fields. Hiroshi Sato, Hiroshi Yoshino (Dept. of Architecture, Tohoku Univ., Aramaki Aza Aoba, Aoba-ku, Sendai, 980-77 Japan), and Muneshige Nagatomo (Kajima Tech. Res. Inst., 19-1 Tobitakyu 2-Chome, Chofu-shi, Tokyo, 182 Japan)

When evaluating speech intelligibility in rooms, the Tri-syllable articulation test is used as one of the standard indicators in Japan. Sometimes there are differences between auditory impression and the score of the articulation test. So the psychological scale values of easiness of speech perception (ESP) were measured by experiments, which indicated differences between ESP and articulation scores and a good correlation ($R=0.9$) between ESP and speech transmission index (STI) in reverberation. The purpose of this paper is to point out relationships between the condition of sound field and ESP. The first of two experiments in this study was done in reverberatory fields. Sound-pressure level (SPL) of direct sound, direct sound to first reflection ratio (D/R), initial delay time, frequency characteristics of reverberation, and reverberation time (RT) were varied. The other experiment was done in simulated fields of actual auditoriums. The result of the first experiment shows D/R and RT has alarge effect on ESP and while varying D/R, the correlation between ESP and STI is not good ($R=0.6$). The second experiment indicates that when the sound source is on the center of the stage, the correlation between STI and ESP is 0.8; and a different tendency is found while using the sound reinforcement system.

4:45

4pAAc3. Investigation of the speech intelligibility in the dome space. Satoshi Inoue, Masahiro Katoh, Kiyoshi Sugino (Inst. of Technol., Tokyu Construction Co., Ltd., 3062-1 Tana, Sagamihara, Kanagawa, 229-11 Japan, ino@etd.tokyu-cnst.co.jp), and Hiroyuki Imaizumi (Natl. Inst. for Resources and Environment, 16-3 Onogawa, Tsukuba, Ibaraki, 305 Japan)

In order to investigate the acoustical characteristics of an underground dome (2 320 m^3), objective and subjective properties were tested and the mutual relationship of them was examined. Then to improve the speech transmission quality there, some simple absorption treatments were given. A series of experiments, carried out under different acoustical conditions, has confirmed the effects of the treatment. The main results are as follows: (1) In the dome space without absorption treatment, the differences of some objective measures and subjective responses (speech intelligibility) were great in places where observation was made, e.g., RASTI value was distributed over a range of 0.17–0.59. (2) It is indicated that the speech transmission quality was high at the observation points where the energy, arriving in the first 0.06 s after the arrival of the direct sound, is predominant, and others are almost low. (3) Among the physical measures, EDT, early/late-arriving sound energy ratio, *ts* (at 1 kHz octave-band), and RASTI were correlated well with speech intelligibility. (4) Rubber tiles on the floor, 12-m cotton canvas hung from the ceiling, and glass wool board were found to be effective in decreasing reverberation time and diffusing the sound. Also, this treatment was useful in improving the speech intelligibility remarkably.

5:05

4pAAc4. Calculation of speech intelligibility using four orthogonal factors involved in autocorrelation functions. Tetsuichi Shoda and Yoichi Ando (Grad. School of Sci. and Technol., Kobe Univ., Rokkodai, Nada, Kobe, 657 Japan)

In this paper, a method of calculating speech intelligibility for the sound field with the direct sound and the first reflection is proposed. This method is based on the model of an auditory-brain system consisting of the autocorrelation mechanisms which is equivalent to the power spectrum. The autocorrelation function (ACF) may play an important role on the speech information processing. Four factors may be extracted from ACF, such that (1) τ_e : the effective duration of ACF (the ten percentile delay) meaning the repetitive feature of signals; (2) τ_1 : the delay time of the first peak of ACF signifying the pitch of signals; (3) ϕ_1 : the amplitude of the first peak indicating the strength of the pitch; and (4) $\Phi(0)$: the power of the signal frame. The distance between the syllable in sound fields and the syllable of the direct sound were calculated by the use of these four factors. Using these distances and its linear combination, speech intelligibility of the syllables in the sound fields may be calculated. Results of speech intelligibility tests as a function of the delay time of the reflection are in good agreement with the calculated values.

4pAO1. Variation in acoustically measured abundance from repeated surveys of an isolated herring population. I. Huse and M. Ostrowski (Inst. of Marine Res., P.O. Box 1870, N-5024 Bergen, Norway)

An isolated population of herring was surveyed acoustically a total of 18 times while wintering in a fjord in northern Norway. Total abundance and variograms were computed for each survey. Three-dimensional distribution graphs are presented. The results are discussed in terms of total variation of acoustic survey estimates.

2:15

4pAO2. Acoustic estimates of zooplankton and micronekton biomass using an ADCP. Patrick H. Ressler, Douglas C. Biggs, and John H. Wormuth (Dept. of Oceanogr., Texas A&M Univ., College Station, TX 77843-3146, pressler@ocean.tamu.edu)

A calibrated 153-kHz narrow-band ADCP (Acoustic Doppler Current Profiler) has been used to collect acoustic backscatter intensity (Sv) data during several cruises in the Gulf of Mexico. Data have been gathered both while on station and while underway along transects through different hydrographic regimes, enabling an examination of both temporal and spatial trends in backscatter. In addition, zooplankton and micronekton stocks were intensively sampled with a 1 $m\hat{2}$ MOCNESS (Multiple Opening-Closing Net Environmental Sensing System). Empirical correlations between spatial and temporal variations in Sv and in standing stocks of zooplankton/micronekton will be presented. Sv measured with an ADCP may be useful as an index of zooplankton and micronekton biomass. The location and abundance of these food stocks are hypothesized to be important in determining the distribution and abundance of marine cetaceans in the Gulf of Mexico. In addition, Sv-derived estimates of such stocks may allow inferences about secondary biological productivity in the Gulf, and the role that mesoscale circulation features might play in driving large-scale patterns. [This ongoing research is supported by the USGS Biological Resources Division and the US Minerals Management Service under USGS BRD Contract No. 1445-C109-96-004. 2:30

4pAO3. Monitoring the growth and mortality rates of pelagic fish with absorption spectroscopy measurements. Orest Diachok (Naval Res. Lab., Washington, DC 20375) and Paul Smith (Southwest Fisheries Sci. Ctr., La Jolla, California, 02038)

The experimental geometry for absorption spectroscopy measurements, which was employed during Modal Lion, can be adapted for monitoring the growth and mortality rate of pelagic fish. During the juvenile stage, in which sardines grow from 3.5 to 13.5 cm over a period of about 1 year and mortality rates are relatively high, absorption spectroscopy measurements (together with complimentary biological and oceanographic measurements) conducted for a few days approximately once per month would permit investigation of the environmental determinants of these parameters. Measurement sites would have to follow the migration route of juvenile sardines over a period of about 1 year. To minimize cost and simplify logistics, a broadband omnidirectional source (instead of a parametric source) would be suspended from a moored ship or buoy. A relatively low source level ($\sim$170 dB) would be adequate. Simulations will be presented of the temporal evolution of the resonance frequency, absorption coefficient, and transmission loss due to sardines between 0.6 and 6.0 kHz. Simulations will illustrate the sensitivity of transmission loss to source and receiver depth, and the average depth and thickness of absorbing layers. In addition, calculations that illustrate the potential of estimating the depth and thickness of absorbing layers by varying the depth of an omnidirectional source will be presented. [This work was supported in part by the Office of Naval Research.]

2:45

4pAO4. Measurements of snapping shrimp colonies using a wideband mobile passive sonar. Marc Olivieri, Stewart A. L. Glegg, and Robert K. Coulson (Ctr. for Acoust. and Vib., Dept. of Ocean Eng., Florida Atlantic Univ., 777 Glades Rd., Boca Raton, FL 33431)

A wideband passive sonar has been developed to study ambient noise levels in coastal regions. During the past two years a large number of measurements have been made with this system in shallow water off Boca Raton, Florida. The results have demonstrated that the noise from snapping shrimp dominates in this area during low sea states. Localization of the colonies has been possible by moving the sonar to different locations over the period of a few hours. Typically the shrimp are clustered close to man-made structures at or near the shore line, with additional smaller colonies on nearby coral reefs. To speed up the data collection the system has been mounted to an autonomous underwater vehicle and on-board intelligence is being developed to optimize the survey locations in real time. Results from a demonstration experiment will be presented. [Work supported by ONR.]

3:00

4pAO5. Using sound to map fish spawning: Determining the seasonality and location of spawning for weakfish and red drum (Family Sciaenidae) within Pamlico Sound, NC. Joseph J. Luczkovich (Dept. of Biol. and Inst. for Coastal and Marine Resources, East Carolina Univ., Greenville, NC 27858 luczkovichj@mail.ecu.edu), Stephen E. Johnson, and Mark W. Sprague (East Carolina Univ., Greenville, NC 27858)

Fish produce species-specific sounds during courtship, during aggressive encounters with other fish of the same species, and as a response to threats from predators. Particular sounds are species-specific and have been recorded from fish during spawning in captivity. Such acoustical data may be used to identify and locate fish that are reproductive in the sea. In this paper, nocturnal sound production and planktonic egg production are correlated for weakfish (*Cynoscion regalis*) and red drum (*Sciaenops ocellatus*) (Family Sciaenidae), two species for which there are concerns over declining stocks. Recordings of underwater sounds and ichthyoplankton net tows were made after sunset at ten sites in Pamlico Sound, NC. Sites were relocated with a differentially corrected Global Positioning System receiver on a biweekly basis from May through October 1997. Based on laboratory studies, weakfish ''purring'' sounds and red drum ''knocking'' sounds only occur during spawning. ''Purring'' was recorded along with sciaenid eggs at stations near Ocracoke and Hatteras Inlets during May through July. ''Knocking'' was recorded in September and October at sites away from the inlets, also occurring with sciaenid eggs in one case. Mapping of sciaenid spawning areas may be possible using acoustical data alone, but may overestimate egg production.

3:15

4pAO6. Using fish sounds to identify spawning activity of weakfish (*Cynoscion regalis*) and red drum (*Sciaenops ocellatus*) in nature. Mark W. Sprague (Dept. of Phys., East Carolina Univ., Greenville, NC 27858, spraguem@mail.ecu.edu), Joseph J. Luczkovich (Inst. for Coastal and Marine Resources, Greenville, NC 27858), and Stephen E. Johnson (East Carolina Univ., Greenville, NC 27858)

In the coastal systems of the southeastern United States, populations of weakfish (*Cynoscion regalis*) and red drum (*Sciaenops ocellatus*) are in decline, and knowledge of their spawning areas is important for the formulation of fisheries management plans. Weakfish and red drum, both members of Family *Sciaenidae*, use their swim bladders to produce species-specific sounds associated with spawning activity. Large spawning aggregations of these fish can produce sound levels as high as 145 dB (re:1 μPa), and these sounds can be used to identify spawning areas. Recordings and spectrograms of spawning sounds will be presented for each species. Water depth, bottom type and contour, sound-speed gradient, and water current gradient all affect the propagation of the fish sounds through the water. Measurements of these factors and the sound level of the fish calls are used to obtain an approximate range to the spawning aggregation. [Work supported by North Carolina Division of Marine Fisheries and U.S. Fish and Wildlife Service.]

4pBV1. Quantification of myocardial blood flow using ultrasound-induced destruction of microbubbles administered as a constant venous infusion. Sanjiv Kaul (Univ. of Virginia, Charlottesville, Virginia)

It was hypothesized that if microbubbles are administered as a continuous infusion, then destroying them in the myocardium and measuring their myocardial reappearance rate at steady state will provide a measure of mean myocardial microbubble velocity. Conversely, measuring their myocardial concentration will provide an assessment of microvascular cross-sectional area (CSA). Myocardial blood flow (MBF) can then be calculated from the product of the two. Accordingly, experiments were performed in 21 dogs where MBF was altered mechanically or pharmacologically in the absence or presence of coronary stenosis. Microbubbles were delivered as a constant infusion, and two-dimensional ultrasound was performed using different PI. The myocardial video intensity (VI) versus PI plots were fitted to an exponential function: $y=A(1-e^{-\beta\tau})$, where A is the plateau VI reflecting the microvascular CSA, and β reflects the rate of rise of VI and hence, microbubble velocity. Excellent correlations were found between flow and β, as well as the product of A and β. It is concluded that MBF can be quantified by destroying microbubbles with ultrasound during a venous infusion.

1:10

4pBV2. Gas-filled liposomes as ultrasound contrast agents for blood pool, thrombus-specific and therapeutic applications. Evan C. Unger (Dept. of Radiology, The Univ. of Arizona, Tucson, AZ 85724-5067, eunger@vms.ccit.arizona.edu), Thomas McCreery, Dekang Shen, GuanLi Wu, Robert Sweitzer, and Qui Wu (ImaRx Pharmaceutical Corp., Tucson, AZ)

Our group has developed technology for stabilizing microbubbles with phospholipid coatings (Aerosomes®-ImaRx Pharmaceutical Corp.). The first agent (MRX-115) is based upon lipid-coated microspheres filled with perfluoropropane gas and is in phase III clinical trials (October, 1997) for radiology and cardiology applications. Myocardial perfusion studies show the potential for the agent to detect ischemia in patients with myocardial infarcts. Targeting ligands have been covalently bound to lipids and incorporated into the stabilizing shells on the microbubbles. The first targeted agent planned for clinical trials is MRX-408 (perfluorobutane gas, linear hexapeptide-RGD analog). *In vitro* studies show enhanced visualization of thrombi, and *in vivo* studies in dogs with arterial and venous thrombi show selective enhancement, even in animals injected with heparin. *In vitro* studies have been performed to test sonothrombolysis comparing MRX-115 to MRX-408 with and without urokinase. The targeted contrast agent MRX-408 increases the rate of clot dissolution with ultrasound. Targeted, tissue-specific agents are feasible for ultrasound. A thrombus-specific ultrasound contrast agent has the potential to improve clot characterization and detection as well as clot lysis.

1:30

4pBV3. Targeted acoustic contrast agents: New opportunities for ultrasound in medical diagnosis and therapy. Gregory M. Lanza (Div. of Cardiology, Campus Box 8220, Barnes-Jewish Hospital, Washington Univ., 216 S. Kingshighway Blvd., St. Louis, MO 63110, greg@soundlab.wustl.edu), Kirk D. Wallace, Rebecca L. Trousil, James G. Miller (Washington Univ., St. Louis, MO), James H. Rose (Iowa State Univ., Ames, IA), Patrick J. Gaffney (NIBSC, Herts, UK), Dana R. Abendschein, Christopher S. Hall, Michael J. Scott, Christine A. Lorenz, Ralph Fuhrhop, and Samuel A. Wickline (Barnes-Jewish Hospital, Washington Univ., St. Louis, MO 63110)

For 30 years, medical professionals have sought the ''magic bullet'' which would allow sensitive detection of disease and facilitate localized administration of potent chemotherapeutic agents without systemic toxicities. Ligand targeted ultrasonic contrast agents have the potential to improve diagnostic sensitivity, port drugs to specific pathologic tissues, and provide dosimetry of the delivered therapeutics. The authors have recently developed a ligand directed, lipid encapsulated perfluorocarbon emulsion particle (250-nm diameter). These particles, when bound to biological surfaces, strikingly increase the acoustic reflectivity, although the particles have low inherent echogenicity. Contrast enhancement of the reflectivity of blood thrombi, fibrin clots, and nitrocellulose membranes has been tentatively explained by a transmission line model. Intravenous injection of the perfluorocarbon emulsion particles has localized and acoustically enhanced remote thrombi which were otherwise difficult to detect. The contrast agent has a 1-h circulatory half-life which greatly facilitates successful systemic targeting. The small particle size of these emulsions affords access to tiny capillary beds and vascular endothelial disruptions such as those following angioplasty. Collectively, these studies suggest perfluorocarbon contrast agents can target molecular epitopes within and proximate to the systemic circulation. These agents are creating new and exciting opportunities for ultrasound in medical diagnosis and therapy.

Contributed Papers

1:50

4pBV4. Disruption of contrast agents for monitoring blood flow. J. Brian Fowlkes (Dept. of Radiology, Univ. of Michigan, Medical Ctr., Kresge Res. Bldg. III R3315, Ann Arbor, MI 48109-0553, fowlkes@umich.edu), Richard T. Rhee, David W. Sirkin, and Paul L. Carson

An experimental system is being developed for controlling the flow of ultrasound contrast agent to create abrupt changes in contrast levels in tissues. Such changes can be used to monitor blood flow through bolus passage and to identify specific feeder vessels. Focused ultrasound (2.25 MHz) has been used to interrupt the flow of the contrast agent MRX-115 (ImaRx Pharmaceuticals, Tucson, AZ) in a tube (6 mm diameter, average velocity of 9.45 cm/s) using short bursts 20 cycles in duration with a pulse repetition frequency (PRF) of 0.75–6.0 kHz. Peak rarefactional pressures (PRP) for effective disruption of contrast agent were only 0.6–1.2 MPa. This corresponds to mechanical indices (MI) of 0.4–0.8 and intensity values which are well within the recommended limits for diagnostic ultrasound, up to 90% of contrast agent signal was eliminated and positive boluses were produced by turning the field off and on. Similar results have been achieved with a 1.8-MHz *in vivo* system in a rabbit model. Therefore the potential exists to use common diagnostic ultrasound to produce contrast disruption suitable for short bolus production. [Work was supported in part by the U.S. Army under Grant No. DAMD17-94-J4144.]

2:05

4pBV5. Effects of pulse width, phase, and intensity on echoes from ultrasound contrast agents. Karen E. Morgan, Paul A. Dayton, Katherine W. Ferrara (Dept. of Biomed. Eng., Univ. of Virginia, Box 377, Health Sci., Charlottesville, VA 22908, kej6u@virginia.edu), Alexander L. Klibanov, and Gary H. Brandenburger (Mallinckrodt, Inc., Hazelwood, MO 63042)

Contrast-assisted imaging shows great promise for the imaging of microvascular perfusion, although current techniques cannot differentiate the echoes from tissue and ultrasound contrast agents. Harmonic schemes for imaging with these agents have limited spatial resolution due to the transmission of a narrow-band pulse. The potential for wideband contrast-assisted imaging through a systematic evaluation of the effects of imaging parameters on the received echoes is evaluated. Our results indicate that the echo intensity received from contrast agents following wideband transmission is at least as large as or larger than that for narrow-band transmission, with both exhibiting nonlinear increases with increasing transmitted signal intensity. While the echo intensity at harmonic multiples of the bubble resonant frequency can be larger for narrow-band insonation, echoes received after wideband insonation demonstrate a broadband spectrum with significant amplitude over a very wide range of frequencies. The authors also demonstrate that the transmission of wideband high intensity pulses produces consistent time domain echoes from microbubbles. These echoes are unchanged whether the microbubbles break or remain intact over several pulses. Additionally, if the phase (order of compressional and rarefactional half-cycles) of the transmitted pulse is changed, the polarity of the received signal changes accordingly for a stationary reflector but remains unchanged for a microbubble.

2:20–2:30 Break

2:30

4pBV6. Characterization of ultrasound-contrast agents by short-burst excitation. Oliver D. Kripfgans (Dept. of Radiology, Univ. of Michigan, Medical Ctr., Kresge Res. Bldg. III R3315, Ann Arbor, MI 48109-0553, oliver.kripfgans@umich.edu), J. Brian Fowlkes, and Paul L. Carson

A two-frequency method has been adapted to the use of short ultrasonic bursts for the determination of bubble size. The advantage of a burst method is threefold. The overall energy transfer into the volume of interest is smaller as compared to cw. Second, it allows simple methods for improving spatial resolution. Finally, only one transducer will eventually be required in a pulse-echo mode. The experimental setup is designed to fully compensate for transducer characteristics and sample artifacts such as attenuation through window material and contrast agent solution. This leads to a constant sound pressure exposure for contrast agent in the focal volume. The data acquisition employs the frequency tracking procedure where spectra for narrow-band excition are analyzed for fundamental, second harmonic, and sidebands. A technique of nonconstant imaging frequency is used to avoid ambiguities due to coincidences between higher harmonics of the fundamental and multiples of the sideband frequencies. Measurements with shell-encapsulated microbubbles showed the behavior demonstrated by previous cw methods. Higher harmonics as well as sidebands were present due to the nonlinear dynamics of the contrast agents. [This work was supported in part by USPHS Grant Nos. RO1 DK42290 and 1RO1 HL54201.]

2:45

4pBV7. Acoustic detection of microbubble destruction in gaseous contrast agents. William T. Shi and Flemming Forsberg (Dept. of Radiol., Thomas Jefferson Univ., Philadelphia, PA 19107)

The destruction of microbubbles from ultrasound contrast agents has recently received much attention because the disintegration can be used to create new imaging modalities and may produce adverse bioeffects as

well. Both passive and active acoustic detection techniques were employed in our experiments to investigate the collective and individual behaviors of contrast microbubbles at different insonification levels. With the passive technique, the oscillation and destruction of microbubbles were studied by characterizing the waveforms of scattered acoustic signals and analyzing the harmonic and noise contents in the spectra of the signals. It was observed that discrete subharmonics and superharmonics (up to the 20th order) were generated at low acoustic pressures. When the bubble destruction occurred at high acoustic pressures, the noise level in the spectra was raised and the discrete harmonic structure in the higher frequency domain reduced to broadband noise. The noise spectrum in the higher frequency range was found to broaden as the acoustic pressure increased. A modified ACD (acoustic cavitation detector) with improved spatial resolution was utilized to study the disintegration process of an individual microbubble. The comparison of results from passive and active detections will be presented.

3:00

4pBV8. Acoustic and system parameters affecting destruction of ultrasound contrast agents. Peter P. Chang, Inder Raj S. Makin, and Lawrence A. Crum (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, pchang@apl.washington.edu)

In order to effectively use ultrasound contrast agents (UCAs), it is necessary to tune the ultrasound scanner parameters to a particular agent or change the characteristics of the UCA to target-specific applications. Both efforts are being sought by ultrasound manufacturers and pharmaceutical companies. The destruction of UCAs is usually undesirable, although it can sometimes be used advantageously such as in harmonic imaging mode. In the present work, changes in acoustic and system parameters such as frequency, transmitted acoustic pressure, pulse repetition frequency, flow rate, diluting media, concentration, and type of contrast agents were measured at both first and second harmonic. A prototype Doppler system previously described [Chang *et al.*, Ultrasound Med. Biol. **22**, 1205–1214 (1996)] has been adapted to carry out these measurements. Results with Albunex show that bubble destruction increases with an increase in flow rate, acoustic pressure, PRF, and decreases with an increase in the concentration of the contrast agent and oxygen content in the diluting medium. In conclusion, the rupture of UCAs are influenced by several imaging parameters. The threshold values when destruction of the agents occurs should be known in order to optimize the use of UCAs in clinical settings. [Work supported by DARPA-TRP.]

3:15

4pBV9. Observations of insonified contrast agents *in vitro* and *in vivo*. Paul Dayton, Karen Morgan, Margaretta Allietta, Kathy Ferrara (Univ. of Virginia, Box 377 HSC, Charlottesville, VA 22908), Alexander Klibanov, and Gary Brandenburger (Mallinckrodt, Inc., Hazelwood, MO 63042)

Ultrasound contrast agents, which may include a gas core and lipid or albumin shell, play an increasingly important role in medical imaging. However, a complex set of phenomena have limited quantitative evaluation of tissue perfusion based on echoes from these microbubbles. With the use of optical microscopy, mechanisms of microbubble destruction during insonation are evaluated, as well as the effects of ultrasonic radiation force. Depending on conditions such as acoustic intensity and dissolved gas concentration in the media, several mechanisms can change the microbubble and promote its destruction during insonation. Slow gas diffusion from the bubble is observed with low-intensity transmission, but with several pulses at a higher intensity, the albumin shell may weaken sufficiently to release the gas core. It is demonstrated that the primary acoustic radiation force has a significant effect on microbubbles when the ultrasound is transmitted with a low acoustic pressure and high pulse repetition frequency. Deflection of the contrast agent streamline to the wall of a small vessel is shown both *in vitro* and *in vivo*. Such manipulation of the contrast agents may be desired in drug delivery applications, as it provides a method of concentrating bubbles in a specific area.

3:30

4pBV10. Ultrasound contrast agent enhances vascular damage in mouse intestines. Richard A. Gies and Douglas L. Miller (P7-53, Battelle Pacific Northwest Natl. Lab., P.O. Box 999, Richland, WA, doug.miller@pnl.gov)

Either Albunex®, a gas-body based contrast agent, or 5% albumin in saline without gas bodies was administered to anesthetized hairless mice at 10 ml/kg by retro-orbital injection. The mice then were exposed at the midsection to 1.09 MHz of ultrasound for 100 s, either continuous (cw) or pulsed (pw, 10 μs pulses repeated at 1 kHz), in a 37 °C water bath. After exposure, the intestines were examined to count petechiae and hemorrhages into the intestinal lumen. cw thresholds for statistically significant petechiae production were 0.7 MPa spatial peak pressure amplitude without added gas bodies, and 0.5 MPa with added gas bodies. At 0.7 MPa the mean counts (five mice) were 22 without and 120 with added gas bodies. A statistically significant number of hemorrhages occurred at 0.7 MPa (three per mouse) with the contrast agent. The pw thresholds with added agent were 1.4 MPa for petechiae and 2.8 MPa for hemorrhage. At 2.8 MPa, average counts were 227 petechiae and 2.4 hemorrhages. No statistically significant vascular damage occurred for pw exposure up to 2.8 MPa without contrast agent. In terms of mechanisms, the effects appeared to be partly thermal for cw, but primarily associated with ultrasonic cavitation for pw exposure. [Work supported by NIH CA42947.]

4pEA1. Determination of the noise attenuation of hearing protectors by numerical modeling of the outer ear. Samir N. V. Gerges and Elizabete Y. Bavastri (Federal Univ. of Santa Catarina Mech. Eng. Dep.-Acoust. and Vibration Lab., Cx. P. 476, Florianópolis, SC, Brazil, gerges@mbox1.ufsc.br)

This paper will address the important practical issues of hearing protectors, used in industry, to protect the workers from high noise levels. Comments on the difficulties for the measurements of hearing protector's noise attenuation is discussed. A new work on the numerical modeling of the outer ear canal, considering the eardrum acoustic impedance, using the finite elements (FEM), infinite FEM for the quantification of the noise attenuation of the protectors is presented. This numerical model considers the geometry of the outer ear, outer ear canal, and the eardrum acoustic characteristics. This numerical model can serve as a quick and low cost tool for the optimization of the protector project and the investigation of the effect of different parameters such as protector insertion, effect of leakage, materials, and others on the protector noise attenuation.

4pEA2. Improved TV/radio listening for hearing impaired. J. G. H. van Zutphen (Tech. Univ. Twente and Audiol. Dept. of the Free Univ. of Amsterdam, The Netherlands), W. F. Druyvesteyn (Philips Res. Labs., Eindhoven, The Netherlands), and C. H. Slump (Tech. Univ. Twente, The Netherlands)

In case different persons, having different preferences for the loudness level, want to listen to one sound program in one room, problems arise concerning the loudness of the reproduced program. An example: person A has a normal hearing threshold, while person B is hearing impaired. A sound reproduction system, consisting of a small array of loudspeakers at the TV/radio can solve this problem with digital signal processing; the directivity pattern of the array is manipulated such that the main lobe is directed to person B. The investigation and the presentation at the conference contains two parts: (1) physical acoustics: design and testing of the loudspeaker array including digital processing, and (2) subjective evaluation with normal-hearing subjects and hearing impaired subjects. The subjects listen (and view) a TV program consisting of a selection from 120 short spoken sentences. The normal-hearing subjects adjust the loudness level at their listening position. The hearing-impaired subjects test the effect of the array. These listening tests show a clear improvement in the speech intelligibility for the hearing-impaired subjects as expressed in the number of correct understood sentences and in subjective terms as ''easier to understand'' or ''less tiring to listen to.''

1:30

4pEA3. Piezoelectric transducer for a hearing aid using PZT thin film. Hidehiko Yasui, Minoru Kurosawa, Takeshi Morita, Takefumi Kanda, and Toshiro Higuchi (Dept. of Precision Machinery Eng., Grad. School of Eng., Univ. of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, 113 Japan, hide@intellect.pe.u-tokyo.ac.jp)

A piezoelectric transducer using a PZT thin film deposited by a hydrothermal method was fabricated for the investigation of ability for an earphone. The PZT material can produce sounds efficiently from an electrical signal. The thin film technology is suitable for the fabrication of a small transducer which is worn in the ear. Especially, the hydrothermal method has merits such as thick film fabrication and possibility of deposition on a round surface. Therefore we can design and fabricate a diaphragm for a small earphone which produces a high enough sound-pressure level for people who have an obstacle for hearing ability. The fabricated transducer had a bimorph construction. The base material was titanium foil 20-μm thick. Both sides of the titanium, PZT thin films 10-μm thick were deposited. The diameter of the transducer was 6 mm. We investigated the ability of the fabricated transducer. Displacement amplitude of the transducer was about 0.9 μm per 5 V driving voltage below the resonance frequency.

1:45

4pEA4. Low-frequency circuit noise in hearing aids. Vishakha W. Rawool (Commun. Disord. and Special Education, Bloomsburg Univ., Bloomsburg, PA 17815)

Some hearing impaired listeners complain about the circuit noise in hearing aids. This is specially true for individuals with high-frequency hearing impairments who have normal hearing in the lower frequencies. In this investigation, the equivalent input noise levels were measured in several different hearing aids: linear, wide dynamic range compression, high-level compression, programmable, and digital aids. For the linear, programmable, and digital aids the measurements were made with two types of frequency responses. One was suitable for a flat moderate hearing impairment and another for a high-frequency hearing impairment. For the linear and compression aids, the noise levels were measured by using two different volume control settings. All the measurements were made by using 11 different special purpose average frequencies ranging from 200 to 5000 Hz. The results suggest generally higher circuit noise in the lower frequencies in all the hearing aids. Changes in volume control settings showed no differences in noise levels. For the programmable aids, the flat versus high-frequency configurations yielded similar noise levels. For the linear and digital aids, the high-frequency configuration yielded higher noise levels in the lower frequencies when compared to the flat configurations.

2:00

4pEA5. High degree of freedom muffler optimization using genetic algorithms: Experimental verification. Siska Pottie and Dick Botteldooren (Information Technol. (INTEC) Univ. Gent st-Pietersnieuwstraat 41 B-9000 Gent, Belgium, pottie@intec.rug.ac.be)

This paper reports on an experimental verification of a nonconventional muffler design. The optimal design is searched using a genetic algorithm (GA). GAs are a powerful optimization technique that are well suited to handle multiparameter optimization problems. The degrees of freedom used to describe the structure is far beyond the usual set. The muffler has a fixed length and width and is described by a set of design rules defining the use of the available space. Different coding alternatives for the GA were analyzed. Best results are obtained with a coding that describes the position and size of the design rules. The performance of the mufflers is characterized by the theoretically achieved sound reduction and by the ease of construction of the optimized muffler. The theoretically achieved sound reduction is calculated using a time domain simulation. In

order to verify the promising theoretical performance of the optimized mufflers, a good performing design is built and tested in the laboratory. General agreement between the theoretical and experimental results is found. Since no conventional muffler design rules are imposed, the optimization is completely open for new approaches which can led to new insights for conventional muffler design.

2:15

4pEA6. Theoretical analysis of reactive silencers with two propagating modes. J. Kergomard and M. Pachebat (Lab. Acoustique, Universite du Maine, Av. O. Messiaen, 72017 Le Mans Cedex 9, France, kergo@laum.univ-lemans.fr)

A general modeling of sound ducts with reactive (or dissipative) treatments considers one main guide and a secondary one (the treatment), with another propagation constant, including discontinuities, coupled to the main one by perforations, i.e., a shunt impedance and a series impedance [see Kergomard *et al.*, Acta Acustica **2**, 1–16 (1994)]. For a periodical system the calculation can be made analytically for a succession of N cells by diagonalization: the impedance matrix of the portion of the duct with treatment can be deduced. At low frequencies only one mode propagates in each duct and the matrices are of fourth order. From the boundary conditions for the treatment the insertion loss (IL) for the main duct is deduced. Examples are an array of coupled resonators, a lining with perforated facing, and a perforated tube muffler with partitions. A conclusion is the proof of the interest of the interferences between two propagating modes of the periodical system: resonances occur and IL is proportional to $\log N$. It is more efficient than a single propagating mode (e.g., in expansion chambers). Compared to the evanescent case (IL proportional to N), it is less efficient but the frequency band is wider. Many facts of practical interest can be deduced.

2:30

4pEA7. Observations of characteristic transmission and reflection coefficients of a splitter duct attenuator. M. Terao and H. Sekine (Dept. of Architecture, Kanagawa Univ., Kanagawaku, Yokohama, 221 Japan)

The characteristic transmission coefficients (including the reflection coefficients) of a splitter duct attenuator with two air channels containing higher-order wave modes were investigated. These were evaluated at interfaces taken in the straight duct sections in both sides of the attenuator and were determined experimentally and numerically (by BEM). The determination method introduced here requires the solution of two sets of the simultaneous equations given by the superposition principle of traveling waves. One is that the sound pressure at a point is the sum of the pressures of all the traveling waves that could possibly exist there, and it was applied to decompose the incoming and outgoing waves of all modes at each interface. The other is that each outgoing wave pressure of each mode at each interface equals the sum of the products of the incoming wave pressures of all modes at all interfaces and the corresponding transmission factors. It was applied to determine, without using an echoic termination, each characteristic transmission coefficient by which each incoming wave contributes to each outgoing wave pressure. The transmission coefficients of the attenuator were obtained for the fundamental and the first-order modes. Agreement of those by experiment and numerical results is substantially good.

4pEA8. Applications of sonic soot cleaning techniques. Jing Tian (Inst. of Acoust., Academia Sinica, Beijing 100080, PROC)

Sonic soot cleaning is a method that is applied to clean the ash or fossil deposit on surfaces of heat exchangers in boilers. The technique includes a set of hardware and software for the designing, production, installation, debugging, and operation of sound wave generators and the controller. Although it has been applied in boilers in power plants, petrochemical works, and general industries worldwide, still most of the correlated basic problems, such as the relationships between sound field and the mass delivery, the heat conduction as well as the combustion process in boilers, have not been well solved. It is almost a purely empirical method that its application is far in the lead of fundamental research. Now in China more than ten institutions and companies are engaged in the research, development, and marketing of sonic soot cleaning techniques. These techniques cover sound generators ranging a frequency domain from infrasound up to ultrasound, under the protection of more than 20 patents. In this paper, several applications are analyzed as examples to demonstrate the effectiveness. Some basic phenomena and unsolved problems are revealed. The course of sonic soot cleaning development is discussed. [Project supported by the Natural Science Fund of China.]

Musical Acoustics: Timbre of Musical Sound II

James H. Irwin, Chair
Electrical and Computer Engineering Technology, ECET, Bradley University, Peoria, Illinois 61625

Contributed Papers

1:00

4pMU1. Validation of a multidimensional distance model for perceptual dissimilarities among musical timbres. Nicolas Misdariis, Bennett Smith, Daniel Presssnitzer, Patrick Susini (Inst. de Recherche et de Coordination Acoustique/Musique (IRCAM), 1 place Igor Stravinsky, F-75004 Paris, France), and Stephen McAdams (IRCAM, F-75004 Paris, France and (CNRS), Univ. René Descartes, EPHE, F-75006 Paris, France)

Several studies dealing with the perception of musical timbre have found significant correlations between acoustical parameters of sounds and their subjective dimensions. Using the conclusions of some of these studies, a calculation method of the perceptual distance between two sounds has been developed. Initially, four parameters are considered: spectral centroid, irregularity of the spectral envelope, attack time, and degree of variation of the spectral envelope over time. For each of these, a transformation factor between the physical axis and the corresponding subjective dimension is obtained by linear regression. After a normalization of the data, the four coefficients then found are those of a linear combination that gives the final distance values. Since this model is based on numerical results derived from experiments that mostly used synthesized sounds, the application to a database of recorded musical instrument sounds needs a strong validation procedure. This procedure involves the adjustment of the

coefficients of the first four parameters as well as the eventual introduction of new ones to attain a perceptually relevant distance between two musical sounds. The progress of this research and the results of the database search engine built on this similarity model will be presented and discussed.

1:15

4pMU2. Timbre effects caused by drumstick tip shapes/sizes. James H. Irwin, Jr. (Elec. and Comput. Eng. and Technol., Bradley Univ., Peoria, IL 61625, jhirwin@bradley.edu)

The relationship between the shape/size of a drumstick tip and the resulting initial spectrum produced by hitting a drumhead was investigated. Contrary to tensioned plate theory, and popular opinion, the amplitudes of the various induced partials were not significantly different when the shape/size of the tip was changed dramatically. The work was extended by using various diameter steel balls to strike the drumhead and it was found that the initial spectra did change for extreme differences in ball diameter. Further investigation showed two, or possibly three, timbre groupings. Present results indicate that small diameter balls (less than 15 mm diameter) induce significant energy above the first few partials of the drumhead, medium diameter balls (15 to 25 mm diameter) induce most of their energy in the first few partials, and perhaps large diameter balls (greater than 25 mm diameter) induce little energy above the lowest partial. These effects are linked to the membrane and plate characteristics of the drumhead. Since most drumstick tips have diameters in the medium range little distinction occurs among their spectra. In all cases the spectra were normalized for energy input, and the drum tension and position of impact were fixed.

1:30

4pMU3. On the intentional use of instrument characteristics in contemporary classical compositions. Alexandra Hettergott (Inst. of Musicology, Univ. of Vienna, Spitalgasse 2, 9. Hof, A-1090 Vienna, Austria)

Compositional intention is likewise subjected to the (mechanical) instruments' sound characteristics and technical possibilities, for instance, the possibility to produce impulsive or stationary sounds, to form (pedaled) chord clusters, or to microtonally retune pitch during performance. These differing techniques may additionally allow several (intended) psychoacoustical effects, as a changing fluctuation (beatings, roughness) or pitch strength, which also have a strong impact on timbre: so in the latter case the pitches' varying distinctiveness may be combined with a ''metallic,'' ''plastic,'' or ''wooden'' sound coloring. Consequently, in composing the decision for strings, either *struck* (piano, also prepared), *bowed* (violin, microtonally tuned), or *plucked* (harpsichord), for *flue, reed* (organ), or *free-reed* (mouth organ) pipes, etc., is also subjected to (*a priori*) intentional reflections aimed on the very (new) sound experience imagined. By means of music and score examples [W. Rihm, J. Cage, G. Scelsi, G. Ligeti, O. Messiaen, T. Hosokawa] as well as spectra and spectrograms the paper sheds some light on the composers' sounding and purposeful use of the mechanical instruments' possibilities in sound production in order to get (close to) the corresponding aesthetics of expression intended.

1:45

4pMU4. Musical instrument perception in cochlear implant listeners. John J. Galvin III and Fan-Gang Zeng (House Ear Inst., 2100 W. 3rd St., 5th Fl., Los Angeles, CA 90057-1922)

To examine the degree to which the cochlear implant preserves acoustic cues for timbre perception, eight cochlear implant and three normal-hearing listeners participated in a closed-set musical instrument identification experiment. Eleven nonpercussive, single-note instrument samples including woodwinds, brass, and strings were selected from the MUMS Classical Sounds CDs and formed a six-token and a nine-token set condition. The stimuli were normalized to have the same duration and RMS amplitude, and edited to include either the natural attack or the steady portion only. Subjects were trained with trial-by-trial feedback until asymptotic performance was achieved on one pitch (a4) and were tested without feedback on another pitch (c4). In the six-instrument task, both normal and implant listeners scored an averaged 70%–80% correct identification performance for both the natural attack and steady-state conditions. In the nine-instrument task, the implant listeners scored 20%–30% lower than the normal control. These results indicate that in a relatively simple six-instrument task, the cochlear implant can provide sufficient cues to support normal-level timbre perception, whereas the distorted spectral transformation via the cochlear implant fails to support a normal-level timbre perception, as the task complexity is increased to require more spectral resolution in the nine-instrument task.

2:00

4pMU5. Signal processing techniques to analyze the effects of guitar geometry on musical timbre. Dominic DiDomenico, Kevin Morris, and Suzanne Keilson (Loyola College, Dept. of Elec. Eng. and Eng. Sci., 4501 N. Charles St., Baltimore, MD 21210, keilson@loyola.edu)

Musical acousticians seek to answer many questions. What makes a particular instrument sound like it does? How do listeners perceive musical sounds? As an undergraduate design project, three guitars of varying shapes (''box,'' ''triangle,'' ''octagon'') were constructed and then compared to the traditional design. Materials were not varied, only the geometry of the sound boxes. The overall volume of each sound box was approximately equal. Digitized samples of the plucked strings of the constructed and traditional guitar were obtained. Conventional Fourier signal analysis of the notes from the three constructed guitars showed similarities to those of the traditional guitar. Other signal processing methods, such as short-time Fourier transform spectrograms, appropriate for the transient signal of the plucked string, were also investigated. Although the signals were broadly similar, analysis revealed differences, which might be attributed to the different geometries. A survey was conducted to assess listener's preferences for the various instruments. The survey was conducted from taped samples of the plucked strings to correlate the importance of psychoacoustics and the physical signal in assessing instrument quality. Listener preference rated the octagon-shaped guitar as highly as the traditional one. [Work supported by the Loyola College Department of Electrical Engineering and Engineering Science, and the Loyola College Hauber Fellowship Fund.]

2:15

4pMU6. The subjective evaluation of resonating sound-art samples and its relation to psychoacoustic measures. Densil A. Cabrera (Dept. of Architectural and Design Sci., Wilkinson Bldg., G04, Univ. of Sydney, NSW 2006, Australia, densil@arch.usyd.edu.au)

A genre of sound-based art is identified, wherein the artist simply records the sound of a continuously resonating acoustic system, with a minimum of intervention in the process. The sound of such works is often close to steady state, and tends to evolve slowly. The sounds include nearly pure tones, tone combinations (sometimes with prominent beats), and sustained noiselike sounds. Fluctuations due to variations in the energy source (often the wind) also occur. It was thought that the abstract nature and simplicity of these sounds would lead to subjective evaluations based largely on fundamental psychoacoustic criteria. Fifty-three samples, of 20 s duration, were arbitrarily selected from the genre, including works by Alvin Lucier, Gordon Monahan, and Roger Winfield. Subjects rated these stimuli on five continuous bipolar scales: (dis)like, (un)interesting, (un)pleasant, emotional arousal, and emotional valence. The stimuli were measured for loudness, pitch characteristics, roughness, fluctuation, and lateralization. Analysis showed emotional arousal to be the strongest response, with significant correlations to loudness, roughness, and pitch. The results point towards the possibility of constructing a perceptual model of this type of minimalist art form. [Work supported by an Australian Postgraduate Award.]

2:30

4pMU7. The dependence of timbre perception on the acoustics of the listening environment. Dae-Up Jeong (Dept. of Architectural and Design Sci., Wilkinson Bldg., G04, Univ. of Sydney, NSW 2006, Australia, jeong_d@arch.su.edu.au) and Fergus R. Fricke (Univ. of Sydney, NSW 2006, Australia)

The acoustic quality of a room for music cannot easily be determined. As timbre is important in music it is possible that the perceived change in timbral quality of a sound in two spaces may give the basis for a measure of acoustic quality. The smallest perceivable change in the timbre of steady-state stimuli was measured in different listening environments through two experiments featuring a spectral centroid and rise time, respectively. Five component harmonic stimuli at 440 Hz were employed. The centroid of the standard stimuli was fixed at 2.95, in which the median amplitude of each component of the standard was set at 0.5, while those of comparison stimuli were varied from 2.93 to 2.41 in steps of 0.02 with a negative spectral tilt. The smallest perceivable change in the rise time was also measured using complex tones containing ten harmonics of 200 Hz (F_0) with linear spectral slopes of -6 dB/oct. Rise times of comparison stimuli were varied from 5 to 25 ms in 2-ms steps, while the fall time was fixed at 5 ms across the stimuli. Results are presented and comments are made on how the acoustics of the listening environment influences the perception of timbre.

2:45

4pMU8. Perceptual analysis of synthesized struck bars. Vincent Roussarie (Inst. de Recherche et de Coordination Acoustique/Musique (IRCAM), 1 place Igor Stravinsky, F-75004 Paris, France), Stephen McAdams (IRCAM, F-75004 Paris, France), and Antoine Chaigne (Ecole Nationale Supérieure des Télécommunications (ENST), F-75013 Paris, France)

This study is part of a project seeking to understand musical timbre and perceptual phenomena of the sound environment. It concerns the sensitivity of listeners to sounds emitted by simple vibrating structures, such as xylophone bars. Previous studies of timbre have characterized this attribute in terms of a small number of perceptual dimensions of an analytic nature (attack time, spectral centroid, spectral flux). Other studies have suggested a return to the physical characteristics of the sound sources themselves in order to understand their influence on timbre perception. Sounds were synthesized with a computer model of the vibrating bar developed at ENST that allows precise control of physical parameters. Listeners made dissimilarity judgments on all pairs of different sounds. Multidimensional scaling analyses of these data yield a perceptual space with dimensions that correspond strongly to the varied physical parameters (material density and the first term of internal damping) as well as to salient auditory dimensions (pitch for the former and a combination of spectral centroid and decay rate for the latter). These results argue in favor of a privileged processing of source characteristics by the auditory system.

4pNSa1. Diagnosis of noise sources from high-speed trains using the microphone-array technique. B. Barsikow (akustik-data Eng. Office, Kirchblick 9, D-14129 Berlin, Germany)

To reduce noise radiated by high-speed trains, abatement at the source is becoming increasingly important. Techniques for accomplishing this task require an exact knowledge of the individual sources involved and their reduction potential. During the past several years, a number of sound-generating components on ICE trains operated by the DB AG (German Railway) have been investigated by the akustikk-data Engineering Office. Microphone arrays provide a useful technology for investigating noise radiated by individual sources. Among the arrays used for recent measurements are the horizontal and vertical interspersed line arrays as well as X-shaped arrays. Examples measured by each of these instruments are shown. Results of these measurements with arrays yield the strength of each source and their speed exponents. In addition, narrow-band analysis of the sound is possible because the effects of the Doppler shift are not present. With this information, the importance of each source to the total radiated noise can be estimated. Examples of such results are given for rolling noise as well as for components emitting aerodynamic noise. For both types of sources, the effectiveness of various abatement measures is discussed.

1:25

4pNSa2. Noise prediction and control for new Norwegian high-speed trains. Matias Ringheim (Kilde Akustikkas, P.O. Box 229, N-5701, Voss, Norway)

The prediction of future noise levels is an important part of the planning process for high-speed trains and tracks. The first Norwegian high-speed tracks will be opened in 1998, using new 200-km/h electric trains based on the Swedish X2000. Strict noise criteria have been defined and extensive noise control measures are necessary both on the train itself and along the track. The noise prediction was performed several years ago, with the early and fairly simple Nordic prediction method. In the final planning stages some of the more critical results were checked against the revised Nordic method. The method enables the calculation of outdoor

energy equivalent levels and maximum levels in octave bands, in simple and complex terrain. The first version of a computer implementation is available. The outdoor results have a form which is suitable for the further calculation of indoor levels, when the building properties are known. The basic aspects of the method, including a summary of available high-speed data, will be presented. Problems related to the prediction and reduction of future noise from new high-speed trains will be summarized.

Contributed Papers

1:45

4pNSa3. Ground-borne vibration measurements of high-speed trains. David A. Towers (Harris Miller Miller & Hanson, Inc., 15 New England Executive Park, Burlington, MA 01803, dtowers@hmmh.com) and Hugh J. Saurenman (Harris Miller Miller & Hanson, Inc., Burlington, MA 01803)

Ground-borne vibration measurements of high-speed train operations were carried out in France for the TGV and Eurostar trains, in Italy for the Pendolino trains, and in Sweden for the X2000 trains. The measurements were made to develop vibration-prediction models for a new guidance manual published by the U.S. Federal Railroad Administration on ''High Speed Ground Transportation Noise and Vibration Impact Assessment.'' The tests included measurements of ground-borne vibration at various distances from the track as well as a procedure to characterize the ground vibration propagation characteristics at each measurement site. The results indicated a wide spread in the vibration data, partly due to differences in the equipment and track condition and partly due to differences in site geology. Further analysis suggested that much of the difference between the trainsets is due to variations in the geology rather than differences in suspension, axle load, or wheel conditions of the trainsets. Applying the characteristics of one type of trainset to different test sites resulted in widely varying ground vibration levels and propagation rates, whereas normalizing the ground vibration from the trainsets to one site substantially reduced the differences in overall vibration level.

2:00

4pNSa4. New noise impact criteria for high-speed ground transportation systems in the United States. Carl E. Hanson (Harris Miller Miller & Hanson, Inc., 15 New England Executive Park, Burlington, MA 01803, chanson@hmmh.com)

New noise impact criteria have been developed by the U. S. Department of Transportation for the assessment of environmental impacts of high-speed rail projects. The environmental impacts of new high-speed rail projects in the United States are the responsibility of the Federal Railroad Administration (FRA). Adoption of these criteria will assure a uniform treatment of noise impacts of new high-speed rail systems throughout the country. The noise impact levels were developed based on well-documented criteria, and on comprehensive social survey data concerning annoyance due to transportation noise. Impact levels are based on the Schultz response curve and include consideration of the combination of project and ambient noise levels. Correction terms are included in the case of high-speed rail (and maglev) to account for startle effects from fast rise times. This presentation discusses the basis for the curves used as thresholds of impact—where noise mitigation is to be considered—and severe impact—where noise mitigation must be implemented. These criteria are included in a new guidance manual published by the FRA on ''High Speed Ground Transportation Noise and Vibration Impact Assessment'' and will be used throughout the USA.

2:15

4pNSa5. Wayside noise measurements of high-speed trains. David A. Towers (Harris Miller Miller & Hanson Inc., 15 New England Executive Park, Burlington, MA 01803, dtowers@hmmh.com)

Wayside noise measurements of high-speed train operations were carried out in the USA for the German ICE, Swedish X2000, and U.S./French RTL-2 Turboliner trains, in France for the TGV and Eurostar trains, in Italy for the Pendolino trains, and in Sweden for the X2000 trains. The measurements in the USA were made as part of the Northeast Corridor Project and the measurements in Europe were made to develop noise-prediction models for a new guidance manual published by the U.S. Federal Railroad Administration on ''High Speed Ground Transportation Noise and Vibration Impact Assessment.'' The results indicate that the TGV, ICE, and RTL-2 trains had similar noise emissions and were typically the quietest of the trains tested. A-weighted noise levels for the X2000 and Pendolino trains averaged about 5 dB higher, and data for the Eurostar trains were scattered over the range for the other trains. Although the higher-speed French trains generated some additional low-frequency aerodynamic noise, this noise did not appear to significantly affect the A-weighted noise levels for train speeds up to nearly 300 kph (186 mph). The results also suggest that at the speeds tested, the observed trains were generally in compliance with the U.S. Federal Railroad Noise Emission Standard.

2:30

4pNSa6. Identification of moving acoustic sources from the pass-by noise. Byoung-Duk Lim and Deok-Ki Kim (Dept. of Mech. Eng., Yeungnam Univ., Gyongsan, Kyungbuk, 712-749, Korea)

The identification of a moving noise source such as a transportation system is usually difficult at high speed since microphones attached to the moving noise source may induce a high level of aerodynamic noise, while the measurement using a fixed microphone suffers from the distortion of the source characteristics due to its motion. In this study a time domain technique based on the finite difference method and regularization is developed for the recovery of the stationary source characteristics from the distorted signal measured at a fixed point. The sources are assumed to be point sources with stationary frequency characteristics, and move along a line at a constant subsonic speed. In the previous work of the present authors recovery of the stationary source signal from a point source requires the information about time origin. For multiple sources it is impossible to set a single time origin that a source signal recovery method using multiple time origins are developed. In the numerical simulations the effects of estimation errors in the parameters, such as the speed of source, time origin, and background noise level, are investigated and the results show the usefulness of this method.

4pNSa7. The acoustical impact of local railway lines. Cristina Pronello (Ing. Cristina Pronello C.so Duca degli Abruzzi n. 24-10129 Torino, Italy, pronello@polito.it)

Local railway lines serve a regional traffic. They have few users since the service offered presents insufficient quality standards. These lines could have more users and they could become metropolitan connections by adopting new vehicles which are faster and more modern. This study has dealt with the current acoustical impact that they produce. Therefore, a number of acoustical measurements have been made along a local railway line. They have been carried out by varying the speed of the trains at a fixed measuring distance of 7.5 m and by varying the measuring distance with a single train speed. The obtained results have shown that current trains produce in the average a greater acoustical impact when compared to modern trains. This has been observed even at slow speeds and with reduced train lengths. Measurements made on a new train, that should soon start its service on the line, have shown that there would be no increase of the produced acoustical level, even with increased speeds. As a consequence, it may be concluded that the current service on the analyzed line could be enhanced by increasing the train speed and the number of runs, maintaining an equivalent daily analogous to the one currently guaranteed.

3:15

4pNSa8. Limits to limits? Tor Kihlman and Wolfgang Kropp (Dept. of Appl. Acoust., Chalmers Univ. of Technol., S-41296 Gothenburg, Sweden)

Today, traffic noise due to cars, trains, and airplanes is the main noise source in urban areas. In accordance with the European Commission's Green paper on Future Noise Policy, 22% of the European population are exposed to outdoor A-weighted noise levels higher than 65 dB and more than 45% are exposed to levels between 55 and 65 dB. This corresponds in total to about 250 million people. To improve the situation is a tremendous challenge and the question arises as to whether a good environment be provided (i.e., levels below 55 dB) for all people in today's cities. Can the demands of 55 dBs only be fulfilled by structuring traffic in a smart way and using noise barriers? Or is a clear change in traffic policy needed from individual traffic to public transport? Different cities with different structures and automobile dependencies are compared in a general study based on statistical data. Detailed information about traffic flow, population structure, and land use is analyzed to verify these results.

3:30

4pNSa9. Effects of traffic noise within the Madrid region. Manuel Recuero, Constantino Gil, and Jorge Grundman (Inst. de Investigacion del Automovil (INSIA), Univ. Politecnica de Madrid, Ctra. Valencia km. 7, 28031 Madrid, Spain)

In this work the results of a 20-question survey about the acoustic environment made on the population of 17 towns are presented. Up to 7141 questionnaires were distributed, where 3272 were conducted in population centers with more than 100 000 inhabitants, 2695 in towns below 100 000 and above 50 000 inhabitants, and 1174 in towns with less than 50 000 inhabitants. The aim of this statistical work is to estimate the citizens' opinions about noise sources in their municipalities, the annoyance that these sources produce, where and when the effect seems stronger, and how the noise affects residential areas. There were also questions concerning the opinions about protection against noise in dwellings and the presumed effects of environmental noise. Finally, it was intended to know how important the residents think the environmental noise problem is, how deep their knowledge is about their rights and the law, and what do they think about measures to improve the situation.

3:45

4pNSa10. Measuring the traffic noise in Valencia. E. Gaja, J. L. Manglano, A. Reig, and S. Sancho (Univ. Politécnica de Valencia, Camino de Vera S/N, 46071 Valencia, Spain)

The City of Valencia has approximately 700 000 inhabitants. Due to this large population, the city is subjected to heavy traffic, and, as a consequence, high acoustic pollution. The Townhall of Valencia is very worried about this acoustic pollution and has commissioned the Laboratory of Acoustics in the Universidad Politécnica de Valencia to work on various projects within the city. Due to the work the department has carried out on behalf of the Townhall of Valencia, it has gained experience measuring with the sonometer. An efficient way of measuring noise within the city that avoids wasting long periods of time has been developed. Continuous 24-hour measurements have been taken by sonometers located in different stations spread out around the city and controlled by the Townhall. With these measurements a method that indicates when to measure, in the morning, afternoon, and at night, as well as the exposure time, has been designed. Other parameters, such as characteristics of the traffic, types of streets, etc., have been considered in order to obtain the time and the exposure time of measuring that represents the level of the noise.

4:00

4pNSa11. Characterization of vehicle noise in Hong Kong. W. T. Ng, M. M. F. Yuen, and W. M. To (Dept. of Mech. Eng., Hong Kong Univ. Sci. Technol., Clear Water Bay, Kowloon, Hong Kong, mewmto@usthk.ust.hk)

There is a common perception among residents of high-rise buildings facing expressways that noise emitted from moving vehicles would be dominated by tire/road interaction and at high-frequency regions. Local government officials believe that the impact on residents of low-frequency noise radiated from car engines would be insignificant, especially after the corrections for the *A*-weighting scale are applied. This paper reports on an extensive survey and some *in situ* sound measurements. It was found that road noise in Hong Kong is dominated by low-frequency noise emitted from heavy vehicles in expressways and by low-frequency noise emitted from heavy and light vehicles driven at a speed below 50 km/h in streets. The measured data were characterized by using time-averaged 1/1 octave band analysis, time-averaged 1/3 octave band analysis, and time-frequency analysis. The Doppler effect was clearly observed at low-frequency regions in joint time-frequency distributions. It is suggested that the *A*-weighting scale would not reflect the true annoyance level of traffic noise. Noisiness should be used to quantify the annoyance caused by moving vehicles. A new noise model is proposed to give a realistic description of noise radiated from a moving vehicle.

4:15

4pNSa12. Multivariate analysis of road traffic noise in Gandia (Spain) during 24 hours and its evolution in the last decades. Jose Romero (Lab. Acoust., Dept. Fisica Aplicada U.V., Facultad de Ciencia Fisicas, Valencia, Spain, Romerof@arrakis.es), Alicia Jiminez, Antonio Sanchis, Albert Marin (Polytecnic Univ. of Valencia, Spain), Amando Garcia (Lab. Acoust., Valencia, Spain), and Grover Zurita (Lulea Univ. of Technol., Sweden)

Road traffic noise is one of the most widespread and growing problems in urban areas. While it has long been known that hearing can be damaged by exposure to noise, it is also believed that continual noise, even at low or moderate intensity, can cause psychological discomfort and sleep disorders. Traffic noise levels in urban areas are increasing, and the areas affected by noise are spreading. As a result of these problems, legislation has been introduced by the city council to control the noise produced by individual vehicles with the aim of eventually producing traffic noise levels which are acceptable to the public. In this paper, therefore, aspects which connect the evolution of the road traffic noise in the last decades and the development of the infrastructure of the city are discussed. The study was carried out in Gandia (Spain), which is situated on the East Coast of the country, 65 kms from Valencia and 100 kms from Benidorn. The population has increased from 50 000 to 60 000 in the last 15 years, and the traffic distribution of the city has changed during this time, with a new bridge and some highways around the urban area. The main objective of this paper is to characterize the effects of the road traffic noise during 24 h (between 1983 and 1997), and including such aspects as traffic density and psychological aspects. The analysis part was performed by using multivariate analysis methods (MVA). Multivariate analysis methods can be used to investigate relationships between all the variables by extracting information from data with many variables and treating them simultaneously.

4:30

4pNSa13. Criteria and control for environmental noise emitted from motor vehicles. Ren Wentang (Noise Vib. Control Key Lab., Beijing Municipal Inst. Labour Protection, No. 55 Tao Ran Ting Rd., Beijing, 100054, China)

The present work investigated the environmental noise in a city from energy distribution and annoyance, and showed that the noise from different kinds of in-use vehicles is the main cause of noise pollution, especially in a city in a developing country. The technology and measures of noise control for in-use vehicles are urgently needed. According to measurement results of noise emission from 1000 vehicles based on ISO 5130, the statistical distribution parameters of stationary noise emission for six types of new vehicles and in-use vehicles are obtained. The statistical parameters show that the technology and measures of noise control for exhaust systems of in-use vehicles are key points. Some technological advances and noise-control measures have been proposed and practiced in China. A measurement procedure and system for vehicles in stationary operation is developed to distinguish some noisy vehicles with lost efficacy of a muffler. Regulations concerning stationary noise limits have been published and followed in China subsequent to the investigation. Reasonable design parameters of exhaust systems for different kinds of vehicles are proposed.

4:45

4pNSa14. A mathematical model for the evaluation and prediction of the mean energy level of traffic noise in Caracas. Nila Montbrun, Victor Rastelli, Alexis Bouza (Dept. de Mecánica, Univ. Simón Bolivar, A.P. 89000 Caracas 1080-A, Venezuela), Jenny Montbrun Di Filippo, and Yamilet Sánchez (Univ. Simón Bolivar, A.P. 89000, Caracas 1080-A, Venezuela)

The increase of the population in capital cities has provoked a serious increase in the acoustical pollution, where the real cause is the traffic noise. Over ten years, sound levels have been measured in several points in the city of Caracas. The main objective was to establish a mathematical model for the mean energy level of traffic noise. This model is a modification and improvement of the model that was used in Germany and Italy. Parameters of the fundamental equations were obtained by the use of large experimental data. In the particular case of Venezuela, an innovation was introduced by the consideration of the motorcycle noise. The obtained model can be used to predict noise pollution in cities and contour maps can be made as well.

4pNSb1. Active local noise control in open space. Jingnan Guo and Jie Pan (Dept. of Mech. and Mater. Eng., Univ. of Western Australia, Nedlands, WA 6907, Australia)

Local noise control, which creates quiet zones in desired areas, is a practical option of active noise control in open space when the control sources and the primary sources are not able to be very close. In most cases, the local control system attenuates the sound pressure in some areas at the cost of total sound power output increase. As a result, while the control system creates a quiet zone in some areas, it causes the sound pressure to increase in others. Two indicators of control efficiency, quiet zone size and total sound power output, are dependent upon the configuration of the control system. It has been found that for the multichannel control system, there exists a range of optimal configuration of control system, in which the control system can create the largest quiet zone with the lowest increase of total sound power output. Outside this range, the control system either becomes useless in creating large quiet zones, or causes great increase of sound pressure in most areas.

1:30

4pNSb2. Adaptive control of sound transmission with neural network algorithms. Jing Tian, Hai Lin, and Mingkun Cheng (Inst. of Acoust., Academia Sinica, Beijing 100080, PROC)

The Artificial Neural Network is widely used for its self-learning, self-organizing adaptability as well as nonlinearity in nature. Active control of structural sound radiation and sound transmission through panels is widely researched recently for its effectiveness and efficiency in the low-frequency range. In this paper, a neural network-based feedforward adaptive controller using the modified Error Back Propagation Learning Algorithm is presented. The controller is realized with a TMS320C25 DSP Board monitored by an IBM PC compatible, and applied to control the sound transmission through a thin panel between two rooms. Experiments showed that the algorithm was superior in robustness and broadband performance. In the adaptive controller, the structure of a traditional multilayered feedforward neural network (MFNN) is modified. Both filtered-X and filtered-U adaptive filters are discussed. Two auxiliary filters are designed to compensate the secondary signal feedback and the error delay. Random gradient estimation method is used to update the weights of MFNN. Several methods to speed the learning rate are also introduced. The causality of the feedforward controller is analyzed, by which the system behavior is greatly improved. Further strategy to improve the controller is also proposed. [Project supported by the Natural Science Fund of China.]

1:45

4pNSb3. Real-time wave separation in a cylindrical pipe with applications to reflectometry and echo-cancellation. Jean Guerard and Xavier Boutillon (Lab. d'Acoustique Musicale, CNRS-Univ. Paris 6, Case 161, 4 place Jussieu, 75252 Paris Cedex 05, France)

Precise control of the acoustical pressure all along a pipe requires that backward and forward propagating waves are separated in real time. This has been achieved by means of an array of up to five microphones, a high-precision analog calculation, and a real-time numerical post-treatment. The separation factor exceeds 40 dB over several kHz, when

special attention to intercalibration issues and to the realization of the analog part is given. The theoretical limit at high frequencies has been reached experimentally. The advantage of a partial analog treatment over a fully numerical one will be discussed. One application consists in reflectometry (and consequently, impedancemetry) without use of the long pipe normally required. Associated with a real-time DSP processor (TMS 320C30), wave separation also permits one to efficiently control the wave reflected by one end. This is done with only one loudspeaker, whose transfer function has been inverted and implemented in the DSP as an IIR filter. This approach of active-control differs from adaptative procedures. Finally, a musical application of the system to a hybrid wind instrument will be presented. [Work supported in part by the French Ministry of Culture.]

2:00

4pNSb4. Active noise control of a single-engine light aircraft cabin. Colin D. Kestell and Colin H. Hansen (Dept. of Mech. Eng., Univ. of Adelaide, Adelaide, SA 5005, Australia, cdkestel@watt.mecheng.adelaide.edu.au)

Active noise control (ANC) shows success and potential in a growing number of commercial applications, one of which is aircraft cabin noise reduction. With the exception of utilizing ANC headsets, light aircraft, which to date offer a high noise environment, have been somewhat overlooked. The importance of weight minimization also prevents installing copious quantities of dampening and insulation materials as a passive noise control measure. While headsets are a pilot's necessity and an obvious target for ''localized'' noise reduction, they are not conducive to either operator or passenger comfort. High noise levels not only render communication difficult but also contribute toward stress and fatigue. A more globalized region of reduced noise will be less restrictive and no doubt provide the occupants with more freedom of movement and overall comfort. Light aircraft operators boasting quieter cabins with a focus on customer comfort will no doubt have a distinct commercial advantage. Using flight trials and laboratory experiments as a basis, this paper will discuss the introduction of ANC into a four-seater Piper Archer. Existing noise levels, objectives, equipment used, methods of approach, and results to date shall be reviewed, as well as the remaining work required to achieve the final goal.

