The previous assumptions enable focus on a precise set of equations and boundary conditions. The density, temperature and pressure of the air at rest are denoted, respectively, by ρ_0 , T_0 and P_0 . The use of complex notations for harmonic waves of frequency, f , is retained with the $e^{i\omega t}$ time dependence, where $\omega = 2\pi f$ is the angular frequency. The complex amplitudes of the air speed and the fluctuating parts of the density, temperature and pressure of the air are, respectively, denoted by \mathbf{u} , ξ , τ and p .

The specific heats at constant volume, C_V , and at constant pressure, C_P , and their ratio $\gamma = C_P/C_V$ will be used as

well as the dynamic and bulk viscosities, μ and λ , the heat conductivity, K , and the Prandtl number, $\text{Pr} = \mu C_P / K$.

Air is assumed to follow the equation of state of a perfect gas:

$$\frac{P_0}{\rho_0 T_0} = C_P - C_V. \quad (1)$$

By the use of logarithmic derivatives, one also gets a relationship between fluctuating quantities:

$$\frac{p}{P_0} - \frac{\tau}{T_0} - \frac{\xi}{\rho_0} = 0. \quad (2)$$

The dynamics of the fluid is governed by the Navier–Stokes equation,³ which can be rewritten after linearization and time Fourier transform as

$$\rho_0 i \omega \mathbf{u} = -\mathbf{grad} p + (\lambda + \mu) \mathbf{grad} \text{div} \mathbf{u} + \mu \Delta \mathbf{u}. \quad (3)$$

Equation (3) must be completed by boundary conditions. As the solid fraction of the porous material is rigid, it has no relative motion and the no-slip condition at the solid interface Σ is written as

$$\mathbf{u}|_{\Sigma} = \mathbf{0} \quad (4)$$

The two previous equations are not sufficient to completely define the fluid flow; the continuity equation³ must be included in the discussion. After linearization and Fourier time transform, it becomes, after Eq. (2), used to eliminate ξ :

$$\text{div} \mathbf{u} + i \omega \frac{\xi}{\rho_0} = \text{div} \mathbf{u} + i \omega \left(\frac{p}{P_0} - \frac{\tau}{T_0} \right) = 0. \quad (5)$$

As Eq. (5) includes the fluctuating temperature, there is a coupling between the dynamics of the acoustic wave and its thermal behavior. It was therefore necessary to include a heat equation in the problem.

The heat equation, linearized and Fourier time transformed, is

$$\rho_0 i \omega C_V \tau = -P_0 \text{div} \mathbf{u} + K \Delta \tau. \quad (6)$$

Equation (6) can be slightly transformed by the use of (5) and (1) to obtain

$$\rho_0 i \omega C_P \tau = i \omega p + K \Delta \tau. \quad (7)$$

As for (3), Eq. (7) needs the definition of boundary conditions. From the assumption of the isothermal solid fraction, one gets

$$\tau|_{\Sigma} = 0, \quad (8)$$

by assuming the continuity of the temperature at the solid interface, which is commonly valid if the fluid is not rarefied (see Bruneau *et al.*⁴ for more general boundary conditions).

The set of equations, (3), (4), (5), (7) and (8), together with the geometry of the pores in the material, define the general mathematical problem to be solved. In principle, any problem of linear acoustics involving porous materials could be dealt within this formalism. However, it cannot be handled efficiently under this formulation except for the case of very simple pore geometries such as Kirchhoff's cylinder.² Therefore, in order to proceed further it is necessary to introduce a simpler description of the acoustics of porous media.

An additional hypothesis of local incompressibility greatly simplifies the problem. It is valid for small Mach numbers and when the local length scale is negligible compared to the acoustic wavelength, two hypotheses which are fulfilled in the linear acoustic regime considered and range of frequency of interest. This local incompressibility hypothesis leads to the concepts of effective density and effective compressibility.

Incompressibility at local scale means that the flow velocity has a zero divergence. Equation (5) is now transformed into

$$\text{div} \mathbf{u} = 0, \quad (9)$$

and Eq. (3) becomes

$$\rho_0 i \omega \mathbf{u} = -\mathbf{grad} p + \mu \Delta \mathbf{u}. \quad (10)$$

Equations (9) and (10) with their boundary condition (4) are now fully decoupled from Eq. (7) and its boundary condition (8). The first set of equations defines a dynamic problem, whereas the second defines a thermal one.

Consider first the dynamic problem: at a given frequency f , the flow is generated by a fluctuating pressure gradient. This pressure gradient $\mathbf{grad} p$ can be separated in a locally constant vector $\mathbf{g} = \mathbf{grad} \langle \mathbf{g} \cdot \mathbf{x} \rangle$ and a corrective pressure gradient $\mathbf{grad} q$. The vector \mathbf{g} , which therefore acts as a macroscopic pressure gradient, will be denoted in the following by the more explicit expression $\mathbf{grad} \langle p \rangle$, where $\langle \cdot \rangle$ represents the local spatial average of a quantity in the pore's domain. By linearity of the dynamic problem, there exists a linear relationship between the constant vector \mathbf{g} and the corresponding velocity field \mathbf{u} , and thus between \mathbf{g} and the average velocity $\langle \mathbf{u} \rangle$. This linear relationship between two vectors imposes the introduction of a second order tensor, the effective density tensor, ρ_{eff} :

$$\rho_{\text{eff}} i \omega \langle \mathbf{u} \rangle = -\mathbf{grad} \langle p \rangle. \quad (11)$$

Notice that (11) corresponds formally to an Euler equation. The dissipative behavior is now included in the complex character of the effective density instead of the viscosity.

If the porous medium is isotropic or presents cubic symmetry, however, the effective density tensor reduces to a sca-

lar effective density ρ_{eff} . For the porous materials commonly used in acoustics, this assumption is satisfactory, and the FCC packing of spheres considered here is, by definition, of cubic symmetry: the consequences of anisotropy will not be discussed in the sequel.⁵

The thermal problem can be treated in the same spirit: here, the temperature field is driven by the fluctuating pressure p , which is nearly homogeneous at a local scale. It is then convenient to consider the pressure p as equal to its local average $\langle p \rangle$, and by linearity of the thermal problem, the temperature field τ and its average $\langle \tau \rangle$ are proportional to $\langle p \rangle$. This yields the introduction of a scalar effective compressibility χ_{eff} :

$$\frac{\langle \tau \rangle}{T_0} = \left(\frac{1}{P_0} - \chi_{\text{eff}} \right) \langle p \rangle. \quad (12)$$

The meaning of this complex quantity appears when (11) and (12) are recoupled, this time at a macroscopic level. From the original continuity equation (5), one gets a macroscopic relation by averaging all quantities at a local scale:

$$\langle \text{div } \mathbf{u} \rangle + i\omega \left(\frac{\langle p \rangle}{P_0} - \frac{\langle \tau \rangle}{T_0} \right) = 0. \quad (13)$$

The first term of (13) is the mean relative increase of volume of a fluid particle, and as the flow is assumed incompressible at a local scale, it reduces to its macroscopic contribution $\text{div} \langle \mathbf{u} \rangle$. With (12), Eq. (13) thus becomes

$$\text{div} \langle \mathbf{u} \rangle = -i\omega \chi_{\text{eff}} \langle p \rangle, \quad (14)$$

and χ_{eff} corresponds formally to the compressibility of the porous medium. Finally, (11) and (14) allows the derivation of a dissipative wave equation in the harmonic regime:

$$\Delta \langle p \rangle + \rho_{\text{eff}} \chi_{\text{eff}} \omega^2 \langle p \rangle = 0. \quad (15)$$

The previous equations and boundary conditions constitute the mathematical formulation of the problem, which has to be solved for the geometry of the selected porous medium.

B. Application to model porous media proposed in the literature

Almost all of the theoretical models proposed in the literature to describe sound propagation and absorption in rigid porous media are successive improvements on the analytical solution for a simple porous medium made of cylindrical tubes. Thus, they can be also considered as simplified versions of a more general solution, which is why the most general model has been presented. However, it is worth recalling the steps that led to this general model.

Kirchhoff's paper¹ dealt with the propagation of an acoustic wave in a cylinder. From his results, a very simple model of porous medium can be built consisting of a collection of identical parallel straight tubes of circular cross-section. The only parameters that this model requires are the radius of the cylinders and the fraction of cylinders in a volume of porous material, i.e. its porosity φ .

As pores are hardly straight in any realistic material, a further step is achieved by considering tortuous tubes. Several authors⁶⁻⁸ introduced a scalar parameter to take the effect of this sinuosity into account with different conventions

for each author; the present paper considers the parameter called tortuosity after Johnson *et al.*,⁸ denoted by α_∞ as it is related to the infinite frequency limit of the dynamic problem. For thin tortuous tubes of constant cross-section, it is equal to $(L/L_0)^2$, where L is the length of the tortuous tube and L_0 is the straight line linking both ends of the tube.

Another generalization concerns the shape of the cross section: if the tubes are no longer circular, two different equivalent radii can be introduced, each corresponding to one end of the frequency spectrum. At zero frequency, the flow is completely viscous and thus follows Darcy's law:

$$\varphi \langle \mathbf{u} \rangle = -\frac{k_0}{\mu} \text{grad} \langle p \rangle, \quad (16)$$

where k_0 is permeability. For circular cylinders of radius R , it corresponds to a Poiseuille flow and $k_0 = \varphi R^2/8$, where φ is the porosity of the porous material. More generally, for any geometry, a low frequency length l can be introduced, defined by $k_0 = \varphi l^2/8$.

In contrast, for very high frequencies, the viscosity has an effect in the vicinity of the solid, in a layer that gets thinner with an increasing frequency. The infinite frequency limit is an inviscid incompressible flow, and a characteristic length Λ , playing the role of a high frequency radius, as introduced by Johnson *et al.*,⁸ defined by

$$\frac{2}{\Lambda} = \frac{\int \int_{\Sigma} \mathbf{u}^2 dS}{\int \int_{\Omega} \mathbf{u}^2 dV}, \quad (17)$$

where Ω is the fluid domain and Σ is its solid border. It is customary to work with Λ and with a shape factor M defined by $l^2 = M \Lambda^2 / \alpha_\infty$ instead of l .

When the cross-section does not vary along the tube, and when its orientation varies smoothly, the speed is always nearly axial and the dynamic problem loses its vector character. Thus, the thermal problem and the dynamic problem have the same analytic form and the geometrical lengths R and Λ are common to both problems. The next generalization comes when the porous medium to be considered does not look like such tubes. Each problem thus has its own characteristic lengths, and two quantities Λ' and M' , respectively, a thermal characteristic length and a thermal form factor, have to be introduced.^{9,10} At this point, the most general model may be found in Allard's classical monograph;¹¹ additionally, a last set of parameters, a dynamic parameter, p , and a thermal parameter, p' , have been introduced to improve the models at low frequency^{12,13} to let the theoretical expressions for the effective density and compressibility match the numerical values at the second order in ω . To the authors' knowledge, they do not have any physical interpretation. Such quantities cannot be mixed up with the pressure, so these notations are kept in this paper.

All of these parameters (porosity φ , tortuosity α_∞ , characteristic lengths Λ and Λ' , shape factors M and M' , supplementary parameters p and p') correspond to either the low or high frequency limit. The general expression to interpolate to finite frequency relies on a remark by Biot⁶ that for straight tubes of several different cross-sections, the corresponding effective densities have the same shape. The theoretical ex-

planation was again provided by Johnson *et al.*⁸ It is based on the principle of causality which restricts the possible interpolating functions for both the effective compressibility and density to have their zeros and poles on the negative portion of the imaginary axis (Champoux and Allard⁹).

$$\rho_{\text{eff}} = \rho_0 \alpha_\infty \left(1 - i \frac{8\mu}{\rho_0 \Lambda^2} \frac{1 - p + p \left(1 + \frac{M^2 \rho_0 \Lambda^2}{2p^2} i \omega \right)^{1/2}}{M \omega} \right), \quad (18)$$

and Lafarge's effective compressibility is

$$\chi_{\text{eff}} = \frac{1}{\gamma P_0} \left(\gamma - \frac{\gamma - 1}{1 - i \frac{8\mu}{\rho_0 \text{Pr} \Lambda'^2} \frac{1 - p' + p' \left(1 + \frac{M'^2 \rho_0 \Lambda'^2 \text{Pr}}{2p'^2} i \omega \right)^{1/2}}{M' \omega}} \right). \quad (19)$$

It must be stressed that all the models presented above make use at least implicitly of the local incompressibility hypothesis. In the next section, the homogenization technique is introduced for two reasons: first, to give a mathematically coherent derivation of the incompressibility hypothesis and of the introduction of the effective density and compressibility, and second to obtain an effective numerical scheme for computing those effective quantities. As far as the general model derivation (and all the simpler models in the literature) does not make use of homogenization, but relies on assumptions which can be derived by homogenization, it makes sense to compare numerical computations based on homogenization with theoretical results using the general model.

III. HOMOGENIZATION

The previous derivation (Sec. II) is not completely rigorous. For example, the incompressibility condition (9) is used with the dynamics equation (3), but it should not be used with the heat equation (6). Another important point is that the set of PDEs (3), (4), (5), (7) and (8) do not define a well-posed problem as the boundary conditions (4) and (8) are defined on the solid interface Σ only. As it was assumed that the fluid percolates in the porous medium, it is not surrounded by the solid, so the limits of the fluid domain are not precisely defined and there is a lack of boundary conditions to complete the PDEs. Finally, all the geometries on which the models were derived have a tubular structure, and the tubes do not form a network as the pores of an open porous medium would. These geometries are also basically anisotropic as the all tubes are directed along a same direction, while the corresponding models intend to describe isotropic media.

When the porous medium has a periodic structure, a mathematical technique, known as periodic homogenization,¹⁴ gives a strong basis for the theory of the

The general model, proposed by Pride *et al.*¹² for the effective density on one hand, and by Lafarge¹³ for the effective compressibility on the other, corresponds to an arbitrary choice of functions parametrized by φ , α_∞ , Λ , Λ' , M , M' , p and p' . The Pride *et al.* effective density is given by

previous paragraph; it ensures that the derivation of Eqs. (11) and (14) is coherent, and it provides a way to compute the effective quantities ρ_{eff} and χ_{eff} . As this paper focuses on predicting the acoustical behavior of a FCC packing of spheres, the technique developed later is suitable.¹⁵

First, the standard homogenization scheme is introduced (Sec. III A), leading to its numerical application using the finite element method (Sec. III B).

A. Standard homogenization scheme

The periodic homogenization technique and its results are now briefly described. The presentation of Boutin *et al.*¹⁴ is followed here and we refer to that paper for the details of their derivation in order to focus on the principal hypotheses and results.

The homogenization procedure begins by introducing a ratio ϵ of a characteristic length of the local scale to a characteristic length of the macroscopic scale. When considering a periodic structure, the natural choice of the small length scale is the size of the unit cell, whereas the natural macroscopic length of an acoustical phenomenon is its wavelength. Homogenized equations are expected to hold when this ratio ϵ is small enough.

The procedure can be split into two steps: the first is physical, and the second is mathematical. The physical step is a matter of estimates, and introducing dimensionless quantities may help. Let us therefore make all the variables dimensionless. For example, the reference pressure being the ambient pressure, P_0 , the acoustic pressure, p , is replaced by a reduced pressure, $p' = p/P_0$. The other reference quantities that can be chosen are the angular frequency, ω , the ambient temperature, T_0 , the isothermal celerity, $c_0 = (P_0/\rho_0)^{1/2}$ (the isothermal celerity is preferred to the adiabatic one to avoid unnecessary prefactors), a corresponding macroscopic length $\lambda_0 = c_0/\omega$, and a corresponding viscosity $\mu_0 = \rho_0 \omega \lambda_0^2$. For this viscosity, however, it is more convenient to chose $\mu_0 \epsilon^2$ instead. Boutin *et al.*¹⁴ argue that the characteristic length

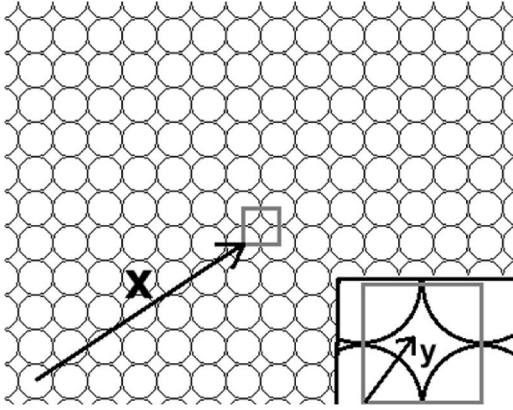

FIG. 2. The macroscopic coordinate \mathbf{x} represents the position of a unit cell, whereas the local coordinate \mathbf{y} represents the position of a point inside that cell.

corresponding to viscous effects is the local length rather than the macroscopic one, and thus an additional ϵ^2 factor coming from the second order derivatives must be introduced. That homogenization scheme, which is followed in this article, is referred to as the standard scheme.

Note also that λ_0 must be used to make the differential operators dimensionless as well as the position variable \mathbf{x} . Denoting the dimensionless variables and operators with a prime symbol, Eq. (3) becomes

$$i\mathbf{u}' = -\mathbf{grad}' p' + \epsilon^2(\lambda' + \mu')\mathbf{grad}'(\text{div}' \mathbf{u}') + \epsilon^2\mu'\Delta' \mathbf{u}'. \quad (20)$$

Equations (5) and (7) become, respectively,

$$\text{div}' \mathbf{u}' = i\tau' - ip' \quad (21)$$

and

$$i\tau' = \frac{\gamma-1}{\gamma} ip' + \frac{\mu'\epsilon^2}{\text{Pr}} \Delta' \tau', \quad (22)$$

where (1) was used and the thermal conductivity was incorporated using the Prandtl number.

The mathematical step of homogenization is actually an asymptotic method, i.e., it provides asymptotic equations from a family of equations parametrized by the ratio ϵ , when this quantity gets small. It first consists of introducing two position variables \mathbf{x} and \mathbf{y} , the former defining the position of a given point at a macroscopic scale and the latter defining it locally. To be clear, \mathbf{x} can be understood as the coordinates of the periodic cell where the point lies, and \mathbf{y} refers to its position inside the cell, as shown in Fig. 2.

As ϵ tends to zero, the cell size gets smaller and smaller, so to work on the same unit cell for any ϵ , the local coordinate, \mathbf{y} , is made dimensionless with a local length such as $\epsilon\lambda_0$, whereas the reference length for \mathbf{x} is the macroscopic one, λ_0 . The reduced coordinates, $\mathbf{x}' = \mathbf{x}/\lambda_0$ and $\mathbf{y}' = \mathbf{y}/\epsilon\lambda_0$, are thus introduced. Any physical quantity depending on position will be considered as a function of both \mathbf{x}' and \mathbf{y}' for a given ϵ . Moreover, its dependence upon ϵ is expanded as a power series as the focus is on the small ϵ limit. As an example, the speed field can be written as

$$\mathbf{u}' = \mathbf{u}'_0(\mathbf{x}', \mathbf{y}') + \epsilon \mathbf{u}'_1(\mathbf{x}', \mathbf{y}') + \epsilon^2 \mathbf{u}'_2(\mathbf{x}', \mathbf{y}') + \dots \quad (23)$$

When ϵ is small, the local behavior does not vary much from one cell to its neighbors, so the dependence upon \mathbf{y}' in (23) is also assumed to be periodic.

The homogenized field is then the average value, with respect to \mathbf{y}' , of the first order field \mathbf{u}'_0 over the periodic cell with respect to \mathbf{y}' . The interesting behavior occurs only at the macroscopic scale and higher order corrections can be ignored if ϵ is small enough. This assumption is always made when applying homogenization.^{14,16}

The dimensionless differential operators are then split into their macroscopic and local components. For example, the gradient operator is expressed as

$$\mathbf{grad}' = \mathbf{grad}'_{\mathbf{x}'} + \frac{1}{\epsilon} \mathbf{grad}'_{\mathbf{y}'}, \quad (24)$$

where the ϵ^{-1} factor comes from the different reference lengths used to make \mathbf{x} and \mathbf{y} dimensionless. When power series such as (23) and two-scale differential operators like (24) are introduced into the dimensionless equations (20), (21) and (22), it yields expansions in increasing powers of ϵ . Identifying the corresponding orders on both members of each equation thereby leads to local equations that will be made explicit.

The higher order in Eq. (21) is ϵ^{-1} , and the corresponding local equation reads as

$$\text{div}'_{\mathbf{y}'} \mathbf{u}'_0 = 0 \quad (25)$$

and the local incompressibility of the fluid speed (9) is found at first order. Equation (20) leads at first order to

$$0 = -\mathbf{grad}'_{\mathbf{y}'} p'_0, \quad (26)$$

which means that the pressure is homogeneous at first order as was assumed above for the heat equation, while at second order one obtains

$$i\mathbf{u}'_0 = -\mathbf{grad}'_{\mathbf{x}'} p'_0 - \mathbf{grad}'_{\mathbf{y}'} p'_1 + \mu' \Delta'_{\mathbf{y}'} \mathbf{u}'_0, \quad (27)$$

which is the dimensionless equation corresponding to (10) and the macroscopic gradient \mathbf{g} introduced above (Sec. II A) corresponds to the gradient of the pressure at first order with respect to the macroscopic variable. A similar conclusion can be obtained for the heat equation, showing that Eq. (7) is valid. The mathematical coherence of the classical derivation is thus justified by the homogenization technique.

The periodicity of any field with respect to \mathbf{y}' is also useful, as it completes the boundary conditions (4) and (8). Thereby, the dynamic and the thermal problems are well posed and can be solved numerically. Thanks to the superposition principle for linear equations, only one computation for the thermal problem and three for the dynamic problem (one by an independent direction of the macroscopic gradient) are required at a given frequency.

A rigorous proof of the validity of the mathematical step, especially concerning the \mathbf{y}' -periodicity and the power series expansion (23), making use of two-scale convergence, can be found in Allaire's thesis.¹⁷

FIG. 3. Mesh of the elementary fluid cell. Anisotropic mesh refinement is visible along the border of the spheres and close to the soldering necks.

B. Numerical implementation

Now that boundary conditions for the dynamic and the thermal problems have been completed by periodic conditions owing to homogenization, both problems deserve a numerical resolution scheme; the authors chose to implement a finite-element method (FEM). Other methods have been suggested in the literature, such as the collocation method¹⁸ and the boundary element method,¹⁹ but only for the dynamic problem. In addition, the collocation method in the paper of Chapman and Higdon¹⁸ is based on spherical harmonics and it seems to be suitable for sphere-based geometries but not for more general ones.

The FEM involves a mesh of elementary polyhedra, on which any function is approximated by simple functions. For example, the present work considered a nonstructured tetrahedral mesh, with linear interpolation functions on each tetrahedron, plus a bubble function (i.e., the product of the four barycentric coordinates of the tetrahedron) for speed degrees of freedom. This last function, supplementing the set in the so-called P1-bubble/P1 approximation,²⁰ must be introduced to ensure the correct convergence of the FEM when the mesh gets thinner. The complete fluid domain of the periodic cell must be meshed. A complementary requirement is that the surface meshes on two bounding surfaces corresponding by periodicity are the same so the periodic boundary conditions can be handled.

Here a physical phenomenon already mentioned above and of capital importance for applying FEM to the problems analyzed here must be emphasized: as frequency increases, the viscous dissipation occurs closer and closer to the solid interface, in a dynamic boundary layer of thickness proportional to $\omega^{-1/2}$. Heat exchanges occur as well in a thermal boundary layer of similar thickness. To give an order of magnitude, at 1 kHz their typical thickness is about 100 μm .

FIG. 4. Real part of the effective density.

Those boundary layers are of crucial importance to characterize absorptive properties of the porous medium at high frequency, as they concentrate the main contribution to energy dissipation. For the FEM to properly describe what happens in the vicinity of the solid, a refined mesh is thus unavoidable. However, it may be too costly in terms of memory to refine the mesh everywhere, so a local refinement close to the solid might be necessary.²¹

The resolution of the thermal problem by FEM, as it is a scalar problem with one PDE only, consists simply in solving a sparse linear system. The dynamic problem is more difficult, and Uzawa's method²² was used to apply the incompressibility condition (9) to (10). The authors refer the reader to the thesis of one of them¹⁶ for the calculation of the matrix elements for tetrahedral elements, the implementation of the boundary conditions (including periodic conditions) and the choice of the numerical method to solve a large sparse linear system being complex and symmetric (but not Hermitian).

IV. RESULTS

This strategy has been applied to a FCC stacking of beads. Figure 3 shows the mesh that was used. The radius of the spheres is here 1 mm, and a soldering neck of radius 150 μm binding the beads together was taken into account. The results of the homogenization technique can be compared to the prediction of the general model (Sec. IV A), other numerical results in the literature (Sec. IV B) and experimental results (Sec. IV C).

A. Comparison with the general model

The effective density and compressibility were computed for several frequencies from 0 to 50 kHz: the results are plotted in Figs. 4 through 6. The theoretical curves, obtained from the general model with computed parameters, are also plotted in these figures.

Concerning the effective density model, the porosity was computed from the volume of the mesh, yielding $\varphi=26\%$ as expected (the correction due to the soldering necks volume is about 0.1%); the tortuosity and the dynamic length Λ were obtained from a potential flow, leading to $\Lambda = 1.64 \times 10^{-4}$ m and $\alpha_\infty = 1.66$. From a steady flow, one can compute the permeability $k_0 = 6.83 \times 10^{-10}$ m², yielding $M = 1.29$ for the dynamic shape factor. The parameter p was obtained from a computation at a very low frequency

FIG. 5. Imaginary part of the effective density.

(10^{-3} Hz). The correlation between the computation and the prediction of the general model (Sec. II) is satisfactory.

For the effective compressibility, Λ' was obtained by a solid surface to volume ratio⁹ on the mesh:

$$\frac{2}{\Lambda'} = \frac{\iint_{\Sigma} dS}{\iiint_{\Omega} dV}, \quad (28)$$

yielding $\Lambda' = 2.49 \times 10^{-4}$ m. The thermal shape factor M' and the parameter p' were derived from computations at very low frequencies (10^{-3} Hz and 10^{-2} Hz) and the values $M' = 1.36$ and $p' = 0.4$ were obtained. The general model provides again a precise prediction of the computed values.

The numerical results at any frequency are correctly described by the general model. Additionally, it is worth noting that the good agreement is not the result of a parameter fitting procedure, since all the parameters were obtained from independent numerical computations at either very low frequencies or at infinite frequency. It is therefore sufficient to compute all the parameters to provide a satisfactory prediction of the effective quantities for all frequencies.

B. Comparison with numerical results of the literature

To the authors' knowledge, all the numerical work on packed beads in the literature have been performed for the dynamic problem. Chapman and Higdon¹⁸ considered the three cubic lattices (SC, BCC and FCC), with overlapping or nonoverlapping spheres depending on the prescribed porosity. In particular, they give the values of the tortuosity, of

FIG. 6. Real part (above) and imaginary part (below) the effective compressibility.

Λ/R and of k_0/R^2 for spheres in contact. Zhou and Sheng²³ computed the tortuosity of a SC packing and its permeability. Finally, Maier *et al.*²⁴ computed the permeability of the FCC packing. The results are gathered in Table I. The computed value of permeability in the present work is very close to that of Maier *et al.*, whereas the Chapman and Higdon value for FCC packing is slightly superior and their tortuosity is also close to the one presented here. The characteristic length, Λ , however, is 32% lower than the value obtained in this study. A possible explanation of this disagreement is that the geometry described above takes soldering necks into account, whereas the Chapman and Higdon geometry consists in spheres with point contacts; as the boundary layer gets small for high frequencies, the influence of the local details of the geometry is stronger for physical parameters defined at high frequencies, i.e. the tortuosity and the dynamic length Λ . Tortuosity, however, usually shows small variations (it hardly exceeds 2 for common geometries), so only Λ is strongly affected by the presence of the necks.

To confirm this qualitative interpretation, a direct computation of α_∞ , Λ and Λ' was performed in the case of straight cylindrical necks (for the sake of meshing efficiency) of varying radius r . Figure 7 shows the three kinds of contact between spheres which are mentioned here (point contact, smooth neck and cylindrical neck). The values α_∞ and Λ are obtained as a result of an inviscid fluid simulation, whereas Λ' was computed as a ratio of a volume to a surface, numeri-

$$h = R - \sqrt{R^2 - r^2}, \quad (29)$$

where V is the volume of the fluid domain in a conventional FCC cell, S its surface and h is the height of a half neck.²⁵

The results for Λ/R and Λ'/R are shown in Fig. 8. The computed value of Λ' is in good agreement with the analytical value and they show a substantial variation with r/R (about 20%). Moreover, the computed value of Λ' on the mesh with a smooth neck is close to the curve for cylindrical necks. Concerning Λ , the numerical results show a stronger dependence on r/R , Λ varying by a factor of 2. The value

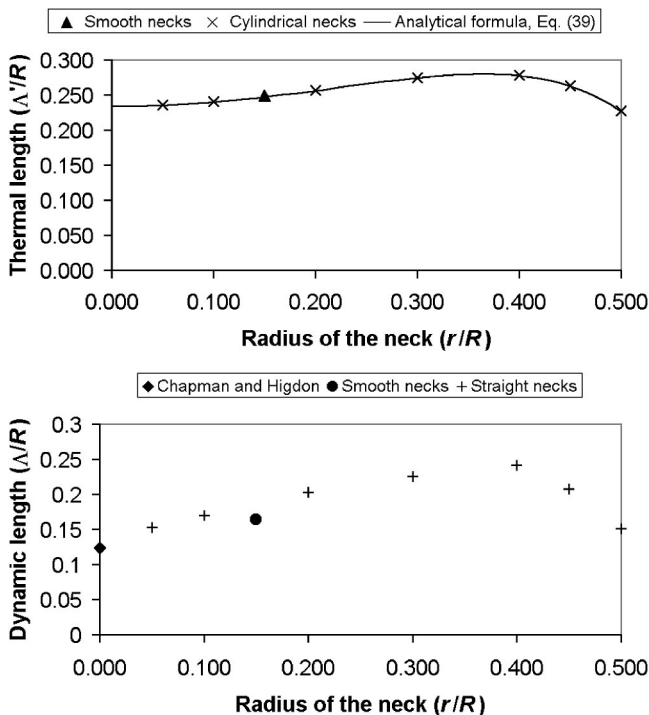

FIG. 8. Characteristic lengths of the equivalent fluid approach as a function of the normalized neck radius for different neck descriptions. (a) Thermal length Λ' ; (b) dynamic length Λ . The values computed above for smooth necks are reported on the graph, as well as the Chapman and Higdon value (Ref. 18) for Λ .

FIG. 9. Tortuosity versus neck radius for cylindrical necks. The value computed above for smooth necks and the Chapman and Higdon value are also reported on the graph.

provided by Chapman and Higdon (i.e., without a neck) seems a satisfactory extension of the computed values of Λ to the case of $r=0$ when meshing becomes difficult, and practically impossible with common meshing software. The value corresponding to the mesh with smooth necks is slightly below the Λ vs r/R curve that can be estimated from Fig. 8, indicating that the shape of the neck plays a role as well.

The numerical simulation provides also the tortuosity. Figure 9 describes its dependence on r/R . The effect of the neck size becomes relevant when r/R reaches about 0.3, the global variation of α_∞ being about 35%. The value computed by Chapman and Higdon is slightly above the plateau for small ratios r/R and the tortuosity obtained with a smooth-neck mesh is slightly above as well. The gap may come from a singular behavior of the analytical inviscid solution in the vicinity of the contact between spheres for the former, whereas for the latter, the disagreement is possibly due to the shape of the neck.

The results presented here thus may be considered to be in good agreement with previous numerical studies and it appears that the high frequency parameters show a rather strong dependence on the size of the soldering necks. It must therefore be taken into account to predict the acoustic behavior of a stack of beads on a broad range of frequencies.

C. Comparison with experimental results of the literature

The numerical results can be compared to previously published results, either experimental measurements or results from a full numerical calculation.

Several measurements of various parameters, summarized in Table II, have been performed on random packings of beads in the literature.

Allard *et al.*²⁶ is the most complete measurement, as it provides values for parameters related to the dynamic problem as well as the thermal problem. The value $M=5$, however, seems too large in comparison with other studies. Charlaix *et al.*²⁷ report measurements on three samples of 50% porosity. Kojima *et al.*^{28,29} measured several samples, two of which being made of sintered glass beads. Baker and Rudnick³⁰ also measured the acoustic parameters on sintered bronze beads. Smeulders *et al.*³¹ limited their study on high

TABLE II. Measurements of different acoustic parameters reported in the literature. The characteristic lengths Λ and Λ' are divided by the sphere radius R . Also, numbers between parentheses refer to values obtained by means of electrical resistance measurements.

frequency parameters for three samples. Finally, Berryman and Blair³² measured $k_0/R^2 = 2.84 \times 10^{-3}$ for a 30% porosity sample.

We made our own experimental measurements based on a least square fit on the absorption curve of several samples between 1000 and 5000 Hz, measured with a Kundt tube of diameter 29 mm. To reduce the number of parameters to be fitted, a simplified model was assumed where $M = M' = p = p' = 1$. The samples were 3 mm high cylinders of either

hollow nickel spheres or full steel beads, in FCC or random packing.

These experimental values provided an order of magnitude of each parameter. It does not seem possible to give a simple law relating tortuosity and porosity, but an interesting correlation can be found between the viscous characteristic length l and the porosity, as it appears in Fig. 10. From Fig. 10, it is possible to derive the following approximate linear relationship:

$$\frac{l}{R} = \frac{4}{3}(\varphi - 0.2). \quad (30)$$

FIG. 10. The correlation between the porosity of the bead packing and the viscous characteristic length, as found in the literature. The first seven sets of values are measurements, whereas the four last sets are numerical results. The straight line shows the approximate linear relationship between the two parameters.

V. CONCLUSION

In the present contribution, the acoustic properties of a regular FCC packing of spherical hollow beads were predicted by means of homogenization and FEM computations, leading to an analytic description of that porous medium in terms of the classical equivalent fluid theory. The predictions agree with previously published numerical and experimental data.

(Received 19 July 2004; revised 6 January 2005; accepted 7 January 2005)

With the recent emergence of surround sound technology, renewed interest has been shown in the problem of sound field reproduction. However, in practical acoustical environments, the performance of sound reproduction techniques are significantly degraded by reverberation. In this paper, we develop a method of sound field reproduction for reverberant environments. The key to this method is an efficient parametrization of the acoustic transfer function over a region of space. Using this parametrization, a practical method has been provided for determining the transfer function between each loudspeaker and every point in the reproduction region. Through several simulation examples, the reverberant field designs have been shown to yield a reproduction accuracy as good as conventional free-field designs, and better than multipoint least squares designs when loudspeaker numbers are limited. The successful reproduction of sound over a wide frequency range has also been demonstrated. This approach reveals the appropriate choices for fundamental design parameters. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1863032]

I. INTRODUCTION

A problem relevant to emerging surround sound technology is a reproduction of a sound field over a region of space. Using a set of loudspeakers, it is possible for listeners to spatialize sound and fully experience what it is actually like to be in the original sound environment. Sound field reproduction has been discussed since the 1960s. However, much of the work so far does not directly address sound field reproduction in reverberant environments. In this paper, using an efficient parametrization of the room transfer function we extend sound field reproduction to reverberant enclosures.

Early work in sound field reproduction was performed by Gerzon.¹ With his ambisonics system, Gerzon reproduced the first-order spherical harmonics terms of a plane wave sound field around a point in space. Ambisonics has since been unified with holography,^{2,3} both of which rely upon the Kirchoff–Helmholtz equation. Here, sound field reproduction inside a control region is achieved by controlling the pressure and its normal derivative over the boundary of the control region.⁴ In similar work, global sound field reproduction techniques^{5,6} have been proposed that control sound pressure over the boundary. By controlling sound at additional points inside the control region, these techniques obviate the need for velocity microphones. Unfortunately, such techniques require a large number of loudspeakers. For a lesser numbers of loudspeakers, Least squares techniques have been suggested by Kirkeby *et al.*^{7,8} Recently, using spherical harmonic analysis, the theoretical minimum number of loudspeakers required for the accurate reproduction of a plane wave has been established.⁹

The reverberant case is made difficult by the rapid variation of the acoustic transfer functions over the room.¹⁰ The

standard approach has been to equalize the transfer functions over multiple points using least squares techniques.^{11,12} However, in such a case, equalization can be poor away from the design points. In contrast, sound field reproduction would require the equalization to extend over the whole control region.

Alternatively, the acoustic transfer functions can be measured and incorporated into the sound field reproduction algorithm directly. Methods for estimating the acoustic transfer functions over a region have been established by Mourjopoulos¹³ and Bharitkar and Kyriakakis,¹⁴ which sample the field at a number of points and use a spatial equalization library. However, for sound field reproduction in a reverberant room, these techniques do not determine transfer functions with sufficient accuracy.

In this paper, we present a method of performing sound field reproduction in a reverberant room. This method is based on an efficient parametrization of the acoustic transfer function in the control region, where the acoustic transfer function is written as the weighted sum of a small number of orthogonal basis functions. Using this parametrization, we reconstruct a sound field accurately over the whole control region. This approach exploits the standing wave structure of the reverberant field generated by each loudspeaker to reproduce the desired sound field. We also describe a practical method for determining the acoustic transfer function between each loudspeaker and the control region, by sampling sound pressure at a small number of points.

This paper is structured as follows. In Sec. II we cast sound field reproduction into a least squares framework and introduce the basis function approach to gain insight into the fundamental parameters of the problem. In Sec. III, we describe a method of measuring the acoustic transfer functions from each speaker to any point within the control region, through measurement of the transfer function parameters of

^{a)}Electronic mail: Thushara.Abhayapala@anu.edu.au

FIG. 1. Use of L loudspeakers to reproduce a desired field in a control region \mathbb{B}^2 with loudspeaker filters $G_l(\omega)$ and acoustical transfer functions $H_l(\mathbf{x}; \omega)$ from the l th loudspeaker to a point $\mathbf{x} \in \mathbb{B}^2$.

the acoustic transfer functions. Separate methods have been derived for the narrow band and wide band cases. The effect of noisy pressure samples on measurement of the parameters has also been analyzed. Finally, in Sec. IV we demonstrate the performance of our sound field reproduction technique with several examples, including a comparison with the multiple point least squares technique.

II. SOUND FIELD REPRODUCTION

In this section, we devise a method of performing two-dimensional 2-D sound field reproduction within a reverberant enclosure. This 2-D technique ensures good reproduction in the plane of the loudspeakers, provided each loudspeaker possesses a sizable vertical dimension. It is applicable to enclosures with highly sound-absorbing floors and ceilings.

The theory we develop in this paper is readily extended to 3-D space. The 2-D basis functions that are described below need only be replaced with 3-D basis functions. Unfortunately, in the case 3-D of reproduction over a volume, much larger numbers of speakers are required.⁹ We focus on reproduction in the plane as it is more practical.

Below we formulate the problem in the frequency domain. The objective is to determine the loudspeaker filter weights required to reproduce a desired sound field in a reverberant room.

A. Problem definition

We aim to reproduce the pressure $P_d(\mathbf{x}; \omega)$ of a desired sound field at each point \mathbf{x} and angular frequency ω in the source-free region of interest \mathbb{B}^2 using an array of L loudspeakers. The desired sound field could be a plane wave, a field resulting from a monopole, a field measured in a real-life scenario or the field of a surround sound system. For purposes of simplifying the analysis in this paper, we choose the control region \mathbb{B}^2 to be the circle of radius R centered about the origin:

$$\mathbb{B}^2 = \{\mathbf{x} \in \mathbb{R}^2 : \|\mathbf{x}\| \leq R\},$$

where $\|\cdot\|$ denotes the Euclidean distance.

As shown in Fig. 1, each loudspeaker l transmits an

output signal $G_l(\omega)$. This signal encapsulates both the input signal applied to loudspeaker l as well as any filtering of it. To characterize the acoustic properties of the enclosure, define the acoustic transfer function $H_l(\mathbf{x}; \omega)$ as the frequency response between loudspeaker l and point \mathbf{x} . $H_l(\mathbf{x}; \omega)$ summarizes the effect of reverberant reflections from the surface of the enclosure on any sound signal transmitted by each loudspeaker. The sound pressure at any point \mathbf{x} due to loudspeaker l is equal to

$$P_l(\mathbf{x}; \omega) = G_l(\omega)H_l(\mathbf{x}; \omega). \quad (1)$$

From Fig. 1, the sound pressure in the reproduced field resulting from the L loudspeakers is then equal to

$$P(\mathbf{x}; \omega) = \sum_{l=1}^L P_l(\mathbf{x}; \omega) = \sum_{l=1}^L G_l(\omega)H_l(\mathbf{x}; \omega). \quad (2)$$

The design task of sound field reproduction is to choose filter weights $G_l(\omega)$ to minimize the normalized reproduction error \mathcal{T} over \mathbb{B}^2 ,

$$\mathcal{T} = \frac{1}{\mathcal{E}} \int_{\mathbb{B}^2} |P(\mathbf{x}; \omega) - P_d(\mathbf{x}; \omega)|^2 da(\mathbf{x}), \quad (3)$$

where the normalizing factor \mathcal{E} is the energy of the desired sound field over \mathbb{B}^2 :

$$\mathcal{E} = \int_{\mathbb{B}^2} |P_d(\mathbf{x}; \omega)|^2 da(\mathbf{x}), \quad (4)$$

$da(\mathbf{x}) = x dx d\phi_x$ is the differential area element at \mathbf{x} , $x = \|\mathbf{x}\|$, and ϕ_x is the polar angle of \mathbf{x} .

The popular approach to solving this problem is to write the least squares solution over a set of uniformly spaced points over \mathbb{B}^2 . (Refs. 7, 8). A better approach is to perform the design over the whole region. This approach is proposed by Asano and Swason¹⁵ for the related problem of equalization. Yet by discretizing, these authors end up implementing a multipoint method. Below we outline a model-based approach, which uses an efficient parametrization for acoustic transfer functions to perform the design over the whole region. This model-based approach is more general than the approach of Asano and Swason¹⁵ and Santillan,¹⁶ which assume that the room is of a rectangular shape. More insight is gained into the design requirements for an accurate reproduction through the model-based approach than through multipoint least squares techniques.

B. Model-based approach

In the model-based approach, we express the sound pressure variables $P_d(\mathbf{x}; \omega)$, $P(\mathbf{x}; \omega)$, and the acoustic transfer functions $H_l(\mathbf{x}; \omega)$ in terms of the basis functions of the sound field. Provided all sound sources (including image sources produced by reflection) lie outside of \mathbb{B}^2 , at any point inside \mathbb{B}^2 the above variables can be written as a weighted sum of the inward-propagating solutions to the wave equation.¹⁷ We write the desired sound pressure $P_d(\mathbf{x}; \omega)$ as

$$P_d(\mathbf{x}; \omega) = \sum_{n=-\infty}^{\infty} \beta_n^{(d)}(\omega) J_n(kx) e^{in\phi_x}, \quad (5)$$

where $\beta_n^{(d)}(\omega)$ is the n th-order sound field coefficient of the desired sound field, $J_n(\cdot)$ is the Bessel function of order n and $k = \omega/c = 2\pi/\lambda$ is the wave number, c is the speed of sound in air, and λ is the acoustic wavelength. The functions $\{J_n(kx)e^{in\phi_x}\}_{n \in \mathbb{Z}}$ are called the basis functions of the sound field. An appropriate choice of sound field coefficients generate any valid sound field inside \mathbb{B}^2 .

Similarly, we write the reproduced sound pressure $P(\mathbf{x}; \omega)$ as

$$P(\mathbf{x}; \omega) = \sum_{n=-\infty}^{\infty} \beta_n(\omega) J_n(kx) e^{in\phi_x}, \quad (6)$$

where $\beta_n(\omega)$ are the coefficients of the reproduced sound field. A reproduction of the sound pressure $P_d(\mathbf{x}; \omega)$ over \mathbb{B}^2 with $P(\mathbf{x}; \omega)$ is equivalent to a reproduction of the sound field coefficients $\{\beta_n^{(d)}(\omega)\}_{n \in \mathbb{Z}}$ with $\{\beta_n(\omega)\}_{n \in \mathbb{Z}}$.

Because the room response is equal to the sound field pressure generated by the unit input signal $G_l(\omega)$, we can also write it as

$$H_l(\mathbf{x}; \omega) = \sum_{n=-\infty}^{\infty} \alpha_n(l, \omega) J_n(kx) e^{in\phi_x}, \quad (7)$$

where $\alpha_n(l, \omega)$ are the sound field coefficients of the room responses for loudspeaker l . These sound field coefficients completely characterize the reverberant sound field generated by each loudspeaker within \mathbb{B}^2 :

Observation 1: When the sound field coefficients $\alpha_n(l, \omega)$ for each loudspeaker are known for a given room, the acoustic transfer function $H_l(\mathbf{x}; \omega)$ between each loudspeaker and any position \mathbf{x} inside \mathbb{B}^2 is also known, and is given by Eq. (7).

Substituting Eq. (5) and Eq. (7) directly into Eq. (2), the coefficients of the reproduced sound field are related to $\alpha_n(l, \omega)$ through

$$\beta_n(\omega) = \sum_{l=1}^L G_l(\omega) \alpha_n(l, \omega). \quad (8)$$

The sequences of coefficients $[\beta_n^{(d)}(\omega)]_n$, $[\beta_n(\omega)]_n$ and $[\alpha_n(l, \omega)]$ associated with any wave field in a source-free region are shown to be bounded.¹⁸ (These coefficients are bounded in the following sense. Any field in the source-free region can be represented as the superposition of plane waves. The coefficients are bounded by the sum of the magnitudes of these plane waves.)

A benefit of the model-based approach is the ability to express key variables in terms of orthogonal functions. Using the orthogonality property of exponential functions,

$$\int_0^{2\pi} e^{-in\phi} e^{im\phi} d\phi = 2\pi \delta_{nm}, \quad (9)$$

we derive an expression for the energy \mathcal{E} and normalized error \mathcal{T} of the reproduced sound field over \mathbb{B}^2 as a function of the sound field coefficients. Starting with the field energy, we substitute Eq. (5) into Eq. (4) to yield

$$\mathcal{E} = \int_{\mathbb{B}^2} \left| \sum_{n=-\infty}^{\infty} \beta_n^{(d)}(\omega) J_n(kx) e^{in\phi_x} \right|^2 da(\mathbf{x}).$$

It follows that

$$\begin{aligned} \mathcal{E} &= \int_{\mathbb{B}^2} \sum_{n_1=-\infty}^{\infty} [\beta_{n_1}^{(d)}(\omega)]^* J_{n_1}(kx) e^{-in_1\phi_x} \\ &\quad \times \sum_{n_2=-\infty}^{\infty} \beta_{n_2}^{(d)}(\omega) J_{n_2}(kx) e^{in_2\phi_x} da(\mathbf{x}) \\ &= \sum_{n_1=-\infty}^{\infty} \sum_{n_2=-\infty}^{\infty} [\beta_{n_1}^{(d)}(\omega)]^* \beta_{n_2}^{(d)}(\omega) \\ &\quad \times \int_0^{2\pi} e^{-in_1\phi_x} e^{in_2\phi_x} d\phi_x \\ &\quad \times \int_0^R J_{n_1}(kx) J_{n_2}(kx) x dx, \end{aligned}$$

where we have applied $da(\mathbf{x}) = x dx d\phi_x$ in the second step. Applying the orthogonality property, Eq. (9), of the exponential functions, the field energy reduces to

$$\begin{aligned} \mathcal{E} &= 2\pi \sum_{n=-\infty}^{\infty} |\beta_n^{(d)}(\omega)|^2 \int_0^R [J_n(kx)]^2 x dx \\ &= K \sum_{n=-\infty}^{\infty} w_n(kR) |\beta_n^{(d)}(\omega)|^2, \end{aligned} \quad (10)$$

where $K = 2\pi/k^2$ and

$$w_n(kR) \triangleq k^2 \int_0^R [J_n(kx)]^2 x dx = \int_0^{kR} [J_n(x)]^2 x dx. \quad (11)$$

The second step was performed with the variable substitution $x' = kx$. Similarly, substituting Eq. (5) and Eq. (6) into Eq. (3), the normalized error becomes

$$\mathcal{T} = \frac{1}{\mathcal{E}} \int_{\mathbb{B}^2} \left| \sum_{n=-\infty}^{\infty} [\beta_n^{(d)}(\omega) - \beta_n(\omega)] J_n(kx) e^{in\phi_x} \right|^2 da(\mathbf{x}).$$

Utilizing the orthogonality property, the normalized error reduces to

$$\mathcal{T} = \frac{K}{\mathcal{E}} \sum_{n=-\infty}^{\infty} w_n(kR) |\beta_n^{(d)}(\omega) - \beta_n(\omega)|^2. \quad (12)$$

We shall call $w_n(kR)$ in (12) the *coefficient weighting function*.

Since the summations in Eq. (5), Eq. (6), and Eq. (7) have infinite numbers of terms, it may seem that the above parametrizations need an infinite number of coefficients. However, in the next section, we show that for any finite control region, they need only a finite number of coefficients to accurately represent a sound field or a room response.

C. Active basis functions

Because of the high-pass character of Bessel functions, not all of the basis functions make a significant energy contribution to the sound field inside \mathbb{B}^2 . Studying Eq. (12), because the sequences of sound field coefficients $[\beta_n^{(d)}(\omega)]_n$ and $[\beta_n(\omega)]_n$ are bounded while from Fig. 2,

FIG. 2. A plot of the coefficient weighting function $w_{|n|}(kR)$ vs $|n|$ for control regions with radii $R=[1\lambda, 2\lambda, \dots, 10\lambda]$. λ is the acoustic wavelength of interest, related to the wave number by $k=2\pi/\lambda$.

$w_n(kR)$ drop rapidly to zero past a threshold, the energy contribution of each term to reproduction error is controlled by $w_n(kR)$.

Previous work^{9,18} asserts that only the basis functions of index up to $N=[kR]$ contribute significant energy to the sound field inside B^2 . This result is supported by Fig. 2, where $w_{|n|}(kR)$ is plotted against $|n|$. [Note the coefficient weighting functions of negative index are a mirror of those of positive index $w_{-n}(kR)=w_n(kR)$. This can be seen by applying the Bessel function property $J_n(x)=(-1)^n J_{-n}(x)$.] The weighting is seen to be small past $|n|>N$. The $2N+1$ basis functions, $J_{-N}(kx)e^{-iN\phi_x}, \dots, J_N(kx)e^{iN\phi_x}$ are referred to as *active* in B^2 . The remaining basis functions are referred to as *inactive* in B^2 . Such basis functions only contribute significant energy to the sound field outside of B^2 .

An accurate sound field reproduction requires the reproduction of these active basis functions. Also, the acoustic transfer functions mentioned in Observation 1 are accurately determined just by measuring the sound field coefficients $\{\alpha_n(l, \omega)\}_{n=-N}^N$ of the active basis functions.

D. Least squares solution

We now derive the least squares solution for the speaker filter weights that minimizes the reproduction error in Eq. (12). This solution is expressed in terms of the sound field coefficients.

Because the weighting of terms in the normalized error in Eq. (12) rapidly diminish for $|n| \geq N$, it can be truncated to

$$\mathcal{T}_{N_T} = \frac{K}{\mathcal{E}} \sum_{n=-N_T}^{N_T} w_n(kR) |\beta_n(\omega) - \beta_n^{(d)}(\omega)|^2, \quad (13)$$

for $N_T \geq N$. This truncated reproduction error \mathcal{T}_{N_T} can be written in matrix form, as follows. Defining the vector of loudspeaker filter weights $\mathbf{g}=[G_1(\omega), G_2(\omega), \dots, G_L(\omega)]^T$, where $[\cdot]^T$ is the matrix transpose operator, the vector of the coefficients of the reproduced sound field $\boldsymbol{\beta}$

$=[\beta_{-N_T}(\omega), \beta_{-N_T+1}(\omega), \dots, \beta_{N_T}(\omega)]^T$, and the matrix of the coefficients of the room responses of all loudspeakers,

$$\mathbf{A} = \begin{bmatrix} \alpha_{-N_T}(1, \omega) & \alpha_{-N_T}(2, \omega) & \cdots & \alpha_{-N_T}(L, \omega) \\ \alpha_{1-N_T}(1, \omega) & \alpha_{1-N_T}(2, \omega) & \cdots & \alpha_{1-N_T}(L, \omega) \\ \vdots & \vdots & \ddots & \vdots \\ \alpha_{N_T}(1, \omega) & \alpha_{N_T}(2, \omega) & \cdots & \alpha_{N_T}(L, \omega) \end{bmatrix}, \quad (14)$$

Eq. (8) can be rewritten as $\boldsymbol{\beta}=\mathbf{A}\mathbf{g}$. Additionally, define the vectors of the coefficients of the desired sound field, $\boldsymbol{\beta}_d=[\beta_{-N_T}^{(d)}(\omega), \beta_{-N_T+1}^{(d)}(\omega), \dots, \beta_{N_T}^{(d)}(\omega)]^T$, and the diagonal weighting matrix,

$$\mathbf{W} = \begin{bmatrix} w_{-N_T}(kR) & 0 & \cdots & 0 \\ 0 & w_{-N_T+1}(kR) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & w_{N_T}(kR) \end{bmatrix}.$$

Writing the numerator of Eq. (13) in matrix form:

$$\sum_{n=-N_T}^{N_T} w_n(kR) |\beta_n(\omega) - \beta_n^{(d)}(\omega)|^2 = (\boldsymbol{\beta} - \boldsymbol{\beta}_d)^H \mathbf{W} (\boldsymbol{\beta} - \boldsymbol{\beta}_d),$$

where $(\cdot)^H$ is the matrix Hermitian operator, the truncated reproduction error can be written as

$$\mathcal{T}_{N_T} = \frac{(\boldsymbol{\beta} - \boldsymbol{\beta}_d)^H \mathbf{W} (\boldsymbol{\beta} - \boldsymbol{\beta}_d)}{\boldsymbol{\beta}_d^H \mathbf{W} \boldsymbol{\beta}_d}.$$

Since $\boldsymbol{\beta}=\mathbf{A}\mathbf{g}$, we expand the truncated reproduction error as a quadratic form in the vector of loudspeaker filter weights:

$$\mathcal{T}_{N_T}(\mathbf{g}) = \frac{1}{d} (\mathbf{g}^H \mathbf{B} \mathbf{g} - \mathbf{b}^H \mathbf{g} - \mathbf{g}^H \mathbf{b} + d),$$

where $\mathbf{B}=\mathbf{A}^H \mathbf{W} \mathbf{A}$, $\mathbf{b}=\mathbf{A}^H \mathbf{W} \boldsymbol{\beta}_d$, $d=\boldsymbol{\beta}_d^H \mathbf{W} \boldsymbol{\beta}_d$. This quadratic form possesses its global minimum at¹⁵

$$\hat{\mathbf{g}} = \mathbf{B}^{-1} \mathbf{b} = (\mathbf{A}^H \mathbf{W} \mathbf{A})^{-1} \mathbf{A}^H \mathbf{W} \boldsymbol{\beta}_d, \quad (15)$$

with the associated minimum in truncated reproduction error:

$$\mathcal{T}_{N_T}(\hat{\mathbf{g}}) = 1 - \frac{1}{d} \mathbf{b}^H \mathbf{B}^{-1} \mathbf{b}.$$

Once $(\mathbf{A}^H \mathbf{W} \mathbf{A})^{-1} \mathbf{A}^H \mathbf{W}$ is computed for the acoustical environment, the reproduced sound field can be changed easily by modifying $\boldsymbol{\beta}_d$.

E. Multiple-point approach

For comparison, we describe the conventional least squares approach, where the sound field is reproduced at several points. Here we aim to reproduce the desired sound field $P_d(\mathbf{x}; \omega)$ over M points $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M$, positioned within the region of interest B^2 with $M \geq L$. Define the vector of desired sound pressure at each point $\mathbf{p}_d=[P_d(\mathbf{x}_1; \omega), P_d(\mathbf{x}_2; \omega), \dots, P_d(\mathbf{x}_M; \omega)]^T$, and the acoustic transfer functions between the loudspeakers and control points into the matrix,

$$\mathbf{H} = \begin{bmatrix} H_1(\mathbf{x}_1; \omega) & H_2(\mathbf{x}_1; \omega) & \cdots & H_L(\mathbf{x}_1; \omega) \\ H_1(\mathbf{x}_2; \omega) & H_2(\mathbf{x}_2; \omega) & \cdots & H_L(\mathbf{x}_2; \omega) \\ \vdots & \vdots & \ddots & \vdots \\ H_1(\mathbf{x}_M; \omega) & H_2(\mathbf{x}_M; \omega) & \cdots & H_L(\mathbf{x}_M; \omega) \end{bmatrix}.$$

The loudspeaker weights are determined from the (possibly overdetermined) system $\mathbf{H}\mathbf{g}=\mathbf{p}$. The least squares solution is then given by $\hat{\mathbf{g}}=\mathbf{H}^\dagger\mathbf{p}$, where $[\cdot]^\dagger$ is the Moore–Penrose inverse.

In Sec. IV, the multiple-point approach has been compared to the model-based approach. We shall see that since the model-based approach targets reproduction over the whole control region, it yields superior performance to the multiple-point approach.

In the next section we describe a method for measuring coefficients for the acoustic transfer function in matrix \mathbf{A} for the model-based approach.

III. ESTIMATION OF SOUND FIELD COEFFICIENTS

In this section we describe how to fully determine the sound field inside a control region \mathbb{B}^2 through measurement of the sound field coefficients. This task is important as it is required to calculate $\{\alpha_n(l, \omega)\}_{n \in \mathbb{Z}}$ that characterize the reverberant field generated by each loudspeaker.

We write the sound pressure $P(\mathbf{x}; \omega)$ inside \mathbb{B}^2 generated by a loudspeaker outside \mathbb{B}^2 in a reverberant enclosure as the basis function expansion:

$$P(\mathbf{x}; \omega) = \sum_{n=-\infty}^{\infty} \beta_n(\omega) J_n(kx) e^{in\phi_x}, \quad (16)$$

where $\beta_n(\omega)$ is the sound field coefficient of order n . To determine the field pressure inside \mathbb{B}^2 , we describe a simple means of measuring $\beta_n(\omega)$.

The method used to determine the sound field coefficients varies depending on whether they are required in a narrow range of frequencies (Sec. III A) or a wide range of frequencies (Sec. III B).

A. Narrow-band method

In the case that sound field reproduction is performed in a narrow frequency range for a choice of R , away from any zero of $J_n(kR)$, good sound field coefficient estimates are obtained by sampling pressure over a single circle of radius R .

1. Computation of sound field coefficients

The sound field coefficients are obtained from the analysis equation,

$$\beta_n(\omega) = \frac{1}{2\pi J_n(kx)} \int_0^{2\pi} P(\mathbf{x}; \omega) e^{-in\phi_x} d\phi_x, \quad (17)$$

provided x is not a zero of $J_n(kx)$. This equation is derived by multiplying both sides of Eq. (16) by $e^{-in'\phi}$, integrating, and applying the orthogonality property. Interpreting this equation, the sound field coefficients and hence sound field can be known in the whole of \mathbb{B}^2 just by measuring sound pressure on a circle of radius x .

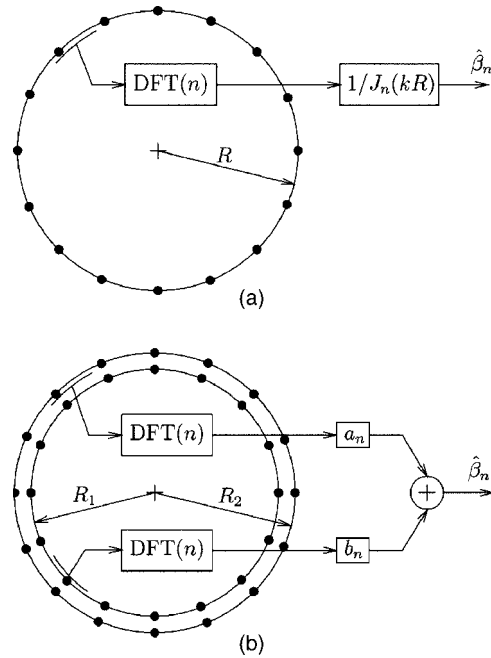

FIG. 3. Proposed methods for measuring the sound field coefficients $\hat{\beta}_n(\omega)$ in (a) the narrow band case where pressure is sampled at one radius R and (b) the wide band case where pressure is sampled at two radii, R_1 and R_2 .

In this paper we sample pressure at $x=R$, on the boundary of \mathbb{B}^2 . Now at a radius x , only basis functions of order up to $[kx]$ are active. Over the boundary all of the active basis functions of \mathbb{B}^2 are active, while the higher-order basis functions are inactive. So heuristically this choice of sampling radius makes sense.

Approximate sound field coefficients $\hat{\beta}_n(\omega)$ are obtained by sampling sound pressure at M evenly spaced points (R, ϕ_m) , where $\phi_m = 2\pi m/M$ for $m=0, 1, \dots, M-1$. Since Eq. (17) shows $\beta_n(\omega) J_n(kR)$ are the Fourier series coefficients of $P(R, \phi; \omega)$ in variable ϕ . Consequently, it can be approximated with the discrete Fourier transform (DFT) relationship:

$$\hat{\beta}_n(\omega) = \frac{1}{J_n(kR)} \text{DFT}\{P(R, \phi_m; \omega)\}(n), \quad (18)$$

where $\text{DFT}\{f(m)\}(n)$ is the M -point DFT, defined by

$$\text{DFT}\{f(m)\}(n) = \frac{1}{M} \sum_{m=0}^{M-1} f(m) e^{-i(2\pi mn/M)}. \quad (19)$$

Coefficients $\hat{\beta}_n(\omega)$ are recognized as the DFT of the sampled field pressure around the circle $\{P(R, 2\pi m/M; \omega)\}_{m=0}^{M-1}$, weighted by the Bessel function term $1/J_n(kR)$ [Fig. 3(a)].

An appropriate choice for M can be deduced by noting that the sound field in \mathbb{B}^2 is the result of $2N+1$ active basis functions. Since one equation is required for each sound field coefficient, we need at least $M=2N+1$ pressure samples where $N=\lceil kR \rceil$.

Due to the presence of $1/J_n(kR)$ in Eq. (18), if kR is near one of the Bessel zeros, coefficient error is amplified. This error amplification can be negated by oversampling pressure, as is seen in the next section.

FIG. 4. Sample measurement parameter ΔN required for several values of ϵ' (in dB). The curves show the ΔN required to ensure that $|J_{\Delta N}(kR)|$ is upper bounded by ϵ' . The total number of pressure samples required is then $N + [\Delta N]$, where N is the number of active basis functions.

2. Approximation error

In Appendix A, we show the error in the approximated sound field coefficients $\hat{\beta}_n(\omega)$ is given by

$$\hat{\beta}_n(\omega) - \beta_n(\omega) = \frac{1}{J_n(kR)} \sum_{q=-\infty, \neq 0}^{\infty} J_{n+qM}(kR) \beta_{n+qM}(\omega). \quad (20)$$

This equation reveals a type of aliasing, since the higher-order coefficients $\{\beta_{n+qM}(\omega)\}_{q=-\infty, \neq 0}^{\infty}$ are mapped onto each $\hat{\beta}_n(\omega)$. It also shows the magnitude of the approximation error is controlled by the size of $1/J_n(kR)$. We shall refer to the summation term in Eq. (20) as the *aliasing error* and the preceding $1/J_n(kR)$ term as the *error scaling*. If $J_n(kR)$ is small, the error scaling is large.

From Eq. (20), each basis function of index $n+qM$ makes a termwise contribution of $[J_{n+qM}(kR)/J_n(kR)]\beta_{n+qM}(\omega)$ for $q \neq 0$ to the approximation error in $\hat{\beta}_n(\omega)$. We now identify a choice of M that ensures the termwise scale factor $J_{n+qM}(kR)/J_n(kR)$ arbitrarily small.

Define κ_n as the largest *termwise scale factor* in $\beta_n(\omega)$:

$$\kappa_n \triangleq \max_{q=-\infty, \dots, \infty, \neq 0} \left| \frac{J_{n+qM}(kR)}{J_n(kR)} \right|, \quad (21)$$

for $n = -N, -N+1, \dots, N$. In Appendix B, the largest termwise scale factor of all of the active basis functions is shown to be bounded by

$$\begin{aligned} \max_{n=-N, \dots, N} \kappa_n &\leq \underbrace{\max_{n=0, \dots, N} 1/|J_n(kR)|}_{\kappa_{\text{es}}} \\ &\times \underbrace{\frac{1}{\sqrt{2\pi(M-N)}} \left[\frac{ekR}{2(M-N)} \right]^{M-N}}_{\text{upper bound on } |J_{M-N}(kR)|}. \end{aligned} \quad (22)$$

The first term in this bound is the maximum error scaling that we shall denote as κ_{es} . The second term is a bound on the Bessel function $J_{M-N}(kR)$ obtained from Jones *et al.*¹⁸ We note in Eq. (22) that the largest termwise scaling factor decays exponentially to zero as M is increased past $N + [ekR/2]$. This observation suggests choosing $M \approx N + [ekR/2]$. However, a better procedure for the choice of M , motivated by the form of Eq. (22) is presented next.

3. Conservative estimate of M

This procedure allows a more accurate choice of M .

- Choose the desired bound ϵ on the termwise scale factor; i.e., choose a bound for which $\max_{n=-N, \dots, N} \kappa_n < \epsilon$.
- Calculate the maximum error scaling:

$$\kappa_{\text{es}} = \max_{n=0, 1, \dots, N} |1/J_n(kR)|.$$
- Determine $\Delta N = M - N$ to guarantee $|J_{N-M}(kR)|$ is upper bounded by $\epsilon' = \epsilon/\kappa_{\text{es}}$ through the relationship

$$\frac{1}{\sqrt{2\pi\Delta N}} \left[\frac{ekR}{2\Delta N} \right]^{\Delta N} = \epsilon'. \quad (23)$$
- The required number of samples $M = N + [\Delta N]$.

A judicious choice of radius R ensures that κ_{es} is minimal. Further, such a choice will result in minimizing the number of required pressure samples.

Interestingly, Fig. 4 shows a linear relationship between ΔN and kR for large kR . Rearranging Eq. (23):

$$\Delta N = \frac{e}{2} (\sqrt{2\pi\Delta N\epsilon'})^{-1/\Delta N} kR.$$

As $\Delta N \rightarrow \infty$, the term $(\sqrt{2\pi\Delta N\epsilon'})^{-1/\Delta N} \rightarrow 1$, causing this expression to reduce to $\Delta N \approx ekR/2$. This relationship explains the linear section of the curves in Fig. 4 and is consistent with the $N + [ekR/2]$ rule.

In summary, we require at least $M = 2N + 1$ pressure samples to measure the sound field coefficients of the active basis functions. An analysis of the error in approximated sound field coefficients shows that for an accurate measurement of sound field coefficients more pressure samples may be required. The larger M is required to negate the effects of error scaling. A conservative procedure for estimating M is summarized above.

B. Wide band method

In frequency ranges and sizes of \mathbb{B}^2 of interest to practical problems, the Bessel term $J_n(kR)$ is guaranteed to be zero at a number of frequencies. These zeros cause problems when designing with the above method over a wide frequency range. For each zero, a basis functions remains unmeasurable.

To illustrate the magnitude of the problem, consider the asymptotic behavior (that is, the behavior for large kR) of the Bessel function:¹⁷

$$J_n(kR) \sim \sqrt{\frac{2}{\pi kR}} \cos(kR - n\pi/2 - \pi/4). \quad (24)$$

FIG. 5. Bessel functions $J_n(kR)$ that are active in a control region of radius 0.3 m and frequencies up to 4 kHz. Each zero of the Bessel functions is marked with a dot (\cdot).

One can see from this equation that each of the Bessel functions has zeros spaced approximately $kR = \pi$ or $f = c/2R$ apart. In a region B^2 with radius $R = 0.3$ m and speed of sound $c = 342$ m/s, each $J_n(kR)$ has zeros spaced 570 Hz apart. In a 0–4 kHz frequency range there are 58 zeros present (Fig. 5). On average, one zero occurs every 69 Hz, with the larger concentration of zeros at higher frequencies.

To combat this problem, we propose an alternative method for the wide-band case. Instead of sampling over a single radius R we sample over two concentric circles of radii $R_1 = R - \delta R$ and $R_2 = R$ [Fig. 3(b)].

1. Computation of sound field coefficients

Multiplying both sides of Eq. (16) by basis function $J_{n'}(kx)e^{-in'\phi_x}$ and integrating over the thin shell of thickness $\delta R = R_2 - R_1$, $\{\mathbf{x} \in \mathbb{R}^2: R_1 \leq \|\mathbf{x}\| \leq R_2\}$, the orthogonality property, Eq. (9), is used to show that

$$\beta_n(\omega) = \frac{1}{2\pi \int_{R_1}^{R_2} [J_n(kx)]^2 x dx} \times \int_{R_1}^{R_2} \int_0^{2\pi} P(\mathbf{x}; \omega) J_n(kx) e^{-in\phi_x} dx d\phi_x.$$

For small δR , we can approximate the integral in x with the zeroth-order approximation:

$$\int_{R_1}^{R_2} f(x) dx \approx \frac{1}{2} [f(R_1) + f(R_2)] \delta R. \quad (25)$$

Using Eq. (25), we express $\beta_n(\omega)$ as a sum of two weighted Fourier series equations. Sampling the field with M evenly spaced sensor pairs positioned at (R_1, ϕ_m) and (R_2, ϕ_m) , the sound field coefficients $\beta_n(\omega)$ are estimated with

$$\hat{\beta}_n(\omega) = a_n(\omega) \text{DFT}\{P(R_1, \phi_m; \omega)\}(n) + b_n(\omega) \text{DFT}\{P(R_2, \phi_m; \omega)\}(n), \quad (26)$$

where for $R_1 \approx R_2$, the DFTs are weighted by

$$a_n(\omega) = \frac{J_n(kR_1)}{[J_n(kR_1)]^2 + [J_n(kR_2)]^2}, \quad (27)$$

$$b_n(\omega) = \frac{J_n(kR_2)}{[J_n(kR_1)]^2 + [J_n(kR_2)]^2}. \quad (28)$$

The approximated sound field coefficients can hence be obtained through taking the DFT of the pressure samples around each circle and calculating a weighted average.

Next we analyze the error in the approximated sound field coefficients.

2. Approximation error

For the wide band method, the error in the approximated sound field coefficients is

$$\hat{\beta}_n(\omega) - \beta_n(\omega) = a_n(\omega) \sum_{q=-\infty, \neq 0}^{\infty} J_{n+qM}(kR_1) \beta_{n+qM}(\omega) + b_n(\omega) \sum_{q=-\infty, \neq 0}^{\infty} J_{n+qM}(kR_2) \beta_{n+qM}(\omega). \quad (29)$$

This expression is proven by substituting Eq. (19) into Eq. (26) and simplifying the resulting expression in a manner similar to that in Appendix A. In contrast to the narrow band case in Eq. (20), the wide band case possesses two error scaling terms, $a_n(\omega)$ and $b_n(\omega)$. Also, the presence of $[J_n(kR_1)]^2 + [J_n(kR_2)]^2$ in the denominators of the error scaling terms [see Eq. (27) and Eq. (28)] improves the robustness at the zeros.

The critical parameter in the wide band technique is δR . δR controls the maximum value of the error scaling terms $a_n(\omega)$ and $b_n(\omega)$, as we will now show. When either kR_1 or kR_2 is a zero of the Bessel function, approximation error simplifies to the narrow band expression in Eq. (20). In the case $J_n(kR_1) = 0$, the error scaling terms reduce to $a_n(\omega) = 0$ and $b_n(\omega) = 1/|J_n(kR_2)|$. For δR small, $J_n(kR_2)$ is also small and the linear approximation $J_n(kR_2) = k\delta R J'_n(kR_1)$ can be made. By the derivative property of the Bessel function $xJ'_n(x) = nJ_n(x) - xJ_{n+1}(x)$, we see that $J'_n(kR_1) = J_{n+1}(kR_1)$, so the nonzero error scaling term is

$$b_n(\omega) \approx \frac{1}{k\delta R |J_{n+1}(kR_1)|}.$$

From this equation, it seems advantageous to choose δR large, as a larger δR implies a smaller error scaling. However, δR cannot be too large, otherwise $J_n(kR_2)$ may coincide with another zero of the same Bessel function. As these Bessel functions are regularly spaced, we can select δR to avoid this case. From Eq. (24) the Bessel zeros of $J_n(kR)$ are spaced π apart, so set $k\delta R < \pi/2$ or $\delta R < \lambda/4$. An appropriate choice of δR is hence 1/4 of the smallest acoustic wavelength of interest.

C. Impact of measurement noise

In real rooms with background noise and sensor noise, it is nontrivial to obtain clean measurements of the acoustical

transfer functions. In this section we study how such noise impacts measurement of the sound field coefficients.

Model the measurement noise $\eta(\mathbf{x};\omega)$ at each sensor position \mathbf{x} as additive white noise of zero mean and variance $\sigma^2(\omega)$. The noisy pressure is

$$\tilde{P}(\mathbf{x};\omega) = P(\mathbf{x};\omega) + \eta(\mathbf{x};\omega). \quad (30)$$

Calculating the DFT of both sides of Eq. (30) and comparing with Eq. (18), the noisy sound field coefficient estimates $\tilde{\beta}_n(\omega)$ are shown to be related to the noiseless estimates $\hat{\beta}_n(\omega)$ by

$$\tilde{\beta}_n(\omega) = \hat{\beta}_n(\omega) + \frac{1}{J_n(kR)} \text{DFT}\{\eta(R, \phi_m; \omega)\}(n).$$

Inserting the definition of the DFT in Eq. (19) and rearranging:

$$\tilde{\beta}_n(\omega) - \hat{\beta}_n(\omega) = \frac{1}{J_n(kR)} \frac{1}{M} \sum_{m=0}^{M-1} \eta(R, \phi_m; \omega) e^{-i(2\pi mn/M)}. \quad (31)$$

Equation (31) is used to derive the mean and variance of the noisy sound field coefficient estimates. Taking the expectation of both sides of Eq. (31), the zero mean property of $\eta(R, \phi_m; \omega)$ implies that

$$E\{\tilde{\beta}_n(\omega) - \hat{\beta}_n(\omega)\} = 0,$$

or $E\{\tilde{\beta}_n(\omega)\} = \hat{\beta}_n(\omega)$. Measurement of the sound field coefficients remains unbiased by noise with zero mean. Multiplying Eq. (31) by its complex conjugate and taking the expectation, the variance is given by

$$\begin{aligned} E\{|\tilde{\beta}_n(\omega) - \hat{\beta}_n(\omega)|^2\} &= \frac{1}{[J_n(kR)]^2} \frac{1}{M^2} \\ &\times \sum_{m_1=0}^{M-1} \sum_{m_2=0}^{M-1} E\{\eta^*(R, \phi_{m_1}; \omega) \\ &\times \eta(R, \phi_{m_2}; \omega)\} \\ &\times \exp\{i2\pi(m_1 - m_2)n/M\}. \end{aligned}$$

In the case that noise is spatially uncorrelated, $E\{\eta^*(R, \phi_{m_1}; \omega) \eta(R, \phi_{m_2}; \omega)\} = \sigma^2(\omega) \delta_{m_1 m_2}$, and the variance reduces to

$$E\{|\tilde{\beta}_n(\omega) - \hat{\beta}_n(\omega)|^2\} = \frac{1}{M} \frac{\sigma^2(\omega)}{J_n(kR)^2}.$$

The variance is influenced by error scaling factor $1/|J_n(kR)|$. In the wide band case, we can use a similar derivation to show that the sound field coefficient estimates are also unbiased and have a variance given by

$$E\{|\tilde{\beta}_n(\omega) - \hat{\beta}_n(\omega)|^2\} = \frac{1}{M} \frac{\sigma^2(\omega)}{[J_n(kR_1)]^2 + [J_n(kR_2)]^2}. \quad (32)$$

The Bessel functions in the denominators of Eq. (32) show that similar error scaling occurs in the noise error of the wide band case.

This error scaling of the measurement noise impacts the

FIG. 6. Layout of loudspeakers (○) and pressure sample points (●) for sound field reproduction in the simulations. Though loudspeakers could be arbitrarily placed, we set them on a circle of radius 2 m centered about [3.8 m, 2.4 m].

measurability of the sound field coefficients. In general, when $J_n(kR)$ is small the error scaling causes a large amplification of measurement noise. For the inactive basis functions, the Bessel terms $J_n(kR)$ are so small as to be effectively zero. The resulting error scaling is so large that the sound field coefficients are unmeasurable, even for a small $\sigma^2(\omega)$.

IV. SIMULATION EXAMPLES

In the following examples, we illustrate the sound reproduction of a plane wave and a single monopole source at a single frequency (Sec. IV A and Sec. IV B) and at a range of frequencies (Sec. III D). Single frequency reproduction is performed at 1 kHz. Then in Sec. IV C we examine the performance of reproduction for the case that the numbers of loudspeakers are inadequate. In Sec. IV D we demonstrate the influence of measurement noise on reproduction error.

The reverberant room parameters and loudspeaker placement are summarized in Fig. 6. The room is rectangular with a wall absorption coefficient of 0.3. Unless otherwise stated, the control region has a radius of 0.3 m. Though the sound field reproduction design technique is applicable for any configuration and type of loudspeaker, we perform the sound field reproduction with a circular array of omnidirectional loudspeakers. This setup yields an average direct-to-reverberant energy ratio from each loudspeaker of -4.4 dB at the center of B^2 .

The loudspeaker requirements of this scenario are governed by the control region parameter $N = \lceil kR \rceil = 6$, prompting the use of $2N + 1 = 13$ loudspeakers. Following the conservative design procedure of Sec. IV A with $\epsilon = -20$ dB, the maximum error scaling is $\kappa = 25$ dB, and from Fig. 4 the $[\Delta N]$ corresponding to $\kappa' = \epsilon/\kappa$ is 14. We hence sample the pressure at $M = N + [\Delta N] = 20$ points to measure the room response coefficients $\alpha_n(l, \omega)$.

The reverberation is generated with a 2-D adaptation of

FIG. 7. The reproduction of a plane wave with 13 speakers and 20 pressure samples in a 0.3 m radius circle, for (a) a free field, (b) the same free field design in the reverberant room, and (c) a reverberant field design in the reverberant room. Reproduction errors are 0.87%, 307%, and 0.85%, respectively.

the image-source method.¹⁹ Each of the room frequency response functions is given by

$$H(\mathbf{x}; \omega) = \mathcal{H}_0^{(2)}(k\|\mathbf{x} - \mathbf{y}\|) + \sum_{n=1}^{N_i} \zeta_n \mathcal{H}_0^{(2)}(k\|\mathbf{x} - \mathbf{y}_n\|),$$

where $\mathcal{H}_0^{(2)}(\cdot)$ is the zeroth-order Hankel function of the second kind, \mathbf{y} is the source position, and ζ_n and \mathbf{y}_n are the position and accumulated reflection coefficient of the n th image-source, respectively. [For the 2-D point source, or a cylindrical source, $\mathcal{H}_0^{(2)}(kr)$ gives the field at a distance r from the source;²⁰ for a 3-D point source, this is equal to the more familiar expression $h_0^{(2)}(kr) = ie^{-ikr}/kr$.] Image-source positions are obtained through the repeated mirroring

about the walls of the enclosure.¹⁹ In simulations below, all the image-sources of up to fifth order were included (totaling $N_i = 60$ image sources).

Sound field reproduction results are illustrated in Figs. 7–9. Here the real and imaginary parts of the complex pressure of the reproduced field are displayed as density plots. Details of the sound field reproduction in each case are described below.

A. Reproduction of a plane wave

First, the field pressure of a plane wave is reproduced. For a plane wave originating from direction $\hat{\mathbf{y}}$:

$$P_d(\mathbf{x}; \omega) = e^{-ik\mathbf{x} \cdot \hat{\mathbf{y}}}.$$

FIG. 8. The reproduction of a monopole in a 0.3 m radius circle of the reverberant room with 13 speakers and 20 pressure samples. The reproduction error is 2.12%. The position of the monopole is marked with a “+.”

Through the Jacobi–Anger expression,²⁰

$$e^{-ik\mathbf{x}\cdot\hat{\mathbf{y}}} = \sum_{n=-\infty}^{\infty} (-i)^n e^{-in\phi_y} J_n(kx) e^{in\phi_x},$$

where ϕ_y is the polar angle of $\hat{\mathbf{y}}$, one sees that the sound field coefficients are given by

$$\beta_n^{(d)}(\omega) = (-i)^n e^{-in\phi_y}.$$

Loudspeaker filter weights are chosen using the least squares approach of Sec. IV D.

Figure 7 illustrates the reproduction of a plane wave approaching from an angle of $\phi_y = \pi/6$. We provide a free field design [Fig. 7(a)], the same free field design in the reverberant room described above [Fig. 7(b)], and the rever-

berant field design [Fig. 7(c)]. With a 307% reproduction error, the reverberant performance of the free-field design is poor. In contrast, the reverberant design performs as well under such conditions as the free-field design does in a free field. Since the -4.4 dB direct-to-reverberant ratio here is common in room environments, we see the importance of reverberant field design techniques.

B. Reproduction of a phantom monopole source

The pressure field of a 2-D monopole source of unit strength is now reproduced. For a monopole source positioned at \mathbf{y} , the sound pressure is

$$P_d(x; \omega) = \mathcal{H}_0^{(2)}(k\|\mathbf{x}-\mathbf{y}\|).$$

FIG. 9. The reproduction of a plane wave in a 0.6 m radius circle of the reverberant room with 13 speakers and 35 pressure samples when designed over (a) the whole region and (b) a region of 0.3 m radius. Reproduction errors are 26.0% and 84.1%, respectively.

FIG. 10. Wide band reproduction of a plane wave in a 0.3 m radius circle with 13 speakers and using 40 pressure samples, using the model-based method (solid lines) and multiple-point method (broken lines). Reproduction error curves have been averaged over 40 trial runs.

Through the addition property of the Hankel function,²⁰

$$\mathcal{H}_0^{(2)}(k\|\mathbf{x}-\mathbf{y}\|) = \sum_{n=-\infty}^{\infty} \mathcal{H}_n^{(2)}(ky) e^{-in\phi_y} J_n(kx) e^{in\phi_x},$$

where $y \triangleq \|\mathbf{y}\|$, one sees that the sound field coefficients are given by

$$\beta_n^{(d)}(\omega) = \mathcal{H}_n^{(2)}(ky) e^{-in\phi_y}.$$

Using the same design technique as for the plane wave reproduction, we simulate the reproduction of a monopole source just outside the region of interest, at $(y, \phi_y) = (0.35 \text{ m}, 3\pi/4)$. Figure 8 shows a good reproduction of this monopole source.

C. Reproduction with an inadequate numbers of speakers

We now illustrate the result of designs with insufficient numbers of speakers. Again a plane wave is reproduced with 13 speakers, but over a region of interest of radius 0.6 m. At this radius, 25 basis functions are active. For comparison, we show the design for a radius of 0.3 m, where only the 13 lowest-order basis functions are reproduced. Because of the larger radius, we require more pressure samples (35 samples) for these designs.

The resulting sound fields are shown in Fig. 9. While the 0.3 m design reproduces accurately over where the 13 lowest-order basis functions are active [Fig. 9(b)], the 0.6 m design reproduces the sound field with better accuracy over the whole region of interest [Fig. 9(a)].

D. Wide band reproduction with measurement noise

Wide band sound field reproduction of a plane wave is performed with noisy pressure samples in the frequency range 100 Hz to 1 kHz, $R_1=0.3 \text{ m}$, and $R_2=0.27 \text{ m}$. The reproduction error is plotted in Fig. 10 for several noise

SNRs averaged over 40 trial runs. This figure shows that at least 30 dB SNR is required for an accurate reproduction over the whole frequency range.

For comparison the multiple-point method has been co-plotted. As can be seen, the model-based method, by performing the least squares design over the whole region of interest, consistently outperforms the multiple-point method, typically up to 5 dB.

The general trend in this curve is that error increases with frequency. This trend is due to the linear increase in demand for loudspeakers and sensors with frequency. Our design uses the same number of loudspeakers and pressure samples for all frequencies. If we desire to flatten the curve, we could use less pressure samples and loudspeakers at lower frequencies where less basis functions are active.

Also observe the peaks in Fig. 10. These peaks occur in the vicinity of the zeros of the Bessel functions $J_0(kR)$ and $J_1(kR)$. Zeros of these Bessel functions at 460 and 730 Hz, respectively. These peaks are hence a direct result of the error scaling mentioned in Sec. IV C. To flatten such peaks, more pressure sampling should be performed about these frequencies, or the sensor pairs further separated (i.e., $\delta R = R_1 - R_2$ should be increased).

V. CONCLUSION

We have described a novel method of performing sound field reproduction in reverberant enclosures. The key to this method is an efficient parametrization of the acoustical transfer functions. Using this parametrization, we have outlined a practical technique to precisely measure the acoustical transfer functions from a loudspeaker to each point in the region of sound reproduction. This approach allows full sound reproduction without prior knowledge of the loudspeaker positions nor the transmission characteristics of each loudspeaker. Through simulation, the reverberant field method is shown to perform as well in a reverberant room as free-field techniques do in a free field, and up to 5 dB better than multipoint least squares designs. The practical implementation of this soundfield reproduction scheme and its subjective performance remain as open questions and shall be addressed in future research.

APPENDIX A: PROOF OF EQ. (20)

Substituting Eq. (19) into Eq. (18) yields

$$\hat{\beta}_n(\omega) = \frac{1}{J_n(kR)} \frac{1}{M} \sum_{m=0}^{M-1} P(R, \phi_m; \omega) e^{-i(2\pi mn/M)}, \quad (\text{A1})$$

where $\phi_m = 2\pi m/M$. Evaluating the basis function expansion of the sound field Eq. (16) at the M points (R, ϕ_m) :

$$P\left(R, \frac{2\pi m}{M}; \omega\right) = \sum_{q=-\infty}^{\infty} \beta_q(\omega) J_q(kR) e^{i(2\pi mq/M)}. \quad (\text{A2})$$

Substituting Eq. (A2) into Eq. (A1) and interchanging summations:

$$\hat{\beta}_n(\omega) = \frac{1}{J_n(kR)} \frac{1}{M} \sum_{q=-\infty}^{\infty} \beta_q(\omega) J_q(kR) \sum_{m=0}^{M-1} e^{i[2\pi m(q-n)]/M}.$$

Now the summation of the complex exponential is given by

$$\sum_{m=0}^{M-1} e^{i[2\pi m(q-n)]/M} = \begin{cases} M, & \text{if } q-n|M, \\ 0, & \text{otherwise.} \end{cases}$$

Hence

$$\hat{\beta}_n(\omega) = \frac{1}{J_n(kR)} \sum_{s=-\infty}^{\infty} \beta_{n+sM}(\omega) J_{n+sM}(kR).$$

Rearranging,

$$\hat{\beta}_n(\omega) - \beta_n(\omega) = \frac{1}{J_n(kR)} \sum_{s=-\infty, \neq 0}^{\infty} \beta_{n+sM}(\omega) \times J_{n+sM}(kR).$$

QED.

APPENDIX B: BOUND ON THE TERMWISE SCALING FACTOR κ_n

For the following discussion, we view $J_n(kR)$ as a function of its order n . For $n \geq N = \lceil kR \rceil$, $J_n(kR)$ is observed to be a monotone decreasing function in n , decaying exponentially toward zero. (This property can be observed in Fig. 5 for n up to 20.) Similarly for $n \geq N$, $|J_{-n}(kR)|$ is also monotone decreasing in n .

From Eq. (21), the largest termwise scaling factor for coefficient $\hat{\beta}(\omega)$ is

$$\kappa_n = \frac{1}{J_n(kR)} \max_{q=-\infty, \dots, \infty, \neq 0} |J_{n+qM}(kR)|.$$

Now since $M > 2N$, for $n = -N, -N+1, \dots, N$ and $q = \pm 1, \pm 2, \dots$, we have $|n+qM| > N$. Each of these Bessel functions $J_{n+qM}(kR)$ is hence sampled over the above-mentioned monotone decreasing interval. Consequently, κ_n is maximized when $|n+qM|$ is minimized:

$$\kappa_n = \begin{cases} J_{-(M-n)}(kR)/J_n(kR), & n \geq 0, \\ J_{M+n}(kR)/J_n(kR), & n < 0. \end{cases}$$

Calculating now the maximum κ_n over the active basis functions of positive index, the termwise scaling factor is bounded by

$$\begin{aligned} \max_{n=0, \dots, N} \kappa_n &= \max_{n=0, \dots, N} \left| \frac{J_{-(M-n)}(kR)}{J_n(kR)} \right| \\ &\leq \max_{n=0, \dots, N} 1/|J_n(kR)| \times \max_{n=0, \dots, N} |J_{-(M-n)}(kR)|. \end{aligned}$$

Again, due to the monotone decreasing property of the Bessel function:

$$\max_{n=0, \dots, N} \kappa_n = \max_{n=0, \dots, N} 1/|J_n(kR)| \times |J_{-(M-N)}(kR)|.$$

Similarly, due to the Bessel function property $J_{-n}(x)$

$= (-1)^n J_n(x)$, the bound is the same for $\max_{n=-N, \dots, -1} \kappa_n$.

Then applying the Bessel function bound from Ref. 18,

$$\max_{n=-N, \dots, N} \kappa_n = \max_{n=0, \dots, N} 1/|J_n(kR)|$$

$$\times \frac{1}{\sqrt{2\pi(M-N)}} \left[\frac{ekR}{2(M-N)} \right]^{M-N}.$$

Microphone array signal processing with application in three-dimensional spatial hearing

Mingsian R. Bai^{a)} and Chenpang Lin

Department of Mechanical Engineering, National Chiao-Tung University, 1001 Ta-Hsueh Road, Hsin-Chu 300, Taiwan, Republic of China

(Received 3 August 2004; revised 4 December 2004; accepted 6 December 2004)

Microphone arrays are known to enhance the directionality and signal-to-noise ratio (SNR) over single-channel sensors. This is considered beneficial in many applications such as video-conferencing systems and hearing aids. However, this advantage comes at the price of the sensation of spatial hearing. The spatial cues due to diffractions of the head and torso are lost if the array is not fitted in the ears. In this paper we present a system that incorporates binaural hearing synthesis into array signal processing, in an attempt to recover the three-dimensional sound image that a human listener would naturally perceive. In the system, the superdirective beamformer is exploited to estimate the direction of arrival (DOA) of the incoming sound. The spatial sound image is restored by steering the beam to the direction found in the DOA session and filtering the array output with the corresponding Head Related Transfer Functions (HRTF). The algorithms have been implemented in real-time fashion using a digital signal processor. Objective and subjective experiments were performed to validate the proposed system. The experimental results showed that the accurate localization of the sound source is achievable using the array system. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1853242]

I. INTRODUCTION

Microphone arrays have received much research interest as a means of acoustic pickup utilized in various applications such as video-conferencing systems¹ and hearing aids.^{2–5} One of the reasons for using an array is to improve signal-to-noise ratio (SNR) that has long been a plaguing problem of, for example, conventional single channel hearing aids. This problem is further aggravated in the environments where reverberations and interferences are present. In comparison with single-channel sensors, microphone arrays provide advantages that the SNR as well as directionality of the sensor can be enhanced using such a system. In particular, an array behaves like a spatial filter, enabling the listener to focus on the signal source such as speech and at the same time reject ambient noise and interference.⁶ This is an attractive feature for hearing-impaired people who may desire low-noise hearing aids. A great number of array signal processing methods can be found in the literature⁷ to design arrays subject to individual requirements in an application. Beamforming and estimation of direction of arrival (DOA) are known to be two major functions of arrays. These two functions serve to track the intended source in a particular direction with high signal quality.

However, the above-mentioned advantages come at the price of sensation of spatial hearing. The spatial cues due to diffractions of the head and torso are lost if the sensors are not fitted in ears. To address the problem, in this paper we present a system that incorporates binaural hearing synthesis into array signal processing, in an attempt to recover the three-dimensional (3-D) sound image that a human listener

would naturally perceive. In order to form a very sharp beam, the superdirective array^{8–13} is employed in the array design. The thus designed beam is then electronically steered in every direction to estimate the DOA. Once the DOA is found, the sound beam is fixed at that direction. Finally, the binaural signals of the spatial sound image are produced by filtering the array output with the corresponding Head Related Transfer Functions (HRTF).¹⁴ The algorithms are implemented in real-time fashion using a digital signal processor, TMS320C32. As such, a low noise sound with high spatial quality is reproduced with the aid of the thus integrated array–HRTF system.

Simulations and experiments are carried out to evaluate the proposed system. The SNR gain and the effects of aperture size on the directivity of the microphone arrays are examined. Objective and subjective tests were performed to see how effective the listeners localize the source of sound using the proposed array system.

II. MICROPHONE ARRAY SIGNAL PROCESSING

It is well known that microphone arrays are capable of enhancing the directionality and signal-to-noise ratio (SNR) over single-channel sensors. This is beneficial in many applications such as hearing aids. In this paper, array signal processing techniques are utilized for the DOA estimation and beamforming. DOA estimation refers to localizing the source direction, while beamforming refers to forming a beam pattern with a specified shape and orientation. In this section, two algorithms will be presented to carry out these tasks of array signal processing, followed by an investigation on the directivity pattern.

FIG. 1. The configuration of a uniform linear array (ULA). A sound source is located in the farfield. \vec{x}_m is the position vector of the m th sensor and \vec{r} is the position vector of the farfield source.

A. Array signal processing algorithms

Figure 1 shows a uniform linear array (ULA), in which sensors are allocated along a straight line with equal spacing d . It is assumed that the sound source is at the farfield and the signals received at the sensors are narrowband with center frequency ω . The spacing between adjacent microphones is less than one-half wavelength to avoid grating lobes.

1. The delay-sum array

A brief review of the delay-sum method is given as follows. For an M -sensor array, the signals received at the sensors, $x_1(t), \dots, x_M(t)$, form the *data vector*

$$\mathbf{x}(t) = \mathbf{a}(\vec{r})s(t) + \mathbf{n}(t), \quad (1)$$

where $\mathbf{a}(\vec{r}) = [e^{j\omega[(\vec{r}_1 \cdot \vec{r})/c]} \dots e^{j\omega[(\vec{r}_M \cdot \vec{r})/c]}]^T$ is termed the *array manifold vector*, \vec{r} is the unit vector pointing to the source, \vec{r}_m , $m = 1, \dots, M$ are the position vectors of the sensors, c is the speed of sound, $s(t)$ represents the baseband signal of the source and $\mathbf{n}(t) = [n_1(t) \dots n_M(t)]^T$ is the noise vector. The beamformer output is the weighted sum of the delayed input signals, given by

$$y(t) = \mathbf{w}^H \mathbf{x}(t) = \mathbf{w}^H \mathbf{a}(\vec{r})s(t) + \mathbf{w}^H \mathbf{n}(t), \quad (2)$$

where $\mathbf{w} = [w_1 \dots w_M]^T$ is the array weight vector and the operator H denotes the complex conjugate transposition. The delay-sum algorithm is to “time align” the received signals by choosing the following weight vector:

$$w_m = \frac{1}{M} e^{-j\omega[(m-1)d \sin \theta/c]} = e^{-j\omega\tau_m}, \quad m = 1, \dots, M, \quad (3)$$

where θ is the look angle (measured from the normal) of the array and is dependent of the source vector \vec{r} and

$$\tau_m = \frac{(m-1)d \sin \theta}{c} \quad (4)$$

is the delay that the m th channel needs to compensate. It can be shown that the delay-sum algorithm attains the maximum signal-to-noise ratio gain (SNRG).⁷ The delay τ_m usually is

TABLE I. FIR filter coefficients for the first-order ($N=1$) and the second-order ($N=2$) Lagrange interpolation.

	w_{m0}	w_{m1}	w_{m2}
$N=1$	$1 - e_m$	e_m	
$N=2$	$(e_m - 1)(e_m - 2)/2$	$-e_m(e_m - 2)$	$e_m(e_m - 1)/2$

not an integer. The simplest approach to deal with these fractional delays is the Lagrange interpolation method.¹⁵ We first divide τ_m by the sampling period T to acquire the fractional delay that can be written into the integer and fractional components, D_m and e_m , respectively,

$$\frac{\tau_m}{T} = D_m + e_m. \quad (5)$$

The Finite Impulse Response (FIR) filter coefficients required to realize the fractional delay are given by

$$w_{mk} = \prod_{\substack{l=0 \\ l \neq k}}^N \frac{e_m - l}{k - l}, \quad k = 0, 1, 2, \dots, N. \quad (6)$$

The coefficients for the Lagrange filters of order $N=1, 2$ are given in Table I. The expectation value of $|y(t)|^2$ plotted versus the look angle θ is called the spatial power spectrum:

$$S(\theta) = E\{|y(t)|^2\} = \mathbf{w}^H \mathbf{R}_{xx} \mathbf{w}, \quad (7)$$

where $\mathbf{R}_{xx} \triangleq E\{\mathbf{x}(t)\mathbf{x}^H(t)\}$ is the *data correlation matrix*. The peak of the spatial power spectrum corresponds to the direction of the sound source.

2. The superdirective array

Another array algorithm employed in this work is the superdirective array.¹³ The principle of this algorithms follows from maximizing the *array gain* that is the measure of improvement of the signal-to-noise ratio between one sensor and the array output,

$$G = \frac{\text{SNR}_{\text{Array}}}{\text{SNR}_{\text{Sensor}}}. \quad (8)$$

The larger the array gain, the higher the ability of the array as a spatial filter to suppress the noise. The above array gain can be shown to be equivalent to¹³

$$G = \frac{|\mathbf{w}^H \mathbf{d}|^2}{\mathbf{w}^H \mathbf{\Gamma}_{nn} \mathbf{w}}, \quad (9)$$

where $\mathbf{\Gamma}_{nn}$ is the *coherence matrix* of the noise and \mathbf{d} is the steering vector of the main axis of the array. It is generally assumed that a diffuse white noise field is spherically isotropic, in which the ab th entry of the matrix takes the form¹³

$$\Gamma_{n_a n_b} = \frac{\sin[k(a-b)d]}{k(a-b)d}. \quad (10)$$

On the other hand, if only the self-noise of the sensors is present, i.e., $\mathbf{\Gamma}_{nn} = \mathbf{I}$, the array gain G reduces to the white noise gain (WNG):

$$\text{WNG} = \frac{|\mathbf{w}^H \mathbf{d}|^2}{\mathbf{w}^H \mathbf{w}}. \quad (11)$$

In general, the larger the array weights, the smaller the WNG and hence the more sensitive to noise is the array. Another important quantity to evaluate arrays, the directivity index (DI) is the logarithmic equivalent of the above-mentioned array gain,

$$DI = 10 \log_{10} \left(\frac{|\mathbf{w}^H \mathbf{d}|^2}{\mathbf{w}^H \mathbf{\Gamma}_{nn} \mathbf{w}} \right), \quad (12)$$

which amounts to the ratio of the main-axis gain over the angle-weighted gain. The larger the DI, the more directional is the array pattern.

The idea of the superdirective design is realized by maximizing the DI in Eq. (12), or equivalently, the array gain in Eq. (8). Equation (8) is in fact a Rayleigh's quotient. The maximization of which can be achieved by solving the following optimization problem:

$$\min_{\mathbf{w}} \mathbf{w}^H \mathbf{\Gamma}_{nn} \mathbf{w}, \quad \text{subject to } \mathbf{w}^H \mathbf{d} = 1. \quad (13)$$

In other words, we look for an optimal weight \mathbf{w} such that the array output power is minimized with the gain at the look direction constrained to unity. Thus, the array aims to receive an undistorted signal response at the main axis and reject unwanted interferences at the other directions. Following the method of the Lagrange multiplier, the solution of Eq. (13) is given as^{7,16}

$$\mathbf{w} = \frac{\mathbf{\Gamma}_{nn}^{-1} \mathbf{d}}{\mathbf{d}^H \mathbf{\Gamma}_{nn}^{-1} \mathbf{d}}. \quad (14)$$

In the low-frequency range, the matrix $\mathbf{\Gamma}_{nn}$ is nearly singular. The direct inverse of $\mathbf{\Gamma}_{nn}$ would prove problematic and results in exceedingly large array weights. To address the problem, a simple regularization procedure is generally utilized by incorporating a positive constant to the main diagonal of the coherence matrix:¹³

$$\mathbf{w}|_{\text{regularized}} = \frac{(\mathbf{\Gamma}_{nn} + \epsilon \mathbf{I})^{-1} \mathbf{d}}{\mathbf{d}^H (\mathbf{\Gamma}_{nn} + \epsilon \mathbf{I})^{-1} \mathbf{d}}. \quad (15)$$

The parameter ϵ can vary anywhere from zero to infinity, which corresponds to the unconstrained superdirective array or the delay-sum array, respectively. For instance, a reasonable value of ϵ to compromise the array directivity and the weight size is 0.01.

The delay-sum method and the superdirective method of a broadside array ($\theta=0^\circ$) are compared in terms of DI, WNG, and optimal weights as follows. Assume that there are 4 sensors equally spaced with 4 cm. Figure 2(a) illustrates the DI of the delay sum and the superdirective arrays with $\epsilon=0.01$. Clearly visible is the improvement of DI below 3 kHz achieved using the superdirective design over the delay-sum method. Figure 2(b) compares the WNG of the delay sum and the superdirective methods with $\epsilon=0.01$ for the broadside array. The WNG of the delay-sum array is larger than the superdirective method at the expense of low-frequency directionality. Figure 2(c) compares the 2-norm of the weight vectors of the delay sum and the superdirective methods with $\epsilon=0.01$ for the broadside array. It can be seen from the result that the optimum weights of the superdirec-

FIG. 2. A comparison of the delay-sum and the superdirective arrays with $\epsilon=0.01$. (a) Directivity index. (b) White noise gain. (c) Optimum weight norm.

tive array are larger than the delay-sum array at low frequencies in order to attain high directionality. The weights of the superdirective array should be maintained under a certain level in order not to create problems of filter implementation. To see more details, Fig. 3 shows the contour plots of direc-

FIG. 3. The contour plots (in a linear scale) of the directional responses versus angle (x axis) and frequency (y axis) of a four-element broadside array. The interelement spacing is 4 cm. (a) Delay-sum array (b) Superdirective array.

tivity versus the angle and frequency of the delay sum and superdirective arrays. The directivity is significantly improved using the superdirective method in the band 500–1500 Hz.

The foregoing analysis based on the narrowband formulation can now be extended to the broadband scenario. The array weights obtained using the superdirective method is associated with the frequency ω . Repeating this process for the frequencies equally spaced in the band of interest gives the frequency response samples of each array filter. Now that the frequency response samples are obtained, the inverse discrete Fourier transform is applied to acquire the impulse response, or the filter coefficients, of the superdirective array. More precisely, if the P_w frequency samples of the array weight are obtained for the m th array filter, the discrete frequency response of the filter is simply

$$H_m(l) = w_m^*(l), \quad l = 1, \dots, P_w. \quad (16)$$

To assure real impulse responses, the frequency response samples $H_m(l)$ at $l = -1, \dots, -(P_w - 1)$ must be mirrored to

$l = P_w + 1, \dots, 2P_w - 1$ with proper symmetry. The FIR filter coefficients can be obtained by applying the inverse discrete Fourier transform (IDFT) to the frequency response samples for each channel:

$$h_m(k) = \frac{1}{2P_w} \sum_{l=0}^{2P_w-1} H_m(l) W_{2P_w}^{-lk},$$

$$k = 1, \dots, (2P_w - 1); \quad m = 1, \dots, M, \quad (17)$$

where $W_{2P_w} = \exp[-j(\pi/P_w)]$. The thus obtained $h_m(k)$ is often noncausal. A circular shift with one-half the IDFT length can be performed to allow for a causal filter. Assume that there are 4 sensors equally spaced with 4 cm. The impulse responses of the superdirective array implemented using 64-tap FIR filters are shown in Fig. 4(a). The frequency responses of the superdirective filters are shown in Figs. 4(b) and 4(c). The impulse responses are symmetric and exhibit sign flipping between the microphones 1 and 2, and also the microphones 3 and 4. The frequency responses show an even more pronounced high gain and phase switching at the low-frequency range. These interesting phenomena suggest that the differential actions are necessary to produce the directivity improvement for superdirective microphones. Nevertheless, the superdirective microphones do not suffer from the poor SNR problem due to the ω^n dependence, as do pure differential microphones.¹⁷

Although there are many techniques available for DOA determination, we choose the simplest but most robust approach, the Fourier beamforming, due to the concern of computational loading of our processor. In the DOA session, angle spectra are calculated by steering the main beam from -90° to 90° using fractional delays.¹⁵ The maxima of angle spectra correspond to the source direction in the farfield. Figure 5 shows the angle spectra estimated at 500, 1000, 2000, and 4000 Hz by using the delay-sum and the superdirective methods, respectively. The result is plotted in a linear scale to facilitate the determination of DOA from the maxima of the angle spectra. The sound source is oriented at 10° , as indicated by the maxima of the angle spectra. The superdirective method produces a sharper DOA estimation than the delay-sum method at 500, 1000, and 2000 Hz. At 4000 Hz and higher, the superdirective method has no particular advantage. However, the side lobes of the superdirective array are larger than the delay-sum array, which is the price to pay for better resolution in DOA estimation. There is obviously a tradeoff between the beamwidth and the side lobes in the array design.