2:15

4pNSb5. Control of exhaust noise from diesel electric locomotives using a hybrid active/passive system. Paul Remington (BBN Technologies, 10 Moulton St., Cambridge, MA 02138), Douglas Hanna, and Scott Knight (BBN Technologies, New London, CT 06320-6147)

Diesel electric locomotives in the US represent a significant source of environmental noise under a variety of operating conditions. There are two primary sources of noise on these locomotives that will have to be reduced before significant reductions can be achieved: exhaust noise and cooling fan noise. Here a system is proposed that uses both active and passive components to control broadband exhaust noise below 3 kHz. The active system utilizes eight actuators and eight residual microphones in a feedforward configuration to control tonal noise below 250 Hz. The passive system is a compact exhaust silencer designed to control exhaust noise above that frequency while still fitting within the limited space available beneath the locomotive hood. Performance estimates for both the active and passive system will be presented along with the results of field tests of a breadboard active system on an F59PHI locomotive. [Work was supported under contract to the Federal Railroad Administration.]

2:45

4pNSb6. Anticipated effectiveness of active noise control in propeller aircraft interiors as determined by sound quality tests. Clemans A. Powell and Brenda M. Sullivan (NASA Langley Res. Ctr., M.S. 462, Hampton, VA 23681-0001, c.a.powell@larc.nasa.gov)

Active noise control technology offers the potential for weight-efficient aircraft interior noise reduction, particularly for propeller airplanes. However, there is little information on how passengers respond to this type of interior noise treatment. This paper presents results of two experiments which use sound quality engineering practices to determine the subjective effectiveness of hypothetical active noise control systems in a range of propeller airplanes. Binaural recordings were made in five different propeller airplanes and a commercial jet using an acoustic mannequin and a digital recording system. The noise stimuli for the tests were prepared by digitally modifying the propeller tones in recordings of each airplane type to simulate active noise control systems with a range of effectiveness and complexity. The noise stimuli were presented to the test subjects through electrostatic headphones to preserve the realism, spatiality, and directionality provided by the binaural system. The two tests differed by the type of judgments made by the subjects: pair comparisons in the first test and numerical category scaling in the second. Changes in subjective response relative to changes in measured sound characteristics afforded by the hypothetical active noise control schemes are presented and are contrasted between the two test methods.

3:00

4pNSb7. Robust feedback active noise control algorithm for impulsive additive noise. Sang-Wook Lee and Koeng-Mo Sung (School of Elec. Eng., Seoul Natl. Univ., Seoul 151-742, Korea, lsw@acoustics.snu.ac.kr)

Active noise control (ANC) is a method to reduce the unwanted noise level by introducing secondary noise which has the same amplitude and antiphase with the primary noise. The feedback ANC algorithm is a kind of linear predictor and it uses only one sensor to get the information about the error signal and reference signal. The filtered-x LMS (least mean square) algorithm is widely used for implementing the ANC system because of its simplicity and good performance. But when the additive noise is impulsive, the performance of LMS-type algorithms are known to be lowered. In this paper, the robust feedback ANC algorithm is proposed when impulsive additive noise is present. Instead of the LMS algorithm, the proportion-sign algorithm (PSA) which is a mixture of LMS and dual sign algorithm (DSA) is used to estimate the primary noise field robustly when impulsive additive noise is present. Computer simulations were performed under impulsive additive noise circumstances and showed better performance with the proposed algorithm than that with the conventional LMS algorithm.

3:15

4pNSb8. Active control of structural sound using an active constrained layer damping treatment. Jun Yang, Jing Tian, and Xiaodong Li (Inst. of Acoust., Academia Sinica, Beijing, 100080, PROC)

In this paper active constrained layer damping (ACLD) treatments are applied to control the noise transmitted into a cavity through a panel. Five of the enclosure walls are rigid and the other wall, which is flexible, is a simply supported panel. The panel is treated with ACLD, which consists of a viscoelastic shear layer sandwiched between a piezoelectric constraining cover sheet and the panel. The piezoelectric layer is utilized to control the panel vibration and the shear deformation of the viscoelastic layer to enhance its energy dissipation characteristics. The coupled structural sound equation of the composite panel and the cavity is derived and analyzed by the Galerkin approximation. The results indicate that combining active and passive controls, as in the case of ACLD treatment, is more effective in controlling the noise transmission. Moreover, such a control strategy is found to require lower control inputs than when the active and passive control actions are used separately.

3:30

4pNSb9. Active noise barrier efficiency improvement using multirate signal processing. Jelena Certic, Slobodan Kovacevic, and Petar Pravica (Univ. of Belgrade, Dept. of Elec. Eng., Bulevar Revolucije 73, Belgrade, Yugoslavia, cetic02996P@buef31.etf.bg.ac.yu)

In this paper, implementation of multirate signal processing techniques in an active noise barrier system was considered. Such a modification of a conventional multiple-error filtered-x LMS algorithm is supposed to give improved overall system performance, by separately controlling two different frequency ranges. The control system consists of one detection microphone, three secondary sources, and three error sensors. The primary signal was a random noise signal with a spectrum that coincides a typical road traffic noise spectrum. Locations of components were the ones found to be optimal in our previous work. Computer simulation was developed to compare the attenuation achieved with a control system that uses a multiple-error filtered-x LMS algorithm and the one involving multirate signal processing. Results of the computer simulation confirmed that attenuation is increased using multirate signal processing.

4pPAa1. Acoustically induced cavitation fusion. Lawrence A. Crum (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

In 1982, Hugh Flynn was issued a patent (No. 4,333,796) for a Method of Generating Energy by Acoustically Induced Cavitation Fusion and Reactor Therefor. Although it was largely ignored at the time, there have been several recent papers that treat the subject of acoustically induced fusion as quite plausible. Such prescience in the area of cavitation research was typical of Hugh's work. This patent shows such an enormous grasp of detail, and suggests Hugh must have given a great deal of thought and energy to its composition. The author will review some of the interesting aspects of this patent as well as describe some of the most recent activity on this topic. He will also reflect on his many rewarding and stimulating experiences with Hugh over the past 30 years.

1:20

4pPAa2. The search for cavitation *in vivo*. Edwin L. Carstensen, Sheryl Gracewski, and Diane Dalecki (Depts. of Elec. Eng. and Mech. Eng. and the Rochester Ctr. for Biomed. Ultrasound, Univ. of Rochester, Rochester, NY 14627)

Until the mid-1970s, it was generally assumed that with the short pulses of ultrasound used in medical diagnosis, there was little need for concern about the possibility of inertial cavitation *in vivo*. Conversations with Hugh Flynn at about that time made it clear that complacency in this respect was not warranted. Flynn carried out a comprehensive theoretical study of the response of microbubbles to diagnostically representative pulse exposures culminating in a publication, which is now the classic basis for an understanding of cavitation in diagnostic medicine. Robert Apfel independently published similar conclusions at about the same time. Flynn's contributions continued in a collaboration with Charles Church. Experimental evidence that cavitation *in vivo* might be relevant to the use of diagnostic ultrasound began with observations of the killing of fruit fly larvae with microsecond length pulses. Later, the mammalian lung was shown to be particularly vulnerable to these exposures. Noting that purely positive pulses were as damaging as purely negative pulses, Ding and Gracewski showed that inertial cavitation is greatly inhibited by bubble constraints that might occur in tissue. Most recently, hemolysis and hemorrhage associated with the use of contrast agents have provided nearly incontrovertible evidence of the occurrence of cavitation *in vivo*.

1:40

4pPAa3. Nonlinear dynamics of bubbles with surfactants. Robert Apfel, Xiaohui Chen, and Jeffrey Ketterling (Yale Univ., New Haven, CT 06520-8286)

Hugh Flynn pioneered many aspects of cavitational phenomena. He even got a patent on the idea that large bubble collapse could be used for inertially induced thermonuclear fusion. Some researchers currently working in the area of sonoluminescence are asking the same questions. One of the key requirements for confining the energy in the collapse of a bubble is maintaining spherical symmetry. Instabilities, such as Rayleigh–Taylor and Kelvin–Helmholtz, can compromise this requirement. Therefore it is useful to examine the role of surfactants in conferring stability on the collapse of bubbles. Codes that have recently permitted the description of superoscillations of liquid drops with surfactants in air [e.g., Apfel *et al.*, Phys. Rev. Lett. **78**, 1912–1915 (1997)] can be applied to the case of a bubble in a liquid. Of particular interest are insoluble surfactants, such as bovine serum albumin, which do not reduce

the surface tension that much, but which greatly increase the surface damping. The role of damping in discouraging or delaying instability of collapsing bubbles in an acoustic field will be presented. [Work supported in part by NASA through Contract No. 958722 managed by the Jet Propulsion Laboratory.]

2:00

4pPAa4. Response curves of bubbles. Werner H. Lauterborn and Robert Mettin (Drittes Physikalisches Institut, Universität Göttingen, D-37073 Göttingen, Germany)

A spherical bubble in a liquid is a nonlinear oscillator that can be set into radial (and surface) oscillations by a sound field. The nonlinear response depends on a set of parameters, mainly the bubble radius, the driving amplitude, and the driving frequency. The response is involved. It consists of an intertwined set of nonlinear resonances, that besides turning over, comprises period doubling sequences to chaos when going up and down in bubble radius, driving frequency, or driving amplitude. A specific feature is the giant resonance appearing for small bubbles and being the host for single bubble sonoluminescence. A set of response curves will be given to acquaint the listener with some understanding of how bubbles behave in a sound field.

2:30

4pPAa5. Bubble dynamics in non-Newtonian fluids. John Allen (Dept. of Mech. Eng., Univ. of Washington, Seattle, WA 98195) and Ronald A. Roy (Boston Univ., Boston, MA 02215)

Nonlinear oscillations of gas bubbles in viscoelastic non-Newtonian fluids remains a relatively unexplored area, but one of increasing importance with the growing use of high intensity ultrasound and contrast agents for imaging enhancement. Previous work by the authors focused on an analytical and numerical study of bubbles governed by linear viscoelastic constitutive equations. This work was constrained by the small deformation assumptions inherent in the equations. New numerical studies of objective viscoelastic constitutive equations reveal the limitations of the linear viscoelastic models and show many novel results. In particular, the risk of bioeffects from medical ultrasound and harmonic imaging applications are stressed. Questions about the trace of the stress tensor are also discussed. [Work supported by NIH and DARPA.]

2:45

4pPAa6. Giant resonance in the dynamics of small bubbles. Iskander Sh. Akhatov (Ufa (Bashkortostan) Branch of Russian Acad. of Sci., K. Marx St. 6, Ufa, 450000, Russia, iskander@ncan.ufanet.ru), Claus-Dieter Ohl, Robert Mettin, Ulrich Parlitz, and Werner Lauterborn (Universität Göttingen, Göttingen, Germany)

For bubble oscillations under medium and large pressure amplitudes a complicated scenario of bifurcations and coexisting (chaotic) attractors exists. However, for very small bubbles in a very strong sound field the dynamics becomes regular and a new type of strong resonance with a thresholdlike increase in oscillation amplitude occurs [E. A. Neppiras and B. E. Noltingk, Proc. Phys. Soc. London Ser. B **64**, 1032 (1951); H. G. Flynn, in *Physical Acoustics Vol. 1*, edited by W. P. Mason (1964), p. 57; W. Lauterborn, Acustica **20**, 105 (1968)]. This phenomenon has a strong influence on many properties of cavitation bubbles. The following aspects are considered: rectified diffusion, stability of the bubble under SBSL conditions, primary and secondary Bjerknes forces, and interpretation of bubble size measurements.

3:00

4pPAa7. Cavitation bubble dynamics induced by ultrasound waves. J-L. Laborde (EDF-DER ADEI, Rte. de Sens-Ecuelles, 77818 Moret-sur-Loing Cedex, France, jean-luc.laborde@edfgdf.fr), C. Bouyer (EDF-DER ADEI, 77818 Moret-sur-Loing Cedex, France), J-P. Caltagirone (ENSCPB-MASTER, 33402 Talence Cedex, France), and A. Gérard (LMP, Université de Boreaux I, 33405 Talence Cedex, France)

Propagation of power ultrasound (from 20 to 800 kHz) through a liquid initiates a not-so-well-known phenomenon called acoustic cavitation. Inceptions and germs grow into bubbles which collapse, possibly giving rise to extreme conditions of temperature and pressure (assessed to be up to 10 000 K and 500 atm). For instance, these conditions initiate and greatly enhance chemical reactions. A high-speed film shot at 500 fps clearly identifies stable and transient cavitation and shows bubble population phenomena. Clouds of bubbles grow up to ten times their emergence size during 15 ms, and move at velocity around 50 cm/s. Mathematical modeling is performed as a new approach to predict where active bubbles are and how intense cavitation is. Then, a first computation, based on Euler's linear acoustic equations, is used to calculate the pressure field in the case of a cylindrical sonoreactor. A second calculation based on fluid dynamics equations is undertaken as CFD codes are very interesting because they also provide velocity and temperature fields, and two phase flows (liquid and bubbles) could be modeled. The comparison with experimental observations (photographs, high-speed film) and measurements (Particule Image Velocity, temperature) shows good agreement with both calculations.

3:15

4pPAa8. Cavitation and capillary wave from a parametric decay scheme. Masanori Sato (Honda Electron. Co., Ltd., 20 Oyamazuka, Otwa-Cho, Toyohashi, Aichi, 441-31 Japan) and Toshitaka Fujii (Toyohashi Univ. of Technol., Hibari-ga-oka, Tempaku-Cho, Toyohashi, Aichi, 441 Japan)

Acoustic cavitation in liquids and capillary waves which cause ultrasonic atomization are considered to be related to the 1/2 subharmonic of ultrasonic surface waves via parametric decay instability. The cavitation bubble oscillation mode is an asymmetric surface bubble oscillation that does not easily emit ultrasonic waves into water and accumulates acoustic energy from longitudinal waves. The capillary waves accumulate acoustic energy in a surface of liquid, enough to be used not only for atomization but also the separation of water-ethanol solution. These were confirmed by experiments using ultrasonic longitudinal waves in water.

3:30

4pPAa9. An optical transducer for the study of the pressure field around a collapsing cavitation bubble. David C. Emmony and Robin D. Alcock (Dept. of Phys., Loughborough Univ., Loughborough, Leicestershire LE11 3TU, UK, DCEmmony@lboro.ac.uk)

An optical reflection transducer using a critical angle technique has been built to study the pressures developed around a single cavitation bubble in water. The bubble was generated at different distances from a planar glass surface, and total internal reflection at the glass water interface gives the pressure through the change in refractive index in both the water and the glass. A simple hemispherical pmma block system has been built to prove the feasibility of the system. In this case the change of the critical angle is not linear, but the use of a modified equilateral glass prism gives the pressure as a function of time around cavitation bubbles with maximum radii of approximately 1.0 mm and gamma values down to 0.3 with a temporal resolution only limited by the photodiode detection electronics (~10 ns). The transducer shows the development of positive pressure as well as the migration of the bubble to the surface and is capable of recording the rarefaction waves due to free surface reflection.

Contributed Papers

All posters will be on display from 12:45 p.m. to 3:45 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 12:45 p.m. to 2:15 p.m. and contributors of even-numbered papers will be at their posters from 2:15 p.m. to 3:45 p.m. To allow for extended viewing time, posters will remain on display until 12:00 noon on Friday, 26 June.

4pPAb1. Enhancement of acoustic cavitation effects by simultaneous multifrequency excitation. Qiping Fang, Beixing He, and Zhongmao Lin (Inst. of Acoust., Chinese Acad. of Sci., Beijing 100080, PROC, qpfang@public.fhnet.cn.net)

Acoustic cavitation can produce many effects. Promoting or inhibiting cavitation depends on different practical purposes. The production of as many cavitation activities as possible is always expected in sonochemistry. Here, the enhancement of acoustic cavitation effects by simultaneous multifrequency excitation, with frequencies in the power ultrasound ranges (20–100 kHz), is studied. One ultrasonic transducer is used to produce multiple ultrasonic frequencies at the same time, rather than several transducers which work at respective frequencies. A probe hydrophone is utilized to measure the subharmonic emission of cavitation and distribution of the acoustic field. The chemical effect of cavitation is determined by the method of iodine release. The results show that simultaneous multifrequency excitation can reduce the cavitation threshold and enhance the chemical effect of cavitation. On the basis of the cavitation bubble dynamics theory, the theoretical analysis proposed attempts to explain this phenomenon, and further discussions are presented. [Work supported by National Natural Science Foundation of China.]

4pPAb2. Nonlinear wave propagation in cylindrical air-filled tubes. Ludovic Menguy and Joël Gilbert (Inst. d'Acoustique et de Mécanique, LAUM UMR CNRS 6617, Ave. O. Messian, BP 535, 72017 Le Mans Cedex, France)

Three dimensional conservation laws are reformulated in a dimensionless form for a cylindrical air-filled tube. Three nondimensional numbers therefore appear, and are used to evaluate the order of magnitude of each term. Simplifying leads to two quasi-unidimensional generalized Burgers equations, which take into account both nonlinear phenomena and viscothermal losses. Special attention is paid to the validity of the different approximations we proposed. The method of multiple scales indicates that the interaction between the two opposite propagative waves is noncumulative and remains a *local* effect. The two Burgers equations are therefore *globally* independent. A numerical computation in the frequency domain solves the Burgers equations in the case of a stationary wave. The signal is supposed to be known at the two ends of the tube (or impedance instead of signal for one extremity). The computation uses the harmonic balance method to calculate the two opposite propagative waves which makes it possible to verify the right conditions in the two extremities. The signal everywhere in the tube is so pieced together. Some experiments are performed with a siren as source in one extremity, and measurements are compared with theoretical results.

4pPAb3. Numerical simulation with experimental validation for nonlinear standing wave phenomena. Zhichi Zhu, Anqi Zhou, Dongtao Huang (Dept. of Eng. Mech., Tsinghua Univ., Beijing, 100084, PROC, zzc-dem@mail.tsinghua.edu.cn), and Ke Liu (Inst. of Acoust., Academia Sinica, Beijing 100080, PROC)

The study of nonlinear standing waves is of great significance to nonlinear acoustics. The strong nonlinear standing wave phenomena are constantly encountered in the experimental studies of acoustics, such as multiplying growth of higher harmonics, saturation of harmonics, bifurcation, and chaos. The experimental study of strong nonlinear standing waves is highly restricted by the sound source, which is very difficult to build up when its sound power becomes very strong. Therefore, in this paper, a numerical approach to the problem was adopted. By the use of Euler equations and MacCormack fourth-order difference method, the multiplying growth and saturation of higher harmonics in a nonlinear standing wave have been numerically simulated. By increasing the sound-pressure level of the excited source from 125 to 190 dB, the entire development

process of the nonlinear standing wave was clearly illustrated. Some new interesting results were obtained from the simulation. For example, the sound-pressure level at zero frequency enlarges quickly with increasing the intensity of the excited source. A detailed comparison between numerical simulation and the relevant experimental results shows that the numerical investigation is successful. [Work supported by NSFC.]

4pPAb4. Acoustics wave propagation from an underground waveguide. Stanislav A. Kostarev (Tunneling Assoc., Sadovaja-Spasskaja 21, 107217, Moscow, Russia)

A simple enough model of an underground acoustic waveguide is proposed. A special structure of nonhomogeneity of the subsurface layer in the soil may lead to the capture of acoustic waves within a channel. In this case, a sound signal will propagate with a sufficiently small decay in comparison with homogeneous media (due to the lack of discrepancy of the wavefront). In this case vibration is observed at large distances from the source. A maximum value of the acoustic level is reached near the axes of the waveguide. In practice, this effect may be significant for the case of vibration generation for buildings on the piles. Under these conditions, enhanced values of vibration may take place even when the vibration of the ground surface is negligible.

4pPAb5. Diffraction of a sound wave on an open end of a half-infinite waveguide with impedance walls and impedance flanges. Evgeni L. Shenderov (Res. and Development Inst. ''Morfizpribor,'' 46, Chkalovski pr. 197376, St. Petersburg, Russia, shend@fs.spb.su)

Diffraction of a plane sound wave on an open end of a waveguide with impedance walls, connected with impedance flanges, is considered. A plane wave is incident upon the waveguide from open space. As a result of diffraction, part of the sound energy is scattered in the half-space and the other part of the energy penetrates into the waveguide. Results of the solution of this problem can be used for calculation of the amplitude of a sound wave, scattered by a hole, in particular, in the backward direction. Besides, one can calculate the sound energy penetrating into the waveguide. Absorption of the energy in the waveguide can be taken into account by introducing impedances with nonzero real parts. The distortion of the directivity pattern of a system of receivers located in the waveguide can also be obtained. The solution of the problem has been carried out by the integral equation method using Green's function of the half-space with an impedance boundary. The equation was solved by expanding an unknown function in the eigenfunctions of the waveguide. It reduces to an infinite set of linear algebraic equations. Results of computation of bistatic diagrams of scattering on the hole and diagrams of backward scattering are presented.

4pPAb6. Dependence on waveguide width of elastic convolver efficiency. Yasuhiko Nakagawa and Suguru Kitabayashi (Faculty of Eng., Yamanashi Univ., Kofu, 400 Japan)

An elastic convolver based on a nonlinear effect in surface acoustic wave (SAW) on a Y-Z·$LiNbO_3$ is widely used as a functional device in the area of communication system. Therefore, the efficiency, which is an important parameter for the SAW convolver, is quite low. There have been many reports on electrode structures and convolver materials for improving the efficiency. In this work, theoretical and experimental results are reported for the optimum width of a ($\Delta = v/v$) waveguide which has high convolver efficiency. The theoretical calculation was obtained by using the scalar potential approximation. The efficiency has a peak at a waveguide width of around 1λ. In order to increase the power density multistrip beam width compressors have been used. Performance of a device having a 4-μs waveguide length, a central frequency of 43 MHz and using 10:1 beam width compressors is described. The validity of the theory is proven experimentally, and, therefore, the optimum waveguide width for the convolver efficiency in a conventional elastic convolver is around one wavelength of the input SAW.

4pPAb7. A new time-domain approach for nonlinear wave propagation: Comparison with the KZK equation approach in the case of an unfocused cw beam. Jahangir Tavakkoli (Inst. of Biomed. Eng., Univ. of Toronto, Toronto, ON M5S 3G9, Canada), Oleg A. Sapozhnikov (Moscow State Univ., Moscow 119899, Russia), Remi Souchon, and Dominique Cathignol (INSERM, 69424 Lyon Cedex 03, France)

A time-domain numerical model for simulating acoustic pulse focusing in soft tissue has already been presented. In this model, the main effects responsible for finite-amplitude wave propagation, i.e., diffraction, frequency-dependent attenuation, and nonlinearity, were taken into account. Here, a comparison between the results of this model with those of the KZK model is presented. Using this model, the acoustic pressure field of a plane circular transducer was simulated in water for a large range of cw-mode input excitation levels. The on- and off-axis pressure-time waveforms and their corresponding harmonic components were calculated using this model and the KZK model, and very good agreement was obtained between the two models. Furthermore, these results were verified by previously published experimental measurements. At present, all implementations of the KZK model are limited to planar or weakly focused sources. This study, along with this group's previous work, reveals the validity of this finite-amplitude wave propagation model for a wide degree of source focusing (from a planar to a highly focused source), and in cw as well as PW modes. It is also shown that the computation time for this model is much less than for the KZK, using the same input parameters.

4pPAb8. Description of nonlinear planar traveling waves in a gas filled tube. Michal Bednarik (CTU-FEE, Technicka 2, 16627 Prague, Czech Republic)

This paper deals with problems for the description of nonlinear planar traveling waves in a gas-filled tube. These waves, which are influenced by the tube-wall boundary layer, can be described by both the Burgers equation and the Khokhlov–Zabolotskaya–Kuznecov's equation with the inclusion of a hereditary integral known as the fractional derivate of order $\frac{1}{2}$. Emphasis is placed on comparison of applicability of both the mentioned equations with respect to experimental data. The applicability of the Burgers model equation is limited by the cutoff frequency of the tube which is exceeded due to the growth of higher harmonic components that is caused by the nonlinear distortion of the primary harmonic shape of waves. The next part of this contribution is dedicated to the presentation of some new approximate solutions of the Burgers equation with a fractional derivate and a brief description of used numerical methods.

4pPAb9. Vibratory gyro-sensor using a trident tuning fork resonator with lateral width set in parallel with a rotationary axis. Yoshiro Tomikawa, Toshiharu Ogasawara, and Norikazu Ishida (Dept. of Elec. Eng. and Information Sci., Yamagata Univ., 4-3-16 Johnan, Yonezawa, Yamagata, 992 Japan)

This paper deals with a new type of piezoelectric vibratory gyro-sensor using a trident tuning fork resonator, which is supported laterally at its base portion, the width direction of which is in parallel with a rotationary axis. The vibratory gyro-sensor is an important and attractive device as an angular velocity sensor, especially, in the vehicle stability control (VSC) system schemed for a practical use in the not so far future. Therefore, many researchers have been engaged in development of such a key device in the VSC system. Some types of piezoelectric vibratory gyro-sensors have also been investigated; for example, two types of vibratory gyro-sensors have been studied using a trident tuning fork resonator: one of

them was vertically supported at its base portion and the other was flatly supported at the same portion. The gyro-sensor dealt with here is one of such types of gyro-sensors; however, its operation principle is different from theirs. That is, this new gyro-sensor is aimed at being constructed using two-mode coupling of flexural and torsional vibrations in tuning fork arms. In this paper, the structure and operation principle of such a new trident tuning fork resonator gyro-sensor are described, with simulated results of vibrational characteristics for designing the resonator, and moreover, experimental results to confirm its operation principle are shown.

4pPAb10. Effects of diffraction on the sensitivity of needle-type ultrasonic receivers. Gerald R. Harris, Paul M. Gammell, and Jeffrey M. Porter (FDA/CDRH, 9200 Corporate Blvd., HFZ-132, Rockville, MD 20850, grh@cdrh.fda.gov)

The low-frequency sensitivity of piezoelectric receivers usually is assumed to be represented accurately by the -3-dB cutoff frequency $f_{co}=(2\pi R_i C_i)^{-1}$, where R_i is the loading (e.g., amplifier) resistance and C_i is the total capacitance. For typical needle-type hydrophones such as used in medical ultrasound exposimetry, f_{co} is less than 50 kHz. However, theoretical studies have shown that diffraction effects at the needle tip can cause a low-frequency rolloff in sensitivity at frequencies much higher than that predicted by this simple electrical model. To examine this effect, broadband frequency response measurements of several needle-type hydrophones were made in the frequency range 0.2–2 MHz. The active sensor material was polyvinylidene fluoride, and needle diameters ranged from a few tenths of a millimeter to approximately 1 mm. In all cases the sensitivity decreased with decreasing frequency, with the -3 dB points all lying above 400 kHz. Such behavior calls the use of these devices into question when accurate knowledge of the pressure waveform is required, particularly with regard to measuring the peak rarefactional pressure in pulsed waveforms displaying significant finite amplitude distortion.

4pPAb11. Study of a volcano-profiled ultrasound field. Gonghuan Du, Enyu Wang, and Yu Zhang (Inst. of Acoust., Nanjing Univ., Nanjing 210093, PROC)

As is known, the volcano-profiled ultrasound field is of interest in the application of ultrasonic therapy for cancer. This paper indicates that when the radial distribution of vibration velocity on the surface of the source satisfies the expression $q(\xi)=(B\xi^2)^n\exp(-B\xi^2)$, the radiation field, which may be expressed analytically, will maintain approximately the volcano profile in the near field. By employing the theory of the electric field and controlling the shape of the back electrode, a volcano-profiled distribution of the normal component of the electric field and accordingly a same-shaped distribution of the vibration velocity are achieved on the surface of the transducer. In order to improve the radiation efficiency of the transducer, the same material (ceramics) as that of the piezoelectric component, however, unpolarized, is chosen for the back electrode. A once-shaping technique is utilized to make the special-shaped back electrode. The test of the ultrasound field is of satisfying result. The last part of the article gives a brief theoretical description of a nonlinear volcano field. [Work supported by NSF of China.]

4pPAb12. The second harmonic component in the focused sound field diffracted by a straight edge. Shigemi Saito and Jung-Soon Kim (Faculty of Marine Sci. and Technol., Tokai Univ., 3-20-1 Orido, Shimizu, Shizuoka, 424 Japan, ssaito@scc.u-tokai.ac.jp)

To analyze the characteristics of the acoustical imaging utilizing higher harmonic components in the focused sound field, the influence of a diffracting edge put into the focal region on the fundamental and second harmonic fields is theoretically and experimentally investigated. A straight rigid edge put normal to the acoustic axis is assumed to diffract a focused Gaussian beam. The second harmonic sound generated both in front of and beyond the edge is taken into account to calculate the diffracted field through the manner using the Green's function for the governing approximate equation. In the experiment, a knife edge is inserted normal to the sound beam formed by the 1.9-MHz focusing Gaussian source employing a concave piezoelectric transducer with an asteroid electrode. The axial field detected by a needle-type hydrophone as well as the signal obtained with another concave transducer is discussed regarding the amplitudes and phase difference of the fundamental and second harmonic components.

4pPAb13. Acoustic streaming and temperature elevation in a high viscous fluid by irradiation of ultrasound beams. Tomoo Kamakura, Hai-Ying Huang (Dept. of Electron., Univ. of Electro-Commun., 1-5-1, Chofugaoka, Chofu-shi, 182 Japan, kamakura@ee.uec.ac.jp), and Kazuhisa Matsuda (Koganei Tech. High School, Tokyo, 184 Japan)

Sound energy losses due to viscosity and heat conduction in a fluid cause the medium movement as acoustic streaming and cause temperature elevation in beams. In most fluids, the buoyancy force by heat expansion is generally weaker than the driving force of the streaming, so the temperature field is basically determined by the heat transfer equation with convective terms. As some physical parameters such as viscosity depend generally on temperature, the sound field is changed with the irradiation time of cw beams. In addition to the viscosity, two other parameters of sound absorption and sound speed are taken account of their temperature dependency in the present theory. The hydrodynamic flow, forced convection heat transfer, and wave equations are simultaneously solved for axisymmetric ultrasound beams by a finite difference scheme. Numerical examples of the streaming velocity and temperature rise are given. They demonstrate that sound pressure amplitude is intrinsically changed with time and sound self-action is generated. The present method of numerical calculation is easily extended to the problems of focusing and multilayered beam systems.

4pPAb14. Inversion of velocity statistical parameters from travel time measurements. Bertrand Iooss (Ecole des Mines de Paris, Ctr. de Géostatistique, 77305 Fontainebleau, France, iooss@cg.ensmp.fr)

Velocity estimation remains one of the main problems of seismic exploration works. Below a certain range of velocity heterogeneities, deterministic methods become impracticable and the small-scale fluctuations of the velocity field can be described as a random field defined by its first and second statistical moments. It reduces the problem to the determination of a few unknowns, like the mean value, the correlation lengths in the various directions of space, the standard deviation, and the type of correlation function. Theoretical formulas link the statistical moments of an anisotropic random velocity field and those of the travel times of an acoustic plane or spherical wave [A. Ishimaru, ''Wave propagation and scattering in random media'' (1978)]. They are based on the smooth perturbation method of Rytov and on the parabolic approximation which neglects the heterogeneities with scales smaller than the wavelength. Validity domains of these approximations are studied. Therefore, inversion formulas are derived and inversion procedures of the velocity statistical parameters are developed. Finally, comparisons are made between theoretical predictions and synthetic results performed via finite difference algorithms.

4pPAb15. Inverse scattering for porous media with rigid frame. Claude Depollier, Zine el Abidine Fellah, and Achour Aknine (Lab. Acoustique, Univ. Le Maine, B.P. 535, Le Mans Cedex 9, France)

The sound propagation in porous materials having a rigid frame filled by air is well described by the equivalent fluid model. In this framework, the interactions between fluid and structure are taken into account in two response factors, the dynamic tortuosity $\alpha(\omega)$ and the dynamic compressibility $\beta(\omega)$ defined by the equations

$$\rho\alpha(\omega)\frac{\partial\langle \mathbf{v}\rangle}{\partial t}=-\nabla\langle p\rangle, \quad \frac{\beta(\omega)}{K_a}\frac{\partial\langle p\rangle}{\partial t}=-\nabla\langle \mathbf{v}\rangle.$$

These functions are related to the thermal exchanges between fluid and frame and to the geometry of the pores and characterize the sound propagation in the porous media. For homogenous porous materials, these response factors can be measured by different methods, but when the material is inhomogeneous, these methods generally fail. A method is proposed for computing the sound field within a one-dimensional porous medium characterized by a spatially varying tortuosity and compressibility profiles. The spatial variation of the medium is assumed to be along the direction of propagation, i.e., it is stratified. Scattering operators and propagation operators are defined and their properties are studied. An inversion algorithm which leads to the reconstruction of the tortuosity and the compressibility is presented. Numerical results are compared to experimental data.

4pPAb16. *A-wave spatial resonances on thin cylindrical shells: Experimental study.** Loïc Martinez, Jean Duclos, and Alain Tinel (L.A.U.E., Pl. R. Schuman, BP 4006, 76610 Le Havre cedex, France)

An experimental study of a thin cylindrical shell in contact with two different fluids is proposed. Using surface wave analysis methods (SWAM), the *A*-wave and *A**-wave attenuation and phase velocity are first measured. The experiments show that when the internal fluid has a sound velocity slower than the external fluid, internal reflection of energy inside the shell generates an *A**-wave in multiple space and time positions. Using those results as a basis hypothesis, the 2-D $Ksi(k,\omega)$ wavenumber-frequency response of the fluid filled target is performed. On this *Ksi* representation, the multiple space *A**-wave echoes cause multiple space resonances on a *Ksi*-cut versus *k*. Those numerical results are investigated using SWAM. The so-identified multiple spatial resonances correspond very well to the earliest shell whispering gallery waves families found by Veksler *et al.* in terms of RST.

4pPAb17. Diffraction and conversion of the *A* wave on a *T* structure. Bruno Morvan, Alain Tinel, and Jean Duclos (L.A.U.E, Universite du Havre, Pl. R. Schuman, BP 4006, 76610 Le Havre, France)

The *A* wave propagates without attenuation in an immersed plane plate. So it can be potentially used in nondestructive inspection for great dimension structure. The *A* wave propagation is well understood in canonical structures (cylindrical shell, infinite plate). In this paper, a *T* structure is studied: a brazed perpendicular plate positioned on another one. This stucture is identified as an attached substructure like stiffeners, bulkheads, rib, etc. The experimental study has been performed with a sample made of different metals (stainless steel, brass) and with plates of different thicknesses (frequency-thickness product $\sim$0.5 to 1.5 MHz mm). The *A* wave is generated at the end of the plate by the conversion of a pulse bulk wave. A second immersed transducer collects the *A*-wave diffracted signal, at the plate's junction, at a given observation angle. It should be noted that the *A* wave is reflected and transmitted; it is also converted into a Lamb wave on the principal plate and the perpendicular plate. The spectral analysis of received signal, for different angles, allows the reconstitution of the Lamb wave dispersion curves.

4pPAb18. Formulation of a boundary value problem by a new principle of diffraction. M. Ueda (Dept. of Intl. Development Eng., Tokyo Inst. of Tech., 2-12-1 O-okayama, Meguro-ku, Tokyo, 152 Japan, ueda@ide.titech.ac.jp)

A new diffraction principle, that is formulated from a viewpoint centered at an observation point by considering wave propagation in a space seen by the observer virtually, has been proposed [M. Ueda, J. Acoust. Soc. Am. **95**, 2354–2361 (1994)]. This new approach allows us to grasp a simple understandable concept of diffraction and to formulate the first rigorous and unique representation of diffracted waves, that is, it satisfies both the wave equation and hard or soft boundary conditions for 3D objects. Thus the diffraction problem for scalar waves is solved by this approach. The presentation is expressed in a form of integral equation. Thus it is another problem to formulate the algorithm to find the solution. In this paper the numerical procedures to formulate the algorithm are described. The boundary value problem is formulated by a new principle of diffraction. The structure of the response function, that shows mutual dependence of potentials at the surface of the object, is made clear by this new formulation and it reveals a special role of the edge point in the diffraction process. The usefulness of the response function is made clear by the analysis of diffraction arisen from a semi-infinite plane.

4pPAb19. Modelization of Kirchhoff scattering by a sound ray algorithm. Jean J. Embrechts (Natl. Fund Sci. Res., Dept. of Acoust., Univ. Liege, Sart Tilman, B28, B4000 Liege 1, Belgium, jjembrechts@ulg.ac.be)

The problem of the modelization of sound scattering by rough surfaces arises in room acoustics computer simulations, when sound diffusion is taken into account, as well as in other acoustical fields of interest. It is shown here how a sound ray algorithm can be applied to simulate a scattering process obeying the Kirchhoff tangent plane approximation. The Kirchhoff formulation for a random rough surface is briefly recalled, with the shadowing function proposed by Bass and Fuks. The scattered intensity is directly proportional to the statistical distribution of the surface slopes, which here is kept as general as possible. Then, it is established that this formulation is strictly equivalent to the result of a suitable sound ray algorithm, when the wavelength approaches zero in the Kirchhoff formulation. This is demonstrated in theory, and then applied to several Gaussian rough surfaces. Moreover, hints are given to extend the mathematical analysis of the sound ray technique to the second-order reflections on the rough surface. This is viewed as a way to take into account multiple scattering, which is neglected by the Kirchhoff approximation. [Work supported by FNRS, Natl. Fund for Scientific Research.]

4pPAb20. Analytical method for radiation and scattering problems in noncanonical domains. Victor T. Grinchenko (Inst. of Hydromechan. NAS of Ukraine, 8/4 Zhelyabov St., 252057 Kiev, Ukraine, vgr@ihm.kiev.ua)

One of the tendencies in modern acoustics is to use analytical solutions of the Helmholtz equation to present the sound field around radiators and scatterers of noncanonical shapes. The *T* matrix and internal source density methods are examples. In the present paper a method called a partial domain method is discussed. An essential point of the method is the notion of general solution of the boundary-value problem for the Helmholtz equation. The boundaries of the objects under consideration are parts of coordinate surfaces in separable systems. However, surfaces may be either coordinate surfaces of different types (as in the case of a finite cylinder) or coordinate surfaces of different systems (as in the case of a cylinder with spherical lids). Theoretical problems of both the method and numerical implementation of one are discussed. Consideration of such aspects of the method as singularity of the field near corner points, nonuniqueness of the wave functions, and extension of boundary conditions gives a basis to make the computation process more effective. The numerical results for some cases of radiation by finite cylinder and cylinder with hemispherical lids are used to illustrate the method.

Session 4pPP

Psychological and Physiological Acoustics: Auditory Attention II (Poster Session)

Christine R. Mason, Chair
Department of Communication and Hearing Research, Boston University, Boston, Massachusetts 02215

Contributed Papers

All posters will be on display from 1:00 p.m. to 5:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 5:00 p.m. To allow for extended viewing time, posters will remain on display until 5:00 p.m. on Friday, 26 June. A cash bar will be set up near the poster session from 5:00 p.m. to 7:30 p.m. preceding the banquet. In order to provide extended viewing of posters in session 5aPP, authors of posters in that session have been requested to display their posters beginning at 1:00 p.m. in Grand Ballroom II.

4pPP1. The auditory attentional blink in a congenitally blind population. Kim M. Goddard, Elzbieta B. Slawinski, and Matthew I. Isaak (Dept. of Psych., Univ. of Calgary, Calgary, AB T2N 1N4, Canada, kgoddard@acs.ucalgary.ca)

The attentional blink (AB), a temporary information processing deficit that follows an attended-to target, has been demonstrated most recently using pure-tone stimuli in a rapid auditory presentation (RAP) paradigm. The current study compared this auditory AB in a group of congenitally blind individuals to nonblind individuals. RAP streams were created using 25 equally loud, randomly generated 1000–2490-Hz tones (11 tones/s). Tones were 85 ms in duration and were separated by a 5-ms silent interval. Target and probe tones were 1500-, 2000-, or 2500-Hz tones increased in intensity by approximately 10 dB SPL relative to the stream tones. In the experimental condition, participants identified the target and probe according to pitch (low, medium, or high). In the control condition, participants performed only the probe task. Probe detection accuracy was measured. Results revealed that in the control condition, participants reported a single loud tone with near ceiling accuracy. In contrast, in the experimental condition, probe detection accuracy was impaired for approximately 270 ms following the target and this impairment was significantly attenuated in the blind population. Findings are discussed in terms of compensatory attentional and temporal processing mechanisms. [Work supported by NSERC.]

4pPP2. The use of visible speech cues (speechreading) for directing auditory attention: Reducing temporal and spectral uncertainty in auditory detection of spoken sentences. Ken W. Grant and Philip F. Seitz (Walter Reed Army Medical Ctr., Army Audiol. and Speech Ctr., Washington, DC 20307-5001)

It is well established that auditory-visual speech recognition is far superior to auditory-only speech recognition. Classic accounts of the benefits of speechreading to speech recognition treat auditory and visual channels as independent sources of information that are integrated early in the speech perception process, most likely at a precategorical stage. The question addressed in this study was whether visible movements of the speech articulators could be used to improve the detection of speech in noise, thus demonstrating an influence of speechreading on the processing of low-level auditory cues. Subjects were required to detect the presence of spoken sentences in noise under three conditions: auditory-only, auditory-visual with a visually matched sentence, and auditory-visual with a visually unmatched sentence. The potential benefits of congruent visual speech cues to auditory detection will be discussed in terms of a reduction of signal uncertainty, in both temporal and spectral domains. In effect, the visual channel may serve to inform the auditory system about when (in time) and where (in frequency) to expect changes in the acoustic signal. [Work supported by NIH Grant DC00792.]

4pPP3. Order effects in the measurement of auditory thresholds during bimodal divided attention. Vishakha W. Rawool (Commun. Disord. and Special Education, Bloomsburg Univ., Bloomsburg, PA 17815)

This study investigated the effect of a visual distraction task on the detection of warbled tones presented at 0.5, 1, 2, and 4 kHz in two orders of presentation. Fourteen subjects responded to warbled tones in two conditions. In the first (attention) condition, the subjects pressed a button everytime they heard the tone. In the second (distraction) condition, they were asked to respond to the tones by turning their heads towards the speaker while solving a cardboard jigsaw puzzle as quickly as possible. The order of attention and distraction conditions was random. Following each correct response, visual reinforcement was presented. For seven of the subjects, the order of presentation of the stimuli was 4, 2, 1, and 0.5 kHz (order 1). For the remaining seven subjects, the order of presentation was 0.5, 1, 2, and 4 kHz (order 2). The same order was maintained in the attention and distraction conditions. Results showed a significant order, attention–distraction, and frequency interaction. The results suggest that distraction can worsen the thresholds at the beginning of the task, but it may cause improvement in thresholds over time. These results will be discussed with reference to dual task attention limits and intersensory facilitation.

4pPP4. The role of memory in the dual-task: Evidence from a frequency/amplitude judgment. Erick Gallun, Anne-Marie Bonnel, and Ervin R. Hafter (Dept. of Psych., Univ. of California, Berkeley, CA 94720, erick@ear.berkeley.edu)

Subjects judged changes in the amplitude and/or frequency of a 100-ms signal either within a trial (experiment one) or between trials (experiment two). Within-trial changes featured roving levels and frequencies, whereas between trial changes were always from the same pool of four stimuli. The cost of making two judgments as opposed to only one was measured by comparing performance in the three conditions (judge amplitude, judge frequency, or judge both). The cost of roving levels and frequencies was measured by comparing performance between the two experiments. It was found that two judgments resulted in a decrease in performance only when the rove was not employed. This agrees with

findings in the bimodal dual-task suggesting that the cost of dividing attention is a result of the use of long-term memory, and that the sensory-trace does not incur a cost in the dual-task. [Research supported by the Nat. Inst. of Health (NIDCD 07787), USA, Univ. of California, USA, and CNRS, France.]

4pPP5. Monitoring the simultaneous presentation of multiple spatialized speech signals in the free field. W. Todd Nelson (AL/CFBA, 2610 Seventh St., Bldg. 441, Wright-Patterson AFB, OH 45433-7901), Robert S. Bolia (Systems Res. Labs., Dayton, OH 45440), Mark A. Ericson, and Richard L. McKinley (AL/CFBA, Wright-Patterson AFB, OH 45433-7901)

The effect of spatial auditory information on listeners' ability to detect, identify, and monitor the simultaneous presentation of multiple speech was evaluated in the free field. Factorial combinations of four variables, including the number of localized speech signals, the angular separation of the speech signals, the location of the speech signals along the horizontal plane, and the sex of the speaker were employed using a completely within-subjects design. Participants were required to detect the presentation of a critical speech signal against a background of nonsignal speech events. Speech stimuli were derived from a coordinated call sign test which consisted of a call sign (''Ringo''), a color (''red''), and a number (''five''). In addition to having high face validity for aviation communication tasks, this measure has been successfully employed in competing message experiments. The experiment was conducted at the USAF Armstrong Laboratory's Auditory Localization Facility—a 277-speaker geodesic sphere housed within an anechoic chamber. Performance efficiency was evaluated in terms of percentage of correct detections and false alarms, reaction time, and signal detection theory indices of perceptual sensitivity and response bias. Implications for the design of spatial auitory displays to enhance communication effectiveness and situation awareness are discussed.

4pPP6. Sequential interactions in discrimination of target frequency increments trailed by irrelevant frequency increments: Effects of target duration and target-irrelevant frequency separation. Blas Espinoza-Varas and Hyunsook Jang (Commun. Sci. and Disord., Univ. of Oklahoma Health Sci. Ctr., Oklahoma City, OK 73190, blas-espinoza-varas@UOKHSC.edu)

Discrimination thresholds were measured for target frequency increments trailed by irrelevant frequency increments. Pairs of pure tones (t_1,t_2) separated by 20 ms of silence were presented on each interval of a three-interval, two-alternative, forced-choice task. Duration was 40 or 80 ms for t_1, and 80 ms for t_2; frequency was 1500 Hz for t_1, and either 500, 1500, or 2500 Hz for t_2; level was 70 dB SPL for t_1 and t_2. On each trial, a ''standard'' pair of tones (interval 1) was followed by two ''comparison'' pairs (interval 2 and 3). One (randomly chosen) ''comparison'' pair contained an adaptively varied target increment in the frequency of t_1. In addition, both comparison stimuli contained identical irrelevant increments in t_2 frequency. Listeners had to determine which ''comparison'' interval contained the target increment. Irrelevant frequency increments elevated target-frequency discrimination thresholds. Threshold elevation was greater with 40-ms than with 80-ms targets. Equal-frequency conditions (1500 Hz for t_1 and t_2) yielded larger threshold elevation than unequal frequency conditions (1500 and 500 Hz or 1500 and 2500 Hz for t_1 and t_2). Irrelevant-increment effects decreased with training. [Funded by OCAST Project HR4-064.]

4pPP7. Interactions of pairs of target and context tones based on relative frequency relation and degree of frequency uncertainty. Donna L. Neff and Rebecca L. Wrage (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131, neff@boystown.org)

Four normal-hearing listeners completed 2IFC sample-discrimination tasks for frequency, in which they judged which of two tone pairs was drawn from the higher of two Gaussian frequency distributions. The center frequencies of the two target distributions were placed at low (400/500 Hz), middle (1128/1410 Hz), or high (3200/4000 Hz) frequency regions. All distributions were equally spaced and equivariant on a logarithmic frequency scale. Pairs of extraneous (to-be-ignored) context tones were added above, flanking, and below the low-, middle-, and high-frequency target regions, respectively. Across conditions, target and context tones used the same frequency regions, but never occupied the same frequency region within condition. Context tones were fixed in frequency, varied between two known frequencies, or were Gaussian distributed. A level jitter was added to derive perceptual weighting functions across stimuli. The results showed little detrimental effect of fixed-frequency context tones, but large individual differences in the effects of known pairs of tones or tones with Gaussian variation. Weighting functions and patterns of frequency interactions among stimuli will be discussed. [Work supported by NIDCD.]

4pPP8. Effects of tonal masker uncertainty on detection. Elzbieta B. Slawinski (Dept of Psych., Univ. of Calgary, Calgary, AB T2N 1N4, Canada, eslawins@acs.ucalgary.ca) and Bertram Scharf (Ctr. de Recherche en Neurosci. Cognit., CNRS, Marseille, France)

The present study was inspired by results of Allen and Wightman [J. Speech Hear. Res. **38**, 503–511 (1995)]. The goal of the present study was to explore the effects of uncertainty of a weak tonal masker (or distractor) on the detection of a tone in noise. The thresholds of three listeners were measured for 1-kHz tone burst (350-ms duration) in broadband noise (300–1800 Hz, at 60 dB SPL). A 2IFC tracking procedure (3 down, 1 up) with six interleaved tracks was used. On each trial, the distractor frequency was selected randomly from six frequencies (525, 800, 925, 1075, 1280, and 1600 Hz) outside of the critical band surrounding the signal. The distractor came on simultaneously with the signal in the signal-plus-noise interval and also at the corresponding moment in the noise-alone interval. The preliminary results indicated that thresholds for the signal increased in the presence of distractors by 3–10 dB, depending on the frequency of the distractors and type of noise. Thresholds were higher for distractors close to the signal frequency, more so in intermittent noise than in continuous noise.

4pPP9. Identification of brief auditory patterns. Gerald Kidd, Jr., Christine R. Mason, and Chung-Yiu P. Chiu (Dept. of Commun. Disord. and Hearing Res. Ctr., Boston Univ., Boston, MA 02215, gkidd@bu.edu)

The identification of brief nonspeech sounds poses a challenging problem for machine-based recognition systems, especially at low signal-to-noise ratios. In contrast, human observers are thought to be remarkably adept at such tasks. However, there are few systematic studies in the literature that have attempted to quantify human psychophysical performance, or the factors that influence performance, for the identification of brief nonspeech sounds in noise. This study examined human identification of brief sequences of tones arranged in six frequency patterns in masked conditions. The stimuli and methods have been described previously [Kidd, Jr. *et al.*, J. Acoust. Soc. Am. **98**, 1977–1986 (1995)]. Several acoustical factors were varied including pattern duration, signal-to-noise ratio, and range of frequencies forming the patterns. Identification performance declined as duration was shortened below 100 ms even when signal energy, or detectability, were equated. For brief patterns at low signal-to-noise ratios, increasing the range of frequencies comprising the patterns improved identification performance. These results provide in-

sight into the limits of human performance in the identification of brief sounds and may prove useful in the design of algorithms for machine-based recognition. [Supported by ONR and NIH.]

4pPP10. Selective attending to auditory streams in complex sequences: Frequency and/or temporal expectations? Carolyn Drake, Renaud Brochard, and Matthieu Adenier (Lab. de Psych. Exp., CNRS URA 316, Univ. Rene Descartes, 28 rue Serpente, 75006, Paris, France)

Both frequency and temporal information influence the perceptual organization of complex sequences: stream segregation is more likely with wider frequency separations and at faster rates. The influence of frequency and temporal information in directing attention to a stream within a complex sequence is investigated. Complex sequences of three subsequences (each with a specific frequency/tempo combination) were preceded by a cue sequence containing different types of information (FT=frequency + tempo, F=frequency, T=tempo, S=silence). The ability to selectively attend to one subsequence was measured by correct detections of a small temporal irregularity in the cued subsequence. When stream segregation was easy (large frequency separations), performance was similar for FT and F (93%), intermediate for T (79%) and random for S (64%): frequency information facilitated selective attending more than temporal information. When stream segregation was hard (small frequency separations), performance was poorer and similar for all conditions (65%): temporal information became predominant when frequency information was less useful. Thus listeners adapt their attending strategies to coincide with the most pertinent information. Results are discussed in terms of diverging predictions of the theories of Bregman [1990] and Jones [1993].

4pPP11. Application of a peripheral model to an attentional filter of missing-fundamental tone. Hiromitsu Miyazono (Dept. of Administration, Pref. Univ. of Kumamoto, 3-1-100 Tsukide Kumamoto, 862 Japan, miyazono@pu-kumamoto.ac.jp), Tsuyoshi Usagawa, and Masanao Ebata (Kumamoto Univ., 2-39-1 Kurokami Kumamoto, 860 Japan)

An attentional filter measured by the probe-signal method is compared with the peripheral auditory filter measured by the notch-noise method. The shape of attentional filter is estimated by the roex (rounded exponential) filter model. However, the attention can be given on a frequency without the signal on the actual frequency. In this study, the attentional filter was measured using a missing-fundamental tone which has no energy on an actual frequency. The missing-fundamental tone was produced by a harmonic signal with 13 components from 1000 Hz to 4000 Hz. The fundamental frequency was set to 250 Hz. The psychometric function is measured on various frequencies and the shift of the function from that of control condition is regarded as the effect of the attentional filter. The filter shape is estimated by the roex model and compared with that of the pure tone. In the frequency region apart from the fundamental, the dynamic range of the filter is smaller than that of pure tone. Near the fundamental, the correlation between the measured value by the probe-signal method and the estimated value by the roex filter for the missing-fundamental tone is smaller than that for the pure tone.

4pPP12. Short-term auditory memory interference: The effect of speech pitch salience. Kazuo Ueda and Naoko Seo (Dept. of Psych., Kyoto Pref. Univ., Hangi-cho, Shimogamo, Kyoto, 606 Japan, h50015@sakura.kudpc.kyoto-u.ac.jp)

The interference effect of speech pitch salience on tone pitch recognition and digit recall was observed. For the pitch recognition task, 11 subjects had to recognize pitches of two harmonic complex tones separated by a 5-s retention interval. During the interval, no sounds or six randomly chosen intervening sounds, either complex tones from a semitone scale or spoken digits, were presented. The speech included natural stimuli and synthesized stimuli with the original and with flattened pitch contours. For the digit recall task, the subjects had to recall serially the intervening digits. They had to perform both tasks in the dual task conditions. The results were: (1) the synthesized speech was equally intelligible as natural speech, (2) both pitch recognition errors and digit recall errors were significantly increased in the dual task conditions compared to the single task conditions, and (3) the synthesized speech with the flattened pitch contours as well as the complex tones had the most deteriorating effect on tone pitch recognition. Thus it became obvious that the weak interference effect of natural speech on tone pitch recognition was due to their pitch ambiguity. [Work supported by Grant-in Aid for Scientific Research and by Nagai Research Fund.]

4pPP13. Changing frequency after-effect of a linear frequency glide. Takuro Kayahara (Intelligent Modeling Lab., Univ. of Tokyo, 2-11-16, Yayoi, Bunkyo-ku, Tokyo, 113 Japan, kayahara@iml.u-tokyo.ac.jp)

After listening to a linear frequency glide in a single direction ten times, subjective frequency change of stationary sine wave in the opposite direction was observed (changing frequency after-effect). Adapting glides had a fixed frequency excursion (ΔF: 960–1040 Hz), five different durations (250, 500, 750, 1000, or 1250 ms), and glided either upward or downward in frequency. Test glides starting from 1000 Hz had three different durations (500, 750, or 1000 ms), and its ΔF increased or decreased according to subject's response. ΔF at subjective stationary frequency was measured using a three-category (''up,'' ''down,'' or ''no change'' in frequency) double-staircase procedure. In the ipsilateral condition (presenting both adapting and test stimuli to the same ear), ΔF in the same direction with the adapting glides was obtained and maximum ΔF (12 Hz) was observed when the duration of each test glide was the same as adapting glides, although, in the contralateral condition, ΔF was very small or none. These results suggest that there is a feature extractor which is selective in changing frequency and its direction at the level before integration of interaural information, and this extractor changes its own property after a relatively short time exposure of a single direction frequency glide.

4pPP14. Dynamic intensity change influences perceived pitch: Attentional differences between musicians and nonmusicians. John G. Neuhoff (Lafayette College, Easton, PA 18042)

The influence of dynamic intensity change on the terminal pitch of ascending frequency glides was tested as a function of terminal frequency and musical experience. Previous work has shown that dynamic intensity change influences perceived pitch [J. G. Neuhoff and M. K. McBeath, J. Exp. Psychol.: Human Percept. Perform. **22**, 970–985 (1996)]. In the current study, musicians and nonmusicians were presented with dynamic tones that changed in both frequency and intensity, and made real-time judgments about perceived pitch change. Results show that for both musicians and nonmusicians, the influence of intensity change on perceived pitch lessened as the terminal frequency approached an octave. Musicians were less susceptible to the effects of intensity change for falling intensity but not for rising intensity. The findings suggest that musicians may have better selective attention to dynamic auditory stimulus dimensions, and the influence of a tonal schema may reduce the influence of intensity change on perceived pitch. The results imply an interplay of musical and nonmusical listening strategies and demonstrate that the two are not mutually exclusive.

4pPP15. Temporal properties of loudness recalibration. Dan Mapes-Riordan and William A. Yost (Parmly Hearing Inst., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626)

Loudness recalibration occurs when a loud (recalibration) tone at frequency $f1$ precedes quieter test tones at frequencies $f1$ and $f2$. Recalibration is a reduction in the perceived loudness of the test tone at $f1$ due to the addition of the recalibration tone. Mapes-Riordan and Yost [J.

Acoust. Soc. Am. **101**, 3170(A) (1997)] showed that the temporal onset of loudness recalibration is relatively fast. The current set of experiments addressed the temporal decay properties of loudness recalibration. The first set of experiments examined the ''local'' temporal characteristics by measuring how the average amount of loudness recalibration varies with the duration of silent gap between the recalibration tone and the first comparison tone. A second set of experiments examined the ''global'' nature of the decay of loudness recalibration by inducing recalibration and then monitoring the decay using an adaptive tracking procedure. The results of these experiments will be discussed in terms of how assimilation processes influence loudness recalibration, what factors make the decay of loudness recalibration relatively slow, and the effect of attention on loudness recalibration. [Work supported by a Program Project Grant from NIDCD.]

4pSA1. Uncertainty in modeling the dynamics of structures in midfrequency range. Kai-Ulrich Machens and Eike Brechlin (Inst. of Tech. Acoust., Univ. of Technol., Berlin, Germany)

Based on measurements of the energy contents in single struts in a complex truss structure (109 struts, 35 joints) [Machens, Dyer. Acustica **81** (1995)], a numerical simulation of the truss dynamics using the direct dynamic stiffness method was performed. Great care was taken to account for flexural, longitudinal, and torsional waves in the struts, moments of inertia and masses of the joints, complex coupling stiffness (translational and rotational) including a loss factor between joints and struts, as well as material damping in the struts. The struts were modeled as Euler–Bernoulli–Beams and additionally as Rayleigh–Timoshenko–Beams. Frequency averaging proved to be important in the midfrequency range as a meaningful comparison with the measured data depends on a high accuracy in modeling and choice of material parameters. The broadband frequency averaged energy in single struts show a high sensitivity towards various factors such as small random variations of the geometry and of the complex coupling stiffnesses as well as the use of first- and second-order beam theory. The results show that a truss, which is built up from simple elements, becomes fuzzy merely by its high number of coupled elements.

4pSA2. Reduction of fluid-loaded ribbed shells to equivalent uniform structures for mid- to high-frequency structural acoustic analysis. Donald B. Bliss (Dept. of Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708) and Linda P. Franzoni (North Carolina State Univ., Raleigh, NC 27695)

The acoustic and vibratory behavior of fluid-loaded shells with ribs and other structural discontinuities is of great interest in naval applications. These structural discontinuities lead to complex phenomena, especially at mid- to high-frequencies where shell wavelengths are shorter than the discontinuity spacing. The methods of homogenization and local/global decomposition can be used to divide this problem into two parts. In the global problem, periodic discontinuities are replaced by an equivalent distributed suspension with slowly varying properties. This problem can be solved much more efficiently than the original problem since all rapidly varying scales have been removed. The local problem is solved separately and independently, except for amplitude information from the global problem. The local problem formulation provides transfer function information that defines the suspension in the global problem. Once the formulation has been developed for a specific structure, the global problem is solved first, and the local solution can be reconstructed afterward. The two constituent parts are then recombined to form a composite solution. As an illustration, this methodology is used to solve for Bloch waves on a structure with identical periodic discontinuities. The application of the theory to nonidentical discontinuities is also explained.

4pSA3. Toward a design methodology for equipment emulators in the shock testing of large structures. Pierre DuPont and J. Gregory McDaniel (Dept. of Aerosp. and Mech. Eng., Boston Univ., Boston, MA 02215)

In a variety of situations, an undesired shock excitation is applied to a master structure which supports shock-sensitive equipment. Often, one wishes to design and test a master structure which transmits the least amount of shock energy to the attached equipment. In scaled testing of new designs, a major task is to design and construct ''equipment emulators,'' inexpensive mechanical systems which approximately mimic the dynamic behavior of the actual full-scale equipment *as seen by the master structure*. This presentation will present new methodologies for designing equipment emulators, assessing their fidelity, and interpreting test data taken in the presence of imperfect emulators. Starting with frequency-domain impedance descriptions of the master structure and actual equipment at the attachment points, this work develops sensitivity metrics which directly relate the fidelity of the emulator to its structural complexity. These ideas may provide a path by which experimentalists can efficiently arrive at conceptual designs of emulators which promise a specified degree of fidelity in terms of system velocities and their associated shock spectra. The ideas are illustrated on simple examples and applied to the emulation of commercial-grade electronic cabinets for the testing of novel ship deck structures. [Work supported by ONR.]

4pSA4. A new finite-element analysis approach for the prediction of minimum and maximum vibroacoustic response of solid–fluid systems. Jean-Sébastien Genot, François Charron, and Noureddine Atalla (Univ. of Sherbrooke, Dept. of Mech. Eng., Sherbrooke, QC J1K 2R1, Canada)

Engineers are aware that identical products do not have necessarily the same dynamic response because of small differences in their dimensions or material properties. The classical finite-element method cannot take account of this fact. Statistical tools are needed. In order to consider the input data variability, new modules have been integrated in a finite-element code to estimate the maximum and minimum response levels (mean quadratic velocity and radiated power) of a structure. Up to now,

numerical modules were generally based on Monte Carlo or perturbation methods. Both have limiting and complementary drawbacks: The Monte Carlo method is accurate but far too slow, even for small finite-element models, while the perturbation scheme is fast, but unable to predict nonlinear behavior of the dynamic response properly with respect to the input variables. The developed approach takes advantage of the response modal decomposition to identify intermediate variables which are nearly linear. The intermediate variables (eigenfrequencies, dynamic factors) are easily interpolated, thus requiring little computation. Results are presented to prove the efficiency of the method.

2:00

4pSA5. FEM aided structural intensity measurement method for thick body. Yoshikazu Koike, Chie Aramaki, Kentaro Nakamura, and Sadayuki Ueha (Precision and Intelligence Lab., Tokyo Inst. of Technol., 4259 Nagatsuda, Midori-ku, Yokohama, 226 Japan)

Many studies about structural intensity(SI) measurement, which is useful to know transmission paths of the vibration energy in a body, have been reported. Most of the works, however, have been done only for thin bodies, such as beams or plates because of the difficulty in measuring interior vibration distribution in thick structures. In this paper, a new SI measurement method applicable to thick bodies is proposed. The entire vibration distribution in the structure is calculated by dynamic analysis of the finite element method (FEM) from the partial surface vibration data if the elastic parameters, the sound velocity, sizes of a body under study, and the locations of excitation and absorption are given *a priori*. The entire SI distribution can be estimated using the results. Based on this method, several SI measurements for thick vibrating bodies have been successfully carried. The merits of this method are as follows. (1) Only surface vibration data of the structure is needed to estimate the entire SI distribution. (2) It is applicable for arbitrary 3-D structures if the conditions mentioned above are satisfied *a priori*. The principle and the experimental results are described in the report.

2:15

4pSA6. Resilient mounting of engines. Anders Nilsson, Leif Kari, and Romain Haettel (MWL, Dept. of Vehicle Eng., KTH, 10044 Stockholm, Sweden)

In any type of vehicle a number of mechanical sources generate structure-borne noise. The energy is transmitted from excitation points to surrounding structures. These radiate noise externally and internally. The most commonly used method to reduce the radiated noise is to mount the sources resiliently to the supporting foundation. The insertion loss due to the resilient mounting can in many cases be extremely poor. This could be due to the break down of the stiffness of the foundation in the audible frequency range. At the same time the stiffness of the mounts could be increased drastically as compared to the static stiffness. A test rig and measurement procedures for determining the dynamic properties of mounts are described. Measured and predicted results are compared for rubber mounts with simple geometries. The insertion loss of a resilient mounting very much depends on the location of the engine feet on a foundation. Case studies relating to passenger vessels and catamarans built with aluminum and sandwiched are presented. Reduction of both noise and weight is discussed.