B. Performance analysis of array

Directivity is an important feature of microphone arrays, which is highly dependent on the aperture size of the arrays. In what follows, simulations and measurements were carried out to examine the directivity pattern of a 4-element linear microphone array. The signals from the microphones are summed directly without any filtering. The interelement spacing is 4 cm and the total length (aperture size) of microphone array is 12 cm. The sound source is positioned at 0°

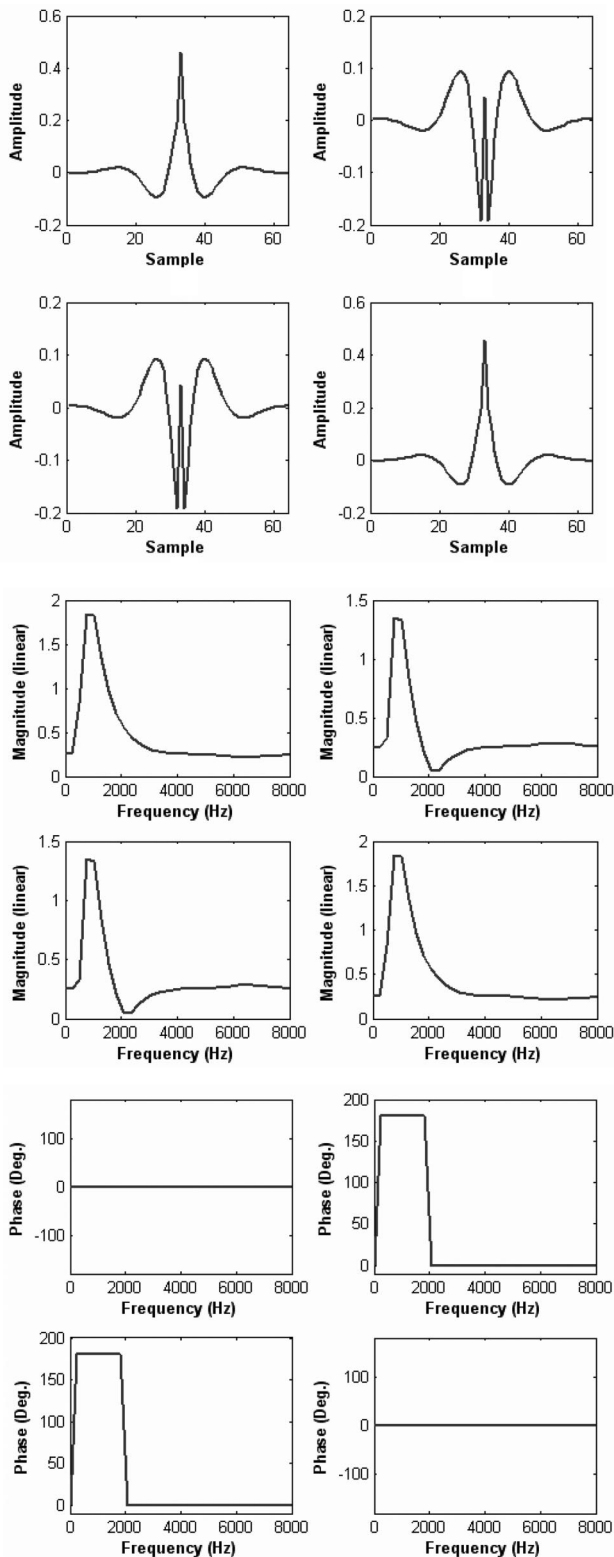

FIG. 4. The characteristics of the superdirective filter. The filter is realized as a 64-tapped FIR filter. The results are shown as 2×2 matrices, where the (1,1), (1,2), (2,1) and (2,2) correspond to the response of the 1st, 2nd, 3rd and 4th sensor, respectively. (a) The impulse response. (b) The frequency response magnitude. (c) The frequency response phase.

For reference, the simulation and measurement results of the directivity patterns of one microphone are shown in Fig. 6. The directivity pattern of one microphone at all frequencies in the simulation is omnidirectional. The directivity pat-

tern at 500 and 1000 Hz of one microphone in the measurement are also omnidirectional, while the measurements at 2000 and 4000 Hz display slight directivity due to the effect of the baffle in which the microphones are embedded.

Figure 7 shows the simulation and measurement results of the directivity patterns of the four-element array. The directivity patterns at 500 and 1000 Hz in the simulation are nearly omnidirectional, while the directivity pattern is quite directional at 2000 and 4000 Hz. The measured data are in close agreement with the simulation. These results indicate that the direct-sum array would display directivity only above 2000 Hz. More sophisticated algorithms must be used to produce significant directivity at a low-frequency range.

Apart from directivity pattern, the SNRs of one microphone and the four-element array are also measured and listed in Table II. The SNR gain improved by a 12 cm aperture microphone array is 11.6 dB, which is close to the theoretical value of 12 dB. This suggests that the SNR can be enhanced over a single sensor by means of array structures.

III. SPATIAL SOUND RESTORATION USING HRTF

As mentioned earlier, microphone arrays have the advantage of improved SNR, directivity, and hence spatial selectivity. These features help the rejection of undesirable effects of room reverberation and acoustic feedback. However, these benefits of arrays can be countered by the loss of three-dimensional (3-D) hearing when applied to hearing aids. To address the problem, a post-filtering technique based on the Head Related Transfer Functions (HRTFs) is presented in the paper in an attempt to restore the 3-D spatial hearing mechanism resulting from the head and torso diffractions of humans. Therefore, using this microphone-HRTF system, hearing-impaired people can hear more spatial-sounding speech and music signals with a better source localization.

A. The method and system architecture

An HRTF is a measurement of the transformation for a specific source direction relative to the head, and describes the filtering process associated with the diffraction of sound by the torso, the head, and the pinnae. HRTFs contain important cues, including the interaural time differences (ITD), the interaural level differences (ILD), and spectral characteristics pertaining to spatial hearing and sound localization. ITD refers to the time difference between the left and right ears for a plane wave incident from a certain direction. ILD refers to the level difference due to the head shadowing effect between the levels of the signals received at both ears. The inverse Fourier transform of a HRTF is termed the head-related impulse responses (HRIR). A 3-D sound field can be created by convolving a source signal with the appropriate HRTF to render sound images positioned arbitrarily around a listener. The HRTF and HRIR database employed in the paper is currently available on the web.¹⁴

The entire system consists of a DOA estimation module, a beamsteering module, and a HRTF post-processing module. The underlying idea of the system will be explained as follows. Rewrite the array output in Eq. (2) with a discrete-time and broadband setting,

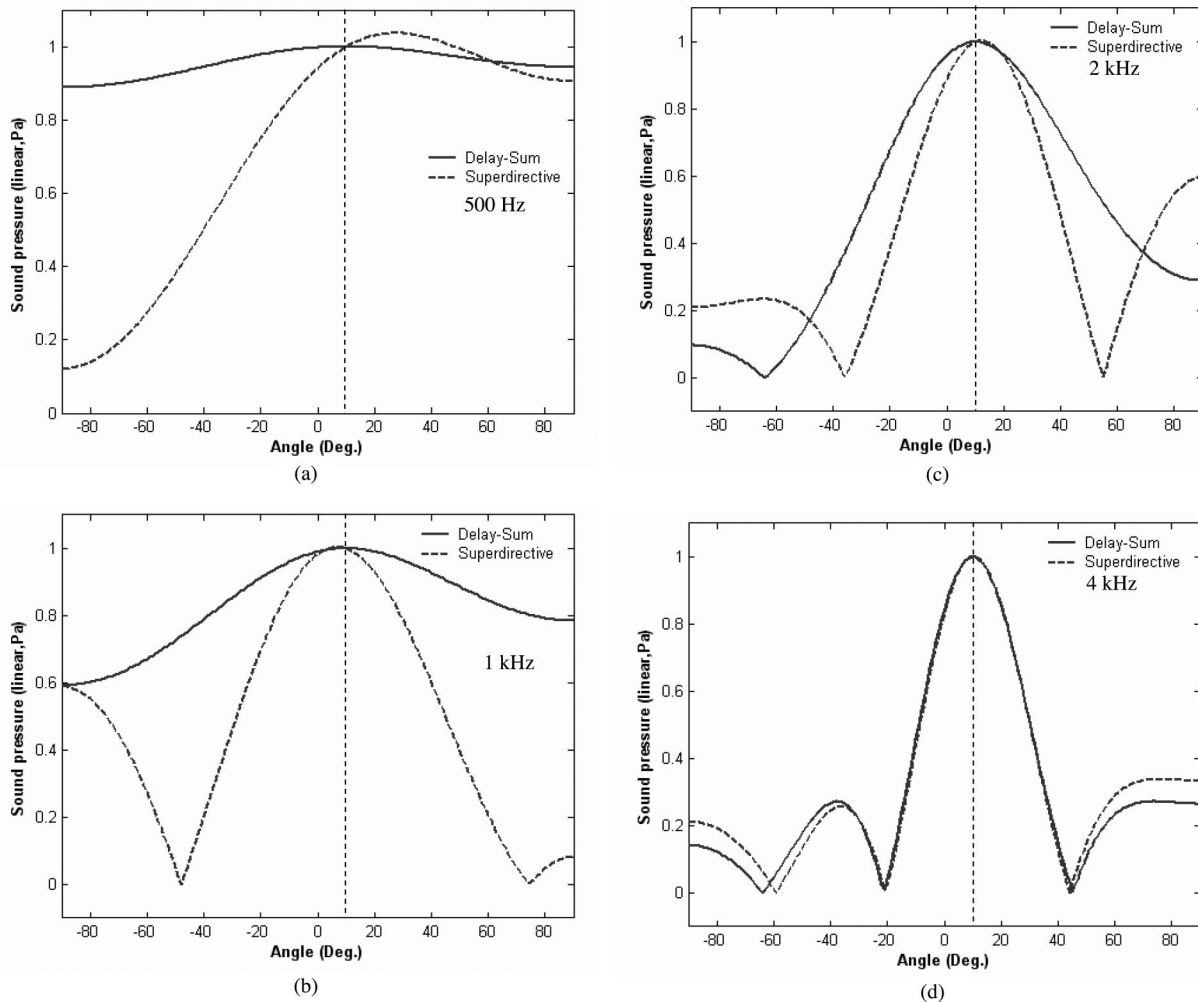

FIG. 5. The simulation results of the DOA estimation (in a linear scale) by the delay-sum and superdirective methods. The sound source is a pure tone and is located at $\theta=10^\circ$, as indicated by a vertical dotted line in the figure. (a) 500 Hz; (b) 1000 Hz; (c) 2000 Hz; (d) 4000 Hz.

$$y(n) = \mathbf{w}^H(n) * \mathbf{x}(n), \quad (18)$$

where $*$ denotes convolution and n is the discrete-time index. In Eq. (17),

$$\mathbf{x}(n) = s(n) * \mathbf{a}(\theta, n) \quad (19)$$

being the data vector received at the microphones, and $\mathbf{a}(\theta, n)$ is the impulse response of the array manifold vector associated with the source direction θ . After a DOA session using the superdirective beamformer, a potential source direction is found. Then, the beam of the array is electronically steered to that direction using the second-order Lagrange interpolation for the steering vector $\mathbf{d} \approx \mathbf{a}$. Note that the beamsteering process should guarantee $\mathbf{w}^H \mathbf{d} \approx 1$. Although this is a fixed beamformer, we choose the simple but practical approach for two reasons. First, apart from processing needs in multichannel array filtering, DOA, HRTF, and real-time display, there is really not much computational power left in the present DSP system to afford sophisticated adaptive algorithms such as the generalized sidelobe canceller (GSC) or the Griffiths beamformer.⁷ Second, adaptive beamformers still have robustness issues in the context of a steering vector error and correlated noise.¹³ In particular, the latter issue frequently occurs in a live room environment such as a car

cabinet, where multipath reflections could lead to an undesirable signal-noise cancellation.

In order to recover the spatial sound image for the array system, as a final step, HRIRs are used to filter the array output to yield the binaural signals for a headphone,

$$\mathbf{y}(n) = \begin{bmatrix} h_L(n) \\ h_R(n) \end{bmatrix} * y(n), \quad (20)$$

where $h_L(n)$ and $h_R(n)$ are the HRIRs of the left and the right ears. In effect, the overall output that the system will produce is

$$\mathbf{y}(n) = \begin{bmatrix} h_L(n) \\ h_R(n) \end{bmatrix} * s(n) * \mathbf{w}^H(n) * \mathbf{a}(\theta, n). \quad (21)$$

The preceding procedure of post-processing for 3-D hearing is summarized in the flow chart of Fig. 8.

B. Experimental verifications

The above-mentioned array signal processing algorithms for 3-D spatial sound restoration with HRTF was implemented on a digital signal processor (DSP), TMS320C32. Figure 9 shows the system block diagram, including a computer equipped with the DSP, a sound source, a four-element

(a)

(b)

FIG. 6. The directivity pattern of one microphone. (a) Simulation. (b) Measurement.

linear microphone array, a preamplifier, and two second-order antialiasing filters with cutoff frequency 8 kHz and a headphone. Four condenser microphones with 6 mm diameter are fitted in a acrylic plastic plate and the interelement spacing of microphones is 4 cm, which gives a total length of 12 cm. The sound source is placed at $\theta=10^\circ$. The sampling rate was chosen to be 16 kHz.

The delay-sum beamformer and the superdirective beamformer are applied to estimate DOA using the DSP system. Figure 10 shows the experimental results of the DOA estimation of obtained using the delay sum and the superdirective methods at 500, 1000, 2000, and 4000 Hz, respectively. A more accurate DOA estimation at 500, 1000, and 2000 Hz can be obtained by using the superdirective method than the delay-sum method because of the narrower beamwidth of the former. This observation is in agreement with the simulation results. At 4000 Hz, two beamformers yielded a comparable performance. Figure 11 shows the DOA estimation obtained using the delay-sum and the superdirective methods, in which case a sound source located at $\theta=10^\circ$ is a

(a)

(b)

FIG. 7. The directivity pattern of a broadside delay-sum array with four microphones equally spaced by 4 cm. (a) Simulation. (b) Measurement.

random noise bandlimited to 8 kHz. An error analysis of DOA estimation obtained experimentally by the delay-sum beamformer and the superdirective beamformer is illustrated in Table III. The average DOA error of the superdirective beamformer is 0° vs 6° obtained using the delay-sum beamformer. The former method significantly outperforms the latter one, owing to its narrower beamwidth (angle resolution).

After the DOA was estimated, the beamformer in conjunction with beam steering was utilized to enhance the sound signals. Only the superdirective beamformer was applied in the following tests because of its superior angle resolution. The fractional delays should be carefully compensated using Lagrange interpolation. Otherwise, a large

TABLE II. The measured SNRs and SNR gain of the single microphone versus the four-element microphone array with a 12 cm aperture.

steering error would arise, especially when the sampling rate is low.

Following the beam-steering session, post-processing based on HRTFs was carried out to realize the 3-D spatial sound. When the location of the sound source is changed, HRTFs were also updated according to the new direction found in the DOA session. In order to evaluate the effectiveness of the system in localizing sound sources, a subjective experiment was conducted. The listening test involved ten human subjects. Random noise bandlimited to 8 kHz was

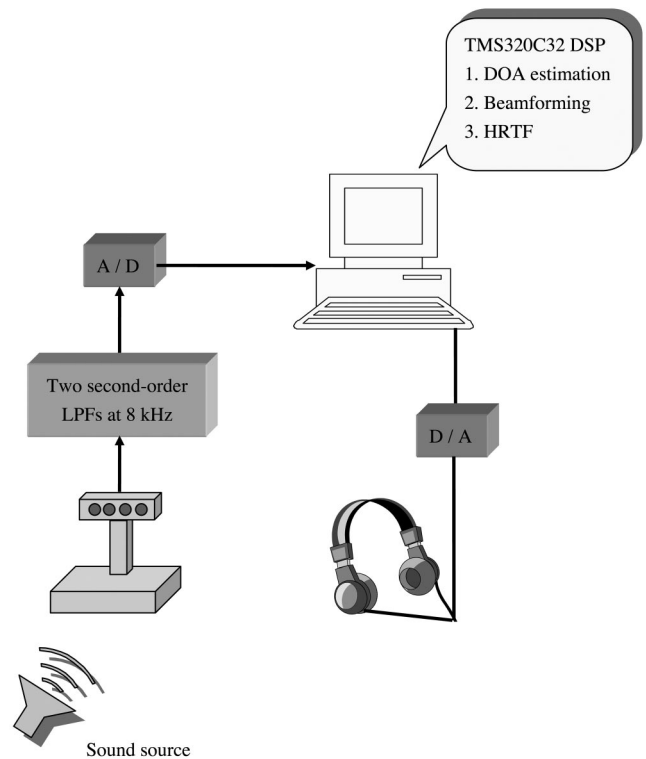

FIG. 9. The block diagram of the array spatial sound system implemented on a DSP, TMS320C32.

used as the source. A headphone was employed as the rendering device. In the experiment, 11 positions, ranging from -50° to 50° with 10° intervals, were preselected to position the source. The distance between the microphone array and the source was 2 m. The experiment was conducted in an anechoic chamber to minimize unwanted reflections. Figure 12 shows the result of the subjective localization experiment. The perceived angles of source are in very good agreement with the presented angles of the source since most data points fall on the diagonal of the plot. Figure 13 shows the statistics of localization errors in a bar chart. It can be seen in the result that the localization errors at $\pm 10^\circ$ and $\pm 50^\circ$ are somewhat larger than the other angles. Overall, the average localization error is 11.7° (nearly one test interval), and the standard deviation is 6.5° . It is noted that the DOA estimation is quite accurate using the superdirective beamformer (0° from Table III), and the discrepancy of the subjective test is due predominantly to the HRTF database. In summary, these results reveal that the developed system is effective in creating a spatial sound field that allows for the practical localization needs of human listeners.

IV. CONCLUSIONS

A microphone array accompanied with 3-D spatial post-processing system has been developed in this paper. Array signal processing algorithms are implemented on a DSP system to accommodate broadband acoustical applications with better SNR and directivity. To further enhance the directivity at the low-frequency range, the superdirective method is exploited in the beamformer design. The entire system consists of a DOA estimation module, a beam steering module, and

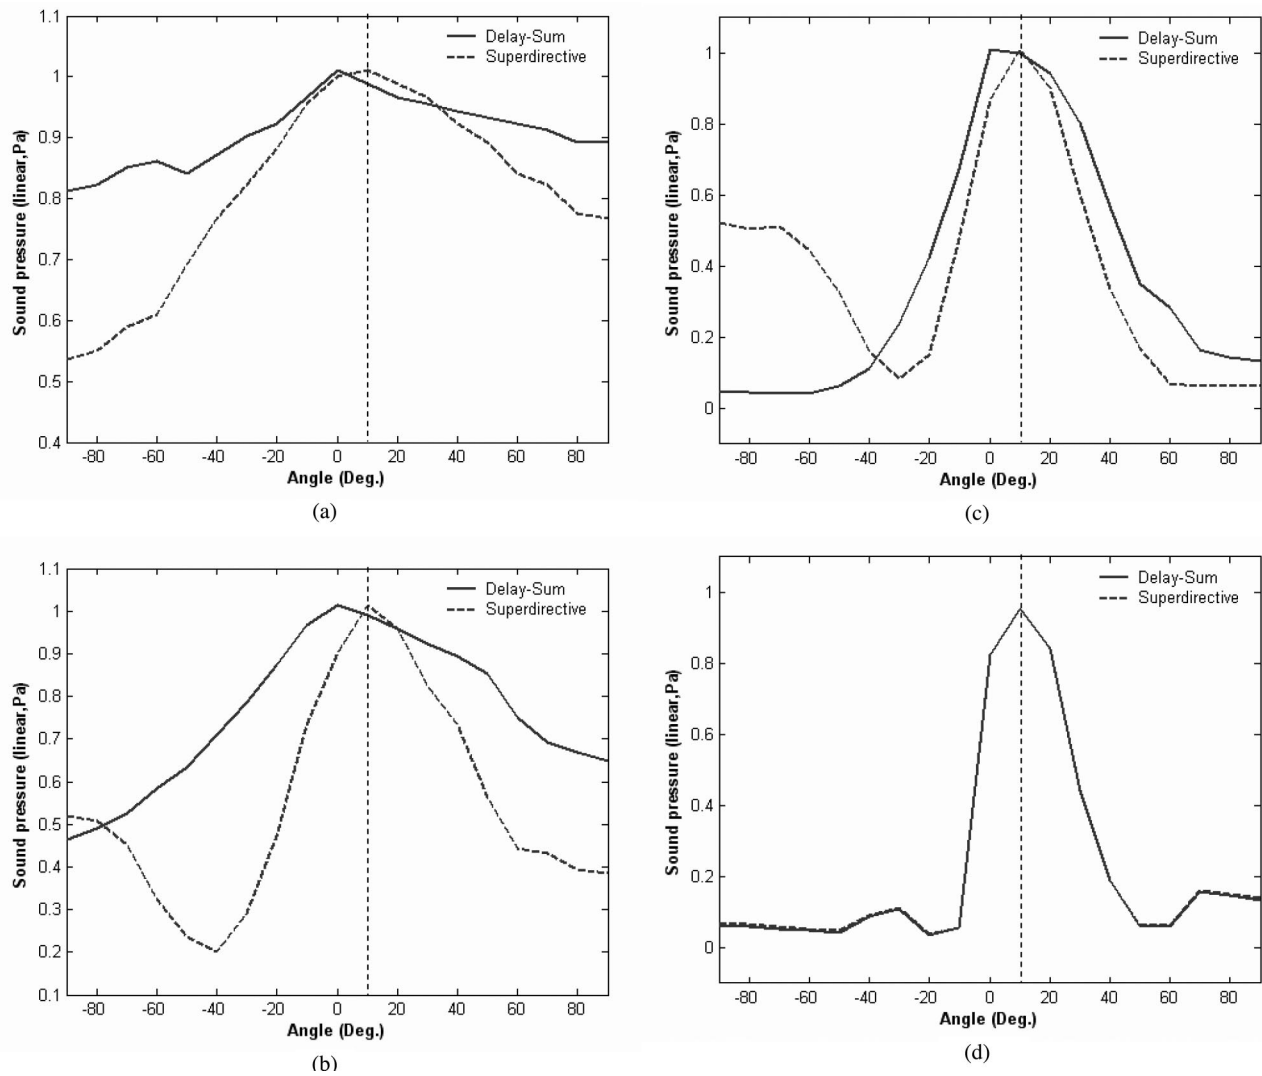

FIG. 10. The experimental results of the DOA estimation (in a linear scale) by the delay-sum and superdirective methods. The sound source is a pure tone and is located at $\theta=10^\circ$, as indicated by a vertical dotted line in the figure. (a) 500 Hz. (b) 1000 Hz. (c) 2000 Hz. (d) 4000 Hz.

an HRTF post-processing module. It was suggested by the reviewer that, instead of free-field HRTFs, stereo room responses should be used. However, the present paper did not choose this approach because we feel that the natural reverberations and responses of the room environment were not lost in beamforming. What had been lost was the information associated with human head scattering and diffraction. In addition, as another practical reason, filtering of room responses is known to be a computationally expensive operation, which is still prohibitive in the present DSP platform used in the research.

Source	Delay-sum beamformer	Superdirective beamformer
500 Hz sine	-10°	0°
1 kHz sine	-10°	0°
2 kHz sine	-10°	0°
4 kHz sine	0°	0°
Broadband random	0°	0°
Average error	6°	0°

FIG. 12. The results of the subjective listening experiment obtained using the proposed array spatial sound system. The perceived angle (y axis) is plotted versus the presented angle (x axis). The 45° line stands for perfect localization.

Simulations and experiments were carried out to investigate the feasibility of the proposed array system. It was found from the results that the array has achieved significant improvement in terms of SNR as well as directivity. A subjective listening experiment was conducted to examine the source localization performance using the present system. The results indicate that the subjects are capable of localizing the presented source direction within an average error of 11.7°.

Although these preliminary tests reveal the potential of the present system, several limitations of the work should be

FIG. 13. The bar chart showing the statistics of localization errors of the subjective listening experiment for each presented angle. The average localization error is 11.7° and the standard deviation is 6.5°.

mentioned. First, the selected sampling rate of 16 kHz was somewhat low because of the limited processing power of the present DSP we used. This gives an effective frequency range of less than 8 kHz, which might be insufficient for sound signals other than speech. However, this limitation is minor and can be removed by using a faster DSP. Second, the system works quite well with continuous and stationary signals but may lose track of the source for transient signals. Tracking algorithms suited to transient signals remain to be investigated. Third, background noise and reflection in a live room may seriously interfere the DOA estimation of the present system—a problem common to array systems. It is worth exploring in the future research algorithms for the DOA estimation that are both sharp and robust in a reverberant environment.

(Received 17 April 2004; revised 15 October 2004; accepted 24 January 2005)

The discrete wavelet transform may be used as a signal-processing tool for visualization and analysis of nonstationary, time-sampled waveforms. The highly desirable property of shift invariance can be obtained at the cost of a moderate increase in computational complexity, and accepting a least-squares inverse (pseudoinverse) in place of a true inverse. A new algorithm for the pseudoinverse of the shift-invariant transform that is easier to implement in array-oriented scripting languages than existing algorithms is presented together with self-contained proofs. Representing only one of the many and varied potential applications, a recorded speech waveform illustrates the benefits of shift invariance with pseudoinvertibility. Visualization shows the glottal modulation of vowel formants and frication noise, revealing secondary glottal pulses and other waveform irregularities. Additionally, performing sound waveform editing operations (i.e., cutting and pasting sections) on the shift-invariant wavelet representation automatically produces quiet, click-free section boundaries in the resulting sound. The capabilities of this wavelet-domain editing technique are demonstrated by changing the rate of a recorded spoken word. Individual pitch periods are repeated to obtain a half-speed result, and alternate individual pitch periods are removed to obtain a double-speed result. The original pitch and formant frequencies are preserved. In informal listening tests, the results are clear and understandable. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1869732]

I. INTRODUCTION

In experimental acoustics, it is common to encounter nonstationary sound waveforms, i.e., those in which the frequency content and amplitude change as a function of time. The conventional approach for analyzing such sounds is to calculate a spectrogram, or short-time Fourier transform (STFT). For a time-sampled waveform $z(t)$, the STFT provides information about the waveform's energy content as a function of both time and frequency, i.e., $F_{\text{STFT}}(z) = E(t, f)$. While the STFT has proven its worth in numerous practical applications, it is ill suited to certain types of sounds, and it lacks some desirable mathematical characteristics. Sounds with frequency content ranging over more than one or two orders of magnitude are often problematic for STFT analysis, because a window long enough to capture low-frequency content (at least one period) will be insensitive to high-frequency sounds of short time duration.

The discrete wavelet transform (DWT) has a severe limitation when used for acoustic waveform analysis: its lack of shift invariance. Let two time-sampled waveforms $z(t)$ and $z'(t)$ be time-shifted copies of one another, such that $z'(t) = z(t + t_0)$ for all t . Calculating the DWT of each, $F_{\text{DWT}}(z) = E(t, n)$, and $F_{\text{DWT}}(z') = E'(t, n)$. Since the DWT is not shift invariant, $E(t, n) \neq E'(t + t_0, n)$. Therefore, the DWT analysis of a sampled sound depends on when the sampling starts, not just when the sound occurs, which is highly undesirable for the study of physical systems. The DWT is critically sampled, i.e., utilizes lower sampling rates

(subsampling) for lower-frequency components. The selection of samples to be skipped in the subsampling process is inextricably linked to the time elapsed since the sampling began. Fortunately, by modifying the DWT to retain all possible samples (performing no subsampling), it is possible to obtain explicit shift invariance.¹⁻³ The resulting shift-invariant discrete wavelet transform (SIDWT) is highly redundant, but since many of the redundant elements are duplicates, the increase in computational complexity is not severe. The full SIDWT may be used as a starting point from which to draw a more efficient representation for lossy compression.⁴ The SIDWT may also be used in full (albeit with the duplicate elements grouped and summed), in which form it has been shown to be an isometry, with applications in data visualization.⁵ Others have described algorithms which are mathematically equivalent to the SIDWT, but which were developed for applications in exploratory statistics, using different nomenclature, i.e., the stationary wavelet transform⁶ and the maximal overlap discrete wavelet transform.⁷ The stationary wavelet transform has also been used successfully for waveform denoising.²

The use of the SIDWT (and its equivalents) to identify features in a waveform; whether signatures of interesting phenomena, experimental artifacts, or noise, leads naturally to the following question. What would the time-sampled waveform look like (or sound like) if the features were louder, softer, appeared at a different time, or were removed altogether? Performing the desired modifications on the SIDWT output is straightforward; the challenge is reversing

the SIDWT to return to a time-sampled waveform. Because of its inherent redundancy, the SIDWT does not have a true inverse in the mathematical sense. However, this fact does not preclude the existence of an algorithm with useful inverse-like behavior. The developers of the stationary wavelet transform also developed such an inverse-like procedure. They showed that averaging together all of the possible shift-induced variations of the IDWT yields intuitively satisfying results.⁶ Likewise, a mathematically equivalent procedure was used to invert the maximal overlap discrete wavelet transform, also with intuitively satisfying results.⁷ The stationary wavelet transform combined with this inverse-like averaging procedure has also been shown to yield good results in waveform denoising.² The wavelet denoising paper states, without proof or discussion, the important mathematical result that the inverse-like procedure is actually the pseudoinverse of the stationary wavelet transform. A recent publication coauthored by one of the present authors describes two examples of sound visualization and modification using the SIDWT and its pseudoinverse (ISIDWT). The discussion and the two examples are narrowly focused on the field of automotive sound quality engineering, and no mathematical material is included.⁸

The goals of this paper are threefold. The first is to describe a newly developed simple and fast convolution algorithm for the ISIDWT, based on the SIDWT algorithm.⁵ The SIDWT, the stationary wavelet transform, and the maximal overlap discrete wavelet transform employ significantly different algorithms, so a discussion of computational issues is included. The second goal is to present a simple, self-contained proof that the ISIDWT is the pseudoinverse of the SIDWT. The statement of this result has been published; we believe the details of the proof should be made available as well. The third goal is to illustrate the potential applications of these new analytical methods in the field of acoustics. Section II covers both the theoretical (II A) and the computational (II B) aspects of the SIDWT and its pseudoinverse. In Sec. III, examples of low-level speech waveform processing illustrate the capabilities of the SIDWT/ISIDWT for visualization, feature separation, and analysis/synthesis. One especially promising way to combine these capabilities is to edit (cut and paste sections) of sound recordings in the shift-invariant wavelet domain. While many audible features are easier to recognize in that domain, the primary benefit is the wavelet pseudoinverse transform automatically prevents the occurrence of the audible clicks and pops that are usually produced at section boundaries by time-domain editing. Illustrative examples of waveforms with strong time localization and a wide frequency range can be found in many different technical fields of study. For the development of digital audio effects in music, it is useful to be able to distinguish transient (time-localized) sounds, such as the pluck of a guitar string, from the steady ringing tone (frequency-localized) that follows.⁹ Research in wavelet-domain modification of musical sounds began in the early days of wavelet theory, e.g., musical applications of complex wavelets,¹⁰ and continues today, e.g., the use of a “lapped” wavelet transform to stitch together segments of musical waveforms.¹¹ The examples most familiar to the authors are drawn from

the myriad of mechanical sounds produced by motor vehicles, e.g., a momentary rattle excited by (and partially masked by) a car door slam, and the motor whine, blade scrape, and reversal thud of a windshield wiper.⁸ The details of speech waveforms, especially the formant resonances modulated by glottal pulses, are also an excellent match to the capabilities of the SIDWT/ISIDWT. The general approach and terminology derives from an *ad hoc* list of recent publications that deal with various details of speech waveforms: pitch period estimation,^{12–14} formant modulation,¹⁵ friction noise modulation,¹⁶ voicing onset,¹⁷ glottal characteristics,¹⁸ and waveform irregularities.¹⁹

II. THE SHIFT-INVARIANT DISCRETE WAVELET TRANSFORM AND ITS PSEUDOINVERSE

A. Theory

Consider a sequence of N physical measurements $z = (z_1, z_2, \dots, z_N)$, e.g., air pressure measured repeatedly at evenly spaced time intervals. Let S denote the set of all such signals. Since $\sum_n z_n^2 < +\infty$, the vector z may be regarded as the coordinates of a single point in a finite energy, N -dimensional vector space, $z \in l^2(\mathbb{Z}_N)$. Implicit in $z \in l^2(\mathbb{Z}_N)$ is the assumption that z is a single period of an infinitely long sequence with a periodicity of N . If this assumption is not physically realistic, care must be taken to insure that the conclusions drawn from the analysis are independent of N .

Let $u \in l^2(\mathbb{Z}_N)$ and $v \in l^2(\mathbb{Z}_N)$ represent two digital filters. Denoting the discrete Fourier transform of u by \hat{u} , we require the system matrix

$$A(n) = \frac{1}{\sqrt{2}} \begin{pmatrix} \hat{u}(n) & \hat{v}(n) \\ \hat{u}\left(n + \frac{N}{2}\right) & \hat{v}\left(n + \frac{N}{2}\right) \end{pmatrix}, \quad (1)$$

to be unitary for each $n = 0, \dots, N-1$ (Ref. 20, p. 173). Therefore, u is the low-pass filter sequence and v the high-pass filter sequence generating the discrete wavelet transform.

Let \bar{u} be the complex conjugate reflection of u defined by $\bar{u}(n) = u^*(N-n)$ for all n . The finite impulse response filtering of z by u is written as a (circular) convolution $z * u$. Most practical applications of these techniques, including the examples presented here, involve only N -element sequences of real numbers, i.e., $x \in \mathbb{R}^N \subset l^2(\mathbb{Z}_N)$. The mathematical results, however, are valid for complex-valued vectors. Assuming that m divides N , a sequence reordering operator R_m , defined by

$$R_m(z) = (z_1, z_{m+1}, \dots, z_{N-(m-1)}, z_2, z_{m+2}, \dots, z_{N-(m-2)}, \dots, z_m, z_{2m}, \dots, z_N), \quad (2)$$

in effect, writes the elements of z into an m by N/m matrix by columns and reads the elements out by rows. For example, if $z = (1, 2, 3, 4, 5, 6, 7, 8)$, then $R_2(z) = (1, 3, 5, 7, 2, 4, 6, 8)$. The inverse of R_m is $R_{N/m}$, i.e., $R_{N/m}(R_m(z)) = z$.

From an N -element input vector, given p such that 2^p divides N , the p -stage shift-invariant discrete wavelet trans-

form T produces a $(p + 1)$ by N matrix.⁵ T may therefore be regarded as a linear map taking each point in S to a point in a $(p + 1)N$ -dimensional vector space \mathbf{W} , i.e.,

$$T: l^2(\mathbb{Z}_N) \rightarrow l^2(\mathbb{Z}_{(p+1)N}). \quad (3)$$

T of z is given by

$$T(z) = (R_{N/2}(x_1), R_{N/4}(x_2), \dots, R_{N/2^p}(x_p), R_{N/2^p}(y_p)), \quad (4)$$

where

$$x_1 = \frac{1}{\sqrt{2}} R_2(z * \tilde{v}) \quad \text{and} \quad y_1 = \frac{1}{\sqrt{2}} R_2(z * \tilde{u}), \quad (5)$$

and for $j = 2, \dots, p$

$$x_j = \frac{1}{\sqrt{2}} R_2(y_{j-1} * \tilde{v}) \quad \text{and} \quad y_j = \frac{1}{\sqrt{2}} R_2(y_{j-1} * \tilde{u}). \quad (6)$$

The set of points mapped by T from S occupies a subspace in \mathbf{W} denoted by range (T).

Being a linear map from an N -dimensional space of signals to a space of larger dimension, the SIDWT does not have an inverse. Of all the points in \mathbf{W} , only those which are in range (T) are directly associated with a point in S . The pseudoinverse works around this limitation by providing every point $w \in \mathbf{W}$ with an *indirect* association to some point $z \in S$. Every w has a unique nearest (in the standard Euclidean norm) neighbor $w' \in \text{range}(T)$ (possibly itself), and the pseudoinverse associates each w with the z that satisfies $T(z) = w'$. This procedure is mathematically equivalent to finding the least-squares solution to an overdetermined system of linear equations. We now define the ISIDWT

$$S: l^2(\mathbb{Z}_{(p+1)N}) \rightarrow l^2(\mathbb{Z}_N), \quad (7)$$

a map taking each point in \mathbf{W} to a point in S . Given $w = (w_1, w_2, \dots, w_{p+1}) \in l^2(\mathbb{Z}_{(p+1)N})$, we compute $S(w)$ by the algorithm

$$\eta_p = \frac{1}{\sqrt{2}} (R_{N/2}(R_{2^p}(w_p)) * v + R_{N/2}(R_{2^p}(w_{p+1})) * u) \quad (8)$$

$$\eta_{p-1} = \frac{1}{\sqrt{2}} (R_{N/2}(R_{2^{p-1}}(w_{p-1})) * v + R_{N/2}(\eta_p) * u) \quad (9)$$

\vdots

$$S(w) = \eta_1 = \frac{1}{\sqrt{2}} (R_{N/2}(R_2(w_1)) * v + R_{N/2}(\eta_2) * u). \quad (10)$$

The relationship between T and S (as defined above) is established by the following theorem.

Theorem 1. S is the least-squares inverse (pseudoinverse) of T , i.e.,

- (i) $ST = \text{id}|_{l^2(\mathbb{Z}_N)}$, and
- (ii) TS is the orthogonal projection of $l^2(\mathbb{Z}_{(p+1)N})$ onto range (T).

According to statement (i), for $w \in \text{range}(T)$, S is the inverse of T , and therefore $S(T(z)) = z$. Statement (ii) ad-

FIG. 1. A block diagram of the SIDWT and ISIDWT for two scale levels, i.e., $p = 2$.

resses the case of $w \notin \text{range}(T)$, which will apply to virtually all w chosen arbitrarily, i.e., not obtained by $w = T(z)$. In this case, $x = T(S(w)) \in \text{range}(T)$ is the unique point in range (T) closest to w , minimizing $\sum_n (x_n - w_n)^2$. A proof of Theorem 1 is given in the Appendix.

B. Computation

The block diagram in Fig. 1 illustrates the processing steps in the SIDWT (analysis phase T) and its pseudoinverse ISIDWT (synthesis phase S) for the two-stage case, i.e., $p = 2$. The analysis begins in the upper-left corner with the input waveform z . The four-block clusters inside the dotted-line boxes on the left side of the diagram depict the recursive analysis steps defined in Eqs. (5) and (6). A p -stage transform employs p of these clusters, yielding $p + 1$ many series $x_1, x_2, \dots, x_p, y_p$, each of length N . The final rearrangement step defined in Eq. (4) reaches the vector space \mathbf{W} , depicted by the central dashed-line box. Completion of the SIDWT is indicated by the vertical arrow leading to $T(z)$ at the top of the diagram. The synthesis begins at the top with w , which in most cases will be a modification of $T(z)$. The first step in the ISIDWT is to undo the final rearrangement step in the SIDWT. After this, the recursive procedure in the dotted-line boxes in the right side of the diagram, as defined in Eqs. (8) and (9), is carried out. The ISIDWT is complete at the top of the diagram where $S(w) = \eta_1$, as in Eq. (10).

Let us look at the computational complexity of the pseudoinverse S . Given $z \in l^2(\mathbb{Z}_N)$, the computational complexity for the transform $T(z)$ is $\mathcal{O}(N \log_2 N)$ according to Ref. 5. We will now show that this result holds for the ISIDWT S as well.

Theorem 2. Let N be a power of 2 and $p \in \mathbb{N}$, with $p \leq \log_2 N$ fixed. Then, the total number of complex multiplications required to compute $S(w)$ for $w \in l^2(\mathbb{Z}_{(p+1)N})$ is $\#_N \leq 2pN + 3pN \log_2 N$.

Proof: In lieu of a detailed proof, we note that S and the analysis algorithm are essentially the same by symmetry.

From Theorem 2 we obtain the result that the computation of S is an $\mathcal{O}(N \log_2 N)$ operation if p is considered to be a fixed number. If we take the Daubechies D4 u and v and perform the convolutions directly instead of using the FFT, then the computational complexity is just $\mathcal{O}(N)$, since u and v have only 4 nonzero entries. This is the minimal order we can expect when working with signals of length N . Since S is a linear map, the error in the output is bounded by the norm of S (a constant) times the error in the input, which means that the algorithm is numerically stable.

The ISIDWT, the stationary wavelet transform, and the maximal overlap discrete wavelet transform are mathematically equivalent in the sense that they yield the same result. However, they utilize significantly different algorithms, so they are not computationally equivalent in all respects. All three may be calculated with $\mathcal{O}(N \log_2 N)$ computational complexity if p is considered fixed.⁵⁻⁷ If implemented in a low-level programming language that allows efficient indexing of individual matrix elements, the performance of the three is expected to be essentially equivalent. However, the ISIDWT is significantly easier to implement in an array-oriented scripting language, because it can be constructed by linking together a few of the standard functions that are commonly provided in such languages. In this way, acceptable performance can be obtained without the need to write, compile, and link an external module written in a lower-level language.

III. APPLICATION TO SPEECH WAVEFORM ANALYSIS

To illustrate the application of the SIDWT/ISIDWT to acoustic waveforms, a detailed analysis of a sound recording of a spoken word is presented below. A recording of a male speaker pronouncing the Japanese word “kaze” with a rising intonation from an on-line speech database maintained for phonetic alphabet research²¹ is shown in Fig. 2. Voiced speech is produced by periodic glottal closure events, which momentarily interrupt the air flow through the larynx. The frequency at which these events occur, denoted by F_0 , is the fundamental frequency of voiced speech. The rising intonation in this example is reflected in Fig. 2, as $F_0 \approx 90$ Hz during the “a” increases to $F_0 \approx 120$ Hz during the “e.” The procedure for glottal period estimation is discussed in detail below.

During spoken vowels, the sharp air-pressure transients known as glottal pulses excite pressure oscillations in the volume acoustic resonances of the vocal tract. The frequency content of these resonances, which fall in the range between ~ 500 Hz to ~ 8 kHz, depending on the size of the vocal tract and the position of the tongue, jaw, and lips, is the primary factor distinguishing one vowel from another. The significant frequency peaks in the pressure oscillations are known as formants, and are denoted F_1, F_2, F_3, F_4 , in order of increasing frequency. The formant amplitude is highest immediately

FIG. 2. A sound recording of a male speaker pronouncing the Japanese word “kaze” with rising intonation, and the voiced fundamental frequency F_0 obtained from glottal period estimates.

after the glottal pulse, at which point the glottis is essentially closed. The amplitude decreases rapidly as energy is lost due to air flow between the lips. When the glottis reopens in preparation for the next glottal pulse, the resulting air flow causes the formant amplitude to decrease even more quickly. This strong amplitude modulation of the formants leads to a widely used quasistatic approximation. In this simplified picture, the frequency content of each formant pulse is assumed to be static, and the (relatively slow) motion of the vocal-tract anatomy (tongue, jaw, and lips) is inferred by comparing the frequency content of consecutive formant pulses. The first six formant pulses in kaze may be seen in Fig. 3. The first formant pulse, which signifies the beginning of the vowel sound “a,” occurs at ~ 0.105 ms. In the sound waveform plot, each formant peak begins at a sharp downward step (a glottal pulse) and oscillates with decreasing amplitude, disappearing before the next glottal pulse. On the spectrogram, labeled “STFT,” each downward step appears as a vertical gray bar; the short time duration of each step maps to broad frequency content. The sampling rate was 44 100 samples/s, and a 352-point Hanning window, shifted in 63-point steps, and zero-padded to 1024-point length, was used in the preparation of spectrograms in this and the next two figures. The gray scale on each spectrogram was adjusted for enhanced contrast.²² Each formant pulse appears as a pair of dark horizontal bands ~ 600 Hz apart, beginning at a vertical bar, and ending before the next vertical bar. This formant frequency content of $F_1 \approx 500$ Hz and $F_2 \approx 1100$ Hz is typical for a male Japanese speaker’s “a.”²³

The scalogram in Fig. 3 labeled “DWT” is obtained from the conventional, shift-variant, discrete wavelet transform. The 8-tap symlet was used for all examples presented here, but the results do not depend critically on the choice of wavelet. The shape of the wavelet (e.g., symlet vs Daubechies) makes little difference here. Shorter wavelet filters (e.g., 4-tap vs 8-tap) will have increased energy in the

FIG. 3. The “ka” from the Japanese word “kaze,” its spectrogram (STFT), its conventional scalogram (DWT), and its shift-invariant scalogram (SIDWT).

upper sidebands, but provide faster calculations and sharper time resolution. The essential preprocessing step for visualization is to transform the oscillatory coefficients within each scale level of $w \in \text{range}(T)$ to a quadratic envelope.⁵ For the coefficients at the m th scale level, w_m , the quadratic envelope $w'_m = w_m^2 + H(w_m)^2$, where H is the Hilbert transform, i.e., a $\pi/2$ phase shift. Following this operation, all of the scalograms presented here were downsampled to fit the available space, and the gray scales were adjusted for enhanced contrast.²² The formant pulses appear as dark, vertical features extending from the 500-Hz to the 8-kHz bands. Their appearance is more varied than on the spectrogram, due to the shift variance of the DWT. Nevertheless, the DWT has been shown to be a reliable method for identifying glottal pulses for F_0 estimation.^{13,14} The scalogram in Fig. 3 labeled “SIDWT” is obtained from the shift-invariant discrete wavelet transform. In the region corresponding to the “k” sound, the SIDWT and DWT scalograms have a similar appearance. In the region corresponding to the voiced “a,”

they are dramatically different. The shift invariance reveals the true reproducibility of the formant pulses, and for each formant pulse shows the amplitude decrease and the gap preceding the next glottal pulse. The voiced region highlights two important differences between the STFT presentation and the SIDWT presentation. First, the STFT has finer frequency resolution than the SIDWT. The two main formants, F_1 and F_2 , are resolved clearly on the STFT, but are not resolved on the SIDWT due to the single-octave bandwidth of the scalogram levels. The second difference is that the STFT has the same time resolution at all frequencies, so transients appear as vertical features. In contrast, the time resolution of the SIDWT scales inversely with the center frequency of each band. For each step upward to a higher-frequency scalogram band, the time resolution is twice as fine. For this reason, a transient feature tends to have a pyramidal appearance on the SIDWT, with a narrow top on a base that broadens at each next lower level. The practical consequence of these two differences is that the SIDWT is not a substitute or a replacement for the STFT, but rather a complement, and the two techniques can be used effectively together.

Figure 4 shows a similar presentation of the “z” from kaze. This sound is produced by a narrow restriction in the mouth. The frictional (turbulent) loss due to the air flowing through the restriction prevents the build-up of formants. The absence of formants does not imply silence, however, because the turbulence produces audible noise called frication. The loudness of the frication varies with the flow of air through the restriction, which in turn is modulated by periodic glottal closures. The modulated frication appears as bursts of noise (glottis open) separated by momentary silences (glottis closed).¹⁶ It is interesting to contrast this timing to that observed with formants, which are loudest when the glottis is closed, and quiet when the glottis is open.

To complete the presentation of kaze, the final vowel “e” is shown in Fig. 5. The time-domain clarity of the formant peaks in the shift-invariant scalogram (SIDWT), compared to the shift-variant scalogram (DWT), is even more evident here than in Fig. 3. The formant pulses are closer together than in Fig. 3, and they also exhibit a second high-frequency pulse in each glottal period. Secondary glottal pulses such as these are often observed in male speech waveforms, and they can be problematic for glottal period estimation algorithms. Interestingly, the phenomenon is usually vowel-dependent, and only traces of secondary pulses can be seen on the “a” in Fig. 3.

An expanded view of two of the formant pulses from Fig. 3 is shown in Fig. 6, as a time history and as a shift-invariant scalogram. The glottal pulses are indicated by “GP.” A periodic signature with a period of ~ 1.7 ms is apparent on the 2-kHz scale as alternating bands of light and dark, and is barely visible on the 1-kHz band. The scalogram as prepared for display is a quadratic function of the wavelet coefficients, and this signature is the difference frequency between the two formant peaks, $1.7 \text{ ms} \approx 1/(F_2 - F_1)$. The difference frequency shows up most clearly on the 2-kHz band because there is significant frequency overlap between adjacent bands, and the strong fundamental F_0 and its strong

FIG. 4. The “z” from the Japanese word “kaze,” its spectrogram (STFT), its conventional scalogram (DWT), and its shift-invariant scalogram (SIDWT).

FIG. 5. The “e” from the Japanese word “kaze,” its spectrogram (STFT), its conventional scalogram (DWT), and its shift-invariant scalogram (SIDWT).

second harmonic overwhelm the $F2 - F1$ difference in the 500-Hz and 1-kHz bands.

A similar view of three of the formant pulses from the vowel sound “e” is shown in Fig. 7, as a time history and as a shift-invariant scalogram. Patterns that appear to be difference frequencies can be seen, but since the formant content of “e” is more complex than the two strong peaks responsible for the signature in Fig. 6, the scalogram signature of the vowel “e” is more complex as well. This expanded view provides a more detailed picture of the secondary glottal pulse labeled “2” in each glottal period, showing that the fundamental periodicity, as well as the gap preceding the glottal closure, are still evident. The F_0 estimate in Fig. 2 was obtained by finding all occurrences of this formant gap-peak signature. For a list of times $t = (t_1, t_2, \dots, t_M)$ at which the M occurrences of the signatures were observed, F_0 at t_n is given by $F_{0n} = 1/(t_{n+1} - t_n)$, where $N = 1, 2, \dots, (M - 1)$. The times t were obtained by finding local maxima in the sum of the quadratic envelopes of the 1- and 2-kHz bands.

An important category of speech-processing techniques known as PSOLA (pitch-synchronized overLap and add) is based on working with the individual glottal pulses.²⁴ A typical application of PSOLA might begin with isolating each glottal pulse by multiplying the speech waveform by a rounded window (e.g., Hanning) centered over each pulse in turn. A typical length for the window would be twice the glottal period. The window length represents a compromise: longer windows allow the neighboring pulses to intrude, and shorter windows (or windows with more steeply sloped time-domain cutoffs) increase spectral leakage. After the individual glottal pulses have been processed in the desired manner, they must be recombined to make a single waveform. A variety of approaches has been used to recombine the individual segments,²⁴ including a technique which utilizes information obtained from wavelet transform analysis.²⁵ In general, PSOLA produces high-quality results, although sometimes annoying artifacts are present.^{26,27} The artifacts are not completely understood, and may be related to the

FIG. 6. The Japanese vowel “a,” and its shift-invariant scalogram. The glottal pulses are indicated by “GP.”

details of how the modified pulses are recombined.

The analysis/synthesis capability of the SIDWT/ISIDWT may be employed to segment and recombine a speech waveform in a manner that is conceptually similar to PSOLA, although the mathematical details are of course quite different. Figures 8 and 9 illustrate the procedure for extracting a single formant pulse from the speech waveform. In Fig. 8 a dashed-line box delineates the region of the scalogram corresponding to the single formant pulse to be extracted, i.e., the time interval $0.133 = t_a < t < t_b = 0.1436$. The edges of the box are aligned with local minima of the sum of the quadratic envelopes of the 2- and 1-kHz bands. The scalogram elements inside this box are preserved, and the remainder of the scalogram is set to zero. Given the speech waveform $z(t)$ over the interval $t_0 \leq t \leq t_c$, and the scalogram $x(t, n) = T(z)$, a function of both time and scale, this modification produces $w(t, n)$ such that

FIG. 8. A single formant pulse signature of the Japanese vowel “a” surrounded by a dashed-line box on the shift-invariant scalogram.

$$w(t, n) = \begin{cases} 0 & : t_0 \leq t < t_a \\ x(t, n) & : t_a \leq t \leq t_b \\ 0 & : t_b < t \leq t_c. \end{cases} \quad (11)$$

To complete the procedure, the extracted single formant pulse z' is obtained from $z' = S(x)$. Figure 9 shows z' , with the original waveform z in gray for comparison. The scalogram $x' = T(z')$ is also shown in Fig. 9, along with the original dashed-line box. The only significant difference between w and x' is the smoothing of the boundaries at t_a and t_b .

To carry the feature extraction procedure described above to completion, the nonzero elements of a scalogram x are segmented into M pieces (x'_1, x'_2, \dots, x'_M) such that $\sum_n x'_n = x$. Then, by the linearity of S , $\sum_n z'_n = z$. The regions of the scalogram where features with strong time localization are absent are segmented at arbitrary time boundaries, with

FIG. 7. The Japanese vowel “e,” and its shift-invariant scalogram. The glottal pulses are indicated by “GP,” with secondary pulses indicated by “2.”

FIG. 9. A single formant pulse of the Japanese vowel “a” extracted by the ISIDWT, with the original waveform in gray for comparison. The shift-invariant scalogram of the reconstructed pulse is shown surrounded by a dashed-line box marking the extracted area.

FIG. 10. A pitch-synchronous spectrogram-like display of the Japanese word “kaze.”

the constraint that the arbitrary segmentation lengths $t_b - t_a$ are similar to those used elsewhere in the scalogram. If the segmentation boundaries are aligned with instants of relative quiet, the operation may be considered a type of synchronous windowing, i.e., windowing synchronized with the amplitude modulation inherent in the waveform. In this example, most of the waveform exhibits strong amplitude modulation, and the width of each window $t_b - t_a$ is large relative to the smoothing at the boundaries observed in Fig. 9. Therefore, the time-domain overlap between adjacent segments is negligible, and

$$\sum_{n=1}^M F(z'_n(t)) \approx F(z'(t)), \quad (12)$$

even for some nonlinear $F(z)$ that are sufficiently local, e.g., quadratic envelope, or spectral density for frequencies $f > 1/(t_b - t_a)$.

To show how the frequency content of the extracted pulses evolves over time, a spectrogram-like display is presented in Fig. 10. The formant pulses obtained from the ISIDWT were zero padded to 1536-point length, and the energy spectral density of each pulse was calculated via the FFT with no further windowing. For comparison, a conventional spectrogram of the original kaze waveform is shown in Fig. 11. This and subsequent spectrograms were prepared with a 512-point Hanning window shifted in 134-point steps, and each windowed segment was zero padded to 1536-point length before calculating the FFT.

This waveform segmentation procedure is a unique and powerful capability of the SIDWT/ISIDWT. In addition to the analysis methods shown above, it has broad utility for copying, cutting, and pasting sections of sound waveforms. Working with the scalogram $x = T(z)$ rather than the sound waveform z has two advantages. First, for all but the simplest waveforms, it is usually easier to find and delineate features of interest in x . Second, cutting segments from x and joining them to make w doesn't result in audible clicks and pops. In conventional waveform editing, such clicks and pops are caused by steps at boundaries where the final value in one

FIG. 11. The spectrogram of the Japanese word “kaze.”

waveform segment differs from the initial value in the next waveform segment. The signature of such a boundary on the scalogram is a peak in the high-frequency scales, reflecting the high-frequency content of the step. It is usually necessary to taper or otherwise reshape the waveforms at each boundary to smooth these steps. However, excessive tapering or reshaping can create other audible artifacts, e.g., a gap in the high-frequency components. In some cases human intervention is required to find the optimal balance. Performing the cutting and joining operations on w creates steps in the scalogram values at boundaries that resemble the steps created on a raw edited sound waveform. However, since they are steps in w , not steps in z , they are not associated with audible clicks and pops. The pseudoinverse smooths the waveform at the boundary in a way that the scalogram signature of the boundary on x' is a rounded step, as close as possible in the least-squares sense to the original sharp step. The pseudoinverse cannot create a click or a pop at the boundary, because that would require a peak on the scalogram x' . A peak at the step location implies scalogram values with magnitude greater than those on either side of the step, which would never be the solution that minimizes $\sum_n (x'_n - x_n)^2$. It should be noted that absence of editing artifacts is no guarantee of realism, since abrupt starts or transitions between sounds of different character may sound false or even unpleasant. Even so, the reliable and automatic prevention of editing artifacts in sound waveforms is a substantial convenience.

A common application of PSOLA is changing the rate of a spoken word without changing the pitch or the frequency content of the formants, i.e., to simulate the same speaker pronouncing the same word, but speaking more rapidly or more slowly. To illustrate the sound waveform editing capabilities of the SIDWT/ISIDWT, the rate of the example waveform kaze has been halved and doubled. The first step in the procedure is to synchronize the analysis with the glottal pulses whenever possible. The spectrogram-like display shown in Fig. 10 was created by identifying M time instants t_i . The t_i in the voiced regions were located at moments of relative quiet in the 1- and 2-kHz bands, and the t_i in the unvoiced regions were merely spaced at regular intervals.

FIG. 12. The spectrogram of the Japanese word “kaze” rate-changed to half-speed.

The M time instants t_i were used as delimiters to segment the scalogram x into a set of $M - 1$ pieces y_i . The segments y_i correspond to individual glottal pulses, similarly sized sections of unvoiced speech, or silence. The notation y_i omits scale levels for simplicity, but all scale levels are implicitly included. If all segments y_i are concatenated in the proper order, $(y_1, y_2, \dots, y_{M-1}) = x$, the original scalogram is recovered. The speech rate was halved by simply duplicating each y_i in the proper sequence, $(y_1, y_1, y_2, y_2, \dots, y_{M-1}, y_{M-1}) = w$. The half-rate waveform z' was then obtained by $S(w) = z'$. A conventional spectrogram of the half-rate waveform is shown in Fig. 12. The speech rate was doubled by concatenating the even-numbered segments $(y_2, y_4, y_6, \dots) = x$, with $S(w) = z'$ as before. The even-numbered segments were chosen because they included the “k” sound; the doubled results from the odd-numbered segments sounded like “aze.” A conventional spectrogram of the double-rate waveform is shown in Fig. 13. Informal listening tests found that both examples were clear and understandable. The realism of the half-rate examples was marred

FIG. 13. The spectrogram of the Japanese word “kaze” rate-changed to double speed.

slightly by a mild low-frequency artifact, but the realism of the double-rate example was excellent.

IV. CONCLUSIONS

Procedures for calculating and inverting the SIDWT are described above via equations (Sec. II A) and as a block diagram (Sec. II B). A self-contained proof that the ISIDWT is the pseudoinverse of the SIDWT is given in the Appendix. The new SIDWT/ISIDWT algorithm described here is mathematically equivalent to the stationary wavelet transform and the maximal overlap discrete wavelet transform, and is easier to implement efficiently in an array-oriented mathematical scripting language. The recorded speech example discussed in Sec. III demonstrates that the SIDWT is useful for visualization and analysis of complicated, nonstationary, acoustic waveforms. The SIDWT provides a clear picture of the sounds excited and modulated by the opening and closing of the glottis in speech. The SIDWT is complementary to the STFT for visualization, as they provide optimal views of different aspects of the waveform. The SIDWT and ISIDWT together provide the capability to segment and reconstruct the sound from each individual glottal period for further visualization and analysis. Examples of half-rate and double-rate speech modification demonstrate the potential for the SIDWT/ISIDWT to prove useful for applications that currently use one of the PSOLA family of techniques.

The visualization capabilities of the SIDWT are constrained by the properties of the underlying discrete wavelet transform. In particular, the single-octave bandwidth resulting from dyadic wavelet scaling means that the tonal content of sound waveforms cannot be observed in detail. In certain situations, some tonal information can be extracted by analysis of sum and difference frequencies. The relative lack of frequency-domain information provided by the SIDWT is not really a loss, however; it is a trade-off, which enables the SIDWT to provide more detailed time-domain information. For the same reason, segmentation and reconstruction operations provide more detailed control in the time domain than in the frequency domain. The most productive way to use the SIDWT/ISIDWT will likely prove to be in concert with the STFT and other frequency-domain methods, e.g., the pitch-synchronous spectrogram-like display presented in Sec. III. The SIDWT and ISIDWT are based on purely mathematical principles, and have no inherent connection to psychoacoustics, e.g., two sound waveforms that are “close” in the sense of human perception of sounds are not guaranteed to be close in the sense of the standard Euclidean norm in redundant wavelet coefficient space. The applicability of the SIDWT/ISIDWT to acoustics can only be judged empirically. The experience to date, while subjective, and limited in scope to the field of automotive sound quality and the two rate-changing examples presented here, has been consistently encouraging. Possible speech-related applications include aspects of automated speech recognition and simplified intonation/formant visualization. Editing sound recordings (cutting and pasting sections) with the SIDWT/ISIDWT is especially convenient since the audible clicks and pops produced at section boundaries by simple time-domain editing procedures are automatically prevented. The rate-modified

speech examples presented here show promise, and the SIDWT/ISIDWT may prove useful for other applications that currently employ PSOLA-based methods. Given the broad scope of research in acoustics, there are many potential applications for the SIDWT/ISIDWT in visualization, manipulation, and analysis of nonstationary sound waveforms.

APPENDIX: PROOF OF THEOREM 1

Our strategy is to prove that T as defined in Sec. II A is an isometry and that S is the adjoint of T . Theorem 1 then follows from a well-known linear algebra fact. According to the definition of T in Sec. II A, we define the mappings

$$T_1: l^2(\mathbb{Z}_N) \ni z \mapsto (x_1, y_1) \in l^2(\mathbb{Z}_{2N}), \quad (\text{A1})$$

and for each stage $j=2, \dots, p$

$$T_j: l^2(\mathbb{Z}_{jN}) \ni (x_1, \dots, x_{j-1}, y_{j-1}) \\ \mapsto (x_1, \dots, x_{j-1}, x_j, y_j) \in l^2(\mathbb{Z}_{(j+1)N}). \quad (\text{A2})$$

Additionally, let $R: l^2(\mathbb{Z}_{(p+1)N}) \mapsto l^2(\mathbb{Z}_{(p+1)N})$ be the reordering given by

$$R(x_1, x_2, \dots, x_p, y_p) = (R_{N/2}(x_1), R_{N/4}(x_2), \dots, \\ R_{N/2^p}(x_p), R_{N/2^p}(y_p)). \quad (\text{A3})$$

Note that the p -stage SIDWT of $z \in l^2(\mathbb{Z}_N)$ is then given by $T(z) = RT_p \cdots T_2 T_1(z)$. Since convolution and reordering are linear maps, each T_j is linear. Therefore, T is a linear transformation.

We will now show that T is an isometry, i.e., that $\langle Tz_1, Tz_2 \rangle = \langle z_1, z_2 \rangle$ for all $z_1, z_2 \in l^2(\mathbb{Z}_N)$. To avoid considering the case $j=1$ separately, in the following let $(x_1, x_0, y_0) = y_0 = z$ and $(x_1, x_0) = 0$.

Theorem 3. The transform T is an isometry.

Proof: We show that for each $j=1, \dots, p$ the mapping T_j is an isometry. Since the reordering operator R is unitary, we have $\langle R w_1, R w_2 \rangle = \langle w_1, w_2 \rangle$ for all $w_1, w_2 \in l^2(\mathbb{Z}_{(p+1)N})$. As a composition of isometries, T is then an isometry.

Let $j \in \{1, \dots, p\}$, $z_1 = (x_1, \dots, x_{j-1}, y_{j-1})$ and $z_2 = (\xi_1, \dots, \xi_{j-1}, \eta_{j-1})$. Then

$$\langle T_j z_1, T_j z_2 \rangle \\ = \left\langle \left(x_1, \dots, x_{j-1}, \frac{1}{\sqrt{2}} R_2(y_{j-1} * \bar{v}), \frac{1}{\sqrt{2}} R_2(y_{j-1} * \bar{u}) \right), \right. \\ \left. \left(\xi_1, \dots, \xi_{j-1}, \frac{1}{\sqrt{2}} R_2(\eta_{j-1} * \bar{v}), \frac{1}{\sqrt{2}} R_2(\eta_{j-1} * \bar{u}) \right) \right\rangle \\ = \langle (x_1, \dots, x_{j-1}), (\xi_1, \dots, \xi_{j-1}) \rangle$$

$$+ \left\langle \frac{1}{\sqrt{2}} R_2(y_{j-1} * \bar{v}), \frac{1}{\sqrt{2}} R_2(\eta_{j-1} * \bar{v}) \right\rangle \\ + \left\langle \frac{1}{\sqrt{2}} R_2(y_{j-1} * \bar{u}), \frac{1}{\sqrt{2}} R_2(\eta_{j-1} * \bar{u}) \right\rangle. \quad (\text{A4})$$

Using the fact that R_2 is unitary, and applying Parseval's relation, we get

$$\left\langle \frac{1}{\sqrt{2}} R_2(y_{j-1} * \bar{v}), \frac{1}{\sqrt{2}} R_2(\eta_{j-1} * \bar{v}) \right\rangle \\ = \frac{1}{2} \langle y_{j-1} * \bar{v}, \eta_{j-1} * \bar{v} \rangle \\ = \frac{1}{2N} \sum_{n=0}^{N-1} \langle \widehat{(y_{j-1} * \bar{v})}(n), \widehat{(\eta_{j-1} * \bar{v})}(n) \rangle \\ = \frac{1}{2N} \sum_{n=0}^{N-1} \langle \hat{y}_{j-1}(n) \hat{v}(n), \hat{\eta}_{j-1}(n) \hat{v}(n) \rangle \\ = \frac{1}{2N} \sum_{n=0}^{N-1} |\hat{v}(n)|^2 \langle \hat{y}_{j-1}(n), \hat{\eta}_{j-1}(n) \rangle. \quad (\text{A5})$$

The same equality holds for \bar{u} instead of \bar{v} . Making use of the known identity $\hat{v}(n) = \hat{v}^*(n)$, we get

$$|\hat{v}(n)|^2 + |\hat{u}(n)|^2 = |\hat{v}(n)|^2 + |\hat{u}(n)|^2 = 2, \quad (\text{A6})$$

since the system matrix $A(n)$ is unitary for all $n=0, \dots, N-1$. This finishes the proof as follows:

$$\langle T_j z_1, T_j z_2 \rangle = \langle (x_1, \dots, x_{j-1}), (\xi_1, \dots, \xi_{j-1}) \rangle \\ + \frac{1}{N} \sum_{n=0}^{N-1} \langle \hat{y}_{j-1}(n), \hat{\eta}_{j-1}(n) \rangle \\ = \langle (x_1, \dots, x_{j-1}), (\xi_1, \dots, \xi_{j-1}) \rangle \\ + \frac{1}{N} \langle \hat{y}_{j-1}, \hat{\eta}_{j-1} \rangle \\ = \langle (x_1, \dots, x_{j-1}), (\xi_1, \dots, \xi_{j-1}) \rangle \\ + \langle y_{j-1}, \eta_{j-1} \rangle \\ = \langle (x_1, \dots, x_{j-1}, y_{j-1}), (\xi_1, \dots, \xi_{j-1}, \eta_{j-1}) \rangle \\ = \langle z_1, z_2 \rangle. \quad \square \quad (\text{A7})$$

Given a linear mapping $L: l^2(\mathbb{Z}_m) \rightarrow l^2(\mathbb{Z}_k)$, $m, k \in \mathbb{N}$, the adjoint operator

$$L^\dagger: l^2(\mathbb{Z}_k) \rightarrow l^2(\mathbb{Z}_m), \quad (\text{A8})$$

is given by the unique mapping defined by the property $\langle Lz, w \rangle = \langle z, L^\dagger w \rangle$ for all $z \in l^2(\mathbb{Z}_m)$, $w \in l^2(\mathbb{Z}_k)$. The matrix corresponding to L^\dagger is just the conjugate transpose of the matrix corresponding to L .

We will show that the ISIDWT S is the adjoint operator of T . To do so, we first prove a lemma.

Lemma. Let $x, y, v \in l^2(\mathbb{Z}_N)$. Then

$$\langle y * \bar{v}, x \rangle = \langle y, x * v \rangle. \quad (\text{A9})$$

Proof: Using Parseval's equality and again the identity $\hat{v}(n) = \hat{v}^*(n)$, we get

$$\begin{aligned} \langle y * \tilde{v}, x \rangle &= \frac{1}{N} \sum_{n=0}^{N-1} \hat{y}(n) \hat{v}(n) \hat{x}^*(n) \\ &= \frac{1}{N} \sum_{n=0}^{N-1} \hat{y}(n) \hat{v}^*(n) \hat{x}^*(n) = \langle y, x * v \rangle, \end{aligned} \quad (\text{A10})$$

which proves that the adjoint of the convolution with v is the convolution with the conjugate reflection \tilde{v} . \square

Following the definition of S in Sec. II A, we define mappings S_j as follows: Let $w = (w_1, w_2, \dots, w_{j+1}) \in l^2(\mathbb{Z}_{(j+1)N})$, where $w_i \in l^2(\mathbb{Z}_N)$ for all $i = 1, \dots, j+1$. Then, for all $j = 1, \dots, p$, we define

$$S_j : l^2(\mathbb{Z}_{(j+1)N}) \ni w \mapsto (w_1, \dots, w_{j-1}, \eta_j) \in l^2(\mathbb{Z}_{jN}), \quad (\text{A11})$$

where

$$\eta_j = \frac{1}{\sqrt{2}} (R_{N/2}(w_{j+1}) * u + R_{N/2}(w_j) * v). \quad (\text{A12})$$

Noting that $S = S_1 S_2 \cdots S_p R^{-1}$, where R^{-1} is the inverse of the reordering operator as defined in Eq. (A3), we can now prove the following theorem.

Theorem 4. $S = T^\dagger$.

Proof: Since $T = R T_p \cdots T_2 T_1$, it follows from the definition of the adjoint that $T^\dagger = T_1^\dagger T_2^\dagger \cdots T_p^\dagger R^\dagger = T_1^\dagger T_2^\dagger \cdots T_p^\dagger R^{-1}$, where we made use of the fact that the adjoint of the unitary operator R is its inverse R^{-1} . Hence, the theorem follows once we show that $T_j^\dagger = S_j$ for all $j = 1, \dots, p$.

We need to prove that $\langle T_j z, w \rangle = \langle z, S_j w \rangle$ for all $z \in l^2(\mathbb{Z}_{jN})$ and $w \in l^2(\mathbb{Z}_{(j+1)N})$. Let $z = (x_1, x_2, \dots, x_{j-1}, y_{j-1})$ and $w = (w_1, w_2, \dots, w_{j+1})$. Then

$$\begin{aligned} \langle T_j z, w \rangle &= \left\langle \left(x_1, x_2, \dots, x_{j-1}, \frac{1}{\sqrt{2}} R_2(y_{j-1} * \tilde{v}), \right. \right. \\ &\quad \left. \left. \frac{1}{\sqrt{2}} R_2(y_{j-1} * \tilde{u}) \right), (w_1, w_2, \dots, w_{j+1}) \right\rangle \\ &= \langle (x_1, x_2, \dots, x_{j-1}), (w_1, w_2, \dots, w_{j-1}) \rangle \\ &\quad + \left\langle \frac{1}{\sqrt{2}} R_2(y_{j-1} * \tilde{v}), w_j \right\rangle \\ &\quad + \left\langle \frac{1}{\sqrt{2}} R_2(y_{j-1} * \tilde{u}), w_{j+1} \right\rangle. \end{aligned} \quad (\text{A13})$$

Note that by the lemma

$$\begin{aligned} \left\langle \frac{1}{\sqrt{2}} R_2(y_{j-1} * \tilde{v}), w_j \right\rangle &= \left\langle y_{j-1} * \tilde{v}, \frac{1}{\sqrt{2}} R_{\frac{N}{2}}(w_j) \right\rangle \\ &= \left\langle y_{j-1}, \frac{1}{\sqrt{2}} R_{\frac{N}{2}}(w_j) * v \right\rangle. \end{aligned} \quad (\text{A14})$$

The same equation holds for u instead of v . So, we conclude that

$$\begin{aligned} \langle T_j z, w \rangle &= \langle (x_1, x_2, \dots, x_{j-1}), (w_1, w_2, \dots, w_{j-1}) \rangle \\ &\quad + \left\langle y_{j-1}, \frac{1}{\sqrt{2}} (R_{\frac{N}{2}}(w_j) * v + R_{\frac{N}{2}}(w_{j+1}) * u) \right\rangle \\ &= \left\langle (x_1, x_2, \dots, x_{j-1}, y_{j-1}), \left(w_1, w_2, \dots, w_{j-1}, \right. \right. \\ &\quad \left. \left. \frac{1}{\sqrt{2}} (R_{\frac{N}{2}}(w_j) * v + R_{\frac{N}{2}}(w_{j+1}) * u) \right) \right\rangle \\ &= \langle z, S_j w \rangle. \square \end{aligned} \quad (\text{A15})$$

We have shown that S is given by T^\dagger . It is well known that a 1–1 linear map L has a unique pseudoinverse given by $(L^\dagger L)^{-1} L^\dagger$. Here, T is not only 1–1 but also an isometry, which is equivalent to $T^\dagger T = id|_{l^2(\mathbb{Z}_N)}$. Thus, the pseudoinverse of T is given by $T^\dagger = S$, which proves Theorem 1.

Instead of u and v in the definition of S , we can use any a and b in $l^2(\mathbb{Z}_N)$, satisfying the condition

$$\hat{a}(n) \hat{a}^*(n) + \hat{b}(n) \hat{b}^*(n) = 2, \quad (\text{A16})$$

for all $n = 0, \dots, N-1$ to obtain a mapping \tilde{S} which is still an inverse of T on the image of T . Since \tilde{S} is computed using convolutions in the same way as S , the number of multiplications required to compute \tilde{S} is the same as for S . However, since then $\tilde{S}^\dagger \neq T$, \tilde{S} is no longer the pseudoinverse, i.e., we lose the notion of ‘‘closeness’’ in the least-squares sense.

Defect imaging with guided waves in a pipe

Takahiro Hayashi^{a)} and Morimasa Murase

Faculty of Engineering, Nagoya Institute of Technology, Gokiso Showa Nagoya, 466-8555, Japan

(Received 22 September 2004; revised 6 January 2005; accepted 7 January 2005)

Guided wave techniques are expected to become an effective means for rapid, long-range inspection of pipes. Such techniques still have many practical difficulties in application, however, due to the complex characteristics of guided waves such as dispersion and their multimodal nature. A defect imaging technique is developed in this study to overcome the complexities of guided wave inspection. Received signals are separated into single-mode waveforms with a mode extraction technique and then spatial waveforms on the pipe surface at an arbitrary time are reconstructed. The predicted waveforms can provide a defect image at the moment when an incident wave arrives at a defect region, which is based on a time-reversal technique. This defect imaging technique is experimentally verified using eight signals detected at eight different circumferential positions. Images of artificial defects are obtained with one-hole and two-hole test pipes, and increasing the frequency of incident waves increases the resolution of the images. Holes and pipe ends are recognizable in the images, but the reconstructed images contain some errors in the area behind the defects where guided waves do not propagate or do not reflect back to the receiving transducers. © 2005 Acoustical Society of America. I. INTRODUCTION

A nondestructive evaluation (NDE) technique for pipe-work has been developed using guided waves acting as ultrasonic modes propagating longitudinally in a pipe. Guided wave NDE is expected to become a rapid long-range inspection technique^{1,2} in which an inspection tool emits guided waves from an accessible part of a pipe, then detects reflected or transmitted guided waves from damaged areas of the pipe that are inaccessible (such as buried or coated regions). Because guided waves propagate as forward or backward traveling waves, transducers lined up on the circumference of a pipe can fully detect reflected waves or transmitted waves. Reflected and transmitted waves contain all of the information about reflective walls and scattering objects. If the detected signals are processed properly, most of this information can be acquired. This characteristic of guided waves is highly beneficial for NDE when considering that not all energy due to refraction and scattering can be detected by NDE using bulk waves.

Guided waves in a pipe, however, have multimodal and dispersive characteristics similar to Lamb waves.^{3,4} These distinctive characteristics make it difficult to evaluate pipe damage and defects with sufficient accuracy and reliability using conventional pulse-echo and pitch-catch techniques to measure amplitude and velocity. For example, the phase and amplitude of signals received from a transducer will often be completely different even at one wavelength away in the longitudinal direction. This is because guided waves are a superposition of many modes having different wavelengths and wave structures. And, because these characteristics of guided waves depend on diameter, thickness, and the material properties of the pipe, the results obtained from one pipe test cannot be directly applied to other types of pipes.

Easy-to-use axisymmetric modes have therefore been adopted for guided wave inspections. Axisymmetric modes have a wide nondispersive region in the dispersion curves, particularly an axisymmetric torsional mode $T(0,1)$ having constant phase and group velocities over all frequency regions. As such, incident pulse signals of axisymmetric modes maintain their waveforms and propagate long distances with a high signal-to-noise ratio. Also, single axisymmetric modes can be detected easily using axisymmetric transducers with no mixing of nonaxisymmetric modes.

However, because axisymmetric modes propagate no information concerning the circumferential direction (such as circumferential location, maldistribution, or size of defects) and defect characterization cannot be accomplished in an axisymmetric mode, several studies on nonaxisymmetric modes of guided waves in a pipe have been recently presented. Ditri⁵ investigated scattering waves from a circumferential crack using the S -parameter formalism and addressed the possibility of crack sizing. Lowe *et al.*⁶ and Alleyne *et al.*⁷ analyzed mode converted guided waves from part-circumferential notches in a pipe both experimentally, using the mode extraction technique, and theoretically, using a finite element model. Li and Rose⁸ experimentally verified the angular profile of guided waves that were estimated by normal mode expansion theory, and determined the position of transducers for defect detection. Demma *et al.*⁹ investigated the reflected guided waves from a part-circumferential notch when a torsional axisymmetric mode is emitted, both experimentally and through FE analysis.

In this paper we describe a defect imaging technique, in which nonaxisymmetric modes, as well as an axisymmetric mode, are considered and an image of defects is obtained after appropriate signal processing. Guided wave propagation at an arbitrary time and point on the surface of a pipe is predicted by a combination of the mode extraction technique

^{a)}Corresponding author; electronic mail: hayashi@nitech.ac.jp

FIG. 1. Group velocity dispersion curves of torsional modes for an aluminum pipe with outer diameter=111 mm and thickness=3.5 mm.

with the reconstruction of spatial waveforms. This technique is based on the time-reversed method proposed by Ing and Fink³ in the sense that received waveforms are played back, but mode extraction and the reconstruction process are required.

The mode extraction technique, which is based on Lowe's method but includes negative circumferential orders, is described first, and defect imaging is described in detail. This imaging technique is then experimentally verified for one-hole and two-hole pipes at various frequencies.

II. THEORY

A. Circumferential mode extraction

The normal mode expansion technique gives the displacement on the surface of a pipe for a harmonic wave $\exp(-i\omega t)$ using the cylindrical coordinate system (r, θ, z) as

$$u(\theta, z, t) = \sum_{n=-\infty}^{+\infty} \sum_{m=1}^{+\infty} \alpha_{nm} \exp(in\theta + ik_{nm}z - i\omega t), \quad (1)$$

where n and α_{nm} represent the circumferential order number (family) and the amplitude of the m th mode in the n th family, respectively.¹⁰⁻¹² Wave numbers k_{nm} consist of several propagating modes with real values and an infinite number of nonpropagating (evanescent) modes having complex values.¹²

Torsional modes $T(n, m)$ dominated mainly by a displacement in the circumferential direction are now considered. For additional details about indices n and m , the reader should refer to Ref. 13, and to the dispersion curves of Fig. 1. Normally, guided wave NDE uses propagating modes with real wave numbers k_{nm} . For axisymmetric torsional modes $T(0, m)$, the minimum frequencies above which the m th propagating modes occur (the cutoff frequencies) are given for general-purpose pipes when the pipe wall thickness is small compared to the radius as

$$f_c = \frac{c_T}{2d}(m-1), \quad (2)$$

where c_T and d are the transverse wave velocity and the thickness of the pipe, respectively. General-purpose pipes, such as schedule pipes, are at most approximately 15 mm thick with a transverse wave velocity of approximately 3200 m/s. The cutoff frequency for $m=2$ is therefore greater than 106 kHz in Eq. (2). When we consider the frequency range

from 20 to 100 kHz, used widely in long-range pipe inspections, modes greater than $m=2$ can be neglected. The displacement on the surface of a pipe in Eq. (1) can be rewritten as

$$u(\theta, z, t) = \sum_{n=-\infty}^{+\infty} \alpha_n \exp(in\theta + ik_n z - i\omega t), \quad (3)$$

where $\alpha_{n1} \equiv \alpha_n$ and $k_{n1} \equiv k_n$, in order to simplify the representation.

Signals received in a small section $r_0 d\theta$ at $z=z_R$ and $\theta=\theta$ are given by $u(\theta, z_R, t)r_0 d\theta$. Multiplying a weight function $\exp(-in_E\theta)$ against the term $u(\theta, z_R, t)r_0 d\theta$, and integrating this with respect to θ , gives extracted waveforms of the n_E th circumferential mode as

$$\begin{aligned} u_{n_E}^{\text{ext}}(z_R, t) &= \int_0^{2\pi} u(\theta, z_R, t) \exp(-in_E\theta) r_0 d\theta \\ &= 2\pi r_0 \alpha_{n_E} \exp(ik_{n_E} z_R - i\omega t). \end{aligned} \quad (4)$$

In practice, receiving sensors are not infinitesimal as indicated by $r_0 d\theta$, and the number of receiving points is finite. Assuming N receiving positions in the circumferential direction at regular intervals as

$$\theta_k = \frac{2\pi}{N}(k-1), \quad (5)$$

and assuming that a displacement is detected in the region with an aperture of $\theta_0 = 2\pi/N$, then the received signals $\theta = \theta_k$ and $z = z_R$ are given by

$$\begin{aligned} u^R(\theta_k, z_R, t) &= \int_{\theta_k - \theta_0/2}^{\theta_k + \theta_0/2} u(\theta, z_R, t) r_0 d\theta \\ &= r_0 \sum_{n=-\infty}^{+\infty} \alpha_n f_n(\theta_0) \exp(in\theta_k + ik_n z_R - i\omega t), \end{aligned} \quad (6)$$

where

$$f_n(\theta_0) = \begin{cases} \theta_0, & \text{for } n=0, \\ \frac{2 \sin(n\theta_0/2)}{n}, & \text{for } n \neq 0. \end{cases} \quad (7)$$

Then, multiplying by the weight function $\exp(-in_E\theta_k)$ and summing with respect to k gives, similar to Eq. (4), the extracted waveforms

$$\begin{aligned} u_{n_E}^{\text{ext}}(z_R, t) &= r_0 \sum_{k=1}^N \sum_{n=-\infty}^{+\infty} \alpha_n f_n(\theta_0) \\ &\quad \times \exp\{i(n-n_E)\theta_k + ik_n z_R - i\omega t\} \\ &\approx r_0 \alpha_{n_E} f_{n_E}(\theta_0) \exp(ik_{n_E} z_R - i\omega t). \end{aligned} \quad (8)$$

It should be noted here that Eq. (8) holds under the condition of $|n_E| \leq N/2 - 1$, because modes lower than n_E are superposed in Eq. (8) for $|n_E| \geq N/2$. In dispersion curves for torsional modes, those modes higher than $n=8$ do not propagate in the frequency regions used in this study (30–70 kHz). Also, for the highly dispersive modes of $n=4-7$, the detected signals become very broad, and only a very small part

FIG. 2. Schematic setup for defect imaging.

of the energy of these modes can be recorded. Therefore, eight different circumferential positions are used to detect the guided waves in later experiments. This corresponds to $N = 8$, and the main propagating modes from $n = -3$ to $+3$ can be extracted.

B. Waveform prediction of dispersive modes and reconstruction of defect images

If the diameter, thickness, and material properties of a pipe are given, then the wave numbers k_{n_E} and phase velocities c_{n_E} of the extracted modes can be theoretically obtained. Once the wave numbers k_{n_E} are given, multiplying $\exp\{ik_{n_E}(z-z_R)\}$ against the extracted waveforms $u^{\text{ext}}(z_R, t)$ obtained from received signals at $z=z_R$ yields predicted waveforms of the n_E th mode at $z=z$ as

$$u_{n_E}^{\text{ext}}(z_R, t) \exp\{ik_{n_E}(z-z_R)\} \approx r_0 \alpha_{n_E} f_{n_E}(\theta_0) \exp(ik_{n_E}z - i\omega t) = u_{n_E}^{\text{ext}}(z, t). \quad (9)$$

Equation (9) is for a harmonic wave of frequency ω . In actual experiments, extracted waveforms in the frequency domain are obtained by FFT first, and then a series of data multiplied by $\exp\{ik_{n_E}(z-z_R)\}$ are transformed back to the time domain by inverse FFT. This process was presented as a dispersion reduction technique for dispersive Lamb waves by Wilcox *et al.*¹⁴

From Eq. (6), waveforms received with uniform weight in the region having an aperture of θ_0 at an arbitrary point (θ, z) on the surface of a pipe are given by

$$u^R(\theta, z, t) = r_0 \sum_{n=-\infty}^{+\infty} \alpha_n f_n(\theta_0) \exp(in\theta + ik_n z - i\omega t). \quad (10)$$

Using the predicted extracted waveforms $u_n^{\text{ext}}(z, t)$ obtained by Eq. (9), Eq. (10) can be rewritten as

$$u^R(\theta, z, t) = \sum_{n=-\infty}^{n=+\infty} u_n^{\text{ext}}(z, t) \exp(in\theta). \quad (11)$$

This equation shows that multiplying $\exp(in\theta)$ against $u_n^{\text{ext}}(z, t)$ obtained in Eq. (9) gives waveforms detected by a receiving transducer with aperture θ_0 at an arbitrary point.

The fact that reflected waves from defects are detected at N different circumferential positions (Fig. 2) is now considered. A $T(0,1)$ mode is emitted at $z=z_S$ toward the defects in the $-z$ direction. The $T(0,1)$ incident wave is reflected back from the defects in the $+z$ direction, and the reflected waveforms are detected by N receiving transducers located at z

FIG. 3. Experimental setup.

$=z_R$. From the N received signals, spatial waveforms at an arbitrary time can be predicted like snapshots at all of the time steps. Since the reflected waveforms are very large at the moment of reflection from a reflective object, the snapshot at this moment shows an image of the reflective object.

III. EXPERIMENT

A. Experimental setup

Figure 3 shows a schematic figure of the experimental setup used in this study. A magnetostrictive sensor (MS sensor) consisting of a nickel plate adhered to the pipe surface and a coil wound on the nickel plate, is used for generating a $T(0,1)$ mode.¹⁵ The nickel plates are magnetized in the circumferential direction and serve as bias magnetic fields. Alternating voltage as four-cycle sinusoidal waves of 30, 50, and 70 kHz are applied to the coil, generating vibration in the circumferential direction by magnetostriction. Two magnetostrictive sensors are used to double the $T(0,1)$ mode signals by applying a time delay to one forward-located sensor (MS sensor2 in Fig. 3). A function generator (NF corporation, WF1944A) and a power amplifier (NF corporation, HSA4051) are used to apply rf signals to the coils.

An electromagnetic acoustic transducer (EMAT) is adopted for noncontact measurements. The experiments of this study require accurate waveform measurements at many different circumferential positions; therefore, noncontact measurement with EMATs is more suitable than contact methods strongly affected by contact pressure and the thickness of the coupling material. The EMAT used in the experiment consists of two permanent magnets (NEOMAX, NEOMAX Co. Ltd., 15 mm \times 6 mm \times 10 mm) and sheet coils fabricated by a printed circuit technique. The EMAT is flexible so that it fits the curvature of the pipe. The sheet coil and

FIG. 4. Waveforms detected at eight different circumferential positions. (a) rf signals; (b) amplified representation of (a).

permanent magnets of the EMAT are arranged to receive shear horizontal waves by Lorentz forces. This transducer, then, receives vibration mainly in the circumferential direction.¹⁶ In order to receive displacement in the region of 1/8 of the circumference, the EMAT is designed to be 44 mm in width. Signals received at the EMAT are magnified 40 dB by a preamplifier and are recorded after 10 signal averagings.

The test objects for this study are aluminum pipes of 4 m in length, 111 mm in diameter, and 3.5 mm in thickness with a longitudinal wave velocity $c_L=6260$ m/s and a transverse wave velocity $c_T=3080$ m/s. The defects are located 0.5 m from the pipe end and one meter from MS sensor1 (Fig. 3). Backward waves may propagate in a direction opposite to the defects, but in this study the test pipes are large enough to separate the necessary signals from the unwanted signals that come from the other side of the pipe.

The receiving EMAT is positioned 1.2 m from the defects and measures signals at eight different circumferential positions. The artificial defects are through-holes of 10 mm in diameter and are located at 0° for the one-hole test pipe and at 0° and 90° for the two-hole test pipe, in the circumferential direction, as shown in Fig. 3.

Figures 4(a) and 4(b) are the waveforms detected at eight different circumferential positions (0° , 45° , 90° , 135° , 180° , 225° , 270° , and 315°) for a one-hole test pipe and 50 kHz incidence. Large signals around $1000 \mu\text{s}$ are backwall echoes from the pipe end 1.5 and 1.7 m in distance from excitation MS sensor1 and the receiving EMAT, respectively. Small signals between 500 and $1000 \mu\text{s}$ are echoes from the defect. Figure 4(b) shows the waveforms of Fig. 4(a) after amplification to discern the waveforms of the defect echoes. The backwall echoes and incident waves around $t=0 \mu\text{s}$ are unnecessary for defect imaging, so all signals from 330 to $980 \mu\text{s}$ are extracted, and other amplitudes are assumed to be zero.

B. Prediction of waveforms reflected at a pipe defect

Figure 5 shows spatial waveforms at three different times predicted by the above process using the detected waveforms of Fig. 4. All images show absolute values of spatial waveforms normalized by the maximum amplitude of spatial waveforms at all time steps. Since (a) $t=195 \mu\text{s}$ is a time when the incident T(0,1) mode has not yet arrived at the

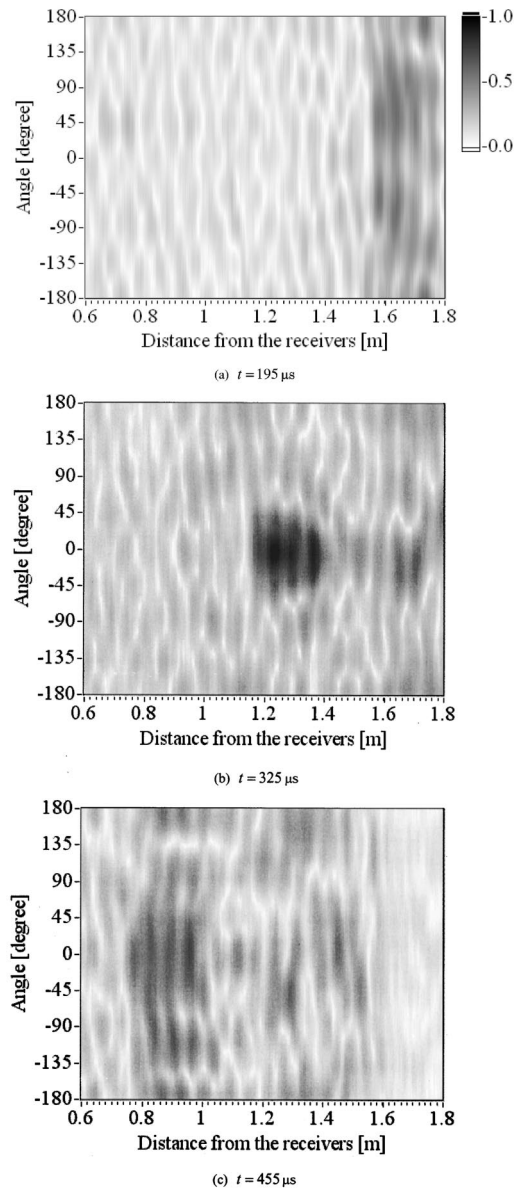

FIG. 5. Snapshots of predicted waveforms at various moments. (a) $t=195 \mu\text{s}$, (b) $t=325 \mu\text{s}$, (c) $t=455 \mu\text{s}$.

defect, the predicted waveform (a) does not give a defect image. In (b), the moment when the incident T(0,1) mode arrives at the defect, a distinct spot with high intensity is present at approximately 1.2 m from the receivers and 0° , which agrees well with the position of the artificial defect. After (b), the waveforms spread out from the defect, as can be seen in (c).

C. Effect of frequency on the predicted waveforms

Next, snapshots of the predicted waveforms in the one-hole pipe at $t=325 \mu\text{s}$ are shown in Fig. 6 for a four-cycle sinusoidal incidence of 30 and 70 kHz. For (a) 30 kHz, the high-intensity spot becomes broad in both the longitudinal and circumferential directions, indicating lower resolution. On the other hand, a better result with higher resolution is obtained in both directions for (b) 70 kHz.

Since resolution in the longitudinal direction is determined by a wave disturbance zone, then in the case of four-

(a) 30 kHz, $t = 325 \mu\text{s}$

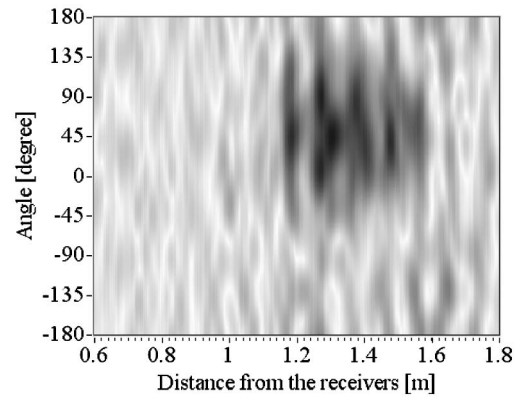

(b) 70 kHz, $t = 325 \mu\text{s}$

FIG. 6. Predicted waveforms for various frequencies at $t = 325 \mu\text{s}$. (a) 30 kHz, $t = 325 \mu\text{s}$; (b) 70 kHz, $t = 325 \mu\text{s}$.

cycle incidence, four times the wavelength is taken as the high-intensity zone. Circumferential resolution is determined by the order of detectable circumferential modes. In the frequency region of approximately 30 kHz, modes of orders higher than T(3,1) cannot be detected due to the cutoff frequency, and the T(2,1) and T(3,1) modes have large dispersion. It is expected, therefore, that signals within the given gate ($t = 330$ to $980 \mu\text{s}$) do not contain all of the energy of the T(2,1) and T(3,1) modes, causing low resolution in the circumferential direction. In contrast, in the high-frequency region of approximately 70 kHz, since higher-order modes such as T(2,1) and T(3,1) have low-dispersion characteristics, most of the energy of the higher-order modes can be obtained, resulting in higher resolution in the circumferential direction.

Figure 7 shows snapshots at the moment when the incident T(0,1) mode arrives at the defects ($t = 325 \mu\text{s}$) for a two-hole test pipe with through-holes at 0° and 90° in the three different frequency regions. In the 30 and 50 kHz defect images, single broad dark regions can be seen, the centers of which are located at about 45° . In the 70 kHz defect image, however, two distinct dark spots can be seen at 0° and 90° , at 1.2 m.

The dark zones even at 70 kHz for both one-hole and two-hole test pipes are shown to be larger than the artificial holes of 10 mm in diameter. We can expect that the dark

(a) 30 kHz

(b) 50 kHz

(c) 70 kHz

FIG. 7. Predicted waveforms at $t = 325 \mu\text{s}$ for a two-hole test pipe and various frequencies. (a) 30 kHz, (b) 50 kHz, (c) 70 kHz.

zones become closer to the circle 10 mm in diameter at higher frequencies. However, since the predicted waveform, as shown in Eq. (10), denotes the waveform at (θ, z, t) measured by the receiving transducer with an aperture of $\theta_0 = 2\pi/N$, the resolution in the circumferential direction is theoretically limited to the aperture of receiving transducers $\theta_0 = 2\pi/N$.

D. Defect imaging considering the arrival region of the incident wave

In Figs. 5–7, which show the waveforms predicted from the received signals, the defect images are obtained as snapshots at the moment that the incident T(0,1) mode arrives at

FIG. 8. Imaging of defects and a pipe end.

a defect region. However, when reflection objects are located at different longitudinal locations, information on the reflection objects in the longitudinal direction cannot be obtained in one snapshot. In this section we describe defect imaging in which such reflection objects are shown in one image. Summing up the images of predicted waveforms at all time steps only in the arrival region of incident wave $T(0,1)$ provides an image of reflection objects, such as defects, pipe ends, weld lines, and branches. Acquiring an image of the two holes and pipe end using the received signals that produced the snapshot image of Fig. 7(c) is now considered. The image in Fig. 7(c) was obtained by gating the received signals between 330 and 980 μs in order to avoid backwall echoes. In the following process, however, the signals are gated between 330 and 1200 μs in order to include reflection waves from the pipe end.

Now, consider the arrival region of an incident $T(0,1)$ mode at a certain time t , which is from $z = c_T t - l\lambda$ to $z = c_T t$, where l and λ are the number of cycles and the wavelength of the incident burst waves, respectively. If reflective walls, such as defects, exist in this region, then the predicted waveforms of the reflected waves become large. In contrast, if there are no reflective objects present, then the predicted waveforms become zero. Thus, summing up the absolute values of the predicted waveforms in the regions for all time steps gives an image of the reflective objects. This is shown in Fig. 8, in which a reflective object with high intensity is present at approximately 1.7 m from the receivers, and two round reflective objects with low intensity are present at 1.2 m, $\theta=0^\circ$ and $\theta=90^\circ$. The two dark regions at 1.2 m agree well with the two artificial holes. The dark region at 1.7 m should indicate the pipe ends, but is not symmetric with respect to the pipe axis and has a nonreflecting region behind the two holes. It is considered that this region cannot be reconstructed as an image due to scattering at the holes and multiple reflections between the holes and the pipe end. However, it is confirmed that this imaging technique has a potential for providing images of reflective objects having longitudinal distributions.

E. Possible errors by measurement conditions

The imaging technique using guided waves presented herein is applicable when guided wave modes can be perfectly separated and dispersion curves are theoretically ob-

tained. However, it is possible to superpose unwanted modes and to change a defect image due to the characteristic of the receivers. In this study, we assume that the EMATs detect only horizontal shear vibration by Lorentz force, but the EMATs can also detect unexpected longitudinal or out-of-plane vibrations. In contrast, if we can separately detect vibrations in all directions and extract flexural modes as well as torsional modes, better defect images can be obtained.

Random noise, largely detected as shown in Fig. 4, may also distort defect images. However, random noise interfering with received signals is reduced in the summation with respect to k in Eq. (8). Therefore, the dark defect zone in Fig. 5(b) appears large compared with other noisy regions. This indicates the robustness of the defect imaging technique against random noise interfering with each waveform.

In this technique, however, the sensitivity of the transducers at all receiving points should coincide because all signals are added and subtracted in the imaging process. Since we use one EMAT for receiving at eight positions in this study, this error must be small, but when using the contact technique, in which it is difficult to control contact pressure and the thickness of the coupling medium, sensitivity mismatching could result in large distortion in defect images. In order to investigate the influence of differences in sensor sensitivity, Fig. 9 shows the defect images when specific signals cannot be properly obtained, for a two-hole test pipe and 70 kHz incidence. Signals were gated from 330 to 980 μs in order to obtain only images of defects and to avoid pipe ends. The defect image in Fig. 9(a) was constructed by using all of the signals, the same signals that were used to obtain Figs. 7(c) and 8. Figures 9(b) and 9(c) were obtained by replacing the first signals received at $\theta=0^\circ$ and the first two signals at $\theta=0^\circ$, 45° with zero-valued samples, respectively, showing the typical case when a portion of the signals cannot be detected due to transducer trouble in practical testing. In Fig. 9(d), only the first signals at $\theta=0^\circ$ are phase-reversed and the other signals are the same, indicating an insufficient contact condition for the contact-type transducers, or a difference in sensor sensitivity. Comparing Figs. 9(a), 9(b), and 9(c), as the number of zero signals increases, a more unwanted dark zone can be seen in the images. In Fig. 9(d), a very large distortion of the defect images can be seen, although only one waveform was reversed. These results reveal that differences in transducer sensitivity, as well as a lack of signals, may cause large image distortion.

IV. CONCLUSIONS

Defect imaging with guided waves was described. A defect image in a pipe was obtained as a spatial waveform by processing signals detected at many different circumferential positions. After a detailed theoretical description, the defect imaging technique was experimentally verified using eight signals detected at eight different circumferential points.

In defect imaging tests for 30, 50, and 70 kHz four-cycle sinusoidal waves, higher resolutions in both the longitudinal and circumferential directions were obtained at higher frequencies. Reconstructed images for two-hole and one-hole pipes agreed well with the test pipes. Moreover, a pipe end

behind two holes could be seen in the image, but an undetectable region was found just behind the holes.

In this study, we used only torsional modes and shear horizontal vibration. From a theoretical point of view, the imaging technique described herein can be applied to longitudinal and flexural modes. Because flexural modes in reflected waves from defects were detectable, combining this technique with other modes should enhance the defect images.

(Received 29 September 2004; revised 24 January 2005; accepted 25 January 2005)

We present a consistent second-order expansion of nonlinear constitutive theories for outer hair cells. For a particular theory, we will test the validity of such a model for small variations in voltage and strain about the resting state of outer hair cells. An analysis of the various terms in the simplified nonlinear model and their relevance to outer hair cell mechanics are presented. Results show that the second-order expansion is adequate for modeling outer hair cell mechanics in a global model of the cochlea. Model predictions agree with the notion that voltage nonlinearities are the dominant ones at low sound levels *in vivo*. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1871753]

I. INTRODUCTION

Outer hair cells (OHCs) along with their stereocilia are believed to be the primary source of nonlinearity in the mammalian cochlea, contributing to its sensitivity and frequency selectivity. These electromotile cells play an important role in generating electrically evoked emissions, distortion product emissions, and influence, to a significant degree, other experimental artifacts seen in the cochlea. For modeling the cochlea it is hence essential to capture OHC behavior. There is a wealth of data in the literature on *in vitro* experiments on OHCs. Results from Parthasarathi *et al.* (2003) indicate that OHC sensitivity to electrical and mechanical resting conditions seen *in vitro* are also important *in vivo*. If we assume that the *in vitro* behavior of OHCs is a fair representation of *in vivo* mechanics, we can proceed to extract information from *in vitro* data to construct models for *in vivo* mechanics.

While there have been attempts in the literature to construct complete OHC models (for instance, Tolomeo and Steele, 1995; Raphael *et al.*, 2000; Spector, 2001; Iwasa, 2001; Deo and Grosh, 2004), none of the current models explain all features of OHC electromotility seen in experiments. For cochlear models the *in vivo* behavior of OHCs is of primary interest. OHCs are subjected to a much narrower range of voltages and strains *in vivo* than in *in vitro* experiments. In this paper, we show how to construct and analyze an OHC model containing first-order nonlinearities. Such a model, while unable to predict OHC response over the range of voltages used in *in vitro* experiments, possesses sufficient richness to describe *in vivo* nonlinearities and response. Furthermore, a first-order model will be easier to incorporate in a global cochlear model and also easier to construct from experiments. The extended area motor model (EAMM) (Deo and Grosh, 2004), which is an extension upon Iwasa's original hypothesis (Iwasa, 1994; Iwasa, 2001), is used as a basis

to construct a simpler model. The EAMM incorporates the most recent experimental findings of voltage-dependent OHC stiffness (He and Dallos, 1999; He and Dallos, 2000) as well as the nonlinear capacitance and motility. The simple model is derived from an energy basis to ensure reciprocity. The dynamic response of OHCs seen in experiments is successfully reproduced by the simple model. The model parameters are related to experiments to illustrate their relevance to OHC behavior.