4pSA7. Assessment of construction vibration impacts on historic structures. Chetlur G. Balachandran (Parsons Brinckerhoff, Inc., One Penn Plaza, New York, NY 10119)

This paper addresses construction-related ground vibration impacts to historic structures located in an area where three options are being considered for providing capacity improvement to an existing roadway. Historic structures within the project area are: a Fort, a Legislature building, an electrical substation, and an auxiliary building. The above fragile structures are more likely to be affected by construction-related ground vibration impacts than by operational traffic-induced vibration impacts. The buildings are in close proximity to the existing heavily traveled roadway and are already experiencing moderate levels of ground vibration from road traffic. Potential vibration effects from heavy construction equipment include annoyance to people inside these buildings and potential for minor damage to the buildings. The particular concern in the present study is to comply with ground-vibration criteria to safeguard identified structures within the project corridor against construction-induced ground vibration. The various national and international criteria that were used to assess vibration impacts together with the results of vibration impact assessment will be presented. Construction of the roadway alternative that would cause the least vibration impact was identified and mitigation was considered.

3:00

4pSA8. Hybrid control for vibration and acoustics. Robert L. Clark (Dept. of Mech. Eng., Duke Univ., Box 90300, Durham, NC 27708) and Dennis Bernstein (Univ. of Michigan, Ann Arbor, MI 48109-2118)

The ''standard problem,'' frequently discussed in the controls literature, is detailed for application to noise and vibration control. Specifically, the feedback, feedforward, and hybrid (combination of feedback and feedforward) control system architectures are developed in the framework of the standard problem. The hybrid measurement structure and problem was formulated to demonstrate that the LQG compensator design for control of stochastic inputs is separable with respect to inputs which can be measured directly. Thus, one can design a feedback controller in the absence of measurable input disturbances if the objective is to combine both feedback and feedforward or adaptive feedforward control for stochastic and measurable inputs, respectively. Once the feedback controller is designed for the stochastic inputs, the feedforward controller required for the measurable input disturbances can be designed in a subsequent formulation of the control problem. Realizing that the design of such compensators is separable serves to simplify the hybrid design process.

3:15

4pSA9. Active control of total structural intensity in a T beam: General case. Sabih I. Hayek and Jungyun Won (Active Vib. Control Lab., Dept. of Eng. Sci. and Mech., Penn State Univ., University Park, PA 16802, sihesm@engr.psu.edu)

The active control of power flow in a T beam was presented at the 134th Meeting of the Acoustical Society of America. In that paper, the mechanical noise source was a shear force in the plane of the T beam. In this paper, the active control of structural intensity in the T beam is achieved for a general shear mechanical noise source that has in-plane and out-of-plane components. The reduction of the total power flow at a control point located midway in the vertical leg of the T beam is achieved through control actuators that are located at one end of the straight part of the T beam. The vector control actuators have components in three-dimensional space in various combinations of normal forces, shear forces, torques, and moments. The efficiency of the structural intensity reduction is considered for local versus global control. Various control strategies are compared which are also aimed at minimizing the cost function that represents the total power requirement for the control process versus the noise input power.

3:30

4pSA10. Vibration isolation of two elastic structures using active compliance at the isolation mounts. Kenneth E. Jones and Y. F. Hwang (Carderock Div., Naval Surface Warfare Ctr., 9500 MacArthur Blvd., West Bethesda, MD 20817-5700)

A mathematical model of the vibration isolation of two elastically connected structures (via isolation mounts) employing active springs is presented. Two elastic structures are connected by an arbitrary number of springs, each made active by the inclusion of a piezoelectric pad at one of

the spring and structure interfaces. Single-input–single-output feedback controllers at each spring support seek to minimize the force transmitted from one structure to the other. Solutions are based upon the formalism of Lagrange's equations using the normal modes of the uncoupled structures as the generalized coordinates. The constraints by the springs and supports are enforced by Lagrange multipliers. A 2-D numerical example of two elastic beams is presented. One beam, driven by a harmonic disturbance force, is coupled to the second elastically supported beam through three active springs. A beam-relative displacement sensor colocated at each spring is the input to an arbitrary feedback filter which can incorporate practical amplifier characteristics and actuator dynamics. Results of the numerical simulation of the feedback control case are discussed.

4pSC1. Fifty-four years in speech research. Gunnar Fant (Dept. of Speech, Music and Hearing, KTH, Stockholm, S-10044, Sweden, gunnar@speech.kth.se)

This is a brief presentation of my scientific career with outlooks on the development of speech research in the last 50 years. It started with an electrical engineering thesis at KTH in 1944–1945. The topic was intelligibility loss as a function of bandwidth reduction in telephony and related problems in assessing the effects of various types of hearing loss. In 1945–1948 I was employed by the Ericsson Telephone Company where I conducted basic studies of the spectral characteristics of Swedish speech sounds. This early period and my two years at MIT, 1949–1951, provided an entry to a pioneering era of speech research with new tools for speech analysis and synthesis and speech production modeling. It was during this time I started my work on the acoustic theory of speech production and established my cooperation with the linguists Roman Jakobson and Morris Halle and with Ken Stevens. I have followed the advent and the progress of speech research through the analog, the digital, and the computer age. Speech research now has the challenge to provide a deeper and more integrated understanding of all levels of the speech communication process. This is the ultimate requirement for the realization of advanced applications.

1:25

4pSC2. Toward models for human production and perception of speech. Kenneth N. Stevens (Res. Lab. of Elec. and Dept. EECS, MIT, 50 Vassar St., 36-517, Cambridge, MA 02139)

Two of the goals of research in speech communication are to develop models of normal speech production and normal speech perception. Related objectives are to uncover the process by which children acquire the knowledge implicit in these models and to determine how the models are modified for disordered speech. Even partial achievement of these goals can have significant practical consequences, including machine recognition and synthesis of speech, and improved methods for diagnosis and remediation of speech disorders. In this paper, a current view of a framework for models of speech production and perception will be described, and some of the steps that have led to refinement of these models over the past 50-odd years will be described. Advances have been made in quantifying acoustic mechanisms of speech production and in specifying the nature of the discrete linguistic representation of an utterance in memory. From studies of speech perception and speech motor control, some understanding has been gained of how properties of the sound are related to the linguistic representation. There are large deficiencies, however, in our understanding of variability in speech due to speaker differences, speaking style, and context. [Work supported in part by NIH Grants DC00075 and DC02525.]

4pSC3. Junctures in speech communication. J. L. Flanagan (CAIP Ctr., Rutgers Univ., 96 Frelinghuysen Rd., Piscataway, NJ 08854-8088)

Several junctures in research on speech communication seem salient over the past 50 years. Under the goad of expensive long-distance transmission, and the criticality of voice communication in a world in turmoil, bandwidth compression methods received strong emphasis in the 1940s. Because transoceanic communication was by HF radio, privacy and encryption were also central issues. These incentives resulted in the Channel Vocoder and a variety of offshoots. By the 1960s, digital computers were being deployed widely and sampled-data theory was well established, providing the systems researcher with a new environment for experimentation—one in which concepts could be rapidly simulated and evaluated. Bandwidth compression continued to be a focus, as computer simulation techniques progressed from classical filter emulation to new designs based solely on digital theory. By the 1980s, broadband connectivity (including transoceanic cable) was becoming pervasive and economical enough that emphasis on bandwidth conservation waned. Concomitantly, digital machines were expanding in capability—but were markedly limited by their inability to

communicate with human users in natural ways. The focus consequently shifted to human/machine communication—especially by conversational means. As we approach the year 2000, a strong research emphasis remains on human/machine communication—but with expanded aspirations for natural interaction. Computer interfaces with multiple modalities—utilizing sight, sound, and touch in combination—are beginning to serve multiple collaborating users. In the same era, explosive deployment of two technologies—cellular telephony and computer networking—has rejuvenated interest in bandwidth conservation and coding for privacy—with many of the early vocoder concepts evolving to sophisticated digital forms implemented on single-chip processors. As we move toward 2020, a special emphasis is likely to be on multilingual communication. And in this time, continued advances in computing, acoustic signal processing, and language modeling should carry translating telephony far beyond the ''phrase book'' stage.

4pSC4. Three questions for a theory of speech. Alvin M. Liberman (Haskins Labs., 270 Crown St., New Haven, CT 06511, liberman@haskins.yale.edu)

On reviewing my 50 years of research, I see that in trying to head theory in the right direction I have been led ever more compellingly by the need to find plausible answers to three questions: (1) What is the basis for the parity between primary motor and perceptual representations that explains how, in the evolution of speech, production and perception managed to proceed in lock step, thus allowing the parties to each two-way exchange to communicate, then as now, in a common code? (2) How does speech meet the requirement, unique to its combinatorial mode, that discrete, invariant, categorical, and distinctly linguistic segments be produced and perceived in strings at rates as high as 20 segments per second? (3) What biological and psychological properties account for the vast difference in the difficulty of acquisition and use between speech and the reading or writing of its alphabetic transcription? Two theories of speech—one quite conventional, the other much less so—provide answers that differ greatly in their plausibility.

2:25

4pSC5. Speech research at the I. P. Pavlov Institute in Leningrad/St. Petersburg. L. A. Chistovich (Early Intervention Inst., St. Petersburg, Russia), J. M. Pickett (Windy Hill Lab, Surry, ME), and R. J. Porter, Jr. (Univ. of New Orleans, New Orleans, LA)

The ''Leningrad Group,'' led by L. A. Christovich and V. A. Kozhevnikov, carried out an extended research program to describe relations between speech perception and speech production and build a model of perception. The work first explored auditory processing mechanisms that could afford closely interdependent connections between auditory information and the control signals for motor production. The resulting model for auditory analysis employed amplitude modulation detectors as well as spectral measurements. The model was evaluated in perception tests with listeners mimicking and shadowing speech sounds and was also employed in a spectrographic display and a scheme for automatic speech recognition.

4pSC6. Speech research from acoustic transmission to gestural analysis. Katherine S. Harris (Dept. of Speech and Hearing Sci., City Univ. of New York, 33 West 42 St., New York, NY 10036, loumau@erols.com)

My training was in experimental psychology at Harvard, where the focus of the department's speech work was the characteristics of sounds affecting their error-free transmission, essentially an extension of the Bell Telephone Laboratories' approach to telephone communication. At Haskins, I began research on the fricative sounds, and discovered the important role of the dynamic characteristics of the sounds in distinguishing among them. In turn, this focus led to an interest in the role of formant movement in speech perception, and ultimately to a study of the characteristics of speech movements themselves. Over the last 50-year period, thanks to some of those on this panel, we have developed a good understanding of the static characteristics of the vocal tract as a producer of speech sounds and the acoustics of speech. However, we still have but a rudimentary account of how the moving articulators develop a dynamic output, and how segmental and suprasegmental transformations of the phonetic message affect this output. Recent instrumental advances should allow the development of an understanding of the dynamics of articulation that parallels our understanding of speech acoustics.

3:20

4pSC7. Chasing ideas in phonetics. Peter Ladefoged (Phonet. Lab., Linguist. Dept., UCLA, Los Angeles, CA 90095-1543, oldfogey@ucla.edu)

In my early career I never stayed long enough in a particular field to be contradicted. I started as a poet learning about the sounds of words with David Abercrombie. Then, remembering my background in physics, I moved to studying acoustic phonetics. From there I became a pseudo-psychologist testing perceptual theories, until a meeting with a physiologist led to work on the respiratory muscles used in speech. Eventually I landed in Africa teaching English phonetics and learning about African languages. So, by the time I was asked to set up a lab at UCLA, I was a specialist in nothing. However, I was able to use my background to describe the sounds of a wide range of languages, becoming a sort of linguist. Computers and bright students led to other ways of analyzing sounds. Building a research group who felt that they had a stake in the development of the lab taught me their varied ideas from statistics to engineering, and the philosophy of linguistics. Now, still looking for the growing edge of the field, I think it might be in the physically observable activity of the brain; but perhaps this is because I have never been a pseudo-neurologist.

3:40

4pSC8. Language and speech. Victoria Fromkin (Dept. of Linguist., Univ. of California, Los Angeles, CA 90024)

It is exciting to note that I have been involved for thirty-six of these important fifty years of phonetic research. In 1962 I entered my first class in Phonetics and Phonology taught by the newly arrived Peter Ladefoged from Edinburgh. That course, and Peter himself, set my goals which have lasted all these years—the relationship between the cognitive knowledge that lay behind our ability to speak and understand. The field of phonetics is varied and researchers have their own agenda and questions to answer. While one's goals may be practical or theoretical, the answers we all find help us understand the incredibly unique ability of the human animal to communicate in a special, linguistic way. Whether studying normal or abnormal speech (speech errors and aphasia), child language, or language decay, we gain insights into the complexities of the process. In recent years, due to new technological tools such as CAT, MRI, fMRI, PET, ERPs, etc., we have the chance to ask new questions. But still it takes an understanding of the linguistic systems underlying the ''speech chain'' to know what questions to ask. Linguists therefore are now, as they have always been, important in the research into speech communication.

4:00

4pSC9. Communication between minds: The ultimate goal of speech communication and the target of research for the next half-century. Hiroya Fujisaki (Dept. of Appl. Electron., Sci. Univ. of Tokyo, 2641 Yamazaki, Noda, 278 Japan)

Needless to say, speech is a manifestation of the information intended by the speaker and is perceived by the listener who tries to retrieve it. Elucidation of the entire process of speech communication thus requires a multidisciplinary approach, as was eminently illustrated by the work of Chiba and Kajiyama about a half-century ago [*The Vowel, Its Nature and Structure*, Tokyo-Kaiseikan (1941)]. Through the efforts of distinguished researchers, supported by the rapid progress in electronics and computers as well as in other means, the ensuing half-century has seen remarkable advances in our understanding of the linguistic, physiological, articulatory, acoustic, sensory, and cognitive processes in normal, developmental, and pathological cases, as well as in technologies for its utilization. As a new millenium of man–machine symbiosis is entered into, however, still deeper understanding becomes necessary in order to establish a friendly human–machine interface through spoken language, often in multimodal and multilingual environments. In the author's view, this can only be achieved by investigating and modeling the mind itself as the ultimate source and destination of information. To that end, speech science will need closer cooperation with related disciplines such as brain science, cognitive science, and artificial intelligence.

4:20–4:50 General Discussion

THURSDAY AFTERNOON, 25 JUNE 1998

CASCADE BALLROOM I, SECTION B (W), 1:30 TO 5:20 P.M.

Session 4pSP

Signal Processing in Acoustics, Engineering Acoustics, Architectural Acoustics and Education in Acoustics: Acoustics in Multimedia—Systems Issues II

David I. Havelock, Chair
National Research Council, M-36 Montreal Road, Ottawa, ON K1A 0R6, Canada

Invited Papers

1:30

4pSP1. Acoustics and psychoacoustics of workstation audio systems. Floyd E. Toole (Harman Intl. Industries, Inc., 8500 Balboa Blvd., Northridge, CA 91329, ftoole@harman.com)

Workstations are widely used as production environments for multimedia, film, and audio programs. For many consumers, they are also the delivery systems for these programs, as well as for others, like music, television, and films, intended for reproduction in various conventional systems and environments. Listeners in workstations therefore must be able to perceive sounds with the appropriate sense of timbre, direction, distance, and ambiance whether the program was created in two-channel stereo, or any of the multichannel surround or binaural 3-D formats. The space constraints, and the usual restriction to two loudspeakers, put special demands on the design of these audio systems. Binaural image-steering techniques will be the basis for most interactive games and, through crosstalk-cancellation, binaural technology will enable realistic replications of two, four, and five-channel audio for music, films, etc. This paper reviews the requirements for workstation audio systems, discusses the key enabling technologies, and summarizes what is known about the appropriate technical specifications, measurement techniques, and subjective evaluation criteria and methodologies for evaluating workstation audio systems.

2:00

4pSP2. Using a personal computer platform to develop an information-rich learning environment for instruction in acoustics. Robert Celmer (Acoust. Prog. and Lab., College of Eng., Univ. of Hartford, 200 Bloomfield Ave., West Hartford, CT 06117, celmer@uhavax.hartford.edu)

Teaching students the subject of acoustics involves large amounts of technical information, including equations, derivations, and example problems. It also requires the explanation of a multitude of concepts, many of which are often difficult for students to grasp and equally frustrating for the instructor to disseminate. Part of the difficulty can be traced to the use of *text* (a visually based medium) to teach about *sound* (an aurally based medium). This presentation will describe the development of multimedia techniques for in-class presentation of acoustics instruction. Some of the materials were developed using certain authoring applications, drawing and animation programs, sound manipulation software, as well as 3D CAD and spectral analysis applets. In addition to the classroom materials, self-paced exercises have been developed to review the material in a student-centered learning environment, along with scheduled interaction time with the instructor for questions, clarifications, and test administration. Demonstrations of the materials for the instruction of acoustical concepts, as well as case studies, will be presented.

Contributed Papers

2:30

4pSP3. The impact of system latency on dynamic performance in virtual acoustic environments. Elizabeth M. Wenzel (NASA–Ames Res. Ctr., M.S. 262-2, Moffett Field, CA 94035-1000, bwenzel@mail.arc.nasa.gov)

Engineering constraints that may be encountered when implementing interactive virtual acoustic displays are examined. In particular, system parameters such as the update rate and total system latency are defined and the impact they may have on perception is discussed. For example, examination of the head motions that listeners used to aid localization in a previous study suggests that some head motions may be as fast as about 175°/s for short time periods. Analysis of latencies in virtual acoustic environments (VAEs) suggests that: (1) commonly specified parameters such as the audio update rate determine only the best-case latency possible in a VAE, (2) total system latency and individual latencies of system components, including head-trackers, are frequently not measured by VAE developers, and (3) typical system latencies may result in undersampling of relative listener-source motion of 175°/s as well as positional instability in the simulated source. To clearly specify the dynamic performance of a particular VAE, users and developers need to make measurements to average system latency, update rate, and their variability using standardized rendering scenarios. Psychoacoustic parameters such as the minimum audible movement angle can then be used as target guidelines to assess whether a given system meets perceptual requirements.

2:50

4pSP4. Immersive audio for desktop systems. Chris Kyriakakis, Tomlinson Holman, Hartmut Neven, and Christoph von der Malsburg (USC, 3740 McClintock Ave., EEB432, Los Angeles, CA 90089-2564)

Numerous applications are envisioned for integrated media workstations to create, edit, and accurately monitor digital video and audio. There are two major classes of limitations that impede the performance of current desktop loudspeaker-based sound systems. The first encompasses problems that arise due to the local acoustical environment, such as early reflections from the CRT and nearby flat surfaces, as well as the design characteristics and performance of the loudspeakers. The second class involves limitations that arise from variations in human listening characteristics and listener movement relative to the loudspeakers. In this paper several findings are presented that are based on acoustical, psychoacoustical, and signal processing methods for delivering accurate sound field representations. Furthermore, a novel vision-based method for accurate listener tracking is presented that eliminates the need for headgear or tethered magnetic devices. Current findings show that this algorithm can be implemented without imposing a significant computational overhead to the host processor. Research directions include adaptive real-time HRTF synthesis based on the tracking information, as well as vision-based pinna shape classification for improved performance.

3:20

4pSP5. Distributed-mode loudspeakers and their impact on intelligibility in multimedia and sound distribution. Peter Mapp (Peter Mapp Assoc., Colchester, UK) and Henry Azima (New Transducers Ltd., Stonehill, Huntingdon, PE18 6ED, UK)

A new class of acoustic radiator has been investigated and shown to exhibit unusual radiation characteristics that can produce enhanced intelligibility under given listening conditions. The improvement mechanisms are investigated and shown to be related to a number of unique features. These include transient response, synergetic decay, lower inherent distortion, directivity, and the diffusivity of acoustic radiation. In a sound system design, it is desirable to produce an even coverage in both spatial and spectral domains. Conventional radiators, the majority of which work under a pistonic regime, exhibit two important characteristics that limit their effectiveness in real-world applications. These are the well-known narrowing of the acoustic radiation (dispersion) angle with increasing frequency and the coherency of the radiation. In contrast, the distributed-mode radiators, an emerging new technology, tend to overcome these obstacles and offer a new approach to improved sound distribution and multimedia. They combine a flat power response with an essentially constant and wide directivity (independent of frequency), augmented by a spatially and temporally diffuse radiation characteristic. The fast transient response results in a signal broadcast with very high clarity. The diffuse nature of the radiation suggests a lower degree of boundary interaction and spectral interference.

3:40

4pSP6. The measurement of coloration in electroacoustic enhancement systems. Mark Poletti (Industrial Res. Ltd., P.O. Box 31-310, Lower Hutt, New Zealand)

The use of electroacoustic systems to enhance the acoustics of concert halls is becoming increasingly prevalent. Regenerative systems are often used for obtaining a source position independent enhancement of reverberation time. However, these systems can produce unnatural acoustics due to the unequal enhancement of the response at different frequencies, a phenomenon termed coloration. Coloration alters the natural Rayleigh statistics of the transfer function magnitudes, and the variation in statistics can be used as a method for quantifying it. This approach avoids the difficulties of examining only the peaks in the transfer function magnitude. A method is developed for measuring the deviation of room transfer functions from Rayleigh statistics. Variance measures are derived. The underlying probability density function is modeled by fitting a three-parameter density termed the generalized gamma function. The maximum deviation of the modeled cumulative distribution from the Rayleigh distribution provides an alternative measure of coloration. The sensitivity of the measures is improved by eliminating the dominant early part of the impulse response, which is largely unaffected by non-in-line systems. An assisted reverberation system simulator is used to simulate the VRA system, which includes a unitary multichannel reverberator in the feedback loop to pro-

vide room volume expansion. The simulations show that the coloration measures increase with loop gain as expected, and are independent of other parameters in the system such as the secondary room reverberation time.

4:00

4pSP7. Criteria for accurate acoustic emulation. David McGrath (Lake DSP pty. Ltd., Sydney, Australia)

The technique of auralization was pioneered by acoustics researchers in the field of concert hall simulation, where an accurate rendering of the acoustics implied that all characteristics of an acoustic space were reproduced, wherever possible. As the convolution technology is pushed into more cost-effective implementations, the broader potential for this technology is being realized. Now the criteria for acoustic emulation must be reevaluated to take into account a number of new factors. This paper explores many relevant criteria for repeatability testing and characterizing the performance of equipment in the presence of realistic three-dimensional noise fields and complex acoustic environments. Such an acoustic system can be accurately emulated using real-time simulation hardware, if a complete characterization of the system can be obtained. This paper discusses methods that are appropriate for the implementation of accurate acoustic emulation, with the emphasis on real world problems and solutions. It is shown how the entire acoustic signal path can be replaced by an appropriate low latency FIR filter, defined using new techniques for impulse response measurement.

4:20

4pSP8. Multichannel audio signal compression and quality assessment for AV communications. Jin-Woo Hong, Dae-Young Jang, and Seong-Han Kim (Electron. and Telecommunications Res. Inst., Yusong, P.O. Box 106, Taejon, 305-600, Korea, jwhong@etri.re.kr)

This paper describes an algorithm for multichannel audio signal compression using the psychoacoustic model, an implementation and the result on quality assessment of real-time operating multichannel audio codec, and a multiplexing technique of synchronization for AV communication. The algorithm which is based on the MPEG-2 audio standard, utilizes psychoacoustic modeling, sub-band analysis and synthesis, and bit allocation for information as key technology. The audio codec was implemented on real-time operation by using a flexible DSP system in which an encoder and a decoder are independently designed for processing a formatted digital audio bit stream, and can compress the multichannel audio data of about 3848 kbits/s into 384 kbits/s. A subjective test for quality assessment of multichannel audio codec was performed using double blind and triple stimuli with hidden reference method. In the test condition with 17 subjects and ten test materials, the test result with 95% confidence intervalshows that all test materials except one (pitch pipe sound) are awarded mean difference grades better than -0.6 and this audio codec is acceptable for AV communication or broadcasting. Finally, a multiplexing method to control time stamp for synchronization of AV communication is, in this paper, introduced from the implementation of HDTV system using this codec.

4:40

4pSP9. Reproduction of CD by providing ultrasonic atmosphere. Jouji Suzuki, Shin'ichiro Kaneko (Dept. of Information and Comput. Sci., Saitama Univ., 255 Shimo-okubo, Urawa, 338 Japan), and Kiyomitsu Ohno (Nihon Tech. Ctr., Tachikawa, Tokyo, 190 Japan)

It is said that the LP sound reproduced by a well-prepared system is superior to the sound of a CD and the difference stems from whether the signal is recorded by analog or digital form. Considering master tape of LP is recorded in digital form, the main difference exists in the bandwidth of the reproduced signal. The signal of a CD is restricted to 20 kHz. On the other hand, the spectrum of an LP signal is extended to 100 kHz. Though the upper limit of hearing acuity of a human is 20 kHz, superior components will contribute to offer more rich and realistic atmosphere. In order to produce a higher-frequency component from CD sound, the folding spectrum of the sampling frequency of 44.1 kHz is utilized. The output signal of a DA converter of a CD player is filtered with BPF of 24–42 kHz. This signal is added to the CD output and presented to listeners. This system is named PULSA (providing ultrasonic atmosphere). A preference test is conducted on conventional CD sound and the sound by PULSA through a wideband static headphone on three minuets of orchestra and opera. It is revealed that PULSA sound is better than the conventional by the ratio of 65 to 35.

5:00

4pSP10. A multi-processor system for the production of virtual sound fields. Felipe Orduña-Bustamante, Ricardo R. Boullosa, and Antonio P. López (Centro de Instrumentos UNAM, Circuito Exterior CU, CP 04510, México DF, Mexico, felipe@aleph.cinstrum.unam.mx)

A multi-processor system is described for the production of virtual sound fields using small arrays of up to four high-quality loudspeakers and up to four control microphones distributed around an artificial head and torso in a lightly damped listening room. The digital signal processing engine consists of four floating point processors interconnected for parallel computation, together with digital and analog converters. The performance of the system is analyzed in terms of the tradeoff between the maximum sampling rates that can be used and the complexity of the digital filter matrices in the different operating modes of the system such as system identification, single-input multiple-error adaptive filtering, and full multichannel filtering with fixed coefficients.

Underwater Acoustics: 3-D Propagation Effects II: Where are We Today in Models and Measurements?

Michael B. Porter, Cochair
Scripps Institute of Oceanography, Marine Physical Laboratory, MC 0205, 8602 La Jolla Shores Drive, La Jolla, California 92037-0205

Alexandra I. Tolstoy, Cochair
4224 Walalae Avenue, Suite 5-260, Honolulu, Hawaii 96816

Chair's Introduction—1:00

Invited Papers

1:05

4pUW1. The 3-D effect on underwater acoustic propagation in the offshore area of Taiwan's coast. Chi-Fang Chen, Jang-Jia Lin (Dept. of Naval Architecture and Ocean Eng., Natl. Taiwan Univ., 73 Chou-Shan Rd., Taipei, Taiwan, ROC), Chung-Wu Wang (Naval Oceanograph. and Hydrographic Office, ROC), and Ding Lee (Yale Univ./Naval Undersea Warfare Ctr., New Haven, CT)

Lately 3-D effects on underwater acoustic propagation have frequently been reported. The major causes for the 3-D effects are the variations in azimuth of bottom topography or water column properties. The offshore regions of Taiwan's coast are of the similar nature. There are submarine canyons in the offshore region of southwest Taiwan. The acoustic propagation is studied numerically using FOR3D. The 3-D effect is found to be more serious along the axis of the canyon's axis than cross the canyon. The field test is also conducted in the region; the measurements are well matched with the numerical results calculated by FOR3D, which indicates the actual 3-D effect exists in the real ocean environment. [Work supported by National Science Council of Republic of China.]

1:25

4pUW2. High-resolution, three-dimensional measurements of low-frequency sound propagation in shallow water. George V. Frisk, Kyle M. Becker, Laurence N. Connor, James A. Doutt, and Cynthia J. Sellers (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

An overview is presented of the modal mapping experiment (MOMAX), which was conducted in March 1997 in the vicinity of the East Coast *STRATAFORM* site. Both fixed and moving source configurations were used to transmit several pure tones in the frequency range 50–300 Hz. The magnitudes and phases of these signals were recorded on several freely drifting buoys, each containing a hydrophone, GPS and acoustic navigation, and radio telemetry. High-resolution, three-dimensional measurements of the sound field were made out to ranges of 10 km and illustrate the influence of the laterally varying seabed, measured with a chirp sonar system. The precision navigation also enabled the creation of a two-dimensional, synthetic aperture planar array, parallel to the ocean surface. The pressure field data measured on the array were transformed into the wave number domain, where the lateral variability of the waveguide manifests itself in the spatially evolving spectral content of the modal field. Finally, the phases of the measured signals show remarkable stability and regularity, even in the context of complex, multimodal fields. This behavior can be exploited to make accurate estimates of the relative source/receiver speed from measurements of the time rate-of-change of the phase. [Work supported by ONR.]

1:45

4pUW3. A fully global hydroacoustic monitoring system for the Comprehensive Nuclear-Test-Ban Treaty—Plans and progress. Martin W. Lawrence and Marta Galindo Arranz (Provisional Tech. Secretariat, Comprehensive Nuclear-Test-Ban Treaty Organization, Vienna Intl. Ctr., A-1400 Vienna, Austria, mlawrence@ctbto.un.or.at)

The first ever fully global hydroacoustic monitoring system is being planned and implemented for use in the verification of a new international treaty, the Comprehensive Nuclear-Test-Ban Treaty (CTBT). This system will provide hydroacoustic monitoring of all the world's oceans for 24 h a day, every day of the year, into the indefinite future. This unique resource will utilize two types of station. One type will be based on a hydrophone at the SOFAR axis depth, cabled back to shore. The other will be based on a seismometer on a small island using detection of the T-phase signal. This latter station relies on a signal which has propagated predominantly through the ocean, but has been converted to seismic energy at the margin of the island. Although this network is being installed for monitoring of nuclear explosions, it will also be a unique resource for scientific investigation of various phenomena. Data will be available to all State Signatories to the CTBT.

2:05

4pUW4. Validation of source region energy partition calculations with small-scale explosive experiments. Douglas B. Clarke, Philip E. Harben, Steven L. Hunter, and Donald W. Rock (Lawrence Livermore Natl. Lab., Livermore, CA 94551)

The decrease in signal energy as the location of a nuclear explosion varies from deep in the ocean to above the ocean surface is a concern for the planned ocean monitoring component of the Comprehensive Test Ban Treaty. Small-scale experiments were designed to validate predictions of energy coupling by nuclear explosions in the ''source region,'' the origin of the signals that propagate in the deep underwater sound (SOFAR) channel. The experiments were performed in a biologically dead lake at a scale length of 1/50 (1/125 000 in explosive energy) relative to one kiloton using 6.82-kg charges of Pentolite 50/50. The acoustic energy coupled into the water was monitored at a 60-m range by a hydrophone string with eight piezoelectric sensors spaced from near-surface to a 30-m depth. Useful data were obtained at five burst locations: 5, 2, 0, −2, and −15 m. Results from the experiments and new calculations support the predicted energy partitioning for above-surface explosions with model and experiment peak pressures agreeing within a factor of two over three orders of magnitude variation. [Work performed under the auspices of the U. S. Department of Energy by the Lawrence Livermore National Laboratory under Contract W-7405-ENG-48.]

2:20

4pUW5. Three-dimensional propagation modeling in shallow water. Gregory J. Orris and John S. Perkins (Naval Res. Lab., Washington, DC 20375)

Much interest exists in problems of shallow-water propagation, where three-dimensional spatially dependent waveguide effects are sometimes very large. In these cases the three-dimensional dependence of the acoustic field can be accounted for in a variety of ways other than solving the often intractable fully coupled problem. There exist several pseudo three-dimensional models that are based on the parabolic equation method (e.g., $N\times 2$D PE [J. S. Perkins and R. N. Bear, J. Acoust. Soc. Am. **72**, 515–522 (1982)], the adiabatic PE [M. D. Collins, J. Acoust. Soc. Am. **93**, 2269–2278 (1993)], the coupled-mode PE [A. T. Abawi *et al.*, J. Acoust. Soc. Am. **102**, 233–238 (1997)] and the spectral PE [G. J. Orris and M. D. Collins, J. Acoust. Soc. Am. **96**, 3499–3503 (1994)]). Yet, because these models are extensions of efficient two-dimensional models they have explicit and implicit limitations on their applicability. Some of the advantages and limitations of these pseudo three-dimensional models will be demonstrated through their application to data collected during the SWellEx-96 and RDS-1 matched-field experiments.

2:35–2:40 Break

2:40

4pUW6. 4-D modeling of sound propagation in shallow water with anisotropic sediment layers. X. Tang, M. Badiey (Marine Studies, Univ. of Delaware, Newark, DE 19716), and W. L. Siegmann (Rensselaer Polytechnic Inst., Troy, NY 12180)

A highly efficient 4-D PE model is developed to study broadband sound propagation at the Atlantic Generating Station (AGS) site. Extensive core data has shown that the sediment at this AGS site consists of multiple layers which vary in both range and azimuth. Consequently, sound propagation in the water column in this area is significantly affected by the complex sediment structure due to the fact that the layered sediment acts like a bandpass filter in which broadband acoustic energy is selectively broken into narrow-band components propagating in different layers, usually referred as sediment mode trapping. The details of the range, azimuth, frequency, and bandwidth dependences as well as their relationships to the sediment structure of such mode trapping effect is numerically explored by performing the 4-D PE model. The empirical orthogonal function representation method is employed to transfer the geoacoustic parameters of the sediment core data into PE inputs. The broadband travel time results at eight different bearings are compared with the existing experimental data. The importance of the 3-D effects is also examined by comparing the numerical results of azimuthal coupled and uncoupled models.

2:55

4pUW7. Wave number extraction techniques for a three-dimensionally varying shallow-water waveguide: A comparison. Kyle M. Becker and George V. Frisk (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543, kbecker@whoi.edu)

Theory shows that the wave number spectrum of a propagating normal mode field is a function of position for a complex, shallow-water waveguide whose acoustic properties vary in three spatial dimensions. By describing the spatially varying content of the modal field, a direct measure of the propagation characteristics of the waveguide can be made. Consequently, to obtain greater sensitivity of the spectrum as a function of position, it is of interest to resolve the contributions from individual modes using as short a data record as possible. To this end, several wave number extraction methods have been applied to synthetic data, as well as real data measured using a synthetic aperture planar array created by several freely drifting buoys. Wave number content as a function of position was extracted using Hankel transforms, best linear estimator techniques, and autoregressive algorithms. Results obtained for frequencies in the range 50–300 Hz are compared for resolution and consistency using data records of various lengths. Based on these results, recommendations are made for the selection of an appropriate extraction algorithm. [Work supported by ONR.]

3:10

4pUW8. Range-dependent matched-field source localization and tracking in shallow water on a continental slope. Lieutenant(N) Martin L. Taillefer and N. Ross Chapman (SEOS, Univ. of Victoria, P.O. Box 3055, Victoria, BC V8W 3P6, Canada)

This paper describes matched-field source localization and tracking of a sound source towed over a continental slope off the western coast of Vancouver Island. The data were collected using a multielement vertical line array (MEVA) as part of the PACIFIC SHELF sea trial carried out during September 1993. The MEVA is a 16-element array with sensors evenly spaced at depths between 90 and 315 m. The target was towed along a linear radial track over a steep slope out to ranges of 5.5–6 km from the array, and then along a navigational arc in water depths from 250 m at the array to 750 m. The target emitted three continuous wave tones in the band 45–72 Hz. In order to model the environment as accurately as possible, the replica fields were calculated using an adiabatic normal-mode approximation which accounted for elastic wave propagation in the bottom. In addition, a bathymetric database was compiled from various echo-soundings of the area. Using conventional linear MFP based on two-dimensional replica fields to determine ambiguity surfaces for any target radial from the array, the target was tracked in range, depth, and bearing along the entire experimental track, with Bartlett processor values as large as 0.87.

3:25

4pUW9. Experimental investigation of matched-field processing in a wedgelike shallow-water environment. Paul A. Baxley (Space and Naval Warfare Systems Ctr., San Diego, Code D881, 49575 Gate Rd. Rm. 170, San Diego, CA 92152-6435, baxley@spawar.navy.mil)

Underwater acoustic propagation in shallow-water wedgelike environments will experience ''bending'' out of the vertical plane containing the source and receiver. Consequently, the time for the energy to travel from

the source to the receiver will be altered, or some paths may miss the receiver altogether. Localization estimates from array processors will be in error if this horizontal multipath propagation is ignored. This phenomenon is investigated experimentally via the analysis of vertical-line-array source-tow data recorded in a steep wedgelike environment near San Clemente Island during the fourth Shallow Water evaluation cell Experiment (SWellEX-4). The source-tows examined were approximately in the cross-slope direction. The objective of this study is (1) to observe the horizontal ''refraction'' effects via an examination of the matched-field localization errors resulting from a neglect of that phenomenon, and (2) to study the feasibility of including modeled horizontal refraction effects into the matched-field processor to enhance localization performance. Geoacoustic parameter inversion was performed at short range so that mismatch in this parameter would not be misinterpreted as a horizontal ''refraction'' effect. A three-dimensional Gaussian beam program was used to generate replica fields, and to perform investigative simulations for the experimental environment. [Work supported by ONR/SPAWARSYSCEN San Diego.]

4pPL1. Trends in modeling of structural-acoustics systems with structural complexity in low- and medium-frequency ranges.
Christian Soize (ONERA, BP 72, 92322 Chatillon Cedex, France, soize@onera.fr)

This paper gives a comprehensive survey of a theoretical approach for predicting the frequency response functions of general complex structural acoustics systems (CSAS) in the low- and medium-frequency ranges. For such a CSAS, the complex structure is made of a master structure coupled with internal substructures presenting structural complexity and corresponding to a large number of secondary subsystems, such as equipment units or internal secondary structures, attached to the master structure. The master structure is a general 3-D dissipative structure with an arbitrary bounded geometry and is made of an anisotropic, inhomogeneous, viscoelastic medium. This complex structure is coupled with an external acoustic fluid via the master structure. The approach is based on the use of fuzzy structure theory, introduced by the author in 1985, including recent developments concerning identification of the fuzzy substructure model parameters. This theory allows the effects of the internal structural complexity on the master structure to be modeled. In addition, the construction of an intrinsic reduced model of the frequency response functions of this CSAS adapted to the medium-frequency range (recently proposed by the author) is presented, which allows simplifications in the calculation of the responses to any deterministic or random excitations.

Meeting of Accredited Standards Committee S3 on Bioacoustics

L. S. Finegold, Chair S3
USAF Armstrong Laboratory, Noise Effects Branch AL/OEBN, 2610 Seventh Street, Wright Patterson Air Force Base, Ohio 43433-7901

R. F. Burkard, Vice Chair S3
Hearing Research Laboratory, State University of New York at Buffalo, 215 Parker Hall, Buffalo, New York 14214

P. D. Schomer, Chair, U. S. Technical Advisory Group (TAG) for ISO/TC 43, Acoustics
U.S. CERL, P.O. Box 9005, Champaign, Illinois 61826-9005

J. Erdreich, Chair, U. S. Technical Advisory Group (TAG) for ISO/TC 108/SC4, Human Exposure to Mechanical Vibration and Shock
Ostergaard Acoustical Associates, 100 Executive Drive, West Orange, New Jersey 07052

H. E. von Gierke, Vice Chair, U. S. Technical Advisory Group (TAG) for ISO/TC 43, Acoustics and ISO/TC 108/SC4, Human Exposure to Mechanical Vibration and Shock
1325 Meadow Lane, Yellow Springs, Ohio 45387

V. Nedzelnitsky, U.S. Technical Advisor (TA) for IEC/TC 29, Electroacoustics
National Institute of Standards and Technology (NIST), Building 233, Room A149, Gaithersburg, Maryland 20899

Accredited Standards Committee S3 on Bioacoustics. The current status of standards under preparation will be discussed. In addition to those topics of interest, including hearing conservation, noise, dosimeters, hearing aids, etc., consideration will be given to new standards which might be needed over the next few years. Open discussion of committee reports is encouraged.

SCOPE OF S3: Standards, specifications, methods of measurement and test, and terminology in the fields of mechanical shock and physiological acoustics, including aspects of general acoustics, shock, and vibration which pertain to biological safety, tolerance, and comfort.

Meeting of Accredited Standards Committee S1 on Acoustics

J. P. Seiler, Chair S1
U. S. Department of Labor, Cochran Mill Road, P.O. Box 18233, Building 038, Pittsburgh, Pennsylvania 15236

G. S. K. Wong, Vice Chair S1
Institute for National Measurement Standards, (INMS), National Research Council, Ottawa, ON K1A 0R6, Canada

P. D. Schomer, Chair, U. S. Technical Advisory Group (TAG) for ISO/TC 43, Acoustics
U. S. CERL, P.O. Box 9005, Champaign, Illinois 61826-9005

H. E. von Gierke, Vice Chair, U. S. Technical Advisory Group (TAG) for ISO/TC 43, Acoustics
1325 Meadow Lane, Yellow Springs, Ohio 45387

V. Nedzelnitsky, U. S. Technical Advisor (TA) for IEC/TC 29, Electroacoustics
National Institute of Standards and Technology (NIST), Building 233, Room A149, Gaithersburg, Maryland 20899

Accredited Standards Committee S1 on Acoustics. Working group chairs will report on their preparation of standards on methods of measurement and testing, and terminology, in physical acoustics, electroacoustics, sonics, ultrasonics, and underwater sound. Work in progress includes measurement of noise sources, noise dosimeters, integrating sound-level meters, and revision and extension of sound level meter specifications. Open discussion of committee reports is encouraged.

SCOPE OF S1: Standards, specifications, methods of measurement and test and terminology in the field of physical acoustics including architectural acoustics, electroacoustics, sonics and ultrasonics, and underwater sound, but excluding those aspects which pertain to biological safety, tolerance and comfort.

Session 5aPLa

Plenary Lecture

Andrea Prosperetti, Chair
Mechanical Engineering, Johns Hopkins University, 122 Latrobe Hall, 3400 North Charles Street, Baltimore, Maryland 21218

Chair's Introduction—8:00

Invited Paper

8:05

5aPLa1. Acoustics of two-phase fluids and sonoluminescence. Robert I. Nigmatulin (Ufa (Bashkortostan) Branch of Russian Acad. of Sci., K. Marx Str. 6, Ufa 450000, Russia, iskander@ncan.ufanet.ru)

The basic equations for dynamics of two-phase mixtures like gas–particle suspensions and bubbly liquids are presented. Heat and mass exchange phenomena near a drop, particle, and gas or vapor bubble are discussed. It is shown that these phenomena play an important role in propagation, attenuation, and amplification of sound waves and shock waves in gas–liquid systems, sometimes leading to paradoxical effects. The dynamics of a sonoluminescing bubble is discussed. There are two stages of the bubble oscillation process: The low Mach number stage when the velocity of the bubble interface is small compared with sound speed in the liquid, and the stage corresponding to the collapsing bubble's compression, when the velocity of the interface may be larger than the sound speed. The analytic solution for the low Mach stage is presented. This solution provides the economical boundary condition around the bubble for an effective numerical code.

Architectural Acoustics: Case Studies of Performance Spaces

Jerald R. Hyde, Chair
Consultant in Acoustics, Box 55, St. Helena, California 94574

Chair's Introduction—7:20

Invited Papers

7:25

5aAA1. The Hong Kong Cultural Centre halls: Acoustical design and measurements. A. Harold Marshall, Johan L. Nielsen, and M. Miklin Halstead (Acoust. Res. Ctr., Univ. of Auckland, New Zealand)

The main performance spaces in the Hong Kong Cultural Centre comprise the Concert Hall, seating 2000 and the Grand Theatre seating 1700. The design of the former is derived from the Christchurch Town Hall which it develops in several important ways, while the latter is a lyric theatre/opera hall with several unique features which are described briefly in this paper. The Centre opened in 1989 following extensive commissioning measurements in the halls. Recently the opportunity has arisen to repeat the measurements using an improved technique in an attempt to document changes following a stage extension. Results from these measurements are compared with the earlier series in each hall. Marshall Day Associates, Auckland, New Zealand was responsible for the room acoustical design of these spaces. [The recent visit to Hong Kong was supported by the Acoustics Research Centre, the Hong Kong Cultural Centre, and the Marsden Fund administered by the Royal Society of New Zealand.]

7:45

5aAA2. Modern measurements, optimized diffusion, and electronic enhancement in a large fan-shaped auditorium. John P. O'Keefe (Aercoustics Eng. Ltd., 50 Ronson Dr., Ste. 127, Toronto, ON M9W 1B3, Canada), Trevor Cox (Univ. of Salford, UK), Neil Muncy (Neil Muncy Assoc., Toronto, Canada), and Steve Barbar (LARES Assoc., Cambridge, MA)

The Hummingbird Centre in Toronto Canada, formerly known as the O'Keefe Centre, is a 3000 seat fan-shaped auditorium, typical of the postwar era. Since it opened in 1960 it has been plagued by complaints about its acoustics. A LARES electronic enhancement system was proposed for the building and a feasibility study was carried out. Modern acoustical measurements lend

credence to the years of complaints. Among other interesting findings, late energy (Glate) is 10–20 dB lower than a traditional shoe-box-shaped concert hall. Such low levels of late energy explain, in part, the image shift and echoes that are found throughout the hall. A side wall echo threatened to compromise the proposed enhancement system. In an effort to reduce the echo, a crescent-shaped diffuser was developed using a BEM optimization routine. Four LARES mainframes are employed in the enhancement system with more than 280 front ported two-way loudspeakers, each of which can be addressed individually. The renovated acoustics have been well received by the owners, users, and patrons.

Contributed Papers

8:05

5aAA3. Recent acoustical measurements in the Christchurch Town Hall Auditorium. A. Harold Marshall, Johan L. Nielsen, and M. Miklin Halstead (Acoust. Res. Ctr., Univ. of Auckland, Private Bag 92019, Auckland, New Zealand, h.marshall@auckland.ac.nz)

Two significant changes have occurred in the Christchurch Town Hall during 1996-97: the original seats have been replaced with a new type and a new Rieger pipe organ has been installed behind the choir seats. A new comprehensive set of acoustic measurements has been made in the unoccupied hall. These are reported and compared in this paper with earlier measurements. A related study on the usefulness of C80 as a clarity measure in concert halls and which makes use of these results is reported in a companion paper. [This work is supported by the Marsden Fund administered by the Royal Society of New Zealand.]

8:20

5aAA4. Calculation and measurement of acoustic factors for the Kirishima International Concert Hall. Tatsumi Nakajima (Takenaka Res. and Development Inst., 5-1, 1-chome Ohtsuka, Inzai, Chiba, 270-13 Japan) and Yoichi Ando (Kobe Univ., Rokkodai, Nada, Kobe, 657 Japan)

The Kirishima International Concert Hall was designed by architect F. Maki with Ando's acoustic design theory. It opened on July 22, 1994. The 770 seat main hall which has a volume of 8475 m^3 was primarily designed for chamber music. Computer simulations made it clear that the acoustical design of the main hall would be an optimum solution with a plan like a leaf shape and a cross section like a bottom of a ship. These were solutions which satisfied requirements for both acoustical and architectural design concepts of the main hall. Getting a low IACC sound field at the front seat was most important. In order to get a low IACC, sound reflections from the stage to the audience floor were examined and studied in the early design processes. Calculation and measurement of acoustic factors of the sound fields in the main hall show: (1) the calculated and the measured IACCs are good in agreement, (2) IACCs tended lower values of about 0.1 than the calculated ones throughout the seats, and (3) the number of reflections needed for predicting IACC is recommended to be about 40 for the practical method of IACC calculation at the design stage of a hall.

8:35

5aAA5. Interrelationship of musical excellence and acoustical excellence: A case study of the Gewandhaus, Leipzig. Pamela Clements (Acoust. Consultant, Jaffe Holden Scarbrough Acoust., Inc., 114A Washington St., Norwalk, CT 06854, pclements@jhsacoustics.com)

A study of changes in orchestral performance practice and repertoire in the Altes Gewandhaus and the Neues Gewandhaus (opened 1884) under the conductor Carl Reinecke was performed. A parallel study of changes in orchestral performance practice and repertoire in the Neues Gewandhaus was also performed when Carl Reinecke was succeeded by Arthur Nikisch in 1895. In the first instance, the orchestra and conductor are the same but the hall changes; in the second instance, the orchestra and hall are the same but the conductor changes. Both old and new halls were regarded as outstanding acoustically, but under Reinecke the orchestra's reputation waned because of conservatism in programming and interpretation. Historical evidence shows that the orchestra went through a difficult period accommodating the new hall's acoustics and emerged with a new sound. Yet, despite the hall's excellent acoustics, the orchestra performed better in another, poorer, acoustic environment under the more dynamic conductor Arthur Nikisch. The orchestra only regained its international reputation later when Nikisch became conductor at the Gewandhaus. The study explores Nikish's response to the hall's acoustic possibilities, and suggests reasons why a hall with a relatively dry acoustic could be pivotal in the orchestra's then becoming a foremost interpreter of the late Romantic repertoire.

8:50

5aAA6. Acoustical design and the characteristics of Sapporo Concert Hall. Yasuhisa Toyota and Katsuji Naniwa (Nagata Acoust., Inc., Minami-Shinjuku-Hoshino Bldg. 8F, 5-23-13 Sendagaya, Shibuya-ku, Tokyo, 151-0051 Japan, toyota@nagata.co.jp)

Sapporo Concert Hall, with 2008 seats in the large hall and 453 seats in the small hall, was opened on July 4, 1997. Both halls were designed for classical music, the large one mainly for orchestral music and the small one for chamber music and recitals. The large hall was designed with the concept of the surrounded stage and ''vineyard steps'' seating arrangement like Philharmonic Hall in Berlin and Suntory Hall in Tokyo. The emphasized points in acoustical design were as follows: (1) Effective use of the ''vineyard steps'' walls which were introduced into the audience area to provide the effective early reflections; (2) installation of the big sound reflectors suspended above the stage area to provide the effective early reflections to musicians and audience around the stage; (3) introduction of heavy material, 150-millimeters-thick concrete, into the main ceiling to get enough response in the low frequencies. The small hall was designed as a typical shoebox hall with narrow width and high ceiling. Acoustically tunable curtains were introduced to make the wide range of acoustical possibilities. The results of the acoustical design and its characteristics will be reported.

9:05

5aAA7. Acoustical renovation of The Opheum Theatre, Vancouver Canada. John P. O'Keefe (Aercoustics Eng. Ltd., 50 Ronson Dr., Ste. 127, Toronto, ON M9W 1B3, Canada), Gilbert A. Soulodre (Commun. Res. Ctr., Ottawa, ON K2H 8S2, Canada), and John S. Bradley (Natl. Res. Council, Ottawa, ON K1A 0R6, Canada)

The Orpheum Theatre is a 2800 seat vaudeville house that was renovated for the Vancouver Symphony in the 1970s. Funds ran out prior to completion and some problematic conditions remained for the following fifteen years. Perhaps the most significant was an image shift heard on the balcony. Two focused reflections arriving at approximately 50 ms made some source locations on the stage appear to be perched in the ceiling. The efficacy of the plastic reflectors above the stage was also questioned. These and other issues were addressed with a complete set of stage and audience measurements in the full-scale room, experiments with a 1:48 small scale model, and listening tests using anechoic music convolved with the full-scale binaural impulse responses. The latter was particularly important because it allowed for reliable quantification of image shift thresholds that were unique to this room. Small scale modeling proved useful in matching the new convex reflectors' radii of curvature to the image shift threshold. The renovation work is complete and the image shift has been completely eradicated.

9:20–9:30 Break

9:30

5aAA8. The best remaining seat. Bodil Vaupel (Arkitekturt Akuslik, Paludan Müllers Plads 1, 5300 Kerteminde, Denmark)

It is important that an auditorium be designed to have as many good seats as possible. Not all seats in an auditorium are equally good. This is manifested in that the audience does not choose its seats randomly. The audience understands intuitively that, generally speaking, the closer a seat

is, and the more straight on, the better it is. Imagine an auditorium with open seating and the audience entering one at a time. People will in turn make a selection of what in their opinion is the *best remaining seat*. The order in which the seats are chosen is an indicator of the rank order of the desirability of the individual seats. As the audience makes its seat selection, a geometric pattern of the occupied seats unfolds, and reveals the boundary of the preferred seats. The perimeters describe the equal desirability curves and outlines the auditorium plan with as many good seats as possible. The audience choice of seat is recorded by time lapse photography. The data are analyzed in a combined computer drawing and mathematics program. A mathematical model has been developed that evaluates the desirability of the seating in an auditorium from the audience's point of view.

9:45

5aAA9. Acoustic design and performance of the Bruce Mason Theatre. Joanne M. Valentine (Marshall Day Asociates, P.O. Box 5811, Wellesley St., Auckland 1, New Zealand, mda@bitz.co.nz)

The Bruce Mason Theatre takes an innovative approach to variable acoustics with the use of a variable volume operable ceiling. The overall acoustic design objective was to achieve excellent acoustics with a high level of reverberance for symphony, and good speech clarity with a reduced level of reverberance for theater and drama. The results of commissioning measurements carried out in the auditorium show that a high degree of variability between the acoustic conditions for symphony mode and theater mode has been achieved, and that the operable ceiling/variable volume concept has proved to be highly successful. This paper presents the design concept developed for the auditorium, the findings of a 1:25 scale acoustic model study, and the results of commissioning measurements carried out in the newly opened theater in September 1996.

10:00

5aAA10. Three-dimensional impulse response measurements on S. Maria Church, Florence, Italy. Angelo Farina (Dipartimento di Ingegneria Industriale, Viale delle Scienze, 43100 Parma, Italy, farina@pcfarina.eng.unipr.it) and Lamberto Tronchin (DIENCA—CIARM Univ. of Bologna, Viale Risorgimento, 2 40136 Bologna, Italy)

The measurement of binaural impulse response procedure for acoustic environments has been established and achieved from the International Standard Organization; following the ISO 3382 many acoustical parameters have been already analyzed in the past, ranging from Royal Albert Hall in London, UK, to Teatro la Fenice in Venice, Italy. In this paper a new procedure for measuring 3D impulse response has been utilized, with the aim to reconstruct the 3D sound field especially for virtual reality purposes. Starting from the definition of B-format impulse responses, the pressure gradient has been measured in the Church by using a homemade apparatus and software, and performing measurements on the three axes, gathering seven different impulse responses, without using expensive microphones already developed. From the measures, the relations between the seven different measurements have been found out, and the results have been compared with the binaural impulse responses measurements performed in the same position at the same time.

10:15

5aAA11. Simultaneous measurements of room-acoustic parameters using different measuring equipment? Tor Halmrast (Statsbygg, pb. 8106 Dep. N-0032, Oslo, Norway), Anders Gade (Tech. Univ. of Denmark, DK-2600 Lyngby, Denmark), and Bjorn Winsvold (Norsonic, pb. 24, N-3408, Tranby, Norway)

Often the results from different room-acoustic measurements in the same hall disagree, and the disagreement is just said to be due to different measuring equipment, or different rigging/temperature, etc. The room acoustic of the Oslo Concert Hall was measured simultaneously, using the following different measuring equipment: (1) MLS/MLSSA (Statsbygg), (2) Sweep-Tone (Tech. Univ. Denmark), and (3) Norsonic 840 with MLS +MatLab. For some of the measurements (4) Pistol and (5) Electrical Impulse were also used. The paper will compare the results from the different measuring equipment, for the most known room-acoustic parameters. For the reverberation time parameters RT and EDT, very good agreement was found between the three main measuring equipments. For Ts and C80 the agreement between these three is good/fair for the higher frequencies, but less good for the bass, especially C80. The measurements with Electric Pulse and Pistol as signals (analyzed through Norsonic +MatLab) indicate good agreement for the reverberation times, but EDT is somewhat higher for the Pistol. For Ts and C80 the Electric Impulse and especially the Pistol give less clearness (higher Ts and lower C80), compared to MLSSA, Sweep Tone, and Norsonic/MLS.

10:30

5aAA12. Design of a circular hall improving the subjective preference at each seat. Akio Takatsu, Hiroyuki Sakai, Shin-ichi Sato, and Yoichi Ando (Grad. School of Sci. and Technol., Kobe Univ., Rokkodai, Nada, Kobe, 657 Japan)

The circular type of the medium-sized (400 seats) multipurpose event hall in Kobe Fashion Plaza, which was named Orvis Hall, was designed based on Ando's theory of subjective preference. Acoustic problems caused by such a circular plan were minimized by means of ceiling diffusion panels, side-wall-reflective panels, and a small room at the back wall preventing echo-disturbance created by the long-path echo or ''Whispering Gallery'' effects. One of the most remarkable systems of this hall is controlling the subsequent reverberation time through blending architectural acoustics and electrical acoustics by use of a hybrid system with both a reverberation control room and a digital reverberator. Therefore the total scale value of subjective preference at each seat is maximized by the four acoustic factors, namely, the delay time of first reflection, the listening level, the subsequent reverberation time, and the IACC. After construction of this hall, four factors at each seat were measured, and results are presented.

Session 5aAO

Acoustical Oceanography and Animal Bioacoustics: Acoustics of Fisheries and Plankton IV

John Hedgepeth, Chair
BioSonics, Inc., 4027 Leary Way, NW, Seattle, Washington 98107

Invited Paper

10:00

5aAO1. Vessel avoidance of wintering Norwegian spring spawning herring. Rune Vabø (Inst. of Marine Res., P. O. Box 1870, N-5024 Bergen, Norway), Kjell Olsen (Univ. of Tromsø, School of Fisheries, N-9000 Tromsø, Norway), and Ingvar Huse (Inst. of Marine Res., Bergen, Norway)

Vessel avoidance during acoustic abundance estimation of herring was investigated. Echo energy values measured from a submerged 38-kHz transducer were recorded and values at the time of passage were compared with corresponding echo energy values from a hull-mounted 18-kHz transducer on the passing vessel. A quantification of the loss in echo energy due to avoidance behavior is presented. Experiments are grouped into nighttime and daytime experiments. While a considerable drop in echo energy at the time of passage was observed at night, insignificant loss was found during the day. A general avoidance reaction pattern was identified in all the nighttime experiments. The magnitude of the vessel avoidance reaction was found to be strongly dependent on depth. Between 40 and 100-m depth some nighttime experiments showed loss in echo energy of the order of 90%. The effect of avoidance behavior decreased with depth below 100 m, but was seen down to 150 m at night. Low daytime response is due to deep daytime herring distribution. Body tilting and vertical and horizontal swimming are suggested explanations for the lower echo energy during passage.

10:20

5aAO2. FishMASS: ADCP technology adapted to split-beam fisheries echo sounding. R. Lee Gordon (RD Instruments, 9855 Businesspark Ave., San Diego, CA 92131, lgordon@rdinstruments.com) and Len Zedel (Memorial Univ. of New Foundland, Canada)

The objective of FishMASS, a NSF-funded research project, is to adapt elements of ADCP technology into split-beam echo sounding. Improvements come from wide bandwidths (50% bandwidth at 300 kHz), incorporation of velocity (Doppler) data, and addition of autonomous operation (battery and recording capacity to allow operation for up to a year). Wide bandwidths can reduce the uncertainty of single-target echoes from 3–6 dB (characteristic of narrowband signals) down to a fraction of a dB. It enables better differentiation of single-target from multiple-target echoes (when targets are separated either radially or at different ranges). The 50% bandwidth gives access to at least part of the target echo spectrum. These three advantages combine to improve both target discrimination and target classification. Split-beam sonars can sometimes track individual targets through their beams to obtain swimming speed. Doppler processing (identical to the processing of broadband ADCPs) will be added to obtain single-ping swimming speeds, both of individuals and groups. Mean velocities allow observation of migration and flux. Statistical products such as velocity standard deviation enable observation of feeding or predator-avoidance behavior. Correlations of velocity with, for example, TS may further aid species classification.

10:35

5aAO3. The digital transducer, new sonar technology. William Acker (BioSonics, Inc., 4027 Leary Way NW, Seattle, WA 98107)

The new digital architecture in sonar technology designed by BioSonics, Inc. has many advantages when compared with traditional analog technology. The echo signal is digitized inside the transducer at a very low signal level. This removes problems of coupled or induced noise when sending the signal through long lines. The system operates with a 3 to 4 dB noise figure in all modes of operation. Another important feature of the system is very high dynamics (>132 dB continuous). This allows receiving of low signals from small targets (i.e., plankton) simultaneously with high level signals (i.e., bottom) without saturation. The echo signal is sampled at a high rate and stored with high accuracy (0.013%) and high resolution (1.8 cm or less). The sonar is PC controlled for simple operation. The large dynamic range means no adjustment in system gain or transmit power. The data acquisition system is virtually automatic because most decisions are in postprocessing. Raw data is stored on the PC's hard drive or similar device. The sonar is available in a wide frequency range (38 kHz–1 MHz) and single, dual, or split beam transducer configuration depending on the application, i.e., biomass, layering effects, bottom typing, etc.

10:50

5aAO4. An acoustic tag ''radar-type'' tracking system for fish behavior studies near structures. John Hedgepeth, Dave Fuhriman (BioSonics, Inc., 4027 Leary Way NW, Seattle, WA 98107, jhedgepeth@biosonicsinc.com), Robert Johnson, and David Geist (PNNL, Battelle Memorial Inst., Richland, WA)

Recent studies of fish behavior around hydroelectric dams have used acoustics with split-beam methodology. A complementary methodology called the tracking transducer takes advantage of split-beam capabilities for expanding fish behavior investigations. The principle of tracking radar, aligning the antenna beam with a target, was applied with an acoustic transducer and dual-axis rotators for tracking individual fish over long periods of time. Deviation of the target from the beam axis produces a correction to point the axis toward the target. Two of these tracking systems have been used to triangulate the position of a small acoustic transmitter implanted in salmonid fish in the forebay of Lower Granite on the Snake River. This paper describes the system design, development, and early implementation. In October 1997 a 6-mm-diameter 200-kHz acoustic tag was placed in a rainbow trout and fish movement was measured near a surface bypass collector. The tracking equipment consisted of two 201-kHz, 6 deg half-power, full-beamwidth transducers placed 12.2 m

apart and 3.0 m below the water surface. Each split-beam transducer was mounted on a high-speed, dual-axis, motorized armature. These armatures were computer controlled and the system automatically followed the tag by using angle estimates provided by the echosounders.

11:05

5aAO5. Field trials using an acoustic buoy to measure fish response to vessel and trawl noise. Chris D. Wilson (Natl. Marine Fisheries Service, NOAA, Seattle, WA, cdwilson@afsc.noaa.gov)

A freely drifting acoustic buoy was constructed to evaluate the response of fish to vessel and trawl noise. The buoy contains an echosounder and split beam transducer operating at 38 kHz. Transducer heading data from the buoy are collected to assess the directivity of the fish response (i.e., movement relative to vessel and trawl). Geographic position of the buoy is monitored via GPS. Data are stored onboard the buoy and telemetered directly to the support vessel. The radio link between the buoy and vessel is used to control the echosounder, receive buoy positions, and remotely generate echograms in real time. GPS data from the buoy are also transmitted via the Argos satellite system to the vessel to locate the buoy in the event that visual, radar, and direct radio contact are lost. Field trials include repeated passes by the NOAA research vessel Miller Freeman past the buoy at different ship speeds while free-running and trawling to determine the behavioral response of walleye pollock (*Theragra chalcogramma*) to vessel and trawl noise. Performance of the buoy and interpretation of the results will be discussed.

11:20

5aAO6. Noise characteristics of Japanese fisheries' research vessels. Yoshimi Takao, Kouichi Sawada, Yoichi Miyanohana, Tsuyoshi Okumura (Natl. Res. Inst. of Fisheries Eng., Ebidai Hasaki, Kashima Ibaraki, 314-04 Japan, ytakao@nrife.affrc.go.jp), Masahiko Furusawa (Tokyo Univ. of Fisheries, Tokyo, 108 Japan), and Doojin Hwang (Yosu Natl. Fisheries Univ., Yosu, Chonnam, 550-749, Korea)

Noise is one of the important problems for hydroacoustic surveys of fisheries resources, because it may cause a large error in estimated results and it may shorten detectable range. It is necessary to estimate and reduce the contribution of acoustic noise for precise and accurate surveys. Noise is classified into low-frequency noise (audible by fish) and high-frequency noise (affecting echo sounders). High-frequency noise usually results in an overestimate of acoustic return. The average power of the high-frequency noise was measured by the echo-integrator. The echo-integrator output was converted into the equivalent noise spectrum level which can be compared with noises received by other quantitative echo-sounding systems or environmental noises. The noise measurements of several fisheries research vessels, ranging from 29.5-m length (RV ''Taka Maru'') to 93-m length (RV ''Kaiyo Maru''), were conducted to know their characteristics of noise. The dependence of noise upon the ship speed and the screw propeller's setting was investigated for each vessel. The vessel's performance for hydroacoustic survey is discussed from a viewpoint of noise level.

5aBVa1. ESWL—The evaluation of a revolution. C. G. Chaussy (Staedt Krankenhaus München—Harlaching, München, Germany)

After 6 years of experimental research at the Departments of Urology and Surgical Research of the Ludwig—Maximilian University in Munich, extracorporeal shock-wave lithotripsy (ESWL) was introduced for clinical use in 1980. Uniquely successful and increasingly requested by stone patients, the method soon became widespread. Currently more than 2000 lithotriptors are in operation worldwide and over 5 000 000 treatments have been carried out successfully. Clinical experience in all centers has proven the safety, reliability, and reproducibility of the method. Currently approximately 70% of nonselected stone patients are eligible to receive ESWL treatment and, when combined with endourological procedures, more than 95% of patients can benefit from this method and thus avoid open surgery.