II. ENERGY-BASED OHC MODELS

OHCs are shell-like hollow cylindrical bodies filled with fluid. The OHC is assumed to be a right-circular cylinder of length L , radius r , and membrane thickness h (see Fig. 1). The applied loads are considered axisymmetric and it is assumed that the principal axis of the material properties coincides with the cylindrical coordinates. All bending stresses on the OHC are neglected. Since the radius to thickness ratio of the OHC is very high, all radial strains are ignored. The motor proteins are assumed to be spread uniformly on the cylindrical OHC surface. These assumptions leave us with charge (Q), voltage (V), axial strain (ϵ_z), axial stress (σ_{zz}), circumferential strain (ϵ_c), and circumferential stress ($\sigma_{\theta\theta}$) as the state variables. Instead of stresses we use tensions, $T_z = \sigma_{zz}h$ and $T_c = \sigma_{\theta\theta}h$, for the forcing state variables to have similarity with the area motor model. Consider the Gibbs free energy per unit surface area of the OHC membrane:

$$G = G(T_z, T_c, V). \quad (1)$$

Experimentally, it is easier to measure strain rather than tension so an energy function with voltage and strains as the independent variables will be more useful. Using the Legendre transformation we obtain

$$W(\epsilon_z, \epsilon_c, V) = G(T_z, T_c, V) + T_z \epsilon_z + T_c \epsilon_c. \quad (2)$$

The corresponding charge and tensions are

^{a)}Electronic mail: ndeo@umich.edu

^{b)}Electronic mail: grosh@umich.edu

FIG. 1. Schematic of an outer hair cell having length L , radius r , and thickness h . F is the external force acting on the OHC. P_0 is the initial fluid pressure and V_0 is the transmembrane voltage.

$$Q = - \frac{\partial W(\varepsilon_z, \varepsilon_c, V)}{\partial V}, \quad (3)$$

$$T_z = \frac{\partial W(\varepsilon_z, \varepsilon_c, V)}{\partial \varepsilon_z}, \quad (4)$$

$$T_c = \frac{\partial W(\varepsilon_z, \varepsilon_c, V)}{\partial \varepsilon_c}. \quad (5)$$

We next specialize to the most common *in vitro* experimental configuration, an intact cylindrical OHC with forcing along its cylindrical axis. For a cylindrical OHC with a fluid pressure P_0 inside the cell, the force equilibrium relations can be written as

$$T_z = \frac{RP_0}{2} + T_{\text{ext}}, \quad (6)$$

$$T_c = RP_0, \quad (7)$$

where T_{ext} is the external axial tension acting on the OHC [$T_{\text{ext}} = F/(2\pi R)$]. After the OHC is pressurized, it is assumed that the cell undergoes incompressible deformation, imposing a constraint on subsequent deformations $\varepsilon_z + 2\varepsilon_c = \varepsilon_{\text{vol}}$; where ε_{vol} , a constant, is the strain due to initial pressurization of the cell (see Iwasa, 1993; Iwasa and Adachi 1997; and Deo and Grosh, 2004; for more details). Since ε_z and ε_c are related, we can replace ε_c in our expressions for energy, stress, and charge. For the rest of the paper, the axial strain ε_z is referred to as simply ε and external tension as T instead of T_{ext} . After the substitution we can write the charge and external load as

$$\frac{\partial W(\varepsilon, V)}{\partial V} = -Q, \quad (8)$$

$$\frac{\partial W(\varepsilon, V)}{\partial \varepsilon} = T_z - \frac{T_c}{2} = T. \quad (9)$$

III. CONSISTENT SECOND-ORDER EXPANSION

The free-energy functions, $W(\varepsilon, V)$, typically have a complex form, dependent on exponentials (Spector, 2000) or

Boltzmann functions (Deo and Grosh, 2004; Iwasa, 2001). We are interested in extracting a simpler OHC model from such energy functions, which works near the resting state. Let V_0 , Q_0 , T_0 , and ε_0 denote voltage, charge, tension, and strain, respectively, at the resting state. Let $q = Q - Q_0$, $t = T - T_0$, $v = V - V_0$, and $\varepsilon = \varepsilon - \varepsilon_0$ denote the shift from the values at a resting state. Expanding Eqs. (8) and (9) in Taylor series about their resting state yields

$$q = - \frac{\partial^2 W}{\partial V^2} \Big|_{\varepsilon_0, V_0} v - \frac{\partial^2 W}{\partial V \partial \varepsilon} \Big|_{\varepsilon_0, V_0} \varepsilon - \frac{1}{2} \frac{\partial^3 W}{\partial V^3} \Big|_{\varepsilon_0, V_0} v^2 - \frac{\partial^3 W}{\partial V^2 \partial \varepsilon} \Big|_{\varepsilon_0, V_0} v \varepsilon - \frac{1}{2} \frac{\partial^3 W}{\partial V \partial \varepsilon^2} \Big|_{\varepsilon_0, V_0} \varepsilon^2 + \mathcal{O}(\varepsilon^3, \varepsilon^2 v, \varepsilon v^2, v^3), \quad (10)$$

$$t = \frac{\partial^2 W}{\partial \varepsilon^2} \Big|_{\varepsilon_0, V_0} \varepsilon + \frac{\partial^2 W}{\partial \varepsilon \partial V} \Big|_{\varepsilon_0, V_0} v + \frac{1}{2} \frac{\partial^3 W}{\partial \varepsilon^3} \Big|_{\varepsilon_0, V_0} \varepsilon^2 + \frac{\partial^3 W}{\partial \varepsilon^2 \partial V} \Big|_{\varepsilon_0, V_0} \varepsilon v + \frac{1}{2} \frac{\partial^3 W}{\partial \varepsilon \partial V^2} \Big|_{\varepsilon_0, V_0} v^2 + \mathcal{O}(\varepsilon^3, \varepsilon^2 v, \varepsilon v^2, v^3). \quad (11)$$

All second-order terms are retained and higher-order terms are neglected. The question to be answered is whether these are sufficient or do we need the higher-order terms. The above expressions can be written in terms of more familiar variables,

$$q = Cv + e\varepsilon + \frac{1}{2} C_2 v^2 + C_1 v \varepsilon - \frac{1}{2} k_1 \varepsilon^2, \quad (12)$$

$$t = k\varepsilon - ev + \frac{1}{2} k_2 \varepsilon^2 + k_1 \varepsilon v - \frac{1}{2} C_1 v^2. \quad (13)$$

In the above expressions [Eqs. (12), (13)] the constants multiplying linear terms are $C = -\partial^2 W / \partial V^2 \Big|_{\varepsilon_0, V_0}$, which is a capacitance-like term, $k = \partial^2 W / \partial \varepsilon^2 \Big|_{\varepsilon_0, V_0}$ a stiffness-like term, and $e = -\partial^2 W / \partial V \partial \varepsilon \Big|_{\varepsilon_0, V_0} = -\partial^2 W / \partial \varepsilon \partial V \Big|_{\varepsilon_0, V_0}$ the electro-mechanical coupling term. The constants multiplying the nonlinear terms are $k_1 = \partial^3 W / \partial V \partial \varepsilon^2 \Big|_{\varepsilon_0, V_0} = \partial^3 W / \partial \varepsilon^2 \partial V \Big|_{\varepsilon_0, V_0}$, $C_1 = -\partial^3 W / \partial V^2 \partial \varepsilon \Big|_{\varepsilon_0, V_0} = -\partial^3 W / \partial \varepsilon \partial V^2 \Big|_{\varepsilon_0, V_0}$, $k_2 = \partial^3 W / \partial \varepsilon^3 \Big|_{\varepsilon_0, V_0}$, and $C_2 = -\partial^3 W / \partial V^3 \Big|_{\varepsilon_0, V_0}$. These quantities can be directly derived from the energy function W or from experiments if the experiments are done with the appropriate parameters held constant. For example, the “stiffness” k can be obtained by keeping the voltage constant and measuring change in tension T as strain ε is changed. The slope of the curve at a certain strain will give “ k ” at that strain and voltage. These expansions will have a limited range of validity as the higher-order terms start dominating at large strains and voltages away from resting values. Note, the free-energy function corresponding to the second-order expansions has cubic terms which can give rise to negative energy if strains and voltage deviate too greatly from equilibrium.

IV. SIMPLIFIED EAMM

For the extended area motor model (Deo and Grosh, 2004), the Gibbs free energy of an OHC is

$$G = -\frac{1}{2}s_z^l T_z^2 - \frac{1}{2}s_c^l T_c^2 - T_z T_c s_{zc}^l - \frac{1}{2}C_{\text{lin}} V^2 - n T_z a_z - n T_c a_c - n q V + n k_B \theta \log(P_e) + G_0, \quad (14)$$

where s_z^l , s_c^l , and s_{zc}^l are compliance coefficients of the motor in long state, a_z and a_c are anisotropic area changes for the motor occurring during state transition in the axial and circumferential directions, respectively, n is the motor density, q is the charge transferred per motor during change of state, C_{lin} is the linear capacitance of the motor, P_e is the Boltzmann probability function governing the change of states, k_B is Boltzmann's constant, θ is the temperature, and G_0 is a constant (see Deo and Grosh, 2004). Specifying the transmembrane voltage and internal turgor pressure at the resting state determines the volume constraint for the EAMM. Once the operating conditions for the OHC (i.e., the external force and transmembrane voltage) have been determined, a simplified version of the extended area motor model can be derived using Eqs. (2), (10), and (11). Any perturbations in strain and voltage will then take place about these resting values as the transmembrane voltage and external force change.

Analytical expressions for the various constants ($C, k, e, C_1, k_1, C_2, k_2$) were obtained from the energy expression for the EAMM for simulating the simple model. Since the expressions are rather long, they have not been reproduced here. The following first-order nonlinear model is for an OHC having a resting transmembrane voltage of -55 mV and resting strain of -0.47% . The OHC is $70 \mu\text{m}$ long and $10 \mu\text{m}$ in diameter. The resting state corresponds to an equal distribution of motors in the long and short state (i.e., $P_e = 0.5$). There is no external force, and turgor pressure at the resting state is 200 Pa. The expressions for the perturbed force and charge are

$$q = 2.117 \times 10^{-2} v - 3.145 \times 10^{-3} \epsilon + 2.713 \times 10^{-2} v^2 + 3.652 \times 10^{-2} v \epsilon + 2.087 \times 10^{-2} \epsilon^2, \quad (15)$$

$$t = 7.201 \times 10^{-3} \epsilon + 3.145 \times 10^{-3} v + 2.247 \times 10^{-2} \epsilon^2 - 4.173 \times 10^{-2} \epsilon v - 1.826 \times 10^{-2} v^2. \quad (16)$$

Here q is in Coulombs, v is in Volts, and t is in N m^{-1} . The constants and their units are also listed in Appendix A.

V. RESULTS

A. Stiffness and capacitance

The total OHC stiffness and capacitance are given by

$$K_{\text{OHC}} = \frac{2\pi R}{L} (k + k_1 v + k_2 \epsilon), \quad (17)$$

$$C_{\text{OHC}} = 2\pi R L (C + C_1 \epsilon + C_2 v). \quad (18)$$

The simplified model yields stiffness and capacitance that are linearly dependent on the strain and voltage. Figure 2 shows stiffness and capacitance versus voltage for three different

FIG. 2. Stiffness and capacitance versus voltage for three different strains (thick lines). Parameters for the simplified model [Eqs. (15) and (16)] have been selected to match the Deo and Grosh (2004) model at resting state $V = -55$ mV and strain of -0.47% . Results from the Deo and Grosh (2004) model are superimposed as thin lines of the same line type. Note the close match in stiffness for the selected range of voltage and strain.

strains. The results from the full EAMM (thin lines) are also superimposed for comparison.

The simplified model captures the stiffness nonlinearity with respect to voltage with a relative error of less than 1.5%. The capacitance is not captured as well since the operating point is near the peak of the capacitance–voltage relation. However, the maximum relative error in capacitance ($\approx 3\%$) is similar to the relative error in stiffness over a 15 mV range of voltage away from the resting voltage of -55 mV. Figure 3 shows stiffness and capacitance as strain is varied for three different voltages.

For a small range of voltage and strain the simple model does capture the overall features of the OHC behavior. In the next section we compare dynamic simulations of the model with experiments to check whether the first-order nonlinear terms are sufficient to generate the nonlinearity seen in experiments.

B. Dynamic simulations

Dynamic experiments on OHCs (He and Dallos, 1999; He and Dallos, 2000) indicate strong nonlinearity with respect to voltage and weak (if any) nonlinearity with respect to strain. In the experiments the OHCs were excited using a glass probe with known stiffness at one frequency (f_1) and a

FIG. 3. Stiffness and capacitance versus strain for three different voltages (thick lines). Parameters for the simplified model [Eqs. (15) and (16)] have been selected to match Deo and Grosh (2004) model at resting state $V = -55$ mV and strain of -0.47% . Results from the Deo and Grosh (2004) model are superimposed as thin lines of the same line type. Note the close match in stiffness for the selected range of voltage and strain.

FIG. 4. Frequency spectrum of OHC response. Simultaneous excitation by mechanical and electrical input. The voltage stimulus is at 10 Hz with 40 mV amplitude while the probe signal is at 100 Hz with 400 nm amplitude. Circles represent data from Fig. 3F in He and Dallos (2000). Note the match at sum and difference frequencies (90 and 100 Hz). Probe stiffness used in the model is 4.73 mN/m.

transmembrane voltage signal at another frequency (f_2). For a voltage signal amplitude of 40 mV at 10 Hz and a probe displacement of amplitude 400 nm at 100 Hz the simple model shows dynamic characteristics similar to what are seen in experiments for same conditions (see Fig. 4). The solution procedure is described in Appendix B.

Figure 4 indicates that the second-order expansion possesses sufficient richness to capture experimentally seen behavior. Contributions arising from higher-order terms will be much smaller than contributions from the second-order terms included in this model and can be ignored.

C. Analysis of terms in the model

1. Further simplifications

The simple model includes all possible voltage and strain nonlinearities up to the second order and they contribute equally to the OHC response for voltage and strain signals of similar amplitude. In the dynamic experiments the amplitude of the voltage signal “ v ” was approximately seven times the strain signal given through the probe (0.04 V versus strain of 5.7×10^{-3} for a $70 \mu\text{m}$ long OHC). Therefore both the dynamic simulation and the experiments do not show any significant harmonics of the mechanical signal. Depending on relative amplitudes of voltage and strain signals, a further simplification of the model may be possible by neglecting nonlinear terms corresponding to the weaker signal. Consider the expression for a change in the external tension “ t ,”

$$t = k\epsilon - ev + \frac{1}{2}k_2\epsilon^2 + k_1\epsilon v - \frac{1}{2}C_1v^2. \quad (19)$$

The term that will produce the sum and difference tones is $k_1\epsilon v$; term $k_2\epsilon^2$ will generate harmonics of the mechanical signal while the remaining nonlinear term C_1v^2 will generate harmonics of the voltage signal. Figure 5 shows effect of neglecting these nonlinear terms on the dynamic response of the model for the same excitation as in Fig. 4. Since we have very weak mechanical harmonics for this experimental setup, ignoring the $k_2\epsilon^2$ term does not affect the overall response. Such simplifications of the first-order nonlinear model will

FIG. 5. Frequency spectrum of OHC response for different model settings. The figure shows the effect of neglecting the nonlinear terms in the model. The terms have been removed one at a time, i.e., when $k_1=0$; other constants have their original value.

depend on the range of strains and voltages the cell will be subjected to *in vivo*.

2. Data on strain and voltage *in vivo*

To model *in vivo* OHC activity amplitudes of voltage and strain *in vivo* are needed. We have significant amount of data on strain versus voltage from *in vitro* experiments; for instance Santos-Sacchi (1991, Fig. 2) indicates a change in strain about 0.7% for a 30 mV voltage change in the absence of external forcing. However, *in vitro* data on electromotile strain should not be relied on to get estimates for *in vivo* strain directly, as we do not have any estimates of the forces acting on the OHCs at a resting state *in vivo*. The voltage-dependent stiffness implies that if there is any OHC preloading *in vivo*, a change in the receptor potential will cause the OHC to undergo strain due to the stiffness change. This strain will be in addition to the electromotile strain caused by the voltage change. The effect of stiffness change is discussed in detail by Parthasarathi *et al.* (2003).

Amplitudes of *in vivo* strain can be estimated from vibration measurements of the organ of Corti. Khanna and Hao (1999) report vibration amplitude of around 400 nm for the reticular lamina (RL) at the third row outer hair cell location for a sound level input of around 90 dB in a temporal bone preparation. The amplitude drops linearly to 40 nm for a 70 dB sound pressure level (SPL). The data was for motion at the apical portion of a guinea-pig cochlea. Vibration levels of the basilar membrane (BM) at the apical end have been found to be several hundred times lower than the RL and in phase with RL motion up to the characteristic frequency of the region (Khanna and Hao, 2000). So if we assume the RL motion amplitude to be a good representation of third row OHC amplitude, that would give us a maximum strain of around 0.0057 (for a $70 \mu\text{m}$ OHC) at 90 dB SPL and maximum strain of around 0.00057 at 70 dB. Estimates of the *in vivo* receptor potential are as high as 35 mV for high-intensity sounds (Dallos, 1985) although a more typical value is around 10 mV (see Fig. 6 in Dallos, 1985). The alternating receptor potential saturates at high sound pressure levels as seen in the small difference in receptor potential at 70 dB SPL and 90 dB SPL (Fig. 6 in Dallos, 1985). If we make a conservative estimate that the receptor potential at

FIG. 6. OHC experiment: initially pressurized, stimulated by applied voltage about the resting potential. Mechanical loading is through a micropipet (modeled as a linear spring). Resting internal fluid pressure P_0 and transmembrane voltage V_0 .

high sound levels is 10 mV, then this would give us a voltage to strain amplitude ratio of 1.75 for 90 dB and 17.5 for 70 dB. Further complicating matters, it is the transmembrane voltage (receptor potential minus extracellular potential) that drives the OHC motility. Experimental measurements of these quantities, which are notoriously difficult (Kossl and Russell, 1992) also yield similar, but lower estimates. This data seems to indicate that at low sound levels, voltage non-linearity will overwhelm any mechanical nonlinearity. If this is true then we can make further simplifications by ignoring the second-order term in ϵ in Eq. (13). Note, however, that the ϵ^2 term has to be retained in the expression for q [Eq. (12)] to maintain reciprocity.

3. Effect of external loading on force-driven motility

The constants in the model are evaluated at a given state of transmembrane voltage, external force, and turgor pressure. It is of interest to investigate how these will vary as the conditions change based on the EAMM. The predictions depend on the model chosen. Experiments can then be used to validate if the model predictions are correct. For instance, if an external compressive force is applied on the OHC, the EAMM predicts the stiffness (k) to decrease and the slope (k_1) of the voltage-dependent stiffness to increase. The k_1 term is the one responsible for the sum-difference tones (see Fig. 5). While the stiffness (k) is always positive, the k_1 term crosses over from negative to positive at a certain external load. The resting turgor pressure in the cell determines the external load at which the slope (k_1) of the voltage-dependent stiffness changes sign. An OHC under compression would therefore exhibit lower stiffness and higher force-driven motility while the amplitude of sum-difference tones will depend on the resting turgor pressure in the cell. Experiments by He and Dallos show that the amplitude of the sum and difference tones can increase or decrease with an increase in cell compression (see Fig. 11 in He and Dallos, 2000). The EAMM predicts the absolute value of k_1 (the sum-difference tone generating term) to decrease and then increase with an increase in compression and therefore is consistent with the two plots in He and Dallos (2000). Since we do not know the exact turgor pressure in the cells, more

of such experimental data showing variation of modulation components in response to increasing compression will help confirm if the EAMM shows the correct behavior. According to the EAMM we should not observe a rise in modulation components followed by a fall in response to increased compression. He and Dallos (2000) also claim to observe both an increase and decrease in force-driven motility with increasing compression. This fact is difficult to reconcile with our current understanding of how stiffness of the OHC changes. For a fixed transmembrane voltage, any external compression should drive the cell into either hyperpolarization or depolarization and therefore to have higher stiffness or lower stiffness, respectively. Variability of turgor pressure cannot explain this phenomenon, as the turgor pressure is just another form of loading. Unless some other factors like “ q ,” the charge transferring across the cell wall also depend on the forcing, this issue is as of yet unresolved.

VI. DISCUSSION

The precise way in which the different parts of the organ of Corti interact is still not clear. Are the OHCs pretensioned at the resting state? Data from Mammano and Ashmore (1993) shows large contraction of OHCs in an isolated cochlear turn preparation when current was passed across the partition. Mammano and Ashmore (1993) state that the OHCs are depolarized by the current and therefore they contract. This will be true if the OHCs are under compression at the resting state, since depolarized OHCs will contract and will have lower stiffness causing them to yield more against compressive forces. On the other hand, if the OHCs are under tension then hyperpolarized OHCs will also exhibit contraction provided shortening due to the increased stiffness dominates any lengthening due to hyperpolarization. This point has also been elaborated upon in Parthasarathi *et al.* (2003). Information on how the tectorial membrane (TM) moves is also very important. Khanna *et al.* (1998) show TM motion to be in phase with RL motion for an apical location (low frequency) and TM velocity to be slightly higher than RL velocity. However, to gauge when stereocilia channels are opening and when they are closing we also need information on the relative RL-TM displacement direction. These questions need to be answered to elaborate on the role played by OHCs in amplifying basilar membrane motion.

The experimental data available on OHCs in literature are of limited use for determining the constants in the simple model introduced here. Consider the capacitance experiments for instance. These are usually performed with no external load on the OHC. So if we construct a model with external force and voltage as the independent variables, then such experiments help yield the capacitance and derivative of the capacitance with respect to voltage at a constant voltage and zero external force. To determine the remaining constants the variation of strain with respect to voltage at a constant external force (zero), and the variation of charge and strain with respect to force at a constant voltage are needed. Except for Dong *et al.* (2002), which looked for reciprocity in a linearized OHC model, such experiments have not been attempted.

TABLE I. Parameter values used for the model.

Parameter	Value	Unit
C	2.117×10^{-2}	$\text{C m}^{-2} \text{V}^{-1}$
C_1	3.652×10^{-2}	$\text{C m}^{-2} \text{V}^{-1}$
C_2	5.426×10^{-2}	$\text{C m}^{-2} \text{V}^{-2}$
e	-3.145×10^{-3}	C m^{-2} or $\text{N m}^{-1} \text{V}^{-1}$
k	7.201×10^{-3}	N m^{-1}
k_1	-4.173×10^{-2}	$\text{N m}^{-1} \text{V}^{-1}$
k_2	4.493×10^{-2}	N m^{-1}

VII. CONCLUSION

The simplified model discussed in this paper is based on a more elaborate model given by Deo and Grosh (2004). There are other models in the literature for OHC electromotility besides the area motor model, for instance, the membrane bending model (Raphael *et al.*, 2000), which assumes flexoelectricity as the basis for OHC electromotility. The second-order expansion presented here will work equally well with such energy-based models.

In a global cochlear model, the OHC representation needs to be accurate only over a small range of voltage and strain seen *in vivo*. As such, these simplified models can be used to represent OHC behavior in global cochlear models. The various parameters of the model can be determined directly from experiments on OHCs or from an approximation of more detailed models, as was done in this paper.

The simplified second-order model provides a good match to OHC behavior for small changes in voltage and strain, provided operating voltages are away from the maxima in the capacitance to voltage relation (see Fig. 2). If it is desired to capture higher fluctuations, a fully nonlinear theory may be needed. A simpler alternative would be to include a third-order voltage term in the charge equation [Eq. (12)], which will give a parabolic dependence of the capacitance on voltage (not shown here). Simulations with such a term included in the model demonstrate an excellent match with the EAMM.

If strains are an order of magnitude smaller than voltage fluctuations, then even simpler expressions can be obtained by ignoring second-order terms in strain. The resulting model will have only voltage-dependent stiffness as is predicted by *in vitro* experiments (He and Dallos, 2000).

APPENDIX:

A. Parameter values

Parameters obtained from the extended area motor model (Deo and Grosh, 2004). Values are for no external forcing, a resting potential of -55 mV, and a resting turgor pressure of 200 Pa (corresponding axial strain is 0.47%). (See Table I.)

B. Dynamic simulations

The experimental setup for the dynamic simulations is shown in Fig. 6. The micropipet spring is in series with the outer hair cell (OHC) spring. Therefore the force acting on the OHC is equal to the stiffness of the micropipet multiplied by its deflection. The displacement of the top of the micropi-

pet spring and the OHC transmembrane voltage are specified. Then using Eq. (13) we can solve for the strain ϵ . Figures 4 and 5 show the Fast Fourier Transform (FFT) of the strain response.

Cochlear outer hair cells (OHC) are critically important for the amplification and sharp frequency selectivity of the mammalian ear. The microchamber experiment has been an effective tool to analyze the OHC high-frequency performance. In this study, the OHC electrical stimulation in the microchamber is simulated. The model takes into account the inertial and viscous properties of fluids inside and outside the cell as well as the viscoelastic and piezoelectric properties of the cell composite membrane (wall). The closed ends of the cylindrical cell were considered as oscillatory rigid plates. The final solution was obtained in terms of Fourier series, and it was checked against the available results of the microchamber experiment. The conditions of the interaction between the cell and pipette was analyzed, and it was found that the amount of slip along the contact surface has a significant effect on the cell electromotile response. The cell's length changes were computed as a function of frequency, and their dependence on the viscosities of both fluids and the cell wall was analyzed. The distribution of the viscous losses inside the fluids was also estimated. The proposed approach can help in a better understanding of the high-frequency OHC electromotility under experimental and physiological conditions. © 2005 Acoustical Society of America. I. INTRODUCTION

Cochlear outer hair cells (OHC) are crucial to the frequency discrimination and tuning during the mammalian hearing process (Geisler, 1998; Dallos, 1996; Ruggero, 1992). These cells are located between the underlying basilar and overlying tectorial membranes. It is believed that, via a novel electromotility (Brownell *et al.*, 1985, 2001), OHCs generate active forces that amplify and sharpen passive vibration of the basilar and tectorial membranes. Recently, a motor protein, named prestin, necessary for OHC electromotility and active hearing has been identified (Zheng *et al.*, 2000; Liberman *et al.*, 2002).

OHCs have shown their active properties in the whole acoustic frequency range. *In vitro* electrical stimulation of OHCs has demonstrated an electromotile response up to tens of kHz (Dallos and Evans, 1995; Frank *et al.*, 1999). It is probably even more important that the OHC is capable of generating a constant active force up to about 100 kHz. The transfer of an electric charge across the cell membrane is an intrinsic part of the mechanism of electromotility (Huang and Santos-Sacchi, 1994; Gale and Ashmore, 1997a). Gale and Ashmore (1997b) have shown that the cell has this ability at frequencies up to 40 kHz, and the amount of the translocated charge stays constant up to 20 kHz.

Despite important evidence for the high-frequency effectiveness of OHC, the mechanism of cells functioning under such conditions is not fully understood. One question is associated with the magnitude of the receptor potential that is supposed to drive the cell electromotile response. High-frequency membrane capacitive filtering of the receptor potential was discussed in the literature (Santo-Sacchi, 1992; Housley and Ashmore, 1992). A number of studies have addressed this problem by considering either a different mechanism of delivering the transmembrane potential (Dallos and Evans, 1995) or finer properties of the cell membrane (Santos-Sacchi *et al.*, 1998; Spector *et al.*, 2003, 2004; Weitzel *et al.*, 2003; Ospeck *et al.*, 2003).

Another key component of the high-frequency mechanics of the OHC is the interaction between the vibrating cell wall and the fluids inside and outside the cell. The intrinsic losses associated with the viscosity of the two fluids limit the high-frequency response of the cell. In a modeling study, Tolomeo and Steele (1998) have computed high-frequency cell's length changes in response to mechanical and electrical stimulations. The authors analyzed the effects of the extracellular and intracellular fluid viscosities considering them both equal to the viscosity of water. In addition to the mentioned factors, the viscosity of the cell wall also contributes to the overall viscous losses and can reduce high-frequency electromotility. This can be especially important for the OHC that has its cytoskeleton, the most viscous component, inside

^{a)}Electronic mail: zliao@bme.jhu.edu

the composite wall. Ratnanather *et al.* (1996) considered a viscoelastic cell wall and computed the high-frequency responses to a mechanical stimulation of the cell. While the estimation of the OHC's wall effective viscosity is still an open problem, there have been experimental studies that contribute to its solution. Ehrenstein and Iwasa (1996) have measured a time constant of the relaxation of tension on the OHC wall. Li *et al.* (2002), by pulling tethers from the membrane, have estimated the apparent membrane viscosity that included the viscous losses in the bilayer as well as friction of the movement of the membrane along the cell cytoskeleton.

The voltage-clamp experiment provides important information on the OHC's electromotile response and nonlinear capacitance. However, the resistive properties of the pipette clamping the membrane potential preclude the measurements under high-frequency conditions. This effect was overcome in the microchamber experiment where an electric field is applied across the cell membrane. Dallos *et al.* (1993), Evans *et al.* (1991), and Hallworth *et al.* (1993) have developed the microchamber technique and proposed a model of the OHC behavior under the condition of this experiment. Later, Dallos and Evans (1995) used this method to observe the high-frequency electromotile responses of OHC. By using the microchamber experiment, Frank *et al.* (1999) not only measured high-frequency electromotility but also estimated the high-frequency active force generated by the cell. Also, He and Dallos (2000) used the microchamber technique to measure the voltage-dependent stiffness of OHC.

The active and passive properties of the cell wall are critically important for the modeling of the OHC mechanics. The effective passive properties of the composite OHC wall can be described by a linear 2D viscoelastic model. The elastic part of the model is represented by the orthotropic elastic moduli (Tolomeo and Steele, 1995; Spector *et al.*, 1998; Iwasa and Adachi, 1997; Spector and Jean, 2003). Anisotropy of the cell wall is associated with the composition of the cell cytoskeleton made of two proteins with different properties. The viscous part of the model is described in terms of the wall viscosity (Ratnanather *et al.*, 1996). For small changes in the transmembrane potential, the active properties of the cell wall fit a linear piezoelectric model (Tolomeo and Steele, 1995; Spector, 2001; Spector and Jean, 2004). The OHC changes its dimensions in response to electrical stimulation, and conversely electric current can be generated across the cell membrane in response to a deformation of the cell. These properties constitute a piezoelectric-type behavior of the material.

In this study, we model the high-frequency electrical stimulation of OHC in the microchamber. In our model, the cell is considered as a circular cylinder with viscoelastic and piezoelectric lateral wall and closed ends. The solution to the problem is given in terms of Fourier series, similar to that proposed by Tolomeo and Steele (1998). We applied our model to the analysis of the data of the microchamber experiment (Evans *et al.*, 1991; Dallos *et al.*, 1993; Dallos and Evans, 1995; Frank *et al.*, 1999). We have shown that the parameters of the experiment, such as the amount of slip at the area of interaction between the cell and pipette and the

set-point potential, have significant effects on the cell response. This finding helps reconcile different versions of the microchamber experiment. We analyze the effects of the viscosities of the wall and of the two surrounding fluids. Finally, we compute the viscous losses inside the external and internal fluids as functions of the radial distance from the cell wall.

II. MODEL

A. Cell wall

We start with the constitutive relations for the cell wall; then, we consider the extracellular and intracellular fluids; after that we analyze the effect of the ends of the cell; and, finally, a solution to the problem is presented in terms of Fourier series. For the cell wall, we use a linear integrative model that describes both the passive and active properties of the OHC. The total resultant forces in the cell wall consist of three parts: orthotropic elastic, viscous, and piezoelectric. The first two of them are associated with the passive properties of the wall, and the third part is determined by its active properties. The equation for the resultants takes the form

$$\begin{bmatrix} N_x \\ N_\theta \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} \\ C_{12} & C_{22} \end{bmatrix} \begin{bmatrix} \frac{\partial u_x}{\partial x} \\ \frac{u_r}{r_c} \end{bmatrix} + \begin{bmatrix} \eta & -\eta \\ -\eta & \eta \end{bmatrix} \begin{bmatrix} \frac{\partial^2 u_x}{\partial x \partial t} \\ \frac{\partial u_r}{r_c \partial t} \end{bmatrix} + V \begin{bmatrix} e_x \\ e_\theta \end{bmatrix}, \quad (1)$$

where N_x and N_θ are the components of the stress resultant (i.e., the product of the stress and cell wall thickness) generated in the cell wall; the subscripts r , x , and θ indicate the radial, axial, and circumferential directions, respectively; C 's are the stiffness moduli; u_x and u_θ are two components of the displacement; η is the cell wall viscosity; t is the time; V is the transmembrane potential change; and e_x and e_θ are two coefficients that determine the production of the local active stress resultant per unit transmembrane potential (Spector *et al.*, 1998, 1999; Spector and Jean, 2003) (Fig. 1). The stress resultants are related to the cell wall tractions by the following equilibrium equations:

$$N_\theta = \sigma_r r_c, \quad (2)$$

$$N_x = - \int_a^x \sigma_{rx} d\bar{x} + N_{\text{end}}, \quad (3)$$

where σ is the traction acting on the cell wall surface, the subscripts r and rx indicate the radial and longitudinal directions, and N_{end} is the force produced by the end cap oscillating in the viscous fluid (see the discussion of this term below). The resultant cell wall tractions are determined from the extracellular and intracellular fluids, and other external sources

$$\vec{\sigma}_{\text{wall}} = \vec{\sigma}_{\text{sti}} + \vec{\sigma}_{\text{ext}} - \vec{\sigma}_{\text{int}}, \quad (4)$$

where $\vec{\sigma}_{\text{wall}}$ is the resultant cell wall traction in the vector form including two components σ_r and σ_{rx} ; $\vec{\sigma}_{\text{ext}}$ and $\vec{\sigma}_{\text{int}}$ are tractions on the cell wall surface exerted by the extracel-

FIG. 1. OHC modeling in microchamber experiment. (a) Microchamber setup. U_{applied} is applied voltage. The transmembrane voltage change in the excluded and included parts are $U_{\text{ex}} = (1-q)U_{\text{applied}}$ and $U_{\text{in}} = -qU_{\text{applied}}$, respectively. Here, q is the exclusion ratio (excluded cell length divided by total cell length). (b) OHC is modeled as a thin-walled circular cylinder with closed ends. The cylindrical wall is surrounded by the viscous intracellular and extracellular fluids. (c) $\vec{\sigma}_{\text{ext}}$ and $\vec{\sigma}_{\text{int}}$ represent the tractions on the cell wall surface due to the extracellular and intracellular fluids, respectively. $\vec{\sigma}_{\text{sti}}$ indicates the applied mechanical stimulation on the cell wall surface from the external resource other than the extracellular and intracellular fluids. $\vec{\sigma}_{\text{ext}}$, $\vec{\sigma}_{\text{int}}$, and $\vec{\sigma}_{\text{sti}}$ are in the vector form, each with two components in the longitudinal and radial directions. These tractions and applied mechanical stimulation mentioned above are balanced by the stress resultant (i.e., the product of the stress and cell wall thickness) generated in the cell wall (N_x, N_θ).

lular and intracellular fluids, respectively; $\vec{\sigma}_{\text{sti}}$ is the applied mechanical stimulation on the cell wall surface from external sources other than extracellular and intracellular fluids. We include the term $\vec{\sigma}_{\text{sti}}$ to compare our results with those of

Tolomeo and Steele (1998), who considered a mechanical perturbation of the cell.

The force and displacement can be expressed as Fourier series defined in the cell domain. For a loading symmetric with respect to the cell center ($x=0$), only odd harmonics is needed, while an antisymmetric loading (such as that in the microchamber experiment) requires only even harmonics (Tolomeo, 1995; Tolomeo and Steele, 1998). Below, we present the equations corresponding to the antisymmetric case, and those for the symmetric case can be obtained by replacing the $\cos(\)$ functions with the $\sin(\)$ functions, and vice versa

$$u_x = \sum_{m=\text{even}}^{m \text{ max}} u_{mx} \cos(\beta_m x) e^{i\omega t},$$

$$u_r = \sum_{m=\text{even}}^{m \text{ max}} u_{mr} \sin(\beta_m x) e^{i\omega t}, \quad (5)$$

$$\sigma_{rx} = \sum_{m=\text{even}}^{m \text{ max}} \sigma_{mrx} \cos(\beta_m x) e^{i\omega t},$$

$$\sigma_r = \sum_{m=\text{even}}^{m \text{ max}} \sigma_{mr} \sin(\beta_m x) e^{i\omega t}, \quad (6)$$

$$Ve_x = \sum_{m=\text{even}}^{m \text{ max}} Q_m \sin(\beta_m x) e^{i\omega t},$$

$$Ve_\theta = \sum_{m=\text{even}}^{m \text{ max}} P_m \sin(\beta_m x) e^{i\omega t}, \quad (7)$$

$$N_{\text{end}} = \sum_{m=\text{even}}^{m \text{ max}} S_m \sin(\beta_m x) e^{i\omega t}, \quad (8)$$

where $\beta_m = m\pi/L$, $Q_m = Ve_x g_m$, $P_m = Ve_\theta g_m$, $S_m = N_{\text{end}} g_m$, and $g_m = -\{2[(-1)^{m/2} - 1]\}/(a\beta_m)$.

Substituting Eqs. (5)–(8) into Eqs. (2)–(3) and Eq. (1), we obtain the m th harmonic equation

$$\begin{bmatrix} \sigma_{mrx} \\ \sigma_{mr} \end{bmatrix} = \begin{bmatrix} (C_{11} + i\omega\eta)\beta_m^2 & -(C_{12} - i\omega\eta)\frac{\beta_m}{r_c} \\ -(C_{12} - i\omega\eta)\frac{\beta_m}{r_c} & (C_{22} + i\omega\eta)\frac{1}{r_c^2} \end{bmatrix} \begin{bmatrix} u_{mx} \\ u_{mr} \end{bmatrix} + \begin{bmatrix} -Q_m\beta_m \\ P_m/r_c \end{bmatrix} + \begin{bmatrix} S_m\beta_m \\ 0 \end{bmatrix}. \quad (9)$$

The above equation can be written in the matrix form

$$\vec{\sigma}_{m,\text{wall}} = \mathbf{k}_{m,\text{wall}} \vec{\mathbf{u}}_m + \vec{\sigma}_{m,\text{piez}} + \vec{\sigma}_{m,\text{end}}. \quad (10)$$

Finally, by combining all harmonics together, we obtain

$$\vec{\sigma}_{\text{wall}} = \mathbf{k}_{\text{wall}} \vec{\mathbf{u}}_{\text{wall}} + \vec{\sigma}_{\text{piez}} + \vec{\sigma}_{\text{end}}. \quad (11)$$

B. Intracellular and extracellular fluids

Fourier series technique is applied to solve linearized Navier–Stokes equations for the intracellular and extracellular fluids. In this method, the fluid velocity is at first decom-

posed into irrotational and rotational components, which are then expressed by the method of separation of variables using Bessel functions. The coefficients of Fourier series in the fluid harmonics are converted into the coefficients in the cell wall harmonics based on the no-slip boundary condition along the fluid–cell interface ($\vec{\mathbf{u}}_{\text{wall}} = \vec{\mathbf{u}}_{\text{fluid}}$). As a result of these derivations, the relationship between the fluid stress jump across cell wall ($\vec{\sigma}_{\text{ext}} - \vec{\sigma}_{\text{int}}$) and the cell deformation can be expressed by the following equation (Tolomeo, 1995; Tolomeo and Steele, 1998):

$$\vec{\sigma}_{\text{ext}} - \vec{\sigma}_{\text{int}} = -\mathbf{k}_{\text{fluid}} \vec{\mathbf{u}}_{\text{wall}}, \quad (12)$$

where $\mathbf{k}_{\text{fluid}}$ is the fluid stiffness matrix using cell wall harmonics.

C. Effect of closed ends

As OHC changes its length periodically, the end cap is subjected to a drag force produced by the viscous intracellular and extracellular fluids. If the end cap is assumed to be a rigid circular plate, the whole drag force will be transmitted to the cell wall. Zhang and Stone (1998) studied oscillatory motions of a circular disk in a viscous flow and gave a high-frequency asymptotic expression for the corresponding drag force

$$F_{\text{end}} = -16 \left[\frac{i\lambda^2}{6} + (1.32e^{i0.27\pi\lambda}) \right] \mu r_c(i\omega) u_{\text{end}} e^{i\omega t}, \quad (13)$$

where $\lambda^2 = \rho \omega r_c^2 / \mu$, μ is the fluid dynamic viscosity, u_{end} is the disk displacement, ω is the oscillatory frequency. We utilize this relationship and express the end force in terms of the end resultant N_{end}

$$N_{\text{end}} = \frac{F_{\text{end}}}{2\pi r_c} = \frac{k_{\text{end}}}{2\pi r_c} u_{\text{end}}, \quad (14)$$

where $k_{\text{end}} = -16[(i\lambda^2/6) + (1.32e^{i0.27\pi\lambda})] \mu r_c(i\omega) e^{i\omega t}$.

D. Final form

Substitution of Eqs. (11) and (12) into Eq. (4) yields

$$(\mathbf{k}_{\text{wall}} + \mathbf{k}_{\text{fluid}}) \vec{\mathbf{u}}_{\text{wall}} = \vec{\boldsymbol{\sigma}}_{\text{sti}} - \vec{\boldsymbol{\sigma}}_{\text{piez}} - \vec{\boldsymbol{\sigma}}_{\text{end}}. \quad (15)$$

Note that

$$\vec{\boldsymbol{\sigma}}_{\text{end}} = \frac{k_{\text{end}}}{2\pi r_c} \begin{pmatrix} g_2\beta_2 \\ 0 \\ g_4\beta_4 \\ 0 \\ g_6\beta_6 \\ 0 \\ \vdots \end{pmatrix} u_{\text{end}} = \frac{k_{\text{end}}}{2\pi r_c} \begin{pmatrix} g_2\beta_2 \\ 0 \\ g_4\beta_4 \\ 0 \\ g_6\beta_6 \\ 0 \\ \vdots \end{pmatrix} (\cos(\beta_2 a) \ 0 \ \cos(\beta_4 a) \ 0 \ \cos(\beta_6 a) \ 0 \ \cdots) \begin{pmatrix} u_{2x} \\ u_{2r} \\ u_{4x} \\ u_{4r} \\ u_{6x} \\ u_{6r} \\ \vdots \end{pmatrix} = \mathbf{k}_{\text{end}} \vec{\mathbf{u}}_{\text{wall}}. \quad (16)$$

With the above equation considered, Eq. (15) becomes

$$\vec{\mathbf{u}}_{\text{wall}} = [\mathbf{k}_{\text{wall}} + \mathbf{k}_{\text{fluid}} + \mathbf{k}_{\text{end}}]^{-1} (\vec{\boldsymbol{\sigma}}_{\text{sti}} - \vec{\boldsymbol{\sigma}}_{\text{piez}}). \quad (17)$$

Here, $\vec{\mathbf{u}}_{\text{wall}}$, $\vec{\boldsymbol{\sigma}}_{\text{sti}}$, and $\vec{\boldsymbol{\sigma}}_{\text{piez}}$ are, respectively, the vectors of the Fourier coefficients of the cell wall displacement, the traction acting on the cell wall surface due to the applied mechanical stimulation (other than those associated with the extracellular and intracellular fluids), and the stress due to the electrical stimulation of the cell. Also, \mathbf{k}_{wall} , $\mathbf{k}_{\text{fluid}}$, and \mathbf{k}_{end} are the matrices that determine the stiffness associated with the cell wall, fluids, and closed end, respectively. Following Tolomeo and Steele (1998), we use 10 harmonics in the cell wall domain and 20 in the fluid domain.

The general procedure of obtaining the cell displacement is described as follows: at first, the applied mechanical or electrical stimulation is expressed in terms of Fourier series; then, this coefficient vector is substituted into Eq. (17) to calculate the vector consisting of coefficients of Fourier series for the displacement; and finally, the cell displacement is calculated from its Fourier series coefficients.

III. RESULTS

A. Parameters used

The parameters of our model include the cell wall orthotropic moduli, the coefficients e_x and e_θ that determine the cell active properties, and the viscosities of the fluids and the cell wall. Spector *et al.* (1998) have derived the relationships between the elastic moduli of the cell wall and the axial stiffness of the OHC, and Spector and Jean (2003) have shown that the results obtained on the basis of different sets

of experiments (Iwasa and Adachi, 1997; Spector *et al.*, 1998) converge if the cell stiffness is about 0.1 N/m. Such cell stiffness is consistent with the latest measurements (Hallworth, 1997). This results in the following estimates of the elastic moduli that we use in our modeling: $C_{11} = 0.096$ N/m, $C_{12} = 0.16$ N/m, $C_{22} = 0.3$ N/m. The coefficients e_x and e_θ are determined by both the elastic moduli (Tolomeo and Steele, 1995; Spector *et al.*, 1999) and the active strains extracted from Dallos *et al.* (1993). The resulting coefficients are equal to $e_x = 0.0029$ N/Vm, $e_\theta = 0.0018$ N/Vm. The viscous properties of the extracellular fluid are similar to those of water, but the viscosity of the intracellular fluid is probably different (higher) because of the presence of various proteins (e.g., G-actin). Fung (1993) mentioned the internal viscosity in some cells being 5–6 times greater than that of water. Luby-Phelps (2000) reported a range of 1×10^{-3} – 10×10^{-3} Ns/m² for cytoplasmic viscosity. While the OHC intracellular viscosity has not yet been measured, we assume that the OHC cytoplasmic viscosity is within a range 1×10^{-3} – 10×10^{-3} Ns/m². The viscosity of the OHC wall is another parameter that has not been measured experimentally. Assuming that the cytoskeleton is the most viscous component of the composite wall, and also that the longitudinally directed spectrin molecules are mainly responsible for the viscous losses in the vibrating cell, we chose the cell wall viscosity on the order of magnitude of 1.0×10^{-7} Ns/m (see further discussion of this parameter below); note that this parameter is expressed as cell surface viscosity and thus has a different dimension than the cytoplasmic viscosity.

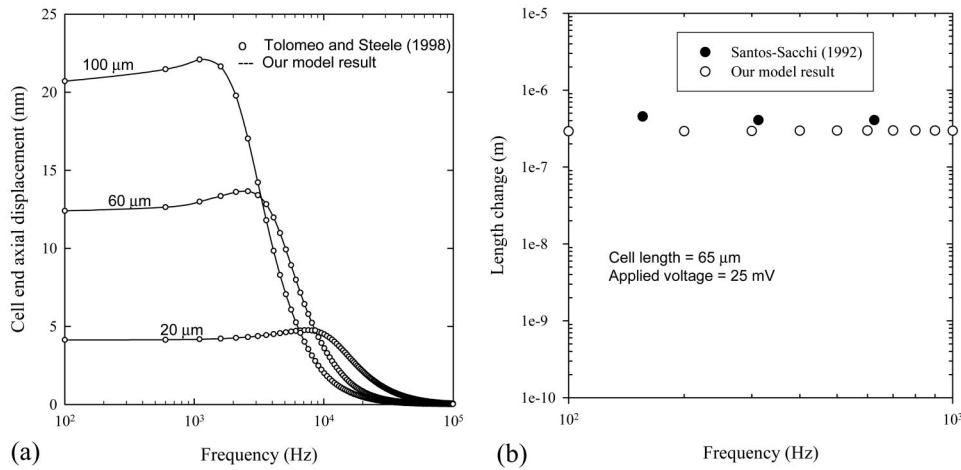

FIG. 2. Validation of our model. (a) Tolomeo and Steele's model (1998) is a specific case that can be achieved by our model through nullifying the effect of the cell wall viscosity and closed end. For the purpose of verifying our code, an example from Tolomeo and Steele's paper (1998) is used to compare with our model results. Our model reproduces Tolomeo and Steele's results. Cell lengths are 20, 60, and 100 μm , and 1-Pa radial stress in the form of first harmonic is applied to the cell wall. (b) Comparison with Santos-Sacchi's experiment (1992). They are in good agreement in the low frequency (less than 1 kHz).

B. Validation of the model

The first validation case is the comparison of the results of our model with Tolomeo and Steele's (1998), who considered OHC as a cylinder with open ends and a purely elastic wall. Thus, we let $\mathbf{k}_{\text{end}}=0$ and $\eta=0$ in Eq. (17) and use the same elastic moduli as Tolomeo and Steele (1998). The externally applied mechanical stimulation is prescribed at 1-Pa radial pressure (stress) in the form of the first harmonic. The loading is symmetric with respect to the cell center ($x=0$). As shown in Fig. 2(a), our model reproduces the results of Tolomeo and Steele (1998).

We use the results of the voltage-clamp experiment (Santos-Sacchi, 1992) as a second validation case. To compare our results with those of Santos-Sacchi (1992), we used the version of the proposed model that is based on no-slip condition along the cell/microchamber interface (see further discussion below). Under this condition, each excluded or included part of the cell will be under conditions equivalent to those in the voltage-clamp experiment if the cell lengths and the transmembrane voltages are the same. In the comparison to Santos-Sacchi's (1992) experiment, we use the elastic moduli and ranges of the fluid and cell wall viscosities discussed in the previous section. However, the viscosity is probably not important in this case because the experimental frequencies are limited to about 1 kHz. The results of the comparison are presented in Fig. 2(b), showing that our predictions are in good agreement with the experimental data in the low frequency (less than 1 kHz). In the high frequency, Santos-Sacchi's experimental data are complicated by the limitation of his instrumentation.

C. Modeling microchamber experiment

In the microchamber experiment, the cell is held by the micropipette along a part of its lateral wall. Below, we show that the amount of slip along the cell/micropipette interface is a significant parameter of the microchamber experiment, and the differences in the interface slip conditions can explain discrepancies in different versions of this experiment. To analyze the effect of the interface slip, we consider two extreme cases: no-slip and full-slip (no-friction) conditions. It is expected that the results of the general case with some

slip and friction will fall within the range between these two extreme cases. For low frequencies, Fig. 3(a) shows that the no-slip condition results in an electromotile response two times greater than that corresponding to the full-slip condition, but this difference reduces at high frequencies. Also, there is a difference in the phase shifts corresponding to these two conditions, especially at high frequencies [Fig. 3(b)]. The axial displacement profiles along the cell are provided in Fig. 4. They show that the zero-displacement point is located at the center of the whole cell length for the no-slip condition and at the center of the excluded/included part of the cell for the full-slip condition, thus causing different effective lengths and electromotile responses in these two cases. Frank *et al.* (1999) obtained smaller cell length changes compared to those by Dallos and Evans (1995), and the reason for that may come from the fact that the set point in Frank's *et al.* experiment (1999) is not at the steepest part of OHC electromechanical transduction curve. Figure 5 shows that indeed by shifting set-point potential to more hyperpolarization our model results can be made closer to those in Frank's *et al.* experiment (1999) (see also the discussion below).

We assume that the ratio of the values of $e_x(e_\theta)$ estimated at two points is equal to that of the corresponding slopes of the electromechanical transduction curve. As a result, it is found that the set-point potential in Frank's experiment may be a -100 mV shift from the normal resting potential or more (Fig. 5).

In Fig. 6, we show the effect of closed ends of the cell on the magnitude and phase of the cell displacement. Although the difference in the magnitude between the closed and open ends is small, the difference in phase is relatively more significant, especially at high frequencies. Figure 7 indicates that an increase in the cell wall viscosity removes the peak in the cell displacement and reduces the corner frequency (i.e., the frequency at which the amplitude of displacement starts to decrease). It is shown in Fig. 8 that an increase in the intracellular fluid viscosity also reduces the corner frequency.

The fluid viscous damping is important for the OHC high-frequency performance. The dissipative energy Φ per volume per time is defined by the following equation (Currie, 1974):

FIG. 3. Modeling microchamber experiment under the full-slip and no-slip conditions (a) amplitude (b) phase. The cell is half included and half excluded.

$$\Phi = 2\mu \left[\left(\frac{\partial v_r}{\partial r} \right)^2 + \left(\frac{v_r}{r} \right)^2 + \left(\frac{\partial v_x}{\partial x} \right)^2 \right] + \mu \left(\frac{\partial v_x}{\partial r} + \frac{\partial v_r}{\partial x} \right)^2, \quad (18)$$

where μ is dynamic viscosity of the fluid, and v_r and v_x are radial and axial velocities, respectively. Figure 9 displays the distribution of energy loss along the radial direction under different frequencies 5, 10, and 50 kHz. The energy loss profiles behave like a classic Stokes boundary layer near an oscillating plate (Lu, 1977), which decrease exponentially away from the cell wall.

Figure 10 shows the results for different exclusion ratio (q) in the microchamber setup. Here, $q = 0.5$ yields the maximum displacement due to the maximum production of excluded cell length and membrane potential at that cell part.

FIG. 4. The axial displacement profiles along the cell. The effective length, which determines cell end movement, is different in voltage-clamp and microchamber (full-slip/no-slip) setup.

IV. DISCUSSION

The amount of slip along the cell/micropipette interface has not been reported in earlier papers (Dallos *et al.*, 1993; Dallos and Evans, 1995; Frank *et al.*, 1999). However, recently, He and Dallos (2000) suggested that the interface slip should be small. It is still important to investigate the sensitivity of the cell electromotile response to the boundary condition along the cell–micropipette interface. Figure 3 shows that the length change under the no-slip condition is larger than that corresponding to the full-slip condition. To explore the underlying mechanism, the distribution of the axial dis-

FIG. 5. Estimation of set-point in Frank's *et al.* (1999) experiment. The electromechanical transduction function curve comes from Dallos *et al.* (1993). Two points are selected to calculate electromechanical responses.

FIG. 6. Closed-end and open-end cases (a) amplitude (b) phase. The difference in the amplitude is small, but the difference in the phase shift reaches around 15 deg at high frequency.

placements along the cell length is given in Fig. 4. Under the no-slip condition, the holding point with the zero displacement is at the cell center, between the excluded and included parts. In this case, the effective length is equal to a half of a cell length. Under the full-slip condition, due to the cell sliding at the interface, the zero-displacement point moves to the center of the excluded–included part of the cell. In contrast to the case of the no-slip condition, the effective length reduces to one-quarter of a cell length, resulting in smaller cell motility, which is half of that corresponding to the no-slip condition. Figure 3 also shows how the corner frequency is affected by the boundary condition with the greater value corresponding to the full-slip condition. In addition, Fig. 3 shows the phase shift versus frequency for two types of

FIG. 7. Effect of the cell wall viscosity (η) on cell electromotility.

boundary conditions. The low-frequency shift is close to 180 deg, which corresponds to a contraction of the cell in response to its depolarization.

Evans *et al.* (1991) and Dallos and Evans (1993) reported electromotility range 0.92–4.74 nm/mV for the cells of 55–72 μm in length when the cell is half-included in the microchamber. These experimental results are in good agreement with our model predictions (1.3–2.7 nm/mV) for the cell length 60 μm . Evans *et al.* (1991) acknowledged that the OHC electromotility may vary significantly (0.92–4.74 nm/mV) even for very similar cells (55–72 μm), and they pointed out potential reasons for that, including individual cell’s variability and possible damage due to isolation. Another cause for this effect, suggested by our model, is the

FIG. 8. Effect of the intracellular fluid viscosity on cell electromotility.

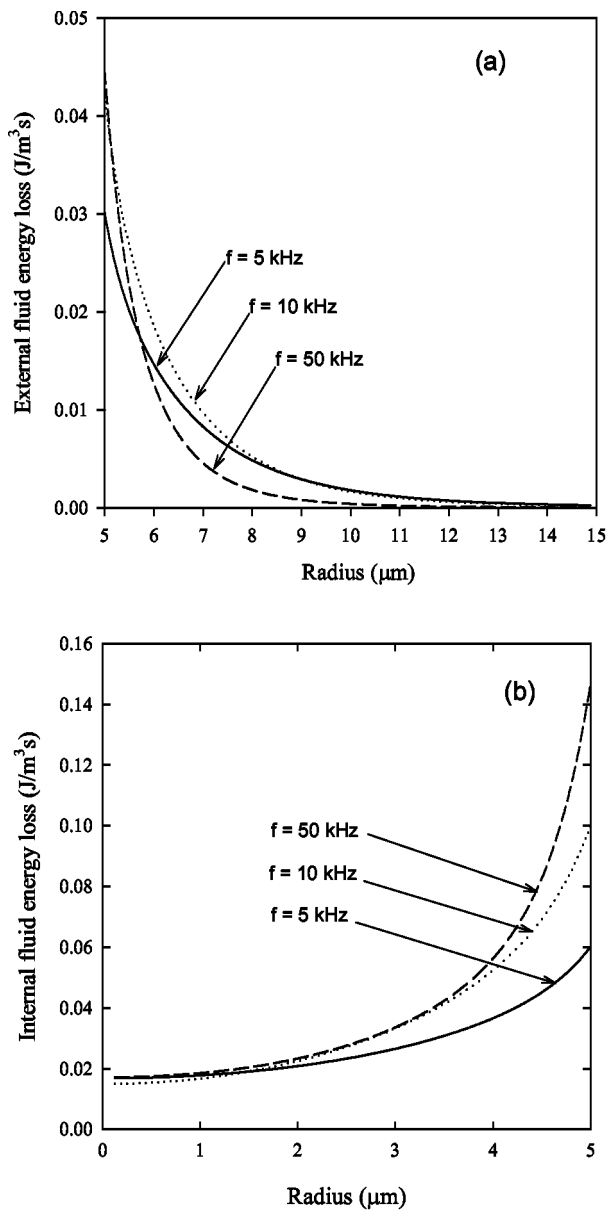

FIG. 9. Distributions of the volume density of the energy loss along radial direction in the (a) external fluid and (b) internal fluid. The axial position is $15 \mu\text{m}$ away from cell center. The frequency is chosen at 5, 10, and 50 kHz. The energy loss in the external fluid decreases exponentially away from the cell wall, indicating a boundary layer effect.

holding condition at the cell–pipette interface. The holding could be loose and the cell could move in and out of the chamber, resulting in a reduction of the electromotile response. Our model predicts that this reduction can reach up to 50%.

In the experiment of Frank *et al.* (1999), the observed cell’s end displacement amplitude (parameter $x_{[\text{nm}]}$ in their paper) is 0.25 nm/mV and the lengths of the cell and its excluded part are 51 and $24 \mu\text{m}$, respectively. The prediction of our model for the cell of a comparable size (the lengths of the cell and its excluded part are 51 and $25.5 \mu\text{m}$, respectively) is in the range of 1.14 – 2.28 nm/mV . These values correspond to the resting potential of -70 mV , and the lower and upper limits come from the full- and no-slip conditions, respectively. Frank *et al.* (1999) noted that their value is

much smaller than that in other experiments (Dallos and Evans, 1995) and pointed out that perhaps the set point in their experiments was not located at the steepest part of the OHC electromechanical transfer function curve. In order to estimate the effect of the set point, we recalculated our predictions assuming more negative (farther from the steepest point of the electromotile response) resting potentials. By assuming the coefficient e_x or e_θ is proportional to the slope of the electromechanical transduction curve, we found that, if the set-point potential shifts 100 mV toward higher polarization, the predicted cell displacement amplitude reduces to 0.25 – 0.5 nm/mV depending on the chosen boundary condition at the cell–pipette interface. Therefore, the results of our modeling are consistent with the available data from the microchamber experiment (Evans *et al.*, 1991, Dallos and Evans, 1995, Frank *et al.*, 1999), and the measurements of different groups can be reconciled by taking into account the set point of the electric potential and the boundary conditions at the cell–pipette interface.

For the cell of $60 \mu\text{m}$ in length, the estimated corner frequency is around 1 – 2 kHz where the lower and upper limits correspond to the no- and full-slip conditions, respectively. For cells of comparable lengths, the corner frequency in Frank’s *et al.* (1999) experiment is about 20 – 30 kHz . Frank *et al.* (1999) have defined $f_{3 \text{ dB}}$ as the frequency at which the amplitude drops 3 dB (50%) from its low-frequency value. Our estimate of $f_{3 \text{ dB}}$ is in the range 6 – 10 kHz depending on the boundary condition. Qualitatively, the computed electromotile response as a function of frequency is similar to that observed by Frank *et al.* (1999). Dallos and Evans (1995) have reported the outer hair cell electromotile response as a two-plateau function of the frequency. Our results do not show the second (high-frequency) plateau of Dallos and Evans’s (1995) experiment. The differences between the results of these two versions of the microchamber experiment could be explained by differences in experimental setups, including the cell’s slip conditions, cell stiffness, etc., but this issue has to be investigated further.

Figure 6 indicates that the effect of the closed ends on the displacement amplitude is small, but it becomes more significant for the phase shift. The difference between two phase shifts increases with frequency and it reaches around 10 deg at 10 kHz and 15 deg at 100 kHz . The results in Fig. 6 correspond to the no-slip conditions, but the effect for the full-slip condition (not shown) is similar.

Our analysis of the viscous effects (Figs. 7 and 8) shows that they result in faster decays in the electromotile responses of the cell and smaller values of the corner frequency. The viscosities of the fluids and the cell wall decrease peaks in the amplitude near the corner frequency, and for realistic values of the parameters, no peaks were found. This is consistent with the results of the microchamber experiment where no tuning was observed in the electromotile response of OHC. Figure 7 demonstrates the effect of the wall viscosity on the peak in the cellular response: increase in the wall viscosity results in the complete elimination of the peak in the cell displacement. Tolomeo (1995) has shown a similar effect of the viscosity of the intracellular fluid. We consider the effect of this viscosity in Fig. 8. In our case, its effect is

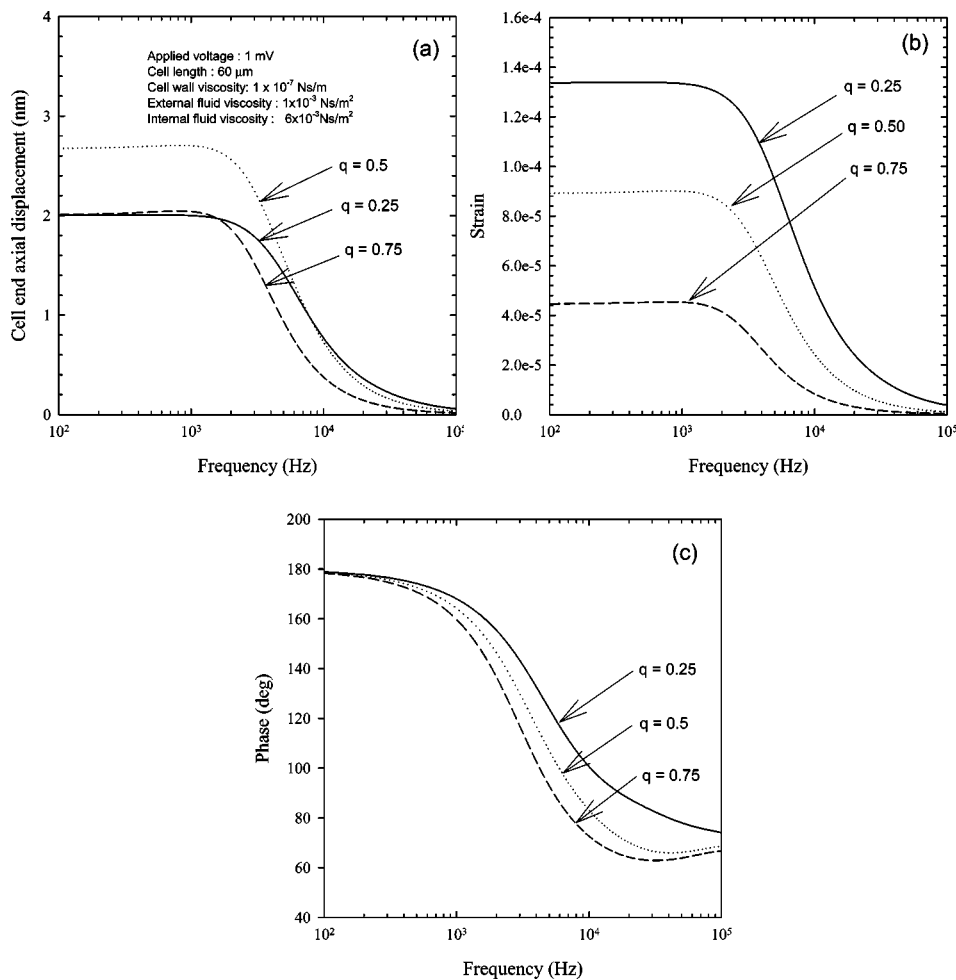

FIG. 10. Effect of exclusion ratio (q) in the microchamber setup (a) amplitude, (b) strain (cell end displacement divided by the length of the excluded part), and (c) phase shift. No-slip condition is considered.

smaller than that in Tolomeo's (1995) study because of greater values of additional viscosity of the cell wall.

We chose the viscosity of the external fluid equal to that of water, and we considered a range of the viscosities of the internal fluid greater than the water viscosity. The cell wall is a composite whose main components are the subsurface cisternae, cortical lattice (cytoskeleton), and the plasma membrane. There is a layer of the extracisternal fluid between the cytoskeleton and the plasma membrane. The bulk viscosities of the subsurface cisternae and the plasma membrane are probably close to that of the lipid bilayer, and the viscosity of the extracisternal fluid is probably equal to that of the intracellular fluid. As in the red blood cell that also has a composite membrane, the most viscous component of the cell wall is probably its cytoskeleton. We assumed that the cytoskeletal spectrin molecules oriented approximately parallel to the cell axis determine the viscous losses associated with the longitudinal vibration of the cell in the microchamber. The viscosity of the spectrin network in red blood cell has been estimated (Evans and Skalak, 1980). The topology of the spectrin networks in these two cells (OHC and red blood cell) is different, but the distances between two neighboring spectrin molecules are close to each other. On the basis of these arguments, we chose the viscosity of the OHC wall close to that of the red blood cell and its cytoskeleton.

The viscous loss is the major contributor to the electromotility decay with frequency, although losses of other na-

ture (e.g., electrical losses in the cell membrane) also play a role. Figure 9 shows the pattern of the distribution of losses (volume densities) within two fluids. The greatest loss occurs at the cell wall, followed by a steep decrease with the distance from the wall. This pattern constitutes a viscous boundary layer, which is more pronounced in the external fluid. We checked our computation of energy loss inside the fluids against the classic Stokes' problem on a vibrating rigid plate in the viscous fluid (Currie, 1974; Lu, 1977), and found a qualitative similarity in these two solutions.

The viscosities of the intracellular fluid and the cell wall have not been measured experimentally, and we have shown the significance of these parameters to high-frequency electromotility of OHC. Thus, our results can stimulate further experiments aimed at the measurements of the viscous parameters of this cell and its components.

In addition to the cell half-included/excluded condition ($q=0.5$) discussed above, our model can be applied to other situations of different exclusion ratio q (Fig. 10). In Fig. 10(a), $q=0.5$ yields the maximum electromotile response under the 1 mV applied voltage, because of the maximum production of the effective length and membrane potential at that cell part. This result is consistent with the result of Dallos *et al.* (1993) in the case of small voltages. In the case when, instead of the absolute length change, the strain (length change divided by the length of the excluded part of the cell) is used [Fig. 10(b)], the effect of parameter q re-

duces to the effect of the transmembrane potential. The transmembrane potential is a decreasing function of q . Similar pattern is observed in the phase shift [Fig. 10(c)].

In the present paper, we concentrate on the frequency effects associated with the interaction of the cell wall with the surrounding viscous fluids and on the viscous effects in the cell wall itself. We also consider the cell as finite, and take into account the distributions of the mechanical characteristics (stresses and strains) along the cell. However, we assume the transmembrane potential and the piezoelectric properties to be uniform. There have been reports on the nonuniform distribution of ion channels (Santos-Sacchi *et al.*, 1997) as well as heterogeneity of the molecular motors (Santos-Sacchi, 2002) along the cell that may have an effect on the piezoelectric and electrical properties of the cell. These effects will be taken into account in the later versions of our model.

Although the corner frequency of the electromotile displacement computed here is lower than the upper limit of the acoustic range, our ultimate interest is in the frequency range of the active force, the factor that determines the amplification of the basilar-membrane vibration. The corner frequency of the active force is greater than that of displacement of a free cell. This is because the cell has to be constrained in order to produce an active force. Such conditions correspond to smaller movement of the cell resulting in smaller viscous losses and higher corner frequency (the analysis of the high-frequency active force production will be published elsewhere).

The ultimate goal of our modeling is to better understand the cochlear amplifier and outer hair cell electromotility under high-frequency conditions. An advanced model of the cochlea that includes “a module,” where the electromechanical properties of an individual outer hair cell are included, can be an effective tool to achieve this goal. A logical first step to develop such a module would be to model the high-frequency performance of an unconstrained outer hair cell. Further steps would be to incorporate the interaction of the cell with the basilar and tectorial membrane, respectively, underlying and overlying the cell. Finally, the module has to be incorporated into the model of the whole cochlea that takes into account the hydrodynamic interaction and anatomical gradients along the cochlea. Thus, this paper presents the results of the first step toward advanced cochlear models. The next step associated with the high-frequency performance of the constrained cell, including the active force production, will be published elsewhere.

In this paper, we modeled high-frequency electromotility of outer hair cells electrically stimulated in the microchamber. We found that the parameters of the microchamber experiment, such as the boundary conditions at the cell–pipette interface and the set-point potential, have a significant effect on the cell response observed in the experiment, and this finding helps reconcile the differences in the existing measurements. The viscous effects (particularly that of the cell wall) eliminate peaks in the electromotile response and play the main role in its decay with frequency. We took into account the cell closed-end effects, and found them to be not very significant. Finally, we identified parameters of the cell

(the viscosities of the wall and intracellular fluid) important for the cell high-frequency performance that have not been experimentally measured in the OHC, and our results should provide a stimulus for conducting new experiments. The developed approach can be used in advanced cochlear models aimed at the analysis of the active processes accompanying mammalian hearing.

(Received 13 February 2004; revised 30 December 2004; accepted 30 December 2004)

Recent studies suggest that an auditory nonlinearity converts second-order sinusoidal amplitude modulation (SAM) (i.e., modulation of SAM depth) into a first-order SAM component, which contributes to the perception of second-order SAM. However, conversion may also occur in other ways such as cochlear filtering. The present experiments explored the source of the first-order SAM component by investigating the ability to detect a 5-Hz, first-order SAM probe in the presence of a second-order SAM masker beating at the probe frequency. Detection performance was measured as a function of masker-carrier modulation frequency, phase relationship between the probe and masker modulator, and probe modulation depth. In experiment 1, the carrier was a 5-kHz sinusoid presented either alone or within a notched-noise masker in order to restrict off-frequency listening. In experiment 2, the carrier was a white noise. The data obtained in both carrier conditions are consistent with the existence of a modulation distortion component. However, the phase yielding poorest detection performance varied across experimental conditions between 0° and 180°, confirming that, in addition to nonlinear mechanisms, cochlear filtering and off-frequency listening play a role in second-order SAM perception. The estimated magnitude of the modulation distortion component ranges from 5%–12%. © 2005 Acoustical Society of America.

I. INTRODUCTION

The ability of human listeners to detect slow modulations in the amplitude of incoming sounds is generally understood using models based on either a low-pass filter/integrator (Viemeister, 1979; Moore *et al.*, 1988) or a modulation filterbank (MFB) (Dau *et al.*, 1997a, 1997b). In a modulation-masking study, Strickland and Viemeister (1996) first mentioned the ability to perceive the envelope beat produced by the addition of two closely spaced modulation components, which is a slow modulation in envelope *depth*. In parallel, electrophysiological work by Shofner *et al.*

(1996) demonstrated that neural units in the ventral cochlear nucleus of the chinchilla show phase-locked responses both to the frequencies of the modulation primaries and to the modulation difference frequency (i.e., the beat frequency) of two-component sinusoidal amplitude modulation (SAM). These findings appeared to be a challenge for current models of temporal-envelope processing, because there was no energy at the beat frequency in the “physical” modulation spectrum of such stimuli. This was interpreted as evidence for the existence of a nonlinearity along the auditory pathway (e.g., compression, saturation, or thresholding) that generates a *modulation distortion component* at the envelope-beat frequency.

Psychoacoustical evidence consistent with the notion that nonlinear processes are involved in temporal-envelope beat perception was provided by Sheft and Yost (1997) and Moore *et al.* (1999). In both studies, the listeners’ sensitivity to a probe modulator was assessed in the presence of a two-

^{a)}Portions of this work were presented at the 27th Annual Midwinter Research Meeting of the Association for Research in Otolaryngology, Daytona Beach, FL, February 2004.

component masker modulator with modulation difference frequency equal to the probe modulation frequency. The probe and masker modulators were either applied to different sinusoidal carriers (Sheft and Yost, 1997) or to the same sinusoidal or narrowband carrier (Moore *et al.*, 1999). Despite the fact that the physical modulation components of the masker were too remote from the probe to yield modulation-masking effects, the results showed that the presence of the beating masker modulators degraded probe-detection thresholds. Taken together, these studies clearly pointed out the need to incorporate an additional nonlinearity into *each* envelope-processing model to account for the masking data.

The distortion-component hypothesis has received further support from psychoacoustical data on second-order SAM detection (Lorenzi *et al.*, 2001a, 2001b; Füllgrabe and Lorenzi, 2003), that is detection of a sinusoidal modulation applied to the modulation depth of a SAM stimulus. In a masking study, Lorenzi *et al.* (2001b) compared second-order SAM detection for a 5-kHz sinusoidal carrier and a 2-Hz wide narrowband-noise carrier centered at 5 kHz. The inherent random amplitude fluctuations in the narrowband noise would be expected to mask any modulation components in the low modulation frequency region (Dau *et al.*, 1997a). The results revealed that second-order SAM detection thresholds were worse for the narrowband noise than for the sinusoidal carrier only for the lowest second-order modulation frequencies. This finding provided evidence that detection of a distortion component at the envelope-beat frequency contributed to second-order SAM detection.

The potential role of cochlear compression in producing distortion in the internal modulation spectrum has been tested in psychoacoustical studies on second-order SAM detection conducted with hearing-impaired (Tandetnik *et al.*, 2001; Füllgrabe *et al.*, 2003) and cochlear implant listeners (Lorenzi *et al.*, 2004). In both groups, cochlear compression was either severely reduced or completely abolished by cochlear damage. However, second-order temporal modulation transfer functions (TMTFs) relating second-order SAM detection thresholds to second-order modulation frequency were normal or near-normal in shape in these listeners. This demonstrated that cochlear damage has little disruptive effect on the detection of second-order SAM, and, if a distortion component is actually used in second-order SAM detection, it must be generated by a nonlinearity other than cochlear compression.

One way to explore the type of nonlinearity involved in the generation of envelope distortion is to determine the relative phase of the distortion component. In a modulation-masking experiment using a 5-kHz sinusoidal carrier, Verhey *et al.* (2003) systematically varied the phase relationship between the probe modulator and the envelope beat cycle of two- and three-component masker modulators. Irrespective of the masker components' modulation frequencies (ranging from 90 to 360 Hz), maximum masking generally occurred in the antiphase (i.e., 180°) condition, where the maxima in the probe modulator coincided with the minima in the beat cycle of the masker envelope. Moreover, when the probe modulation was in-phase with the envelope beat, masked thresholds were lower than those measured in the unmasked

condition. Taken together, these observations indicated that the generated distortion component was in-phase with the envelope beat cycle. However, with relatively low (i.e., 40 and 45 Hz) modulation components, the phase-dependent masking effects were less pronounced and maximum masking occurred—when observed—at 90° and 180°. In agreement with the hearing-impaired data discussed above, Verhey *et al.* (2003) concluded that the distortion component could not be accounted for by a compressive nonlinearity, which would have yielded a 180° out-of-phase distortion component, that is, maximum masking in the 0° condition. By contrast, the masking data were globally consistent with the notion of “venelope” extraction proposed by Ewert *et al.* (2002). In their functional model of temporal-envelope processing, envelope-beat information is extracted by computing the so-called venelope (the Hilbert envelope of the ac-coupled Hilbert envelope), which is then attenuated and combined with the first-order SAM. In response to complex temporal envelopes, such a mechanism produces an internal modulation component at the envelope-beat frequency that is in-phase with the envelope beat cycle (Ewert *et al.*, 2002; Verhey *et al.*, 2003), and therefore correctly predicts the empirically obtained maximum masking effects for the antiphase condition.

In an attempt to clarify the phase and magnitude of the distortion component, Sek and Moore (2004) measured psychometric functions for detecting a 5-Hz SAM probe applied to a 4-kHz sinusoidal carrier in the presence of a masker modulator with components at 50 and 55 Hz. This time, performance was poorest when the probe modulation was 135° out-of-phase with the masker envelope beat, similar to the phase effect obtained by Verhey *et al.* (2003), but not entirely consistent with predictions based on venelope extraction. In addition, as already apparent in masking data obtained by Verhey *et al.* (2003) using comparable modulation frequencies, the phase effect did vary somewhat across listeners. The effective modulation depth of the distortion component was estimated by Sek and Moore (2004) to be rather weak, at about 3%; however, the authors acknowledged the possibility that the chosen probe phase may not have been optimal to estimate the maximum effective magnitude of the distortion component.

Overall, the preceding studies do not yield fully converging outcomes and showed some degree of inter-listener variability, consistent with the idea that the envelope-beat information may not be converted into a first-order SAM component *via* a single, presumably nonlinear, mechanism. Ewert *et al.* (2002) and Verhey *et al.* (2003) already noted that such a conversion may occur *via* cochlear filtering, provided subjects make use of the output of an auditory filter that is not centered on the carrier frequency. Introduction of a component at the second-order frequency *via* cochlear filtering would mainly occur for sinusoidal carriers. However, it is conceivable that such a conversion also occurs for broadband-noise carriers, especially when the frequency of the first-order SAM carrying the second-order modulation is relatively high (Viemeister, 2003).

Our purpose in the present study was therefore to demonstrate the existence of a “genuine” modulation distortion

component generated by the auditory system in response to second-order masker modulators, and to evaluate the role of other sources of conversion involved in second-order SAM perception. The experiments reported here addressed these issues by investigating the effect of a second-order masker modulator on the detectability of a first-order probe modulator whose modulation frequency corresponded to the periodicity of the masker's envelope beat. Using different carrier signals, the characteristics (i.e., phase and magnitude) of the modulation distortion component were investigated by measuring detection performance as a function of (i) the carrier (or first-order) modulation frequency of the masker; (ii) the phase relationship between the probe and masker modulator; and (iii) the probe modulation depth.

Finally, previous modulation masking studies exploring the phase of the distortion component used procedures with feedback. Using feedback might have led listeners to use *any* cue when performing the detection task (rather than choosing the interval where the modulation depth was greater). This issue seems particularly important when a 2IFC procedure is used in which listeners may change their strategy based on feedback. In their second experiment, Sek and Moore (2004) measured psychometric functions for probe modulation detection as a function of probe depth when no feedback was provided; however, they used a phase relationship between the probe and masker modulator that had been obtained in a previous experiment using feedback. Here, in all masking conditions, no feedback was provided; this was intended to allow us to observe genuine effects of cancellation between the probe modulator and first-order SAM component resulting from conversion, when they were out-of-phase.

II. EXPERIMENT 1: MASKED AND UNMASKED MODULATION DETECTION USING A SINUSOIDAL CARRIER

A. Rationale

Our aim in this experiment was to extend previously published studies conducted with sinusoidal carriers investigating the nature of the nonlinear mechanism involved in the perception of temporal-envelope beat information. Using a 5-kHz sinusoidal carrier, detection performance for a 5-Hz SAM probe was measured in the presence of a second-order SAM masker fluctuating at the probe frequency, as a function of the relative probe phase. Different masker-carrier modulation frequencies were chosen between 32 and 180 Hz to cover the range of modulation frequencies used in earlier studies (Moore *et al.*, 1999; Verhey *et al.*, 2003; Sek and Moore, 2004). Unlike these studies, the sinusoidal carrier was presented within a notched noise to restrict off-frequency listening. To clarify the effects of off-frequency listening, measurements were replicated when the notched-noise masker was removed. The masking study was preceded by a systematic assessment of the listeners' sensitivity to first- and second-order SAM to ensure that the first-order probe and second-order masker modulations were audible in all experimental conditions.

B. First- and second-order TMTFs

1. Listeners

Three listeners aged 20 to 30 years participated in the experiment. All listeners had audiometric thresholds less than 15 dB HL between 0.25 and 8 kHz. One listener was author CF, who had extensive previous experience with psychoacoustic experiments. The other two were volunteers who were paid for their services. Prior to data collection, all listeners received training for about four hours to stabilize thresholds.

2. Stimuli and procedure

All stimuli were generated with a Personal Computer using a 16-bit D/A converter operating at a sampling frequency of 44.1 kHz, and were delivered diotically *via* Sennheiser HD 25-13 earphones. The carrier was a 5-kHz sinusoid presented at 70 dB SPL within a notched-noise masker. The masker was obtained by adding a low-pass noise (cutoff frequency=2917 Hz; roll-off=90 dB/octave) and a high-pass noise (cutoff frequency=7500 Hz; roll-off=90 dB/octave) presented at 20 and 7 dB (rms) below the carrier level, respectively. The corresponding noise spectrum was chosen so that the carrier-to-noise ratio would have been high only for a limited range of auditory filter center frequencies close to the carrier frequency (Alcántara *et al.*, 2003). In all experiments, the stimulus duration was 2 s, including 50-ms rise/fall times shaped using a raised-cosine function. All listeners were tested individually in a sound-attenuating booth.

For the measurement of first-order TMTFs, listeners had to detect SAM applied to the sinusoidal carrier. On each trial, a standard and a target stimulus were presented in random order with an interstimulus interval (ISI) of 1 s. The standard corresponded to the unmodulated carrier. The target corresponded to the carrier that was sinusoidally amplitude modulated at a modulation frequency f_m of 2, 10, 40, 80, or 160 Hz. The target's temporal envelope is given by

$$T_1(t) = 1 + m \sin(2\pi f_m t + \phi), \quad (1)$$

where m is the modulation depth ($0 \leq m \leq 1$), and ϕ is the starting phase of the modulation, randomized in each interval. The overall power was the same in both intervals.

SAM detection thresholds were obtained using an adaptive two-interval, two-alternative forced-choice (2I, 2AFC) procedure with a two-down, one-up stepping rule that estimates the modulation depth m necessary for 70.7% correct detection (Levitt, 1971). Listeners received visual feedback after each trial. The step size was initially 4 dB (in terms of $20 \log m$), and was reduced to 2 dB after the first two reversals. The arithmetic mean of the values of m at the last 10 reversals in a block of 16 reversals was taken as the threshold estimate for that block (reported in %). The final threshold is based on three repeated measures.

For the measurement of second-order TMTFs, listeners had to detect sinusoidal modulation of the modulation depth of first-order SAM. Again, on each trial, a standard and a target stimulus were presented in random order with an ISI of 1 s. The standard had first-order SAM of a given modu-

lation frequency f_m and a fixed modulation depth m of 0.5 (i.e., 50%). The expression describing the standard's temporal envelope was

$$S_2(t) = 1 + 0.5 \sin(2\pi f_m t + \phi), \quad (2)$$

where ϕ represents the starting phase of the modulation, which was randomized for each interval. The target had SAM whose modulation depth was sinusoidally modulated at a (second-order) modulation frequency f'_m . The expression describing the target's temporal envelope was

$$T_2(t) = 1 + [0.5 + m' \sin(2\pi f'_m t + \phi)] \sin(2\pi f_m t + \phi), \quad (3)$$

where m' is the second-order modulation depth ($0 \leq m' \leq 0.5$) and ϕ represents the starting phase of the modulations, randomized for each interval. The overall power was the same in both intervals. The carrier modulation frequency f_m was either 32, 64, or 180 Hz, and the corresponding second-order modulation frequencies f'_m were (i) 2, 5, and 10 Hz, (ii) 2, 5, 10, and 20 Hz, and (iii) 2, 5, 10, 20, 40, and 80 Hz, respectively. Second-order SAM detection thresholds (i.e., m' at threshold) were obtained using an identical 2I, 2AFC psychophysical procedure to that used to determine first-order SAM detection thresholds.

3. Results and discussion

Individual first- (filled squares) and second-order (open symbols) TMTFs for the three listeners are shown in Fig. 1. In agreement with previous experiments using sinusoidal carriers (Viemeister, 1979; Kohlrausch *et al.*, 2000; Lorenzi *et al.*, 2001b; Moore and Glasberg, 2001), first-order SAM detection thresholds show a low- or all-pass characteristic for the range of f_m under study. In all listeners, thresholds are roughly constant ($m \approx 6\%$ or -24 dB expressed as $20 \log m$) at the lowest modulation frequencies; they tend to increase only slightly with f_m for two listeners, but more substantially for listener CF (with a clear increase above 40 Hz). Overall, the thresholds required to detect SAM of a sinusoidal carrier presented in a notched noise are increased by a factor of 3 (10 dB) relative to those obtained in identical but unmasked conditions (Lorenzi *et al.*, 2001b). This difference presumably reflects the contribution of off-frequency listening in the absence of masking noise, which is advantageous because there is less cochlear compression on the high-frequency side of the excitation pattern evoked by the carrier, so the effective magnitude of the modulation is greater on the high-frequency side than at its center (Zwicker, 1956). In addition, some energy from the notched-noise masker may have leaked into the auditory filter centered on the carrier. The fact that the cutoff frequency of the average TMTF is somewhat lower than that reported in previous studies may then be attributed to the increasing masking effect of intrinsic random fluctuations of the notched-noise masker at higher modulation frequencies (Dau *et al.*, 1997a).

The second-order TMTFs show roughly constant thresholds for most second-order modulation frequencies, although a low-pass characteristic with a -3 dB cutoff frequency at or above 20 Hz is apparent when $f_m = 180$ Hz. Moreover, second-order modulation detection thresholds decrease by a

FIG. 1. Individual first- (filled squares) and second-order (open symbols) TMTFs for the three listeners using a 5-kHz sinusoidal carrier presented within a notched-noise masker. First- and second-order modulation depths at threshold m and m' (in %) are plotted as a function of first- and second-order modulation frequency f_m and f'_m , respectively. The right axis shows detection thresholds in dB (in terms of $20 \log m$ or $20 \log m'$). The parameter for the second-order TMTFs is the carrier modulation frequency: $f_m = 32$ (circles), 64 (diamonds), and 180 Hz (triangles). Error bars represent \pm one standard deviation from the mean threshold across three repeated measures.

factor of 1.5 (3 dB) when f_m increases from 32 to 180 Hz. These observations are roughly consistent with data reported by Lorenzi *et al.* (2001b) for similar carrier modulation frequencies using an unmasked 5-kHz carrier. However, as for first-order SAM detection, the average sensitivity to second-order SAM was consistently poorer by approximately a factor of 3 (10 dB) when off-frequency listening was restricted than when off-frequency listening was possible (Lorenzi *et al.*, 2001b).

C. Detection of a 5-Hz probe modulator in the presence of a 5-Hz, second-order SAM masker: Phase effects

1. Stimuli and procedure

The three listeners used to assess SAM-detection thresholds participated in this experiment. The detectability of a

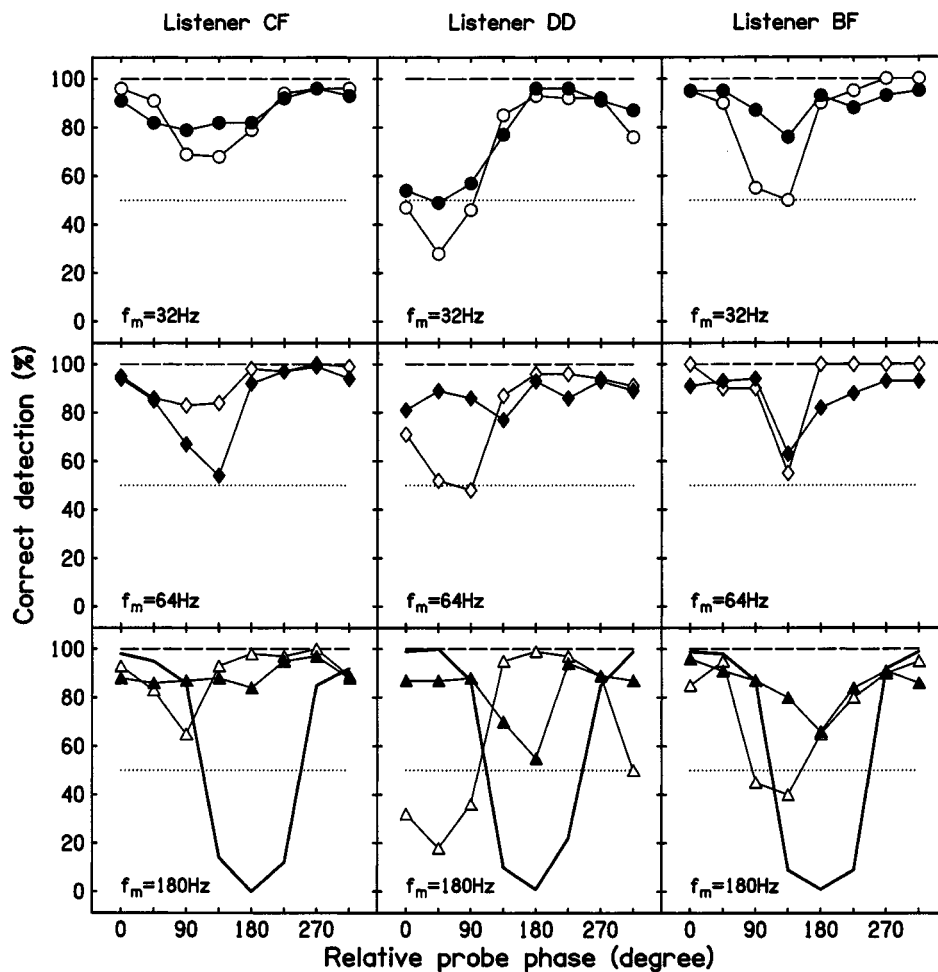

FIG. 2. Individual detection scores for 20%, 5-Hz probe modulation of a 5-kHz sinusoidal carrier presented within a notched-noise masker, measured in three listeners (columns). Performance is plotted as a function of the phase relationship between the probe and (i) a 5-Hz, second-order SAM masker for carrier modulation frequencies of 32 (open circles, upper row), 64 (open diamonds, middle row), and 180 Hz (open triangles, lower row); and (ii) a 20%, 5-Hz SAM masker (bold line, lower row). In each panel, unmasked probe detection scores are indicated by the long-dashed line. Filled symbols correspond to masked detection performance when the notched noise was removed. The dotted line represents performance at chance level.

20%, 5-Hz SAM probe was measured using a 2I, 2AFC procedure with constant stimuli. The probe was applied to a 5-kHz sinusoidal carrier embedded within the notched-noise masker, and presented either:

- (1) Alone, without any additional SAM masker (unmasked detection condition).
- (2) In the presence of a second-order SAM masker that was applied to the sinusoidal carrier in both intervals. The first-order modulation frequency of the masker was 32, 64, or 180 Hz, while the second-order modulation frequency was fixed at 5 Hz. The first- and second-order modulation depths of the masker modulator were set to 40%. All masker modulation components started in sine phase. Eight phase relationships between the probe and masker modulators were used: 0°, 45°, 90°, 135°, 180°, 225°, 270°, and 315°. In this condition, performance was also assessed without the notched-noise masker.
- (3) In the presence of a first-order SAM masker applied to the sinusoidal carrier in both intervals. The probe and masker modulators had identical modulation depths of 20% and modulation frequencies of 5 Hz. As with the second-order masker modulator, the phase relationship between probe and masker modulators was shifted in steps of 45° from 0° to 315°.

The inspection of first- and second-order modulation detection thresholds reported above indicates that in the present

experimental conditions, all first- and second-order modulation components were audible when presented individually.

Prior to data collection, listeners received 20 practice trials in each experimental condition. Detection scores presented here are based on 100 trials.

2. Results and discussion

Figure 2 shows individual probe detection scores for the three listeners (columns) as a function of the phase relationship between the probe and the masker modulator. Using a notched-noise masker, detection performance is perfect for all listeners when the 20% probe modulator is presented alone (long-dashed line), and decreases when a second-order masker modulator (open symbols) is added, despite the fact that the individual modulation components of the latter are remote in frequency from the probe modulator. This can be explained in terms of an interaction of the probe modulator with a modulation distortion component produced in response to the second-order modulator: sometimes the probe modulator would have been in-phase with the distortion component, so that they added, and sometimes the two would have been out-of-phase, so that they cancelled. Since no feedback was provided in the masked conditions, a drop of detection performance below chance level for a given phase relationship reflects the fact that listeners tended to choose the standard instead of the target interval as the one

containing the more salient 5-Hz SAM, consistent with the notion that the probe modulation was (partially) cancelled.

The results show that the phase relationship between the probe and masker modulators leading to the poorest performance does not vary with masker-carrier modulation frequency *within* the same listener. However, as already observed to a lesser degree in previous studies (Verhey *et al.*, 2003; Sek and Moore, 2004), phase effects do vary *across* listeners with maximum masking occurring for probe phases of 45° to 135°. Such a shift is not expected if there were a *single* static nonlinearity, as postulated in the literature (Moore *et al.*, 1999; Verhey *et al.*, 2003), but may be explained by the existence of several static nonlinearities introducing distortion into the internal representation of complex temporal envelopes. The exact contribution of each nonlinearity would have to be listener-specific to account for the observed inter-listener variability.

The replication of the experiment without the notched-noise masker (filled symbols) yields a similar pattern of results for $f_m = 32$ Hz in all listeners, but shows important differences for $f_m = 64$ and 180 Hz for two out of the three listeners. This suggests that, for the lowest f_m under study, the phase effect is not substantially influenced by off-frequency listening. In contrast, but in agreement with recent data reported by Sek and Moore (2004), the maximum decrease in performance for $f_m = 64$ Hz now occurs consistently around 135°. For listener DD, the phase at which performance is worst is shifted by +45°, relative to what was obtained in the notched-noise condition. An even stronger discrepancy between the results obtained with and without the notched noise is observed for $f_m = 180$ Hz. Here, two listeners show a clear shift of the phase yielding the poorest performance when the notched-noise masker is removed. The worst detection scores occur at 180° in listeners DD and BF, while no phase-dependent masking effect is observed anymore in listener CF. In comparison, Verhey *et al.* (2003) reported the poorest detection performance systematically occurring at 180° for a wide range of f_m , except for the lowest f_m under study.

The fact that probe detectability is not only dependent on phase but also varies with f_m when the notched noise is removed suggests that listeners use off-frequency listening in certain conditions. Off-frequency listening may influence performance in two ways. First, although there is no modulation component at the second-order frequency in the modulation spectrum of the stimulus, the envelope at the output of an auditory filter tuned away from the signal frequency may contain such a component (e.g., Ewert *et al.*, 2002). Second, basilar-membrane compression is strong for auditory filters tuned close to the signal frequency, but weak for the more remote filters. This might affect the balance between different sources of nonlinearity. This interpretation seems however less likely given the observation that hearing-impaired and cochlear implant listeners show quasi-normal sensitivity to second-order SAM (Tandetnik *et al.*, 2001; Füllgrabe *et al.*, 2003; Lorenzi *et al.*, 2004).

In the present experiment, the clearest indication of conversion *via* cochlear filtering and off-frequency listening is obtained for two out of the three listeners at $f_m = 180$ Hz.

Here, the phase dependence of probe detectability for a 5-Hz, first-order SAM masker (bold line, lower row) is nearly identical to that measured for the second-order SAM masker.

The present results obtained without a notched-noise masker are at least partially consistent with phase effects previously reported by Verhey *et al.* (2003) and Sek and Moore (2004), suggesting that off-frequency listening might also have occurred in these studies. This assumption is emphasized by the observation that Verhey *et al.* (2003) failed to find clear phase-dependent masking effects when a masker modulator with low (i.e., 40 and 45 Hz) components was used. Thus, the masking effects reported by Verhey *et al.* (2003) and Sek and Moore (2004) may not *solely* reflect an interaction between the probe and a genuine modulation distortion component.

It is noteworthy that, when a carrier modulation frequency of 64 or 180 Hz and no notched-noise masker was used, listeners reported the presence of a weak high-pitch tone in the standard interval only. Therefore, despite the fact that listeners received instructions to choose the interval containing the most salient 5-Hz modulation, listeners may have used both cues to perform the detection task when no notched noise was used.

III. EXPERIMENT 2: MASKED AND UNMASKED MODULATION DETECTION USING NOISE CARRIERS

A. Rationale

The preceding experiment showed that nonlinear mechanisms are indeed involved in the conversion of second-order SAM into a first-order SAM component. However, the results also suggested that, under certain conditions, second-order SAM is converted into a first-order SAM component *via* cochlear filtering. A similar conversion may occur for broadband-noise carriers, especially when the carrier modulation frequency is high (i.e., greater than the bandwidth of the excited auditory filters). Simulations of the output of cochlear filters were therefore performed to evaluate the existence of this source of conversion for broadband-noise stimuli.

Figure 3 shows the responses of an array of gammatone filters (Patterson *et al.*, 1987) to a 5-Hz, second-order SAM noise (0–20 kHz). Two carrier modulation frequencies [$f_m = 64$ (diamonds) and 180 Hz (triangles)] falling within the frequency range of modulation primaries used in previous psychoacoustical studies (Moore *et al.*, 1999; Verhey *et al.*, 2003; Sek and Moore, 2004), and a high carrier modulation frequency of 2 kHz (circles) were used. Modulation depths m and m' were set to 40%. Also shown are responses to an unmodulated noise (filled squares) and a 8%, 5-Hz (first-order) SAM noise (filled inverted triangles). The magnitude (left panel) and phase (right panel) of the 5-Hz (first-order) SAM component observed at the filter outputs are shown as a function of filter center frequency (CF). For all three carrier modulation frequencies, the data confirm that the responses of cochlear filters (modeled here as linear filters) contain indeed a first-order modulation component at 5 Hz. When $f_m = 2$ kHz, a 5-Hz modulation component is observed at all CFs and its magnitude and phase are about the same as those

FIG. 3. Simulations of outputs of linear auditory filters in response to second-order SAM noise (0–20 kHz) with carrier modulation frequencies of 64 (diamonds), 180 (triangles), and 2000 Hz (circles). Also are shown responses to an unmodulated (filled squares) and a 8%, 5-Hz SAM noise (filled inverted triangles). The magnitude (left panel) and phase (right panel) of the 5-Hz (first-order) SAM component at the outputs of auditory filters are shown as a function of the filter center frequency (CF). Each data point corresponds to the mean of 2500 presentations of each stimulus. Note that, in referencing the measured phase at each frequency to a cosine at that frequency, a sine function would have a phase value of -1.57 ($-\pi/2$) rad re:cos.

obtained with 8%, 5-Hz (first-order) SAM. In other words, the maxima of this first-order modulation component coincide with the maxima in the envelope beat cycle of the second-order SAM. For the lower carrier modulation frequencies, the 5-Hz modulation component only occurs at the outputs of filters with low CFs (i.e., with ERBs smaller than roughly $2 \times f_m$) and its magnitude increases progressively as CF decreases. The 5-Hz modulation component at the outputs of auditory filters with CF-below approximately 300 Hz (when $f_m = 64$ Hz) and 1 kHz (when $f_m = 180$ Hz) is roughly in sine phase (i.e., in-phase with the second-order SAM). For filters with higher CFs, the modulation component shifts progressively out-of-phase with the second-order modulator.

The following experiments were designed to investigate the relative contribution of each source of conversion (i.e., cochlear filtering and auditory nonlinearities) in the case of broadband-noise carriers. Again, probe detectability was measured behaviorally as a function of the phase relationship between the probe modulator and a second-order SAM masker fluctuating at the probe frequency. The masking data for a carrier modulation frequency of 64 Hz were compared using a white noise and 6-kHz wide bandlimited noise (4–10 kHz). This comparison allowed determining whether cancellation effects could still be observed for broadband-noise carriers, even though conversion through cochlear filtering did not occur in this case (cf. the left panel of Fig. 3). This experiment also allowed assessing the relative phase of the genuine modulation distortion component when using a noise carrier. Additional masking data were collected with the white-noise carrier for the other two carrier modulation frequencies used in the simulations (180 Hz and 2 kHz) for which conversion through cochlear filtering was shown to occur in most or all filters. Finally, probe detectability was assessed as a function of probe modulation depth in the white-noise carrier condition in order to quantify the magnitude of the generated first-order SAM component for each masker-carrier modulation frequency. As in the first experi-

ment, the modulation-masking experiments were preceded by a systematic assessment of the listeners' sensitivity to first- and second-order SAM white noise.

B. First- and second-order TMTFs

1. Listeners

Four listeners ranging in age between 18 and 30 years were tested. One of them was author CF and the other three were paid volunteers. All listeners had absolute thresholds less than 15 dB HL at all audiometric frequencies. Practice of 3 h was given prior to data collection.

2. Stimuli and procedure

The apparatus, procedure, and stimulus parameters were the same as for experiment 1, except that (i) a different set of earphones (Sennheiser HD 565) was used; (ii) SAM was applied to a white-noise carrier; (iii) first-order SAM detection thresholds were obtained for $f_m = 2, 10, 40, 160,$ and 2000 Hz; and (iv) second-order SAM detection thresholds were obtained for carrier modulation frequencies f_m of 64, 180, and 2000 Hz; the second-order modulation frequencies f'_m were 2, 5, 10, and 20 Hz when $f_m = 64$ Hz, 2, 5, 10, 20, 40, and 80 Hz when $f_m = 180$ Hz, and 2, 5, 10, 20, 40, 80, and 160 Hz when $f_m = 2000$ Hz.

3. Results and discussion

Figure 4 shows individual first- (filled squares) and second-order (open symbols) TMTFs for the four listeners. Consistent with previous data obtained with broadband-noise carriers (Viemeister, 1979; Bacon and Viemeister, 1985; Lorenzi *et al.*, 2001a), the first-order TMTFs are low-pass in shape with thresholds of about 3% (-30 dB) for the lowest values of f_m , and a -3 dB cutoff frequency below 40 Hz. Note that listeners required modulation depths ranging from 45% to 51% (-6.9 dB to -5.8 dB) to reach the threshold

FIG. 4. Individual first- (filled squares) and second-order (open symbols) TMTFs for the four listeners using a white-noise carrier. The carrier modulation frequency of the second-order SAM was 64 (diamonds), 180 (triangles), and 2000 Hz (circles). Otherwise as in Fig. 1.

criterion of 70.7% correct for 2-kHz SAM. This means that, in the case of second-order SAM with a 50% carrier SAM (as was used to measure second-order TMTFs), the first-order modulation was approximately at threshold.

Similar to data reported by Lorenzi *et al.* (2001a), second-order TMTFs with $f_m = 64$ (diamonds) and 180 Hz (triangles) show a low-pass characteristic, with average sensitivity decreasing and cutoff frequency increasing with carrier modulation frequency. Second-order TMTFs obtained with $f_m = 2$ kHz (circles) show constant thresholds of about 13% (-18 dB) at the lowest second-order SAM frequencies, and increase progressively beyond $f'_m = 20$ Hz. The shapes of these second-order TMTFs mirror quite closely the first-order TMTFs, suggesting that the second-order SAM was detected using the same (but attenuated) cue as used for first-order SAM detection.

C. Detection of a 5-Hz probe modulator in the presence of a 5-Hz, second-order SAM masker: Phase effects

1. Stimuli and procedure

For the same four listeners, the detectability of a 5-Hz SAM probe applied to a white-noise carrier was measured, following the same protocol as in experiment 1, except that (i) Sennheiser HD 565 earphones were used; (ii) the probe modulation depth was fixed at a supra-threshold level of 5%, and therefore the modulation depth of the first-order SAM masker was also 5%; and (iii) the second-order masker-carrier modulation frequency was either 64, 180, or 2000 Hz. As for the experiment conducted with the sinusoidal carrier, the detection data shown in Fig. 4 indicate that all first- and second-order modulation components were audible when presented individually.

Two (CF,CB) out of the four listeners were tested when $f_m = 64$ and 2000 Hz using a 6-kHz wide broadband noise as a carrier instead of an unfiltered white noise. The

bandlimited-noise carrier was obtained by bandpass filtering a white noise between 4 and 10 kHz (roll-off=120 dB/octave). The spectrum level was fixed at 32 dB. Complementary low and high unmodulated noise flankers (with frequency ranges of 0–4 and 10–22.5 kHz) were added to the modulated bandlimited noise with spectrum levels of 34 and 29 dB, respectively. This was done to prevent listeners from performing the detection task using spectral cues or combination tones (Wiegrebe and Patterson, 1999).

2. Results and discussion

Figure 5 shows individual detection scores for the white-noise (open symbols) and bandlimited-noise (filled symbols) conditions. Data for the three carrier modulation frequencies (rows) are shown as a function of relative probe phase.

As expected based on the SAM-detection data (Fig. 4), near-perfect detection performance is observed in the white-noise condition when the 5% probe modulator is presented alone (long-dashed line). Detection performance drops to about 73% correct when the carrier is bandlimited (short-dashed line). Overall, adding a second-order masker modulator to the SAM probe degrades performance for both types of noise carriers. Moreover, as in the previous masking experiment using a sinusoidal carrier, probe detection varies with the phase relationship between the probe and masker modulators, but the probe phases giving maximum and minimum detectability depend on the masker-carrier modulation frequency. In contrast to the previously collected data, all phase effects are highly consistent across listeners.

The upper row shows the data for a second-order SAM masker with $f_m = 64$ Hz in the white-noise and bandlimited-noise conditions. In both cases, the detectability of the probe varies in essentially the same way as a function of relative probe phase. Minimum and maximum detectability occur for $0/45^\circ$ and $180/225^\circ$, respectively. The fact that the overall pattern of results is very similar for both noise carriers can be taken as evidence that cochlear filtering does not contribute to the observed phase effects when $f_m = 64$ Hz. Consequently, the observed cancellation effects demonstrate the existence of a genuine distortion component with a phase of $180/225^\circ$. Surprisingly, this phase is neither consistent with previously published data (in which off-frequency may have occurred) nor with the results from experiment 1 (in which off-frequency listening was, however, precluded). This discrepancy concerning the phase of the modulation distortion component between studies using noise and sinusoidal carriers remains unexplained.