5aBVa2. Extracorporeal shock waves act by shock wave–gas bubble interaction. M. Delius (Inst. for Surgical Res., Univ. of Munich, Klinikum Grosshadern, 81366 Munich, Germany) and W. Eisenmenger (Institut für Physik 1, Univ. of Stuttgart, 70569 Stuttgart, Germany)

Previous animal experimental data had suggested that extracorporeal shock waves acted by the interaction of shock waves with remnant gas bubbles left from cavitational activity of previous shocks. *In vitro* experiments had shown that haemolysis from shock waves were reduced by $>95\%$ by static express pressures from only $1–4\times10^5$ kPa in the exposure vessel. This was interpreted as evidence for a reduced shock wave–gas bubble interaction by compression of the remnant gas bubbles by the excess pressure.

Additional experiments have shown that haemolysis was lower at $0.2-1\times10^5$ kPa excess pressure when the same number of shock waves was administered more slowly. Application of a single strong shock to red blood cells had little effect on haemolysis yet application of two shocks caused an increase of haemolysis by 500%. Static excess pressure abolished the increase. The only interpretation one can think of is that the first shock had caused remnant gas bubbles which acted strongly at the second shock. The term shock-wave gas-bubble interaction is well known from cavitation physics and should be used more often to describe the mechanism of action of extracorporeal shock waves.

5aBVa3. Can SWL-induced cavitation and renal injury be separated from SWL-induced impairment of renal hemodynamics? Andrew P. Evan (Dept. of Anatomy, Indiana Univ. School of Medicine, MS 259, 635 Barnhill Dr., Indianapolis, IN 46202), Lynn R. Willis, Bret A. Connors, James A. McAteer, James E. Lingeman, Robin O. Cleveland, Michael R. Bailey, and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

SWL to one kidney causes localized tissue damage and impairment of tubular function, but reduces renal plasma flow (RPF) in both kidneys. We examined the effect of SWL voltage (kV) and inversion of the waveform (IW) on these localized and bilateral effects of SWL. Five-week-old pigs were anesthetized for either sham-SWL or SWL (2000 shocks, unmodified HM3) at 12, 18, or 24 kV or 2000 shocks, 24 kV, with a reflector that inverts the waveform. RPF and tubular extraction of PAH (E_{PAH}) were measured 1 h before and 1 and 4 h after SWL. E_{PAH} estimates tubular secretion function. SWL significantly reduced RPF to similar degrees at each kV. E_{PAH} was not significantly reduced in the 12-kV group, but was reduced to progressively greater degrees in the 18 and 24 kV groups. IW eliminated ultrasonic evidence of cavitation, produced minimal tissue damage, and eliminated the reduction of E_{PAH}. It did not eliminate the reduction of RPF. The data suggest that shock-wave voltage and cavitation may be related to the tissue injury and reduced E_{PAH} induced by SWL, but suggests that neither may be directly related to the impairment of RPF. [Work supported by NIH, PO1 DK43881.]

5aBVa4. The potential of lithotripter shock waves for gene therapy of tumors. Douglas L. Miller, Richard A. Gies, Brian D. Thrall (P7-53, Battelle Pacific Northwest Natl. Lab., P.O. Box 999, Richland, WA, doug.miller@pnl.gov), and Shiping Bao (Washington State Univ., Richland, WA)

Tissue destruction by lithotripter shock-wave-induced cavitation can be effective for antitumor therapy. Since DNA transfection can be accomplished through cavitation-induced sonoporation, the potential may exist for an advantageous combination of shock wave and gene therapy of tumors. B16 mouse melanoma cells were cultured by standard methods and a luciferase reporter vector was used as the DNA plasmid. The shock-wave generation system, similar to a Dornier HM-3 lithotripter, had peak pressure amplitudes of 24.4 MPa positive and 5.2 MPa negative. *In vitro* exposures of cell suspensions indicated that results were greatly enhanced by leaving an air space in the exposure chambers to promote cavitation activity. For *in vivo* exposure, cells were implanted subcutaneously in C57BL/6 mice 10–14 days before treatment. DNA at 0.2 mg/ml and sometimes air at 10% of tumor volume was injected intratumorally before exposure. Exposure to 800 shock waves, followed by culture of isolated tumor cells for one day, yielded 1.1 (0.43 SE) pg luciferase production per 10^6 cells, increasing to 7.5 (2.5 SE) pg/10^6 cells for air injection. Significant luciferase production occurred for 200, 400, 800, and 1200 shock waves with air injection. Gene transfer therefore can be induced during lithotripter shock-wave treatment of tumors. [Work supported by NIH Grant No. CA42947.]

10:45

5aBVa5. Effects of lithotripter fields on biological tissues. Diane Dalecki (Dept. of Elec. Eng. and the Rochester Ctr. for Biomed. Ultrasound, Univ. of Rochester, Rochester, NY 14627)

Biological effects resulting from exposure to lithotripter fields include hemorrhage in soft tissues, such as the kidney, lung, and intestine, the production of premature cardiac contractions, malformations in the chicken embryo, and killing of *Drosophila* larvae. Pulsed ultrasound can produce similar bioeffects at comparable pressure thresholds. Tissues that contain gas bodies, either naturally or after the addition of ultrasound contrast agents, are particularly susceptible to damage from low-amplitude lithotripter fields. Lung and intestine contain gas naturally and are hemorrhaged by exposure to lithotripter fields on the order of 1 MPa. After the introduction of an ultrasound contrast agent into the vasculature, many organs and tissues, such as the bladder, kidney, fat, muscle, and mesentery, show extensive hemorrhage after exposure to lithotripter pressures less than 2 MPa. Tissues near developing bone are also selectively susceptible to damage from exposure to low-amplitude lithotripter fields. The thresholds for hemorrhage in tissues near developing bone, such as the fetal head, limbs, and ribs, are all less than 1 MPa for exposures with a piezoelectric lithotripter. Cavitation and purely mechanical forces have been investigated as possible mechanisms for these biological effects of lithotripter fields.

11:05

5aBVa6. Biomechanical effects of ESWL shock waves. Bradford Sturtevant and Murtuza Lokhandwalla (Grad. Aeronautical Labs., Calif. Inst. of Tech., Pasadena, CA 91125)

Impulsive stress in the repeated shock waves administered in ESWL is the mechanical stimulus of injury to the kidney. In order to better understand the mechanical origins of injury, the interaction of focused shock waves with simple, planar polymeric membranes immersed in tissue-mimicking fluids was studied. The ESWL shocks in uniform, noncavitating liquids do not cause damage, but after passing through tissue or simulated tissue they do. This result suggests that the acoustic inhomogeneity of tissue may contribute to injury from ESWL. Shocks with large amplitude and short rise time (e.g., in uniform media) cause no damage in noncavitating fluids, while long-rise-time, dispersed shock waves, though only moderately attenuated, do. A continuum model is

described which incorporates the mechanical properties of the tissue and accounts for the effect on its strength of microscopic inhomogeneities. It is shown that when transient tensile stress is applied it takes a finite time for failure to occur, so if the pulse is not long enough the material survives, in qualitative agreement with the behavior described above. A definition of dose at failure is derived in terms of the stress applied to the membrane by each shock wave, the strain rate, and the material failure stress.

11:25

5aBVa7. Effects of tissue constraining on shock wave-induced bubble oscillation *in vivo*. Pei Zhong (Dept. of Mech. Eng. and Mat. Sci., Duke Univ., Box 90300, Durham, NC 27708)

Using a focused hydrophone (1 MHz), acoustic emission (AE) associated with the rapid oscillaton of cavitation bubbles induced by lithotripter shock waves was measured in kidney pelvis and renal parenchyma of a swine model, and compared with the AE produced in water under the same lithotripsy conditions. At each lithotripter output setting (between 16 and 24 kV), the duration of the primary bubble expansion/collapse was found to decrease as the AE was measured from water to kidney pelvis and renal parenchyma, respectively. As the number of shock waves delivered increased, the ratio of the primary bubble expansion/collapse to the subsequent ringing time was found to be almost unchanged in water, but varied significantly in both pelvis and renal parenchyma. These findings indicate a tissue-constraining effect on lithotripter shock wave-induced bubble oscillation *in vivo*. [Work supported by NIH.]

5aBVa8. SWL cavitation damage *in vitro*: Pressurization unmasks a differential response of foil targets and isolated cells. James A. McAteer, Mark A. Stonehill, Karin Colmenares, James C. Williams, Jr., Andrew P. Evan (Dept. of Anatomy, Indiana Univ. School of Medicine, 635 Barnhill Dr., Indianapolis, IN 46202-5120, mcateer@anatomy.iupui.edu), Robin O. Cleveland (Boston Univ., Boston, MA 02115), Michael R. Bailey, and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

To better understand the role of cavitation in kidney stone comminution and renal injury pressurization (Delius UMB23:1997) to regulate cavitation bubble activity *in vitro* was used. A low acoustic impedance chamber (8×15 cm) that only minimally altered lithotripter shock-wave pressure and waveform was constructed to house targets (aluminum foils or vials of kidney epithelial cells) under pressure (0–1400 psi). Cells exhibited lytic injury and foils sustained pitting at atmospheric pressure, but high pressure (1400 psi) prevented lysis and pitting. The pressure threshold for reduced damage was dramatically different for cells versus foils. Cell lysis was prevented at very low pressure ($>$ 30 psi), while substantially greater pressure ($\sim$600 psi) was needed to prevent pitting. Modest pressure (25–300 psi) actually enhanced pitting. SWL *in vitro* cell lysis and foil pitting are both likely due to cavitation. However, interactions between cavitation bubbles and these two targets appear to be quite different. Our observations are consistent with those of Delius and support his suggestion that it may be possible to reduce cavitation-mediated cell damage by regulating ambient pressure. The finding that slight pressure increased the number of cavitation events on foils suggests that modest overpressure might enhance stone comminution. [Supported by NIH PO1-DK43881.]

12:00

5aBVa9. Effect of overpressure on dissolution and cavitation of bubbles stabilized on a metal surface. Robin O. Cleveland (Dept. of Aerosp. and Mech. Eng., Boston Univ., Boston, MA 02215), Michael R. Bailey, Lawrence A. Crum (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105), Mark A. Stonehill, James C. Williams, Jr., and James A. McAteer (Indiana Univ. School of Medicine, Indianapolis, IN 46202-5120)

Recent experimental evidence indicates that static overpressure dramatically reduces lithotripsy-induced cell damage or stone comminution [Delius, Ultrasound Med. Biol. **24**, 611–617]. The hypothesis is that the damage and comminution are due to cavitation and that overpressure dissolves the small gas bubbles which act as cavitation nuclei. Delius observed, however, that the overpressure to protect cells (1 atm) was significantly lower than for stones (10 atm). In similar experiments cell lysis and pitting of aluminum foil as indicators of cavitation are used; the thresholds were 1 and 30 atm, respectively. In addition, the authors observed that pitting of foils increased for overpressures up to 20 atm. It is proposed that crevices in the foil stabilize cavitation nuclei whereas the bubbles dissolve in fluids. Foil damage increased because overpressure is small relative to the shock wave pressures that drive bubble expansion but is the dominant driving force at bubble collapse. Calculations using the Gilmore equation predict that overpressures up to 30 atm hasten and intensify cavitation collapses and over 60 atm eliminate cavitation, in qualitative agreement with our foil data. The calculated collapse time was confirmed experimentally by passive cavitation detection. If bubbles are stabilized in crevices in kidney stones, overpressure may provide a safer, more effective lithotripsy treatment. [Work supported by NIH-PO1-DK43881.]

5aBVb1. Are blood clots Biot solids? Pierre D. Mourad and Steven G. Kargl (Appl. Phys. Lab., UW, 1013 NE 40th St., Seattle, WA 98105, pierre@apl.washington.edu)

Blood clots are saturated porous solids. Their unwanted presence in veins and arteries is the source of a variety of medical problems. Their destruction (thrombolysis) via ultrasound and various enzymes (ultrasound-enhanced thrombolysis, or UET) is still a poorly understood phenomenon. The current view is that cavitation is the mechanism behind UET. This presentation begins with a review of the structure of blood clots and natural thrombolysis. Following that is a review of the literature on UET pointing out that cavitation is at best part of the story, at least *in vitro*, and more suspect *in vivo*. Next is a motivation of the Biot theory (a theory for how sound propagates through and interacts with porous solids) and its application to blood clots. The results of the work thus far predict that blood clots are Biot solids, which has implications for understanding UET. [Work sponsored by DARPA.]

5aBVb2. A stratified model for ultrasonic propagation in cancellous bone. Elinor R. Hubbuck, Timothy G. Leighton, Paul R. White (Inst. of Sound and Vib. Res., Univ. of Southampton, Southampton SO17 3BJ, Great Britain), and Graham W. Petley (Southampton Univ. Hospitals NHS Trust, Southampton, Great Britain)

A new model for ultrasonic wave propagation in cancellous bone is presented here. The model treats cancellous bone as a stratified medium of periodically alternating solid–fluid layers, and considers propagation of two compressional modes, analogous to the fast and slow waves of Biot theory, in terms of slowness surfaces. The behavior of the two modes is examined *in vitro* using bovine bone samples over a range of incidence angles. Two modes are seen when the cancellous structure is parallel to the propagation direction, but only one mode propagates normal to the structure, and the velocity of the fast wave increases with angle of incidence away from the normal. This behavior can be explained in terms of an angular dependent inertial coupling effect, in keeping with the theory of propagation in stratified media of periodically alternating fluid–solid layers. Quantitative agreement with theory is good. Although the structure being analyzed is essentially an oversimplification of the structure of cancellous bone, the agreement with theory suggests the stratified model offers potential for future research.

5aBVb3. Effects of the structural anisotropy and the porosity on ultrasonic wave propagation in bovine cancellous bone. Takahiko Otani and Atsushi Hosokawa (Dept. of Elec. Eng., Doshisha Univ., 610-0321 Kyotanabe-shi, Japan)

Ultrasonic wave propagation in water-saturated bovine cancellous (spongy) bone has been experimentally studied *in vitro* by a pulse transmission technique. Fast and slow longitudinal waves have been clearly observed in the earlier investigation when the acoustic wave propagates to the direction of the trabeculae orientation [A. Hosokawa and T. Otani, J. Acoust. Soc. Am. **101**, 558–562 (1997)]. In the present study, propagation speeds of the fast and the slow waves were measured as a function of the propagation angle to the trabeculae orientation. Experimental results show that the propagation speed of the fast wave and the amplitude of the slow wave depend greatly on the angle to the trabeculae orientation, and the speed of the slow wave and the amplitude of the fast wave are little affected by the angle of the trabeculae orientation. The propagation speeds of both waves were also experimentally examined as a function of the porosity. Measured results are discussed in relation to the structural anisotropy and the porosity using Biot's theory.

5aBVb4. Wideband laser-acoustic spectroscopy of proteins. Alexander A. Karabutov and Natalia B. Podymova (Dept. of Phys., Moscow State Univ., Moscow, Russia 119899, karabut@gpwp1.phys.msu.su)

The absorption of ultrasound in a frequency range of 2–50 MHz in proteins was investigated with a wideband laser-ultrasonic spectrometer. It was found that for fresh chicken proteins ultrasonic absorption is proportional to the squared frequency. Denaturation of proteins transforms the spectrum of ultrasonic absorption to the first power of frequency dependence. In the hole frequency range the ultrasonic absorption in denaturated protein is higher than in the fresh one. The possibility of laser ultrasonic diagnostics of proteins is discussed.

5aBVb5. Wideband acoustics spectroscopy of liquid phantoms of biological tissues. Valery G. Andreev, Yury A. Pischalnikov (Dept. of Acoust., Phys. Faculty, Moscow State Univ., Moscow 119899, Russia, andreev@na.phys.msu.su), Alexander A. Karabutov, and Natal'ya B. Podymova (Moscow State Univ., Moscow 119899, Russia)

Biological tissues have a specific frequency dependence of the ultrasonic absorption and sound-speed dispersion. It makes fruitful the diagnostics of tissues by studying these parameters. It is necessary to carry out the spectroscopic investigation in a wide frequency band in a real time. Pulsed laser ultrasonic spectroscopy is the most useful technique to solve this problem. The method of wideband acoustic spectroscopy with laser thermo-optical source is proposed. A Q-switched YAG-Nd laser was explored to excite the short acoustic transients (pulse duration 12 ns, amplitude up to 8 MPa) by an especially produced thermo-optical generator. The acoustic transients transmitted through the medium under the testing were detected by a wideband transducer (frequency band 2–350 MHz). The absorption of ultrasound was calculated by FFT. The absorption in glycerol, acetic acid, and butanediol was investigated in a frequency band 2–50 MHz. The spectra of relaxation times were calculated. [Work supported by RFBR and CRDF.]

5aBVb6. The necessity for acoustics in the biomedical engineering program. Daniel R. Raichel (Dept. of Mech. Eng., Steinman Hall, The City College of The City Univ. of New York, New York, NY 10031) and Latif Jiji (The City College of CUNY, New York, NY 10031)

Biomedical engineering constitutes the fastest growing segment of all engineering fields. In order to effectively deal with a wide variety of engineering problems, the biomedical engineer needs to be a ''jack of all trades'' insofar that he or she should be able to meet challenging problems in mechanics, electronics, thermal analyses, fluid mechanics, materials, manufacturing techniques, etc. In the medical field, acoustics (particularly ultrasound) is used for both diagnostic and therapeutic purposes, and new devices are continuously being developed to provide better diagnostic imaging or more effective therapy. As a part of the biomedical engineering program, undergraduate and graduate students need to gain better understanding of acoustical physics, the effects of sound and ultrasound on living organisms, the principles of measurements, imaging processes, and data analysis concepts. Laboratory experience is essential, and practical experience in a teaching medical hospital would definitely be salutary. The time constraint imposed by a four-year undergraduate program, which also needs to meet ABET criteria, effectively limits the expository scope, and it follows that additional, more intensive training may be better achieved through post-baccalaureate (master's degree and doctoral levels) programs.

5aEA1. Finite-element simulation of piezoelectric transformers. Takao Tsuchiya, Yukio Kagawa, and Hiroki Okamura (Dept. of Elec. and Electron. Eng., Okayama Univ., Okayama, 700 Japan)

A three-dimensional finite-element approach to the characteristic prediction of piezoelectric transformers is presented. For a numerical example, a Rosen-type piezoelectric transformer is considered. The electrical input admittance and the transmission or transfer characteristics are demonstrated for the fundamental longitudinal mode operation. Based on these characteristics, the lumped parameters are extracted to form the electrical equivalent circuit. The effect of the loading or termination condition on the output voltage and the conversion efficiency are also examined. The numerical results are then compared with the experimental results. Examination is then extended to the optimum design in terms of efficiency and the output voltage.

9:30

5aEA2. A tubular piezoelectric actuator and its characteristic analysis by finite-element modeling. Naoto Wakatsuki, Takao Tsuchiya, Yukio Kagawa, and Kazumichi Hatta (Dept. of Elec. and Electron. Eng., Okayama Univ., Okayama, 700 Japan)

Three-dimensional motion is sometimes required in an actuator. A tubular configuration is proposed to realize the three-dimensional motion at the tip. A cylindrical shell piezoceramic, polarized in the radial direction, is provided with several pairs of electrodes on both surfaces of the shell. The combination of the voltages with proper sense makes it possible to control the motion. The displacements or the forces at the tip are expressed in terms of the linear combination of the electrical input voltages on each pair of electrodes. The coefficient of each term is to be determined by the experiment or numerical simulation. Here, the determination of the coefficients is made by finite-element modeling for which the code previously developed is utilized.

9:45

5aEA3. Substructuring in the finite-element analysis of sonar transducer arrays. J. R. Dunn (School of Electron. & Elec. Eng., Univ. of Birmingham, Edgbaston, Birmingham B15 2TT, England, j.r.dunn@bham.ac.uk), C-L. Chen (6F-3, Taipei, Taiwan), and B. V. Smith (Univ. of Birmingham, Edgbaston, Birmingham B15 2TT, England)

Finite-element (FE) analysis of arrays of sonar transducers becomes costly in memory and computation time for arrays with many elements. This becomes even more severe a problem if the individual transducers have complex structures. However, because in many cases the individual transducer elements are identical, it is possible to treat them as repeated substructures; each substructure may then be viewed as a superelement which is defined by only those nodes which couple into the overall structure of the array. This technique is analogous to the use of Thevenin equivalent sources in the analysis of complex electrical circuits. By the use of this technique it is possible to analyze the electroacoustic performance of larger arrays than hitherto possible within the limitations set by the computer memory. This paper describes this superelement technique and results are presented for a simple two-element transducer array analyzed for its free (unloaded) vibration behavior both by full FE analysis of the complete structure and by the substructuring technique. The results of the two methods are shown to agree very closely, and measurements on an experimental model compare favorably with the theoretical predictions.

10:00

5aEA4. Sonar simulation and display techniques. Yuhong Guo, Hong Liu, and Junying Hui (Dept. of Underwater Acoust. Eng., Harbin Eng. Univ., 150001 Harbin, PROC, guoyh@public.hr.hl.cn)

This paper describes techniques used in the simulation and display of a passive sonar system. The sonar and its environment models, including target, channel, noise background, and array, and a complete sonar signal processing chain are developed in the simulation system. Based upon the simulation system, different display techniques are studied. Modeling for performance assessment of a colored brightness mode sonar display is difficult because of its relation to human visual psychology and physiology. A concept of ''visual threshold'' is proposed in the paper; based on it, as well as the statistical model of display data, detection performance of

the sonar display system can be analyzed quantitatively and theoretically. The second-decision method, based on the statistical property of LOFAR display, and a four-dimensional display technique are presented in the paper.

10:30

5aEA5. A new method of multibeamforming for a swath bathymetry sonar system and its MIMD parallel architecture. Haisen Li, Lan Yao, and Xinsheng Xu (Dept. of Underwater Acoust. Eng., Harbin Eng. Univ., Harbin 150001, PROC, euipc@public.hr.hl.cn)

In a swath bathymetry sonar system, real-time multibeamforming is required in order to increase the coverage and the efficiency. To determine the direction of seafloor echo accurately, traditional beamforming must work at a high sample rate, the interpolation is used to reduce computing amounts, but when there are tens of receiving channels and beams, the interpolation filter algorithm will rapidly increase computing amounts to result in the real-time multibeamforming, this is very difficult. Combining with a swath bathymetry sonar system, a new method of quadrature beamforming is described in this paper. It combines time domain beamforming with phase shifting beamforming to process the available bandpass signal. To reduce sample rate, a mixing frequency technique is used. A quadrature component is obtained from a single-channel A/D converter utilizing Hilbert transformation and its coefficient is weighted with Hamming window function, therefore, amplitude and phase is highly accurate. Comparing with the traditional beamforming method, the method presented in the paper is characterized by high accuracy, less sample rate, and less computation complexity, easily realized with a high speed DSP device. The parallel pipeline architecture is given based on TMS320C30. Simulating and lake trial results show that the method is right and efficient. The method is universal for active sonar.

10:45

5aEA6. Specific acoustic impedance of the ultrasonic field by the square flat transducers. Tohru Imamura (Natl. Res. Lab. Metrology, 1-1-4, Umezono, Tsukuba, Ibaraki, 305 Japan, imam@nrlm.go.jp)

Sound pressure, particle velocity, and specific acoustic impedance are investigated, using the case where square flat transducers are tilted from a parallel condition. Specific acoustic impedance is a quotient of sound pressure by particle velocity. Particle velocity is computed by numerical quadruple integration with Huygens's principle, and compared with that of the plane wave. The ratio of the half side length (a) of the square flat transducer to the wavelength (λ) of the ultrasonic wave is set at 2.5, and the distance between the transducers is set at 5a or 10a. The feature of the phase delay leap of the specific acoustic impedance on the central axis of the circular flat transducer does not appear for the square case.

11:00

5aEA7. Estimation of equivalent circuit parameters for piezoelectric transducer using least-squares method. Byung-Doo Jun (R & D 3 Gr., LG Precision Co. Ltd., 148-1 Mabuk-ri, Gusung-Myun, Yongin-shi Kyunggi-do, 449-910, Korea) and Koeng-Mo Sung (Seoul Natl. Univ., Seoul 151-742, Korea)

In general, the resonance method has been used for estimating the equivalent circuit parameters for the underwater piezoelectric transducer. Sometimes, however, it is difficult to estimate the equivalent circuit parameters when the measured electrical impedances have an imaginary part at resonant and antiresonant frequency. In this paper, to estimate the equivalent circuit parameters of the piezoelectric transducers, equivalent circuit equation is modified and the least-squares method is applied. Equivalent circuit equation is composed of real and imaginary equations, respectively. With these equations, matrix form Yule–Walker equations are formulated. The least-squares method is applied with measured electrical impedance data over the effective frequency band to solve these equations. The procedure is as follows: First, four variables which are functions of five equivalent circuit parameters (R, L, C) are obtained by the least-squares method. Then, initial equivalent circuit parameters can be extracted by solving four equations which contain five parameters, one of which is assumed. Finally, by iteration and update, all the equivalent circuit parameters can be estimated with considerably small error. The impedance characteristics of the piezoelectric transducer with estimated parameters are in good agreement with measured ones.

11:15

5aEA8. Study of compound structured ultrasonic transducer made of PZT/PVDF. Moo Joon Kim, Dong Hyun Kim, and Kang Lyeol Ha (Dept. of Phys., Pukyong Natl. Univ., 599-1 Daeyon-dong, Nam-gu, Pusan 608-737, Korea)

When the piezoelectric ceramic, PZT is used in the water it needs matching layers for efficient energy transmission. PZT is known as the proper piezoelectric material for the transmitter by reason of the large electromechanical coupling factor. So actually PZT has been used for the nondestructive testing or ultrasonic diagnostic instrument as good material. In the meantime, there is a kind of polymer by the name of PVDF. Its acoustic impedence is similar to water, so PVDF does not need matching layers but it is not a proper material for the transmitter because of the small electromechanical coupling factor. However, the receiving sensitivity of PVDF is very flat through the wide frequency range. So it is known as a proper material for the receiver like wideband hydrophone. Therefore in this paper it is suggested that the transducer which transmits and receives signals by PZT and PVDF, respectively, could be constructed compositively, and the transmitting and receiving feature of the transducer was investigated theoretically and experimentally.

5aMU2. Dynamic optimal tuning of electronic keyboards as they are being played. James E. Steck (Dept. of Mech. Eng., Wichita State Univ., Wichita, KS 67260-0133, steck@me.twsu.edu) and Dean K. Roush (Wichita State Univ., Wichita, KS 67260)

The 12-tone equally tempered musical scale can produce noticeably imperfect matching of acoustic harmonics when some combinations of tones are played together. The lower partials (harmonics) which should match, do not. For a 12-tone octave, if a small number of tones in the octave are to be sounded simultaneously, a tuning can be found which produces harmonic errors that are much less than that of equal temperament. Historically, these tunings have been discovered, explored, and abandoned in favor of equal temperament because they generally have much worse harmonic error for tone combinations other than those for which the tuning was optimized. Here, a mathematical description of the total harmonic error of a musical instrument is presented along with a mathematical method which solves for a tuning (tone frequencies) that minimize this total error. The optimal tuning calculations have been implemented in ''C'' code on a 166-MHZ pentium desktop personal computer equipped with a Creative Labs Sound Blaster AWE 32 soundcard, with a MIDI keyboard attached. The ''C'' code reads the keys (tones) being played on the keyboard, calculates the optimal tuning, and sounds the tones on the PC soundcard at the optimally tuned fundamental frequencies.

9:30

5aMU3. On the use of elements of piano notes to improve the identification of polyphonic piano sounds. Lucile Rossi and Gerard Girolami (Univ. of Corsica, Quartier Grosseti, 20250 Corte, France, lrossi@univ-corse.fr)

An original algorithm for identifying polyphonic piano sounds signals, based only on the use of frequential positions of note partials, has been developed by the authors [Rossi and Girolami, J. Acoust. Soc. Am. **100**, 2842(A) (1996)]. This paper presents a study of the evolution of the amplitude of piano notes' partials and their energy, carried out to see if these elements can be used to improve the identification of notes in cases like short notes, long notes, repeated notes, and polyphonic sounds. In the case of monophonic sounds, Doval [Ph.D. thesis, University of Paris VI (1994)] has shown that the evolution of the amplitude of piano notes' partials along with their frequency variations can be used to identify the fundamental frequency of signals. The case of polyphonic piano sounds (several notes played simultaneously on the same piano) is more difficult, but if a particular behavior of partials belonging to a given note could be detected, for example, synchronous variations or typical amplitude evolution, the sorting of partials would be more reliable, the identification of notes more efficient, and the detection of notes' onsets more precise.

9:45

5aMU4. A new accurate model-based music synthesis technique by using recurrent neural networks. S. F. Liang (Dept. of Control Eng., Natl. Chiao-Tung Univ., Hsin-Chu, Taiwan) and Alvin W. Y. Su (Dept. of CSIE, Chung-Hwa Univ., Hsin-Chu, Taiwan)

Reproduction of the tones generated by playing a particular musical instrument electronically remains an open and difficult problem. An accurate model-based analysis/synthesis approach with respect to plucked-string instruments by using recurrent neural networks is proposed. The procedure is described as follows. A recurrent neural network corresponding to the physical model of a musical string is first configured. The vibration of a plucked string is measured and used as the training data of the neural network. The backpropagation-through-time method is used to train the network such that output of this network can be matched to the measured data as close as possible. The well-trained neural network is then used as our synthesis model for this particular string. Since the characteristics of a string keep changing over the period of vibration, it is also necessary to update the parameters of the neural network during the synthesis process. In our experiments the synthesized tones and the real tones sounded almost identical. These results will also be demonstrated during the presentation in ICA/ASA 98 if this paper is accepted. [This Work is supported by both NSF, Taiwan and Computer/Communication Lab. ITRI, Taiwan.]

10:00

5aMU5. Musical instrument synthesis by nonregenerative nonlinear processing. James W. Beauchamp (School of Music and Dept. of Elec. and Comput. Eng., Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801)

When a sinusoid is distorted by a nonlinear function, a complex tone is produced. An nth degree polynomial nonlinear function produces an output waveform containing n harmonics. Moreover, when the amplitude of the input sine wave changes, the harmonic structure of the output changes in a way which can be predicted from the polynomial coefficients. Also, the coefficients can be set to provide any arbitrary magnitude spectrum when the sine wave has a particular amplitude, say unity. Generally, the spectral centroid, a measure of the spectral bandwidth, increases monotonically as the input amplitude increases. This possibility is enhanced by placing a high-pass filter at the output. An acoustic instrument sound can be imitated by (1) performing time-variant harmonic analysis on it, (2) selecting a representative spectrum from it to determine the polynomial coefficients, (3) measuring the sound's time-varying spectral centroid and rms amplitude, and (4) coercing the sine wave amplitude to change so that the spectral centroid of the output matches that of the original sound. The amplitude of the original sound is matched by a multiplier at the nonlinear output. This method has been successfully used to synthesize instruments such as the trumpet, saxophone, clarinet, oboe, and piano.

10:15

5aMU6. Time-domain modeling and numerical simulation of timpani. Leïla Rhaouti, Patrick Joly (Inria-Rocquencourt, BP 105, 78153 Le Chesnay Cedex, France), and Antoine Chaigne (Enst, Paris Cedex 13, France)

Timpani are made of a circular elastic membrane stretched over a enclosed air cavity and set into vibrations by the impact of a mallet. The motion of the membrane is coupled with both the external and internal sound pressure field. A time-domain model of this instrument has been developed in order to investigate the influence of the main geometrical and physical quantities on the resulting sound. This model consists of a set of partial differential equations which govern the displacement of the membrane and the acoustic pressure inside and outside the cavity, respectively. These equations are coupled with a nonlinear differential equation which governs the excitation by the mallet. A numerical scheme has been derived from this model using three-dimensional finite element methods. Absorbing conditions have been implemented to simulate the free space. The validity of the model is illustrated by successive snapshots showing both the pressure field and membrane displacement. In addition, time histories of energetic quantities are presented for a better understanding of energy balance between membrane, cavity, and external space in real instruments. Sound examples are obtained by simulating the sound pressure at specific positions corresponding to the player's ears.

10:30

5aMU7. Modeling Chinese musical instruments. Andrew B. Horner and Lydia Ayers (Dept. of Comput. Sci., Hong Kong Univ. of Sci. and Technol., Clear Water Bay, Kowloon, Hong Kong, horner@cs.ust.hk)

Chinese instruments include a range of colorful instruments with distinctive characters. For example, the dizi is the most common Chinese flute, and it has a bright buzzing quality produced by a rice paper membrane glued over a hole. This paper describes models for more than 20 Chinese traditional and folk instruments using group additive synthesis with genetic algorithm-optimized parameters. Other types of Chinese flutes modeled include the xiao (vertical flute), paixiao (panpipes), and xun (ocarina). The sheng is a mouth organ with a ring of bamboo pipes attached to a wind chamber, and dates back to 1500 BC. A folk version of the sheng, called the lusheng, has also been modeled, as well as the bawu and hulusi, folk instruments that sound similar to the clarinet. The player's mouth completely covers the bawu's blowhole, which has a vibrating reed cut into a copper strip covering the hole. The hulusi has a playing tube and multiple drone tubes. Several pitched percussion and plucked string instruments have also been modeled. The presentation will show the acoustic instruments, their sound, their spectra, and resynthesized excerpts of music written for these instruments.

5aNSa1. Low-frequency noise around airports. Michel Vallet and Jean Claude Bruyere (INRETS, 25 avenue Francois Mitterrand, Case 24 69675, Bron Cedex, France)

The sound frequency weighting PNdB has been proposed by Kryter (1959) to assess the noise from jet engine aircrafts. Due to the technical evolution of aircraft engines, and to choose a frequency weighting common to all transport systems, the dB(A-weighted) has begun to be used as the acoustical unit around airports; the PNdB is still used for noise certification purposes. A study of noise measurements that was carried out around French airports allows one to see some noticeable differences between acoustical levels, respectively, expressed in dB(A) and dB(C). The difference varies between 4 dB for the landing of recent aircrafts to 14 dB at take-off for 50/70-seat propeller aircrafts. If one considers the additional frequency decrease due to the walls and windows in housing, the pertinence of dB(A) weighting could be questioned for aircraft noise received by people living a long distance from the airport. This question is of interest in light of the new ANSI method for assessing combined noises (Schomer, 1997): this method suggests using the C frequency weighting for sounds with strong low-frequency content.

9:15

5aNSa2. Subjective response to aircraft flyover noise. Sherilyn A. Brown (Structural Acoust. Branch, NASA Langley Res. Ctr., M.S. 463, Hampton, VA 23681, s.a.brown@larc.nasa.gov) and R. David Hilliard (Wyle Labs., Hampton, VA 23666)

In order to obtain increased understanding of community response to aircraft noise, a comprehensive subjective study was designed and implemented to realistically simulate the aircraft noise exposure experienced by residents living both near and far from airports. The test was designed to present a wide range of daily aircraft noise exposures ranging broadly in both quantity and amplitude. The In-Home study was supported by a computer controlled sound playback system which exposed test subjects to aircraft sounds during a daily 14 h test period. This system provided a degree of control over the noise exposure not found in community situations and a degree of situational realism not available in the laboratory. Each day the system played from 0 to 448 flyovers as the test subject went about his or her normal activities. At the end of the day, the test subjects rated their annoyance to the flyovers they had heard. The noise exposures presented during 9 weeks simulated different combinations of runway activity, aircraft flyover altitude, rush hour conditions, and occasional loud aircraft among many low sound level flights. Subsequent data analysis will

seek to provide a basis of understanding of annoyance response to enhance predictive algorithms for a wide range of aircraft noise exposure conditions.

9:30

5aNSa3. Low-flying military aircraft noise—Operational flying. Ian H. Flindell (Inst. of Sound and Vib. Res., Univ. of Southampton, UK) and Ralph J. Weston (Royal Air Force Inst. of Health, Aylesbury, Buckinghamshire, UK)

The distribution of military low-flying training across Great Britain is essentially random within the permitted low-flying areas, although there are certain areas where above-average concentrations of flights occur. However, there are very little data available on actual flight tracks as flown, and training operations are normally conducted so as to encourage as much flexibility as possible. This means that calculations of noise exposure in different areas have to be based to a considerable extent on assumptions about typical flight track distributions, using aircraft noise source reference levels extrapolated from data collected under specially arranged measurement trials. This paper reports the results of a number of recent field surveys carried out in representative overflown areas which show generally good agreement between the assumptions made about typical flight distributions, the special trials data, and actual operational flying.

9:45

5aNSa4. Converting noise level into number of noisy events: A new method to quantify *k* factors reveals area-dependent over- and underenergetic responses around the same airport. Karl Th. Kalveram (Univ. of Duesseldorf, Dept. of Cybernetical Psych., 40225 Duesseldorf, Germany, kalveram@uni-duesseldorf.de)

For aircraft noise, caused by N flight movements within observation time T, with average maximum noise level $L_{\max}$ and duration d_t, the energy equivalent noise level L_{eq3} is approximated by $Q(k,d)=L_{\max}+k^*\log N+d^*\log(dt/T)$, if $k=d=10$. This seems to enable a trade-off between $L_{\max}$, N, and dt. However, the problem is not to keep the L_{eq3} constant, but the subjective annoyance, and this in turn depends on whether people process alterations of $L_{\max}$, N, and dt corresponding to energy equivalence ($k=d=10$) or not. Therefore, valid measurements of public noise responses by $Q(k,d)$ require the estimation of k and d from empirical data. However, multiple correlation techniques mostly used for this purpose lead to contradictory and invalid estimates for k. This paper presents an alternative method, utilizing dose-response curves based on regression of annoyance with $L_{\max}$ at fixed numbers of overflights. Results are independent from the selected annoyance ratings and furthermore also valid for nonlinear dose–response curves. Based on curves characterizing small ($N<5000$), medium ($50000<N<200000$), and large ($200000<N$) airports [Rice (1980)], the proposed procedure predicts a crossover effect also for different areas of the same airport, i.e., $k>10$ for low k and $k<10$ for high noise levels, if this airport changes from medium to large.

10:00

5aNSa5. Relational anomalies in A weighted and linear scale sound level measurements associated with jet aircraft departures. Errol Nelson P.E. QEP (Optimum Environment, P.O. Box 114, Issaquah, WA 98027) and Allan Furney (Regional Commission on Airport Affairs, Des Moines, WA 98198)

Noise levels from jet aircraft operations at major airports are often perceived by nearby residents as being louder and more intrusive than claimed by airport proprietors. This can cause heated opposition by citizens to airport development and expansion plans. To further clarify the issue, a noise study was conducted using four noise meters; two Type 1 and two Type 2. Simultaneous sound level measurements were taken on the A-weighted and linear scales in airport and nonairport noise environments; and included octave band analyses. In both noise environments the average differential between full spectrum A-weighted and linear scale measurements is approximately 15 dB, except when influenced by jet aircraft departures. During jet aircraft departures, this A/linear differential was as small as 4 dB; and the smaller the difference between simultaneous measurements the louder the perceived noise from the departing plane. This measurement anomaly was unique to departing jet aircraft. Propeller driven aircraft operations, or jet aircraft landings, showed little or no change in the A/linear noise differential. The measurements suggest that a significant amount of noise is not being measured by the sound level meters during jet aircraft departures: either deducted by weighting filters or due to instrument limitations. However, by conducting simultaneous measurements of A weighted and linear scale sound levels, this relational anomaly can provide a simple, realistic indicator of jet aircraft loudness in the airport noise environment.

8:30

5aNSb1. The use of frequency-dependent velocity scaling as a diagnostic tool. Daniel Quinlan (Bell Labs., Lucent Technologies, 600 Mountain Ave., Murray Hill, NJ 07974, dbq@lucent.com)

This paper will discuss a method for investigating broadband aeroacoustic noise sources. The method is based upon the use of frequency-dependent velocity scaling. The dependence of sound power level upon a characteristic velocity is determined experimentally, and that dependence is used as an indicator of primary aeroacoustic processes. The procedure yields an identification of distinct frequency bands within which source trends are observable. Each band is presumed to be controlled by different processes, and the set of likely processes is fixed according to the average velocity exponent value obtained. In principal, the method is applicable to low-speed aeroacoustic source identification problems where a characteristic flow speed can be measured and systematically varied. Measurements of sound radiated by flow over a flat plate were used to evaluate the performance of the method. The procedure was then applied to a small axial fan typical of those used to cool electronic systems. For the fan, the frequency-dependent velocity scaling demonstrated that shifts in dominant aeroacoustic processes occur near 2 kHz and above 4 kHz. The results added insight to a related study which demonstrated that tip gap flows were the primary source of broadband noise above 2 kHz.

8:45

5aNSb2. Noise diagnostic and reduction of a scooter engine motorcycle. Cho H. Lu (Mech. Industry Res. Labs., Industrial Technol. Res. Inst., Hsinchu, Taiwan 310, R.O.C., 830562@mirl.itri.org.tw) and Jen C. Cheng (Natl. Huwel Inst. of Technol., Huwel, Taiwan, R.O.C.)

This paper presents an appropriate way to reduce the noise of a scooter engine motorcycle. In order to investigate the noise contribution of each engine component, the lead covering method was used to rank the noise source. With the noise spectra from measuring the pass-by noise and releasing the lead cover on each component sequentially, the correlations between specific frequencies and each component of the engine were found. Furthermore, the noise characteristics of all components were cataloged into the airborne noise and the structure-borne noise. In this research, it was shown that the airborne noise was usually coming from the air cleaner or muffler. Additionally, the power transmission mechanism like CVT or crankcase generated the structure-borne noise. Based on the diagnostic results above, some modifications of the motorcycle had been done, for example, isolating of the CVT-cover and the crankcase-cover, fixing of high density material at the air cleaner box and adding another layer around the exhaust pipe. For the pass-by noise measurement, it was shown that the noise level of the scooter was reduced by 2.5 dB(A). [Submitted For Noise ''Outstanding Young Presenter'' Paper Award.]

9:00

5aNSb3. Noise in non-premixed turbulent syngas flames. Sikke A. Klein and Jim B. W. Kok (Dept. of Mech. Eng., Univ. of Twente, P.O. Box 217, NL 7500 AE Enschede, The Netherlands, s.a.klein@wb.utwente.nl)

A turbulent syngas flame may generate acoustic noise of high acoustic intensity in a combustion chamber. This may lead to the failure of construction components in a gas turbine engine in periods of the order of 1–100 hours. The research as described in the literature has almost exclusively been performed on the generation of noise in premixed methane or propane flames. Syngas fuel is a mixture of hydrogen and carbon monoxide, and the burners used are of the non-premixed type. In this research, the effect of turbulence and syngas composition on noise generation is investigated. A laboratory is set up to test syngas flames of a thermal power of 50 kW in a cylindrical air-cooled combustion chamber. Experiments are performed at several fuel compositions and burner inlet conditions. The flame sound intensity is measured in the combustion chamber equipped with acoustic dampers. The paper discusses the measured sound spectra. A model is derived for the generation of sound in a turbulent non-premixed flame. In this model it is shown that the sound generation is related to the dependence of density on mixture fraction in a flame with fast chemistry. A fluctuation in mixture fraction will lead to sound generation.

9:15

5aNSb4. Prediction and reduction of centrifugal blower noises. Christopher L. Banks and Sean F. Wu (Dept. of Mech. Eng., Wayne State Univ., 5050 Anthony Wayne Dr., Detroit, MA 48202)

This paper presents the results of an investigation of centrifugal blower noises. Experiments on three different types of blowers were conducted to determine the major noise generation mechanisms. The information thus gained has led to an innovative noise reduction method utilizing a stationary, noncontacting transition mesh. Experiments showed that an overall noise reduction of 3 to 5 dB was achieved for all the blowers running at impeller speeds in the range of 10 to 30 m/s. In addition, a semianalytical model was developed to predict noise spectra from dimensionally similar centrifugal blowers. This model yielded an acoustic power proportional to the fourth power of the blower speeds. Comparisons of the calculated and measured noise spectra from different blowers running under various speeds were demonstrated. Good agreements were obtained in all cases. [Work supported by Ford Motor Company.]

5aNSc1. Supportive sound environments in building research. Birgitta Berglund (Inst. of Environ. Medicine and Dept. of Psych., Stockholm Univ., Stockholm, Sweden), Edward Hojan, and Anna Furmann (Inst. of Acoust., Adam Mickiewicz Univ., Poznan, Poland)

The aim of this research is to create good sound environments in rooms of ordinary buildings (schools, dwellings, offices, hospitals) for people with hearing deficits. If the deterioration of hearing with age is considered, this group of people may represent a majority rather than a minority of the population. From the many evaluation criteria of natural sounds, both stationary and nonstationary and in room environments, used by subjects, the authors have identified independent ones. These criteria may be named attributes and primarily define the ''quality'' of the sound-perception space in rooms. New experiments involving perceptual evaluation of sound and environments by 40 randomly chosen subjects and the use of multidimensional data analysis confirm in part our earlier results regarding the particular evaluation criteria applied [Furmann *et al.,* J. Acoust. **4**, 535–551 (1991)]. According to Stevens' argument, it seems that the relationship between the values of the evaluation scale and the perceptions are identical for people of normal and impaired hearing although their perceptions may differ.

10:00

5aNSc2. Features of Japanese soundscapes recognized by foreigners: A questionnaire survey on sounds for the foreigners living in Fukuoka. Shin-ichiro Iwamiya (Dept. of Acoust. Design, Kyushu Inst. of Design, 4-9-1, Shiobaru, Minami-ku, Fukuoka, 815-8540 Japan, iwamiya@kyushu-id.ac.jp)

A questionnaire survey on odd sounds for foreigners living in Fukuoka was done to clarify the feature of Japanese soundscapes recognized by those whose cultural background is different from the Japanese. The foreigners were asked to point out the sound which they usually heard in Japan but heard less in their home countries and their impressions, and the

sound which they usually heard in their home countries but heard less in Japan and their impressions. The traffic sound signal for the blind, the exhaust noise by wild bike riders, the peddlers' cries, and the election campaign broadcast are the typical sounds only heard in Japan. The foreigners usually have a good image for the traffic sound signal for the blind and the peddlers' cries. In contrast, they have a negative impression on the muffler noise by wild riders and speeches concerning election. The Japanese soundscape is characterized by these sounds which we hear in daily life. Comparison between the sounds usually heard in Japan and those heard less in Japan shows that there are too many public sounds, such as announcements using public-address systems and music at the shopping centers, and few natural sounds and human voices in Japan.

10:15

5aNSc3. The acoustic and sound design for a museum exhibition on indigenous music and dance. Peter G. Coulter (Museum of Appl. Arts and Sci., P.O. Box K346, Haymarket, Sydney, Australia 2000)

Museum exhibitions commonly use visual design to orientate and inform the visitor. At the Powerhouse museum in Sydney, Australia, an exhibition (entitiled Ngaramang Bayumi) was recently developed on indigenous music and dance. This exhibition was designed to orient the visitor using aural cues, in addition to the visual. This has been achieved by the use of acoustic design and through the use of a specialized sound systems that presents a 3-D sound (ambisonics), that calls and guides the visitor through the space. The experience, along with audiovisuals, objects, text, and graphics uses unusual geometries, layouts, and building materials. Using this design as a case study, this presentation will explain the research and development of the acoustic elements within the exhibition. These are the elements of cross talk, sound quality, sound focusing, sound isolation, sound ambience, localization, dynamic range, and reverberation times. Visitor reaction to the exhibition will also be discused.

10:30

5aNSc4. Survey on the actual condition of the sound environment in commercial spaces. Michiko So and Sho Kimura (Dept. of Architecture, College of Sci. Technol., Nihon Univ., 1-8 Kanda-Surugadai, Chiyoda-ku, Tokyo, 101 Japan, czf01070@niftyserve.or.jp)

Many people use a great variety of commercial spaces in their daily life, and are exposed to such a peculiar sound environment both consciously and unconsciously. In order to gain a comprehension of the user's awareness of the sound environment in commercial spaces, a survey was conducted on residents of the Tokyo Metropolitan Area (1198 effective responses were received). The result shows a great majority of those questioned regard the sound environment as one of the features that enhance the atmosphere or the character of commercial spaces. Accordingly, the design of the sound environment plays a role as one of the important factors in creating the atmosphere of individual commercial spaces. On the other hand, it was also revealed that under current conditions, the loudness, articulation, quality, the manner of presentation of background music and announcements, etc. (especially how to use PA systems in noisy surroundings), in individual commercial spaces were not adequately adjusted or designed in many cases. This is associated with the limits of preference and the potential question of the awareness of the users.

5aPAa1. Nonlinear bubble dynamics and light emission in single-bubble sonoluminescence. Felipe Gaitan (Natl. Ctr. for Physical Acoust., University, MS 38677) and Glynn Holt (Boston Univ., Boston, MA 02215)

The paradigm system for studying light emission from bubbles has been a single, acoustically levitated air bubble in water. Such a bubble, whose volume pulsations are forced by the time-varying portion of the levitating acoustic field, has a rich dynamic life over a large range of the driving pressure-bubble size parameter space. Measurements have been made of bubble dynamics over a large part of a bubble's parameter space, including the light emission regime. In the context of these measurements, the relationship between observed light emission and the activity of the oscillating bubble will be discussed. In particular, it will be explained how the constraints of mechanical stability and mass flux stability dictate what all experiments in SBSL have seen, namely a very small window of parameter space where light is observed to be emitted. Experimental evidence will be presented to make a clear distinction between features of SL which are due to the mechanism for light emission and those that are due to the dynamics of gas bubbles. [Work supported by NASA and the Office of Naval Research.]

9:40

5aPAa2. Pulse width and shape in single bubble sonoluminescence. Bruno Gompf, Gerald Nick, Rainer Pecha, and Wolfgang Eisenmenger (1.Physikalisches Institut, Universitaet Stuttgart, Pfaffenwaldring 57, D-70550 Stuttgart, Germany)

To test the different theoretical models describing the light emitting process in SBSL measurements of the width and shape of the emitted light pulses are essential. The light pulses have been characterized by two independent methods: with time-correlated single photon counting and with a streak camera. Both methods lead to the same results. The pulse width strongly depends on the parameter's driving pressure, gas and gas concentration and temperature and varies between 60 ps and more than 300 ps, and there is no difference between the red and uv part of the spectrum. The streak camera results additionally show that the pulse shape is slightly asymmetric with a steeper ascent and a slower descent. This asymmetry increases with decreasing temperature.

10:00

5aPAa3. Predictions for upscaling sonoluminescence. Sascha Hilgenfeldt and Detlef Lohse (Dept. of Phys., Univ. of Marburg, Renthof 6, 35032 Marburg, Germany, lohse@stat.physik.uni-marburg.de)

Detailed comparison between the hydrodynamical/chemical approach towards single bubble sonoluminescence (SBSL) and recent experimental data is offered. In particular, the water temperature dependence is focused on. Moreover, detailed predictions of how to upscale SBSL are presented.

10:20

5aPAa4. Single-bubble sonoluminescence and liquid fracture. A. Prosperetti (Dept. of Mech. Eng., Johns Hopkins Univ., Baltimore, MD 21218)

Attention is drawn to the fact that the very mechanism that traps a bubble in a standing acoustic wave causes it to execute an oscillatory translational motion in the direction of gravity. A bubble driven below resonance will move up during the collapse phase and down during the expansion phase. A bubble translating and collapsing develops a jet in the direction of motion. It is hypothesized that sonoluminescence is due to the collision of this jet with the other side of the bubble surface. The mechanism of light emission is a ''fracture'' process of the liquid that initially cannot respond by flowing due to the very short rise time of the applied pressure. The picosecond duration of the light flash is the time it takes for the microjet overpressure to be relieved by reflection from the microjet free surface. Several other observed features of sonoluminescence (such as noble gas and temperature sensitivity, anomalous mass loss process, effect of surfactants) can also be explained, at least qualitatively. [Work supported by the Office of Naval Research.]

10:40

5aPAa5. Conditions during multibubble sonoluminescence. Kenneth S. Suslick, William B. McNamara III, and Yuri Didenko (Dept. of Chemistry, Univ. of Illinois, 601 S. Goodwin Ave., Urbana, IL 61801, ksuslick@uiuc.edu)

Acoustic cavitation results in extraordinary transient conditions inside the collapsing bubble. In addition to interesting chemical effects (sonochemistry), cavitation also produces light emission. Such sonoluminescence from cavitating clouds of bubbles [''multi-bubble sonoluminescence'' (MBSL)] in room-temperature liquids closely resembles flame emission. Effective emission temperatures have been obtained for MBSL from excited state metal atom emission (from sonolysis of several volatile metal carbonyls). From the relative intensities of multiple line emissions from Cr, Mo, and Fe, emission temperatures have been calculated and are all in close agreement with each other. The effects of bubble contents can alter the observed temperatures and this has been now directly observed for the first time. In addition, effective pressures can be estimated from line broadening and line shifts of the metal atom emission. The effective transient conditions formed during cavitation of bubble clouds are roughly 5000 K, 500 atm, which implies heating and cooling rates in excess of 1e10 K/s. Temperatures reached during single bubble sonoluminescence (SBSL) are likely to be very much higher.

11:00–11:10 Break

11:10

5aPAa6. Sonoluminescence and its neighbor cavitation bubble luminescence. Werner H. Lauterborn and Thomas Kurz (Drittes Physikalisches Institut, Universität Göttingen, D-37073 Göttingen, Germany)

The field of sonoluminescence, the making of light from sound, and the related field of cavitation bubble luminescence are reviewed. The single-bubble acoustic trap invented by Crum has started great activities through the enhanced possibilities of observing the dynamics of a single bubble in great detail. The question of spherical versus aspherical collapse in light emission and problems of enhancing the light output are addressed. For sonochemistry the case of many bubbles versus a single bubble is important. Some results on the dynamics of multi-bubble systems and their light emission are given. One neighbor of sonoluminescence, i.e., cavitation bubble luminescence from laser-induced bubbles, may be of great help for clarifying some aspects of light emission from collapsing bubbles.

11:30

5aPAa7. Predictions for stable sonoluminescence in nonaqueous liquids. Michael P. Brenner (Dept. of Math., MIT, Cambridge, MA 02139), Sascha Hilgenfeldt, and Detlef Lohse (Univ. of Marburg, Marburg, Germany)

The oscillation behavior of single sonoluminescing bubbles, and therefore their stability and the intensity of light emission, depends on a multitude of material parameters, including viscosity, surface tension, and liquid vapor. It is shown in analytical and numerical computations how substitution of water by nonaqueous fluids affects the domain for stable and unstable sonoluminescing bubbles in parameter space.

11:45

5aPAa8. Novel techniques for manipulating single-bubble sonoluminescence. Kirk Hargreaves, Thomas J. Matula, Lawrence A. Crum (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105), and William C. Moss (Lawrence Livermore Natl. Lab., Livermore, CA 94550)

Various acoustical methods are currently being utilized to manipulate the radial oscillations of single bubbles undergoing sonoluminescence. Previous measurements have shown that the addition of higher harmonics to the drive frequency [J. Holzfuss, R. Mettin, and W. Lauterborn (private communication)] can result in an increase in the light intensity by as much as 50%. The radial response is also dramatically affected by the addition of higher harmonics. Nonlinear bubble dynamics equations agree well with the measured radial response. This and related work will be described. [Work supported by NSF and under the auspices of the U. S. Department of Energy at Lawrence Livermore National Laboratory under Contract No. W-7405-Eng-48.]

12:00

5aPAa9. Abrupt drive pressure variations for probing the extinction threshold mechanism for single-bubble sonoluminescence. Thomas J. Matula and Lawrence A. Crum (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

A novel method utilizing abrupt drive pressure amplitude changes has been used to probe transient conditions in single-bubble sonoluminescence (SBSL). This technique has been used to probe the incipient luminescence threshold [Matula and Crum, Phys. Rev. Lett. (submitted)], where it was found that sonoluminescence from air bubbles depend on the time the bubbles spend in the sonoluminescing state. The abrupt pressure change technique has also recently been used to probe SBSL behavior near the extinction threshold. Simultaneous measurements of the radial response and light emission may be used to better understand the mechanism for SBSL extinction.

FRIDAY MORNING, 26 JUNE 1998 ASPEN ROOM (S), 9:15 TO 10:45 A.M.

Session 5aPAb

Physical Acoustics: Acousto-Optics and Opto-Acoustics

5aPAb1. Planar backward projection of transient fields obtained from optical imaging methods. Gregory Clement, Ruiming Liu, Stephen Letcher (Dept. of Phys., Univ. of Rhode Island, Kingston, RI 02881, gcle0008@uriacc.uri.edu), and Peter Stepanishen (Univ. of Rhode Island, Kingston, RI 02881)

A polarimetric fiber-optic detection system is used to reconstruct the field in front of a planar source. The field is then back-projected toward the source using a filtered wave vector/frequency domain method. This method is compared with a second temporal projection technique that records data over space at a specific time and projects the field to an earlier time. Numerical results will be presented to illustrate the two methods. Experimental results from a pulsed ultrasonic transducer will be presented and discussed.

5aPAb2. Measurement of ultrasonic displacement vector with an *F*-*P* interferometer. Menglu Qian, Yongdong Pan (Inst. of Acoust., Tongji Univ., Shanghai 200092, PROC), and Zhongxian Zhang (Zhejiang Univ., Hangzhou 310027, PROC)

The laser interferometer technique for receiving ultrasound has potential for a wide range of noncontact ultrasonic measurements and has therefore received considerable interest in recent years. Several interferometric methods for detecting the normal displacement components of ultrasound have been developed and applied to nondestructive evaluation for material characterization. In order to study the propagation of ultrasound in a medium and to characterize materials more accurately, detecting both normal and tangent components of ultrasonic displacement simultaneously is necessary. Therefore, an *F*-*P* interferometer, which receives scattering lights at scattering angles $+\theta$ and $-\theta$ from sample surfaces and measures the ultrasonic displacement vector simultaneously, is introduced in this paper. In order to increase the scattering light intensity and determine the scattering angle θ precisely, a new method for modification of a sample surface is introduced and some experiments are presented in this paper.

5aPAb3. Two-frequency degeneracy of an acousto-optic interaction in paratellurite. Alexander Yurchenko and Vladimir Moskalev (Dept. of Quantum Radiophys., Kiev Taras Shevchenko Univ., 64, Vladimirskaya str., 252033 Kiev, Ukraine, alyur@boy.rpd.univ.kiev.ua)

Earlier unknown effects of an acousto-optic interaction degeneracy in paratellurite have been studied. Its essence compared to described phenomena lies in the fact that a light beam can be diffracted twice by acoustic waves with different frequencies instead of being typically diffracted twice by the same acoustic wave. It happens due to strong acoustic anisot-

ropy of paratellurite. Bragg conditions resulting in the degeneracy can be satisfied under a certain frequency correlation of two acoustic slow shear waves. A light beam diffracted by one spectral component of a complex acoustic signal can be effectively diffracted again by another spectral component. Thus, a physical mechanism of this effect is the same as it is in the ordinary case but it is observed under different conditions (different frequencies). Necessary calculations of such interactions have been carried out. The frequency of the ''unfavorable'' spectral component was calculated depending on the frequency of the ''useful'' one for the case of nonaxial acousto-optic interaction in paratellurite. The found effect was shown to take place and to be important for real acousto-optic devices. In the studied case, the frequencies of acoustic waves interacting with a light beam were equal to 44.7 and 43.2 MHz, respectively.

5aPAb4. Visualization of a phase structure of sound field in a Bragg cell. Vadim Goncharov, Leonid Ilchenko, Vladimir Moskalev, Eugene Smirnov, and Alexander Yurchenko (Dept. of Quantum Radiophys., Kiev Taras Shevchenko Univ., 64, Vladimirskaya str., 252033 Kiev, Ukraine, gva@boy.rpd.univ.kiev.ua)

A phase structure of a sound field in a Bragg cell was investigated experimentally using a dual-beam, dual-frequency laser system. The technique used allows the recording of a spatial phase structure of diffracted light field to visualize phase nonuniformities of a sound field. The underlying physical principle of this technique is to probe an analyzed phase object using two slightly separated in space light beams with different optical frequencies. A difference frequency signal, which is obtained as a photodetector output in an optical heterodyne system, contains information about a phase difference of the adjacent areas of the sound field. When the probing beams are diffracted by a Bragg cell, their optical frequencies are shifted by the same acoustic frequency, so that the difference is the same at any Bragg cell operating frequency. A Bragg cell on paratellurite operating around 100 MHz was investigated. Focused laser beams with a difference of optical frequencies equal to 1 MHz were used as probing beams. Pictures were obtained which demonstrated dependencies of a phase structure of diffracted light on frequency and sound power. Phase nonuniformities across the sound field up to three wavelengths have been estimated. [Work supported by EOARD.]

5aPAb5. Radiation acoustics—photoacoustics and acousto-optics of penetrating radiation. Leonid M. Lyamshev (N. N. Andreev Acoust. Inst., Shvernik st. 4, 117036 Moscow, Russia, bvp@asu.acoins.msk.su)

Photoacoustics is a science about optical generation of sound in a substance. The study of light diffraction by acoustic waves is the subject of acousto-optics. Light is a beam of particles, i.e., photons. In this connection the study of sound generation by beams of electrons, protons, neutrons, and other particles in a substance, as well as the study of matter waves' (particle beams) diffraction by ultrasound may be considered correspondingly as photoacoustics and acousto-optics of penetrating radiation. Combined together, this is the field which got the name of radiation acoustics. It develops at the interface of acoustics, nuclear physics, solid state physics, and physics of high energy and elementary particles [see L. M. Lyamshev, *Radiation Acoustics* (Nauka-Fizmatgiz, Moscow, 1996), in Russian]. Some universal laws characterizing generation of sound by beams of penetrating radiation are discussed. The problem of acoustic–radiational interaction is considered using the examples of diffraction of x rays and thermal neutrons by ultrasound in solids. [Work supported by RFBR.]

5aPAb6. Photoacoustic signal in the system of a thin oil layer on the water surface. Antoni Sliwinski, Stanislaw Pogorzelski, and Janusz Szurkowski (Inst. of Experimental Phys., Univ. of Gdansk, 80-952 Gdansk, Poland, fizas@univ.gda.pl)

Thin layers of different kinds of oils spread on the water surface (using standard techniques) were examined by photoacoustic spectroscopy (PAS) methods. Both techniques of excitation were applied: the classic one with a modulated light beam as well as with a laser pulse beam. It was demonstrated that the mechanism of molecular interaction at the oil–water interface represents a good model for determination of the correlation between PAS signal characteristics (amplitude and phase) and physicochemical properties of the thin layer system. The results obtained have confirmed the existence of a very sharp separation of the oil and water phases. Variations in physical properties of layers of different thickness like surface and interface tension thermal conductivity and heat capacity and optical absorption coefficients influenced by different agents (e.g., surfactants) could be detected with the PAS methods applied. [Work supported by KBN.]

All posters will be on display from 7:45 a.m. to 10:45 a.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 7:45 a.m. to 9:15 a.m. and contributors of even-numbered papers will be at their posters from 9:15 a.m. to 10:45 a.m. To allow for extended viewing time, authors have been requested to place their posters on display on Thursday afternoon beginning at 1:00 p.m. in Grand Ballroom II.

5aPP1. Perceptual consequences of amplitude perturbation in the wavelet coding of speech. Nicolle H. van Schijndel, Tammo Houtgast, and Joost M. Festen (Dept. of Otolaryngol., Univ. Hospital VU, P.O. Box 7057, 1007 MB Amsterdam, The Netherlands, NH.vanSchijndel@azvu.nl)

Wavelet coding of sound is a frequency–time representation that may be able to mirror the properties of auditory coding at a peripheral level, provided that we use the proper so-called mother wavelet. Previous experiments based on intensity discrimination [van Schijndel *et al.*, J. Acoust. Soc. Am. (submitted)] suggested a Gaussian-shaped wavelet with a bandwidth of 1/3 oct. Based on this function, a wavelet coding and reconstruction algorithm has been developed. The frequency–time plane is split up: one wavelet per three periods along the time axis and nine wavelets per octave along the frequency axis. In this study the amplitude of the wavelet coefficients is manipulated before the stage of reconstruction. The perceptual effect of amplitude perturbation on speech perception is studied. A (partial) answer to the following questions will be presented: (1) what degree of amplitude perturbation is just noticeable to the subject, and (2) how is speech intelligibility affected by suprathreshold amplitude perturbation. The results may provide insight into the acuity of the auditory amplitude coding and its effect on speech intelligibility. [Work supported by the Netherlands Organization for the Advancement of Pure Research (N.W.O.).]

5aPP2. The effect of spectral resolution on speech perception in a multitalker babble background. Bom Jun Kwon and Christopher W. Turner (Dept. of Speech Pathol. and Audiol., Univ. of Iowa, Iowa City, IA 52242)

Does finer spectral resolution always have an advantage for speech recognition? In this experiment, speech was divided into separate bands within which spectral information was removed by replacing the fine structure with noise; the temporal envelope cues of each band remained intact. Normal-hearing subjects identified consonants in a/C/a for speech and babble processed with 1, 2, 4, and 8 bands, in addition to the unprocessed speech and babble, for a range of signal-to-babble ratios. For high S/B ratios our results agree with earlier results, in that performance improved with increases in the number of bands, and higher transmission of information was observed for voicing and manner than place of articulation [Shannon *et al.*, Science **270**, 303–304 (1995)]. However, as S/B decreased, the advantage of better spectral resolution was reduced. This suggests that for speech in a competing babble background, increased spectral resolution not only increases the saliency of speech, but at the same time makes background babble a more effective distracter. Thus the benefit provided by fine spectral resolution depends upon the task and S/B ratio. [Work supported by NIDCD.]

5aPP3. Application of auditory models to discrimination thresholds of voicing parameters. Shari L. Campbell (Dept. of Commun. Sci. and Disord., Univ. of Georgia, 514 Aderhold Hall, Athens, GA 30602), Kathryn H. Arehart (Univ. of Colorado, CB 409, Boulder, CO 80309), Ronald C. Scherer (Bowling Green State Univ., Bowling Green, OH 43403), and Amy N. Butler (Univ. of Georgia, Athens, GA 30602)

A recent study [Scherer *et al.*, J. Voice (to be published)] reported discrimination thresholds for synthesized complex tones emulating glottal flow waveforms and output pressure waveforms for the vowel /a/. Each signal type was varied along both an open quotient and a speed quotient continuum using standard values associated with normal voice production. jnds for the output pressure signals were significantly larger than for the glottal flow signals. The current experiment compared quantities derived from ''auditory-perceptual'' representations of the acoustic signals. These quantities (centers of gravity and Euclidean distances) were computed for both the raw amplitude spectra and for modeled excitation patterns and specific loudness patterns. Overall loudness and overall sharpness were also estimated. The comparisons indicated ways in which auditory modeling can enhance our understanding of basic issues in voice and speech perception. [Work supported by UGA College of Education.]

5aPP4. Audio signals in domestic appliances evaluated in terms of the hearing ability of older adults. Kenji Kurakata, Yasuyoshi Kuba, Yasuo Kuchinomachi (Natl. Inst. of Bioscience and Human-Technol., 1-1 Higashi, Tsukuba, Ibaraki, 305 Japan, kurakata@nibh.go.jp), and Kazuma Matsushita (Natl. Inst. of Technol. and Evaluation, Tokyo, 151 Japan)

The audio signals used in domestic appliances currently available on the market in Japan were recorded to identify suitable signals for the hearing ability of older adults. The results of the analysis indicated the following three problems: (1) Some appliances use high-frequency tones around 4000 Hz. Since these sounds are hard for older adults with presbycusis to hear, it would be better to use signals with lower frequencies. However, the problem here is that if the frequency is lowered, then the signal might be masked by domestic sounds whose power would be greater relative to the low-frequency signals. (2) The signals used by some

appliances are too soft. The intensity of some signals should be adjusted to compensate for the hearing loss among older adults. (3) The sounds used in these appliances are often very similar in terms of both timbre and temporal ringing patterns. That may cause confusion because it is difficult to identify which appliance is signaling.

5aPP5. The effects of age and hearing impairment on the time course of backward masking. Sara Elizabeth Gehr and Mitchell Sommers (Washington Univ., Dept. of Psych., 1 Brookings Dr., Campus Box 1125, St. Louis, MO 63130)

The present study was designed to assess the effects of age and hearing loss on the time course of backward masking. Thresholds for detecting a 10-ms, 500-Hz tone were measured as a function of the temporal separation between the signal and a 50-ms broadband masker in normal-hearing young listeners (18–25), normal-hearing older adults (65–82), and hearing-impaired older adults. Younger subjects exhibited less initial masking, had steeper recovery functions, and asymptoted closer to their unmasked thresholds than either group of older adults. Comparisons between the normal-hearing and hearing-impaired older individuals indicated a slower time course of recovery from backward masking for listeners with hearing loss. Differences between the two groups of normal-hearing listeners (young and old) suggest that age, independent of hearing loss, affects the temporal course of backward masking. Differences between the normal-hearing and hearing-impaired elderly listeners, however, indicate that age-related hearing impairment may also alter the rate of recovery from backward masking. [Work supported by the Brookdale Foundation and NIA.]

5aPP6. Speech intelligibility and localization in a complex environment by listeners with hearing impairments. Monica L. Hawley, Ruth Y. Litovsky, and H. Steven Colburn (Hearing Res. Ctr. and Dept. of Biomed. Eng., Boston Univ., Boston, MA 02215)

Listeners with hearing impairments often complain of difficulties when trying to communicate in a complex environment such as a cocktail party. Explorations of the dependence of the intelligibility and localizability of speech on the number and spatial positions of simultaneous interfering sources are reported on. Target sources are sentences spoken by a female and interfering sources include other sentences or speech-shaped noise. The total number of sources played at any one time varied between one and four. Listeners with normal hearing, profound monaural deafness, and with symmetric sensorineural hearing impairments were tested. Listeners were tested without hearing aids. Previous work in free field and with virtual stimuli has shown that bilaterally hearing-impaired listeners show large intersubject differences in their performance in both speech intelligibility and localization tasks. In the present study an investigation was made to see whether these intersubject differences are related to each listener's sensitivity to specific binaural cues. Therefore, in addition to localization and speech intelligibility, performance in discrimination of interaural time and level, as well as binaural masking level differences in each listener was measured. The goal of this study is to determine the extent to which performance on speech-based tasks can be accounted for by basic binaural abilities. [Work supported by NIH-NIDCD DC00100.]

5aPP7. Monotic and dichotic musical-interval identification in listeners with cochlear-based hearing loss. Kathryn H. Arehart (Univ. of Colorado, Speech, Lang., Hearing Sci., CB 409, Boulder, CO 80309) and Edward M. Burns (Univ. of Washington, Seattle, WA 98195)

This study examined musical-interval identification in musically experienced listeners with cochlear-based hearing loss. Sounds had missing fundamentals ranging from 100–500 Hz. These missing fundamentals were conveyed by two successive harmonics presented either to the same ear or to separate ears. Performance was measured as a function of the average rank of the lowest harmonic for both monotic and dichotic conditions at both 20 dB sensation level (SL) and 30 dB SL. In both monotic and dichotic conditions, listeners with cochlear-based hearing loss demonstrated excellent musical-interval identification at low fundamental frequencies and low average ranks, but abnormally poor recognition at higher fundamental frequencies and higher average ranks. The results will be related to auditory deficits which might affect complex-tone pitch perception in listeners with cochlear-based hearing loss, and will be discussed in the context of modern pitch theories. [Work supported by Deafness Research Foundation.]

5aPP8. Minimum bandwidth required for speech-reception by normal-hearing and hearing-impaired listeners. Ingrid M. Noordhoek, Tammo Houtgast, and Joost M. Festen (Dept. of Otolaryngol., Univ. Hospital VU, P.O. Box 7057, 1007 MB Amsterdam, The Netherlands, im.noordhoek@azvu.nl)

A new adaptive test has been developed to determine the bandwidth of speech (with a center frequency of 1 kHz) required for 50% intelligibility. Measuring this speech-reception *bandwidth* threshold (SR*B*T), in addition to the more common speech-reception threshold (SRT) *in noise*, may be useful in investigating the factors underlying impaired suprathreshold speech perception. A wider-than-normal SR*B*T points to a deterioration in suprathreshold sound processing in the 1-kHz frequency region. Both the SRT in noise and the SR*B*T were measured for 10 normal-hearing and 34 hearing-impaired listeners. To keep the speech signal above hearing threshold for all frequencies, speech and noise spectra were shaped to fit in the dynamic range of individual listeners. The average SR*B*T of the normal-hearing listeners was 1.4 oct. Most hearing-impaired listeners needed a wider bandwidth to reach 50% intelligibility. Some wider SR*B*Ts were predicted by the SII model (speech intelligibility index) from a high presentation level or narrow dynamic range. The remaining differences between the performance of normal-hearing and hearing-impaired listeners are probably caused by an impaired suprathreshold sound processing in the 1-kHz frequency region. [Work supported by the Foundation ''Heinsius-Houbolt Fonds.'']

5aPP9. Loudness of dynamic stimuli in cochlear-impaired listeners. Chaoying Zhang and Fan-Gang Zeng (House Ear Inst., 2100 West Third St., Los Angeles, CA 90057)

In normal hearing listeners, a temporally fluctuating sound with modulating frequencies from 4 to 400 Hz was found to be louder than predicted by its averaged power. The louder sensation due to temporal fluctuation was also found to be overall level-dependent: approaching peak amplitude loudness at a comfortably loud level, becoming less at lower sensation levels, and disappearing at higher levels. If this level-dependent loudness effect were related to the nonlinear cochlear compression, then it would disappear in cochlear-impaired listeners because their nonlinear compression is presumably damaged. Three listeners with clinically diagnosed cochlear impairment balanced loudness between white noise and sinusoidally amplitude-modulated noise. The results showed that the modulated noise was louder for modulating frequencies between 4 and 400 Hz at all three sensation levels, consistent with the hypothesis that the overall level effect on loudness of dynamic stimuli is related to the cochlear compression. These results indicate that loudness of dynamic stimuli is governed by two different mechanisms: a retrocochlear temporal processing mechanism which is presumably preserved in both normal and cochlear-impaired listeners, and a cochlear mechanism which provides amplitude compression at high levels in normal listeners and is damaged in the cochlear-impaired listeners. [Work supported by NIDCD.]

5aPP10. Further effects of cochlear loss on ICP loudness adaptation, and loudness constancy. Rebecca Schnieder Ludwig, Hongwei Dou, Ernest M. Weiler, Laura W. Kretschmer, David E. Sandman (ML #379, CSD, Univ. of Cincinnati, Cincinnati, OH 45221), and Eleanor Stromberg (Cincinnati Speech & Hearing Ctr.)

ICP loudness adaptation depends on an ipsilateral comparison paradigm with a short increasing or decreasing referent value to reveal loudness adaptation. Janson *et al.* [Br. J. Audiol. **29**, 288–297 (1996)] found the intensity-based function for ICP loudness adaptation for those with a high-frequency loss differed significantly from normal listeners. Loss of loudness constancy in normal listeners was consistent, loss in those with a cochlear loss showed a negative progression as intensity increased, as if it were the inverse of recruitment. The purpose of the present study was to compare ICP adaptation to recruitment. ICP adaptation and recruitment were tested in ten high-frequency loss (probably noise induced) and ten age-matched normal hearing individuals. Although the evidence for recruitment was generally found in those with hearing loss, there was no simple relationship to ICP adaptation. Variation among measures of recruitment, implications of abnormal loudness constancy for speech perception, and the possible use of measures of otoacoustic emissions for future studies will be discussed.

5aPP11. Evoked otoacoustic emissions, suppression and comparison to loudness constancy, at speech frequencies. Ernest M. Weiler, Hongwei Dou, Robert S. Tannen, David E. Sandman, William N. Dember, and Joel S. Warm (ML #379, Hearing Lab., CSD, Univ. of Cincinnati, Cincinnati, OH 45221)

Spontaneous otoacoustic emissions (SOAE) reflect spontaneous activity of the outer hair cells of the cochlea. Suppression of transient evoked otoacoustic emissions (TEOAE) bears operational similarity to loudness adaptation determined by the ipsilateral comparison paradigm (ICP). The present study gathered these measures from 41 normal hearing adults (5 male, 36 female, 20–45 years old). There was no significant relationship between spontaneous SOAE, but there was a significant relationship ($r = -0.36$, $p < 0.05$) between ICP loudness adaptation and suppression of TEOAEs. The relationship between these two active measures has implications for failure of adaptation or the apparent loudness constancy in the speech range revealed by simple adaptation measures. It has been previously noted that the ICP technique yields adaptation in the speech frequencies between 40 and 80 dB, where the simple adaptation apparently does not [Weiler, Sandman, and Dou, program abstract 4pPPa10, J. Acoust. Soc. Am. **101**, 3177 (1997)]. Implications will be discussed in terms of the results uncovered in this study.

5aPP12. Virtual midplane localization of subjects with sensorineural hearing loss. Helen J. Simon (Smith-Kettlewell Eye Res. Inst., 2232 Webster St., San Francisco, CA 94115, helen@skivs.ski.org) and Inna Aleksandrovsky (Univ. of California, Berkeley, CA)

This paper reports the results of a study that investigated localization performance of simulated externalized signals in sensorineural hearing loss (SNHL) listeners when signals were presented with either unbalanced [equal sensation level (EqSL)] or balanced [equal sound-pressure level (EqSPL)] hearing aid gain at the two ears. In previous reports from this laboratory, it has been found that when equalizing by SL, the perceived lateral position was essentially linearly dependent on the degree and direction of asymmetry in normal-hearing (NH) and SNHL listeners. Equalizing by SPL showed no such dependency. It was hypothesized that the current practice of fitting ''binaural'' hearing aids in asymmetric SNHL listeners using prescription formulas might result in SPL imbalance which would disrupt the previously adapted system and impair localization. The present study was designed to address this issue by measuring localization using a simulated externalized auditory image combined with head position control of IID and ITD to spatially fix the image. Absolute and signed error deviations from center were analyzed. Significant interactions of group (NH versus SNHL)* frequency and balance (EqSL or Eq SPL)* frequency were found. These data will be discussed in terms of auditory adaptation and strategies of fitting binaural hearing aids. [Work supported by NIDRR.]

5aPP13. Use of temporal information in recognition of amplitude-compressed speech by older adults. Pamela E. Souza and Johanna J. Larsen (Dept. of Speech and Hearing Sci., Univ. of Washington, 1417 NE 42nd St., Seattle, WA 98105, psouza@u.washington.edu)

Amplitude compression alters the speech envelope and under some conditions can reduce the availability of temporal cues for speech recognition. This may be a particular problem for older listeners, who demonstrated temporal resolution deficits in some studies. Older and younger hearing-impaired listeners were tested on their recognition of VCV syllables processed using the signal-correlated noise (SCN) method [Schroeder, J. Acoust. Soc. Am. **44**, 1735–1736 (1968)]. This method results in a time-varying speech envelope modulating a noise carrier, and preserves temporal cues while minimizing spectral information. Recognition scores were obtained for uncompressed SCN syllables and for the same speech tokens after digital processing with a syllabic compression algorithm. In control conditions, recognition was tested for VCVs that included both temporal and spectral information. Younger and older listener groups were matched for mean hearing thresholds up to 4 kHz. A high-pass masker was included to eliminate contributions from the basal end of the cochlea. When compared to younger listeners with similar hearing losses, the older listeners demonstrated poorer performance on the compressed SCN signals. These results suggest that the poorer temporal resolution abilities of older listeners may play a role in their understanding of amplitude-compressed speech.

5aPP14. Apparent effects of the use of digital hearing aid ''CLAIDHA'' on the several hearing functions of the impaired listeners. Hiroshi Hidaka, Naoko Sasaki, Tetsuaki Kawase, Tomonori Takasaka (Dept. of Otolaryngol., Tohoku Univ. School of Medicine), Kenji Ozawa, Yôiti Suzuki, and Toshio Sone (Res. Inst. of Elec. Commun., Tohoku Univ.)

The portable digital hearing aid system CLAIDHA (compensate loudness by analyzing input signal digital hearing aid), which employs frequency-dependent amplitude compression based on narrow-band compensation, has been developed [Asano *et al.* (1991)]. The patients with hearing loss using hearing aids experience a new sound world as amplified by the device. It seems to be important to know the apparent change of hearing function by the use of a hearing aid. In the present study, the apparent effects of CLAIDHA amplification especially on the intensity discriminability and the masking function were examined in the patients with hearing loss. The results obtained indicate that the CLAIDHA amplification often improves not only the apparent thresholds but also the apparent masking relation between two tones as compared to simple linear amplification; i.e., in the CLAIDHA amplification, more signals could be heard under the same masking condition. On the other hand, from the viewpoint of intensity discriminability, when the compression ratios of the amplification were larger than two, the IDL (intensity difference limen) rapidly increased more than expected. The advantage of the compressive amplification of the CLAIDHA system will be discussed.

5aPP15. The effect of frequency-modulation systems on the communication skills of deaf–blind children. Barbara Franklin (Dept. of Special Education, San Francisco State Univ., 1600 Holloway Ave., San Francisco, CA 94132, dick3580@aol.com)

Classrooms and other public places provide a poor acoustical environment for individuals who have a hearing loss, and it is often difficult for them to discriminate between the speaker and background noise with a hearing aid. The use of a frequency-modulation (FM) system can often reduce this problem by providing a constant sound pressure level of the

speaker's voice. The effect of FM systems on communication skills of deaf–blind children was investigated using a single-subject alternating treatment design. There was a marked improvement for a number of the subjects in the FM condition. The results will be discussed along with individual case studies. FM technology has exploded. A relatively new type of FM receiver is now available which combines the hearing aid and FM in a single behind-the-ear unit (BTE/FM). The most recent development is a ''boot'' attachment which changes a standard over-the-ear hearing aid into a FM system. An overview of these FM systems will be presented. [Work supported by OSERS.]

5aPP16. A metric for determining the degree of compression of a processed signal. Jon C. Schmidt[a)] and Janet C. Rutledge[b)] (Dept. of Elec. Eng. and Comput. Sci., Northwestern Univ., Evanston, IL 60208-3118, jschmidt@resound.com)

When attempting to compare different compression algorithms or different parameter settings of a given compression algorithm, there is a need to compare equivalent amounts of compression. Listening tests that have varied only one parameter while fixing the others have obtained the expected results that increasing the amount of compression that occurs creates a more audible difference between the compressed version and the original. Since there are several parameters that influence the actual amount of compression that occurs, it is desirable to know which set of parameters will create to the least perceptual difference from the original signal for a given amount of compression. Unfortunately, there is not a well-defined approach for determining the amount of compression that has been imparted to a signal. The peak/RMS ratio is woefully inadequate for many compression contexts. Two degree of compression metrics are proposed that can be used to determine the amount of compression by direct analysis of the audio signal before and after compression. These metrics give excellent results in predicting the ratings of subject-based testing on the audio quality of several different audio segments across several parameter variations. [a)]Currently with ReSound. [b)]Currently with the University of Maryland Medical Center.

5aPP17. Modeling tactile speech perception with auditory simulations. Albert T. Lash, Janet M. Weisenberger, and Ying Xu (Speech and Hearing Sci., Ohio State Univ., Columbus, OH 43210)

A useful technique for gaining insights into the perception of speech stimuli presented via vibrotactile aids is to model this perception by presenting degraded auditory stimuli to normal-hearing observers. It is likely that spectral, temporal, and intensive properties of the tactile system could all affect tactile speech perception. In the present experiments, tactile perceptual data were collected for a set of nonsense syllables presented via a vibrotactile vocoder to normal-hearing subjects. The same subjects were tested with sets of degraded auditory stimuli that were modified by reducing spectral, temporal, or intensive parameters. Spectral reductions alone, achieved by reducing the number of filter channels and broadening filter bandwidths, did not appreciably affect auditory performance, nor did intensity reductions, achieved by reducing dynamic range and intensity quantization. Although temporal reductions, achieved by low-pass filtering the stimuli, did result in lower perceptual scores, the pattern of stimulus confusions did not correlate highly with the tactile data. Pairwise and three-way combinations of spectral, temporal, and intensive parameters yielded more promising correlations. Implications for constructing a comprehensive model of vibrotactile speech perception are discussed. [Work supported by NIH.]

5aPP18. A design of a tactile voice coder with different tactile sensations for the hearing impaired. Chikamune Wada, Shuichi Ino, Hisakazu Shoji, and Tohru Ifukube (Res. Inst. for Electron. Sci., Hokkaido Univ., N12 W6, Kita-ku, Sapporo, 060 Japan, chik@sense.hokudai.ac.jp)

A tactile voice coder is a device which changes a speech sound into a vibratory pattern and presents it to the tactile sense of the hearing impaired. The authors have been improving the tactile voice coder in order that the hearing impaired can identify consonants easier. The use of a convex stimuli pattern, similar to Braille, in addition to the vibratory stimuli is proposed, as one of the ways of improving the tactile voice coder. The authors have made this proposal based on the hypotheses that the combination of the vibratory stimuli and the convex stimuli could transmit more speech information. From the combination of basic experiments, the authors have found that presenting a vowel using the convex stimuli and a consonant using the vibratory stimuli was better than only using the vibratory stimuli. Therefore, based on our findings, the authors have designed a new tactile voice coder which uses a different tactile sensation.

5aPP19. Sensitivity of transiently evoked otoacoustic emission to a long-term exposure of impulsive noise. Amnon Duvdevany and Miriam Furst (Dept. of Eng., Tel-Aviv Univ., Tel-Aviv, Israel, mira@eng.tau.ac.il)

In spite of the regular use of ear protectors, 30%–40% of the soldiers that are often exposed to impulsive blast noise are suffering from hearing loss. The purpose of the present study is to find in what ears click-evoked otoacoustic emissions (COAEs) were influenced by the noise exposure. The preliminary study included testing of 15 healthy soldiers. They were exposed to blast noise (M-16 riffles) accompanied by replicas from a semi-enclosed firing range in two consecutive sessions, followed by half a year of exposure to continuous blast noise (service period). In each stage COAEs were measured. The blast noise was precisely measured with microphones located next to the shooters' ears. None of the soldiers acquired a hearing loss. In most subjects COAE levels have significantly changed in the frequency range 2.5–4 kHz. It decreased in the postexposure condition relative to the preexposure by ~3 dB. It increased before the second training session by ~8 dB, and it decreased in the last measurement by ~5 dB. A protection and a destruction mechanism are possibly operating. The protection mechanism reduces the cochlear amplification and causes a reduction in COAE level. The destruction mechanism increases the cochlear nonuniformity which causes an increase in COAE level.

5aPP20. The effects of dexamethasone following an acute acoustic trauma. William A. Ahroon, Ann R. Johnson, B. Sheldon Hagar, and Roger P. Hamernik (Plattsburgh State Univ., Plattsburgh, NY 12901)

An acute acoustic trauma (AAT) results when the unprotected ear is exposed to very high sound pressure levels, usually as the result of an industrial or military accident. There is no commonly accepted treatment in the U.S. for an AAT. A study was performed to evaluate the effects of a corticoid steroid (dexamethasone) on the hearing loss from a series of blast waves that would simulate an AAT. Dexamethasone is commonly used as an anti-inflammatory agent in veterinary medicine. Groups of chinchillas were exposed individually to ten 160-dB peak SPL reverberant blast waves from a conventional shock tube at a rate of one blast per minute. Immediately following the exposure, the animals were injected with dexamethasone alone (1.0–2.0 mg/kg IV) or in combination with dimethyl sulfoxide (DMSO), a free-radical scavenger. Individual groups of animals showed the well-known extreme variability in hearing losses as noted in earlier studies [e.g., R. P. Hamernik *et al.*, J. Acoust. Soc. Am. **90**, 197–204 (1991)]. Examining the median permanent threshold shifts (PTS) of the groups of animals showed a distinct dose-response effect with increasing dosages of dexamethasone associated with lower levels of PTS in the frequency region most affected by the noise exposure.

5aPP21. Protective effects of magnesium on noise-induced hearing loss: Animal studies. Fred Scheibe and Heidemarie Haupt (Dept. of Otorhinolaryngology, Charité-Hospital, Humboldt Univ., Schumannstr. 20-21, D-10117 Berlin, Germany, fscheibe@rz.charite.hu-berlin.de)

Magnesium (Mg) deficiency was found to increase noise-induced hearing loss in laboratory animals. This paper reports both prophylactic and therapeutic effects of Mg on the acoustic trauma produced by a high-level impulse noise series (L_{peak} 167 dB, 38 min, 1/s). Hearing loss was tested by auditory brainstem response audiometry at frequencies between 0.5 and 32 kHz. Permanent hearing threshold shifts (PTS) were measured 1 week after the exposure. For the prophylaxis experiments, anesthetized guinea pigs with either a physiologically high or low Mg status, produced by different diets, were used. For the therapy experiments, animals with the low Mg status received (immediately after exposure) either Mg injections combined with a Mg-rich diet or saline as a placebo. Total Mg concentrations of perilymph, cerebrospinal fluid, and plasma were analyzed to test the Mg status of the animals. The PTS was found to be significantly lower in the high-Mg group than in the low-Mg group. This also applies to the PTS found between the therapy and the placebo groups. There was a good correlation between the PTS and the perilymphatic Mg. The intracochlear Mg level seems to play an important role in the acoustic trauma. [Supported by German Defence Ministry.]

5aPP22. Effects of impulse noise on the hearing of fetal sheep *in utero*. Kenneth J. Gerhardt (Dept. of Commun. Processes and Disord., Univ. of Florida, Box 117420 Gainesville, FL 32611-7420, gerhardt@cpd.ufl.edu), Xinyan Huang, and Robert M. Abrams (Univ. of Florida, Gainesville, FL 32610)

Knowledge of the transmission of exogenous sounds to the fetal head and the effects that these sounds have on fetal hearing is incomplete. The purposes of this study were to measure the transmission of impulse noise into the uterus and to evaluate the effects of impulse noise delivered to pregnant sheep on the hearing of the fetus *in utero*. A shock tube produced impulses that averaged 169.7 dB peak sound pressure level (pSPL) in air. In the uterus, the pSPL varied as a function of fetal head location. When the fetal head was against the abdominal wall, peak levels were within 2 dB of airborne levels and the stimulus resembled a Friedlander wave. When the fetal head was deep within the uterus, the duration of the impulse increased and the peak amplitude decreased. In some instances the decrease in pSPL exceeded 10 dB. Slight elevations of evoked potential thresholds were noted but only for low-frequency stimuli. The integrity of hair cells from these animals was assessed using scanning electron microscopy.

5aSA1. Moment and force mobilities of semi-infinite tapered beams. Eugene J. M. Nijman (CRF, Strada Torino 50, 10043 Orbassano, Italy, e.nijman@crf.it) and Bjorn A. T. Petersson (Loughborough Univ., Leicestershire LE11 3TU, UK)

The implications of spatially varying structural properties for flexural vibrations will be addressed for beamlike systems. Under the assumption of pure bending, closed-form expressions for the mobilities of a semi-infinite wedge have been derived. The influence of tapering on the energy flow is analyzed for the structural system constituted by a finite length taper attached to a semi-infinite, uniform beam. It is found that the main distinction from the uniform case is a comparatively broadbanded transition from flexural vibrations governed by the properties of the deep part of the system to vibrations governed by those of the slender part. This transition region is featured by a stiffness-controlled global behavior in the case of a moment-to-rotational response, whereas a global resonant behavior is found in the case of force-to-translational response. It is also demonstrated that constructive and destructive interferences due to reflections from the discontinuity between the two structural members are superimposed on the global behavior. Based on the complete expressions for the configurations studied, estimation procedures for the mobilities will be proposed. In addition, experimental results will be presented which corroborate the description developed and the parameter influence established.

9:35

5aSA2. Vibrational power transmission in asymmetric framework structures. Jane L. Horner (Dept. AAETS, Loughborough Univ., Loughborough, Leicestershire LE11 3TU, England)

When attempting to control the vibration transmitted from, say, a machine into and through the structure upon which it is mounted, it is desirable to be able to identify and quantify the vibration paths in the structure. Knowledge of transmission path characteristics enables procedures to be carried out, for example, to reduce vibration levels at points remote from the source, perhaps with the objective of reducing unwanted radiation of sound. One method for obtaining transmission path information is to use the concept of vibrational power transmission. Many machines are installed on frameworks constructed from beamlike members. By using the concept of vibrational power it is possible to compare the contributions from each wave type. Wave motion techniques are used to determine the expressions for vibrational power for each of the various wave types present. The results from the analysis show the amount of vibrational power carried by each wave type and the direction of propagation. Consideration is given to the effect on the vibrational power transmission of introducing misalignment of junctions in previously symmetric framework structures. Unlike other techniques using vibrational power to analyze frameworks, the model keeps the contributions from each of the various wave types separate.

9:55

5aSA3. Vibration transmission via a nonideal beam junction: FEM and analytical combined methods. Igor Grouchetski (Krylov Shipbuilding Res. Inst., 196158 St. Petersburg, Russia) and Eric Rébillard (Chalmers Univ. of Technol., 412 96 Gotheburg, Sweden)

The study is devoted to the calculation of the vibration transmission via a nonideal junction; the example considered is an L-beam system including two steel beams and an elastic block between them. A combination of two calculation methods is used. A finite element method (package ABAQUS) is used to determine the stiffness characteristics of the elastic block having a rectangular parallelpiped shape. These stiffness characteristics are substituted into the calculation for the vibrational behavior of the L-beam system. For such a calculation, the transfer matrix method (TMM) is applied. The experimental approach of the study is divided into two different parts. First the tension-compression and the shear stiffnesses of the elastic block are measured, and, second, the transfer mobility through the complete L-beam system with the rubber elastic block between the two beams is measured. For the two cases, calculated and measured results are compared.

10:15

5aSA4. Measurement of flexural intensity using a dual-mode fiber-optic sensor. Bernard J. Sklanka (Aero/Noise/Propulsion Lab., Boeing Commercial Airplane Group, P.O. Box 3707, Seattle, WA 98124-2207, bernard.j.sklanka@boeing.com), Karl M. Reichard, and Timothy E. McDevitt (Penn State Univ., State College, PA 16804)

An experiment was performed which demonstrated the use of distributed optical fiber sensors to measure power flow in a damped cantilevered beam. Dual-mode optical fiber sensors are an implementation of an optical fiber interferometer in which one fiber acts as both the sensing and reference arms. When bonded to the surface of a structure the sensor provides a distributed measurement of the strain along the length of the sensor. The sensors output is proportional to the integral of the axial component of the strain along the length of the fiber. Two optical fiber sensors were used to measure power flow in a damped cantilevered beam. Finite difference and finite sum approximations were used to determine bending moment and rotational velocity from the output of the fiber sensors. These quantities were then used to calculate the far-field structural intensity. The structural intensity measured using the optical fiber sensors was compared to the structural intensity measured using a two-accelerometer method.

10:35

5aSA5. The condition for beam-bending modes to dominate in the vibro-acoustic behavior of a circular cylindrical shell. Chong Wang and Joseph C. S. Lai (Acoust. and Vib. Unit, Univ. College, Univ. of New South Wales, Australian Defence Force Acad., Canberra, ACT 2600, Australia, c-wang@adfa.oz.au)

The acoustic radiation from circular cylindrical shells is of fundamental and applied interest primarily because cylindrical shells are widely used in industries. However, according to previous studies, only a few special cases, for example, a cylindrical shell under the assumption of beam bending, can be solved analytically. Obviously, in practice, the vibration behavior of a cylindrical shell may not be assumed to be beam bending in the whole frequency range of interest. This is because the vibration behavior of a cylindrical shell changes with frequency. Therefore, it is important to determine the condition under which a circular cylindrical shell would behave like beam bending so that the analytical solution could be used correctly. In this paper, an analysis of the basic vibration behavior of circular cylindrical shells using the Love's equations shows that for an infinite length cylindrical shell, the beam-bending wave would always be propagating with other flexural waves of different circumferential mode numbers. However, for a finite-length circular cylindrical shell, below the cutoff frequency of $n=2$ mode, beam-bending modes would dominate the vibration response so that it can be treated as a beam with reasonable accuracy. This analytical result is supported by calculations obtained using the boundary element method.

10:55

5aSA6. The effect of rib resonances on the vibration and wave scattering of a ribbed cylindrical shell. Martin H. Marcus (Naval Res. Lab., 4555 Overlook Ave., S.W., Washington, DC 20375, marcus@astro.nrl.navy.mil)

Wave phenomena have previously been observed for cylindrical shells with periodically spaced ribs. The understanding of these waves, such as Bragg and Bloch waves, requires knowledge of the periodicity of the ribs and how they interact with each other. In this paper, the understanding of the individual rib resonances gives explanation to the resonance bands that are seen in both experiment and numerical simulations. For these resonances, periodicity becomes less important in computing the frequencies of resonances on the shell and in the far field. However, lack of periodicity in rib spacing and size affects the width and strength of these resonance bands. [Work supported by ONR.]

11:15

5aSA7. A simple model for structure-borne sound transmission based on direct wave and first reflections. Jian Liang and Bjorn A. T. Petersson (Dept. AAETS, Loughborough Univ., Loughborough, Leicestershire LE11 3TU, England)

In finite structures, the total wave field is composed of the direct wave, the first reflections as well as multiple, higher-order reflections. When the structural damping is significant and the divergence of the wave is considered, it is reasonable to assume that those waves reflected more than once only contribute marginally to the total field, and thus can be ignored to a first approximation. This suggests a simple description of the field which takes the direct wave and the first reflections into account. The semi-infinite system realizes an example of such models. The question addressed herein is the performance of those simple descriptions. This contribution first presents an investigation of the performance for one-dimensional systems. It is shown that the corresponding semi-infinite system can be used to: (1) predict the nodal lines in the spatial domain and the locations of deep troughs in the frequency domain; (2) obtain accurate motion transmissibilities. Second, the extrapolation to two-dimensional systems is presented, accompanied by results for platelike structures.

11:35

5aSA8. Estimating the vibration energy of an elastic structure via the input impedance. Yuri I. Bobrovnitskii (Lab. of Structural Acoust., Mech. Eng. Res. Inst. of the Russian Acad. of Sci., M. Kharitonievsky Str., 4, 101830 Moscow, Russia, imash@space.ru)

The following problem is posed and solved: given an elastic structure vibrating under the action of a harmonic point force, find the time-average potential and kinetic energy, loss factor, and other energy characteristics of the structure if known are only the complex amplitudes of the force and velocity response at the driving point, f and v. The structure is assumed to be linear, with viscous and hysteric damping not necessarily proportional. It is shown that the problem has a mathematically exact solution only for lossless systems. For structures with losses, there exist rather accurate estimates valid at low and middle frequencies. The main result is the equation relating the total vibration energy of the structure to the derivative of its input impedance, f/v, or mobility, v/f, with respect to frequency. Computer simulation examples with typical structures (rod, plate) illustrate the accuracy and the range of validity of the estimates. The results presented allow one to obtain the energy characteristics of a forced vibrating structure by the most economic way: without measuring or computing the response all over the structure and using only the data measured at one singular point.

11:55

5aSA9. Improving convergence in scattering problems by smoothing discrete constraints using an approximate convolution with a smoothed composite Green's function. Rickard C. Loftman and Donald B. Bliss (Mech. Eng. and Mater. Sci., Duke Univ., Box 90300, Durham, NC 27708)

A method for efficiently treating discrete structural constraints using an approximate Green's function approach to smooth the constraint influence is presented. A method called analytical/numerical matching is used to formulate a composite Green's function that captures the local high-resolution content associated with the discrete force in a separate analytic local solution. This local solution in turn implies a smooth replacement for the original discrete force. This replacement is approximately integrated following the Green's function formalism modified by a Taylor expansion of the forcing strength function. A smooth replacement for the discrete constraint results. This new smoothed problem converges more rapidly than the original discrete one. However, the difference between the smooth solution and the original is retained in the analytic local solution. The result is a composite solution of the original system that is more accurate for a given computational resolution compared with treating the discrete constraint influence directly. In the present example, a modal method is used. Therefore, a given computational resolution is measured by number of modes calculated. The method is demonstrated in the case of beam incident scattering from an infinite thin elastic shell periodically constrained by rings. [Work supported by ONR.]

5aSC1. Vocal tract shape estimation using three noninvasive transducers. Russel Long, Brad Story, and Ingo Titze (WJ Gould Voice Res. Ctr., Denver Ctr. for the Performing Arts, 1245 Champa St., Denver, CO 80204)

Sentence-level speech simulation requires a description of vocal tract shape parameters as a function of time. Vowel-like configurations can often be derived from a microphone signal; however, the influence of consonants may be more easily detected with the use of additional signals. The electroglottograph (EGG) and an articulatory transducer [McGarr and Lofqvist, J. Acoust. Soc. Am. **72**, 34–42 (1982)] are employed to increase the accuracy of vocal tract shape estimation. The microphone signal is analyzed on a frame-by-frame basis for spectral features, energy, and zero-crossing rate. The EGG provides information regarding voicing onset and offset, and the articulatory signal is used to indicate closure and lip rounding. These data are combined to select an appropriate area function for each frame of the sentence. The resulting temporal map of area functions is interpolated and sent to a wave reflection simulator to reconstruct the speech. [Work supported by NIH Grant No. DCO2532.]

8:30

5aSC2. Simulation of sentence-level speech based on measured vocal tract area functions. Brad Story, Ingo Titze, and Russel Long (WJ Gould Voice Res. Ctr., Denver Ctr. for the Performing Arts, 1245 Champa St., Denver, CO 80204)

An inventory of vocal tract area functions, acquired from magnetic resonance imaging experiments, is used as the basis for creating simulations of sentence-level speech. A first approach is a ''brute-force'' method in which a phonetic transcription of a sentence is time aligned with the recorded acoustic signal. Each element of the transcription is assigned one of the stored vocal tract area functions in the acquired inventory, thus serving as a ''target'' through which the time-varying area function should pass. This method has produced intelligible speech but maintains a machinelike quality. A second approach uses a parametric representation of the MRI-acquired area function inventory based on a principal components analysis to generate area functions not in the original inventory. The first three formants of each generated area function were computed and stored in a database, thus creating a mapping between formant frequencies and vocal tract parameters (area functions). Except for the edge of the formant space, the mapping between formants and area functions is one-to-one. This method produces connected speech with natural sounding vowels when only a microphone signal is used but requires additional signals to derive the consonantal contribution to the vocal tract shape. [Supported by NIH grant RO1 DC02532.]

8:45

5aSC3. Effects of naturally occurring external loads on jaw movements during speech. Douglas M. Shiller, Paul L. Gribble, and David J. Ostry (McGill Univ., Montreal, QC, Canada, ostry@motion.psych.mcgill.ca)

The achieved positions of speech articulators are determined by a combination of intrinsic forces due to muscles and extrinsic forces due to gravity and to head and body motion. If not compensated for, changes in these extrinsic forces will affect articulator positions in behaviors such as speech. In this paper, the extent to which speakers adjust control signals to jaw muscles to compensate for the effects on the jaw due to changes in speaker orientation relative to gravity is assessed. Whether control signals are adjusted to compensate for loads arising during locomotion is also assessed. In one study, subjects produce speech utterances where head and body orientation relative to gravity are varied. In another study, subjects produce speech sequences during locomotion such that the timing of the step cycle applies the maximum load force during either the consonant related (jaw elevated) or vowel related (jaw lowered) phase of movement. The empirically observed patterns of jaw motion are compared with predictions of a model of jaw and hyoid motion which includes muscle properties, dynamics, and modeled neural signals. The hypothesis that during speech, control signals to jaw muscles remain unchanged with variation in these extrinsic loads is specifically tested.

5aSC4. Contrasting chest and falsettolike vibration patterns of the vocal folds. David A. Berry and Douglas W. Montequin (Univ. of Iowa, Dept. of Speech Pathol. and Audiol., 334 WJSHC, Iowa City, IA 52242)

Using excised larynges, a hemilarynx methodology was used in order to view vocal fold vibrations from a medial aspect. This was accomplished by removing one fold, inserting a glass plate at the glottal midline, and

mounting the remaining fold against the glass plate. A stereoscopic imaging system was used to perform 3D tracking of small markers (microsutures) placed on the folds. Chest and falsettolike vibrations patterns were imaged and quantified. These two vibrations patterns will be contrasted with each other, and discussed in terms of previous qualitative comparisons of these phonation types in the literature. [Work supported by Grant No. R29 DC03072 from the National Institute on Deafness and Other Communication Disorders.]

9:15–9:30 Break

9:30

5aSC5. The effect of shear thinning in vocal fold tissues—or why we can phonate over two octaves in pitch. Ingo Titze and Roger Chan (Dept. of Speech Pathol. and Audiol. and The Natl. Ctr. for Voice and Speech, Univ. of Iowa, Iowa City, IA 52242)

The shear modulus and viscosity of vocal fold tissues was measured with a rheometer in the frequency range of 1–30 Hz. Extrapolation to phonation frequencies was possible. As in most biological tissues (and for polymers in general), the shear modulus was found to be roughly constant and the viscosity varied inversely with frequency. This makes the damping ratio only a weak function of frequency in phonation. Since self-oscillation of the vocal folds is critically dependent on this damping ratio, it is reasoned that large *F*0 ranges (on the order of two octaves) are possible only because of this decrease in viscosity, an effect known as shear thinning. A molecular interpretation is given for this effect. [Work supported by NIDCD, Grant No. P60 DC00976.]

9:45

5aSC6. Pressure-flow relationship in a biophysical model of phonation. Fariborz Alipour and Ingo Titze (Dept. of Speech Pathol. and Audiol., The Univ. of Iowa, Iowa City, IA 52242)

Simulation data are presented from a computer model that combines vocal fold tissue mechanics, laryngeal aerodynamics, and vocal tract acoustics. These simulations are based upon the laws of physics that govern airflow, vibration of the vocal folds, and wave propagation in the vocal tract. The tissue mechanics was modeled with the finite element method with 100 nodes and 166 elements in each layer of the 15-layer model. The laryngeal aerodynamics was modeled by the solution of two-dimensional unsteady Navier–Stokes equations with a finite volume method with a 64 $\times$82 nonuniform staggered grid. The model has been used to demonstrate self-oscillatory characteristics of the vocal folds and the flow pattern in the larynx. In this study, simulations were performed for lung pressure ranging from 4 to 24 cm of water. Adduction control was simulated with activation of thyroarytenoid (TA) muscle that caused increased tension and bulging of the vocal folds. Results are reported for glottal waveform, nodal coordinates, and velocity distributions in the larynx. Preliminary data suggest that the relationship between mean pressure and mean flow is almost linear. Frequency and amplitude contours of the model as functions of the lung's pressure and TA activation level reveal their increasing pattern with these parameters.

10:00

5aSC7. Perception of coarticulated vowels by prelingual infants: Formant transitions specify vowel identity. Ocke-Schwen Bohn (Engelsk Inst., Aarhus Univ., DK-8000 Aarhus C, Denmark, engosb@hum.aau.dk) and Linda Polka (School of Commun. Sci. and Disord., McGill Univ., Montreal, Canada)

German-learning infants were tested for discrimination of four German vowel contrasts in the Silent Center paradigm to examine which acoustic properties of coarticulated vowels (target-spectral, dynamic-spectral) define vowel identity in prelingual infants. Acoustic analyses of naturally produced original syllables (/dVt/ with V=/i, e, I, E, o, U/) revealed no vowel inherent spectral change but only formant movement associated with the gestures for the initial and final consonants. The original syllables were electronically modified to obtain test syllables which contained target-spectral information (the vowel nucleus only), only initial or only final formant transitions, or initial and final transitions in their appropriate temporal relationship, with the vowel nucleus attenuated to silence. Four groups of ten infants each (aged 7–11 months) were tested in the conditioned headturn procedure for discrimination of the test syllables. Each group was tested on one of four contrasts (/i/–/e/, /e/–/I/, /E/–/I/, /o/–/U/) after they had discriminated that contrast successfully in the unmodified condition. Results indicate that target spectral information is not needed to discriminate native contrasts; rather, dynamic spectral information spread over syllable onsets and offsets is sufficient to specify vowel identity in infants. [Work supported by grants of the Deutsche Forschungsgemeinschaft to O.-S. Bohn.]

10:15

5aSC8. Some observations of the tense–lax distinction theory with reference to English and Korean. Dae W. Kim (Dept. of English, College of Education, Pusan Natl. Univ., Gumjong-Gu, Pusan 609-735, South Korea, dwokim@hyowon.cc.pusan.ac.kr)

A series of experiments with 13 subjects in total and with /VCV/, /CVC/, /CVCVCV/, and /CVCVC/ words, using various techniques, was undertaken to verify the hypothesis that the speaker may select at least one of muscles involved in the articulation of a phoneme so that either timing or amplitude variable and/or both of the selected muscle(s) could distinguish /p/ from /b/ in English and /ph, p′/ from /p/ in Korean. The English /p/ and the Korean aspirated /ph/ and unaspirated /p′/ were tense, and the English /b/ and the Korean unaspirated /p/ lax. Findings: (1) The EMG data, obtained from the *orbicularis oris* superior muscle and the depressor *anguli oris* muscle, supported the tense–lax opposition, except for one English subject in stressed syllables; (2) The leveled peak intraoral air-pressure, an output of the synchronized respiratory muscle activities during bilabial stops, backed up the tense–lax distinction, except for one English subject in unstressed syllables, and there was intermuscle compensation between the labial muscle activities and the respiratory muscle activities; (3) The data of the maximum lingual contact in alveolar stops also supported the tense–lax distinction theory. Thus it can be said that the hypothesis has been verified in both languages.

10:30

5aSC9. Speech intelligibility is highly tolerant of cross-channel spectral asynchrony. Steven Greenberg (Intl. Comput. Sci. Inst., 1947 Center St., Berkeley, CA 94704, steveng@icsi.berkeley.edu) and Takayuki Arai (Intl. Comput. Sci. Inst., Berkeley, CA)

A detailed auditory analysis of the short-term acoustic spectrum is generally considered essential for understanding spoken language. This assumption is called into question by the results of an experiment in which the spectrum of spoken sentences (from the TIMIT corpus) was partitioned into quarter-octave channels and the onset of each channel shifted in time relative to the others so as to desynchronize spectral information across the frequency plane. Intelligibility of sentential material (as measured in terms of word accuracy) is unaffected by a (maximum) onset jitter of 80 ms or less and remains high (>75%) even for jitter intervals of 140 ms. Only when the jitter imposed across channels exceeds 220 ms does intelligibility fall below 50%. These results imply that the cues required to understand spoken language are not optimally specified in the short-term spectral domain, but may rather be based on some other set of representational cues such as the modulation spectrogram [S. Greenberg and B. Kingsbury, Proc. IEEE ICASSP (1997), pp. 1647–1650]. Consistent with this hypothesis is the fact that intelligibility (as a function of onset-jitter interval) is highly correlated with the magnitude of the modulation spectrum between 3 and 8 Hz.

Chair's Introduction—9:15

Invited Papers

9:20

5aSP1. Beyond current medical ultrasonic imaging: Opportunities for advanced signal processing. James G. Miller (Dept. of Phys., Washington Univ., St. Louis, MO 63105)

This keynote address will illustrate some aspects of current medical ultrasonic imaging and attempt to identify areas in which advanced signal processing may be able to contribute to the enhancement and extension of clinical ultrasound. Examples will be drawn primarily from echocardiography, in part because of challenges specifically associated with imaging the beating heart. The presentation will address the goals and needs of the (medical) user in order to avoid approaches which are technically elegant but clinically irrelevant. One feature peculiar to medical imaging, which limits the effective resolution to far less than the expected theoretical limit for the few hundred micrometer wavelength imaging systems in current use, is the subtle variation of elastic properties of soft tissue and the corresponding local variation in the speed of sound. Both random and systematic (for example, anisotropic) variations contribute to degradation in image quality, including the effect known as speckle. Opportunities for advanced signal processing may include not only approaches designed to enhance image resolution but also contributions to areas such as contrast agents and tissue characterization. The talk is designed to provide a broad overview which might serve as a common reference point for subsequent presentations.

10:00

5aSP2. The evolution of medical ultrasonic imaging systems. John M. Reid (Consultant 16711 254 Ave. SE, Issaquah, WA 98027)

A limit to effective soft tissue imaging is set by the acoustic properties of tissue. The attenuation is roughly proportional, and the size of a resolution element inversely proportional to frequency. Thus the number of resolution elements per image is fixed. Accordingly, acoustic frequencies from about 1 to 50 MHz are required. Effective imaging has required the development and application of innovative high-frequency hardware; particularly the transducers. These have progressed from single element types to 512 element arrays in production, with two-dimensional arrays having 1282 elements in development. The electronics now require many more channels with a dynamic range exceeding 100 dB and, with the introduction of digital methods, even multiple very fast A/D converters in the beamformer. Display devices have gone from WWII CRT's with 200 spots per radius to digital image stores on CRT's with thousands of spots available. These can now do image processing with software. The earlier systems survive in some applications that require them. The single element types are still used in high-frequency catheters, for example. The wideband transducers have opened up new methods, enhanced Doppler, contrast and tissue imaging that use a wider range of frequencies than previously possible. The single element types are still used in high-frequency catheters, for example.

5aSP3. 3-D ultrasound imaging of the prostate. Aaron Fenster and Donal Downey (Robarts Res. Inst., London, ON N6A 5K8, Canada)

An important aspect that needs improvement in medical ultrasound systems is related to the 2-D imaging of the prostate. 2-D viewing of 3-D anatomy limits our ability to quantify and visualize prostate disease and is partly responsible for the reported variabilities. This occurs because: (i) the diagnostician must integrate multiple 2-D images in his mind during the procedure, leading to inefficiency and variability; (ii) The 2-D ultrasound images represent a thin plane at some arbitrary angle in the body, making it difficult to localize the image plane. To overcome these difficulties, we have developed a 3-D ultrasound system to image the prostate. Our 3-D ultrasound imaging system consists of: a conventional ultrasound machine and transducer; a custom-built assembly for rotating the probe under microcomputer control; a microcomputer with a video grabber; and software to reconstruct and display 3-D images. A typical scan of 200 2-D B-mode images takes only 13 s, and the reconstruction less than 1 s. This paper will detail the 3-D imaging approach and its use for imaging the prostate in 3-D. Various applications will be discussed related to prostate cancer diagnosis, prostate volume measurements, and 3-D ultrasound-guided therapeutic procedures such as cryosurgery.

5aSP4. The analysis and classification of small-scale tissue structures using the generalized spectrum. Kevin D. Donohue (Dept. of Elec. Eng., Univ. of Kentucky, Lexington, KY 40506), Flemming Forsberg, and Ethan J. Halpern (Thomas Jefferson Univ. Hospital, Philadelphia, PA 19107)

Conventional ultrasonic imaging systems primarily use backscattered signals for creating qualitative images that reveal large-scale structures, such as tissue boundaries. Efforts to extract additional quantitative information have resulted in limited success. The nonstationarities of the scatterers comprising biological tissue often violate conditions for applying common signal characterization and estimation methods. In addition, ultrasonic tissue properties (such as attenuation, velocity, scatterer density, size, and structure) ambiguously encode information into the backscattered signal, making it difficult or impossible to extract and quantify a single property. This paper presents the generalized spectrum (GS) as a method for analyzing and quantifying the properties of small-scale resolvable structures (on the order of 1 to 4 mm), which result from tissue structures such as lobules, ducts, and vessels. The GS extends the capabilities of power spectral density to include meaningful phase information that results from small-scale structure. The relevant properties of the GS include its ability to reduce the effects' diffuse scatterers (speckle), and permit normalization schemes that significantly limit the effects of system response and attenuation from the overlying tissue. An implementation of the GS in an analysis and classification of normal and metastic liver tissues is also described.

5aSP5. A Wold decomposition-based autonomous system for detecting breast lesions in ultrasound images of the breast. Georgia Georgiou and Fernand S. Cohen (Imaging and Comput. Vision Ctr., Dept. of Elec. and Comput. Eng., Philadelphia, PA 19104)

This paper presents an autonomous system for detecting lesions in the breast. The Wold decomposition algorithm described is used to decompose the RF echo of the breast into its diffuse and coherent components. The coherent component is modeled as a periodic sequence and the diffuse component is modeled as an autoregressive time series of low order. The parameters of the model are estimated from selected regions of the RF image and used as detection features. The database of images that was used contained 370 B-scan images from 52 patients, obtained in the Radiology department of the Thomas Jefferson Hospital. The pathologies of interest are carcinoma fibrocystic and stromal fibrosis disease and fibroadenoma. Empirical ROC techniques were used to evaluate the detection rate on single parameters of the model, such as the residual error variance and the autoregressive parameters of the diffuse component of the RF echo. The area under the empirical ROC curve for detecting lesion regions versus normal RF regions is 0.901. The area under the ROC curve for detecting carcinoma versus normal regions is 0.904. The corresponding areas for normal regions versus stromal fibrosis/fibrocystic regions and fibroadenoma regions are 0.942 and 0.899, respectively.

5aSP6. Tracking and correcting for organ motion artifacts in ultrasound tomography systems. Amar C. Dhanantwari (Dept. of Elec. and Comput. Eng., Univ. of Western Ontario, London, ON N6A 5B9, Canada) and Stergios Stergiopoulos (Defence and Civil Inst. of Environ. Medicine, P.O. Box 2000, North York, ON M3M 3B9, Canada)

Motion artifacts have been identified as a problem in medical tomography systems. This problem, however, is well known in other types of real-time imaging systems such as radar satellites and sonars. In this case it has been found that the application of an overlap processing scheme [J. Acoust. Soc. Am. **86**, 158–171 (1989)] increases the resolution of a phased array imaging system and corrects for motion artifacts as well. Reported results have shown that the problem of correcting motion artifacts in synthetic aperture applications is centered on the estimation of a phase correction factor. This correction factor is then used to compensate for the temporal phase differences between sequential sensor-array measurements in order to synthesize the spatial information coherently. This paper describes an approach which tracks the organ motion and allows the artifacts to be isolated in ultrasound tomography systems. Two sources are utilized so that two sets of projections are generated that are identical in space but separated in time. Then the spatial overlap correlator processing scheme is used to synthesize the 2-D projection data coherently. This provides the desired phase correction factor, which compensates for the phase fluctuations caused by the subject's organ-motion effects and tracks the organ motion.

12:30

5aSP7. Wavefront distortion measurements in the human breast. R. C. Gauss, G. E. Trahey (Dept. of Biomed. Eng., Duke Univ., 136 Eng. Bldg., Durham, NC 27708, rgauss@acpub.duke.edu), and M. S. Soo (Duke Univ. Medical Ctr., Durham, NC 27710)

Published wavefront distortion (phase aberration) measurements for the human breast have been inconsistent, ranging from mild phase aberrations (8 ns rms) to severe phase aberrations (67 ns rms). These measurements are required to specify arrays and assess the potentials of and appropriate algorithms for adaptive imaging. They require high interelement uniformity so that receive signal variations between elements can be attributed to wave propagation effects. Array elements must be small to minimize the integration of the arriving wavefront across the face of the element. The array aperture must be large enough to allow target visualization and to provide high correlations between neighboring elements for pulse-echo measurements. An apparatus to make concurrent pulse-echo and pitch-catch (through transmission) waveform measurements in a clinical setting has been developed. The breast is stabilized between opposing transducers with light compression. After fixing the position of the transducers, pulse-echo and pitch-catch snapshots are captured sequentially with tissue and reference phantom targets. Data were collected from four views of the left breast in 12 volunteers. The rms phase error was significantly smaller for pulse-echo measurements (25 ± 14 ns rms) than for pitch-catch measurements (60 ± 23 ns rms). [Work supported by NIH.]

9:20

5aUW1. A practical model for high-frequency seabed bistatic scattering strength. Darrell R. Jackson (Appl. Phys. Lab., College of Ocean and Fishery Sci., Univ. of Washington, Seattle, WA 98105) and Anatoliy N. Ivakin (Andreev Acoust. Inst., Shvernika 4, Moscow 117036, Russia)

The authors have previously reported a model for bistatic scattering by elastic seabeds. This model is extended here to cases of larger roughness by replacing the rough-interface perturbation approximation with the small-slope approximation [Yang and Broschat, J. Acoust. Soc. Am. **96**, 1796–1804 (1994)]. Consistency with older models is shown by comparisons of calculations for silt and sand examples. Correlations between volume fluctuations of different types (e.g., density and compressional wave speed) are considered, and it is shown that the effects of such correlations are more readily observed in bistatic scattering measurements as opposed to backscattering measurements. Finally, the importance of elastic effects in scattering by rocky seabeds is illustrated. [Work supported by ONR.]

9:40

5aUW2. High-frequency bistatic scattering from sediments—experiments and modeling. Kevin Williams and Dajun Tang (Appl. Phys. Lab., College of Ocean and Fishery Sci., Univ. of Washington, Seattle, WA 98105, williams@apl.washington.edu)

Typically, for frequencies in the 10–100 kHz range, the interaction of sound with the ocean bottom is a scattering process. Use of bistatic geometries can give insight into the scattering process not possible via traditional monostatic experiments. The trade-off is that such experiments are more difficult and more data are needed to get statistically meaningful results to compare with models. During the last 5 years, the Coastal Benthic Boundary Layer (CBBL) program allowed the opportunity to develop and fine-tune one method of obtaining bistatic data. That evolution will be briefly described and the data from three sites (one mud, one sand, one sand-silt-clay) shown. The sand and sand-silt-clay site data are compared with a model based on surface roughness and volume perturbation scattering. The mud site had methane bubbles embedded within it and the data are compared with a model based on bubble scattering. The physical insight derivable from the model/data comparison in the mud case will be discussed. [Work supported by ONR.]

5aUW3. Models of volume and roughness scattering in stratified seabeds. Anatoliy N. Ivakin (Andreev Acoust. Inst., Shvernika 4, Moscow 117036, Russia, aniva@glasnet.ru)

At high frequencies, two mechanisms of seabed scattering are usually taken into account which are due to roughness of the seabed surface (sediment–water interface) and volume inhomogeneities of near-surface sediment. The mean parameters of bottom medium are usually considered as independent from spatial coordinates. This corresponds to the assumption that sound penetration into the sediment is sufficiently small because of strong absorption. In this paper, more general models are considered where seabeds are assumed as statistically stratified (plane-layered on the average) with the mean parameters taken as various functions of depth. In particular, they can be step functions corresponding to different types of sediments in different layers. Another type of stratification corresponds to continuous depth-dependences and involve gradients of mean parameters. Effects of stratification are shown to be important at lower frequences due to scattering from internal interfaces and volume inhomogeneities of deep layers as well as the influence of regular refraction and reflection within seabed medium. As numerical examples, angular dependencies of the scattering strength in both monostatic and bistatic cases at different frequencies are calculated for seabeds of various types. Comparison with available data is presented and discussed. [Work supported by ONR.]

10:12

5aUW4. Bottom volume scattering—Modeling and data analysis. Dan Li, George V. Frisk (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543), and Dajun Tang (Univ. of Washington, Seattle, WA 98105)

As part of the Acoustic Reverberation Special Research Program (ARSRP), low-frequency bottom scattering from a deep ocean sediment pond was measured using an omnidirectional source and a vertical line-receiving array deployed near the bottom. Sediment volume heterogeneities were found to be the major contributor to the measured scattered fields [Tang *et al.*, J. Acoust. Soc. Am. **98**, 508–516 (1995)]. Taking advantage of the experimental geometry, a model is developed which can generate realizations of three-dimensional random inhomogeneities in sediments and can simulate scattered fields based on these realizations using a perturbation approach. In this model, the broadband propagator (the Green's function) is obtained using an exact numerical method.

Therefore, the model can handle any layered sediment environments with scatterers distributed within any of the layers. The model predictions are compared to the experimental data across the available frequency band, and the results are favorable. [Work supported by ONR.]

10:24

5aUW5. High-frequency bottom backscattering from a homogeneous seabed. Kevin B. Briggs (Marine Geosciences Div., Naval Res. Lab., Stennis Space Center, MS 39529, kbriggs@zephyr.nrlssc.navy.mil) and Steve Stanic (Acoust. Div., Naval Res. Lab., Stennis Space Center, MS 39529)

High-frequency acoustic backscattering was measured from a sandy site located in very shallow water (8 m) off Tirrenia, Italy, at a range of frequencies and grazing angles. Concomitant measurements of the seabed indicated that the very fine sand was well sorted, relatively uniform with respect to vertical and horizontal distribution of compressional wave velocity and attenuation, and depleted with respect to biological activity. Bottom scattering strengths were very low and variability of sediment parameters was exceptionally low. Coefficients of variation determined for sediment compressional wave velocity and attenuation were 0.29% and 7.2%, respectively. These data compare with previously recorded minima of 0.30% and 14.8% for the same respective parameters, in nearshore, mobile fine sands from the Gulf of Mexico and the Pacific Ocean. Lack of variability in sediment sound velocity and density concurrent with low acoustic bottom scattering strength measurements would endorse recent modeling approaches that predict scattering from sediment impedance fluctuations. Acoustic data are compared with predictions from the composite roughness model (modified for inclusion of sediment volume scattering parameters) at various frequencies and grazing angles in order to test the model's response at minimal perturbation of seabed properties.

10:36

5aUW6. A porous medium with porosity variations. Nicholas P. Chotiros (Appl. Res. Labs., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029)

The BiotUs equations of acoustic propagation in porous media have no inherent scattering mechanism, because the pores are modeled as smooth-sided tubular passages with constant cross section. They predict two compressional and one shear wave that propagate independently. Real porous media usually have pores with varying cross section, which may be considered as variations in porosity on a microscopic scale. Although any single variation on such a scale would have a negligible effect on the acoustics of the medium, the cumulative effect of a field of such variations is unknown. A one-dimensional structure with varying porosity was modeled numerically to study its properities as an acoustic medium. It was found that, not only does it possess an inherent volume scattering strength, but it also allows energy transfer between the three types of waves as they propagate. [Work supported by ONR 321 OA.]

5aUW7. A comparison of bistatic scattering from two geologically distinct mid-ocean ridges. Chin Swee Chia (MIT, 77 Massachusetts Ave., Cambridge, MA 02139) and Laurie T. Fialkowski (Naval Res. Lab., Washington, DC 20375)

A comparison is made of bistatic scattering from two distinct deep-ocean ridges. The ridges are located along a segment valley on the western flank of the Mid-Atlantic Ridge (MAR). The acoustic data sets were acquired during the Main Acoustics Experiment of the Acoustic Reverberation Special Research Program. Detailed analysis of bistatic scattering from one of these ridges, named B′, has been previously presented by some of the authors. The purpose of this paper is to present a similar analysis for the second ridge, C′, for comparative purposes. This comparison is important because the ridges span the two geologically distinct classes found in the MAR. There is a possibility, therefore, that their scattering characteristics may be extrapolated to ridges throughout the MAR. For example, B′ is an ''outside corner'' and therefore is composed of highly lineated scarps and terraces, while C′ is an ''inside corner'' that is characteristically amorphous with irregular large-throw normal faults. While major scarps on these ridges can be easily resolved by the towed-array system, smaller-scale anomalies such as gullies and trellises are often underresolved by nearly an order of magnitude. These anomalies are found to introduce large variances in the bistatic scattering characteristics of a given scarp.

11:15

5aUW8. Multistatic scattering from anisotropically rough interfaces in horizontally stratified waveguides. Jaiyong Lee (MIT, Cambridge, MA 02139) and Henrik Schmidt (SACLANT Undersea Res. Ctr., La Spezia, Italy)

A model of multistatic scattering and reverberation from an anisotropically rough seabed in shallow water has been developed by combining a scattering theory based the method of small perturbations [W. A. Kuperman and H. Schmidt, J. Acoust. Soc. Am. **79**, 1767–1777 (1986)] with a seismo-acoustic propagation model [H. Schmidt and J. Glattetre, J. Acoust. Soc. Am. **78**, 2105–2114 (1985)]. This new computational model provides full 3-D wave theory simulations of multistatic rough bottom reverberation in horizontally stratified waveguides. The seabed and sub-bottom roughnesses are represented by anisotropic roughness patches covering the actual sonar footprint. The scattering theory convolves the incident sonar field with the roughness to provide a distribution of virtual source panels that are then fed into the propagation model to provide a numerically efficient azimuthal Fourier series of wave number integrals for evaluating the 3-D reverberant field. The efficiency of the new hybrid model enables the modeling of 3-D field statistics by *Monte Carlo* simulation, as well as time-domain field simulations by Fourier synthesis. The model has been verified by comparison with analytical solutions for the simple problem of determining the 3-D multistatic scattering strength of a randomly rough interface separating two fluid half-spaces. Here the new model is used to investigate the dependence of the multistatic reverberant field on environmental parameters such as anisotropic roughness statistics, and bottom stratification and composition. [Work supported by ONR.]

11:27

5aUW9. Integral equation method for bistatic volume scattering from the seafloor. Christopher D. Jones and Darrell R. Jackson (Appl. Phys. Lab., College of Ocean and Fishery Sci., Univ. of Washington, Seattle, WA 98105)

In most theoretical developments of sediment volume scattering, the medium is assumed to have weak fluctuations in sound speed and density and is assumed to be statistically homogeneous. An exact integral equation method has been developed and is used to test these assumptions. Small perturbation theory results for single frequency bistatic scattering from the seafloor are compared with Monte Carlo simulations. Half-space and multiple scattering effects not included in most previous treatments are observed.