The middle row shows the masking data for the white-noise condition when f_m is 180 Hz. Maximum and minimum scores occur on average at about 270° and $90/135^\circ$, respectively. However, in this case, performance does not fall below chance (except for listener CA). Another pattern is obtained for $f_m = 2$ kHz (open circles, lower row), where maximum scores are observed for phase relationships of 0° , 45° , and 315° , and performance consistently drops to a minimum at 180° . The fact that performance for the out-of-phase condition approaches closely the worst possible detection score suggests that the probe modulator and the first-order SAM component resulting from conversion are of similar

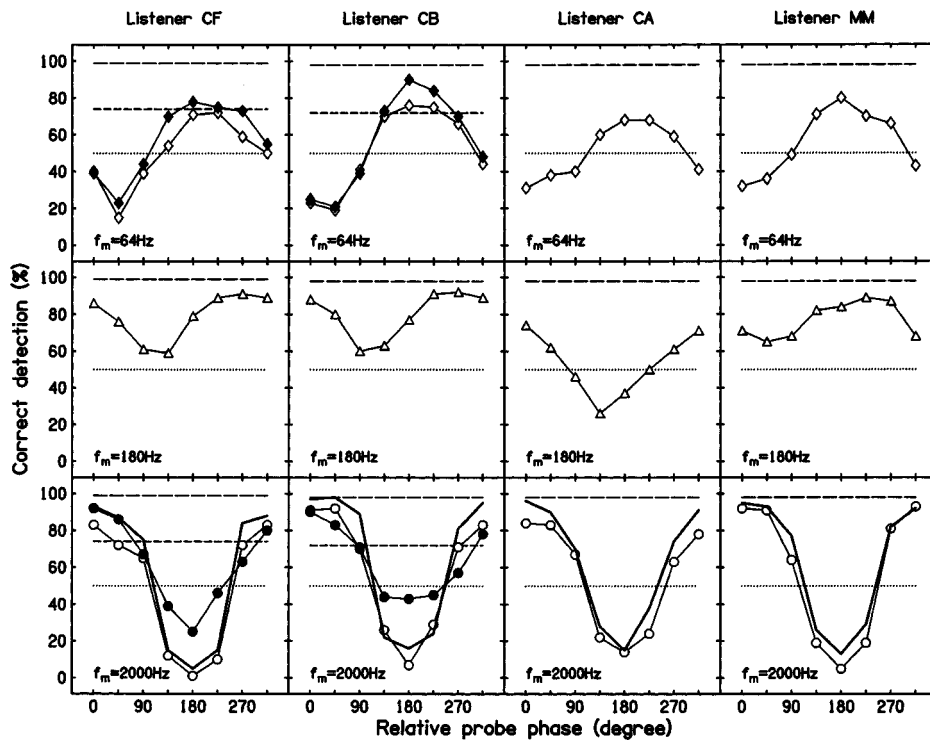

FIG. 5. Individual detection scores for 5%, 5-Hz probe modulation of a white-noise (open symbols) and bandlimited-noise (filled symbols) carrier, measured for four listeners (columns). Carrier modulation frequency of the second-order SAM masker was fixed at 64 (diamonds, upper row), 180 (triangles, middle row), or 2000 Hz (circles, lower row). The modulation depth of the 5-Hz SAM masker (bold line, lower row) was set to 5%. Unmasked probe detection scores are indicated for the white-noise (long-dashed line) and bandlimited-noise (short-dashed line) conditions. The dotted line represents performance at chance level.

magnitude and approximately in antiphase, so that they almost cancel each other out. In agreement with this idea, the pattern of results for the 5%, first-order SAM masker (bold line, lower row), is nearly identical to that for the second-order SAM white noise with $f_m = 2$ kHz. These data appear consistent with what would be predicted if detection performance were *mainly* determined by the interaction between the probe modulator and the 8%, first-order SAM component appearing at the output of cochlear filters at all CFs (cf. Fig. 3). The progressive change in the phase yielding maximum cancellation with an increase in f_m from 64 to 2 kHz is therefore in line with the notion that the contribution of the first-order SAM component resulting from cochlear conversion increases with carrier modulation frequency.¹

D. Detection of a 5-Hz probe modulator in the presence of a 5-Hz, second-order SAM masker: Effects of probe modulation depth

1. Stimuli and procedure

Psychometric functions were measured for detecting a 5-Hz SAM probe in the presence of a second-order SAM masker as a function of the probe modulation depth in the white-noise condition. Three of the original four listeners were tested. The apparatus, procedure, and stimuli were identical to those described in Sec. III C, except that, for each masker-carrier modulation frequency, the probe phase was fixed for each listener at the value yielding the poorest performance in the previous experiment (cf. Fig. 5). We assumed that, for this value, the probe modulator and the first-order SAM component resulting from conversion of envelope-beat information were 180° out-of-phase. The modulation depth of the probe modulator was either 1.25%, 2.5%, 5%, 10%, or 20%.

2. Results and discussion

Figure 6 shows individual detection scores for the three listeners as a function of probe modulation depth for each carrier modulation frequency of the second-order masker. The psychometric functions obtained with $f_m = 64$ Hz (diamonds) and 2000 Hz (circles) are nonmonotonic and show a u-shape, with worst performance occurring for intermediate probe depths of 5% and 10%. When $f_m = 180$ Hz (triangles), the deleterious effect of the masker is generally reduced; the psychometric functions increase monotonically with increasing probe depth with worst performance occurring consistently for probe depths of 1.25% to 5%. Taken together, these patterns of results suggest that the magnitude of the first-order conversion component is strictly below 20%. This upper limit of the estimated magnitude is somewhat higher than the 3% value reported in earlier studies using a sinusoidal audio carrier (Moore *et al.*, 1999; Sek and Moore, 2004).

FIG. 6. Individual masked detection scores for 5%, 5-Hz probe modulation of a white-noise carrier as a function of probe modulation depth, measured for three listeners. The masker was 5-Hz, second-order SAM with carrier modulation frequency of 64 (diamonds), 180 (triangles), and 2000 Hz (circles). The phase relationship between the probe and each second-order SAM masker was fixed in such a way as to correspond to the phase condition yielding the maximum degradation of performance in Fig. 5. Performance at chance level is indicated by the dotted line.

TABLE I. Estimated magnitude m_c in % (or in terms of $20 \log m_c$, given in parentheses) of the first-order SAM component, yielding the highest correlation coefficient r between predicted and observed probe detection performance. The masker-carrier modulation frequency f_m was 64, 180, or 2000 Hz.

	$f_m = 64$ Hz		$f_m = 180$ Hz		$f_m = 2000$ Hz	
	m_c	r	m_c	r	m_c	r
CF	12 (-18.4)	0.99	2 (-34)	0.94	8 (-21.9)	0.97
CB	11 (-19.2)	0.97	2 (-34)	0.95	7 (-23.1)	0.99
MM	5 (-26)	0.99	2 (-34)	0.96	7 (-23.1)	0.99

E. Simulations

Taken together, the empirical results and simulations appear consistent with the notion that for broadband-noise carriers: (i) both cochlear filtering and nonlinear mechanisms can introduce first-order SAM components into the internal representation of the envelope of a second-order SAM stimulus; (ii) these first-order SAM components—when present simultaneously—interact according to their own phase and magnitude, resulting in a “compound” first-order SAM component; and (iii) detectability of a first-order SAM probe in the presence of a second-order SAM masker is determined by the specific interaction of the (compound or not) first-order SAM component and the first-order SAM probe. This “cancellation hypothesis” was further tested using an approach similar to that taken by Sek and Moore (2004) to model their detection data.

This model assumes that listeners perform the probe detection task on the basis of a change in the depth of the 5-Hz modulation. In other words, listeners distinguish the 5-Hz SAM conversion component of depth m_c in the standard interval from the 5-Hz SAM in the target interval of magnitude m_{sum} , corresponding to the vector sum of the first-order SAM component (of depth m_c) and the probe modulation (of depth m_p). For some probe phases, the first-order SAM component and the probe modulation tend to cancel, leading to a small value of m_{sum} . Since performance is assumed to be monotonically related to $m_{\text{sum}} - m_c$, poor performance is expected in this condition.

To test this prediction, for each listener a starting value was used for m_c . Assuming that the first-order SAM component was 180° out-of-phase with the probe modulation in the last experiment (for each listener, the probe phase was fixed at the value yielding the poorest performance), the value of m_{sum} was calculated for each probe modulation depth used to obtain the psychometric functions in Sec. III D. The correlation of the d' values (computed from the obtained percent correct scores) with the values of $m_{\text{sum}} - m_c$ was then determined, and the value of m_c was systematically varied to determine the value giving the highest correlation. The resulting values of m_c and correlation coefficients are given in Table I. Scatter plots of the values of d' against the values of $m_{\text{sum}} - m_c$ were fitted with regression lines, and those lines were used to generate predicted values of d' for each probe modulation depth (data not shown). There was no

evidence of any systematic discrepancy between the predicted and observed d' values.

As shown in Table I, the values of m_c ranged from 2% to 12% (i.e., -34 dB to -18.4 dB expressed as $20 \log m_c$), with correlations between d' and $m_{\text{sum}} - m_c$ ranging from 0.94 to 0.99). This suggests that, when $f_m = 64$ or 2000 Hz, the first-order SAM component is easily detectable (cf. first-order SAM detection thresholds shown in Fig. 4). In contrast, when $f_m = 180$ Hz, the first-order SAM component is barely audible, consistent with earlier estimates of the effective magnitude of the modulation distortion component using a sinusoidal carrier (Moore *et al.*, 1999; Sek and Moore, 2004). Combining these magnitude estimates and the simulated outputs of cochlear filters suggests that the magnitude of the genuine modulation distortion component (i.e., for low carrier modulation frequencies where cochlear filtering does not play a role) ranges from 5% to 12%. In addition, in the case of the 2 kHz carrier modulation frequency, the first-order SAM component seems to result entirely from cochlear conversion since its estimated magnitude corresponds precisely to the magnitude of the first-order SAM component observed at the output of cochlear filters in response to a second-order SAM with $f_m = 2000$ Hz.

IV. CONCLUSIONS

The following conclusions can be drawn from the reported data.

- (1) Consistent with earlier modulation masking studies, the detectability of a SAM probe was degraded in the presence of second-order SAM masker beating at the probe frequency, even though all components in the modulation spectrum of the masker were remote from the probe frequency. The effect depended on the stimulus parameters, such as masker-carrier modulation frequency, phase relationship between the probe modulator and the second-order SAM masker, and probe modulation depth, as well as the type of carrier signal.
- (2) When a sinusoidal carrier is used, the results indicate that off-frequency listening influences detection performance, revealing that, for higher carrier modulation frequencies, cochlear filtering is potentially involved in the conversion of the beat of complex envelopes into a first-order modulation component. However, the fact that masking effects were still observed when off-frequency listening was precluded argues for the existence of a genuine modulation distortion component. In this condition, the phase effects varied across listeners from 45° to 135° , suggesting that several nonlinear mechanisms may be involved in the generation of modulation distortion.
- (3) When a white-noise carrier is used, combined empirical results and computer simulations of the outputs of auditory filters indicate, again, that cochlear filtering is potentially involved in the conversion of the beat of complex envelopes into a first-order modulation component, but mainly for high carrier modulation frequencies (e.g., 2 kHz). The masking effects observed at lower carrier modulation frequencies when no other sources of conversion play a role (e.g., cochlear filtering or sideband

reflection) are in line with the existence of a modulation distortion component with a phase of $180/225^\circ$ relative to the envelope beat.

- (4) When a white-noise carrier is used, the magnitude of the first-order modulation presumably resulting from one or the interaction of several sources of conversion ranges from 1% to 12% when first- and second-order modulation depths are fixed at 40%. This suggests that this component may be largely audible under certain stimulus conditions. The magnitude of the genuine modulation distortion component is estimated between 5% and 12% when the carrier modulation frequency is 64 Hz.

¹In addition to cochlear filtering, conversion may also occur physically for broadband-noise carriers through intermodulation introduced by sideband reflection. Modulation adds upper and lower sidebands to each spectral component of the carrier with a carrier-to-sideband frequency separation equal to the frequency of the specific modulator component. When sideband placement is either below dc or above the Nyquist frequency of a digital signal, the sidebands mirror about those respective points. A consequence of this sideband reflection is intermodulation in the modulation domain. That is, components are added to the modulation spectrum at the sum and the difference terms between integer multiples of the component frequencies of the modulator. In the case of second-order SAM, this includes a significant component at the second-order modulation frequency. With a white-noise carrier and a relatively high frequency of the first-order SAM carrying the second-order modulation, noticeable sideband reflection can occur. However, since the overall patterns of results in the bandlimited-noise condition, in which reflected sidebands were removed and/or masked (Fig. 5, filled symbols), are similar to those obtained in the white-noise condition (Fig. 5, open symbols), it may be concluded that sideband reflection did not influence the present results obtained with the white-noise carrier.

The effect of spatial separation on informational masking of speech in normal-hearing and hearing-impaired listeners^{a)}

(Received 20 April 2004; revised 30 September 2004; accepted 5 January 2005)

The ability to understand speech in a multi-source environment containing informational masking may depend on the perceptual arrangement of signal and masker objects in space. In normal-hearing listeners, Arbogast *et al.* [J. Acoust. Soc. Am. **112**, 2086–2098 (2002)] found an 18-dB spatial release from a primarily informational masker, compared to 7 dB for a primarily energetic masker. This article extends the earlier work to include the study of listeners with sensorineural hearing loss. Listeners performed closed-set speech recognition in two spatial conditions: 0° and 90° separation between signal and masker. Three maskers were tested: (1) the different-band sentence masker was designed to be primarily informational; (2) the different-band noise masker was a control for the different-band sentence; and (3) the same-band noise masker was designed to be primarily energetic. The spatial release from the different-band sentence was larger than for the other maskers, but was smaller (10 dB) for the hearing-impaired group than for the normal-hearing group (15 dB). The smaller benefit for the hearing-impaired listeners can be partially explained by masker sensation level. However, the results suggest that hearing-impaired listeners can use the perceptual effect of spatial separation to improve speech recognition in the presence of a primarily informational masker. © 2005 Acoustical Society of America. I. INTRODUCTION

The “cocktail party” environment (Cherry, 1953) is particularly difficult for many listeners with sensorineural hearing loss.¹ This environment contains multiple speech sources and often a listener faces the problem of understanding one talker while ignoring one or more others speaking at the same time. Cherry (1953) identified spatial separation between sound sources as one of several potential means by which listeners solve the cocktail party problem. A speech signal masked by speech is affected by at least two types of masking: *energetic* and *informational* (Freyman *et al.*, 1999, 2001; Brungart, 2001; Brungart *et al.*, 2001; Arbogast *et al.* 2002; see also earlier work by Carhart *et al.*, 1968). A noise, on the other hand, generally produces primarily energetic masking.

Energetic masking originates in the peripheral auditory system where the response of the auditory nerve to the masker does not change appreciably when the signal is added. Informational masking, on the other hand, originates at some point beyond the auditory periphery and occurs despite an adequate representation of the signal in the system. At the simplest level, informational masking is masking that cannot be accounted for by energetic masking, similar to what Carhart *et al.* (1968) referred to as “perceptual masking.” Informational masking is believed to occur due to listener uncertainty and/or to a high degree of similarity be-

tween the masker and the signal along one or more relevant stimulus dimensions (e.g., Watson, 1987; Neff and Green, 1987; Kidd *et al.*, 2002b; Durlach *et al.*, 2003b). There is currently considerable discussion about how best to define or compute informational masking and how to relate the results from different speech and nonspeech tasks (e.g., Durlach *et al.*, 2003a). For the purposes of the current study and for these stimuli and experimental task, informational masking is defined as masking beyond that which can be accounted for by energetic masking and is largely due, we believe, to similarity between the signal and masker, often causing them to be confused or attention to be directed to the wrong source.

In normal-hearing listeners the benefit of spatial separation of sources depends on the type of masking. Using non-speech stimuli, Kidd *et al.* (1998) found a significantly larger spatial release from an informational masker (5–40 dB) than from an energetic masker (less than 10 dB) for the identification of pure-tone frequency patterns. Freyman *et al.* (1999), using natural speech stimuli, found no spatial release from a noise masker when the precedence effect was used to create a *perceived* spatial separation between signal and masker. However, there was a 4- to 10-dB spatial release for a speech masker. They concluded that the release was from the informational portion of the masking produced by the speech masker and due to perceptual segregation of the two sources in space (Freyman *et al.*, 1999, 2001). However, natural speech signals and maskers played simultaneously have substantial spectral overlap and thus are likely to contain significant amounts of energetic masking. They also produce an amount of informational masking that is difficult to quantify or control. Therefore, Arbogast *et al.* (2002) used

^{a)}Portions of this research were presented at the Midwinter Meeting of the Association for Research in Otolaryngology, Daytona Beach, FL, January 2003. This research has been included as a portion of a doctoral dissertation by the first author.

processed speech stimuli in order to control, as best as possible, the ratio of informational to energetic masking. They measured the spatial release from masking for a 90° separation of signal and masker and found an 18-dB release from a primarily informational masker and a 7-dB release from a primarily energetic masker. The larger advantage for the informational masker was attributed to the perceptual effect of spatial separation, similar to the interpretation of Freyman *et al.* (1999, 2001). Hearing-impaired listeners generally obtain a spatial release from masking (noise or natural speech masking) that is smaller than normal-hearing listeners (e.g., Peissig and Kollmeier, 1997; Duquesnoy, 1983; Bronkhorst and Plomp, 1989; Hawley, 2000). However, it is not known if these listeners can use the perceptual effect of spatial separation to improve performance in the presence of a masker that is primarily informational.

Previous studies using pure-tone stimuli have found that hearing-impaired listeners can use segregation cues to obtain a release from informational masking, but the release is either smaller or requires a more obvious cue than for normal-hearing listeners [Grose and Hall (1996) for a melody recognition task; Kidd *et al.* (2002a) for detection of a spectrotemporally coherent tone in a spectrotemporally incoherent masker]. It is not known whether listeners with hearing loss can use spatial separation cues to overcome informational masking. Sound sources in realistic environments are often located in different places, affording potential cues for perceptually segregating the sounds they produce. Therefore, it is of considerable interest to determine how well listeners with hearing loss can use spatial cues to reduce informational masking.

The current study investigated the effect of informational versus energetic masking and normal versus impaired hearing on spatial release from masking. Listeners with normal hearing were included to provide age-matched controls. This study used the same stimuli and procedures as Arbogast *et al.* (2002). These stimuli and procedures have the advantage of retaining a high degree of speech intelligibility in a straightforward task that is perhaps less abstract than some nonspeech detection/discrimination tasks while providing better isolation of informational masking than is possible using natural speech. The speech stimuli in the current experiments were a modified version of cochlear implant simulation speech (Shannon *et al.*, 1995) processed in a way that greatly reduces spectral overlap between signal and masker, providing greater isolation of informational masking. In addition to the masker designed to produce primarily informational masking, two other maskers were included. One masker was a control for any potential energetic masking caused by the informational masker. The other was constructed to maximize energetic masking and minimize informational masking, and was included in order to compare the spatial release from masking obtained for primarily informational and primarily energetic maskers. Therefore, the effect of spatial separation was examined as a function of three types of maskers that generate different amounts of masking and which are assumed to originate primarily in either the peripheral (energetic) or the central (informational) portions of the auditory system. The current methods and procedures

TABLE I. Demographic and audiologic data for the hearing-impaired listeners. PTA is the pure-tone average of 500, 1000, and 2000 Hz, in dB HL. WRS (R/L)=word recognition score (right/left). HA=hearing aid.

	Age	Sex	Length of loss (years)	PTA	WRS (R/L)	Etiology	HA use

HI9	67	F	60	48	72/80	unknown/genetic?	bilateral, frequently, 35 years
HI10	79	F	several years	48	80/88	unknown/age?	bilateral, occasional, 1 year

were nearly identical to Arbogast *et al.* (2002) and therefore will only be described briefly here.

II. METHODS

A. Listeners

Two groups of ten listeners were tested. Listeners received monetary compensation for their participation. The normal-hearing (NH) group had audiometric pure-tone thresholds of 20 dB HL or better in each ear for frequencies between 250 and 6000 Hz. In order to ensure a similar age range in each listener group, each NH listener was roughly matched in age (within a decade) to a HI listener. NH listeners ranged in age from 19 to 77 years. Hearing-impaired listeners ranged in age from 19 to 79 years. The hearing-impaired (HI) group was composed of listeners with bilateral, symmetrical sensorineural hearing loss of probable cochlear origin. Symmetrical loss was defined as pure-tone audiometric air-conduction thresholds within ± 10 dB in each ear at most audiometric frequencies between 250 and 6000 Hz. Table I details demographic and audiologic information about the HI listeners. The duration and etiology of hearing loss, as well as hearing aid use, was obtained from a listener questionnaire. Listeners were ordered from lowest to highest threshold in quiet for the speech stimuli used in this study.

The reported duration of hearing loss ranged from 3 to 60 years. The degree of loss ranged from mild to moderate and the configuration ranged from flat to gradually sloping. The mean pure-tone average (of 500, 1000 and 2000 Hz) was

FIG. 1. Mean audiometric thresholds in dB HL for the hearing-impaired listeners. Error bars are ± 1 standard deviation.

37 dB HL. Word recognition scores ranged from 72% to 100% correct but were within $\pm 12\%$ between the ears of any individual listener, using standard, monosyllabic materials. Six of the ten HI listeners wore hearing aids (all bilaterally; testing was unaided). Figure 1 plots mean audiometric thresholds (obtained using standard clinical procedures) in dB HL for the HI group.

B. Stimuli

The stimuli were the same as those used by Arbogast *et al.* (2002) and are described in detail in that article. A brief description is given here. The four male talkers of the coordinate response measure (CRM) corpus of sentences (Bolia *et al.*, 2000) were used. Each sentence had the structure: “Ready [callsign] go to [color] [number] now.” Signal sentences had the callsign “Baron” and each was paired with a randomly chosen masker sentence with a different callsign, color, number, and talker. Each sentence was digitally pre-processed to produce a set of 15 pure tones modulated by the speech envelope in the $\frac{1}{3}$ -octave band centered at each frequency. Center frequencies were evenly spaced on a logarithmic scale from 215 to 4891 Hz. For details of the preprocessing, see Arbogast *et al.* (2002). Signal sentences were generated by combining eight (out of 15) randomly chosen bands. Each masker sentence was used to create three different types of maskers (described below). Signal and masker sentence onset was simultaneous.

1. Different-band sentence (DBS) masker

The different-band sentence (DBS) masker was generated by combining six randomly chosen bands excluding the eight bands used for the signal. Therefore, each signal/DBS masker pair contained mutually exclusive bands. The top panel of Fig. 2 shows the magnitude spectra of a signal/DBS masker pair. The signal is gray and the masker is black. The DBS masker was intended to produce primarily informational masking because it did not overlap the signal in frequency and was similar to the signal sentence in terms of intelligibility (Brungart *et al.*, 2004), overall sound quality due to the pure-tone carriers, and use of the same speech corpus for signal and masker.

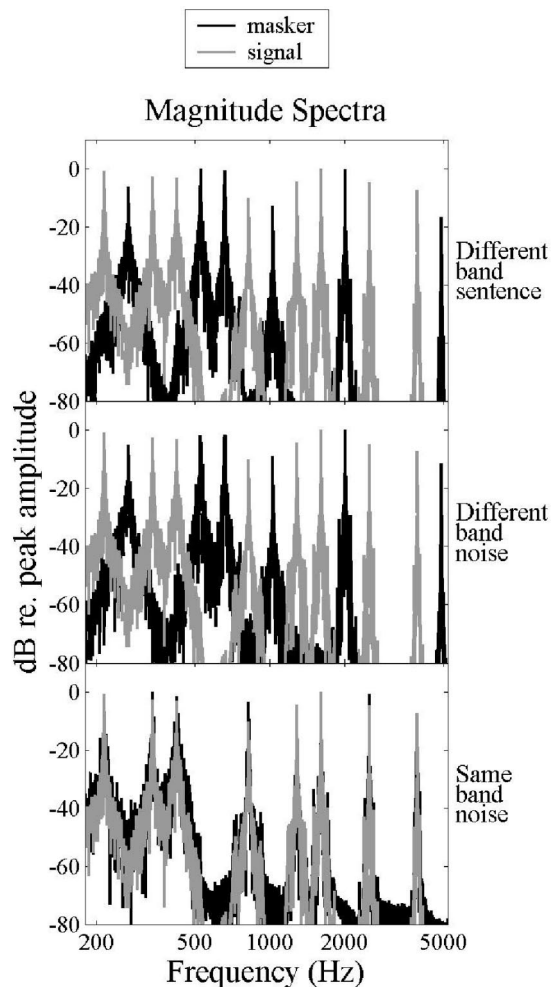

FIG. 2. Magnitude spectra for a sample signal sentence and the three types of processing for the masker sentence. The same signal sentence is plotted in gray in each panel. The black indicates the masker sentence for the different-band sentence masker (top panel), the different-band noise masker (middle panel), and the same-band noise masker (bottom panel).

2. Different-band noise (DBN) masker

The long-term complex spectrum of each DBS masker, described above, was used to shape the spectrum of a random, broadband Gaussian noise and the result was inverse fast Fourier transformed. This masker was intended to produce the same minimal amount of energetic masking as the DBS masker, but also to produce minimal informational masking because it was unintelligible and qualitatively dissimilar from the signal sentence.² This masker was included as a control for energetic masking in the DBS masker. The magnitude spectra of a DBN/signal sentence pair are shown in the middle panel of Fig. 2. The envelope of the DBN masker contains amplitude modulation because the stimulus is essentially the sum of multiple narrow-band noises.³

3. Same-band noise (SBN) masker

This masker was comprised of eight bands of noise that exactly overlapped the eight bands of the signal with which it was paired. The long-term complex spectrum of the eight-band masker sentence was used to shape the spectrum of a broadband Gaussian noise, and the result was inverse fast

Fourier transformed. The magnitude spectra of a SBN/signal sentence pair are shown in the lower panel of Fig. 2. Energetic masking was maximized because the magnitude spectra of signal and masker overlapped. Informational masking was minimized because the masker had no intelligibility and, as with the DBN masker, was qualitatively dissimilar to the signal sentence. The envelope of the SBN masker is similar to that of the DBN masker.

C. Procedures

The experiment took place in a soundfield, located within a single-walled, 12×13 ft², IAC sound booth. When two stimuli were present, they were played simultaneously via two Pioneer S-DF3-K speakers located 5 ft from the listener, one at 0° azimuth and the other at 90° azimuth to the right in the horizontal plane approximately level with the ears. The signal was always played from the speaker located at 0° azimuth. Stimuli were played through Tucker-Davis Technologies (TDT) hardware. The signal and the masker sentences were played through separate channels. Stimuli were converted at a rate of 50 kHz via a 16-bit, 8-channel D/A converter (DA8), low-pass filtered at 20 kHz (FT-6), and attenuated (PA-4). The signal was sent through a programmable switch (SS-1) to route it to the desired signal speaker. The signal and masker were sent to mixers where they were summed if presented to the same speaker. The stimuli were passed through power amplifiers (Tascam) and then to one or two speakers in the soundfield, depending on the experimental condition.

The task was one-interval forced-choice with two responses required on each trial. The first response (color) had four alternatives (blue, red, green, white), while the second response (number) had eight alternatives (1–8). Signal-alone thresholds were obtained using 30-trial blocks of a one-up, one-down adaptive procedure that estimates the 50% correct point on the psychometric function (Levitt, 1971). Masked data were collected with the method of constant stimuli. Four signal levels were chosen for each listener and condition individually in order to estimate the psychometric function. The aim was to produce performance ranging from just above chance to nearly 100% correct. The exact signal levels and level intervals varied depending on the listener, the condition, and the early psychometric function results. Signal levels were mixed randomly within every 50-trial block. On each trial, the listener was required to identify the color and number from the sentence with the call sign “Baron” by entering values on a computer keyboard. Response feedback was provided after each trial.

Each of the three types of maskers was tested in two spatial separation conditions, 0° and 90°, for a total of six masked conditions. In addition, one signal-only condition was tested. The signal sentence was always played at the 0° location and the masker, when present, was played at either the 0° or the 90° location. Each block of trials contained only one spatial separation condition and one masker type. The masker level was set for each listener to approximately 40 dB SL (above signal-alone threshold). However, if comfort or equipment limits were lower, then the highest possible masker level was used. The equipment limit was 88 dB SPL,

but in order to allow for a +10 dB S/M (necessary in most cases to define the upper portion of the psychometric function), the highest masker level permitted was 78 dB SPL. Two blocks of signal-alone identification thresholds were collected first. Masked data were collected in sets of two blocks, each of the same masker/spatial separation condition. Sets of blocks containing each masker and spatial separation condition were alternated to balance any learning effects equally across all conditions. A minimum of 100 trials per signal level was obtained for each spatial separation and masker type. Data were collected within four sessions of 2 h each. Listeners were instructed to keep the head straight, facing the 0° location throughout stimulus presentation.

Training included a 50-trial block of practice of the signal-alone condition. The signal sentences were presented at a comfortable level from the 0° speaker. After achieving a minimum of 90% correct they completed four 50-trial practice blocks of the masked condition with the DBS masker only. This practice included two blocks each for the two spatial separation conditions. The S/M was fixed at +15 dB for the first block and +10 dB for the second block.

Each response was considered correct only if both the color and number of the signal sentence were identified accurately. The psychometric functions were fit by the Nelder-Mead simplex method (FMINS function in MATLAB) with a logistic of the form

$$p(c) = \alpha + ((1.0 - \alpha) / (1.0 + e^{-k(x-m)})), \quad (1)$$

where $\alpha=0.03125$ (chance performance for 1 out of 32), k is the slope of the function, m is the level of the midpoint (about 51.5% correct), and x is the signal sentence level.

III. RESULTS

The amount of spatial release (SR) from masking was calculated as the S/M required for 51% correct performance for the 0° condition minus that for the 90° condition. The amount of informational masking created by the DBS masker was estimated by taking the difference between the midpoints of the psychometric functions for the DBS and DBN maskers presented at 0°. This estimate was based on the type of masking each of the two maskers was intended to produce as discussed above. The purpose of the estimate of informational masking in the current study was to provide a means of comparing performance between listeners and groups.

All listeners were able to perform the task with greater than 90% accuracy in quiet within the first one to two practice blocks. Practice performance for the signal presented with the informational masker was generally good, ranging from 76% to 100% correct, depending on spatial separation and S/M. Masker SLs for the NH group ranged from 33.5 to 43.9 dB with a mean of 38.4 dB. Masker SLs for the HI group ranged from 21.5 to 38.5 dB with a mean of 32.5 dB.

All psychometric functions were orderly and monotonic. Overall, the results were consistent with those from the earlier study (Arbogast *et al.*, 2002), which did not exhibit performance plateaus or dips at S/Ms just below 0 dB. The logistic fits to both the NH and HI data were very good. The

TABLE II. Signal-to-masker ratio at m for the normal-hearing listeners for the two spatial separation conditions. The results for each masker are given in separate subtables. Quiet threshold (Quiet) in dB SPL and masker sensation level (SL) in dB, as well as variance accounted for by the logistic fit (var), are also included. The final column gives the difference between spatial conditions for m .

variance accounted for by the fit in each instance was greater than 92%, and in most cases it was 98% or better. Tables II and III list the S/M at the midpoint (m) from the fitted psychometric functions for NH and HI listeners, respectively. HI listeners are numbered in the same manner as in Table I (ordered by quiet threshold). Each NH listener was matched with a HI listener by age, and then given the same number as their HI counterpart.

A. Signal-to-masker ratios

Figure 3 plots the mean S/M at the midpoint of the psychometric function for the two listener groups and spatial separation conditions. Each panel is for a different masker.

The figure reveals that S/M varied with masker type, listener group, and spatial separation condition. The signifi-

cance of these variations is discussed in more detail below in the context of a statistical analysis of the data.

1. Factors influencing S/M

The S/M data were submitted to an ANOVA with one between-subjects factor (group—NH/HI) and two within-subjects factors (masker and spatial separation). All three main effects were significant: masker [$F(2,36)=330.6$, $p<0.001$], spatial separation [$F(1,18)=237.6$, $p<0.001$], and group [$F(1,18)=20.6$, $p<0.001$]. *Posthoc* simple contrasts revealed that the average S/M ratio for each masker was significantly different from the others. The interaction of masker and spatial separation was significant [$F(2,36)=76.1$, $p<0.001$] as well as the interaction of masker and

group [$F(2,36)=41.1, p<0.001$]. The three-way interaction between masker, group, and spatial separation was also significant [$F(2,36)=13.1, p<0.001$].

Three important points regarding the S/M data were confirmed by the ANOVA results. First, the masker by group interaction revealed that S/M was greater for the HI group than the NH group for the DBS and DBN maskers, but not for the SBN masker. Perhaps most importantly, for the DBN masker the HI group S/M was 13 dB greater than for the NH group. Recalling that the DBN masker estimates energetic masking in the DBS masker, this indicates that the HI group experienced significantly more energetic masking than the NH group for both the DBN and DBS maskers. Second, the main effect of masker and posthoc tests revealed that the DBS masker resulted in a significantly greater S/M than the DBN masker, suggesting that a substantial amount of informational masking was produced by the DBS masker. At 0° the DBS masker caused an additional 22.0 dB of masking in the NH group and an additional 12.3 dB of masking in the HI

group. Third, SR depends on both the type of masker and the listener group.

This three-way interaction is illustrated in Fig. 4 which plots the SR obtained by each group for each of the three maskers. To investigate this interaction further, three one-way ANOVAs were performed on the SR data, one for each masker type, with group as the single between-subjects factor. The results revealed that the SR for the DBS masker was significantly greater for the NH group (15.3 dB) than for the HI group (9.5 dB) [$F(1,18)=9.9, p<0.01$]. However, the SR for the other two maskers was similar for the two groups (3.3 and 4.0 for the DBN [$F(1,18)=0.9, p=0.37$]; 5.9 and 6.4 for the SBN [$F(1,18)=0.3, p=0.59$], for NH and HI, respectively).

Although the HI group obtained a smaller SR than the NH group for the DBS masker, the HI group's advantage was still larger for this masker than it was for the SBN masker (by about 3 dB on average). However, this 3-dB mean difference in SR between the DBS and SBN maskers for the HI

FIG. 3. Group mean signal-to-masker ratios at the 51% correct point on the psychometric function plotted for each listener group (NH/HI). The top panel is for the DBS masker, the middle is for the DBN masker, and the bottom panel is for the SBN masker. Data for the 0° separation condition are plotted in the left half of each panel, and the 90° separation data are plotted in the right half of each panel. The error bars are ± 1 standard deviation.

group is small relative to the nearly 10-dB difference found for the NH group.

2. Factors related to spatial release from informational masking

The NH and HI groups differed in SR for the DBS masker only. Therefore, a correlational analysis was performed which focused on the SR from this masker. One of the factors investigated was an estimate of the amount of informational masking produced by the DBS masker. The DBS masker produced a mean of 22.0 dB of informational masking in the NH group, but a mean of only 12.3 dB of informational masking in the HI group. The majority of the difference between groups can be accounted for by the difference in S/M for the DBN masker (13 dB greater for the HI group than the NH group).

For the NH group, Pearson correlation coefficients were not significant ($p > 0.05$) between SR for the DBS masker and the factors of age ($r = 0.38$), quiet threshold ($r = -0.09$), or masker SL ($r = 0.45$). SR in the NH group was significantly correlated with the estimated amount of infor-

FIG. 4. Spatial release from masking for the two listener groups. The top panel is for the DBS masker, the middle panel is for the DBN masker, and the lower panel is for the SBN masker. The data are group means and the error bars are ± 1 standard deviation.

mational masking ($r = 0.74$, $p < 0.02$). However, a single outlier (NH1) appeared to be responsible for this significant relation. When the outlier was excluded, the correlation was no longer significant ($r = 0.3$, $p = 0.39$).

For the HI group, SR was significantly correlated with the amount of informational masking ($r = 0.76$, $p < 0.01$). In addition, SR was correlated with age ($r = -0.81$, $p < 0.01$), quiet threshold ($r = -0.81$, $p < 0.01$), masker SL ($r = 0.88$, $p < 0.01$), and the mean word recognition score for the two ears ($r = 0.65$, $p < 0.05$). SR was not significantly related to hearing aid use ($r = -0.4$, $p = 0.29$), length of hearing aid use ($r = -0.2$, $p = 0.69$), or length of hearing loss ($r = -0.4$, $p = 0.32$). Age and quiet threshold were not significantly correlated with each other ($r = 0.39$, $p = 0.27$) and, therefore, these two factors may have influenced SR independently. However, quiet threshold and masker SL were significantly correlated with each other ($r = -0.88$, $p < 0.01$), as expected because the masker level was mainly determined by quiet threshold. However, the existence of this correlation means that the relation between SR and quiet threshold may have been a by-product of masker SL. In order to tease these variables apart, a stepwise regression

analysis was performed with SR from the DBS masker as the dependent variable and amount of informational masking, age, quiet threshold, masker SL, and mean word recognition score as the independent variables. The analysis revealed that the combination of amount of informational masking, masker SL, and age explained 97% of the variance in SR from the DBS masker ($p < 0.05$ for all three variables). Quiet threshold and mean word recognition score did not significantly increase the variance accounted for ($p > 0.10$). Type II partial correlations (variable added last) revealed that the amount of informational masking accounts for 6%, masker SL accounts for 12%, and age accounts for 10% of the variance in SR from the DBS masker.

3. The influence of masker sensation level on spatial release from informational masking

Overall, the HI group was tested at a lower masker SL (32.5 dB) than the NH group (38.4 dB). While the mean difference in sensation level was not large, individual sensation levels ranged from 21.5 dB up to 43.9 dB. Therefore, the analysis above was repeated after excluding two from each group. The masker SL for each of these four listeners was more than 1 standard deviation from the mean masker SL of all 20 listeners. NH5, NH7, HI9, and HI10 were excluded. After excluding these listeners, group mean masker sensation levels were 37.3 dB for the NH group and 35.1 dB for the HI group.

SR for the DBS masker remained larger for the revised NH group (15.3 dB) than for the revised HI group (11.1 dB). However, SR for the revised HI group was larger than for the original HI group (9.5 dB). The small increase in SR was mainly due to better performance in the 90° condition. An independent-sample *t*-test revealed that the SR for the DBS masker was not significantly different between the revised NH and HI listener groups [$t(8.9) = 2.2, p = 0.06$].

Four of the NH listeners (NH2, NH5, NH8, and NH10) were retested using a lower masker sensation level. The mean masker SL was 38.8 dB for their first run through the experiment. The second time through the experiment, the mean masker SL was 25.8 dB. SR averaged 18.7 dB for the higher masker SL and 12.3 dB for the lower masker SL. This difference just missed reaching significance on a paired-sample *t*-test [$t(3) = 2.7, p = 0.07$], perhaps due to the small number of listeners. However, in all four cases, SR from the DBS masker was smaller for the lower masker SL than for the higher masker SL.

B. Errors

The proportion of incorrect responses matching the masker sentence was calculated excluding data at the lowest and highest signal levels tested for each listener. This left two signal levels in the middle of the psychometric function from which to analyze the error patterns. Very low S/Ms were excluded because listeners may have purposely responded with some other color/number combination than that heard clearly from the masker sentence in order to increase their chance of guessing correctly. Very high S/Ms were excluded because few errors occurred.

FIG. 5. Percent of incorrect responses that matched the DBS masker color (top panel) or number (lower panel) for the two listener groups. The 0° data are in the left half of each panel and the 90° data are in the right half. The data are group means and the error bars are ± 1 standard deviation. The percent of errors expected by chance is given by the solid line in each panel (33.3% for color and 14.3% for number).

Figure 5 shows the mean percent of errors that matched the DBS masker color and number for the two spatial separation conditions and listener groups. The top panel is for the color response and the lower panel is for the number response. The percent of errors expected for a random distribution of incorrect responses is indicated by the solid line in each panel (33.3% for color; 14.3% for number).

The mean percents of errors from the masker for the NH group in the 0° condition were 70% and 77% for color and number, respectively; for the HI group they were 79% and 83%, respectively. This indicates that listeners in both groups often confused the signal and masker sentences when they were played from the same location. In the 90° condition, the percents of errors from the masker for the NH group were 58% each for color and number; and for the HI group they were 67% and 59% for color and number, respectively. Therefore, both groups of listeners confused the signal and masker sentences less often in the 90° condition than in the 0° condition. A repeated-measures ANOVA with group as the between-subjects factor and spatial separation as the within-subjects factor confirmed a significant main effect of spatial separation for both color [$F(1,18) = 32.37, p < 0.001$] and number [$F(1,18) = 28.86, p < 0.001$]. However, the main effect of group just missed significance for the color response [$F(1,18) = 4.3, p = 0.053$], and was not significant for the number response [$F(1,18) = 0.39, p = 0.54$]. The interaction of spatial separation and group was also not significant for color [$F(1,18) \sim 0, p = 0.99$] or number [$F(1,18) = 0.50, p = 0.49$].

IV. DISCUSSION

A. Informational and energetic masking

Consistent with Arbogast *et al.* (2002), the DBS masker appears to have produced the intended type of masking in both normal-hearing and hearing-impaired listeners. The DBS masker caused 22 dB of informational masking for the normal-hearing group and 12 dB of informational masking for the hearing-impaired group. In a different group of normal-hearing listeners Arbogast *et al.* (2002) also found 22 dB of informational masking. The large proportion of confusions, in both listener groups, between the signal and DBS masker also supports the interpretation that a significant amount of informational masking was present (Brungart, 2001; Brungart *et al.*, 2001; Arbogast *et al.*, 2002). For the 0° condition, both listener groups responded with the masker color and number an average of 75% and 80% of the time, respectively. In the previous group of normal-hearing listeners, Arbogast *et al.* (2002) found the same.

However, the DBS masker produced less informational masking in the hearing-impaired group than in the normal-hearing group. This may be due to greater energetic masking in hearing-impaired than normal-hearing listeners as measured by the DBN masker,⁴ probably as a result of wider auditory filters (e.g., Glasberg and Moore, 1986; Leek and Summers, 1993). The greater amount of energetic masking for the DBN masker for the hearing-impaired group suggests that they will experience a greater amount of energetic masking for the DBS masker also. There are at least two reasons why more energetic masking in the DBS masker might lead to less informational masking in that same masker. One reason is a ceiling effect. Given the baseline S/M due to energetic masking (DBN masker) for the hearing-impaired group (−12 dB), if the DBS masker produced the same amount of informational masking as in normal-hearing listeners (22 dB), one would expect the DBS masker to result in a mean midpoint S/M of about +10 dB for the hearing-impaired group (−12 dB +22 dB of informational masking = +10 dB). However, the actual mean for this group was close to 0 dB S/M. The hearing-impaired listeners may have been able to segregate the signal and masker sentences when the signal sentence was louder than the masker sentence. Therefore, there may have been a critical point just beyond 0 dB S/M for which the available/effective cues changed and the task became relatively easy. Most of the normal-hearing listeners did not reach that ceiling because of the lower S/M for the DBN masker. Brungart (2001), using the (unprocessed) CRM materials and test procedures, reported that performance in speech on speech masking for two different same-sex talkers (one target, one masker) was at about 60% correct at 0 dB S/M. Increasing the level of the target by only 6 dB increased performance to nearly 90% correct, consistent with the proposition that a positive S/M drives performance rapidly toward asymptote.

It is also possible that within a single masker, informational masking decreases when energetic masking increases. Kidd *et al.* (2003) measured harmonicity discrimination of a multi-tone complex in the presence of multi-tone informational maskers. The binaural advantage decreased as the

number of components in the informational masker increased. The interpretation was that increasing the number of components resulted in an increase in energetic masking because masker components were more likely to fall close in frequency to signal components. The increase in energetic masking caused a decrease in informational masking, resulting in a reduced binaural advantage. Similarly, other studies have reported a decrease in informational masking when energetic masking was increased by increasing the number of tones in a multi-tone masker for the task of detecting a pure-tone signal (e.g., Neff and Green, 1987; Oh and Lutfi, 1998).

B. Spatial release from masking

1. DBN masker

The spatial release from the DBN masker averaged 3.7 dB for all 20 listeners, and was not significantly different for the two listener groups. This is very similar to the 3.6-dB release from this same masker found by Arbogast *et al.* (2002) in normal-hearing listeners. It is difficult to compare this result to that of previous research because the masking was off-frequency and mainly energetic. However, one might expect a smaller release from this masker than from an on-frequency energetic masker based on the results of Zwicker and Henning (1984). They found that the masking level difference decreased significantly when the signal and masker did not overlap in frequency than when they were spectrally matched.

2. SBN masker

The mean spatial release from the SBN masker was 6.1 dB for all listeners, and was also not significantly different for the two listener groups. This value is consistent with that found by Arbogast *et al.* (2002) for the same masker (6.9 dB). Similarly, previous research has found spatial release from energetic masking in the range of 5 to 10 dB (Hawley, 2000; Duquesnoy, 1983; Peissig and Kollmeier, 1997; Bronkhorst and Plomp, 1988, 1989, 1990, 1992; Freyman *et al.*, 1999; Zurek, 1993) for a 90° separation between signal and masker. Other studies of hearing-impaired listeners have found mean spatial releases from energetic masking for suprathreshold speech recognition that are somewhat smaller than that found for normal-hearing listeners in the same study (Peissig and Kollmeier, 1997; Duquesnoy, 1983; Bronkhorst and Plomp, 1989). However, similar to the current research, two studies have found that the hearing-impaired group obtained nearly the same release (within 1.5–2 dB) as the normal-hearing group (Bronkhorst and Plomp, 1990; 1992).

3. DBS masker

The mean spatial release from the DBS masker was significantly larger for the normal-hearing group (15.3 dB) than for the hearing-impaired group (9.5 dB). However, for both groups, the spatial release from the DBS masker was significantly larger than the spatial release from either of the other two maskers. The size of the effect for the normal-hearing listeners was smaller than the 18.4-dB release found by Arbogast *et al.* (2002) for the same masker. This difference

may be attributed to the number and mix of listeners tested. The previous study tested four listeners and the range of spatial release produced was only 4 dB. All four listeners were fairly similar to each other for this task. In the current study, the range of spatial release was 15 dB. There were two listeners in particular (NH1 and NH3) with fairly small spatial releases. NH1 performed extremely well for the 0° condition and therefore could not improve by a large amount for the 90° condition. NH3, for some unknown reason, did not perform as well as the other normal-hearing listeners for the 90° condition.

Other studies have also found significant differences in spatial release between informational and energetic maskers. Kidd *et al.* (1998), using pure-tone stimuli, and Freyman *et al.* (1999), using natural speech stimuli, found that the spatial release from a masker producing a high proportion of informational masking was significantly larger than from a masker producing a high proportion of energetic masking. In Kidd *et al.* (1998), the release was 0 to 20 dB larger than the corresponding release from an energetic masker, depending on the listener and the signal frequency. In Freyman *et al.* (1999), the release was about 6 dB larger than from an energetic masker. Therefore, the larger spatial release found in the current study is consistent with the presence of a significant amount of informational masking. The expected spatial release due to binaural interaction and headshadow effects for the DBS masker can be estimated from the DBN masker, which had the same long-term magnitude spectrum as the DBS masker, but minimal informational masking. The release for this control masker was only 3.7 dB. Therefore 5 dB (for the hearing-impaired listeners) to 11 dB (for the normal-hearing listeners) of the spatial effect was beyond that expected for a primarily energetic masker with the same long-term magnitude spectrum as the DBS masker, and therefore most likely attributable to release from informational masking.

It is difficult to compare the results for the DBS masker to other speech research because, in addition to using natural speech stimuli (for which the ratio of informational to energetic masking likely is smaller), stimuli were configured in a way that inadvertently reduced informational masking (reduced stimulus uncertainty by holding the masker sentence constant and/or used a strong segregation cue such as male versus female) in order for the listener to be able to label the signal sentence. Therefore, energetic masking probably played the dominant role in much of this work and the results are more comparable to those found for the SBN masker of the current study. For normal-hearing listeners, Hawley *et al.* (2004) did find a larger spatial release (10–12 dB) from two- and three-talker maskers (where all talkers were the same as the signal talker) than from a two- or three-talker speech-shaped noise or speech-envelope-modulated speech-shaped noise (6–7 dB). However, these conditions were not tested in hearing-impaired listeners.

The results of previous research using pure-tone stimuli have suggested that hearing-impaired listeners do not benefit as much as normal-hearing listeners from segregation of a signal from an informational masker using cues other than spatial separation (cf. Kidd *et al.*, 2002a; Grose and Hall,

1996). Although the results of the current study appear to agree, two factors complicate this interpretation. One factor is that not all listeners in this study were tested at approximately the same masker sensation level and this appears to have at least partially influenced the results, as illustrated by the results of the reanalysis taking sensation level into account. The second factor, which may be related, is that the DBS masker did not produce as much informational masking in the hearing-impaired listeners as in the normal-hearing listeners. If both of these factors were carefully controlled, the difference between groups might very well diminish. Controlling for sensation level is entirely feasible, but controlling for informational masking may be more of a challenge.

Sensation level may have an impact on spatial release because both may be related to the amount of informational masking produced. Alexander and Lutfi (2003) found that informational masking decreased with decreasing masker sensation level in pure-tone stimuli. In addition, it is logical that as informational masking decreases, spatial release from informational masking will also decrease because there is less masking from which to be released. However, the reason for the relation between sensation level and amount of informational masking is not clear. The current research also found other factors relating to spatial release from the DBS masker in the hearing-impaired listeners, including (but not limited to) quiet threshold, age, and word recognition score.

Spatial release from informational masking was also reflected in the errors made by both groups of listeners. When the DBS masker was moved to the 90° position, the percents of incorrect responses matching the masker sentence dropped significantly by 12 and 20 percentage points for color and number responses, respectively. The decreased confusion between signal and masker implies a release from informational masking. This is similar to the finding of Brungart (2001) that when natural signal and masker sentences were segregated by voice fundamental frequency there was a decrease in the number of signal-masker confusions relative to when the two sentences were from the same talker or same-sex talkers.

The larger spatial advantage for the DBS masker than for the SBN masker implies that the perceptual effect of spatial separation between signal and masker (Freyman *et al.*, 1999, 2001; Arbogast *et al.*, 2002) can be used by both normal-hearing and hearing-impaired listeners to decrease informational masking. The ability to perceive that the signal and masker originate from separate locations in space allows the listener to label each sentence appropriately as “signal” or “masker,” effectively reducing confusion between the two sentences, thus reducing informational masking. This implies that the higher-level processes that allow for this perceptual effect are functioning effectively in listeners with peripheral hearing loss. This is consistent with the results of Noble *et al.* (1997), showing that both normal-hearing and hearing-impaired listeners can correctly indicate when two simultaneously presented, equal-level, suprathreshold sources (speech and noise) are spatially separated by 54° more than 85% of the time. Larger azimuthal separations were not tested, but one could speculate that performance would be at

least equal to, if not better than, 85% for a 90° separation. The current research, however, cannot determine if these higher-level processes in hearing-impaired listeners are functioning as well as they do in normal-hearing listeners. While the statistical results of the equal sensation level comparison suggest that they are, the hearing-impaired listeners still did not achieve the same spatial release as the normal-hearing listeners at equivalent sensation levels. In addition, the amount of informational masking created in each listener group differed, confounding the interpretation of the results. However, because listeners with hearing loss were able to benefit significantly from the perceptual effect of spatial separation, it is important to design and fit auditory prostheses in a way that retains the cues that underlie this perceptual effect. The most basic approach would be to provide bilateral amplification for bilateral hearing losses, when appropriate.

The authors are grateful to Andrew Brughera for critical technical assistance and to Robert Shannon and Qian-Jie Fu of House Ear Institute for providing the cochlear implant simulation program. The authors also thank Armin Kohlrausch and two anonymous reviewers for helpful comments on an earlier version of this paper.

¹In the current document, the general term “hearing impaired,” “hearing impairment,” or “hearing loss” will always refer to sensorineural hearing loss, presumably of cochlear origin.

²Although unintelligible, we cannot rule out the possibility that the DBN masker produced a small amount of informational masking because of the trial-to-trial uncertainty about the frequencies of the bands comprising the masker.

³The temporal modulation characteristics of DBS and DBN maskers have recently been studied by Kidd *et al.* (2004). They found that the envelope spectra of the two are similar with maxima in the 1–5-Hz region and a reduction in magnitude above 10 Hz. The envelope spectrum for the DBN has a slightly higher dc component than the DBS and varies smoothly over the range measured. The DBS masker, however, has small peaks roughly corresponding to modulation frequencies that are the inverse of the durations expected of syllables and words. The measured correlation between the envelopes of the DBS and the DBN maskers derived from the same speech sample was near zero.

⁴This statement is made based on S/Ms at the midpoints of the psychometric functions for the DBN masker played at 0° (–25 dB for the NH group; –12 dB for the HI group). Another way to compare groups in terms of energetic masking is to calculate the threshold shift from quiet for the DBN masker. Using this method, the amount of energetic masking is still significantly larger in the HI group (20.7 dB) than the NH group (13.2 dB), but the difference between groups is smaller (7 dB) than when calculated using S/M (13 dB).