11:39

5aUW10. Time/frequency spread for bistatic geometries. R. Lee Culver and Christopher J. Link (Appl. Res. Lab., Penn State Univ., P.O. Box 30, State College, PA 16804)

The overall goal of this work is to develop a functional characterization of, and empirical models for, high-frequency, broadband acoustic propagation through a shallow ocean channel. One important aspect of this characterization is the time/frequency spread, which quantifies how much signals spread in time and frequency as they propagate. Because time and frequency spread are random quantities which vary from pulse to pulse, time/frequency spread must be characterized using a second-order statistic, e.g., the scattering function, which is the expected value of the mean-square spreading function. The scattering function has been measured in the following ocean environments: sandy gravel bottom, isovelocity sound

speed profile (SSP); rough rock bottom, slightly downward-refracting SSP; and mud bottom, upward-refracting SSP. A statistical model for the scattering function is being developed for these environments based upon radial basis function decompositions of the scattering function estimates. The ultimate use of a scattering function model will be with simulation to assess and optimize acoustic receiver performance. [Work is sponsored by the Office of Naval Research Ocean Acoustics Program.]

11:51

5aUW11. Sound waves attenuation in shallow water with rough boundaries. Boris G. Katsnelson, Sergey A. Pereselkov (Dept. of Phys., Voronezh Univ., 1 University Sq., Voronezh 394693 Voronezh, Russia), Venedict M. Kuz'kin, and Valery G. Petnikov (General Phys. Inst., 137333 Moscow, Russia)

Here the object is to estimate the effect of scattering by randomly rough seabed and surface waves on attenuation of low-frequency sound waves in shallow water. The experiment was pursued with CW signals (100 and 230 Hz) in Barents Sea. The transmission loss and interference pattern of a sound field were measured within 100 km of the acoustic sources. Mesoscale relief of the bottom with spatial resolution 10 m and wind parameters were recorded as well. The experimental results (the average sound intensity) were compared with theoretical ones calculated with and without taking into account seabed and surface roughness. The calculation was carried out on the base of modal theory of sound scattering by rough boundaries in a waveguide. It was demonstrated that the random roughness substantially affects the transmission loss for long distances. In this paper the method is suggested for bottom parameter estimation using the statistical attributes of sound field in shallow water with random rough boundaries as well. [The work was supported by Russian Foundation of Basic Research (Grant 96-02-17194).]

12:03

5aUW12. Modal theory of sound propagation in a random irregular shallow-water waveguide (numerical calculation and diffusion approach). Boris G. Katsnelson and Sergey A. Pereselkov (Dept. of Phys., Voronezh Univ., 1 University Sq., Voronezh 394693 Voronezh, Russia)

Sound field changing due to scattering by random irregularities in shallow water is considered. Shallow water is a randomly inhomogeneous media bounded by absorbing bottom and surface, which are randomly irregular (rough) as well. Longitudinal scales of all types of irregularities are greater than cross scales. Sound field is the sum of modes with random amplitudes. A system of stochastic differential equations for modal amplitudes is derived. Asymptotic approximation is used to obtain equations for statistical moments of modal amplitudes. The behavior of average modal intensity is described by diffusion equation. Comparative analysis of scattering and absorbing effects on sound propagation is carried out. Scattering leads to two processes: intensity transformation from a coherent (average) field component into a noncoherent (random) one, and intensity redistribution between modes. The next problem is interference structure alteration due to scattering and absorption. This alteration leads in turn to space redistribution of the field intensity. It is shown that for the ranges from the source, a much greater than ''automodel range'' situation takes place, and that depth dependence of intensity is constant in range. It is the result of equilibrium between two phenomena: modal intensity absorbing and modal intensity redistribution due to scattering. Some examples are considered. [Work was supported by RFBR (Grant 97-05-64878).]

11:05

5aPLb1. Nonlinearity, complexity, and the sounds of musical instruments. Neville H. Fletcher (Res. School of Physical Sci., Australian Natl. Univ., Canberra 0200, Australia, neville.fletcher@anu.edu.au)

Musical instruments can be treated to a first approximation as linear harmonic systems, but closer examination shows that they are, almost without exception, nonlinear and inharmonic. Sustained-tone instruments such as violins and clarinets can be characterized as ''essentially nonlinear'' and owe their deceptively simple behavior to mode locking due to strong nonlinearity. When the nonlinearity is weakened, the behavior becomes complex, with inharmonic and multiphonic sounds that are sometimes exploited in modern music. In contrast, impulsively excited instruments, such as guitars, pianos, gongs, and cymbals, may be described as ''incidentally nonlinear.'' They would function quite acceptably if the nonlinearity were to be eliminated but, when it becomes strong, they exhibit physically and aurally interesting behavior such as period doubling, frequency multiplication cascades, and chaotic oscillation. This paper will explore some of these phenomena and demonstrate both their physical origins and musical utility.

5pAAa1. Classroom acoustics I: The acoustical learning environment: Participatory action research in classrooms. Mary Jo Hasell, Philip Abbott, Gary W. Siebein, Martin A. Gold, Hee Won Lee, Mitchell Lehde, John Ashby, Michael Ermann, and Carl C. Crandell (Architecture Technol. Res. Ctr., 336 ARCH, Univ. of Florida, P.O. Box 115702, Gainesville, FL 32611-5702)

This pilot study used participatory fieldwork in a number of kindergarten through eighth grade classrooms to evaluate the acoustic setting that supports learning. Dynamic interactions among administrators, teachers, students, parents, and research team members makes a difference in learning. It was found that classroom interaction depends on the social make-up, anticipated behavior, intellectual level, teaching method and theories, and hearing capacity of participants, as well as the physical characteristics of the classrooms. Participatory action research (PAR) resulted in the development of appropriate classroom observation tools utilizing checklists, summary scales, and hierarchial rating scales. The learning climate, lesson clarity, instructional variety, task orientation, and student engagement were used to identify variables for acoustical studies. The PAR was instrumental in determining the protocol for the acoustical measurement studies described in Classroom Acoustics II. Field observations began with an understanding of the adaptive behaviors of the classroom participants such as how the teachers modified their location and sometimes even the furniture to maintain short speaker to listener distances. The findings indicate a range of solutions are needed to improve the acoustical learning environment including innovative teaching methods, improving room acoustical design, reducing background noise levels, and, in some cases, using amplification systems.

1:50

5pAAa2. Classroom acoustics II: Acoustical conditions in elementary school classrooms. Martin A. Gold, Hee Won Lee, Gary W. Siebein, Mitchell Lehde, John Ashby, Michael Ermann, Mary Jo Hasell, Philip Abbott, and Carl C. Crandell (Architecture Technol. Res. Ctr., 231 ARCH, Univ. of Florida, P.O. Box 115702, Gainesville, FL 32611-5702)

Acoustical measurements of speech transmission index, reverberation time, early reverberation time, early-to-late energy ratios, loudness (or relative strength), articulation index, background noise levels, and signal-to-noise ratios were made in a number of elementary school classrooms in one school district to see how many rooms actually had acceptable acoustical conditions. The source and receiver locations for the acoustical measurements were determined through the participatory action research (PAR) described in Classroom Acoustics I. Measurements were made using a TEF analyzer with custom software to compute additional acoustical measurements. Both omni-directional and directional loudspeakers were used for the source signals. The acoustical measurements were conducted in a variety of source receiver conditions as observed in the PAR studies in the classrooms. General observations are related regarding the relationship between the measurements and the PAR. For example, the STI was always greater than 0.75 for the conditions under which the teachers actually taught. Speaker-to-listener distances of 4 m or less were observed for many classroom activities. Likewise the teachers employed many creative ways to control the behavior of the students to reduce background noise levels while they actually spoke.

2:05

5pAAa3. Classroom acoustics III: Acoustical model studies of elementary school classrooms. Gary W. Siebein, Mitchell Lehde, Hee Won Lee, John Ashby, Michael Ermann, Martin A. Gold, Mary Jo Hasell, Philip Abbott, and Carl C. Crandell (Architecture Technol. Res. Ctr., 231 ARCH, Univ. of Florida, P.O. Box 115702, Gainesville, FL 32611-5702)

A 1:4 scale model was constructed with a series of interchangeable wall and ceiling panels to allow a battery of acoustical tests to be conducted for a variety of classroom designs. The walls and ceiling of the room could be changed from sound absorbent to sound reflective materials quickly. Scale furniture was also constructed for the room. The walls of the model could be adjusted from approximately 7 to 10 meters in length and from 2.5 m in height to 7 m in height. Acoustical measurements of speech transmission index, reverberation time, early reverberation time, early-to-late energy ratios, loudness (or relative strength), and articulation index were made in a number of simulated elementary school classrooms using both a TEF analyzer and impulse spark techniques. Classrooms where field measurements were taken as described in Classroom Acoustics II were modified to attempt to improve acoustical conditions in the rooms. The location and amount of absorbent material, the location and amount of sound reflective material, and the room volume were the major variables considered. In general rooms that followed good architectural acoustics design principles produced favorable acoustical measurements.

2:20

5pAAa4. Classroom acoustics IV: Speech perception of normal-hearing and hearing-impaired children in classrooms. Carl C. Crandell, Gary W. Siebein, Martin A. Gold, Mary Jo Hasell, Philip Abbott, Mitchell Lehde, and Hee Won Lee (Architecture Technol. Res. Ctr., 231 ARCH, Univ. of Florida, P.O. Box 115702, Gainesville, FL 32611-5702)

The present investigation examined the speech-perception abilities of normal-hearing and hearing-impaired children in a number of classroom environments. Speech perception was assessed as a function of teacher location, background noise levels, early sound reflections, reverberation time, and signal-to-noise ratio. Specific acoustical measurement procedures are described in Classroom Acoustics I and II. Speech perception was assessed by nonsense syllables, monosyllabic words, and sentences. Normal-hearing populations included children, aged 5–17 years, who are progressing normally in school; learning-disabled children; children with central auditory processing deficits; articulatory- and/or language-disordered children; children with developmental delays and/or attention deficits; and children for whom English is a second language. Hearing-impaired populations consisted of children with minimal-to-severe degrees of bilateral and unilateral, sensorineural or conductive hearing loss. Data will be discussed in view of developing appropriate classroom acoustics for normal-hearing and hearing-impaired pediatric listeners.

2:35

5pAAa5. Assessing speech intelligibility in classrooms at the University of Washington. Dean Heerwagen (Dept. of Architecture, Univ. of Washington, Box 355720, Seattle, WA 98195-5720) and Tarik Khiati (Dept. of Urban Design and Planning, Univ. of Washington)

The University's Committee on Accessibility has initiated an investigation of classroom acoustical conditions. This investigation has been undertaken in response to complaints made by University faculty members who state that they are experiencing difficulties in understanding student's speech during class sessions, when students ask questions or engage in discussion. A survey of University faculty identified 75 problematic classrooms (out of the 300+ classrooms on the University campus). A sample of generally representative classrooms has been selected: these classrooms (and class sessions held in the classrooms) are being systematically measured to determine their acoustical properties. Seven parameters have been anticipated as the causes of inferior speech intelligibility: to strong background noise levels, too weak signal-to-noise ratios, excessive reverberation, too great speak-to-listener distances, various speaker idiosyncrasies (e.g., accenting, mumbling, rapidity, using unfamiliar verbiage, and so forth), acoustical defects of the classroom, and faulty amplification systems. To date, measurements show that the principal acoustical faults causing these intelligibility difficulties are high background noise levels, inadequate amounts and locations of absorptive materials and assemblies, and student speech characteristics including too-long distances separating faculty and students. In selected classrooms corrections are being undertaken.

All posters will be on display from 1:00 p.m. to 5:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 5:00 p.m.

5pAAb1. Characterizing scattering from room surfaces. Tristan J. Hargreaves, Trevor J. Cox, Y. W. Lam (Dept. of Acoust. and Audio Eng., Univ. of Salford, Salford M5 4WT, UK), and Peter D'Antonio (RPG Diffusor Systems, Inc., Upper Marlboro, MD 20772)

There is a need to characterize the scattering from room surfaces in terms of a diffusion parameter. Such a parameter is required for many geometric room acoustic models and to enable the relative diffusion performance of surfaces to be evaluated. In addition, it is hoped that the characterization of scattering will aid designers of rooms. This paper examines the derivation of diffusion parameters from the distribution of scattered energy, which is one possible route to characterizing surface scattering. Previous investigations have concentrated on obtaining diffusion parameters from two-dimensional polar distributions—either measurements or predictions using BEM techniques. The advantages and disadvantages of these parameters are outlined and an alternative parameter of this type which overcomes some of the disadvantages is described. A new capability to perform measurements in three dimensions, which has broadened the applicability of the results from this study, is described. Extending the use of existing two-dimensional diffusion parameters to characterize hemispherical scattering will be discussed. Some solutions to the problems which arise when using these parameters to characterize scattering from large surfaces or those mounted in baffles will be presented.

5pAAb2. Numerical study on sound absorption characteristics of brick/block absorbing walls. Shinichi Sakamoto, Dong-Jun Joe, Hideki Tachibana (Inst. of Industrial Sci., Univ. of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo, 106 Japan), and Hikari Mukai (Ono Sokki Co., Ltd., 1-16-1 Hakusan, Midori-ku, Yokohama, 226 Japan)

The brick/block absorbing walls with openings and backing air space with porous materials are often used for absorption in low frequencies. The absorption in low frequencies can be explained by the well-known theory of Helmholtz resonance. In some measurement results of absorption coefficient, however, high absorption coefficients are seen in high frequencies. Regarding this problem, the authors have been investigating theoretically and experimentally as presented at the last ASA meeting (at Penn. State). Following these studies, further numerical analysis was carried out on simple 2-D models. The wave phenomena in the cavity and backing space/material were formulated by combining the FEM with the

scattering wave theory. Comparison between the calculated result and the result of a 1/10 scale model experiment has indicated the validity of the numerical analysis.

5pAAb3. Absorption characteristics of a double-leaf membrane with an absorptive layer in its cavity. Kimihiro Sakagami, Toru Uyama (Environ. Acoust. Lab., Faculty of Eng., Kobe Univ., Rokko, Nada, Kobe, 657 Japan), Masakazu Kiyama (Kobe Univ., Rokko, Nada, Kobe, 657 Japan), and Masayuki Morimoto (Kobe Univ., Rokko, Nada, Kobe, 657 Japan)

Absorption characteristics of double-leaf membranes with an absorptive layer in the cavity are theoretically analyzed. The double-leaf membrane is modeled as two infinite membranes with a cavity between them, which consists of three layers of arbitrary media. The theory also includes the effect of permeability of the interior leaf. The effects of parameters of the absorptive layer on the absorption characteristics are discussed through numerical examples. The absorption characteristics of an impermeable double-leaf membrane are characterized by a mass-spring resonance peak at low frequencies. This peak becomes larger and shifts to lower frequencies as the thickness of the absorptive layer increases. The absorption characteristics are, in permeable cases, similar to those of the conventional porous absorbents; the absorption is low at low frequencies and higher at high frequencies. As the thickness of the absorptive layer increases, the absorption becomes higher at all frequencies. The change in position of the absorptive layer affects the absorption characteristics of the double-leaf membrane. This effect is related to the standing-wave sound field in the cavity. The flow resistance of the absorptive layer has an optimum value to maximize the absorption of a double-leaf membrane.

5pAAb4. Numerical simulations of the modified Schroeder diffuser structure. Antti Jrvinen, Lauri Savioja (Helsinki Univ. of Technol., Lab. of Acoust. and Audio Signal Processing, P.O. Box 3000, FIN-02015 HUT, Finland), and Kaarina Melkas (Nokia Res. Ctr., FIN-33721 Tampere, Finland)

Schroeder diffusers are widely used in architectural acoustics because they offer unique diffusion characteristics. It has been recently shown that the Schroeder diffusers are also efficient low-frequency absorbers. In this paper a new modified Schroeder diffuser structure is presented. The new folded structure allows one to extend the low-frequency limit of the Schroeder diffuser so that the cutoff frequency is not directly proportional to the depth of the structure. Other important advantage of the new structure is that the total volume of the structure is fully utilized as a diffuser. The modified structure is also easier to manufacture than the traditional Schroeder diffusers. The modified structure is compared with the traditional ones by numerical simulations and measurements. Both the radiation and absorption characteristics are modeled. Modeling techniques, such as finite element and boundary element method and finite difference time domain methods, are applied and compared with each other.

5pAAb5. Evaluation of spatial information from artificial head and four-microphone array measurements. Joerg Becker and Markus Sapp (Insitut für Elektrische Nachrichtentechnik, RWTH Aachen, 52056 Aachen, Germany)

Examinations on the acoustic qualities of enclosures are mostly restricted to the evaluation of single-number quantities like ''reverberation time'' and ''gravity time'' or criteria which qualify the perceptual qualities, for example, ''definition'' or ''clarity index.'' Most of these criteria are measured monaurally, although the spatial distribution of the reflections is essential for the acoustic quality of rooms. Spatial information can be registered with multimicrophone arrays or artificial heads. On the one hand it is easier to get the spatial information by using microphone arrays and on the other hand aurally adequate recordings can only be made with artifical heads. This paper focuses on the further development of algorithms for detecting virtual sound sources and compares evaluations of artifical head recordings with those made by a 4-microphone array.

5pAAb6. Combined beam tracing and Biot transfer-matrix model for predicting sound fields in enclosed spaces. Murray Hodgson, Andrew Wareing, and Callum Campbell (UBC Occupational Hygiene Prog. and Dept. of Mech. Eng., 3rd Fl., 2206 East Mall, Vancouver, BC V6T 1Z3, Canada, hodgson@mech.ubc.ca)

Numerous methods exist for predicting sound fields in enclosed spaces such as rooms, aircraft cabins, and the sea. These are generally energetic approaches which ignore phase and associated wave effects, and which describe sound reflection from surfaces by the energy absorption coefficient. Many, such as ray tracing, require long calculation times. In the work reported here, a new model is presented which is computationally efficient, includes phase, and decribes surface reflection by the angularly varying surface impedance. It is a triangular-beam-tracing algorithm, combined with a Biot-theory transfer-matrix model for laterally homogeneous, multilayer, poroelastic surfaces. The Biot model has been validated in the case of plates, porous materials, and seabeds. The combined approach is being validated in comparison with predictions by analytic and numerical approaches, and with experiment. The model is being used to study the effect of surface extended reaction on enclosed sound fields.

5pAAb7. Broadening the frequency range of panel absorbers by adding an inner layer of microperforated-plate. Jian Kang, Xueqin Zha, and Helmut V. Fuchs (Fraunhofer-Institut fur Bauphysik (IBP), Nobelstr. 12, D-70569 Stuttgart, Germany, kang@ibp.fhg.de)

A disadvantage of panel absorbers, namely a panel backed by an airspace, is that the effective frequency range is usually rather narrow. It has been theoretically demonstrated that the absorption range can be broadened by introducing a microperforated-plate between the panel and the back wall [J. Kang, IBP Report 1993]. In this paper, a series of experimental results on the effectiveness of this method is presented. The experiments were carried out using the single microphone FFT technology in an impedance tube. It is shown that with an inserted microperforated-plate the acoustic resistance of the whole structure is greater than that of the outer panel alone. When the parameters of the microperforated-plate are carefully selected, the absorption range can be effectively extended in both low- and high-frequency directions. Typically the improvement is around 1 oct. The effectiveness of the microperforated layer is much less when its resonance frequency is considerably higher than that of the outer panel alone. [Work supported by AvH.]

5pAAb8. Reverberation time predictions using neural network analysis. Joseph Nannariello and Fergus Fricke (Architectural and Design Sci. Dept., Univ. of Sydney, NSW 2006, Australia)

The study aims to utilize neural network analysis to develop a method to predict the reverberation time for enclosures—in the low and mid frequencies—by using neural networks that have been trained with constructional and acoustical data. The study begins with the hypothesis that, in practice, reverberation time predictions are too difficult to undertake using existing computer models, and too inaccurate when using other methods. Specifically, the study aims at providing an expeditious and accurate method of predicting the reverberation time of enclosures at the initial design stage. To substantiate the hypothesis, and to bring into effect the aims of the study, assessments are made of the predictive powers of the trained neural networks. The results of the investigations have indicated that there is a good basis for using trained neural networks to predict the reverberation time for enclosures. The results have also shown that neural network analysis can identify those variables that have an effect on the predicted reverberation times.

5pAAb9. Sound fields caused by diffuse-type reflectors with periodic profile. Daiji Takahashi (Grad. School of Eng., Kyoto Univ., Kyoto, 606-01 Japan, tkhs@archi.kyoto-u.ac.jp)

For the purpose of providing highly diffuse reflections, the reflection surface is often periodically corrugated. The degree of diffusion of this periodic type diffuser can be evaluated by an objective criterion named $DNSD$ [D. Takahashi, J. Acoust. Soc. Jpn. (E) **16**, 51–58 (1995)], the value of which varies in the range 0–1; $DNSD=0$ for a perfect diffusion, and $DNSD=1$ for a specular reflection. Optimum diffuse reflectors with periodic profiles can be designed by using this criterion, but this type of diffusion might have some aspect of misgivings due to its periodicity, which may be a kind of so-called ''tone coloration.'' In other words, the highly diffuse reflections might have a problem of some particular effect on the spectrum caused by the interference between the direct and the reflected waves, and the effect might be different from an ordinary case of the plane surface. In this report, for the three types of reflectors, the calculated results of the SPL characteristics of the reflected field as well as the diffusion performances are presented and mutually discussed in comparison with the measured data from $\frac{1}{8}$-scale model experiments.

5pAAb10. Directivity patterns of small explosions. Miguel Arana (Phys. Dept., Public Univ. of Navarra, 31006, Pamplona, Spain)

There are methods and equipment for the generation, amplification, and emission of acoustic impulses in order to evaluate the acoustic characteristics of a room by means of the Fourier transform from its impulse response. However, the responses of this equipment (especially the inertia of the loudspeakers and its lack of linearity) produce acoustic signals that do not reproduce reliably the necessary acoustic impulses. A notable dispersion was found in the measurements accomplished with these systems. The directivity patterns of small explosions have been measured and analyzed with the purpose of using them as impulsive acoustic sources. The typical durations of these impulses are between 0.1 and 0.2 ms. The sound power spectrum is relatively smooth from 1 to 10 kHz. The mean acoustic power is around 200 W (143 dB, Ref. 1 pW). For this an experimental device with 16 channels and software based on LabView were used. This communication will show the experimental device as well as the obtained results (mainly the dispersion of both the acoustic power and directivity patterns). [Work supported by Education Department of Government of Navarra.]

5pAAb11. Sound absorption measurements in diffuse field: A study of parameters. Marco Nabuco, Paulo Massarani (Acoust. Testing Lab., DIAVI/INMETRO), and Roberto Tenenbaum (Acoust. and Vib. Lab., COPPE/ Federal Univ. of Rio de Janeiro)

Many researchers have been studying the sound absorption coefficient measurement technique in reverberation chambers, since Sabine presented his formulation during the end of the last century, in order to find reasons for data frequently obtained bigger than 100%, normally correlated to the edge effects of the sample. Some researchers have studied the implications of the lack of diffuseness on the sound absorption data. This paper presents the data obtained for the sound absorption coefficient measured in a 200-m^3 reverberation chamber at the National Institute of Metrology, Standardisation and Industrial Quality-INMETRO, in Brazil, for different areas and configurations materials, from 1 to the standardized 12-m^2 sample. Also presented is the steady-state standard deviation, the cross-correlation between microphones, and the shape of the decays curves to qualify the diffuseness both in steady as well as during the transient state. At last is presented the data obtained using a steady-state measurement of the sound absorption using a standard reference sound source calibrated in semianechoic chamber.

5pAAb12. Dependence of accuracy of reverberation time measurement on input filters. Dragana S. Sumarac (Faculty of Elec. Eng., P.O. Box 35-54, 11001 Belgrade, Yugoslavia, esumarad@ubbg.etf.bg.ac.yu)

In this paper, attention was paid to the standard method for measuring frequency characteristics of reverberation time in rooms. The influence of transfer function characteristics of 1/1 and 1/3 digital octave input filters on differences in measuring values of reverberation time was studied. Procedures for complete digital analysis of recorded impulse response of the room were designed. All procedures were designed by the MATLAB software package. The verification of that measuring software was performed on a great number of recorded impulses in real rooms. The several classes of 1/1 and 1/3 digital octave FIR and IIR filters were designed according to the international standard IEC 225. The complete analysis was performed using the recorded reverberation decay curve in 20 rooms significantly different in volume and reverberation time values. The rooms were excited with broadband pink noise and short duration impulses. The values of measured reverberation times were statistically analyzed to show the expected variance that can appear due to differences of applied 1/1 and 1/3 digital input filters.

5pAAb13. Reverberation time directly obtained from a squared impulse response envelope. Fumiaki Satoh (Dept. of Architecture, Chiba Inst. of Technol., Tsudanuma 2-17-1, Narashino-shi, Chiba, 275 Japan, f_satoh@cc.it-chiba.ac.jp), Yoshito Hidaka (Dept. of Elec. Eng., Tohwa Univ., Chikushigaoka 1-1-1, Minami-ku, Fukuoka-shi, 815 Japan), and Hideki Tachibana (Tokyo Univ., Tokyo, 106 Japan)

For the measurement of reverberation time, a method of directly regressing the envelope of a squared impulse response (direct method) was examined using 100 data obtained in 14 auditoria. The results were compared with those obtained by the integrated impulse response method (Schroeder method) and a very high coincidence was found between them. It has also found that the direct method is more robust to background noise than the Schroeder method and in the former method relatively short-time data will do compared with the latter method.

5pAAb14. Effects of flow resistance on acoustic performance of permeable elastic-plate absorbers. Manabu Tanaka (Bldg. Res. Corp., Osaka-Suita, 5650873 Japan) and Daiji Takahashi (Kyoto Univ., Kyoto, 6068317 Japan)

In general vibration theories of thin elastic plate, the plates have been assumed to be nonpermeable. However, previous work on permeable membranes revealed that the acoustic properties of a membrane are strongly affected by its permeability [Takahashi *et al.*, J. Acoust. Soc. Am. **99**, 3003–3009 (1996)]. In this study, permeable elastic-plate absorbers are proposed and their acoustic performance is examined by means of numerical analysis. For the simplest model, a theory for sound transmission through and sound reflection by a single permeable plate absorber with the oblique incidence of steady-state plane wave is developed. In this theory, permeability of the plate is represented by unit-depth flow resistivity [MKS-rayl/m]. Subsequently, for more complex models, structured absorbers composed of the facing of a permeable plate and several layers of air and/or absorptive materials are investigated theoretically. With these theoretical models, parametric surveys are executed to evaluate the acoustic performance of permeable elastic-plate absorbers. As a result of numerical calculations, it becomes clear that the flow resistance of the permeable elastic plate has a remarkable influence on its acoustic characteristics, especially at high frequencies.

5pAAb15. Qualitative evaluations of the acoustics of rooms: Real room studies and headphone studies. Martin A. Gold (Architectural Acoust. Res. Group, 231 ARCH, Univ. of Florida, P.O. Box 115702, Gainesville, FL 32611-5702)

This pilot study attempts to qualify the use of headphones to evaluate the listening conditions of existing and proposed architectural spaces. Qualitative listening evaluations of speech and music were conducted in multiple locations in three different listening environments: a 2000-seat multipurpose concert hall, a 600-seat lecture room, and a 120-seat lecture room. Groups of college age students were asked to evaluate loudness, clarity, reverberance, spatial impression, and background noise using a questionnaire with a seven-point bipolar rating scale [Cervone (1990)]. The speech and music sources were played through two adjacent loudspeakers at the front of the respective rooms while the students completed the evaluation forms. The speech and music sources were binaurally recorded on a DAT at the listener locations in the respective rooms. At a later time, students were asked to evaluate the acoustical qualities of the binaural recordings made in the rooms using the same questionnaire. The recordings were presented to the listeners in a random order in a blind subjective evaluation. Data from real room evaluations and headphone studies are compared and conclusions are drawn regarding the potential for headphone listening experiments as a means to study qualitative aspects of room acoustics.

5pAAb16. On the acoustical characteristic of a balloon. Anthony P. Nash (Charles M. Salter Associates, 130 Sutter, Ste. 500, San Francisco, CA 94104, tnash@cmsalter.com)

It is common to use a transient acoustical signal when testing the properties of large architectural spaces. Some of the traditional signal sources include pistol shots, pulses from loudspeakers, etc. Assuming the background noise is reasonably low, an inflated balloon can be a very effective signal source in this application. The published literature contains little documentation regarding the sound power, directional properties, and repeatability of an exploding balloon. A carefully controlled experiment was conducted involving a series of balloons exploded in an environment where the closest reflecting surface was located more than 15 m from the source. Several microphones ringing the source were used to measure the free-field acoustical transient on a multi-channel tape recorder. The measured data will demonstrate that a properly inflated balloon is a very satisfactory (and lightweight!) sound source.

5pAAb17. Sound absorption by a large-size isolated acoustic resonator with a cylindrical cavity. V. J. Stauskis (Vilnius Gediminas Tech. Univ., Saulėtekio al. 11, 2040 LT, Vilnius, Lithuania)

An acoustical structure consisting of a large-scale isolated resonator with a large-diameter cylindrical cavity may be used. This resonator differs essentially from the classical Helmholtz resonator whose cavity is only several millimeters in diameter and lined with a sound-absorbing material. Formulas are presented with which the impedance of the cavity, the impedances both inside and outside the cavity, and the impedance of the volume of the resonator are calculated. A radiation directivity pattern expressed by Bessel's function is used to find the radiation impedance. Calculations show that the sound energy is absorbed by resonators made of sound-reflecting materials. The larger the cavity diameter is, the larger the sound absorption. Absorption is of a resonant character with the resonant frequency at 60 Hz. A resonator measuring 200×200 cm, with the cavity diameter 50 cm and the distance to the rigid surface being 30 cm, absorbs 3.5 m^2 of sound energy at the resonant frequency. At very low frequencies, changes in the imaginary parts of both cavity and radiation impedances occur along with the increase in the cavity diameter and frequency.

5pAAb18. Influence of distance and sound recording system on intelligibility and depth localization in highly reverberant conditions. Ruiz Robert (Laboratoire d'acoustique, Univ. de Toulouse-le Mirail, 5 allees Antonio Machado, 31058 Toulouse Cedex 1, France) and Ballet Isabelle (Univ. de Toulouse-le Mirail, 31058 Toulouse Cedex 1, France)

Speech intelligibility degrades when the listener moves from the source. In a highly reverberant and empty church, scores are measured at different distances from a loudspeaker and compared with those obtained from recordings of the speech at the same location. The phonetic material is a set of phonetically balanced lists of triphonemic French words. Two monophonic (omnidirectional, cardiod) and one stereophonic (ORTF) systems are used. Listening of recorded lists is performed with the same loudspeaker(s) as in the church. Results of the experiment indicate smaller variations of scores with the distance. An important improvement of scores is obtained with the stereophonic system. A second experiment consists of using a sound material composed of two voices performing a singing exercise edited in monophony in order to create two distinct sound planes. Listening tests allow the quantiication of the depth localization variations with distance and sound recording system. Results show a good respect of distance and reveal a sudden change in depth localization for stereophony. Acoustical properties of the church, distance factors of the microphones, properties of the stereophony against monophony, and real listening conditions are considered to discuss the experiments.

5pAAb19. Sound field in long enclosures with diffusely reflecting boundaries. Judicaël Picaut, Laurent Simon (LAUM UMR 6613, Univ. du Maine, 72017 Le Mans Cedex 9, France), and Jean-Dominique Polack (Univ. Paris VI, Case 161, 75252 Paris Cedex 05, France)

The sound field modelization by a diffusion equation is used to predict the sound propagation in long enclosures with diffusely reflecting boundaries. The diffusion equation is solved for time-varying sources and particularly in the steady state. Analytical expressions of sound attenuation and reverberation in infinite enclosures are given. Their simplicity makes them easy to apply to realistic diffusing long enclosures. For wide cross sections of enclosures and when absorption at the beginning and at the end walls is high, solutions for finite enclosures are also proposed. The source location and the absorption of each wall are taken into account in the model. Comparisons between analytical solutions, numerical simulations, and classical theory of diffuse sound field show good agreements. [Work supported by the PIR-Villes CNRS.]

5pAAb20. Reverberance of an existing hall in relation to subsequent reverberation time and SPL. Shigeo Hase (Grad. School of Sci. and Technol., Kobe Univ., Rokkodai, Nada, Kobe, 657-8501 Japan), Akio Takatsu (Showa sekkei, Inc., 1-2-1-8000, Benten, Minato-ku, Osaka, Japan), Shin-ichi Sato, Hiroyuki Sakai, and Yoichi Ando (Kobe Univ., Rokkodai, Nada, Kobe, 657-8501 Japan)

Psychological tests in relation to reverberance of sound fields were conducted in an existing hall which is a medium-sized multipurpose hall with 400 seats. Music and speech as sound sources were radiated from an omnidirectional dodecahedron loudspeaker on the stage. Paired-comparison tests were applied for the sound fields changing two orthogonal factors. These factors were the subsequent reverberation time T_{sub} and the SPL. The T_{sub} were adjusted by a hybrid system involving the reverberation control room and an electroacoustic system. 21 subjects took part in this test. The results indicate that the reverberance is influenced independently on the T_{sub} and the SPL. The reverberance increases with increasing both the T_{sub} and the SPL.

5pAO1. Bioacoustic resonance absorption spectroscopy. Orest Diachok (Naval Res. Lab., Washington, DC 20375)

Absorption losses at the resonance frequencies of sardines up to about 18 dB at 1.3 kHz at night, 15 dB at 1.7 kHz during the day and 35 dB at 2.7 kHz at dawn were observed at a range of 12 km during Modal Lion, a multidisciplinary experiment designed to isolate absorptivity due to fish from other effects on long-range propagation at a relatively shallow (83 m) site in the Gulf of Lion. Comparison of transmission loss measurements with a numerical sound propagation model that incorporates absorption layers in the water column permitted estimation of the average absorption coefficient, depth, and thickness of absorption layers. The depths and thickness of layers estimated from sound propagation measurements were in good agreement with echo sounder data. The measured resonance frequencies of dispersed fish at night were within 13% of theoretical computations, based on swim bladder dimensions which were derived from near coincident samples of adult (~16 cm long) sardines. A smaller absorption line at 3.9 kHz at night is consistent with the resonance frequency of dispersed juvenile sardines, which are known to be ~6 cm long, based on historical data. Measured resonance frequencies of sardines in schools were about 0.59 times the resonance frequency of dispersed sardines. The observed frequency shift is analogous to previously observed frequency shifts associated with ''clouds'' of bubbles. The results presented here suggest the possibility of long-term tomographic mapping of fish parameters over large areas using transmission loss measurements. [This work was supported by The Office of Naval Research.]

5pAO2. The application of wideband signals in fisheries and plankton acoustics. John E. Ehrenberg and Thomas C. Torkelson (Hydroacoustic Technol., Inc., 715 NE Northlake Way, Seattle, WA 98105-6429)

Over the last 30 years, there have been considerable improvements in techniques developed for acoustic assessment of fisheries and plankton populations. Techniques have evolved from analog echo integrators used to obtain crude abundance estimates to digital multiple-beam techniques for measuring *in situ* target strength, location, and velocity of individual targets. These advancements have been largely due to digital signal processing techniques applied to signals at the output of an echo sounder. Constant-frequency sine wave (CW) pulses have been used with nearly all plankton and fisheries assessment systems. The same digital signal processing technology used to improve post-processing is now finding its way into biological assessment echo sounders that use FM slide/chirp signals. Systems with time-bandwidth products of up to 50 have been developed and implemented to provide a signal-to-noise advantage in excess of 15 dB when compared to CW pulse signals with the same spatial resolution. This paper describes the implementation and application of FM slide/chirp signals for echo integration and target strength measurement. Practical implementation issues, such as the use of pulse shaping for range side-lobe control, are discussed. Recent data collected with a multifrequency acoustic assessment system developed for WHOI are presented.

5pAO3. Wideband fisheries sounder. From individual echoes analysis to classification of schools at sea. Manell E. Zakharia (CPE Lyon, LISA (EP92 CNRS)/LASSSO, 43 Bd du 11 Novembre 1918, BP 2077 69616 Villeurbanne Cedex, France, zakharia@cpe.fr)

Several works have been carried out in the last decade concerning wideband fisheries systems and their ability to discriminate fish species. The paper will first review previous work showing the relevance of wideband systems for fisheries acoustics (analysis of individual echoes). A short description of a wideband prototype (20 to 80 kHz) will then be given showing the technological issues. An emphasis will be made on the analysis of fish schools either in a controlled situation (lakes) or at sea. Wideband echo processing was based on autoregressive modeling of individual pings (modeling of spectrum resonances). This modeling concentrates the information contained in the wideband echo in a reduced set of parameters that could be used for classification. A neural network was trained to recognize several fish species. Ground truth was achieved by species identification, at sea, using associated trawling. For the construction of an echo data base, only monospecific schools were considered. Classification results at sea using only the spectral signature of the echoes were as high as 75% from a single ping. Lake tests have shown that the use of several pings (ten and above) could increase the recognition rate to more than 90%.

5pAO4. Searching for species identifiers in multifrequency target strength variability. James Dawson (BioSonics, Inc., 4027 Leary Way NW, Seattle, WA 98107)

Acoustic research has shown that the species of some schooling fish can be assigned based solely on measurement parameters from acoustic returns. For single targets, this process is complicated by the high variability of *in-situ* target strength (TS) measurements. Attempts at speciation based on the patterns of TS variability were confounded by interactions between acoustic frequency and fish directivity. Initial attempts at defining speciation parameters based on multifrequency target strength measures look promising. This paper reports on the results of simultaneously measuring the *in-situ* target strength of fish at 38-, 120-, and 420-kHz acoustic frequencies, and proposes the definition of several speciation parameters.

5pAO5. A broadband acoustic fish identification system. Gerald Denny and Patrick Simpson (Sci. Fishery Systems, Inc., P.O. Box 242065, Anchorage, AK 99524, scifish@alaska.net)

A broadband fish identification system has been built and tested in the Great Lakes, Prince William Sound, and the Bering Sea. Unique signatures have been obtained on free swimming and captive animals. These signatures include jellyfish, euphausiids, Pacific Rockfish, and Walleye Pollock. Acoustic characteristics and utilization of the system will be discussed, as well as results of *in situ* data collection.

5pAO6. The use of two freqencies to interpret acoustic scattering layers. Denise R. McKelvey (Natl. Marine Fisheries Service, NOAA, 7600 Sand Point Way NE, Seattle, WA 98115, denise.mckelvey@afsc.noaa.gov)

The use of multiple frequencies during acoustic stock assessment surveys allow methods to be used, which can discriminate between different species groups based on their scattering properties and assist in target species identification, thus improving estimates of biomass. Research, using multiple frequencies to study zooplankton, have used the difference in backscatter between several frequencies to identify the species or species groups comprising the scattering layers. This paper presents the results of using a dual-frequency differencing algorithm on 120- and 38-kHz mean volume backscatter strength (MVBS) data collected during a 1995 United States west coast acoustic survey of Pacific hake (*Merluccius productus*) as a means to acoustically separate hake from zooplankton. Scatterers were sampled using various nets with mouth areas ranging from 5 to 1000 m^2. Backscatter data from both frequencies were corrected for background noise. The effect of species composition, time of day, depth, and density of scatterers on the (delta)MVBS data were evaluated. Results indicate that the dual-frequency differencing algorithm shows a marked difference between fish and zooplankton (delta)MVBS and can be used to distinguish between fish and zooplankton scattering layers.

5pAO7. Fish'n krill: A 38/120-kHz acoustic separation. Yvan Simard (Dept. of Fisheries and Oceans, Maurice-Lamontagne Inst., P.O. Box 1000, Mont-Joli, QC G5H 3Z4, Canada, simardy@dfo-mpo.gc.ca)

Volume backscattering data (Sv) at 38 and 120 kHz were collected in the Gulf of St. Lawrence, during daylight, in regions where krill scattering layers (SL) and pelagic fish (mainly capelin) were present. The SLs and fish aggregations were sampled with the Bioness zooplankton samples and with small-mesh pelagic trawls equipped with acoustic monitoring systems. Echointegration was performed on small bins of ~5 m vertically and ~50 m horizontally. Comparisons of Sv at the two frequencies indicated that krill SLs had stronger backscattering at 120 than at 38 kHz, as expected. The ratio was relatively constant within the same SL, but varied from one SL to the other in parallel with the size of krill. The backscattering from fish schools or fish aggregations or fish layers was stronger at 38 kHz than at 120 kHz. This permitted the separation of fish from krill on the echograms, even for complex cases where fish were embedded in krill SL or had structural patterns that mimic the signature of krill SL. The 38/120-kHz backscattering ratio appears therefore useful to separate krill from fish, or vice-versa, for better interpretation and estimation of these taxa individually.

5pAO8. Multifrequency acoustic assessment of fisheries and plankton resources. Thomas C. Torkelson (Hydroacoustic Technol., Inc., 715 NE Northlake Way, Seattle, WA 98115-6429), Thomas C. Austin, and Peter H. Wiebe (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

The range of target species encountered in marine biological resource assessment and the inability to obtain a broad view of these resources by direct physical sampling techniques has lead to the utilization of various indirect measurement techniques. Among these techniques is the use of acoustics (sonar) to determine biomass distribution through integration and target strength measurements. WHOI is using a multifrequency acoustic system to obtain more accurate measurements of target species on the Georges Bank. The system uses advanced acoustic techniques to enhance detectability at the lower trophic levels and uses an advanced towing technique to enable sampling over the water column to depths in excess of 200 m. This presentation discusses the challenges encountered with indirect acoustic sampling and the techniques implemented to meet them. The system to be discussed operates at frequencies between 38 kHz and 2 MHz, using either FM slide (chirp) or traditional CW acoustic pulses.

5pAO9. Pulse compression processing of zooplankton echoes. Joseph D. Warren (MIT/WHOI Joint Prog. in Oceanogr. and Ocean Eng., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543, jwarren@whoi.edu), Timothy K. Stanton, Dezhang Chu (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543), and Duncan E. McGehee (Tracor Appl. Sci., San Diego, CA 92123-4333)

A pulse compression process was used to analyze echoes from individual animals of three distinct morphological groups of zooplankton. The groups studied were fluidlike animals (Euphausiids, decapod shrimp), elastic-shelled (Gastropods), and animals containing a gas inclusion (Siphonophores). A broadband chirp signal was used to insonify freshly collected animals that were then tethered in a seawater tank either in the laboratory or on the deck of a ship. The decapod shrimp was tethered to a stepper motor and was rotated in 1-deg increments. The other experiments had some animals fixed and others moving freely. The pulse compression processing of the echoes from the animals temporally resolved multiple returns from an individual. Using existing scattering models [Stanton *et al.*, J. Acoust. Soc. Am. (to be published)], the temporal and amplitude differences of the returns were used to estimate size and orientation. Estimates of the size of the animal were made for the Euphausiids, Gastropods, and Siphonophores, while orientation estimates were made for the decapod shrimp. These results agreed well with the actual dimensions of the animals.

3:35

5pAO10. Multistatic, multifrequency scattering from zooplankton. C. F. Greenlaw, D. V. Holliday, and D. E. McGehee (Tracor Appl. Sci., Inc., 4669 Murphy Canyon Rd., San Diego, CA 92123)

Very satisfactory results have been obtained in estimating size abundances of small zooplankton such as copepods from inversion of multifrequency backscattering measurements. Application of this method has become almost routine in many situations. Fluctuations in the scatterer physical properties (density and compressibility) tend principally to cause errors in the abundance estimates whereas size estimates are largely unaffected. The model commonly employed for small crustacean scatterers, a truncated-mode version of the Anderson fluid sphere model, predicts bistatic scattering as well as monostatic backscattering. The behavior of bistatic scattering at angles approaching 90 deg predicted by this model shows that scattering spectra at these angles are quite sensitive to physical properties. This suggests that simultaneous measurements at multiple frequencies and one or more off-axis angles might permit estimation of the physical properties of zooplanktonic scatterers as well as their sizes. Preliminary modeling has been done for a single fluid scatterer to illustrate

the potential for simultaneous estimation of size, density, and compressibility of zooplanktonic organisms in a laboratory setting. The character of the bistatic scattering may argue for nontraditional methods for inverting this sort of data.

3:50

5pAO11. Laboratory studies and theoretical modeling of bistatic scattering of fish. Li Ding (VITech Innovative Res. and Consulting, Victoria, BC V8P 3MB, Canada) and Zhen Ye (Natl. Central Univ., Taiwan, R.O.C.)

Bistatic scattering of fish, in particular forward scattering (scattering in the forward direction), has been identified as a potential means of detecting fish, supplementary to the traditional backscattering. A series of laboratory experiments has been conducted over the past 2 years to measure bistatic scattering characteristics of fish, including forward scattering strength and scattering patterns around the forward direction. It is observed that the forward scattering strength increases rapidly with acoustic frequency and is much stronger than the backscattering strength. The measured scattering patterns (at 120 and 200 kHz) suggest that the scattering is strongest in the forward direction when the incident wave is normal to the fish, and drops by 10–20 dB when the scattering angle deviates from the forward direction by a few degrees. In the latter case, the scattering strength is still much stronger than backscattering strength. These results are compared with a recently developed deformed cylinder model, and with a shelled cylinder model currently under development. [Work supported by the Science and Technology Agency of Japan, the Department of Fisheries and Oceans of Canada, and the National Central University of Taiwan.]

1:30

5pBV1. Shock wave measuring techniques in liquids. Wolfgang Eisenmenger (Physikalisches Inst., Univ. of Stuttgart, Pfaffenwaldring 57, 70550 Stuttgart, es@pi1.physik.uni-stuttgart.de)

The parameters of shock waves in liquids as used for lithotripsy have been measured with needle-, membrane-, and fiber optic probe hydrophones. The true rise times of planar shock waves are determined by surface detection or by the transient response of piezoelectric crystals. The different measuring techniques are compared with respect to their suitability for the determination of shock wave parameters, such as risetime, pulse width, positive and negative pressure amplitudes, and also with respect to aging, calibration sensitivity lifetime, etc. The fiber optic probe hydrophone appears as an optimum high precision standard for calibrated shock wave measurements in lithotripsy. Finally, aspects of the shock parameters with respect to the stone destruction efficiency are discussed.

1:50

5pBV2. Full-wave modeling of lithotripter fields. Eckard Steiger (Inst. für Hoechstfrequenztechnik und Elektronik/Akustik, Univ. of Karlsruhe, D-76128 Karlsruhe, Germany, eckard.steiger@etec.uni-karlsruhe.de)

The propagation of extracorporeal shock wave lithotripter pressure pulses is considered. A computational modeling must account for the effects of diffraction, nonlinear steepening and generation, and propagation of shock waves. Some commercial lithotripters are reflector focusing systems. Therefore, reflections at curved boundaries have to be considered. For specific interests in the propagation through and the interaction with human tissue structures, refraction, absorption, and scattering must be included. A full-wave model based on a set of nonlinear acoustic time domain equations is applied. This system is discretized to obtain a finite difference representation of broad bandwidth and low dispersive character. To enable an accurate shock wave computation an algorithm that modifies the temporal and spatial resolution adaptively is developed. Exemplary a reflector focusing lithotripter is modeled. To validate the model resulting computed wave profiles are compared with measured ones. The measurements are performed using a fiber-optic probe hydrophone. Excellent agreements show the method to provide an accurate and flexible tool for field predictions of complex devices. Characterizing parameters like −6-dB focal regions and energy quantities can be obtained, too. A human tissue model is applied to obtain predictions of the relevant parameters inside the human body.

2:10

5pBV3. Acoustic shock-wave induced cavitation: A comparison of theory and experiment. Andrew J. Coleman and Mark D. Cahill (Medical Phys. Directorate, Guys' & St. Thomas' Hospital Trust, Lambeth Palace Rd., London SE1 7EH, UK, a.coleman@umds.ac.uk)

A calibrated membrane hydrophone has been used to make measurements of pressure in a cavitating field generated in water by a single 30-μs duration ultrasound pulse with a 0.2-MHz center frequency and a peak negative pressure (p_-) variable from 0.5 to 5 MPa as employed in clinical lithotripsy. The acoustic emission from cavitation in the vicinity of the hydrophone is identified as the high-frequency ($>$1 MHz) component of the waveform. This ''cavitation component'' is compared with theoretical predictions of the pressure radiated by a bubble made using the Gilmore model [C. C. Church, J. Acoust. Soc. Am. **86**, 215–227 (1989)]. The model was run for initial bubble radii of 1–100 μm using the measured pressure waveform to drive the radial dynamics of the bubble. The theory predicts a transition from completely driven dynamics at p_- below 3 MPa to largely undriven dynamics above 3 MPa. This transition, which is substantially independent of bubble size, is experimentally observed and occurs at a measured p_- of 3 ± 0.4 MPa. The time between the pressure pulse and the first undriven inertial collapse is predicted to increase approximately twice as rapidly with increasing amplitude as is measured. A mechanism resulting in shorter than predicted collapse times is discussed. [Work supported by the Medical Research Council, UK.]

2:30

5pBV4. A new shock pressure waveform to amplify transient cavitation effect. Dominique Cathignol (INSERM U281, 151 Cours Albert Thomas, 69424 Lyon Cedex 03, France, cathignol@lyon151.inserm.fr), Jahangir Tavakkoli, Françgoise Chavrier, Alain Birer, Alex Arefiev, and Mathieu Prigent

Shock-wave-induced tissue damage and/or stone disintegration are greatly dependent on cavitation effect. In order to control this effect in tissue, a new piezocomposite shock-wave generator (200 mm in diameter and focused at 190 mm) has been developed with the capability of producing two different kinds of shock pressure-time waveform at its focus (type 1: a tensile wave followed by a compressive wave, and type 2: a compressive wave followed by a tensile wave). The cavitation effects produced by these two pressure waveforms were compared in the following experiments: (1) measurement of cavitation bubble collapse time (defined as the time difference between the shock wave arrival and the main bubble collapse), (2) study of cavitation-induced destructive effects in the agar gel, (3) study of disintegration rate on plaster balls (a kidney stone-mimicking material), and (4) study of cavitation-induced destructive effects on rabbit liver *in vivo*. All of these experiments revealed the amplified effect of transient cavitation produced by the type 1 pressure-time waveform. Comparisons with a computed simulation using the Gilmore Akulichef model, taking into account the rectified diffusion, confirm the experimental results. It is concluded that the temporal characteristics of the shock pressure waveform have a major influence on transient cavitation.

2:50

5pBV5. Stone tracking with time-reversal techniques. J. L. Thomas and M. Fink (Laboratoire Ondes et Acoustique, Ecole Superieure de Physique et de Chimie, Industrielles de la Ville de Paris, Universite Denis Diderot, 10 rue Vauquelin, 75231 Paris Cedex 05, France)

Time reversal of ultrasonic fields allows a very efficient approach to focusing pulsed ultrasonic waves through lossless inhomogeneous media. Time reversal mirrors (TRM) are made of large transducer arrays, allowing the incident acoustic field to be sampled, time reversed and reemitted. Time reversal processing permits a choice of any temporal window to be time reversed, allowing operation in an iterative mode. In multitarget media, this process converges on the most reflective target, i.e., the dominant scatterer. The time reversal process is applied to track, in real time a moving gall bladder or kidney stone embedded in its surrounding medium. The feasibility of adaptative beam forming techniques to track the stone during a lithotripsy treatment is investigated. It is shown that TRM allows sharp focusing on one bright point of the stone. Once the bright point is selected, a time of flight profile is determined and used in a least-mean-square method to calculate the spatial coordinates of the stone. Stone trajectories can be tracked by this technique at 30 Hz.

3:25

5pBV6. On a mechanism of target disintegration at a shock wave focusing in ESWL systems. Valery K. Kedrinskii (Lavrentyev Inst. of Hydrodynamics, Lavrentyev prospect 15, Novosibirsk 630090, Russia)

It is well known how the lithotriptors operate and the discussion concerning the mechanisms of target disintegration are continued. Meanwhile, to understand these mechanisms means to obtain a possibility to influence on the fracture process. The spall mechanism, as a result of acting with the shear forces, the crack growth inside a stone, and an erosion mechanism (impacts of cumulative microjets forming at bubble collapse in the cavitation zone near a target wall), were suggested by Sturtevant, Kuwahara, Delius, Takayama, Groenig, Crum, and others to explain the disintegration effects observed. At the same time, all authors do not deny a rise of the cavitation zone in the vicinity of a focus under the action of a negative pressure phase in ''a tail'' of a shock wave. However, the role of the cavitation cluster is interpreted in different ways assuming that this effect is a secondary one. This paper proposes an approach to the estimation of the disintegration mechanism, which is based on the development and dynamics of the cavity cluster in a focus vicinity. Within the framework of a two-phase model of cavitating liquid the problem of bubbly cluster development and its collapse on a solid wall are considered. The experimental data on a simulation of cavity cluster pulsation on a target and the idea that hydraulic impacts generated by cluster can determine the mechanics of target disintegration in a focusing zone of shock wave and its rarefaction phase are discussed.

3:45

5pBV7. First *in vitro* experiments using a new reflector to concentrate shock waves for extracorporeal shock wave lithotripsy. Achim M. Loske and Fernando E. Prieto (Inst. Física, UNAM, México D.F., México)

Electrohydraulic lithotripters to perform extracorporeal shock wave lithotripsy (ESWL) treatments use symmetrical reflectors in order to concentrate the energy generated in one of their foci ($F1$). The new reflector presented here was designed in an attempt to increase the efficiency of ESWL. It is obtained by combining sectors of two rotationally symmetric ellipsoidal reflectors with different separations between their foci $F1$ and $F2$. These sectors are joined together in such a way that the $F1$ foci coincide, creating a separation between the $F2$ foci. The purpose is to temporally and spatially dephase the shock wave generated at $F1$. This is achieved because the initial shock wave is divided, by reflection, into two shock fronts converging toward two, rather than one, $F2$ foci. Pressure measurements, and *in vitro* experiments using kidney-stone models and dog kidneys, indicate that the new design could be more efficient in breaking up renal stones, without producing more tissue damage. The performance of the new reflector was compared with one having the geometry of a Dornier HM3 (nonmodified) reflector. Both reflectors were installed separately in an electrohydraulic experimental shock wave generator (MEXILIT II). [Work supported by DGAPA IN502694, UNAM.]

5pBV8. Use of two pulses to control cavitation in lithotripsy. Michael R. Bailey (Appl. Phys. Lab, 1013 NE 40th St., Seattle, WA 98105), Robin O. Cleveland (Boston Univ., Boston, MA 02215), David T. Blackstock (Appl. Res. Labs., Austin, TX 78713), and Lawrence A. Crum (Appl. Phys. Lab., Seattle, WA 98105)

In lithotripsy acoustic cavitation appears to play a role in both comminution of kidney stones and damage to tissue. To investigate the role of cavitation, we used a pair of confocal electrohydraulic lithotripters (ellipsoidal reflectors). A delay in firing of Δt modified the cavitation field without altering the peak positive and negative pressures. Bubble collapse time t_c, measured by passively detecting acoustic emissions generated by the bubble, was used as a measure of cavitation activity. A two-pulse sequence from the source shortened t_c relative to the single pulse value t_{c1}. Collapse times calculated by using the Gilmore equation agreed well with measurements. Relative intensity of bubble collapse was determined by depth of pits created in aluminium foil. For pulse delays $\Delta t < 0.3t_{c1}$ the pit size decreased, a result that implies the second pulse stifled the collapse. Conversely, for delays in the range $0.5t_{c1} < \Delta t < t_{c1}$, cavitation apparently intensified, since pit depth increased by a factor of up to 2. Pit depth correlates well with (calculated) pressure radiated by the bubble. When the two reflectors were pointed at each other and fired simultaneously, pitting was localized to a spot less than 1 cm in diameter. [Work supported by ONR, ARL:UT IR & D, and NIH PO1-DK43881.]

4:20

5pBV9. Detection and control of lithotripsy-induced cavitation in blood. Brenda Jordan (Dept. of Biol., Tennessee State Univ., Nashville, TN 37209-1561), Michael R. Bailey (Appl. Phys. Lab., Seattle, WA 98105), Robin O. Cleveland (Boston Univ., Boston, MA 02215), and Lawrence A. Crum (Appl. Phys. Lab., Seattle, WA 98105)

Monitoring and controlling cavitation offer ways of isolating the role of cavitation in lithotripsy-induced cell damage. Finger cots containing 7 ml of PBS-diluted blood (3% hematocrit) were treated by 100 lithotripter pulses focused by either a conventional rigid reflector or a pressure-release reflector. The rigid reflector produced 7% hemolysis at 18 kV. The pressure-release reflector, which produces an equally strong acoustic pulse but less intense cavitation, produced 1% hemolysis which was indistinguishable from control levels. A passive cavitation detector consisting of two confocal focused transducers operating in coincidence was used to monitor cavitation within each blood sample. With the rigid reflector, each transducer recorded a spike when pre-existing bubbles were collapsed by the positive portion of the lithotripter pulse and a second spike when the bubbles, caused to grow by the negative portion of the pulse, underwent inertial collapse. The time between spikes was 1.25–1.5 times longer in blood than in water. The results appear to indicate that transient cavitation is an important mechanism in lithotripsy-induced hemolysis, that lithotripter-induced cavitation can be monitored in cell samples, and that bubble dynamics in blood and water are not identical. [Work supported by NIH PO1 DK43881, UW STAR, and DARPA/ONR.]

4:35

5pBV10. Experiments on the relation of shock wave parameters to stone disintegration. Thomas Dreyer, Rainer E. Riedlinger, and Eckard Steiger (Inst. für Hoechstfrequenztechnik und Elektronik/Akustik, Univ. of Karlsruhe, Kaiserstr. 12, D-76128 Karlsruhe, Germany, thomas.dreyer@etec.uni-karlsruhe.de)

The sound field of different focusing piezoelectric transducers designed for lithotripsy was investigated. The shock wave parameters according to proposed standards, e.g., FDA Draft 1991, were determined. The parameters achieved are based on measurements using a fiber-optical probe hydrophone. In contrast to PVDF-based hydrophones, this hydrophone is able to give a correct representation also of the tensile components of a complete signal and provides a higher spatial resolution. Thus some shock wave parameters like beam energy can be calculated more precisely. The different lithotripter pulses were applied to model stones *in vitro*, recording the amounts of removed material. Fragmentation results were compared with the different parameters. Attempts were made to arrange these parameters according to their relevance to disintegration. The evaluation of these experiments revealed up to now that there is no significant relation between some of the shock wave parameters and fragmentation efficiency. It is concluded that most of the proposed parameters do not describe well the efficacy of different lithotripter sources on concrements.

5pEAa1. Scattering by a horizontal strip on a hard side wall. Djamel Ouis and Sven Lindblad (Eng. Acoust., LTH, Lund Univ., P.O. Box 118, S-221 00, Lund, Sweden, djamel.ouis@kstr.lth.se)

The study of the effect of a horizontal hard striplike element on a side wall is presented. This may give an estimate of the usefulness of such elements in reinforcing the early sound components in a listening room. The theoretical calculations are based on geometrical assumptions in combination with a diffraction model to take into account the diffraction by the edge of the scattering element. This latter is based on the time-domain theory of Biot and Tolstoy for the diffraction by a hard wedge applied to the half-plane. An accurate and useful approximation for the diffracted field in the frequency domain using Fresnel integrals is presented. Some measurements on a scale model are also presented.

1:15

5pEAa2. Acoustic wave scattering from a coated cylindrical shell. Sung H. Ko (Naval Undersea Warfare Ctr. Div., Newport, RI 02841)

A theoretical model was developed to evaluate the effect of a coating on a cylindrical shell. The coating is designed to reduce the flexural wave noise generated by the vibration of the cylindrical shell. In underwater applications, this coating is called an inner decoupler. The outer surface of the composite structure, which consists of the cylindrical shell and the inner decoupler, is in contact with water; the core (cavity) of the structure contains air. The analysis of the problem is made for a double-layer cylindrical structure that is immersed in water. The theory of elasticity, the elastic wave propagation, the acoustic wave propagation, and pertinent boundary conditions are used in formulating the problem. The two-dimensional problem is treated in this study. This implies that all the quantities are independent of the axial coordinate. Numerically calculated results for both coated and uncoated cylindrical shells are presented to compare these two directivity patterns.

1:30

5pEAa3. Numerical solution of the linearized Euler equations with high-order centered schemes. John A. Ekaterinaris (Nielsen Eng. and Res., 526 Clyde Ave., Mountain View, CA 94043-2212)

The unsteady, linearized Euler equations governing propagation of acoustic disturbances in the presence of a uniform free stream or sound scattering from solid surfaces are solved numerically. The governing equations are discretized in space using the standard fourth- and sixth-order central-difference schemes, and compact finite-difference schemes with spectrallike resolution are also used. The semidiscrete system of equations obtained after space discretization is marched in time using high-order, Runge–Kutta schemes. Numerical boundary conditions are applied at the far field in order to limit the extent of the computational domain. Solutions are computed first on Cartesian, equally spaced grids. Computed results for propagation of a pulse in a uniform medium are compared with existing analytic solutions. Next, sound scattering from a cylinder surface is computed using a nonuniform body-fitted numerical mesh. The effects of grid spacing, time accuracy, the method used for space discretization, and the boundary conditions on the computed solutions are investigated.

5pEAa4. Modeling acoustic radiation from end-initiated explosive line charges. William J. Marshall, Jr. (BBN Technologies, Union Station, New London, CT 06320, bmarshall@bbn.com)

Acoustic radiation produced by end-fired explosive line charges has been examined experimentally and theoretically. In terms of directivity effects, line charges are found to behave like beam-steered continuous arrays over moderately wide bands. This talk briefly summarizes measured waveforms and derives a math model which predicts levels and spectrum shapes from such sources over a wide range of view angles and source characteristics. The model is driven by two parameters which may be extracted from experimental data. The result is a practical means of designing explosive line arrays to desired source levels, bandwidths, and beam patterns. [Work supported by DARPA.]

2:00

5pEAa5. Resonant frequencies in degeneration of hybrid longitudinal and torsional vibration system. LiQun Zhang and TieYing Zhou (Dept. of Modern Appl. Phys., TsingHua Univ., Beijing, PROC)

The Langevin vibrator is made of the longitudinal and torsional piezoelectric plates, which can be used for an ultrasonic motor and an ultrasonic welding transducer. Because of the difference between the longitudinal and torsional sound velocity, their resonant frequencies are not equal. To make resonant frequencies of two vibration modes in degeneration, a matching block with a thin neck was connected to the end of the vibrator. Two calculation methods, a dimension network which transmits matrixes and a finite element method have been used. The feasibility of frequencies tuning through a matching block has been analyzed and how to effect the resonant frequency by the radius and thickness of the thin neck and matching block has been summarized. The resonant frequencies of several steel cylinders with variant thin necks and matching blocks were calculated. Some experimental results of measuring the resonant frequencies have been compared with the calculation. According to the calculation and experimental results, a prototype of hybrid longitudinal-torsional ultrasonic motor has been manufactured, and it can be operated very well [Tomikawa *et al.*, IEEE Trans. Ultrason. Ferroelectr. Freq. Control **39** (1992)].

2:15

5pEAa6. The estimation of an interior sound field by source methods. Gee-Pinn James Too and Shing Maw Wang (Dept. of Naval Architecture and Marine Eng., Natl. Cheng Kung Univ., 1 Ta-Hsueh Rd., Tainan, Taiwan 70101, R.O.C.)

In an earlier study, three different source methods (SSM, similar source method; IPSM, internal parallel source method; ISM, internal source method) were successfully developed to estimate radiation and scattering sound field. All these are methods of estimating exterior sound fields which are not suitable for estimating interior sound fields. In this study, the similar source method is modified to estimate the interior sound field. The modification is to move the sources to somewhere outside the boundary surface in order to estimate the interior sound field and to prevent the singularity problem when the source point is close to the field point. Finally, the sound field inside a 2D infinite cylinder and in a car will be estimated. The results will be compared with the results obtained by the boundary element method.

5pEAb1. Insertion loss measurements of an acoustical enclosure by using Intensity and MLS methods. Pedro Cobo, Carlos Ranz, Salvador Santiago, Jose Pons, Manuel Siguero, and Carmen Delgado (Instituto de Acustica, CSIC, Serrano 144, 28006 Madrid, Spain, iacpc24@fresno.csic.es)

The Insertion Loss (IL) is one of the most appropriate descriptors for the acoustical performance of an enclosure. The IL is conventionally measured by comparing either sound power of space-averaged sound-pressure measurements before and after enclosing the sound source. In this paper, a comparison is made between a power-based IL measurement, using a sound intensity meter, and a pressure-based IL measurement, using the MLS method. Special attention is paid to practical and technical aspects of both methods, such as time consuming, low-frequency limit, signal-to-noise ratio, and background noise immunity. [Work supported by CICYT, Project AMB97-1175-C03-01.]

3:15

5pEAb2. Intensity measurements in various rooms: A new intensity probe. W. F. Druyvesteyn (Philips Res. Labs., Eindhoven, The Netherlands) and H. E. de Bree (MESA Res. Inst., The Netherlands)

The main advantage of acoustic intensity measurements is that in a reverberant room the direct and the reverberant sound field can be determined. This property has been tested using the Bruel & Kjaer p-p probe in four different rooms (anechoic, reverberant and two listening rooms). As compared to the results in the anechoic room, small deviations, which can be positive and negative, were found. The deviations can be explained using a model of early reflections. A new intensity probe consisting of a microphone and a sound velocity sensor has been tested and compared with the Bruel & Kjaer p-p probe. The sound (particle) velocity sensor contains the Microflown, a novel micro-machined sensor. This silicon-based velocity microphone operates on a thermal principle. The dimensions of the Microflown are on the order of a cubic millimeter. For symmetry considerations, however, the sensors were packaged in a quarter inch package. Experiments were done in the anechoic and in the reverberation room. A good agreement was found.

3:30

5pEAb3. *In situ* absorption measurements using a transfer function technique and MLS. G. Dutilleux, U. R. Kristiansen, and T. E. Vigran (Norwegian Univ. of Sci. and Technol., NTNU, Acoust. Group, Dept. of Telecommunications, N-7034 Trondheim, Norway, tor.erik.virgran@tele.ntnu.no)

The transfer function (or two-microphone) technique is a tool for measuring materials absorption related parameters as impedance or absorption coefficients. But this method is laboratory bound in its original form due to free field assumption and practical issues. It is shown that after proper modifications the transfer function technique can be used successfully in noisy and reverberating fields and work well at low frequency even in small measurement rooms, becoming therefore a really *in situ* measurement technique. A wide frequency range implementation is presented, based on a two-channel MLS measurement system, ''energy ratio invariant'' time windowing, a basic specular reflection propagation model with spherical decoupling, and a particular geometrical configuration. The measurement method is tested on a wide range of absorbers. For impedance measurements using infinite surface propagation models the uniqueness of the inversion procedure is investigated using the conformal mapping technique. In addition, faster inversion and model computation routines are proposed. Measurement results obtained under realistic *in situ* conditions are provided and compared with reference methods.

3:45

5pEAb4. Lumped impedance of a planar discontinuity in an acoustic waveguide. Ralph T. Muehleisen (Dept. of Civil, Environ., and Architect. Eng., Univ. of Colorado, Boulder, CO 80309) and Anthony A. Atchley (Penn State Univ., P.O. Box 30, State College, PA 16804)

When modeling planar discontinuities in acoustic waveguides at low frequencies, the standard assumptions involve continuity of pressure and volume velocity at the discontinuity. While continuity of volume velocity is required by mass conservation, excitation of evanescent higher-order modes and thermoviscous loss suggest that pressure is not continuous across the discontinuity. Such a pressure loss can be modeled by a series acoustic impedance. A new model for a lumped series impedance at a planar waveguide discontinuity has been developed and is presented. The model uses a modal expansion of the acoustic field near the discontinuity and matrix techniques to obtain a closed-form approximation for the re-

sistive and reactive elements of the series impedance. As an example of the accuracy of the model, the prediction of the resonance frequency of a constricted annular resonator is presented. [This work was supported by the Office of Naval Research and the American Society of Engineering Education.]

4:00

5pEAb5. A short water-filled pulse tube for the measurement of the acoustic properties of materials at low frequencies. Debra M. Kenney (Carderock Div., Naval Surface Warfare Ctr., 9500 MacArthur Blvd., West Bethesda, MD 20817, kennde@oasys.dt.navy.mil) and Peter H. Rogers (Georgia Inst. of Technol., Atlanta, GA 30332)

A method of measuring the acoustic properties of materials at low frequencies in a water-filled pulse tube, which was a fraction of a wavelength long, was investigated. The method employed active sound cancellation at the end of the tube opposite from the sample, and signal processing of two hydrophone signals to separate the signal incident on the sample from its reflection. Two analytical models were developed and an experimental tube was built to examine the feasibility of such measurements. The results from the simulation and experiment suggest that the short water-filled pulse tube would be useful for measuring compliant materials at moderately low frequencies (down to 300 Hz), but not for measuring high impedance materials or for making measurements at very low frequencies. The simulation and experiment showed that the thicker the sample, relative to a wavelength, the lower the sensitivity to experimental errors. Fortunately, many of the materials of interest in underwater acoustics are compliant materials with relatively slow phase velocities and consequently shorter wavelengths. The impedance of the backing behind the sample also influences the sensitivity of results to errors in the measurements. [Work supported by ONR and NSF.]

4:15

5pEAb6. The generation of low-frequency acoustic waves in electrolytes. Bronislaw Zoltogorski (Wroclaw Univ. of Technol., Inst. of Telecommunication and Acoust., Wybrzeze Wyspianskiego 27, 50-370 Wroclaw, Poland)

The phenomenon of the generation of acoustic waves in liquids based on interaction of alternating ion current and constant magnetic field is analyzed. The properties of such a magneto-electric transducer having no mechanical vibrating elements is examined theoretically (with the use of an electric equivalent circuit) and experimentally. The following measurements were carried out: (1) amplitude of conductivity current as a function of frequency, (2) amplitude of acoustic pressure at the distance of 0.5 m without constant magnetic field and (3) with magnetic field. For water from a municipal water-pipe network, the upper limit frequency of the current characteristic is 4 to 5 kHz. The same frequency properties exhibit a pressure characteristic. The directional pattern of the source depends on the shape of the electrodes and can be optimized for special aims. The energetic efficiency of the transducer is not great because the majority of the electric power is converted into heat and causes an increase in temperature of the liquid. That process is relative to a big value of resistance of weak electrolytes. That type of transducer can be applied in liquids without ion conductivity by submerging a container with very thin rubber walls and with mounted electrodes and filling with an electrolyte.

5pPAa1. Energy focusing in bubbly flows. Seth Putterman, Keith Weninger, Robert A. Hiller,[a] and Bradley P. Barber[b] (Phys. Dept., Univ. of California, Los Angeles, CA 90095)

Sonoluminescence, cavitation damage at surfaces, and cavitation in accelerating flows are realizations of spectacular levels of energy focusing in nature. In a resonant sound field a single trapped bubble of gas can focus the ambient sound energy by 12 orders of magnitude to generate a clocklike string of picosecond flashes of ultraviolet light. [Barber *et al.*, ''Defining the unknowns of sonoluminescence,'' Phys. Rep. **281**, 65 (1977)]. In more complicated geometries a high level of sound leads to the formation of hemispherical bubbles attached to an exposed surface. These bubbles also emit light and in addition damage the surface. Measurements show that the pulsation of these bubbles maintains the hemispherical symmetry [Weninger *et al.*, ''Sonoluminescence from an isolated bubble on a solid surface,'' Phys. Rev. E **56**, 6745 (1997)], thus raising the question as to whether cavitation damage is due to (micro)jets or imploding (hemispherical) shock waves. Finally, flow through a Venturi tube generates a stream of bubbles which also emit subnanosecond flashes of light [F. B. Peterson and T. P. Anderson, Phys. Fluids **10**, 874 (1967)]. Luminescence from an isolated trapped bubble in water seems to work well with any noble gas, whereas luminescence from cavitating flows and surface bubbles is quite dependent on xenon [argon bubbles appear to give no light at all]. The width of the SL flash [Gompf *et al.*, Phys. Rev. Lett. **79**, 1405 (1997), Hiller *et al.*, Phys. Rev. Lett. **80**, 1090 (1998)] has been found to be independent of wavelength suggesting that

light is emitted from a new high energy phase of matter-probably a cold dense nano-plasma. The key unknowns of SL are the size and temperature of the hot spot from which the light is emitted. Experiments aimed at measuring these quantities will be discussed. [Research supported by the NSF.] [a)]Present address: CMS, Los Alamos National Laboratories, Los Alamos, NM. 5pPAa2. Sonoluminescence stability for gas saturations down to 0.01 Torr. Robert E. Apfel and Jeffrey A. Ketterling (Dept. of Mech. Eng., Yale Univ., 9 Hillhouse Ave., New Haven, CT 06520-8286)

Water solutions with very small argon partial pressures were investigated. The experiments were performed in a sealed cell. The argon was used in both a pure form and in mixtures with other gases. A regime of stable sonoluminescence was seen at lower driving pressures for argon partial pressures down to 0.01 Torr. Mie scattering, light pulse measurements, and visual observations over tens of thousands of cycles were used to determine if the bubble was stable. As the drive pressure was increased, the bubble moved into a slow time scale instability on the order of several seconds which sometimes caused break up. These experiments are discussed and compared to other published data involving gas mixtures at saturation levels up to 1 atm.

5pPAa3. Evolution of a sonoluminescence bubble under a magnetic field. J. B. Young, H. Cho, and W. Kang (James Franck Inst. and Dept. of Phys., Univ. of Chicago, 5640 S. Ellis Ave., Chicago, IL 60637)

Studies of sonoluminescence (SL) in magnetic fields up to 20 T have revealed a striking magnetic field dependence. The intensity of emitted light is suppressed under increasing magnetic fields and vanishes above threshold magnetic field that depends on the applied sound pressure. Further increase in the magnetic field leads to the destruction of the bubble through dissolution. At a constant magnetic field, the light intensity is found to increase roughly linearly with increasing sound pressure until the bubble disappears above a cut-off pressure which depends on the strength of the magnetic field. The cut-off pressure is found to approximately double between 0 and 20 T. Further study of the SL bubble through the measurement of the phase of the emitted radiation relative to acoustic drive shows a large increase in phase under magnetic fields. These results suggest that the bubble grows significantly in size and that there may be a substantial modification of bubble dynamics under magnetic field. The origin of the observed effects, possibly due to magnetic field-induced anisotropies in the SL bubble, will be discussed in light of our recent anisotropy studies under magnetic fields.

2:00

5pPAa4. Computed spectral and temporal emissions from a sonoluminescing bubble. William C. Moss and David A. Young (Lawrence Livermore Natl. Lab., L-200, 7000 East Ave., Livermore, CA 94551, wmoss@llnl.gov)

Although the mechanism of emission in single bubble sonoluminescence (SBSL) has still not been identified conclusively, the ''plasma'' model [Moss *et al.*, Science **276**, 1398–1401 (1997)] appears to explain more features of SBSL than other models. Recent measurements of the light pulses emitted by SBSL [Gompf *et al.*, Phys. Rev. Lett. **79**, 1405–1408 (1997)] show that the pulse widths may be longer than the original UCLA measurements and can vary between 60 and 250 ps. These new results provide information for improving the modeling of the energy loss and emission mechanisms in the plasma model. In particular, the plasma can be described more accurately as a ''strongly coupled plasma'' (a plasma with a small Debye screening length). The main difference between the strongly coupled plasma and our earlier plasma model is that there is less energy loss by electron thermal conduction in the strongly coupled plasma, which gives rise to longer calculated pulse widths that are consistent with the new experimental data. [This work was performed under the auspices of the U. S. Department of Energy by Lawrence Livermore National Laboratory under Contract No. W-7405-Eng-48.]

2:20

5pPAa5. Gas dynamics of mixtures within sonoluminescence bubbles. Andrew Szeri and Brian Storey (Dept. of Mech. Eng., Univ. of California—Berkeley, Berkeley, CA 94720-1740)

Sonoluminescence experiments are often conducted using mixtures of gases intentionally dissolved in the liquid, and, presumably, resident in the bubble interior. Even when only a single gas is dissolved in the host liquid, vapor is undoubtedly present within the bubble in addition to the intended gas. Hence, all sonoluminescence experiments can be assumed to involve gas mixtures even though the contents of the bubbles cannot be directly assayed. Two constituents of a gas mixture will have differing solubility in the host liquid, which complicates the amount of each species one would expect is resident within a bubble, depending on how the experiment was prepared. Moreover, there is little opportunity for mixing of the bubble contents due to the highly spherically symmetric nature of single-bubble sonoluminescence. Using the methods of computational fluid dynamics, the fate of gas mixtures within a strongly driven bubble is investigated. [Work was supported by a grant from the National Science Foundation.]

5pPAa6. Time-resolved measurements of optical emission from sonoluminescence. D. Froula, R. W. Lee, W. C. Moss, P. E. Young (Lawrence Livermore Natl. Lab.), and T. J. Matula (Univ. of Washington, Seattle, WA 98105)

The results of detailed measurements of sonoluminescence from a gas bubble that is acoustically driven in deionized water are presented. The pulse width and relative jitter of the optical flash and the minimum and ambient radius of the bubble as a function of the driving pressure, temperature, and gas concentration of the water are measured. The optical flash is collected by an f/1.4 lens, and then optically relayed onto the slit of a Hamamatsu C1587 optical streak camera which records the time evolution of the flash with picosecond resolution. Single event streaks are obtained, showing FWHM pulse widths of 200–400 ps, comparable to recently reported results [Gompf *et al.*, Phys. Rev. Lett. **79**, 1405 (1997)]. The jitter of the flash between events has been found to be a minimum of ± 200 ps. Mie scattering has been used to measure the maximum and ambient bubble radius at the same time for comparison to the model [Moss *et al.*, Science **276**, 1398 (1997)]. The consequences of these results on modeling will also be discussed. [This work was performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under Contract No. W-7405-Eng-48.]

3:15

5pPAa7. Single-bubble sonoluminescence: Acoustic emission measurements with a fiber-optic probe hydrophone. Bruno Gompf, Zhaoqiu Wang, Rainer Pecha, Wolfgang Eisenmenger (1. Physikalisches Inst., Univ. of Stuttgart, Pfaffenwaldring 57, D-70550 Stuttgart, Germany), and Ralf Guenther (Natural and Medical Sci. Inst., Eberhardtstr. 29, D-72762 Reutlingen, Germany)

In single-bubble sonoluminescence additionally to the short light pulses, the bubble emits in the collapse phase a sound wave which can be measured with a fiber-optic probe hydrophone [Staudenraus and Eisenmenger, Ultrasonics **31**, 267 (1993)]. This type of hydrophone is an absolute ultrasonic wideband reference standard. Compared to piezoelectric hydrophones it allows measurements with higher spatial (0.1 mm) and temporal (10 ns) resolution. The intensity and the width of the emitted sound wave increase with increasing driving pressure, but vary only slightly with water temperature in contrast to the emitted light intensity. The total radiated energy of the sound wave is below 10% of the initial energy of the bubble. The results are compared with earlier measurements on transient cavitation bubbles and with new theoretical results.

3:30

5pPAa8. Luminescence from spherically and aspherically collapsing laser-induced bubbles. Claus-Dieter Ohl, Olgert Lindau, and Werner Lauterborn (Drittes Physikalisches Institut, Univ. of Göttingen, Bürgerstr. 42-44, D-37073 Göttingen, Germany, ohl@physik3.gwdg.de)

Luminescence from laser-induced cavitation bubbles (SCBL) is investigated experimentally. This experimental technique offers several advantages over the acoustical driving technique for luminescence studies: The optical resolution of the imaging system allows the investigation of the shape of the luminescence spot. This technique facilitates the study of the spherical asymmetries during the bubble collapse phase. Finally, complications due to gas diffusion and Bjerknes forces are avoided. Comparison with theory gives good agreement between the size of the luminescence spot and the observed minimum bubble size for spherical symmetry. A rigid boundary greatly influences the light output; SCBL is only observed for a mildly aspherical bubble collapse.

3:45

5pPAa9. On the theory of supercompression of a gas bubble in a liquid-filled flask. Robert I. Nigmatulin, Iskander Sh. Akhatov, Nelya K. Vakhitova (Ufa (Bashkortostan) Branch of Russian Acad. of Sci., 6 K. Marx St., Ufa, 450000, Russia, iskander@ncan.ufanet.ru), and Richard T. Lahey, Jr. (Rensselaer Polytechnic Inst., Troy, NY 12180-3590)

The spherically symmetric problem of the oscillations of a gas bubble in the center of a spherical flask filled with a compressible liquid that is excited by pressure oscillations on the flask wall is considered. A generalization of the Rayleigh–Plesset equation for a compressible liquid is given in the form of two ordinary difference-differential equations that take into account the pressure waves that are reflected from the bubble and those that are incident on the bubble from the flask wall. The initial value problem for the initiation of bubble oscillations due to flask wall excitation and for the evolution of these oscillations is considered. Linear and nonlinear periodic bubble oscillations are analyzed analytically. Nonlinear resonant and near-resonant solutions for the bubble nonharmonic oscillations, which are excited by harmonic pressure oscillations on the flask wall, are obtained. The influence of heat transfer phenomena on the bubble oscillations is analyzed.

4:00

5pPAa10. Observations of single-bubble sonoluminescence in simulated microgravity and hypergravity. Jeremy E. Young, Nathaniel K. Hicks, A. C. Binner, Susan Richardson, Mark J. Marr-Lyon, and Philip L. Marston (Dept. of Phys., Washington State Univ., Pullman, WA 99164-2814)

Single-bubble sonoluminescence (SBSL) in water occurs when a bubble undergoes highly nonlinear volume oscillations in a sound field. In the presence of gravity, the SBSL bubble experiences a buoyancy force described by $\rho g V(t)$. There is also a Bjerknes force from the sound field. The time average of these two forces balances at the equilibrium location. If the SBSL apparatus is in normal gravity the bubble is displaced from the pressure antinode of the acoustic standing wave [Matula *et al.*, J. Acoust. Soc. Am. **102**, 1522–1524 (1997)]. Because of this displacement, the bubble has a vertical oscillation. One method of exploring the effects of the translational oscillations is to compare the light output of SBSL in microgravity to the light output of SBSL in normal or hypergravity. These were examined by an experiment performed aboard NASA's KC-135A. The airplane performs parabolic maneuvers, giving short periods of microgravity and hypergravity (approximately 0 and 2 g, respectively). The results suggest a correlation of higher light output in microgravity than in hypergravity. [Work supported by Flags Up Feed, Inc., Space Grant Consortium, NASA, and W.S.U.]

4:15

5pPAa11. Analytical results for the conditions of shock formation inside SBSL bubbles. Ralf Guenther (Natural and Medical Sci. Inst., Eberhardstr. 29, D-72762 Reutlingen, Germany)

The mechanism of light emission during single-bubble sonoluminescence is still an unresolved question. Of central importance in this respect is whether a converging shock forms inside the bubble. Using an expansion of the fields inside the bubble, a set of dimensionless equations is derived, which allows exact solutions as well as perturbative treatment during different stages of the bubble collapse. The transition from nonshock to shock solutions is obtained as a function of dimensionless con-

stants characterizing the dynamics. The explicit form of spatial distributions of temperature, velocity, and density is derived and consequences for the light emission are discussed.

4:30

5pPAa12. Shock formation in a sonoluminescing gas bubble. Takeru Yano (Mech. Sci. Dept., Hokkaido Univ., Sapporo, 060 Japan, yano@lebes-me.eng.hokudai.ac.jp)

Whether a shock is formed or not in a sonoluminescing gas bubble is a fundamental problem in the sonoluminescence study. The problem is numerically studied by solving Euler equations of gasdynamics in conjunction with an approximate equation of Keller type for the motion of the bubble radius. A high-resolution TVD upwind finite-difference scheme is used for Euler equations and a fourth-order Runge–Kutta method for a Keller-type equation. The result shows that, owing to the strong nonlinearity of the bubble motion, a slight increase of the driving pressure over a critical value makes the maximum collapse speed of a bubble wall supersonic, and hence the gas behavior changes from a nearly incompressible and adiabatic flow to a compressible one including a shock wave. The relation between the critical driving pressure and other parameters (the driving frequency, the initial bubble radius, etc.) is analyzed. The maximum temperature and pressure attained in the bubble are compared with those in earlier theoretical and numerical works.

4:45

5pPAa13. Thermal wave from a sonoluminescing gas bubble. Yoon-Pyo Lee, Sarng-Woo Karng (Korea Inst. of Sci. and Technol., P.O. Box 131, Cheongryang, Seoul, Korea), and Ho-Young Kwak (Chung-Ang Univ., Seoul, 156-756, Korea)

Heat diffusion from the sonoluminescing gas bubble which produces a high temperature and pressure environment adjacent to the bubble wall was considered by solving the heat diffusion equation numerically. The boundary conditions employed in this calculation are the time-varying bubble wall temperature obtained from the analytical solutions around the collapse point. The thermal boundary layer was found to be decreased rapidly during the collapse as expected. The heat flux at the collapse exceed 3 GW/m^2. After the collapse a solitonlike heat wave, which was generated due to the rapid increase in the bubble wall temperature at/near the collapse for the sonoluminescing gas bubble, was found to propagate through the medium. On the other hand, the liquid temperature near the bubble decreases after the collapse for the nonsonoluminescing case. [Work supported by Korea Science and Engineering Foundation.]

5pPAa14. Effect of quantum radiation pressure on the bubble dynamics in sonoluminescence. Weizhong Chen and Rongjue Wei (Inst. of Acoust. and State Key Lab. of Mod. Acoust., Nanjing Univ., Nanjing 210093, PROC, wzchen@nju.edu.cn)

In the theoretical frame of quantum vacuum radiation (QVR), the effect of the QVR on the gas bubble dynamics in the single bubble sonoluminescence is studied. The dominated hydrodynamic equation of the gas bubble trapped in a liquid, Rayleigh–Plesset equation, has been modified by considering the reaction of the radiation force on the bubble surface and therefore causing a loss of energy. In the modified model the collapse and expansion of the bubble, especially near the turnaround at minimum radius, related to photon emission instead of independence on it. The numerical computation shows that the emission energy due to the QVR seems too low to explain the experimental data, if some present values of parameters, such as the ambient radius of the bubble and the sound pressure in liquid, are used. The radiation energy due to the QVR, however, can arise by changing those parameters. Based on this, it is concluded that the QVR may be a possible candidate for mechanisms of the sonoluminescence. [Work supported by NSF of China.]

5pPAa15. Sonoluminescence: The effect of magnetic fields in the Planck theory. T. V. Prevenslik (2E Greenery Court, Discovery Bay, Hong Kong)

Sonoluminescence (SL) observed in the cavitation of water may be explained by the Planck theory of SL that treats the bubbles as collapsing miniature masers having a Planck energy intrinsic to the dimensions of the maser cavity. Microwaves at frequencies proportional to the collapse velocity are created in the bubble wall molecules as the Planck energy at optical frequencies is absorbed. Because of the interaction between the microwaves and molecular dipole moments, the Planck energy accumulates in the electronic state of polar molecules with a rotation quantum state. As the bubble wall is polarized, intense electrical fields develop to charge the bubble surface molecules to visible photon levels. By this theory, SL can only be observed if the maser walls close to optical dimensions thereby allowing the bubble wall molecules to accumulate Planck energy to the 3–6-eV levels necessary to produce VIS-UV photons. Closure to optical dimensions is assured by imposing a net positive collision pressure. The consistency of the Planck theory of SL was assessed with data on the effects of applied magnetic fields on SL. The net pressure was taken as the difference between the stagnation pressure in bringing the liquid bubble walls to rest and the pressure generated by the magnetic field in the presence of a charged bubble wall. Consistency with the Planck theory of SL is found as the SL intensity with magnetic field is parabolic and the peak SL intensity is linear with collapse velocity.

5pPAb1. Chaotic dynamics in acoustics. Werner H. Lauterborn (Drittes Physikalisches Inst., Univ. of Göttingen, D-37073 Göttingen, Germany)

The theory developed for the description of chaotic and nonlinear dynamical systems also pertains to acoustics. A survey is given of the new ideas and methods that for experimentalists rely on the embedding of experimentally obtained data (time series) into high-dimensional spaces. The embedding is the starting point of nonlinear time series analysis for determining the static (fractal dimensions) and dynamic (Lyapunov exponents) properties of the point sets (attractors) obtained. Acoustical systems that can be investigated with these methods are, for instance, vibrating liquid surfaces (Faraday experiment), vibrating machines, musical instruments, nonlinear oscillators, speech and hearing, bubble dynamics, and acoustic cavitation.

1:25

5pPAb2. Nonlinearities in the bioeffects of ultrasound. Edwin L. Carstensen (Dept. of Elec. Eng. and Rochester Ctr. for Biomed. Ultrasound, Univ. of Rochester, Rochester, NY 14627)

Biological effects of ultrasound involve nonlinear phenomena (1) in the propagation of sound itself, (2) in the generation of acoustic cavitation, and (3) in the biochemistry, physiology, and pathology of the biological system. Most nonthermal bioeffects of interest to users of diagnostic ultrasound require acoustic pressures great enough that the wave can become distorted by nonlinear propagation. Under limiting conditions this process can increase the absorption parameter of weakly absorbing media by orders of magnitude and make the absorption parameter of a material such as water as great as the linear absorption coefficient of liver tissue. At low amplitudes the response of the bubbles is dominated by the acoustic pressure. At a critical acoustic pressure, however, the inertia of the surrounding medium becomes controlling. At this threshold of acoustic pressure a 10% or 20% increase in acoustic pressure leads to an increase in the collapse pressure in the bubble by orders of magnitude. The rates of biochemical processes, including denaturation of biological macromolecules, are exponential functions of the temperature. Whether the physical process of heating by ultrasound is linear or nonlinear, this leads to a very strong nonlinear dependence of thermal tissue damage and teratological effects upon the levels of ultrasound.

5pPAb3. Solitary waves and solitons in acoustics. Nobumasa Sugimoto (Dept. of Mech. Eng., Fac. of Eng. Sci., Univ. of Osaka, Toyonaka, Osaka, 560 Japan)

This study reports on the propagation of acoustic solitary waves and solitons in ordinary air. In theory, it can be predicted by using a long and rigid tube with an array of Helmholtz resonators (or more generally, compact and closed side branches) connected to it with equal axial spacing. In the framework of nonlinear acoustics, the theory exploits three assumptions: (1) a plane wave over the tube, (2) continuum approximation for the array, and (3) negligibly small dissipation. It can be shown that solitary waves are *compressive*, that their speed is *subsonic* but faster than a threshold value determined by the array, and that the solitary waves tend to solitons of Korteweg–de Vries type asymptotically as the speed approaches the threshold. Thus it may be possible to implement a ''soliton tube.'' As the speed approaches the linear speed of sound, the height of the solitary waves becomes greater, approaching the limiting value. Discussions are given on amplification of solitary waves and also on solitary waves in a tube with a double array of resonators.

2:05

5pPAb4. Some consideration of processes of soliton formation from an initially sinusoidal wave form in a thin fiber of fused silica. Akira Nakamura (Dept. of Elect. Eng., Fukui Inst. of Technol., 3-6-1, Gakuen, Fukui, 910 Japan)

Soliton formation processes in a thin fiber of fused silica by computer simulation are discussed. It has already been found that tone-burst sinusoidal sound successively makes solitons from negative half-periods coming in order in the wave train. In this case, the first soliton made from the first negative period is the most stable with respect to the following solitons, because some disturbances caused by preceding positive pressure periods are delayed and superposed with following negative pressure periods. Then, the pressure profiles of these subsequent negative periods are changed. Therefore, nonlinear distortion is affected. In this paper the intention is to discuss the difference of soliton formation processes between two single sinusoidal pulses with preceding negative and positive periods. A preceding negative period makes a stable soliton without any disturbance generated from the following positive pressure part, while the disturbance from the preceding positive period gives change to the pressure profile of following negative period, then nonlinear distortion of this negative period is affected. As a result, frequency spectra of both are differing with the propagation. Discussion is made by operational treatment using a nonlinear distortion operator and linear propagation operator.

5pPAb5. Fast spectral algorithm for modeling focused sound beams in a highly nonlinear regime. Vera A. Khokhlova (Dept. of Acoust., Phys. Faculty, Moscow State Univ., Moscow 119899, Russia, vera@na.phys.msu.su), Michalakis A. Averkiou (ATL Ultrasound, Bothell, WA 98041-3003), Steven J. Younghouse, Mark F. Hamilton (Univ. of Texas at Austin, Austin, TX 78712-1063), and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

Numerical modeling of high-intensity focused sound beams is important for medical applications of ultrasound. The KZK equation, which may be modified to include relaxation in the time domain or arbitrary absorption and dispersion in the frequency domain, is widely used to model ultrasound beams in tissue. Numerical solutions are available in either the time or frequency domain, but they become time consuming at high intensities when thin shocks are developed. To speed up calculations, a known high-frequency asymptotic result for shocks can be incorporated in the frequency domain algorithm. In comparison with exclusively numerical schemes, the present approach substantially reduces the number of harmonics and thus the computation time [Yu. A. Pishchal'nikov, O. A. Sapozhnikov, and V. A. Khokhlova, Acoust. Phys. **42**, 362–367 (1996)]. Focused cw beams radiated from Gaussian and piston sources are simulated in water and biological tissue. The accuracy of the asymptotic approach is verified via conventional numerical methods of solution. It is shown that the present asymptotic method provides accurate results with a considerable reduction in computation time. In combination with conventional numerical schemes, the developed asymptotic method provides an effective tool for investigating focused sound beams for a wide range of parameters. 5pPAb6. Acoustic nonlinearity calculations using the Tait equation of state. Bruce Hartmann, Gilbert F. Lee, and Edward Balizer (Naval Surface Warfare Ctr., West Bethesda, MD 20817-5700)

Beyer's B/A parameter of acoustic nonlinearity was calculated using the Tait equation of state supplemented with specific heat results, in the same manner as done earlier with our equation of state [J. Acoust. Soc. Am. **82**, 614 (1987)]. Calculations were made of sound speed, sound-speed temperature and pressure derivatives, the two components of B/A, and the value of B/A for a series of six n-alkane liquids as well as the limiting case of molten polyethylene. All these results were compared with experimental data from the literature. In addition, a comparison of the results with Ballou's rule (linear relation of B/A versus reciprocal sound speed) was made. Overall, values calculated using the Tait equation are found to agree with experiment about as well as our equation of state, though the pressure derivatives of the sound speed and the final value of B/A are generally not as accurate using the Tait equation. [Work supported by the Naval Surface Warfare Center's In-house Laboratory Independent Research Program.]

5pPAb7. Acoustic streaming near Albunex spheres. Gerard Gormley and Junru Wu (Dept. of Phys., Univ. of Vermont, Burlington, VT 05405)

Acoustic streaming near bubbles in an external standing-wave sound field has been an interesting research topic for decades. It was relatively difficult to visualize the acoustic streaming pattern experimentally, especially for small bubbles due to the instability of the bubbles and difficulties associated with the optical technique. Using Albunex spheres (a contrast agent for ultrasonic imaging), a specially designed microscope device, and a video peak store technique, several acoustic streaming patterns around a single and a pair of Albunex spheres of tens of micrometers radius in a 160-kHz ultrasonic standing wave field have been recorded. Spatial peak pressure amplitude of the standing wave was estimated to be in the order of 0.5 MPa by using optical interferometry. The acoustic streaming velocity was in the range of 50–100 μ/s.

5pPAb8. Acoustical nonlinearity and its images in biomedicine. X. F. Gong, D. Zhang, S. G. Ye, X. Z. Liu, X. Chen, and W. Y. Zhang (Inst. of Acoust., State Key Lab. of Modern Acoust., Nanjing Univ., Nanjing, 210093, PROC)

Some acoustical nonlinear effects in biological media at medical ultrasonic frequencies and intensities were studied experimentally. These phenomena include wave distortion, harmonic generation, energy transformation, extra-attenuation, departure of intensity response curve from linear relation, etc. The influence of these effects on medical ultrasonic diagnosis and therapy was discussed. As a basic parameter in nonlinear acoustics, the acoustical nonlinearity parameter can describe the above-mentioned nonlinear effects and provide some information on the structure and composition of biological tissues. Thus the imaging method of an acoustical nonlinearity parameter using secondary wave detection was developed and investigated. Nonlinearity parameter tomography for normal and a series of pathological porcine tissues was presented. The results obtained in experiments indicate that the difference between normal and diseased tissue in nonlinearity parameter tomography is more sensitive than that in linear parameter tomography. Therefore, nonlinearity parameter tomography may become a novel imaging method for tissue characterization. [Work supported by NSF of China.]

3:35

5pPAb9. Determination of the acoustic nonlinearity parameter B/A using a phase locked ultrasonic interferometer. Jevon R. Davies, Jonathan Tapson (Univ. of Cape Town, Elec. Eng., Private Bag, Rondebosch, 7700, South Africa), and Bruce J. P. Mortimer (Cape Technikon, Cape Town, 8000, South Africa)

The acoustic nonlinearity parameter B/A is an important parameter for characterizing acoustic propagation in fluids. Recent developments in the fields of shock waves and biomedical ultrasonics have necessitated an accurate method for measuring this quantity. This paper presents a new technique based on an ultrasonic interferometer that allows accurate measurements of the change in sound speed within a liquid cavity. The system makes use of a novel continuous wave phase locking principle, which has

the effect of nullifying many of the nonlinearities inherent in the acoustic interferometer. The phase lock circuitry automatically adjusts the frequency so as to keep an exact integer number of waves in the cavity regardless of changes in sound speed. Using this principle, B/A is determined by relating a small change in ambient pressure (less than 2 bar) to a change in frequency under isentropic conditions. B/A values are calculated using this experimental setup for several liquids including two slow sound-speed fluorocarbon liquids, FC-43 and FC-75. These liquids are unique in that they have the lowest range of sound speeds of any organic liquids and in that they have the highest values of B/A recorded thus far.

3:50

5pPAb10. Experimental measurement and numerical modeling of nonlinear propagation in biological fluids. Victor F. Humphrey (Dept. of Phys., Univ. of Bath, Claverton Down, Bath BA2 7AY, UK), Prashant K. Verma (Leicester Royal Infirmary, Leicester LE1 5WW, UK), and Francis A. Duck (Royal United Hospital, Combe Park, Bath BA1 3NG, UK)

The nonlinear pressure fields generated in three biological fluids (amniotic fluid, urine, and a 4.5% human albumin solution) by a circular 2.25-MHz transducer have been investigated experimentally using a flexible measurement facility and compared with numerical predictions. The acoustic field was generated by a single element 38-mm-diameter transducer coupled to a PMMA lens with a focal gain of 12 in water for source pressures from 0.007 to 0.244 MPa. The experimental results illustrate significant harmonic generation in all three fluids which may have safety and imaging implications. In addition, the facility was used to make low level measurements of the acoustic parameters of the fluids, including the frequency dependence of attenuation, at both room and physiological temperature. This data has been used in conjunction with a finite difference model based on the Khokhlov–Zabolotskaya–Kuznetsov equation (the Bergen Code) to model the experiments. The agreement with experiment was found to be generally good, indicating that this type of model may be useful for predicting *in-vivo* pressure distributions given an accurate knowledge of the medium parameters. [Work supported by EPSRC].

4:05

5pPAb11. Asymptotically unified exact solutions of the Khokhlov–Zabolotskaya equation. Yuri N. Makov (Dept. of Phys., Moscow State Univ., Moscow 119899, Russia, makov@acs364.phys.msu.su)

For the large distance traversed by the sonic beam the exact analytical and physically realistic solutions of the Khokhlov–Zabolotskaya (KZ) equation were found for the first time. The procedure of finding these solutions as the self-similar traveling waves identifies their asymptotical generality with respect to the initial arbitrary wave profiles. The resulting solutions consist of the periodically repeating parts of the second-order curvers such as hyperbolas, ellipses, and, in particular, parabolas. The boundaries between these parts are defined with the use of the preserved integrals of the KZ equation. The influence of nonlinearity, diffraction, which is seen in many-dimensional cases, and initial curvature of the phase front of the wave beam on the forming of the typical form of a specific asymptotical wave profile (N shaped or U shaped) was discussed. A comparison was made between analytical solutions with the numerical results for the KZ equation and the experimental data and a full agreement was discovered. These solutions play the same role among all the variations of solutions of the KZ equation, such as the well-known sawtoothlike wave for the equation of the simple waves (Riemann's equation). [Work supported by CRDF.]

5pPP1. Binaural coherence and the localization of sound in rooms. William M. Hartmann, Zachary A. Constan (Phys. and Astron., Michigan State Univ., East Lansing, MI 48824), and Brad Rakerd (Michigan State Univ., East Lansing, MI 48824)

The absorption coefficient of materials tends to decrease with decreasing frequency. Therefore, the ratio of direct to reverberant sound is normally least favorable at low frequency, and binaural coherence tends to be a minimum. However, the ability to localize sounds using interaural time differences (ITD) in the steady-state waveform requires binaural coherence, especially at low frequency. Lateralization experiments, using a forced-choice staircase technique, indicate that adequate localization based on ITD requires binaural coherence of at least 0.2. Measurements of binaural coherence in rooms find that binaural coherence is often less than that, which means that ITD cues can only be used on the transient portions of a signal. By contrast, interaural level differences are perceptually useful at high frequencies and increasingly dominate the localization of steady-state sounds as the environment becomes more reverberant. [Work supported by the NIDCD, Grant No. DC00181.]

5pPP2. Interaural correlation sensitivity. John F. Culling, Matthew Spurchise, and H. Steven Colburn (Dept. of Biomed. Eng., Boston Univ., 44 Cummington St., Boston, MA 02215)

Sensitivity to differences in interaural correlation was measured as a function of reference interaural correlation and frequency (250 to 1500 Hz) for narrow-band-noise stimuli (1.3 ERBs wide) and for the same stimuli spectrally fringed by a broadband correlated noise. d′ was measured for two-interval discriminations between fixed pairs of correlation values, and these measurements were used to generate cumulative d′ versus correlation curves for each stimulus frequency and type. The perceptual cue reported by subjects was perceived as intracranial breadth for narrow-band stimuli (wider image for lower correlation) and loudness of a whistling sound heard at the frequency of the decorrelated band for the fringed stimuli (louder for lower correlation). At low correlations, sensitivity was greater for fringed than for narrow-band stimuli at all frequencies, but at higher correlations, sensitivity was often greater for narrow-band stimuli. For fringed stimuli, cumulative sensitivity was greater at low frequencies than at high frequencies, but listeners produced varied patterns for narrow-band stimuli. The forms of cumulative d′ curves as a function of frequency were interpolated using an eight-parameter fitted function.

Such functions may be used to predict listeners' perceptions of stimuli that vary across frequency in interaural correlation. [Work supported by MRC and NIDCD Grant No. DC00100.]

5pPP3. Modeling the ''effective'' binaural signal processing. Carsten Zerbs (Graduiertenkolleg Psychoakustik, Univ. of Oldenburg, P.O. Box 2503, 26111 Oldenburg, Germany, cz@medi.physik.uni-oldenburg.de), Torsten Dau, and Birger Kollmeier (Univ. of Oldenburg, 26111 Oldenburg, Germany)

This paper describes a quantitative model for binaural processing in the auditory system. To overcome shortcomings of several proposed models, a monaural stage is employed for signal preprocessing [Dau *et al.*, J. Acoust. Soc. Am. **99**, 3615–3622 (1996)], which is able to simulate a large variety of monaural detection data. A binaural processing stage is added following Durlach's EC model which is also a simple functional unit with a small set of constant parameters unit. The decision algorithm for both the monaural and the binaural channel is realized as an optimal detector in the same way as described in the monaural model. In the simulations the whole adaptive measurement procedure with the actual signals is realized. The model describes both monaural as well as binaural thresholds. The typical binaural masking experiments with the following stimulus parameters and their combinations were examined: signal frequency, signal duration, masker bandwidth, interaural masker and signal phase, interaural masker correlation, and delay in simultaneous and forward masking conditions. The model describes the experimental data with an accuracy of a few dB with some exceptions. Model predictions are discussed and compared to the performance of human observers and to predictions of other binaural models.

5pPP4. The influence of masker variability on estimates of monaural and binaural critical bandwidths. Armin Kohlrausch, Steven van de Par, and Jeroen Breebaart (IPO Ctr. for Res. on User–System Interaction, P.O. Box 513, NL-5600 MB Eindhoven, The Netherlands)

If integration bandwidths are derived from band-widening masking experiments, binaural estimates are usually a factor 2 to 3 larger than monaural estimates, at least at high levels. It is proposed that this difference does not reflect ''different critical bandwidths,'' but that it is a consequence of detection statistics. In monaural experiments, the variability in the masker energy limits detectability of the signal. Therefore with increasing subcritical bandwidths, the S/N ratio at threshold decreases. In binaural NoSπ experiments, the S/N ratio at subcritical bandwidths remains constant because the masker correlation is always 1 without uncertainty. Due to this absence of external variability in the masker correlation, detection must be limited by internal noise. Binaural detection in *narrowband* conditions can gain from the spread of excitation across several critical bands, assuming that the internal noises are uncorrelated. The wider binaural critical band is then caused by masking the off-frequency spread through masker components outside the central critical band (for binaural model simulations, see Breebaart *et al.*). In this study it is shown that this scheme also applies to monaural frozen-noise maskers, which do not have external variability. In agreement with results from binaural experiments, the integration bandwidths increase considerably with masker level.

2:00

5pPP5. Modeling spectral integration in binaural signal detection. Jeroen Breebaart, Steven van de Par, and Armin Kohlrausch (IPO Ctr. for Res. on User–System Interaction, P.O. Box 513, NL-5600 MB Eindhoven, The Netherlands)

Estimates of critical bandwidths in binaural experiments vary considerably across experimental conditions. For masking experiments using signals of varying bandwidths (i.e., spectral integration), and experiments with a frequency-dependent interaural masker correlation, bandwidth estimates agree with those from monaural experiments. However, if auditory bandwidths are estimated from binaural band-widening masking experiments, the effective bandwidth is usually a factor of 2 to 3 times larger than monaural estimates. One often ignored detail is that this difference between monaural and binaural estimates decreases with decreasing masker level [Hall *et al.*, J. Acoust. Soc. Am. **73**, 894–898 (1983)]. Using the binaural model described by Breebaart *et al.*, we have simulated the binaural experiments described above. It can be shown that, without any parameter change in the model, basically all relevant conditions can be modeled accurately, including the band-widening and spectral integration experiments. In agreement with the scheme discussed by Kohlrausch *et al.*, detection in binaural narrow-band-noise conditions is improved by analyzing the internal representation in several adjacent filters. It is concluded that the absence of this detection advantage in monaural random-noise conditions is the primary cause for the so-called ''wider binaural critical band.''

2:15

5pPP6. The role of the head related transfer function low-frequency component for sound localization on a median plane. Motoki Yairi, Yasuko Kuroki, Masayuki Morimoto (Environ. Acoust. Lab., Faculty of Eng., Kobe Univ., Nada, Kobe, 657 Japan), and Kazuhiro Iida (AVC Res. Lab. Matsushita Comm. Ind., Saedo, Tsuzuki, Yokohama, Japan)

Asano *et al.* [J. Acoust. Soc. Am. **88**, 159–168 (1990)] demonstrated that localization is not accurate for the simulation of sound sources on the median plane when the low-frequency component of head related transfer functions (HRTFs) are smoothed. In the present localization experiment, the low- and high-frequency components of white-noise stimuli were separated at fc=4.8 kHz (−48 dB/oct.). Those components were independently presented from different directions. Results show that the sound image is localized in the direction from which the high-frequency component is presented, regardless of the direction of low-frequency component, showing that the low-frequency component has no evident effect on the sound localization on a median plane. Based on the results of these two experiments, it is concluded that only the high-frequency component of an HRTF provides spectral cues for sound localization on a median plane. However, changing the low-frequency component of the HRTF, which is unlikely to naturally occur in sound localization on a median plane, may interfere with accurate localization.

2:45

5pPP7. The AUDIS catalog of human HRTFs. Jens Blauert, Marc Brueggen (Ruhr Univ., D-44780 Bochum, Germany, blauert@ika.ruhr-uni-bochum.de), Adelbert W. Bronkhorst, Rob Drullman (TNO NL-3769 ZG Soesterberg), Gerard Reynaud, Lionel Pellieux (Sextant Avionique, F-33166 Saint-Medard-en-Jalles), Winfried Krebber, and Roland Sottek (Head Acoust. GmbH, D-52134, Herzogenrath, Germany)

In the European-Union-funded project AUDIS (AUditory DISplay), a multipurpose auditory display for 3D hearing applications is being developed. The main goal is to develop a special sound generator in combination with an auditory-symbol database that can, for example, be used in the avionic and automotive industry. As the project relies heavily on binaural technology and, hence, on the availability of reliable human HRTF data, a special program for collecting data has been undertaken. In the course of this program, round-robin tests have been performed in four different laboratories. Differences in the data across the different laboratories have been analyzed. The analysis resulted in recommendations for common measuring procedures to be applied. A catalog of HRTFs has then been collected and perceptual verification tests have been performed. It is planned to make the catalog publicly available. In the presentation, the measuring methods applied and the contents of the catalog will be discussed.

3:00

5pPP8. A modeling of distance perception based on an auditory parallax model. Yôiti Suzuki, Shouichi Takane, Hae-Young Kim, and Toshio Sone (Res. Inst. of Elec. Comm., Tohoku Univ., Sendai-shi, 980-8577 Japan)

Distance perception of sound from a source (<5 m) situated close to a listener was studied under the state without information on intensity and reflections using a small movable loudspeaker in an anechoic room. Distance perception in such a condition is modeled by use of the difference in HRTF (head-related transfer function) due to the parallax angle calculated from the difference between directions from each ear to the source. This model is called the ''auditory parallax model'' here. Sound signals to realize this model were digitally synthesized for the listening experiment. In addition, an experiment with an actual sound source and one with HRTF synthesized as precisely as possible were also conducted. The distances obtained for sound with the auditory parallax model and that with synthesized HRTF showed very similar tendencies to those with actual sound sources. That is, in all the three conditions, the perceived distance of a sound image monotonically increased with the physical distance of source for distances up to around 1.2 m. If the presented distance was over 1.2 m, the perceived distance increased lower. These results show that the cues for the distance perception derived by the auditory parallax model is almost sufficient.

3:15

5pPP9. Evidence of spatially tuned auditory analyzers. Russell L. Martin (AOD, AMRL, P.O. Box 4331, Melbourne Australia, 3001) and Ester Klimkeit (Monash Univ., Clayton, Australia, 3168)

The primary-plus-probe uncertainty technique was used to explore the possibility that analyzers tuned to different spatial locations exist within the human auditory system. Eight subjects' psychometric functions for detection of a 500-Hz tone when presented from a speaker located at 0 and 90 degrees azimuth were measured in each of two conditions. In the first, the intermixed condition, subjects knew that 80% of signals would be presented from one location (the primary location) and 20% would be presented from the other (the probe location). In the second, subjects knew that all signals would be presented from either the primary or probe location. For each subject the primary location was 0 degrees for half the sessions and 90 degrees for the others. Each function was measured using a two-interval forced-choice task and five signal levels ranging from 7.5 dB above to 4.5 dB below the subject's previously estimated threshold. For primary location signals, average functions for the two conditions were indistinguishable. For probe location signals, however, functions differed, reflecting significantly poorer detection performance in the intermixed condition [$F(1,7)=3D22.38$, $p<0.01$]. This uncertainty effect provides support for the notion that spatially tuned analyzers exist within the auditory system.

3:30

5pPP10. Detection of Doppler-like signals. Mark A. Ericson and Lawrence L. Feth (The Ohio State Univ., Dept. of Speech and Hearing Sci., Columbus, OH 43221)

Moving sounds induce a Doppler shift of frequency in direct proportion to a sound source's velocity. Concurrent with the frequency change is a change in intensity related to the source's velocity and distance from the listener. These simultaneous changes in frequency and intensity may be audible for any moving sound source. Jorasz and Dooley [Arch. Acoust. **21**, 149–157 (1996)] modeled the physical effects of constant velocity motion on a sound source's frequency and intensity as observed at a single point in space. Three linear trajectories of a sound source were simulated over headphones for different minimal distances between the moving sound source and observer. These minimal distances were 1, 10, and 100 m. An adaptive tracking procedure was used to determine detection thresholds for velocity induced changes in frequency and intensity. Intensity and frequency were varied independently as well as together. A series of experiments was conducted to test a perceptual model of these Doppler effects.

5pSA1. Measurement and analysis of the structure-borne sound of a fan installation: Evaluation of source signal filtering techniques and rotational degrees of freedom. Michael A. Sanderson, Lars Ivarsson (Dept. of Appl. Acoust., Chalmers Univ. of Technol., 412 96 Gothenburg, Sweden, mike@ta.chalmers.se), and Andrej G. Troshin (Krylov Shipbuilding Res. Inst., St. Petersburg, Russia)

The structure-borne sound characteristics of a commonly found fan installation were examined through measurements and further analyses in the frequency range up to 500 Hz. The focus was to determine the prediction improvements by including the rotational degrees of freedom. Free velocities of the fan were measured in five degrees of freedom (in-plane rotation or twisting motion were neglected), while fan mobilities were measured and foundation mobilities were predicted in three degrees of freedom: a translational and two rotational, those resulting in bending motion. The two in-plane translations were considered by transforming their motion to rotations resulting in moment excitations on the foundation. Measurements were also made of the corresponding isolators' stiffness values. Comparisons are made with power measurements of the complete system. It was found that an unsatisfactory moment excitation resulted in one of the rotational degrees of freedom while employing a twin shaker arrangement when determining the fans' mobilities. Therefore, a source signal filtering technique was applied to improve the mea-

surement. Comparisons are made with the originally measured mobilities. [This work has been supported by the Swedish Council for Building Research (BFR) through Contract 950192-8 and the Swedish Research Council for Engineering Sciences (TFR) through Contract 95-160.]

5pSA2. Modeling the vibration behavior of an induction motor. Chong Wang and Joseph C. S. Lai (Acoust. and Vib. Unit, Univ. College, Univ. of New South Wales, Australian Defence Force Acad., Canberra, ACT 2600, Australia, c-wang@adfa.oz.au)

With the advent of power electronics, variable speed induction motors are finding increased use in industries because of their low cost and savings in energy usage. However, the acoustic noise emitted by the motor increases due to switching harmonics introduced by the electronic inverters. Consequently, the vibro-acoustic behavior of the motor structure has attracted more attention. In this paper, considerations given to modeling the vibration behavior of a 2.2-kW induction motor will be discussed. By comparing the calculated natural frequencies and the mode shapes with the results obtained from experimental modal testing, the effects of the teeth of the stator, windings, outer casing, slots, endshields, and support on the overall vibration behavior are analyzed. The results show that when modeling the vibration behavior of a motor structure, the laminated stator should be treated as an orthotropic structure, and the teeth of the stator could be neglected. As the outer casing, endshields, and the support all affect the vibration properties of the whole structure, these substructures should be incorporated in the model to improve the accuracy.

1:40

5pSA3. Model-based shaping of vibroacoustic properties of gears. Stanislaw Radkowski (Vibroacoustic Lab. IPBM PW, 02-524 Poland, Warszawa, Narbutta 84)

The work undertakes an issue of estimating and predicting the level and structure of the vibroacoustic signal generated by a pair of toothed wheels and propagated by the structure of the gear's housing. Assuming that the basic role in transmission of such diagnostic information is played by the phenomena of amplitude and phase modulation of the vibroacoustic signal, it is pointed to the significance of the signal's nonlinear components. For that reason in this work a model of a signal in the form of a Volterra series is assumed, which enables examination of the influence that disturb nonlinear components. On the basis of exemplary analysis of the contact conditions disturbances, the possibility of the generation of a bilinear component is presented. What serves this purpose is the model of nonlinear and instantaneous contact. Simultaneously problems of selection of signal analysis methods that enable realization of assumed aims are presented. Emphasizing the fact that defect development does not always lead to a significant growth of the vibroacoustic signal's power, the importance of methods of higher-order spectral analysis like bispectrum and bicepstrum has been shown.

2:00

5pSA4. Experimental identification of mechanical joint dynamic properties. Olivier Chiello, Franck C. Sgard (LASH, DGCB URA CNRS 1652, ENTPE—Rue Maurice Audin, 69518 Vaulx-en-Velin, Cedex, France, olivier.chiello@entpe.fr), and Noureddine Atalla (GAUS, Univ. de Sherbrooke, QC J1K 2R1, Canada)

Large structures are often composed of substructures connected through mechanical joints. The dynamic behavior of these joints is generally difficult to characterize. In this paper, a method for identifying dynamic joint characteristics is presented. Joint properties are extracted directly from measured frequency responses of the assembled structure. Measurement points are not taken on the interface between the structure components. This feature is of practical importance since it is often difficult to directly attach a transducer on the joint. The method only requires the knowledge of the frequency responses of the substructures taken separately. These responses can be either measured, analytically calculated, or simulated by FEM. The presented approach allows for the determination of the joint properties as a function of frequency. The joint properties extracted from one assembled structure can be used to predict the behavior of another structure assembled with the same joint condition. The applicability of the proposed method is investigated by numerical simulations. Errors in simulated frequency responses are introduced to investigate the robustness of the method. It is shown that the accuracy of the identified results is good.

2:20

5pSA5. The vibroacoustical analysis of the teeming crane. Jerzy W. Wiciak, Ryszard J. Panuszka, and Marek A. Iwaniec (Structural Acoust. and Intelligent Mater. Group, Tech. Univ. of Mining and Metallurgy, Al. Mickiewicza 30, 30-059 Cracow, Poland)

The present article considers the vibration analysis of the teeming crane (lifting capacity $Q=160$ tons) and noise caused by working units of the crane. The vibroacoustical investigations and theoretical analysis have been applied to the main bridge with box-trapezoid cross section. In the article there is shown a comparison of the vibration acceleration and dynamic stress that have been measured in real structure with calculations obtained by means of the finite element method. The correct and incorrect (two-stage) reduction roll gear running also was considered. The significant influence of the incorrect reduction roll gear running on the dynamic parameters was noticed. The noise caused by working units of the crane has been presented for three operating conditions: when the tilting ladle was descending, when it was hoisting, and pass-by load running of the teeming crane. [Work supported by TUMM, Cracow, Poland.]

2:40

5pSA6. Metal and composite aircraft panels: Selection of parameters optimal from the viewpoint of acoustic fatigue lifetime. Nikolay I. Baranov, Sergey N. Baranov, Lev S. Kuravsky, and Konstantin P. Zhukov (''RusAvia'' Res. Group, Mikoyan Design Bureau, 6 Leningradskoe Shosse, 125190 Moscow, Russia)

Optimization techniques to ensure synthesis of stiffened and laminated composite panels subjected to acoustic excitation are presented. The criteria for optimization are established to balance the structure weight and fatigue life. Test spectrum of loading pressure fluctuations is in use, with the parameters of pressure correlation ensuring the greatest response. For stiffened structures, stress spectra and corresponding root-mean-square values in points of maximum response are computed by means of special software to draw the special final diagrams that connect nondimensional structure parameters and optimization criteria. These diagrams are then used to select optimal parameters of reinforcement. For composite structures, correlation of the nondimensional parameters representing structure stress level, acoustic load level, dominant frequency of vibration, and panel anisotropy is computed by the same technique. The functions computed are later used to estimate how the criterion for optimization depends on the number of layers, lay-up sequence, and the directions of fibers. The approach proposed allows aerospace designers to select and motivate their decisions having increased confidence in the development and modifications of these structures.

Session 5pSC

Speech Communication: Segmental Phonetics, L2, and Cross Language Studies (Poster Session)

5pSC1. Do nasalized fricatives exist? John J. Ohala (Dept. of Linguist., Univ. of California at Berkeley, 2337 Dwinelle Hall #2650, Berkeley, CA), Maria-Josep Sole (Univ. Autonoma de Barcelona, 08193 Bellaterra, Barcelona, Spain), and Goangshiuan S. Ying (Univ. of California at Berkeley, Berkeley, CA)

It has been claimed that nasalized fricatives, even sibilant fricatives, exist in some languages. To assess this claim we sought to discover how much velopharyngeal opening can be present before the acoustic and auditory characteristics of fricatives are affected. Two trained phoneticians produced steady-state voiced and voiceless strong and weak fricatives. The back pressure was intermittently bled with a tube of varying diameter (and thus impedance) inserted into the speaker's mouth via the buccal sulcus and the gap behind the back molars, simulating nasal leakage. Intraoral pressure (Po) was sampled via a catheter inserted into the pharynx through the nose. The changes in amplitude and quality of frication were analyzed acoustically. We found that (1) a vent area of about 18 mm^2 caused auditorily and acoustically noticeable lessening of fricative energy, e.g., sibilants sounded more like nonsibilants, (2) for a given vent aperture, Po was diminished less for voiceless than voiced fricatives (because the voiced fricatives have higher upstream impedance at the glottis) and consequently the same vent aperture impaired the amplitude and quality of frication of voiced fricatives more than voiceless ones. Thus the aerodynamic requirements for fricatives seem to be relatively narrow and unforgiving. [Research supported by Committee on Research, UCB, and by DGICYT, Spain, PB 96-1158.]

5pSC2. Aerodynamic characteristics of trills. Maria-Josep Sole (Dept. of English, Univ. Autonoma de Barcelona, 08193 Bellaterra, Barcelona, Spain, sole@cc.uab.es), John J. Ohala, and S. Goangshiuan Ying (Univ. of California at Berkeley, Berkeley, CA 94720-2650)

What are the aerodynamic conditions required for trills? To find out we had two subjects produce steady-state voiced, voiceless, and ejective alveolar trills. The backpressure during trills was intermittently bled with a tube of varying diameter (and thus impedance) inserted in the speaker's mouth via the buccal sulcus and gap behind the back molars. Intraoral pressure was measured via a catheter inserted into the pharynx through the nose. The variation, impairment, or extinction of trilling as a function of gradual decrease in intraoral pressure was analyzed acoustically. It was found that (1) bleeding the oro-pharyngeal pressure by 2 cm H_2O impaired sustained trilling; (2) the minimum Po required to sustain tongue-tip vibration is lower than that required to initiate it; (3) extinction (and reinitiation) of trilling generally results in a fricative; (4) the range of Po variation for trills is narrower than that for fricatives; (5) voiceless and ejective trills are significantly less affected by venting the backpressure than voiced trills. The behavior of trills in varying aerodynamic conditions accounts for observed phonological patterns: final trill devoicing, alternation between trills and fricatives, co-occurrence of trilling and frication, and limited distribution of trills. [Work supported by DGICYT, Spain, PB 96-1158, and by Committee on Research, UCB.]

5pSC3. Motor equivalence in the production of /ʃ/. Joseph S. Perkell, Melanie L. Matthies, and Majid Zandipour (Speech Commun. Group, R.L.E., MIT, Rm. 36-511, 50 Vassar St., Cambridge, MA 02139)

To explore the idea that speech motor goals are acoustic targets, upper lip protrusion and tongue blade fronting were examined in the sibilant /ʃ/ for evidence of motor equivalence in eight speakers of American English. Positive correlations across multiple repetitions of /ʃ/ (motor equivalence) would occur if the upper lip compensated with more protrusion when the tongue blade was further forward and vice versa. This motor equivalence would serve to maintain an adequate front cavity size for good acoustic separation from /s/ and enhance the acoustic stability of /ʃ/. It was hypothesized that motor equivalence would be found among less prototypical tokens, as elicited in a ''clear+fast'' speaking condition. Acoustic spectral analyses indicated excellent acoustic separation between the two sibilants, even in the ''clear+fast'' condition. There were significant positive correlations of the tongue-blade and upper lip movements for 28% of all possible cases, with considerable individual variation. When motor equivalence could be compared across the speaking condition, the tokens produced with the motor equivalent pattern were acoustically less prototypical. No occurrences of negative movement correlations were found. One possible source of individual variation may be the use of saturation (quantal) effects, which could also enhance acoustic stability. [Work supported by NIH.]

5pSC4. Further results on the perception of place coarticulation in Taiwanese stops. Shu-hui Peng and Terrance Nearey (Dept. of Linguist., Univ. of Alberta, 4-32 Assiniboia Hall, Edmonton, AB T6G 2E7, Canada, speng@gpu.srv.ualberta.ca.)

Previous study of place coarticulation using logistic discrimination [Peng and Nearey, J. Acoust. Soc. Am. **101**, 3110(A) (1997)] showed that 87% of Taiwanese word-final dental or velar stops in stop consonant clusters [CVstop1-stop2V(C)] spoken in various speech rates were correctly classified based on formant transitions from the preceding vowel. This automatic classification was sigificantly (though only moderately) correlated with categorization by Taiwanese speakers in a concept formation test. An earlier study [Peng (1996)] also showed that there was not a consistent correlation between Taiwanese listeners' categorization of the stops and patterns of gestural overlapping shown in EPG measurements. To avoid complication involving listeners' difficulty with the concept formation task and the influence of native speakers' lexical knowledge, the present study examined the perception of the stops by phonetically trained

listeners in a different experimental paradigm. Listeners were asked to identify the consonant clusters (tt, kk, tk, kt) from the excised first word in a four-way forced choice identification test. The phonetic judgments of these listeners will be compared with the categorization by Taiwanese speakers, the results of discriminant analysis, and EPG measurements.

5pSC5. Ejectives in Tanana Athabaskan. Siri G. Tuttle (Univ. of Washington, Dept. of Linguist., Box 354340, Seattle, WA 98195, iris@u.washington.edu)

Ejectives in Athabaskan languages have been investigated phonetically by Lindau (1984), McDonough and Ladefoged (1993), in Navajo, and by Davis and Hargus (1994, 1996) in Babine/Witsuwit'en. In the latter two investigations, three different types of production were found associated with glottal consonants, only one of which showed the classic ejective pattern with a silent period. Examination of samples of Tanana Athabaskan recorded in 1961, 1962, 1974, and the early 1990s found similar variation in samples of this Alaskan Athabaskan language. There appeared, however, to be no examples of ejectives without silent periods in the oldest samples (1961 and 1962). This suggests the hypothesis that the ejective without silent period is an innovation in the last generation of Tanana speakers. Recordings analyzed include a set of standardized word lists recorded by McKennan in 1962 with speakers of Minto, Chena, and Salcha dialects; texts of Teddy Charlie (Minto) recorded by Michael Krauss in 1962; and 3keywords2 recordings of Isabel Charlie (Minto) and Eva Moffit (Salcha) recorded by James Kari and Siri Tuttle in 1991. [This work has been supported by NSF.]

5pSC6. Perception of synthesized Hindi geminate and cluster sounds. Nisheeth Shrotriya and Shyam S. Agrawal (Speech Technol. Group, CEERI Ctr., CSIR Complex, Hillside Rd., New Delhi-12, India)

This paper describes the various differences in acoustic parameters of geminate, nongeminate, and cluster sounds of Hindi, which can be used for their perceptual distinction. Words containing these sounds were synthesized using a PC-based Klatt synthesizer, which uses a set of about 60 parameters. For distinction between geminate and nongeminate sounds, the parameters such as duration of the plosive gap and preceding vowel, and the formant frequencies and intensity of the burst are important but the closure duration plays the most significant role. This difference is of the order of 1:1.5. However, if the closure duration is reduced to 50% or less, the unvoiced sounds are perceived as voiced sounds. In the case of the cluster (-C1C2-) words containing stop consonants, when C1 and C2 have the different places of articulation, a burst is observed in the middle of the closure. It was found that this burst has no perceptual effect when it was moved to the left and right positions adjacent to the vowels. Even the removal of the burst has no perceptual effect.

5pSC7. Integration of acoustic cues in Spanish voiced stops. Sergio Feijóo, Santiago Fernández, and Ramón Balsa (Dpto. Física Aplicada, Fac. de Física, 15706, Santiago, Spain, fasergio@uscmail.usc.es)

In Spanish, voiced stops in initial position usually show the presence of a voice bar before the release burst. In this study, the perception of word-initial voiced stops when the voice bar is removed is examined. Nine men and nine women pronounced 15 Spanish words in which the initial consonant was /b/, /d/, or /g/ in combination with the vowels /a/, /e/, /i/, /o/, /u/. Seventeen subjects with normal hearing heard the stops in two conditions: (1) whole voice bar + 102.4 ms of signal from burst onset; (2) 102.4 ms from burst onset. In condition (2), tokens were perceived as the correct stop, as its voiceless counterpart, or as an ambiguous signal. Removing the voice bar caused 37% of /b/ tokens to be classified as /p/; 41% of /d/s to be classified as /t/s ; and 19% of /g/s to be classified as /k/s. The change in voicing characteristics was significantly more marked for women. The results indicate that the integration of the voice bar with the burst and the vowel plays a relevant role in the perception of voicing in voiced stops, especially in women's speech, smoothing the dynamic frequency characteristics of burst and vowel.

5pSC8. Acoustic properties of English fricatives. Allard Jongman, Joan Sereno, Ratree Wayland, and Serena Wong (Cornell Phonet. Lab., Dept. of Modern Lang., Cornell Univ., Ithaca, NY 14853)

A fundamental issue in speech research concerns whether distinctions in terms of place of articulation are more succesfully captured by local (static) or global (and/or dynamic) properties of the speech signal. While most studies of place of articulation have investigated stop consonants, it is uncertain whether these properties can successfully classify fricatives. In the present study, both static and dynamic metrics were used to investigate place of articulation in fricatives. Static metrics include spectral peak location, noise duration, and noise amplitude; dynamic metrics include relative amplitude, locus equations, and spectral moments. Twenty speakers produced the fricatives /f, v, θ, ð, s, z, ʃ, ʒ/ followed by the vowels /i, e, æ, ɑ, o, u/. Preliminary results based on ANOVA and discriminant analysis suggest that all metrics could distinguish nonsibilant /f, v, θ, ð/ from sibilant /s, z, ʃ, ʒ/. In addition, spectral moments separated /s, z/ from /ʃ, ʒ/ with about 95% accuracy and /f, v/ from /θ, ð/ with about 65% accuracy while locus equations only served to separate labiodental /f, v/ from all other fricatives. Accuracy of the metrics will also be compared to human perception data. [Work supported by NIH.]

5pSC9. Role of *F*1 in the perception of voice offset time as a cue for preaspiration. Jörgen Pind (Dept. of Psych., Univ. of Iceland, Oddi, IS-101 Reykjavík, Iceland, jorgen@rhi.hi.is)

Preaspiration, an [h]-like sound inserted between a vowel and a following stop consonant, can be cued by voice offset time (VOffT), a speech cue which is a mirror image of voice onset time (VOT). Previous research has shown VOffT to be an effective cue for preaspiration and also that the perception of VOffT differs from the perception of VOT in that the former cue is much more sensitive to the duration of a preceding vowel than is VOT to the duration of a following vowel [J. Pind, Q. J. Exp. Psychol. 49A, 745–764 (1996)]. The hypothesis has been put forward that this is due to the fact that preaspiration in Icelandic follows a phonemically short vowel, whereas aspiration can precede either a long or a short vowel. Vowel quantity will therefore affect phoneme boundaries for VOffT, not for VOT. This hypothesis was confirmed in experiments where vowel spectra were used to manipulate quantity rather than vowel duration. The present paper reports experiments investigating whether this effect could possibly be mediated through the effect of *F*1 on perceived voicing. [Supported by Icelandic Science Foundation and University of Iceland.]

5pSC10. Vowel and consonant durations as cues for quantity in Icelandic. Jörgen Pind (Dept. of Psych., Univ. of Iceland, Oddi, IS-101 Reykjavík, Iceland, jorgen@rhi.hi.is)

Icelandic distinguishes short and long consonants and vowels in stressed syllables. Phonologically, these show complementary quantity in that a short vowel is followed by a long consonant and vice versa. Perceptual experiments have shown that the ratio of vowel to consonant duration is the major cue for quantity, although the vowel spectrum can override the relational cue in those cases where there is a marked difference in the spectral character of the long and short vowels [J. Pind, Scand. J. Psychol. **37**, 121–131 (1996)]. Measurements will be reported of vowel and consonant durations in stressed syllables in words spoken repeatedly in sentence frames and in longer connected texts. The utterances were read at different speaking rates. Two questions are of major interest in this study: (1) To what extent do vowel and consonant durations in different environments support a relational cue for quantity? and (2) Is the dura-

tional cue weaker in those cases where the spectra of short and long vowels provide another cue for quantity? [Work supported by the Icelandic Science Foundation and University of Iceland.]

5pSC11. Timing effects on successive alveolar consonants in Swedish. Robert Bannert and Peter E. Czigler (Dept. of Phonet., Umeå Univ., S-90187 Umeå, Sweden)

The duration of a consonant is potentially affected by various factors related to the phonetic nature of the segment and its phonetic environment. The present study addresses the concurrent effects of prominence, syllable structure, and manner of articulation in intervocalic /s/+alveolar consonant /t, n, l/, and alveolar consonant+/s/ clusters in Swedish. Six real words, imbedded in a carrier sentence, were repeated five times with, and five times without, focal accent by ten native speakers of standard Swedish. Results show that the duration of a cluster, and the duration of its constituent consonants, are longer with focal accent than without focal accent. Consonant clusters with /s/ as the first member do not differ in duration from consonant clusters with /s/ as the second member. Clusters containing an alveolar stop are shorter than clusters with an alveolar nasal or alveolar liquid. The duration of /s/ is always longer than the duration of any adjacent alveolar stop, nasal or liquid. A number of interactions was found between prominence, cluster structure, and manner of articulation, indicating clear differences between the patterns of cluster internal timing for the investigated cluster pairs. These differences will be presented, compared with data on American English, and discussed.

5pSC12. Acoustic and perceptual effects of vowel length on voice onset time in Thai stops. Chutamanee Onsuwan and Patrice S. Beddor (Prog. in Linguist., Univ. of Michigan, Ann Arbor, MI 48109, beddor@umich.edu)

In Thai, vowel length (e.g., [pan]-[paan]) and unaspirated–aspirated stop (e.g., [pan]-[p^han]) distinctions are contrastive; this study examines possible acoustic and perceptual interactions between these temporal properties. VOT and vowel duration were measured for five repetitions of 40 (near-) minimal word pairs beginning with aspirated or unaspirated bilabial, alveolar, or velar stops followed by long or short vowels, produced by three native Thai speakers. Although VOT for velars was slightly longer (about 5 ms) before long than before short vowels, the overall acoustic picture across places of articulation showed no systematic effect of vowel length. To test for perceptual influences of contrastive vowel length on VOT, a 15-step 0–90 ms VOT continuum was created by editing the aspiration portion of naturally produced [p^haan]. The VOT continuum was spliced onto the vowel portion of four different natural tokens, [pan], [paan], [p^han], and [p^haan], creating four continua, two with long vowels and two with short. Identification tests were presented to 18 native Thai listeners. Responses to the continua created from the originally unaspirated tokens ([pan], [paan]) showed robust effects of vowel length: the long vowel continuum elicited more aspirated ([p^h]) responses. A compensatory account of the perceptual findings is offered. [Work supported by NSF.]

5pSC13. Perception of glottalized consonants in Babine/Witsuwit'en. Katharine Davis and Sharon Hargus (Dept. of Linguist., Univ. of Washington, Box 354340, Seattle, WA 98195-4340)

Previous studies of Babine/Witsuwit'en have shown speaker differences in the production of glottalized stops [Davis and Hargus, J. Acoust. Soc. Am. **100**, 2690 (1996)]. The present study investigates native listeners' perception of the glottal/nonglottal contrast. Ten subjects were presented with 16 naturally produced minimal pairs contrasting glottalized and voiceless unaspirated stops or affricates. These tokens, interspersed with 18 control minimal pairs, were presented in random order. Listeners' judgments were recorded on a forced-choice answer sheet. The task was performed twice, once with a male voice and once with a female voice. Subjects showed greater confusion when identifying members of the glottal/nonglottal contrast than when identifying members of the control contrasts (84% correct versus 93% correct). Among control items, voiceless unaspirated and voiceless aspirated pairs were correctly distinguished 97% of the time. ANOVA results considering all experimental factors (subject, speaker, place of articulation, etc.) will be presented. In addition, acoustic analyses of correctly identified versus confused glottal/nonglottal pairs will be presented. Particular attention will be paid to significant factors (VOT, *F*0) from earlier production studies.

5pSC14. A perceptual experiment on Thai consonant types and tones. Rungpat Roengpitya (Univ. of California, Berkeley)

Tonogenesis in Thai arose historically from neutralization of voicing contrast prevocalic consonants: new higher tonal variants after what had been voiceless consonants and new lower variants after the earlier voiced consonants. Today, Thai has again acquired a series of voiced stops and the same allophonic variation in *F*0 may be observed on the tones following voiced and voiceless stops. How important are these *F*0 cues to Thai listeners? Can one stage of the tonal multiplication process that shaped Thai tonal systems be demonstrated in the lab? A perceptual experiment was conducted. Six pairs of Thai words with voiced and voiceless initial stops were recorded, spliced at six different points of time, and put into contexts. These tokens were played to 11 native-Thai subjects for judgment as voiced or voiceless. The result showed that listeners tended to identify those syllables with gated-out bursts and closures as voiceless. However, there was a significant success at differentiating voiced and voiceless stops at gates past these points. It remains to be determined whether the cues that facilitate this are *F*0, vowel amplitude, or voice quality. If *F*0 plays a role, then this result mirrors the rise of distinctive tones in the Thai history.

5pSC15. The nasal vowels of Iberian Portuguese. Maria Joao C. Galvao (Univ. of Washington, Dept of Linguist., Box# 354340, Seattle, WA 98195-4340, mgalvao@u.washington.edu)

Previous analysis [Mateus, ''Aspectos da Fonologia Portuguesa'' (1982)] of Iberian Portuguese nasal vowels has suggested that there are three degrees of nasality, predictable from syllable structure and from the presence or absence of an underlying nasal consonant following the nasal vowel. This study addresses the question of whether vowel quality affects the degree of phonetic nasality in Portuguese. Nasalance measurements of seven native speakers of Portuguese were obtained via a Kay Nasometer 6200, while spectrographic analysis was provided by a Kay CSL 4300B. The present analysis confirms that a trace of the nasal consonant is phonetically present which provides a peak target for the nasal vowel, but the degree of nasality of the vowel itself is solely determined by vowel height: as occurs in other languages with nasal vowels, high vowels have a more constricted oral air passage and hence higher nasalance percentage.

5pSC16. EMG evidence for the automaticity of intrinsic *F*0 of vowels. D. H. Whalen, Bryan Gick, Masanobu Kumada (Haskins Labs., 270 Crown St., New Haven, CT 06511), and Kiyoshi Honda (ATR Human Information Processing Res. Labs, 2-2 Hikaridai Seika-cho Soraku-gun, Kyoto, 619-02 Japan)

Although vowels can be produced with many *F*0 values, high vowels' *F*0s tend to be higher than low vowels', a tendency found for every language examined. Nonetheless, this ''intrinsic *F*0'' (or *IF*0) has been called a deliberate ''enhancement'' of the speech signal, aiding vowel height perception. Since *IF*0 remains constant with the number of vowels in a language, this enhancement seems unlikely. The only positive evidence for it is that activity of the cricothyroid (CT) muscle, which primarily raises *F*0, is larger for high vowels than for low. The present experiment explores this by having subjects produce vowels at slightly different *F*0s, with the differences being similar to the *IF*0 magnitude for each

subject. The first subject (of four planned) showed no vowel height difference in CT; further, an analysis factoring out $F0$ as a covariate showed that high vowels had higher CT activation. Thus different vowels involve different levels of CT activity for a given $F0$; previous findings were likely due not to $F0$ control but to $F0$/vowel quality interactions. Even the EMG evidence, then, renders $IF0$ an unlikely speech enhancement. Rather, $IF0$ appears to be an automatic consequence of vowel production. [Supported by NIH Grant DC-02717.]

5pSC17. Interacting spectral and temporal properties in Jamaican Creole and Jamaican English vowel production. Alicia Beckford (Program in Linguist., Univ. of Michigan, 1076 Frieze Bldg., Ann Arbor, MI 48109-1285)

The vowel system of Jamaican Creole has been described as exploiting a contrastive length distinction, wherein long vowels and falling diphthongs contrast with single vowels in identical phonological environments [Wells (1973); Mead (1996)]. For example, /pan/ on, pan, can /tan/ stand /pen/ pen /paan/ to grasp /taan/ turn /pien/ pain. However, the nature of the relative contributions of spectral and temporal differences remains unclear. The interactions between spectral ($F1/F2$) and temporal properties, and their roles in shaping a three-dimensional vowel space ($F1\times F2\times$length) were examined in an acoustic study of the vowel production of 24 speakers at different points along the creole continuum from Jamaican Creole to Jamaican English. Data suggest that Jamaican Creole and Jamaican English speakers utilize vowel duration differently. It will be demonstrated in this paper that, for the Creole speakers, vowel duration functions to enhance slight spectral distinctions among low central and upper-mid-back vowels /a,o,u/. [Mead, ''On the phonology and orthography of Jamaican Creole,'' J. Pidgin Creole Languages (1996); Wells, *Jamaican Pronunciation in London* (Blackwell, London, 1973).]

5pSC18. The effect of $F3$ on the /ʊ–ɪ/ boundary. Matthew R. Buehler and Anna K. Nábělek (Dept. of Audiol. and Speech Pathol., Univ. of Tennessee at Knoxville, 457 S. Stadium Hall, Knoxville, TN 37996)

Boundary locations (50% response points of identification) were tested for /ʊ–ɪ/ continua for two different values of $F3$. All formants were steady-state. $F1=250$ Hz, $F2$ was varied in 20 steps from 1000 to 2000 Hz, and $F3=2500$ or 3000 Hz. All stimuli were 200-ms long. The boundaries for the two continua were determined with ten subjects. The boundary for $F3=2500$ Hz was 1652 Hz and for $F3=3000$ Hz was 1526 Hz. The difference between the boundaries was significant. These results indicate that $F3$ can affect the perception of $F2$. When $F3$ was increased the stimuli were identified as /ɪ/ at a significantly decreased value of $F2$.

5pSC19. The effect of transition slope and transition duration on vowel reduction in V_1V_2 complexes. Pierre L. Divenyi (Experimental Audiol. Res. (151), V. A. Medical Ctr., Martinez, CA 94553) and René Carré (Ecole Nationale Supérieure de Télécommunications, Paris, France)

Digital V_1V_2 vowel pairs were generated using a cascade-parallel formant synthesizer. The duration of V_1 was 100 ms and that of a completed V_2 150 ms, while the duration of the transition was varied between 40 and 100 ms, depending on the condition. For each of six English V_1V_2 pairs (/iɑ/, /ɑi/, /iu/, /ui/, /uɑ/, and /ɑu/) 8–12 tokens were obtained by progressively cutting back the V_2 portion and the vowel transition in 10-ms steps. Separately for each vowel pair, the cut-back tokens were presented to trained listeners who had to indicate their confidence level (using a 4-point scale) that the final portion of the token was, indeed, the vowel V_2. Since high-confidence V_2 responses were given not only to tokens that actually reached V_2, we observed vowel reduction; the degree of vowel reduction (VR) was measured as the severity of the cut-back at which such a misperception occurred at a certain percent of the time. Using this measure, we determined the degree of VR for different durations and velocities of transition. In general, VR was larger for steeper transition slopes and for durations around 80–100 ms. [Work supported by NATO Office of Scientific Research, a grant from N.I.H., and the V.A. Medical Research.]

5pSC20. Acoustic correlates of ''devoiced'' vowels in standard modern Japanese. J. Kevin Varden (Meiji Gakuin Univ., Dept. of English, Meiji Gakuin Univ., 1-2-37 Shirokane-dai, Minato-ku, Tokyo, 108 Japan, varden@ltr.meijigakuin.ac.jp)

This paper documents the acoustic characteristics of what have been called devoiced vowels in Tokyo Japanese, traditionally attributed to the phonological rule of high vowel devoicing [T. J. Vance, Introduction to Japanese Phonology (1987)]. More recently they have been attributed to articulatory gesture overlap [S-A. Jun and M. E. Beckman, Paper, Annual Meeting of the LSA (1993)]. Current research by the author indicates both processes are consistent with the data. The vowels which have undergone phonological processing, however, are not simply devoiced; they have undergone a process of obstruentization similar to that found in the Turkish language of Uyghur discussed both pedologically [R. F. Hahn, Spoken Uyghur (1991)] and phonologically [E. M. Kaisse, Language **68**, 313–332 (1992)]. Specifically, the vowel sites surface as voiceless fricatives at the place of articulation of the preceding voiceless consonant. This is evidenced acoustically by high-frequency frication in spectrograms and a high number of zero crossings. Additionally, formant frequency information is preserved, as evidenced by formant bars in spectrograms and spectral sections, allowing the perception of the original vowels in the face of heavy loss of vocality.

5pSC21. Nasal vibration spectra in vowels. Mechtild Tronnier (Dept. of Linguist. and Phonet., Lund Univ., Helgonabacken 12, S-22362 Lund, Sweden, mechtild.tronnier@ling.lu.se)

An accelerometer microphone attached to the upper part of the nose for measuring pathological nasality has been applied. The advantage of this technique is the easy application, the minor degree of invasiveness, and the minimal speaker distraction. The analysis of the obtained signal has been subject to discussion. Some researchers judged from signal intensity whether speech was produced on a hypernasal level or not. Others calculated the intensity ratio of the accelerometer signal to a voice source signal to eliminate intensity variation. The analysis of the spectral pattern of the accelerometer signal is suggested here. Spectral information in such a signal is a good indicator to reflect the velar port opening, which results in nasal resonance and nasal vibration at the nasal surface. Different vowels induce a different degree of velar opening, which does not necessarily reflect the degree of perceived nasality and measured acoustic resonance. This is due to different nasal and oral impedance of the vowels. Therefore, the spectral patterns of individual vowels in the accelerometer signal are described here. Simultaneously, a fiberendoscopic film has been recorded, showing the velar opening to confirm visually the presence or absence of velopharyngeal coupling.

5pSC22. Perceived vowel quantity in Swedish: Effects of postvocalic voicing. Dawn M. Behne (Norwegian Univ. of Sci. and Technol., 7034 Trondheim, Norway), Peter E. Czigler, and Kirk P. H. Sullivan (Umea Univ., 90187 Umea, Sweden)

Swedish is described as having a distinction between phonologically long and short vowels. This distinction is realized primarily through the duration of the vowels, but in some cases also through resonance characteristics of the vowels. In Swedish, like many languages, vowel duration is also longer preceding a voiced postvocalic consonant than a voiceless one. This study examines the weight of vowel duration and the first and second formant frequencies F_1-F_2 frequencies when distinguishing phonologi-

cally long and short vowel before a voiceless consonant (experiment 1) and before a voiced consonant (experiment 2). For three pairs of Swedish vowels ([iː]-[ɪ], [oː]-[ɔ], [ɑː]-[a]) 100 /kVt/ (experiment 1) and 100 /kVd/ (experiment 2) words were resynthesized having ten degrees of vowel duration and ten degrees of F_1 and F_2 adjustment. In both experiments listeners decided whether presented words contained a phonologically long or short vowel. Reaction times were also recorded. Results show that vowel duration is a more dominant cue than the first and second formant for distinguishing phonologically long and short vowels. However, for [ɑː] and [a] the perceptual influence of vowel duration and spectral attributes appears to be more complex. These findings are discussed for vowels preceding postvocalic voiceless and voiced consonants.

5pSC23. Isolating the critical segment of AE /r/ and /l/ to enhance non-native perception. Rieko Kubo, John S. Pruitt, and Reiko Akahane-Yamada (ATR Human Information Processing Res. Labs., 2-2 Hikaridai, Seika-cho, Soraku-gun, Kyoto, 619-02 Japan, rkubo@hip.atr.co.jp)

Brief synthetic stop-consonant+vowel syllables as short as 20 ms are reliably identified for place of articulation. Further, removal of the steady-state vowel in synthetic stop-consonant+vowel series improves discrimination performance, but does not affect identification. Subsequently, vowel truncation of consonant-vowel syllables has been used to improve native English speaker's perception of Hindi dental and retroflex stop-consonants. Whether such truncation techniques are effective for native speakers of Japanese on the AE liquids /r/ and /l/ was examined. The /r/ or /l/ segment from 50 minimal word pairs, produced in five phonemic positions, was isolated by truncating the surrounding phonemic environment. Six durations of the segment were created: 60, 100, 140, 180, 220 ms, and full-length (unedited productions). Native Japanese speakers were asked to identify the target phoneme for each segment, which was presented in a random sequence but blocked by speaker and segment duration. Segment duration significantly affected performance. Interestingly, while longer segments were perceived better than full-length stimuli, shorter segments were not perceived as well. Identification training with these stimuli confirmed the effectiveness of such manipulations. The implications of these findings are discussed with regard to theories of cross-language speech perception and methods of training non-native contrasts.

5pSC24. English vowel production by native speakers of Beijing Mandarin. Xinchun Wang and Murray J. Munro (Dept. of Linguist., Simon Fraser Univ., Burnaby, BC V5A 1S6, Canada, jxwang@sfu.ca)

Ten English vowels produced in a controlled elicitation paradigm by 15 Beijing Mandarin speakers and 15 native English speakers were randomly presented to trained English listeners who identified them in a forced-choice listening task. Although the non-native productions of the vowels with Mandarin counterparts were generally as intelligible as those of the native English speakers, the remaining vowels were produced with varying degrees of intelligibility. The results suggested a strong influence of the $L1$ vowel system on the production of $L2$ vowels. In particular, acoustic analyses revealed that the acccented English vowels tended to be ''pulled'' toward their Mandarin counterparts so that they fell between the English and Mandarin vowels in an $F1-F2$ space. Spectral overlap in the tense–lax pairs accounted for some intelligibility problems, while the dense distribution of second-language ($L2$) vowels in the area of the vowel space where the $L1$ vowel system is less crowded apparently increased the level of difficulty for the $L2$ learners in producing some vowels. The results are discussed in terms of error prediction models for $L2$ speech learning.

5pSC25. The effect of immersion on second language productions: The acquisition of American English /r/ and /l/ by Japanese children. Jesica C. Downs-Pruitt, Reiko Akahane-Yamada (ATR-HIP Labs, 2-2 Hikaridai, Seika-cho, Soraku-gun, Kyoto, 619-02 Japan, jcpruitt@hip.atr.co.jp), Reiko Mazuka (Duke Univ., Durham, NC 27708), and Akiko Hayashi (Tokyo Gakugei Univ., 4-1-1, Nukui-Kita, Koganei-Shi, 184 Japan)

Many studies have shown that the American English (AE) /r/ and /l/ are difficult for adult native speakers of Japanese to perceive and produce, sometimes even after substantial experience and/or intense training. In fact, there are many reports of first language ($L1$) effects on second language ($L2$) learning. Common lore promotes immersion as the best method of second language learning, particularly for overcoming $L1$ biases. The current study examined the effect of English-language immersion on Japanese children's productions of AE /r/ and /l/. We studied productions from children in three age groups, 4-, 6-, and 8-year-olds. Native Japanese children, who had been immersed in an English-language environment, nonimmersed Japanese children, and native English children produced English-language words and nonwords which included /r/, /l/, and /w/ in three positions. The productions were evaluated by categorizing them into one of seven categories, which included a ''correct'' and ''distorted'' category for each intended gesture, as well as an ''other'' category. Significant differences in intelligibility were found dependent upon the age and language-experience group. Furthermore, the children in the three language-experience groups showed different substitution patterns. The results are discussed in the context of recent theories of $L1$ development and $L2$ learning.

5pSC26. Modification of $L2$ vowel production by perception training as evaluated by acoustic analysis and native speakers. Reiko Akahane-Yamada (ATR HIP Labs., Seika, Soraku, Kyoto, 619-02 Japan, yamada@hip.atr.co.jp), Winifred Strange (Univ. of South Florida, Tampa, FL 33620-8150), Jesica C. Downs-Pruitt (ATR HIP Labs., Seika, Soraku, Kyoto, 619-02 Japan), and Yasushi Masuda (Grad. School of Information Sci. NAIST, 8916-5 Takayama, Ikoma, Nara, 630-01 Japan / ATR HIP Labs.)

Recent cross-language studies have shown that there is a link between speech perception and speech production when learning second language ($L2$) consonants. This paper reports additional evidence for such a link from a study which examines whether identification training of $L2$ vowels improves the trainees' production ability. Twenty native speakers of Japanese served as subjects. Half of the subjects received a pretest, identification training on English /ɑ, æ, ʌ/ and a post-test. For the other half of the subjects, only the pretest and post-test were administered. In addition to the perception test, productions of the English vowels were recorded in the pre- and post-test. These productions were later examined in two ways; acoustical analysis and evaluation by native English speakers. Identification ability significantly improved from pretest to post-test for the trained group, but not for the untrained group as reported by Strange and Akahane-Yamada [J. Acoust. Soc. Am. **102**, 3137 (1997)]. More importantly, production ability showed a significant improvement from pretest to post-test for the trained group, suggesting that there is a link between vowel perception and vowel production. The results are discussed in the context of the theories of $L2$ learning.

5pSC27. Categorial discrimination of English and Japanese vowels and consonants by native Japanese and English subjects. Susan G. Guion, James E. Flege (Dept. of Rehab. Sci., VH503, Univ. of Alabama, Birmingham, AL 35294, guionsg@uab.edu), Reiko Akahane-Yamada, and Jesica C. Downs-Pruitt (ATR, Kyoto, 619-02 Japan)

Categorial discrimination tests (CDTs) with equal opportunities for ''hits'' and ''false alarms'' assessed native Japanese and English subjects' perception of English and Japanese segmental contrasts. The stimuli consisted of vowels and consonants spoken at two rates by five native speakers each of English and Japanese. The listeners chose the odd item out in

triads, if there was one, or responded ''none'' if they heard three physically different tokens of a single vowel or consonant. A' scores were computed for each contrast. The subjects were ten native English (NE) controls, ten ''experienced'' bilinguals (Japanese speakers who had spent several years in the United States), and ten ''inexperienced'' bilinguals (Japanese speakers who had never lived outside Japan, but had studied English in school). Analysis of the CDT results will help determine (1) if the subjects differ in their ability to discriminate consonants and vowels, (2) if perceptual sensitivity to vowel and/or consonant contrasts is affected by the speech rate, and (3) if the experienced bilinguals more closely resemble the NE controls than the inexperienced bilinguals do. [Work supported by NIH.]

5pSC28. Effects of listener training on intelligibility of Chinese-accented English. Catherine L. Rogers (Dept. of Speech and Hearing Sci., Ohio State Univ., 110 Pressey Hall, 1070 Carmack Rd., Columbus, OH 43210, rogers.140@osu.edu)

Previous research has demonstrated significant improvements in the intelligibility of synthetic speech following listener training [E. Schwab *et al.*, Human Factors **27**, 395–408 (1985)]. In the present study, the effect of listener training on second-language speech intelligibility was investigated. Chinese-accented words and sentences were presented to four groups of native English listeners—one training and one control group for each of two speakers. On word trials, listeners were instructed to select the word presented from two minimal-pair alternatives; on sentence trials, listeners were instructed to write down what they heard. Listener responses were scored as percent of intended words correctly identified. The two training groups participated in three 1-h training sessions. Auditory and visual feedback was provided to listeners during the training sessions only. Performance of the training and control groups was compared across pre- and posttraining test sessions. Improvement in minimal-pair word intelligibility following training was found across speakers for the training group, relative to the control group; a similar but smaller improvement in sentence intelligibility was found. Word results will be discussed in terms of improvement in discriminability following training for the twelve phonemic contrasts tested. [Work supported in part by NIH-NIDCD Grant No. 2R44DC02213.]

5pSC29. An instance-based model of Japanese speech recognition by native and non-native listeners. Kiyoko Yoneyama and Keith Johnson (Dept. of Linguist., Ohio State Univ., 222 Oxley Hall, 1712 Neil Ave., Columbus, OH 43210)

Japanese has a short and long segment contrast (*oji-san* versus *ojii-san*, *kita* versus *kitta*, and *kana* versus *kanna*). Previous research has shown that this durational property is one of the characteristics of moras in Japanese. It has also been reported that Japanese learners generally have difficulty in acquiring this contrast, but after extensive language experience with Japanese, they do learn the contrast. This suggests that the contrasts and similarities are based on remembered instances of linguistic objects in various environments during a lifetime. This paper investigates whether an instance-based approach of speech recognition can replicate performance by native listeners and second language learners of Japanese. An instance-based model was trained with naturally produced utterances of *koma* spin and *komma* comma and then tested on a 24-step nasal duration continuum from *koma* to *komma* [T. Uchida, doctoral dissertation, Nagoya University (1996)]. The identification function produced by the model was very similar to identification responses produced by native Japanese listeners. Additional simulations trained with utterances produced by English native speakers (e.g., *coma*, *comma*) will be reported. These simulations will address the role of linguistic experience in second language acquisition. [Supported by NIDCD R29-016435-06.]

5pSC30. Training American listeners to perceive and produce Mandarin tones. Yue Wang, Allard Jongman, and Joan A. Sereno (Dept. of Linguist. and Modern Lang., Cornell Univ., Ithaca, NY 14853, yw36@cornell.edu)

Auditory training of non-native speech contrasts is based on the assumption that the perceptual system of adults can be modified. Previous research has shown substantial improvements in the identification of segmental distinctions which are absent in the listeners' native language after a simple phonetic laboratory training procedure. However, it is not known whether such a training procedure is applicable to the acquisition of non-native suprasegmental contrasts. In the present study, native speakers of English are trained to perceive Mandarin lexical tones, using the high-variability procedure shown to be efficient in previous studies concerning the generalization and long-term retention of the training effects. In 20 sessions lasting four weeks, ten American learners of Chinese are trained to identify the four tones in natural words occurring in different phonetic contexts, and spoken by different talkers. The results of the pre- and post-tests are compared to determine if suprasegmental contrasts can be obtained and improved by training, if the contrasts obtained can be generalized to novel words and talkers, if contrasts can be maintained long after training, and if learning gained perceptually can be transferred to production. The results will be discussed in terms of nonnative perceptual modifications at the suprasegmental level.

5pSC31. A CALL system for teaching the duration and phone quality of Japanese tokushuhaku. Goh Kawai and Keikichi Hirose (Univ. of Tokyo, Dept. of Information and Commun. Eng., 7-3-1 Hongo, Bunkyo-ku, Tokyo, 113 Japan, goh@kawai.com)

This paper describes a CALL (computer-aided language learning) system that teaches the pronunciation of Japanese tokushuhaku (long vowels, the mora nasal, and mora obstruents) to beginning learners of Japanese as a second language. The system detects mispronounced tokushuhaku durations and quality, including, for instance, shortened or lengthened tokushuhaku, dentalized mora nasals, diphthongized long vowels, and aspirated plosives. Learners are prompted by the system to read tokushuhaku minimal pairs aloud. Tokushuhaku durations are measured using speech recognition and compared with distributions of native speakers. Mistakes in phone quality are detected using a speech recognizer incorporating bilingual monophone models of both the learner's native and target languages. HMMs for the two languages are trained separately on language-dependent speech data, but are bundled together during recognition so that the closest phone recognized indicates the non-nativeness of the utterance should the recognized phone not be Japanese. Knowing the phonetics and phonology of the learner's native language can identify non-native articulatory gestures that result in Japanese pronunciation errors, thus allowing precise corrective feedback to the learner. The paper includes an overview of the system, its reliability, validity, and effectiveness in the foreigen language classroom.

5pSC32. The organization of articulator gestures: A comparison of Swedish, Bulgarian, and Greenlandic. Sidney A. J. Wood (Dept. of Linguist., Univ. of Lund, Helgonabacken 12, S-22362 Lund, Sweden, sidney.wood@ling.lu.se)

This paper reports speech articulator gestures in Swedish, Bulgarian, and Greenlandic to study universal and language-specific components in articulation. This work is based on analysis of movements of individual articulators from x-ray motion films of speech, and continues from previous reports from this study by Wood [J. Phon. **7**, 25–43 (1979); **19**, 281–292 (1991); Proc. 3rd Conf. I.C.P.L.A., 191–200, Helsinki (1994); Proc. 13th I.C.Ph.S. Vol. 1, 392–395, Stockholm (1995); J. Phon. **24**, 139–164 (1996); Proc. 4th Speech Prod. Sem., 61–64, Grenoble (1996); Speech Commun., (in press)], and by Wood and Pettersson [Folia Ling. **22**, 239–262 (1988)]. Common principles concerned utilization and integration of articulator gestures (articulator gestures executed in approach, hold, and withdrawal phases, four tongue body gestures used, all gestures

available for vowels and consonants, gesture conflicts resolved by gesture queuing, coarticulation and assimilations implemented by coproduction). Language-specific principles concerned implementation of assimilations like palatalization of alveolar stops in Bulgarian and uvularization of vowels in Greenlandic. One assimilation, palatalization of velar consonants, is common to all three languages. A model of gesture programming based on these results is proposed.

5pSC33. The relationship between non-native phoneme perception and the MMN. Janet W. Stack and Susan D. Dalebout (Commun. Disord. Prog., Univ. of Virginia, 2205 Fontaine Ave., Charlottesville, VA 22903 jws8n@virginia.edu)

The mismatch negativity (MMN) auditory-evoked potential reflects the detection of minimal stimulus differences at a preattentive level. It has been reported that the MMN reflects acoustic, rather than phonetic processing of speech stimuli. The purpose of the present study was to examine the relationship between discrimination at a neurophysiologic level, as reflected by the MMN, and the behavioral ability of native speakers of American English to discriminate and label pairs of Hindi stop consonants that are contrasted by a place of articulation feature that is not phonemic in English. These pairs were the voiceless unaspirated Hindi stop consonants, dental and retroflex /t/, and the voiced unaspirated Hindi stops, dental and retroflex /d/. The present study addressed two questions: (1) whether the MMN response would be evoked by acoustic differences resulting from differences in place of articulation, even though behavioral discrimination ability was poor; and (2) whether there would be a difference in the presence/absence or other parameters (latency, duration, amplitude, and area) of the MMN response depending on which voicing contrast was presented.

5pSC34. Acquisition of language-specific word-initial unvoiced stops: VOT, intensity, and spectral shape in American English and Swedish. Eugene H. Buder (Univ. of Memphis, Memphis, TN 38105, ehbuder@memphis.edu) and Carol Stoel-Gammon (Univ. of Washington, Seattle, WA 98105-6246)

By 30 months of age, children learning American English (AE) or Swedish (S) have begun to acquire language specific aspects of word-initial /t/s [Stoel-Gammon *et al.*, Phonetica **51**, 146–158 (1994)]. The coronal stop is ostensibly alveolar in AE and dental in S, suggesting a place mechanism for the distinctive acoustic measures obtained from both adults and toddlers from these languages (specifically burst frequency shape as measured by spectral mean and standard deviation, and burst intensity as calibrated to following vowel). However, these measures, as well as voice onset time, are also distinctive in the same directions for other unvoiced stop consonants in adults and children, suggesting a system-wide mechanism for language-specific behaviors in this domain. Current results on word-initial /p/s, /t/s, and /k/s from both 24-month- and 30-month-old children are interpreted as evidence for early acquisition of specific allophonic phonetic aspects of consonants. [Work supported by NICHD.]

5pSC35. The effects of postvocalic voicing on the duration of high front vowels in Swedish and American English: Developmental data. Carol Stoel-Gammon (Univ. of Washington, Seattle, WA 98105-6246) and Eugene H. Buder (Univ. of Memphis, Memphis, TN 38105)

In most languages of the world, a vowel preceding a voiced obstruent is longer than the same vowel preceding a voiceless obstruent. Although the effect of postvocalic voicing on vowel duration is often considered to be phonetically driven, the extent of influence differs considerably across languages. In English, for example, vowels preceding voiced obstruents are nearly twice as long as those preceding voiceless obstruents, whereas in Swedish, the influence is minimal, perhaps because vowel length is phonemically contrastive in this language. The present study examines acquisition data from Swedish and American children, aged 24 and 30 months, to determine developmental patterns of vowel duration associated with context-sensitive voicing. It was hypothesized that the 24-month-old children from both language backgrounds would exhibit the phonetically based tendency for vowels to be significantly longer in the voiced context, but that at 30 months of age, the effects of final consonant voicing would be much stronger in English than in Swedish. Durational measures of high front vowels (tense/long /i/ and its short/lax counterpart) supported the proposed hypothesis. [Work supported by NICHD.]

5pSC36. Perceptual assimilation of Hindi dental and retroflex stop-consonants by native English and Japanese speakers. John S. Pruitt, Reiko Akahane-Yamada (ATR Human Information Processing Res. Labs., 2-2 Hikaridai, Seika-cho, Soraku-gun, Kyoto, 619-02 Japan, jspruitt@hip.atr.co.jp), and Winifred Strange (Univ. of South Florida, Tampa, FL 33620)

Previous research has shown that English speakers have great difficulty distinguishing the dental and retroflex stop-consonants of the Hindi language. However, native Japanese speakers have somewhat less difficulty perceiving this contrast even though it is not employed in the Japanese language. Best and colleagues have attributed similar differences in the perception of non-native speech sounds to differences in the assimilation of such sounds to native-language speech categories [Best, McRoberts, and Sithole, J. Exp. Psych: Human Percept. Perform. **14** (1988)]. According to Best's Perceptual Assimilation Model (PAM), four patterns of assimilation have been described which are purportedly predictive of perceptual difficulty. To determine if this model could be applied to the present case, native speakers of English and Japanese transcribed multiple instances of the Hindi consonants in different voicing/manner classes, produced with different vowels. Marked differences were found between the responses of the two language groups which were partially dependent upon the voicing/manner class of the contrast. Interestingly, an assimilation pattern emerged which was different from those discussed in PAM. Implications of these findings for PAM and for perceptual training of non-native speech sounds will be discussed. [Work supported in part by NIDCD.]

5pSC37. Comparison of American English vowel production and identification by native speakers of Luso-Portuguese. Christina F. Famoso, Patricia N. Schwartz (Dept. of Speech, Commun. Sci., and Theatre, St. John's Univ., Jamaica, NY 11439), and Adelia DaSilva (Blythedale Children's Hospital, Valhalla, NY)

Learning a new language requires mastering the phonetic as well as lexical and syntactical aspects of the new language. As part of a larger study of second-language learning, the identification of American English vowels by speakers of Luso-Portuguese and the identification of those speakers' productions by native speakers of American English were explored. Four adult bilingual Luso-Portuguese/English speakers (two women and two men) participated in this study. The subjects performed two tasks. First, they identified ten English words (ten repetitions of each, presented in random order, of: heed, hid, head, had, hod, hawed, hood, who'd, hud, heard) produced by a native speaker of American English. Then recordings were made of the subjects as they produced four repetitions each, in random order, of these ten English words. These recordings were digitized using SoundDesigner II software with an audiomedia board on a Macintosh Quadra 800 computer. Listening tapes will be prepared, using SoundDesigner II software, for identification of the Luso-Portuguese speakers' vowels by native American English speakers. The results of the

identification of the Luso-Portuguese speakers' vowels will be compared with the identification of American English vowels by the native Luso-Portuguese speakers. [Work supported by St. John's University.]

5pSC38. Acoustic analysis of American English vowels by native speakers of Luso-Portuguese. Patricia N. Schwartz, Christina F. Famoso (Dept. of Speech, Commun. Sci., and Theatre, St. John's Univ., Jamaica, NY 11439), and Adelia DaSilva (Blythedale Children's Hospital, Valhalla, NY)

The ability of individuals to learn a new language requires mastering the phonetic as well as lexical and syntactical aspects of the new language. As part of a larger study of second-language learning, the acoustical characteristics of American English vowel production by native speakers of Luso-Portuguese were explored, and these characteristics were compared with the identification of these speakers' English vowels by native speakers of American English. Four adult bilingual Luso-Portuguese/English speakers (two women and two men) participated in this study. Recordings were made of the subjects as they produced four repetitions each, in random order, of 10 English words (heed, hid, head, had, hod, hawed, hood, who'd, hud, heard). The recordings were digitized using SoundDesigner II software with an audiomedia board; formant frequency analyses will be carried out using Signalyze 2.0 software implemented on a Macintosh Quadra 800 computer. The acoustical analyses will be examined in light of the identification of the Luso-Portuguese speakers' English vowels by native speakers of American English (reported in another paper at this meeting). [Work supported by St. John's University.]

5pSC39. Comparison of American English vowel production and identification by native speakers of Russian. Fredericka Bell-Berti (Dept. of Speech, Commun. Sci., and Theatre, St. John's Univ., Jamaica, NY 11439), Lisa Jayne Romano, and Eugenia Lorin (St. John's Univ., Jamaica, NY 11439)

Learning a new language requires mastering the phonetic as well as lexical and syntactical aspects of the new language. As part of a larger study of second-language learning, the identification of American English vowels by speakers of Russian and the identification of those speakers' productions by native speakers of American English were explored. Four adult bilingual Russian/English speakers (two women and two men) participated in this study. The subjects performed two tasks. First, they identified ten English words (ten repetitions of each, presented in random order, of: heed, hid, head, had, hod, hawed, hood, who'd, hud, heard) produced by a native speaker of American English. Then recordings were made of the subjects as they produced four repetitions each, in random order, of these ten English words. These recordings were digitized using SoundDesigner II software with an audiomedia board on a Macintosh Quadra 800 computer. Listening tapes will be prepared, using SoundDesigner II software, for identification of the Russian speakers' vowels by native American English speakers. The results of the identification of the Russian speaker's vowels will be compared with the identification of American English vowels by the native Russian speakers. [Work supported by St. John's University.]

5pSC40. Acoustic analysis of American English vowels by native speakers of Russian. Lisa Jayne Romano (Dept. of Speech, Commun. Sci., and Theatre, St. John's Univ., Jamaica, NY 11439), Fredericka Bell-Berti (St. John's Univ., Jamaica, NY 11439), and Eugenia Lorin (St. John's Univ., Jamaica, NY 11439)

The ability of individuals to learn a new language requires mastering the phonetic as well as lexical and syntactical aspects of the new language. As part of a larger study of second-language learning, the acoustical characteristics of American English vowel production by native speakers of Russian were explored and these characteristics were compared with the identification of these speakers' English vowels by native speakers of American English. Four adult bilingual Russian/English speakers (two women and two men) participated in this study. Recordings were made of the subjects as they produced four repetitions each, in random order, of ten English words (heed, hid, head, had, hod, hawed, hood, who'd, hud, heard). The recordings were digitized using SoundDesigner II software with an audiomedia board; formant frequency analyses will be carried out using Signayze 2.0 software implemented on a Macintosh Quadra 800 computer. The acoustical analyses will be examined in light of the identification of the Russian speakers' English vowels by native speakers of American English (reported in another paper at this meeting). [Work supported by St. John's University.]

5pSC41. Is allophonic variation in Japanese /ɾ/ a factor in Japanese listeners' difficulty in perceiving English /ɹ-l/? Mieko Ueno, Patrice S. Beddor (Prog. in Linguist., Univ. of Michigan, Ann Arbor, MI 48109, beddor@umich.edu), and Reiko Akayane-Yamada (ATR Human Information Processing Res. Labs., Kyoto, Japan)

Japanese listeners' difficulty in perceiving the English liquid (/ɹ-l/) contrast has been attributed to various phonological and phonetic factors. To explore allophonic variation in the Japansese flap as a contributing factor, American English listeners' perception of Japanese /ɾ/ was investigated in a range of phonetic contexts. Stimuli were 152 Japanese words containing /ɾ/ in all phonotactically possible contexts produced by two native Japanese speakers. Three stimulus randomizations were presented to 12 American English listeners for identification as ''l,'' ''r,'' ''D'' (=flap), ''d,'' ''t,'' ''no sound,'' or ''other sound.'' Results showed strong effects of syllable structure: Japanese /ɾ/ sounded more stoplike (''D,'' ''d,'' ''t'' responses) in consonantal contexts and more liquidlike (''r,'' ''l'' responses) in vocalic contexts. However, liquid responses were more likely to be ''r'' intervocalically, compared with ''l'' in initial position. Vowel quality also had a strong effect: Japanese /ɾ/ elicited more stop responses in high vowel ([i u]) contexts and more liquid responses in lower vowel ([a o]) contexts. Acoustic measures of the stimuli were generally consistent with the perceptual patterns. The perceptual and acoustic findings are compared with the results of recent training studies [Akayane-Yamada, Proc. 3rd Joint Meeting of ASA-ASJ, 953–958 (1996)] with Japanese listeners on English /ɹ–l/.

5pSC42. The perception of place of articulation in three coronal nasal contrasts. James D. Harnsberger (Prog. in Linguist., Univ. of Michigan, 1076 Frieze Bldg., Ann Arbor, MI 48109, jharns@umich.edu)

Place of articulation contrasts which undergo perceptual assimilation are often difficult to discriminate if absent in a listener's native language, as demonstrated by American English (AE) listeners with Hindi dental-retroflex stops [Polka (1991)] and Salish velar-uvular ejectives [Werker and Tees (1984)]. To see if this pattern generalizes to other manners of articulation, nasal contrasts (dental-alveolar, dental-retroflex, alveolar-retroflex) from three languages (Malayalam, Marathi, and Oriya), varying in talker, syllabic position, and vowel context, were presented to speakers of Malayalam, Marathi, and Oriya (control groups), and Bengali, AE, Tamil, and Punjabi in two tests: AXB discrimination, and identification with goodness ratings. AE and Bengali were chosen because both possess

a single relevant perceptual category for these stimuli, an alveolar nasal. Tamil and Punjabi were selected for their two nasal categories, dental and retroflex. Of the contrasts tested, Malayalam dental-alveolar was the most challenging, with all non-native groups performing at-chance on the AXB test. The discriminability of the other contrasts proved to be highly dependent on the particular talker, syllable position, or vowel context, with performance ranging from at-chance to 98.4%. An acoustic analysis of the stimuli will also be provided.

5pSC43. Vowel perception by formant variation. Byunggon Yang (English Dept., Dongeui Univ., Kayadong Pusanjingu, Pusan 614-714, Korea)

The acoustic parameters of six Korean vowels produced by a healthy male subject with normal hearing were analyzed to synthesize the six vowels by a formant synthesis method. The f_0, amplitude envelopes, and the first six formant values were elaborately matched to the those of the original vowels. Then, F_1 and F_2 values of the synthesis file were modified by 50 Hz over and under the original values but not interfering with adjacent formants. F_3 varied 500 Hz over and under the original values by 100 Hz to obtain 270 stimuli. Twenty male and female subjects in a quiet room listened to the original vowel followed by the corresponding synthesized one 0.5 s later and judged whether they sounded qualitatively ''similar'' or ''different.'' From the experiment, it was found that male subjects responded ''similar'' within the range of variance by an average of 163 Hz for F_1, 415 Hz for F_2; and 843 Hz for F_3. Female subjects showed 40-Hz higher range than males. The ranges supported the nonlinearity of the human auditory scale in the speech sound. This suggests that the validity of exact formant frequency measurement varies according to frequency levels.

5pSC44. Cross-linguistic evidence for the acquisition of accent by the onset of word use. Rory A. DePaolis, Marilyn M. Vihman (Dept. of Psych., Univ. of Wales, Bangor, Bangor LL57 2DG, Gwynedd, UK, r.depaolis@bangor.ac.uk), and Leonard P. Lefkovitch (Carleton Univ., Ottawa, Canada)

An investigation of the acoustic correlates of stress or accent in infant vocalizations was undertaken using five English- and five French-learning participants at two developmental points, the onset of word use (10–13 months) and late in the single-word period (14–19 months). A data base of 555 disyllabic utterances (words and babble) was digitized from naturalistic recordings and quantified acoustically by indices of duration, amplitude, and fundamental frequency (F_0). Cluster analysis as well as the results of perceptual judgments (i.e., both a bottom-up and a top-down approach) revealed a developmental trend toward the adult prosodic system. In addition, acoustic comparisons of French and American infants at both developmental points revealed differences in their use of amplitude, F_0, and duration to accent a syllable. The differences were traceable to the adult patterns for the respective adult languages. These results suggest that infants' perceptual attunement to prosody in the prelinguistic period manifests itself in the beginnings of adultlike production as early as the onset of word use. 5pUW1. Implications of a bistatic treatment for the second echo from a normal incidence sonar. Gary J. Heald (Defence Evaluation and Res. Agency, Weymouth, Dorset, England) and Nicholas G. Pace (Univ. of Bath, Claverton Down, Bath, England)

Echo sounders have traditionally been used for the measurement of water depth but recent developments have shown how the information contained in the acoustic backscatter, related to the sediment type, may be extracted. As echo sounders operate at normal incidence it is possible to use the first and second backscatter from the seabed for sediment discrimination. This study has investigated why additional information may be contained in the second backscatter. It is shown that the geometry for the second backscatter must be treated as an on-axis bistatic configuration in which the source is effectively 3 water depths above the seabed. The resulting scattering equations are used to show how the range dependence of the scattering places the receiver in the near field for the second echo. The importance of the sensor geometry and the processing of the received signals are also discussed. As a result, it is shown that the combination of information contained in the first and second backscatter may be used to descriminate between different sediments. The result from tank experiments using a 200-kHz transducer over different sediments has allowed comparison with the theory and shows the effect of different water surface roughness on the second backscatter.

5pUW2. In-plane bistatic calculations of sub-bottom volume reverberation in shallow water. Dale D. Ellis and Paul C. Hines (Defence Res. Establishment Atlantic, P.O. Box 1012, Dartmouth, NS B2Y 3Z7, Canada)

A shallow-water reverberation model based on normal modes and ray-mode analogies has been previously developed [J. Acoust. Soc. Am. **97**, 2804–2814 (1995)]. It was first developed for boundary scattering and recently extended to handle volume reverberation in both the water and sub-bottom. The volume scattering is formulated in terms of an empirical plane-wave scattering function, which depends on depth but which can also depend on the incident and scattered angles. Our first approximation for the volume reverberation

is to choose the scattering to be isotropic, but to get a better approximation based on physical parameters, the in-plane bistatic scattering function of Hines is used [J. Acoust. Soc. Am. **99**, 836–844 (1996)]. In this paper, calculations of shallow-water reverberation are made with the Hines scattering function used as input to the normal-mode model. Results are compared with reverberation assuming isotropic scattering in the bottom, as well as with reverberation due to bottom interface scattering using Lambert's rule.

5pUW3. A review of the SSA for rough surface scattering. Shira L. Broschat (School of Elec. Eng. and Comput. Sci., Washington State Univ., P.O. Box 642752, Pullman, WA 99164-2752) and Eric I. Thorsos (Univ. of Washington, Seattle, WA 98105)

The small slope approximation (SSA) for scattering from rough surfaces was introduced by Voronovich in the mid-1980s [A. G. Voronovich, Sov. Phys. JETP **62**, 65–70 (1985)]. Numerical studies have shown that the SSA gives excellent results over a broad range of scattering angles. However, in the high-frequency limit the second-order (in the field) SSA scattering amplitude reduces to the geometrical optics result and, thus, to a single scattering model limited to local interactions with the surface. In this paper, small slope theory will be reviewed briefly, expressions for the bistatic scattering cross section will be presented, and numerical results will be shown for a number of different problems and several different roughness spectra. In addition, in an effort to extend the nonlocal scattering effects, Voronovich modified the SSA. He applied the same approach underlying the SSA, but he began by iterating the integral equation of the second kind [A. G. Voronovich, Waves Random Media **6**, 151–167 (1996)] which led to the nonlocal small slope approximation (NLSSA). While the main focus of this talk will be the SSA, the NLSSA will be compared with the SSA for selected results. [Work supported by ONR.]

1:57

5pUW4. The lowest-order small slope approximation for rough surface scattering. Eric I. Thorsos (Appl. Phys. Lab., College of Ocean and Fishery Sci., Univ. of Washington, Seattle, WA 98105) and Shira L. Broschat (Washington State Univ., P.O. Box 642752, Pullman, WA 99164-2752)

The small slope approximation (SSA) [A. G. Voronovich, Sov. Phys. JETP **62**, 65–70 (1985)] for scattering from rough surfaces leads to a systematic series and improved accuracy is obtained by using higher terms in the series. Numerical implementation of the lowest-order SSA for the scattering cross section has the same level of effort required as for the Kirchhoff approximation (a single integration for one-dimensional surfaces, a double integral for two-dimensional surfaces), while higher orders require higher-order integrations. Thus the accuracy of the lowest-order SSA is of considerable practical interest. In this paper, the accuracy of lowest-order SSA will be illustrated for surfaces with power-law roughness spectra through comparison with exact numerical results. Both Dirichlet and two-fluid boundary conditions will be considered. For typical power-law spectra, the accuracy of the lowest-order SSA is generally quite good. [Work supported by ONR.]

5pUW5. The Kirchhoff approximation: A new iterative solution. Suzanne T. McDaniel (4035 Luxury Ln., Bremerton, WA 98311)

A new iterative solution to the problem of sea surface scattering is obtained which has the Kirchhoff approximation as its leading term. This solution is obtained by transforming an integral equation of the first kind for the surface potential to one of the second kind, and applying the method of successive approximations. The advantages of this method are that the conditions under which this solution converges may be readily established and the solution may be iterated to sufficiently high order in the interaction to examine the rate at which it converges. A numerical example of scattering from an echelette grating is considered, and the regime of convergence established. It is found that the new iterative solution converges only for such surfaces on which $k\sigma\sigma' < \pi$ where k is the wave number of the scattered radiation and σ and σ' are, respectively, the rms surface height and slope. This finding raises doubts concerning the regime in which the Kirchhoff approximation is traditionally deemed applicable. Finally, numerical studies are presented to illustrate the convergence of the iterative solution.

5pUW6. Statistical characteristics of bistatic sea surface scatter. Peter D. Neumann (Planning Systems, Inc., 7923 Jones Branch Dr., McLean, VA 22102) and R. Lee Culver (Penn State Univ., University Park, PA 16804)

The characterization of reverberation, from the surface, the bottom, and/or the volume, is important in advancing the understanding of the mechanisms involved in underwater sound scattering. Numerous experiments and much theoretical work have been done in the area of monostatic reverberation, but the area of bistatic reverberation has been much less researched. This certainly is a result of the much more complex geometries involved in bistatic reverberation. This work studies the statistics of bistatic sea surface reverberation data from the FLIP experiment conducted in January of 1992. The data were verified as homogeneous and normally distributed using the Kolmogorov–Smirnov two-sample test with a confidence interval, α, equal to 0.1. Using a technique by which ensembles from different times were combined, meaningful deviations from a normal distribution were observed at the highest wind speed of 7.2 m/s. The bistatic surface scattering strengths were calculated from the data and compared with the predictions of a theory developed by S. T. McDaniel for the prediction of bistatic surface scattering strengths. The comparison showed good agreement with a rms deviation of about 3 dB. [Work supported by ONR.]

5pUW7. Time dependence in forward scattering: Experimental results and model comparisons derived from sea surface and seabed bistatic cross sections. Peter H. Dahl and Kevin L. Williams (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98195)

In shallow, littoral regions the acoustic transmission channel can often be governed by the process of forward scattering from both the sea surface and seabed. In this paper, measurements of the intensity time dependence of high-frequency O(10) kHz sound that has been forward scattered from both the sea surface and seabed are discussed along with simulated time series for this process. The data are from an experiment conducted near Key West, Florida in waters 25-m deep, for which the seabed was characterized by a carbonate sand-silt-clay mixture. The simulated time series are derived from the bistatic cross sections for sea surface and seabed by convolving the bistatic scattering impulse response with the waveform emitted from the transmitter. For the seabed *in situ* estimates of sediment properties were used as inputs to a model described in Williams and Jackson [J. Acoust. Soc. Am. (submitted)]. For the sea surface, the necessary representation of the two-dimensional surface wave correlation function was derived from estimates of the directional wave spectrum. The latter were measured with a directional wave buoy that operated in the immediate vicinity of the acoustic measurements. [Work supported by ONR Code 321OA.]

5pUW8. Stacking and averaging techniques for bottom echo characterization. Daniel D. Sternlicht and Christian P. deMoustier (Marine Physical Lab., Scripps Inst. of Oceanogr., 9500 Gilman Dr., La Jolla, CA 92093-0205)

Bottom-looking sonars operating at frequencies greater than 30 kHz transmit acoustic signals which penetrate at most a few meters into seafloor sediments, making them well suited to characterize the water/sediment interface. Acoustic wavelengths at these frequencies are small compared to the rms relief of the interface, resulting in bottom echoes dominated by incoherent energy and varying significantly in amplitude and shape as the sonar translates longitudinally above the interface. Because of this variability, echoes must be treated stochastically and determining the average shape of the bottom echo involves careful selection of stacking and averaging algorithms. Comparisons of a geoacoustic temporal model with 33- and 93-kHz backscatter echoes from sand and silt substrates reveal that a representative echo shape is obtained by averaging echoes along-track over a distance roughly equivalent to the 6-dB footprint diameter of the sonar beam pattern. To be meaningful, such averaging must be performed on echoes that have been aligned in time, thus removing effects due to transducer heave as well as small depth variations over consecutive pings. Echo alignment techniques based on thresholding minima, maxima, or half energy, on low-pass filtering techniques and on carrier frequency phase tracking, have been investigated and their relative merits are discussed. 5pUW9. A comparison of the finite-difference time-domain and integral equation methods for scattering from shallow water sediment bottoms. Frank D. Hastings, John B. Schneider, Shira L. Broschat (School of Elec. Eng. and Comput. Sci., Washington State Univ., Pullman, WA 99164-2752, shira@eecs.wsu.edu), and Eric I. Thorsos (Univ. of Washington, Seattle, WA 98105)

Scattering from sediment bottoms has a significant effect on acoustic propagation in shallow water. When shear effects are negligible, the water–sediment interface can be modeled using a fluid–fluid model. In this paper, finite-difference time-domain (FDTD) and integral equation (IE) results are compared for a fluid–fluid rough interface. Both methods are exact in that they make no physical approximations, and both can be used either to benchmark approximate analytical methods or to study the propagation problem directly. The comparison presented verifies the numerical accuracy of the two methods. Scattering strengths are computed using a Monte Carlo average over a set of 50 surfaces. Results for single surface realizations are presented as well. Both single-scale Gaussian and multiscale modified power law (MPL) roughness spectra results are presented. While the MPL spectrum is more realistic for shallow water problems, the Gaussian spectrum gives low scattering levels in the backscatter direction, permitting a stringent test of numerical accuracy. Several different bottom types are considered for which the shear speeds are negligible, and attenuation has not been included. For all cases, the FDTD and IE results are obtained using the same surface realizations. In general, the results agree well. [Work supported by ONR.]

5pUW10. Shallow-water in-plane bistatic scattering experiment. D. Vance Crowe, Paul C. Hines, and Patrick J. Barry (Defence Res. Establishment Atlantic, Dartmouth, NS, Canada)

Every reverberation experiment done in shallow water is by its nature, bistatic at long ranges. That is to say, in addition to simple monostatic returns, the received signal is composed of energy arriving along bottom bounce paths for which incident and scattered angles are different. Therefore, it is possible to measure in-plane bistatic scattering strength using a monostatic geometry [Hines, Crowe, and Ellis, J. Acoust. Soc. Am. (in review)]. Noting this, a simple array consisting of a pair of free-flooding-ring projectors and two hydrophones was used to measure monostatic and bistatic scatter in 100 m of water on the Scotian Shelf. A series of linear FM (LFM) pulses was transmitted in four frequency bands over the range 900 to 2100 Hz. The reverberation data between the first bottom return and the first surface return provided estimates of monostatic backscatter strength for grazing angles down to 10°. Data arriving after the first-bottom–first-surface interaction provided estimates of in-plane bistatic scattering strength for pairs of incident and scattered grazing angles (ϕ_i, ϕ_s) down to (7°, 57°). In this paper, the experiment and data are described in light of the monostatic and bistatic arrivals.

5pUW11. Sediment density heterogeneity spectra estimated from digital X-radiographs. Dajun Tang (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105, djtang@apl.washington.edu) and Robert A. Wheatcroft (Oregon State Univ., Corvallis, OR 97331)

It has been confirmed that sediment volume heterogeneity is one of the major bottom scattering mechanisms, especially in soft-sediment areas. In most cases, scattering by sediment heterogeneity can be modeled by a first-order perturbations technique. The crucial input to such models is the spectrum of sediment spatial heterogeneity. It is difficult to obtain reliable data to estimate such spectra, however, because (1) two-dimensional data sets collected from statistically similar sites are needed, and (2) the data need to cover several orders of magnitude in spatial dimensions. Digital X-radiographs of sediment cores provide an ideal form of data for estimating the spectrum of sub-bottom density variability. Here the data processing procedures will be provided in detail, and physical insights into the resultant spectra discussed. Last, bistatic scattering coefficients resulting from these spectra will be presented.

5pUW12. Measurement and modeling of bistatic scattering on the Florida Atlantic coastal shelf. Tokuo Yamamoto, Christopher Day, and Murat Kuru (Univ. of Miami, Div. of Appl. Marine Phys., 4600 Rickenbacker Cswy., Miami, FL 33149)

Measurements of bistatic sea floor scattering on the Fort Pierce, Florida shelf are presented. Scattering measurements have been collected using a new 32 element bilinear acoustic array. According to the volume and roughness scattering models of Yamamoto (1996) and Jackson *et al.* (1992), bistatic scattering depends on the bottom sediment characteristics, the interface roughness, and the incident and scattered grazing angles. Parameters for the combined volume and roughness scattering model are estimated using the observed bottom roughness and tomographically measured sediment sound speed and attenuation. Observations of bistatic scattering are compared to the combined scattering model. Good agreement between the observed and modeled scattering pattern permits an accurate mapping of mean sound speeds, attenuation, densities, and their three-dimensional spatial spectra using observations of bistatic scattering. 5pUW13. Analysis of laboratory measurements of sound propagating into an unconsolidated water-saturated porous media. Harry J. Simpson and Brian H. Houston (Naval Res. Lab., 4555 Overlook Ave., SW, Washington, DC 20375-5350, simpson@fugazi.nrl.navy.mil)

A series of measurements in the NRL shallow-water laboratory have been conducted to understand the propagation of sound into and within an unconsolidated water-saturated porous medium. The initial set of measurements was taken to quantify sound penetration as a function of incident angle and interface roughness and to identify the types of waves generated within the water-saturated sandy bottom. These investigations included two-dimensional synthetic array measurements for both a smoothed and a roughened interface. Additionally, above interface and buried source, one-dimensional synthetic array measurements were taken to investigate specifically the types of compressional waves generated within the sandy bottom. To complete the physical characterization of the wave speeds

propagating in the bottom, measurements of the shear wave speeds have been made. These measurements provide a large data base for analysis to understand the physics of this sandy bottom, which consists of a 3.0-m-deep bed of a manufactured 212-μm mean diameter sand. Analysis of these measurements using Biot models and other fluid models is presented. In addition, analysis of enhanced sound penetration at shallow grazing angles due to a roughened interface is discussed. [Work supported by ONR.]

5pUW14. The low-frequency radiation and scattering of sound from bubble distributions near the sea surface. William M. Carey (Dept. of Ocean Eng., MIT, Cambridge, MA 02139) and Ronald A. Roy (Boston Univ., Boston, MA 02215)

Microbubble plumes are produced when waves break and are convected to depth by the vortical wave motion. The question is, What role is played by these distributions in the production and scattering of sound near the sea surface at low frequency (LF)? Deep- and shallow-water ambient noise show dramatic increases with wave breaking. Individual wave breaking events show radiation down to 30 Hz. Tipping water-filled trough and bucket experiments show LF radiation associated with the entrainment of known bubble size distributions; suggesting that single bubbles cannot be the cause of this radiation. Microbubble distributions with void fractions greater than 0.01% act as collective monopole resonant oscillators excited by the energy of formation. Multipole expansions show the radiation is described by a modified Minnaert expression and a dipole radiation pattern (owing to the presence of the sea surface). Since the plume stays put, scattered sound would have a zero Doppler shift with ample Doppler spread. Acoustic images of the sea surface show discrete scattering events, while experiments show LF scattering from free bubble distributions. Results are shown which indicate that bubble plumes from breaking waves not only radiate but scatter LF sound. [Work sponsored by ONR.]

5pUW15. Inversion of bistatic reverberation and scattering measurements for seabottom properties. Andrew Rogers, Greg Muncill, and Peter Neumann (Planning Systems, Inc., 7923 Jones Branch Dr., McLean, VA 22102, arogers@plansys.com)

Considerations associated with the inversion of bistatic reverberation and scattering data from a three-dimensional space are discussed. The SCARAB (SCAttering and ReverberAtion from the Bottom) acoustic propagation and scattering model has been the kernel for the study. This model considers three-dimensional, non-plane-wave, range-independent acoustic signals in both mono- and bistatic source receiver configurations. Due to the computationally expensive problem of computing a reverberative field which includes many hybrid acoustic paths and the iterative nature of the inverse process, inversion for seabottom properties requires highly effective search parameter space reduction and algorithm optimization. The parameter space reduction methods and simulated annealing and genetic optimization algorithms utilized are discussed, and their effectiveness measured against several test cases. 5pUW16. High-frequency sound propagation in shallow water with rough surface scattering. X. Tang, M. Badiey (Marine Studies, Univ. of Delaware, Newark, DE 19716), and J. Simmen (Office of Naval Res., ONR 3210A, Arlington, VA 22217)

Sound propagation at mid to high frequencies (1–20 kHz) in shallow-water environments is extremely complicated, variable, and poorly understood due to multiple processes that cover a wide range of temporal and spatial scales. Numerical simulations using a full-wave PE model are carried out to interpret the acoustic data taken during very carefully designed experiments at a shallow-water site inside the Delaware Bay. Records of broadband acoustic wave time series (from hours to days) are numerically reproduced by using the collected environmental data as input to the PE model. The statistics of both measured and simulated multipath signals are calculated and compared in the presence of rough sea-surface scattering and surface bubble layer attenuation. The surface wind effects can be separated from the slowly varying volume fluctuations of sound speed, by comparing the temporal variations; while it can be separated from the bottom effects by examining different multipath arrivals. The dependence of coherence on the parameters of wind strength and acoustic frequency is examined.

5pUW17. Recent observations of high-frequency acoustic wave propagation in the Delaware Bay. M. Badiey (Marine Studies, Univ. of Delaware, Newark, DE 19716), S. Forsythe (Naval Undersea Warefare Ctr., Newport, RI 02841), J. Simmen (Office of Naval Res., ONR 3210A, Arlington, VA 22217), and X. Tang (Univ. of Delaware, Newark, DE 19716)

Broadband acoustic propagation measurements, as well as complementary environmental measurements including CTD, ADCP, and wind speed, have been conducted in the Delaware Bay during March and September, 1997. With the data from these complete experiments, acoustic pulse travel time and intensity are related to the sound-speed fluctuations in the water column, the sea-surface profile, and the bottom roughness. The direct arrival between acoustic source and receiver contains information about ocean current and temperature, while the arrival corresponding to a single surface bounce contains additional information about the sea-surface roughness. Independent measurements of temperature and current allow the sorting of acoustic fluctuations due to ocean volume fluctuations from those due to sea-surface fluctuations. Coherence of the broadband acoustic signals is calculated from the observed data and is found to be correlated with the environmental parameters.