(Received 1 March 2004; revised 27 December 2004; accepted 31 December 2004)

The SII model in its present form (ANSI S3.5-1997, American National Standards Institute, New York) can accurately describe intelligibility for speech in stationary noise but fails to do so for nonstationary noise maskers. Here, an extension to the SII model is proposed with the aim to predict the speech intelligibility in both stationary and fluctuating noise. The basic principle of the present approach is that both speech and noise signal are partitioned into small time frames. Within each time frame the conventional SII is determined, yielding the speech information available to the listener at that time frame. Next, the SII values of these time frames are averaged, resulting in the SII for that particular condition. Using speech reception threshold (SRT) data from the literature, the extension to the present SII model can give a good account for SRTs in stationary noise, fluctuating speech noise, interrupted noise, and multiple-talker noise. The predictions for sinusoidally intensity modulated (SIM) noise and real speech or speech-like maskers are better than with the original SII model, but are still not accurate. For the latter type of maskers, informational masking may play a role. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1861713]

I. INTRODUCTION

In daily life, speech is not always equally intelligible due to the presence of background noise. This noise may mask part of the speech signal such that not all speech information is available to the listener. In order to be able to predict the speech intelligibility under such masking conditions, French and Steinberg (1947), Fletcher and Galt (1950), and later Kryter (1962a, b) initiated a calculation scheme, known as the Articulation Index (AI), which at present still is used by a number of investigators (Rankovic, 1998, 2002; Hogan and Turner, 1998; Müsch and Buus, 2001; Brungart, 2001; Turner and Henry, 2002; Dubno *et al.*, 2002, 2003). In 1984, Pavlovic and others (Dirks *et al.*, 1986; Kamm *et al.*, 1985; Pavlovic, 1984, 1987; Pavlovic and Studebaker, 1984; Pavlovic *et al.*, 1986; Studebaker *et al.*, 1987, 1994) started to re-examine the AI calculation scheme, which has led to a new method accepted as the ANSI S3.5-1997 (1997). Since its revision in 1997, the method is named the Speech Intelligibility Index (SII).

For a given speech-in-noise condition, the SII is calculated from the speech spectrum, the noise spectrum, and the listener's hearing threshold. Both speech and noise signal are filtered into frequency bands. Within each frequency band the factor audibility is derived from the signal-to-noise ratio (SNR) in that band indicating the degree to which the speech is audible. Since not all frequency bands contain an equal

amount of speech information (i.e., are not equally important for intelligibility), bands are weighted by the so-called band-importance function. The band-importance function indicates to which degree each frequency band contributes to intelligibility. It depends on the type of speech material involved (e.g., single words or sentences), and other factors. Finally, the SII is determined by accumulation of the audibility across the different frequency bands, weighted by the band-importance function. The resulting SII is a number between zero and unity. The SII can be seen as the proportion of the total speech information available to the listener. An SII of zero indicates that no speech information is available to the listener, an SII of unity indicates that all speech information is available. Model parameters have been chosen such that the SII is highly correlated to intelligibility. The SII model has been developed to predict the *average* speech intelligibility for a given speech-in-noise condition; it does not attempt to predict the intelligibility of the individual utterances (phonemes or words) of a speech fragment. Also, speech redundancy or contextual effects, which are inherent to meaningful speech, are captured in the SII model by choice of the model parameters. Higher speech redundancy simply results in less information (i.e., a lower value for the SII) required for understanding the speech message. Within the context of the present paper, an important observation is that the existing SII model does not take into account any fluctuation in the masking noise, since the SII is computed from the long-term speech and noise spectrum. Therefore, the SII

^{a)}Electronic mail: k.s.rhebergen@amc.uva.nl

^{b)}Electronic mail: n.j.versfeld@amc.uva.nl

is independent of the amount of fluctuations in the noise signal.

Numerous papers have reported on experiments dealing with speech intelligibility in fluctuating noise. In almost all cases, normal-hearing listeners perform better in conditions with fluctuating noise compared to those with stationary noise of the same rms level (Miller, 1947; Miller and Licklider, 1950; Licklider and Guttman, 1957; de Laat and Plomp, 1983; Duquesnoy, 1983; Festen, 1987, 1993; Festen and Plomp, 1990; Gustafsson and Arlinger, 1994; Bacon *et al.*, 1998; Peters *et al.*, 1998; Brungart, 2001; Versfeld and Dreschler, 2002; Dubno *et al.*, 2002; Nelson *et al.*, 2003). In many cases, this finding has been phenomenologically explained by stating that the listener is “able to catch glimpses of the speech during the short silent periods of the masking noise” (Howard-Jones and Rosen, 1992, 1993; Festen, 1993; Peters *et al.*, 1998). Recently, Oxenham and co-workers (Oxenham and Plack, 1997; Plack and Oxenham, 1998; Oxenham *et al.*, 2004) proposed that the nonlinear behavior of the basilar membrane enables increased gain during the silent periods, allowing increased audibility. In hearing-impaired subjects, this nonlinear behavior is less or even absent, which results in decreased audibility during absence of masking noise.

So far, the SII model has been validated only for stationary masking noises, for which it works well. However, it fails to predict speech intelligibility accurately in the case of fluctuating noise maskers (Festen and Plomp, 1990; Houtgast *et al.*, 1992; Versfeld and Dreschler, 2002). Other methods, such as the Speech Transmission Index (STI, Steeneken and Houtgast, 1980), or even the speech-based STI (van Wijn-gaarden, 2002) also fail at this point. To our knowledge, there is still no method that can predict the speech intelligibility in fluctuating noise accurately. Yet, since most real-life noises do exhibit strong variations over time, there is great interest in a procedure that is able to predict speech intelligibility in fluctuating noises adequately.

In the present paper, an extension to the SII model is proposed in order to be able to predict the speech intelligibility not only in stationary noise, but also in fluctuating noise. The extension consists of an approach where, for a given condition, both speech and noise signal are partitioned into small time frames. Within each time frame, the conventional SII is determined, yielding the speech information available to the listener at that time frame. Next, the SII values of these time frames are averaged, resulting in the SII for that particular noise type. It is hypothesized that this averaged SII is closely related to the speech intelligibility for that condition.

In the next section, an outline of the existing SII model is given. It is followed by a detailed description of the extensions to the existing model, which are introduced to allow predictions of the speech intelligibility in fluctuating noises as well. In extending the SII model, attention has been given to stay as close as possible to the original SII model, thus making as few adaptations as possible. In the choice of the model parameters, this paper concentrates on experiments where speech intelligibility has been assessed with the method of the so-called speech reception threshold (SRT), as

described by Plomp and Mimpen (1979). With this method, short everyday sentences are used as speech materials. In Sec. II C the SRT method is described in some detail. Next (in Sec. III) data from the literature are used to evaluate the extended SII model. Finally, in Sec. IV, predictions and limitations of the extended SII model will be discussed.

II. MODEL DESCRIPTION

A. The SII model

A detailed description of the SII model is given in ANSI S3.5-1997 (1997). Here, a brief overview is given so that in the next section the extensions to the existing model are easier to follow.

The SII model basically calculates the average amount of speech information available to a listener. To that extent, the model uses the long-term averaged speech spectrum and the long-term averaged noise spectrum as input. Both speech and noise spectrum are defined as the spectrum level (in dB/Hz) at the eardrum of the listener. Within the model, an option exists to partition the speech and noise spectrum into octave bands, one-third-octave bands, or critical bands. In this paper, spectra are partitioned into critical bands (given in Table I of the ANSI S3.5-1997 standard), although the other two options are equally valid. Within each critical band, the spectrum level is separately determined for both speech and noise. Next, correction factors are taken into account for effects such as upward spread of masking for both speech and noise, inaudibility due to the auditory threshold for pure tones, and distortion due to excessive high speech or noise levels. Then, within each frequency band, the difference between the speech and noise level (signal-to-noise ratio, or SNR) is calculated and this value is multiplied with the so-called band-importance function, which results in the proportion of information in that band that is available to the listener. The band-importance function may depend on the type of speech materials (e.g., sentences or words), or level. Finally, these values are added, yielding the Speech Intelligibility Index (SII), or the amount of speech information available to the listener. For normal-hearing listeners, the SII has proven to be closely related to the average intelligibility in a given condition where speech is masked by a stationary noise masker (Pavlovic, 1987).

B. Extension to the SII model

Since the SII model uses the long-term averaged speech and noise spectrum as input, all temporal characteristics of these signals are lost. As mentioned in the Introduction, large differences in intelligibility exist between masking noises that differ from each other solely with respect to temporal fluctuations (e.g., steady-state versus fluctuating noise). In this section, an extension is presented that does take the temporal characteristics of the masking noise into account. In essence, the SII model is adapted such that the SII is calculated within small time frames, after which the average SII is calculated.

A block diagram of the calculation scheme is presented in Fig. 1. Both speech and noise are analyzed separately for the SII calculation. Although, in principle, regular speech could be used as the speech input signal, speech-shaped

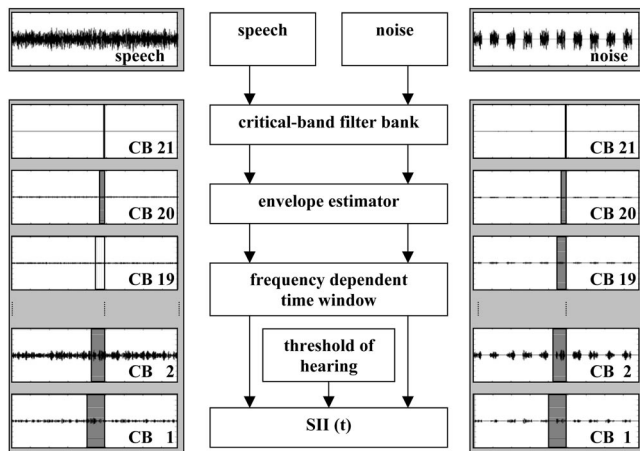

FIG. 1. Schematic overview of the calculation scheme for the extended SII model. A detailed description is given in the main text. The input speech signal (stationary Gaussian noise with the long-term average spectrum of speech) and input noise (in this example interrupted noise with the long-term average spectrum of speech) are separately filtered by a 21 critical-band (CB) filter bank. The envelope of the input speech and noise are estimated in every CB (1–21); the instantaneous intensity is estimated in a frequency-dependent time window, as indicated by the shaded bars (CB1=35 ms to CB21=9.4 ms). Every 9.4 ms an SII is calculated as described by ANSI S3.5-1997. For each of the approximately 200 steps (of 9.4 ms), the instantaneous SII(t) is determined (sentence of about 2 s). Last, the SII for that speech-in-noise condition is determined by averaging across all instantaneous SII(t) values.

noise (i.e., stationary Gaussian noise with the long-term average spectrum of speech) was used. The main reason for this is that, in combination with stationary noise as a noise masker, all SII values are identical to those obtained with the existing SII model. This prerequisite is not easily fulfilled when normal speech signals would be used.

The SII is in principle designed to predict the average intelligibility of speech in noise and not the intelligibility of individual words or phonemes. In any case, the SII is badly defined in case of silent periods occurring within the normal speech signal because, regardless of the masking noise, the SII will always be zero. Thus, even when a speech signal is presented at a clear level without any masking noise, the SII based on regular speech never will reach unity, due to the inherent silent periods in the speech signal. Moreover, problems will occur if one considers the silent periods between sentences. It is clear that large differences in SII may occur when the silent periods between sentences vary, whereas the actual intelligibility should not be different.

The most straightforward approach to determine the SII within small time frames is to window the speech and noise signal at a given point in time, calculate the frequency spectrum (by means of a fast Fourier transform, FFT), and derive an SII from the resulting speech and noise spectrum and the threshold of hearing. However, in order to be able to track the perceptually relevant fluctuations over time, the window length should be small enough. This means that the time window should have a duration of several milliseconds, which is the temporal resolution for normal-hearing listeners based on gap-detection thresholds in the higher frequency bands (Plomp, 1964; Shailer and Moore, 1983, 1987; Glasberg and Moore, 1992; Eddins *et al.*, 1992; Oxenham and

Moore, 1994, 1997; Moore *et al.*, 1996; Plack and Oxenham, 1998; Moore, 1997). Unfortunately, such a short time window leads to the signal-analytical problem that the level in the lower frequency bands is not estimated accurately. On the other hand, a longer time window leads to a poorer grasp of the temporal variations of the signal.

It is known that the temporal resolution of the auditory system is frequency dependent (Shailer and Moore, 1983, 1987). Time constants (i.e., integration times) for the lower frequency bands are larger than those for the higher bands. To overcome the analysis problems on the one hand, and to stay close to the characteristics of the auditory system with respect to temporal resolution on the other hand, the signal was first filtered into 21 critical bands, and the window length was chosen to be relatively short in the higher bands and relatively long in the lower bands. Since in the original SII calculations the frequency bands are essentially nonoverlapping (after all, the intensity within each filter band was derived from the frequency spectrum), a FIR filter bank of order 200 [MATLAB function `firl(200,Wn)`] was used to filter the entire speech and noise signal into the separate bands. Within each band, the temporal envelope was determined by means of a Hilbert transform. At a given time frame, rectangular windows were used with window lengths ranging from 35 ms at the lowest band (150 Hz), to 9.4 ms at the highest band (8000 Hz). These window lengths were taken from Moore (1997, Chap. 4) for gap detection and have been multiplied by 2.5. The factor 2.5 was chosen to provide a good fit to the present data set, as will be discussed below. The windows were aligned such that they ended simultaneously. Within each time frame the intensity was determined, and these, together with the absolute threshold for hearing were used as input to calculate the instantaneous SII, for that given time frame. To calculate the SII, the so-called speech perception in noise (SPIN) weighting function (ANSI S3.5-1997, 1997, Table B.1) was used. This choice seems to be valid, since the speech materials of Plomp and Mimpen (1979) are closely related to the SPIN materials with respect to sentence length and redundancy. Last, the SII for the speech-in-noise condition under consideration was determined by averaging across all instantaneous SII values.

C. Speech reception threshold

In the present paper, the proposed extension to the SII model was evaluated using existing data from the literature. The data differ from each other with respect to a number of variables that all can have an effect on intelligibility, hence on the parameter settings of the SII model. For example, it is known that the type of speech material (monosyllables, words, sentences, etc.), open or closed response set, and native or non-native language acquisition can have a large effect on intelligibility (Bosman and Smoorenburg, 1995; Drullman and Bronkhorst, 2000; van Wijngaarden, 2003). Next, similarity between masker and target, e.g., in the case where both target and masker consist of a male voice (Bronkhorst and Plomp, 1992; Bronkhorst, 2000), has a detrimental effect on the actual threshold (i.e., the signal-to-noise ratio that results in just-intelligible speech). Also, the experimental paradigm influences threshold to a large extent.

The adaptive SRT procedure according to Plomp and Mimpen (1979), and the Just to Follow Conversation (Hygge *et al.*, 1992; Larsby and Arlinger, 1994) result in different threshold levels for the same speech material. Additionally, differences in data acquisition (e.g., strictness of sentence scoring) may have an effect on threshold level. Furthermore, different presentation methods (through headphones, loudspeakers, monaural, binaural, diotic, or dichotic presentation) evidently affect threshold level. If one considers masking noises bearing silent periods, it is likely that, even within a group of normal-hearing subjects, differences in hearing level may affect audibility, and thus intelligibility. Finally, when dealing with spectral differences between masker and target, the method used for calibrating signal levels (e.g., rms, dBA) may have a clear effect.

To enable a comparison between data obtained in different studies, in the present study only thresholds are used that were obtained with the so-called speech reception threshold (SRT) method for sentences, as described by Plomp and Mimpen (1979). Speech materials consist of simple everyday sentences, having a length of 8 to 9 syllables (Plomp and Mimpen, 1979; Nilsson *et al.*, 1994; Versfeld *et al.*, 2000). The SRT is defined as the signal-to-noise ratio (SNR) needed for 50% sentence intelligibility. The SRT is estimated as described by Plomp and Mimpen (1979): A list of 13 sentences, unknown to the listener, is monaurally presented via headphones. The masking noise is presented at a fixed level, whereas the sentence level is varied adaptively. The first sentence starts at a very unfavorable SNR, and is repeated each time at a 4-dB higher level until the listener is able to repeat every word of this sentence exactly. The SNR of the 12 remaining sentences is varied adaptively with a step size of 2 dB using a one-up, one-down procedure. The SNR of the next sentence is increased by 2 dB after an incorrect response and decreased by 2 dB after a correct response. The average adjusted SNR of sentence 4 through 13 is adopted as the SRT for that particular noise condition. With the speech material of Plomp and Mimpen (1979), normal-hearing listeners require an SNR in stationary speech-shaped noise of -5 to -4 dB, which corresponds to an SII between 0.3 and 0.4 (Steeneken, 1992; Bronkhorst, 2000; Noordhoek, 2000; Versfeld and Dreschler, 2002; van Wijngaarden, 2002, 2003). This means that roughly one-third of the speech information is required to the normal-hearing listener (i.e., the SII is between 0.3 and 0.4) to reach the SRT for these sentences.

III. MODEL PREDICTIONS

A. Steady-state speech noise

Speech intelligibility in stationary speech-shaped noise can be well predicted by the existing SII model. There are numerous papers dealing with the SRT in stationary speech noise, and all report for normal-hearing listeners at a fixed noise level between 60 and 80 dBA an SRT for sentences of approximately -4.5 dB (de Laat and Plomp, 1983; Middelweerd *et al.*, 1990; Festen, 1987; Festen and Plomp, 1990; ter Keurs *et al.*, 1993; Versfeld and Dreschler, 2002; Neij-

FIG. 2. Representation of the SII with the extended SII model for a speech-in-noise sample of 2 s. The upper panel represents a speech signal of a female speaker. The middle panel represents a stationary speech-shaped masking speech noise. The noise has been scaled to 60 dBA. The target has been scaled to 55.5 dBA, which results in an SNR of -4.5 dB. The lower panel displays the resulting instantaneous SII as a function of time. The SII averaged across time is equal to 0.35.

huis, 2002). For speech in stationary speech noise, an SRT of -4.5 dB results for the existing SII model in an SII value of 0.35.

Figure 2 displays the results of a calculation with the extended SII model for speech in stationary speech noise. The upper panel in Fig. 2 displays the waveform of a speech signal representation (that is—a stationary speech-shaped noise signal instead of an actual speech signal, as discussed in the previous section) with a duration of 2 seconds, presented at a level of 55.5 dBA. Here, speech noise was taken from Versfeld *et al.* (2000) for the female speaker. The middle panel shows a 2-s sample of the stationary speech-shaped noise masker derived from the same female speaker, at a level of 60 dBA. The lower panel in Fig. 2 shows the resulting instantaneous SII, where the SII has been determined every 9.4 ms. Due to the fact that speech and noise signal are uncorrelated (different noise samples), small fluctuations in the instantaneous SII occur. It is easy to see that the SII, averaged across the 2-s sample, is between 0.3 and 0.4. In fact, the average is 0.35, which is identical to the value obtained by the existing SII model. Many conditions with speech in stationary noise have been studied, and all calculations show that neither speech type nor noise type result in differences between the existing SII model and the present extended SII model. In conclusion, the extended SII model yields exactly the same results as the existing SII model, as long as a stationary masking noise is used.

B. Speech noise with a speech-like modulation spectrum

As discussed above, the existing SII model is not able to correctly predict intelligibility for speech in modulated noise. This section deals with speech intelligibility for speech in noise with a speech-like spectrum and a single-speaker modulation spectrum. The generation of this type of noise is described by Festen and Plomp (1990). With normal-hearing

FIG. 3. Representation of the SII with the extended SII model for a speech-in-noise sample of 2 s. The upper panel represents a speech signal of a female speaker. The middle panel represents a fluctuating speech-shaped masking speech noise, as used by Festen and Plomp (1990). The noise has been scaled to 60 dBA. The target has been scaled to 48 dBA, which results in an SNR of -12 dB. The lower panel displays the resulting instantaneous SII as a function of time. The SII averaged across time is equal to 0.35.

subjects, several papers report for this condition an SRT around -12 dB (Festen and Plomp, 1990; ter Keurs *et al.*, 1993; Versfeld and Dreschler, 2002; Neijenhuis *et al.*, 2002), when the noise level is between 60 and 80 dBA. Computations with the existing SII model yield a score of 0.089, which is far too low. Figure 3 displays the results of the calculations with the extended SII model, similar to the previous section. The upper panel displays the waveform of a speech signal (again, taken as a stationary speech-shaped noise signal) with a duration of 2 seconds, presented at a level of 48 dBA. The middle panel shows a 2-s sample of the modulated speech noise masker, at a level of 60 dBA. The lower panel in Fig. 3 shows the resulting instantaneous SII, where, in contrast to the findings in Fig. 2, the SII value greatly varies over time. It ranges from values close to zero (at points in time where the speech is entirely masked by the masking noise) to values near unity (at points where the masking noise is momentarily absent). The lower panel thus denotes the amount of speech information available to the listener as a function of time. Averaging across time results in an SII score of 0.35. Because large fluctuations exist over time, a suitably long period has to be chosen to average across. The time interval required to reach stable values for the SII depends on the periodicity, or alternatively, randomness, of the signal as well as on the modulation frequencies in the masking signal. With the present type of masking noise, where the modulations are most prominent near 4 Hz, a period of 2 s appears to be long enough to reach a between-samples standard deviation for the SII of 0.0056. Increasing the period to 4 s decreases the standard deviation of the SII to 0.0030.

Figure 4 displays the SII as a function of the SNR. Here, the masking noise has been kept fixed at 60 dBA, and the level of the speech has been varied between 30 and 80 dBA (thus between SNRs of -30 and $+20$ dB). With stationary speech noise (denoted as filled symbols in Fig. 4) the SII

FIG. 4. SII as a function of SNR as calculated with the extended SII model. Filled symbols denote calculations with a stationary noise masker with the long-term spectrum of the female target speaker. Open symbols denote calculations with a fluctuating noise masker with the long-term spectrum of the female target speaker and a speech-like modulation spectrum. The level of the noises was set to 60 dBA.

starts to deviate from zero as the SNR reaches a value of -15 dB and increases almost linearly with the SNR up to a value of $+15$ dB. At this value, the speech level is about 75 dBA, and the distortion factor in the SII model prevents the SII from reaching unity. The behavior of the SII as a function of SNR with stationary noise is identical for the existing and the extended SII model. Differences between the two models arise when fluctuating noise is used as a masker. Since the existing SII model does not take the amplitude modulations in the noise masker into account, the SII as calculated with the existing SII model will be identical to that calculated for stationary noise. The SII as a function of SNR for fluctuating noise predicted by the extended SII model is given with open symbols in Fig. 4. Even at very low signal-to-noise ratios, there is still some speech information available to the listener and the SII exceeds zero. Increasing the SNR causes the SII to increase, but the slope of the function is not as steep as that calculated for speech in stationary noise. Again, at higher speech levels, the distortion factor of the SII model causes the function to level off, such that the SII does not reach unity. An important observation seen in Fig. 4 is that a constant SII value of 0.35 (the information required to reach threshold) results in an SRT of -4.5 dB for stationary masking noise and -12 dB for fluctuating masking noise.

C. Interrupted speech noise

de Laat and Plomp (1983) measured SRTs for sentences in interrupted (gated) speech noise with a duty cycle of 50%. Modulation frequency was 10 Hz. Masking noise was presented at 65, 75, or 85 dBA. Figure 5 displays the calculations with the extended SII model, similar to Figs. 2 and 3. The upper and middle panel show the speech signal and masking noise signal, respectively. Signal and noise level are 42 and 65 dBA, respectively. The SNR thus is -23 dB. The lower panel shows the SII as a function of time. As seen earlier, the SII is close to zero when the masking noise is present, and is close to unity when the masking noise is absent. Due to the longer integration times in the lower fre-

FIG. 5. Representation of the SII with the extended SII model for a speech-in-noise sample of 2 s. The upper panel represents a speech signal of a female speaker. The middle panel represents an interrupted speech-shaped masking speech noise, as used by de Laat and Plomp (1983). The noise has been scaled to 65 dBA. The target has been scaled to 42 dBA, which results in an SNR of -23 dB. The lower panel displays the resulting instantaneous SII as a function of time. The SII averaged across time is equal to 0.35.

quency bands, the SII does not change as rapidly as the interrupted noise, but rather smears out over time. Again, the SII averaged across time is equal to 0.35.

Figure 6 displays the SII as a function of SNR for stationary speech noise (filled symbols), and for the three conditions with 10-Hz interrupted noise used in de Laat and Plomp (1983, open symbols; noise at 65, 75, and 85 dBA). At low SNRs (between -15 and -35 dB), speech is entirely masked at moments when the masking noise is present, and it is audible in the gaps. Due to the gaps in the masking noise, values for the SII are relatively independent of SNR and are still quite large, on the order of 0.3. At even lower SNRs (below -35 dB), SII eventually decreases to zero, due to the fact that the speech signal will fall below the absolute

FIG. 6. SII as a function of SNR as calculated with the extended SII model. Filled symbols denote calculations with a stationary noise masker with the long-term spectrum of the female target speaker at a level of 60 dBA. Open squares, circles, and triangles denote calculations with the interrupted noise masker with the long-term spectrum of the female target speaker where the level of the noise was set to 65, 75, and 85 dBA, respectively.

FIG. 7. SII as a function of SNR as calculated with the extended SII model. Filled symbols denote calculations with a stationary noise masker with the long-term spectrum of the female target speaker at a level of 75 dBA. Open squares, circles, diamonds, and triangles denote calculations with SIM noise as a masker at a level of 75 dBA, and a modulation frequency of 4, 8, 16, and 32 Hz, respectively.

threshold. Absolute threshold here has been taken equal to 0 dB (HL). At an SNR of -15 and larger, portions of the speech signal start to exceed the noise signal, and SII increases. Again, at high speech levels, distortion occurs which causes the function to level off. de Laat and Plomp (1983) found an SRT of -23 , -26 , and -29 dB at a presentation level of the noise of 65, 75, and 85 dBA, respectively. Figure 6 shows that for these conditions a large variation in the SNR causes only a slight variation in the SII. At time frames where the noise signal is present, no speech information is available; but at time frames where the noise masker is absent, the amount of speech information available is determined by the degree of temporal resolution (i.e., forward and backward masking) as well as by the absolute threshold of hearing. Nevertheless, while computations with the existing SII model give an SII of zero, the extended SII model results in values near 0.35.

D. Sinusoidally intensity-modulated speech noise

Festen (1987) measured the SRT for sentences in 100% sinusoidally intensity-modulated (SIM) speech noise. At a presentation level of the noise of 75 dBA he found SRTs of -7.5 , -9 , -10 , -10.2 , and -4 dB for modulation frequencies of 4, 8, 16, 32, and “infinity” Hz (steady state), respectively. Figure 7 displays the SII as a function of SNR for stationary speech noise (filled symbols), and for four conditions with SIM noise used in the study of Festen (1987, open symbols). Computations with the extended SII model, given an SII of 0.35, result in SRTs of -10 , -9 , -8 , -6.3 , and -4 dB for the above-mentioned conditions. The predicted SRT in a 4-Hz SIM noise with the extended SII model seems to be lower compared to SRT values obtained by Festen (1987). Furthermore, the predicted SRT in a 16- or a 32-Hz SIM noise with the extended SII model seems to be higher compared to SRT values obtained by Festen (1987). Although the SRT values obtained with the extended SII model indicate an improvement over the existing model (which pre-

FIG. 8. SII as a function of SNR as calculated with the extended SII model. Filled symbols denote calculations with a stationary noise masker with the long-term spectrum of the female target speaker. Open squares, circles, diamonds, and triangles denote calculations with noise derived from a single, two, four, and six speakers speech-shaped noise. The level of the noises was set to 65 dBA.

dicts an SRT of -4 dB for all conditions), there are still some deviations. So far, no explanation can be given for this result.

E. Multiple-talker noise

There are numerous papers dealing with the SRT for speech in the presence of one or more competing talkers (e.g., Festen and Plomp, 1990; Bronkhorst and Plomp, 1992; Bronkhorst, 2000; Drullman and Bronkhorst, 2000; Brungart, 2001; Brungart *et al.*, 2001, 2002). It is generally observed that the SRT becomes worse as the number of competing voices increases (Miller, 1947; Carhart *et al.*, 1969; Bronkhorst and Plomp, 1992), eventually resulting in the SRT for stationary speech noise. Bronkhorst and Plomp (1992) measured the SRT for sentences masked by speech-shaped noise modulated by the envelope derived from one, two, four, or six interfering speakers. Observed SRTs were -9.7 , -9.9 , -7.2 , and -6.4 dB, respectively. The stimuli, i.e., speech and fluctuating speech noise, were recorded with a KEMAR manikin and presented monaurally to the subjects. Figure 8 displays for the four conditions of Bronkhorst and Plomp (1992) calculations of the extended SII model as a function of the signal-to-noise ratio where it was attempted to simulate Bronkhorst and Plomp's (1992) speech-shaped noises. It shows that at an SII value fixed at 0.35, the SRT increases from -12 dB (for a single interfering speech shaped noise) to -6 dB (for six interfering speech-shaped noises). Although the masking noises were regenerated, since the original masking noises of Bronkhorst and Plomp (1992) were not available, the trend is similar to that reported in the original study.

IV. DISCUSSION

Figure 9 displays the relationship between the observed SRT (i.e., as measured in actual experiments) and the SRT as predicted by the extended SII model for all conditions de-

FIG. 9. For a number of different masking noises, the SRT (dB) predicted with the extended SII model is plotted as a function of the observed SRT (dB). Conditions are denoted in short in the figure.

scribed in the previous section, as well as some other conditions that will be discussed below. SRTs were calculated by taking the hearing loss fixed at 0 dB(HL) at all audiometric frequencies, and by setting the threshold value of the SII to 0.35. Different SRTs were obtained by taking the associated sample of the masking noise. The diagonal indicates the points where the observed and predicted SRT are equal. Points under the diagonal indicate an overestimation (with respect to performance) of the predicted SRT; points above the diagonal indicate that listeners generally perform better than predicted by the extended SII model. All predicted SRT values are within a few decibels of the diagonal, or even lie on the diagonal, indicating that the model does well with the present set of data. The extended SII model yields a substantial improvement over the existing model. Since the latter is insensitive to modulations in the masking noise, it thus predicts for practically all conditions an SRT of -4.5 dB. The most important finding of this paper is that average speech intelligibility in fluctuating noise can be modeled by averaging the amount of speech information across time.

If the data in Fig. 9 are considered in detail, some of the results obtained with the SIM noises of Festen (1987) seem to deviate to some degree from the diagonal. Festen (1987) found lowest SRTs for modulation frequencies of 16 and 32 Hz. His finding is in contrast with most data from the literature that indicate maximum performance at 10 Hz (Miller and Licklider, 1950; Licklider and Guttman, 1957; Gustafsson and Arlinger, 1994; Trine, 1995; Bronkhorst, 2000; Nelson *et al.*, 2003). The difference in the position of the minimum may be attributable to differences in stimulus type (gated noise versus SIM noise) and speech materials (word versus sentence scoring). There appears to be a large difference in the SRT results (about 16 dB) found by de Laat and Plomp (1983) and Festen (1987) obtained with about the same modulation frequencies [modulation frequency: 10 Hz; SRT: -26 dB for de Laat and Plomp (1983), compared to modulation frequency: 8 Hz: SRT -10 dB for Festen (1987)]. Festen (1987) suggested that this discrepancy can be due to the relatively broad and deep minimum in the inter-

rupted noise compared to that in the SIM noise (Fig. 2 from Festen, 1987). The SRT values, obtained with 16- and 32-Hz SIM noise are very similar, *viz.*, -10 dB, and are 2 to 3 dB better than predicted by the extended SII model. As for now, we have no explanation for this part of Festen's (1987) data. Increasing the modulation frequency of the SIM noise results in gaps that are sufficiently small such that they start to fall within the time window of the extended SII model (*i.e.*, smaller than 35 ms). This results in a decrease in performance, and finally performance will approach that of stationary noise. This condition is indicated by "SIMinf.Hz" in Fig. 9, and is close to the diagonal. Decreasing the modulation frequency to 8 Hz also results in a point close to the diagonal. However, a further decrease of the modulation frequency to 4 Hz again results in a deviation from the diagonal. The overestimation of the 4-Hz SIM noise may be accounted for by the fact that with these slow modulation rates, masking of complete words in a sentence can occur. This phenomenon has already been observed by Miller and Licklider (1950), who found optimal performance around modulation rates of 10 Hz. The mere fact that complete words are masked implies that the SRT procedure—where every word of the sentence needs to be repeated correctly—is unsuitable for these low modulation frequencies. Indeed, Trine (1995) shows that in the so-called Just-to-Follow-Conversation (JFC) procedure, the signal-to-noise ratio keeps on decreasing below modulation rates of 8 Hz. In this procedure, the subject is asked to adjust the level of speech in a fixed given noise masker such that he or she is able to "just follow" the speech. This procedure does not require the intelligibility of individual syllables, words, or even sentences. Therefore, the optimum performance for 8 Hz is a procedural artifact. Hence, to validate the extended SII model for masking noises comprising modulation rates of, say, 8 Hz and below, procedures other than the SRT procedure of Plomp and Mimpen (1979) should be utilized.

A. Effect of informational masking

The extended SII model may not be able to predict SRTs accurately in conditions where speech and masking noise interfere at a higher level. One example of such interference is when both target speech and masking noise are derived from the same speaker. In that condition, the listener is confused since he or she does not know which signal represents the target and which components of the signal represents the masker. Festen and Plomp (1990) describe a number of conditions where speech is masked by a single speaker or by multiple speakers. Indeed, performance for speech intelligibility in time-reversed masking speech is better than for forward-masking speech. This additional masking, on top of energetic masking, is called informational masking (Bronkhorst, 2000; Brungart, 2001; Brungart *et al.*, 2001): The spoken message of real interfering speech accounts for a rise in SRT.

In another experiment, Festen (1993) measured SRTs in other speech-like maskers. The target speech was uttered by a female speaker (of Plomp and Mimpen, 1979). The interfering speech consisted of comparable sentences from a male voice (Smooenburg, 1992). In the reference condition, the

FIG. 10. The SRT (dB) predicted with the extended SII model is plotted as a function of the observed SRT (dB) for the noise maskers used in Festen (1993). Conditions are denoted by abbreviations in the figure. In conditions B02 through B24, conditions consisted of speech fragments that were manipulated by shifting individual frequency bands of the noise masker independently over time. In conditions CB3, CB6, SB3, and SB6, half of the speech masker was replaced by stationary speech noise. For further details the reader is referred to the main text.

interfering speech signal consisted of a concatenation of sentences, with no pauses between the sentences. Five other conditions were derived from this reference condition by first dividing the masking speech stream into 2, 3, 6, 12, or 24 separate frequency bands that next were independently shifted in time. One may see this masker as an addition of 2, 3, 4, 6, 12, or 24 speakers where the speech of the individual speakers does not overlap in frequency. The result is a masker that sounds very speech-like. The measured SRTs as well as the SRTs calculated with the extended SII model are displayed in Fig. 10. Different conditions are denoted as B02, B03, B06, B12, and B24, where the number denotes the number of frequency bands. The extended SII model appears to overestimate the observed SRT values of all conditions by 4 to 5 dB. Although speech and noise masker were well discernible, informational masking may have played a role, since the maskers still resembled running speech.

In addition to these conditions, Festen (1993) generated other maskers, where the upper 1/3 octave of each frequency band in the 3- and 6-band speech masker was replaced by noise of the same level as the time average of the original masker. Maskers therefore consisted half of stationary speech-shaped noise. The modulated part was either synchronous in time (labeled in Fig. 10 as "CB" for "constant bands") or shifted in time (labeled in Fig. 10 as "SB" for "shifted bands"). As can be seen in Fig. 10, the extended SII model is able to predict the SRT of all these noise conditions (CB3, CB6, SB3, and SB6) reasonably well, probably due to the fact that the masker is less speech-like.

In summary, when speech-like maskers are used, it is expected that the obtained thresholds are worse than predicted by the extended SII model due to additional (*i.e.*, informational) masking.

B. Steepness of the psychometric function

Festen and Plomp (1990) measured entire psychometric functions for speech in stationary and fluctuating noise. Given the larger dynamic range of fluctuating noise, one would expect a larger range in SNR in which the speech is audible, hence a shallower slope for the fluctuating noise masker. Indeed, with normal-hearing subjects, at the level for which a score of 50% is obtained, Festen and Plomp (1990) found a slope of 21.0%/dB and 11.9%/dB for stationary noise and fluctuating noise, respectively. The present Fig. 4, too, shows a shallower slope for fluctuating noise. With the extended SII model, it is possible to predict the slope of the curve obtained with fluctuating noise from that obtained with stationary noise. To that end, it first should be noted that for SNRs from -9 to -1 dB the psychometric curve with stationary noise in Fig. 6 of Festen and Plomp (1990) ranges from 0% to 100%. Figure 4 shows that this SNR range corresponds to a range for the SII of 0.2 to 0.5. An important observation hence is that within the range of 0.2 to 0.5 of the SII, sentence intelligibility changes from 0% to 100%. Within that range for the SII, both curves in Fig. 4 can be well approximated by a linear function. The curve for stationary noise is given by

$$SII_S = (15 + SNR_S)/30, \quad (1)$$

the curve for fluctuating noise is given by

$$SII_F = (27 + SNR_F)/40. \quad (2)$$

Festen and Plomp (1990) describe their curves with a logistic function

$$p(SNR) = \frac{1}{1 + e^{(M - SNR)/S}}, \quad (3)$$

where M is the SNR for which the probability on a correct response $p(SNR)$ is equal to 0.5, and S is the steepness of the function at $p(SNR) = 0.5$. For the stationary noise curve in Fig. 6 of Festen and Plomp (1990), $M = -4.7$ dB and $S = 1.19$ dB (corresponding to 21.0%/dB as given by Festen and Plomp, 1990). For the fluctuating noise curve, $M = -9.7$ dB and $S = 2.10$ dB (corresponding to 11.9%/dB). The data of Fig. 6 of Festen and Plomp (1990) are replotted in Fig. 11, together with the two functions given by Festen and Plomp (1990), given as solid curves. When $SII_S = SII_F$, Eqs. (1) and (2) give the relation between SNR_S and SNR_F

$$SNR_S = (21 + 3SNR_F)/4. \quad (4)$$

By insertion of Eq. (4) into Eq. (3), the shape of the function for fluctuating noise is obtained. This curve is plotted as a dotted line in Fig. 11. The predicted curve for fluctuating noise has a slope of 15.6%/dB and a value for M of -13.3 dB. The curve is about 3.8 dB to the left of the data of Festen and Plomp (1990), but has a slope that fits very well to the data of Festen and Plomp (1990), as can be seen when the curve is shifted 3.8 dB to the right, as has been done in Fig. 11 (dashed curve). The slope fits their data even better than their calculated slope of 11.9%/dB. The fact that the calculated curve does not fall on top of the data of Festen and

FIG. 11. Percentage of sentences correct as a function of signal-to-noise ratio (dB), for a stationary noise masker (open symbols) and fluctuating noise masker (filled symbols) (replotted from Festen and Plomp, 1990). The two solid curves represent Festen and Plomp's (1990) fit to the data. The dotted curve is predicted by the extended SII model, based on the curve given by Festen and Plomp (1990) for stationary noise. The dashed curve (without symbols) is identical to the dotted curve, except for a shift of 3.8 dB to the right.

Plomp (1990) is due to the fact that Festen and Plomp (1990) shifted their data to the average results.

C. Effect of absolute threshold

With the calculation of the SII, it was assumed that all subjects had normal hearing; that is, thresholds for all frequencies were taken equal to 0 dB(HL). In real life, thresholds deviate to some degree from this value, but with the normal-hearing group it is generally assumed (ANSI S3.6-1996, 1996) that the hearing level is equal to or less than 15 dB(HL). Given the dynamic range of speech (30 dB) and the presentation level of the masking noise, one can calculate the effect of an elevated threshold. With stationary speech noise as a masker, audibility of average conversational speech starts to play a role only at losses of 50 dB(HL) and larger, as can be calculated with the existing SII model. In contrast, with fluctuating noise and interrupted noise, effects become already noticeable at thresholds of 30 or 15 dB(HL), respectively. The effect of hearing loss on the SII is depicted in Fig. 12 for both a stationary noise masker and an interrupted noise masker. As can be seen in this figure, elevating the threshold from 0 to 15 dB(HL) has no effect on the SII with stationary noise, but has a clear effect with interrupted noise. The two curves with interrupted noise start to overlap near an SNR of -15 dB. For the calculations with the extended SII model, little differences in prediction of the SRT in stationary noise were found by variation of the absolute threshold (HL < 50 dB). Figure 12 nevertheless shows that with these fluctuating noise maskers, the effect of absolute threshold can be substantial, especially at lower presentation levels. This could account for the large standard deviation between subjects found by SRT in fluctuating noises (de Laet and Plomp, 1983; Festen, 1987, 1993; Festen and Plomp, 1990; Bronkhorst, 2000; Versfeld and Dreschler, 2002) com-

FIG. 12. SII as a function of SNR as calculated with the extended SII model. Filled symbols denote calculations with the absolute threshold set to 0 dB(HL). Open symbols denote calculations with the threshold set to 15 dB(HL). Circles and triangles indicate calculations with a stationary noise masker and squares indicate calculations with interrupted noise masker, respectively, both with the long-term spectrum of the female target speaker. The level of the noises was set to 65 dBA.

pared to the small standard deviation between subjects found by SRT in stationary noises (Plomp and Mimpen, 1979).

D. Effect of window length

With the presentation of the extended SII model, the signals were windowed in time and the length of the time window was frequency dependent. The choice of the time windows was adapted from Moore (1997) and was based on psychophysical data. As discussed above, given these settings, the extended SII model is able to predict the data well. Within a time window, level variations of the signal are averaged. Thus, the longer the time window, the more the signal is smoothed, thus the more the obtained SII will resemble the existing SII (i.e., the SII of stationary noise). On the other hand, if the time windows are taken smaller, all signal variations are caught, which in the case of highly fluctuating maskers as interrupted noise results in better SRTs than actually measured. Calculations have been performed to check whether a single fixed window length for all frequency bands could account for the present data set as well. The results of these calculations show that an optimum fit was obtained with a fixed window length of 12 ms, but that this approach could not account for the data as well as the approach with frequency dependent windows. Yet, it remains possible to manipulate the lengths of the individual time windows, in order to reach an even better fit to the data. However, the present choice of parameters does well, and has the advantage that the window lengths are derived from psychoacoustical measurements. In this paper, rectangular windows have been taken, but future experiments may point to the use of differently shaped windows, such as an exponential window. The latter shape may be more similar to the shape of the forward-masking function.

E. Extensions to the model

In this paper the authors purposely have tried to stay as close as possible to the existing SII model. Extensions to the existing SII model have been proposed, which seem to work well for the SRT with sentences in a given number of noise maskers. To see to what extent the model can be generalized to other types of speech material and noise maskers, measurements should be performed. Although the basic assumptions regarding the extensions may remain valid, it seems plausible that, as with the existing SII model, different speech materials require different weighting functions or window lengths. With the present data set, an SII of 0.35 corresponded to the amount of information required to reach the SRT. These data were obtained with normal-hearing listeners. As discussed extensively by Noordhoek (2000), hearing-impaired subjects often require more speech information to reach threshold, which she attributed to suprathreshold deficits. These deficits probably deal with a decrease in spectral or temporal resolution. With the extended SII model, both decreases in resolution can in principle be modeled by increasing the width of the different frequency bands, or by increasing the window length or window shape. Perhaps more sophisticated adaptations to the SII model [such as the temporal window model of Oxenham (Oxenham and Moore, 1997; Oxenham and Plack, 1997)] are required. It is left to future research to find the extent to which the model is able to describe the data.

F. Other extensions to the SII model

Another shortcoming of the SII model is its inability to account for synergetic and redundant interactions among the various spectral regions of the speech spectrum (Steeneken and Houtgast, 1999; Müsch and Buus, 2001). Due to fact that the SII uses the long-term spectrum of speech and noise (minimum length of 30 s; ANSI S3.5-1997, 1997), these interactions among the various frequency bands are lost. Nevertheless, speech communication is remarkably robust for normal-hearing listeners and does not have to be broadband to be highly intelligible (Allen, 1994; Warren *et al.*, 1995; Lippmann, 1996; Stickney and Assmann, 2000). Steeneken and Houtgast (1999, 2002) implemented a frequency-dependent redundancy correction factor to the STI model, which accounts for synergetic and redundant interactions. Since the STI is related to the SII (van Wijngaarden, 2002), it is in principle possible to implement this redundancy correction factor in the SII calculation method.

V. SUMMARY

The present paper describes an SII-based approach to model SRTs (speech reception thresholds) for sentences masked by fluctuating noise. The basic principle of this approach is that both speech and noise signal are partitioned into small time frames. Within each time frame the instantaneous SII is determined, yielding the speech information available to the listener at that time frame. Next, the SII values of these time frames are averaged, resulting in the SII for that particular noise type. From the literature many SRT values are available for a variety of noise types. In this paper,

it is shown that this approach can give a good account for most existing data. Hence, it forms a valuable extension to the existing SII (ANSI S3.5-1997, 1997) model.

ACKNOWLEDGMENTS

The authors acknowledge Joost Festen and Rob Drullman for providing sound materials of the masking noises used in their papers. Tammo Houtgast, Joost Festen, Gaston Hilkhuisen, and Wouter Dreschler are acknowledged for the stimulating discussions. We are also grateful to Maarten van Beurden, Wouter Dreschler, and Bas Franck for their comments on earlier versions of this paper. We thank the associate editor, Peter Assmann, and the two anonymous reviewers for their detailed constructive comments. Finally, Jan Koopman and especially László Körössy are acknowledged for their help with the computer programming.

Perception of pitch location within a speaker's F0 range^{a)}

Douglas N. Honorof^{b)} and D. H. Whalen

Haskins Laboratories, 270 Crown Street, New Haven, Connecticut 06511

(Received 24 March 2004; revision received 2 November 2004; accepted 5 November 2004)

Fundamental frequency (F0) is used for many purposes in speech, but its linguistic significance is based on its relation to the speaker's range, not its absolute value. While it may be that listeners can gauge a specific pitch relative to a speaker's range by recognizing it from experience, whether they can do the same for an unfamiliar voice is an open question. The present experiment explored that question. Twenty native speakers of English (10 male, 10 female) produced the vowel /a/ with a spoken (not sung) voice quality at varying pitches within their own ranges. Listeners then judged, without familiarization or context, where each isolated F0 lay within each speaker's range. Correlations were high both for the entire range (0.721) and for the range minus the extremes (0.609). Correlations were somewhat higher when the F0s were related to the range of all the speakers, either separated by sex (0.830) or pooled (0.848), but several factors discussed here may help account for this pattern. Regardless, the present data provide strong support for the hypothesis that listeners are able to locate an F0 reliably within a range without external context or prior exposure to a speaker's voice. © 2005 Acoustical Society of America. I. INTRODUCTION

Fundamental frequency (F0) carries information about many different linguistic and paralinguistic aspects of the speech signal, but it does so in a speaker-dependent way. A pitch-accent system like that of Japanese, for example, distinguishes words on the basis of which mora bears a shift in relative F0. However, F0 height is not specified by the language in general; rather, what counts as high or low varies by speaker (Leather, 1983; Moore and Jongman, 1997). Irrespective of which parameters require F0 manipulation in a given phonology, the most obvious source of difference in pitch is speaker sex. Peterson and Barney (1952) found a difference of approximately three-quarters of an octave between adult males and adult females in average F0s of citation-form monosyllables across vowels, and approximately a full octave's difference when comparing analogous F0 measures for adult males and children. It appears, then, that "high pitch" cannot be specified as a particular F0 value, because any value (if attainable) could be high for some speakers and low for others.

How, then, do listeners gauge where within the speaker's range a particular pitch lies? One possibility, of course, is that direct exposure to a voice over time allows a listener to learn the range of pitches that a speaker can and does produce. If so, the perception of linguistic pitch targets may become possible as a function of exposure to a speaker's voice. Indeed, there is evidence that familiarity with a voice is a factor in speech perception. For example, words spoken by familiar voices are easier to recognize (Palmeri *et al.*, 1993) and identify in noise (Nygard and Pisoni, 1998). Such effects of familiarity in perception are not surprising given that linguistic and sociophonetic features are intertwined

with speaker-indexical information in the speech signal (Ladefoged and Broadbent, 1957; Fellowes *et al.*, 1997; Remez *et al.*, 1997) and in word memory (Goldinger, 1996). It may be that listeners perform "speaker normalization" in order to strip away linguistically extraneous information from the linguistic message, but it is at least as likely, as recent findings suggest, that listeners use a normalization strategy in order to disentangle invariant phonological information and invariant speaker information from each other without necessarily forgetting the latter (see Sheffert and Fowler, 1995). There may remain much that we do not yet understand about how speaker normalization is accomplished by human listeners (e.g., Johnson and Mullennix, 1997), but we should be careful not to assume that perception always entails a computational process of normalization. Clearly, listeners successfully perceive the speech of unfamiliar voices—voices not stored in memory. In such cases, no exposure-based normalization strategy is available to the listener.

It is unclear whether previous exposure to a voice is required for accurate pitch perception. When a sentential context is given, listeners can estimate the location of a pitch within a speaker's range (Wong and Diehl, 2003). Other studies suggest success with contexts even shorter than a sentence. For example, in some languages, there are utterances as short as a single syllable that span a large region of the speaking range as in the case of the falling tone of standard Mandarin, in which case exposure to a single utterance of a single tone might, conceivably, provide enough information about a speaker's range to allow listeners to normalize F0. Indeed, a study by Moore and Jongman (1997) indicates that perception of a Mandarin tone having an F0 turning point or change in F0 does not depend on context, thus dynamic F0 is presumably calibrated syllable internally. If prior exposure to a short contour is required for the listener to succeed at normalizing pitch, logically, the listener should

^{a)}Portions of this work were presented at the 146th Meeting of the Acoustical Society of America, Austin, Texas, November 2003.

^{b)}Electronic mail: honorof@haskins.yale.edu

not be able to normalize pitch correctly if presented only with *steady* F0s. It remains to be seen whether listeners can correctly assess the location of F0 within the spoken pitch range (*tessiture*) of an unfamiliar individual on the basis of isolated *natural* utterances without first having been exposed to F0 contours within the speaker's range.

If perception of steady F0 does not require prior exposure to the speaker's range, we must determine how the listener is able to accomplish the task. One basis for pitch location within an F0 range might be voice quality. The literature has produced a number of differing claims regarding the nature of dependencies between voice quality (as reflected in glottal pulse characteristics) and F0. Common measures of glottal pulse characteristics include overall intensity, the open quotient of the voice source (that is, the relative time during which the glottis remains open during a pitch period), skewness of the glottal pulse, the strength of the relationship between the amplitudes of F0 and $F0^2$ (that is, $H2-H1$), etc. Swerts and Veldhuis (2001) review this literature and present the results of a highly constrained study of their own aimed at exploring the proposal that listeners "might be able to locate an utterance in a speaker's speech range on the basis of voice quality (298)." They conclude that there is some evidence that the perception of F0 depends on voice quality, but do not go so far as to explore directly the ramifications of such a finding for perception (see also Fant *et al.*, 1985; Klatt and Klatt, 1990; Gobl and Ní Chasaide, 1992). Di Paolo and Faber (1990) have reported that voice quality (breathy versus creaky phonation as indexed by $F1-F0$) can be used by listeners to distinguish tense from lax vowels. Taken as a whole, these studies make direct assessment of voice quality a possible means for the immediate normalization of an individual speaker's pitch without prior exposure to a broad range of productions by the voice of the individual. Therefore, we hypothesize that listeners should be able to use immediately available information about voice quality to locate where within a speaker's range the pitch of a vowel lies, even when presented with unfamiliar voices and virtually no context for their judgments.

If listeners are unable to perform this task, we will have to conclude that the perception of pitch does indeed require contextualization or familiarization with a particular speaker's pitch range. If, on the other hand, as predicted, listeners are able to successfully identify the relative location of isolated steady pitches without prior exposure to a speaker's voice (and thus to a speaker's *tessiture*), we will have evidence that acoustic parameters of some sort must co-vary with F0 so as to make an immediate identification of relative F0 possible.

II. METHODS

A. Materials

1. Speakers

Twenty native speakers of North American English (10 men, 10 women) participated in the production phase of the experiment. Ages ranged from 20 to 78. Each speaker passed a prescreening administered by questionnaire. The answers of those who participated in the production phase of the ex-

periment indicated that they had neither training nor experience as a vocal soloist, that they were nonsmokers (for at least the preceding five years), that they were in good vocal health (including the absence of symptoms of congestion, coughing, post-nasal drip, or fatigue on the day of the test), that they were not prone to severe or chronic respiratory allergies, and that they had never received the diagnosis of a communication disorder, vocal-fold pathology, or neuromotor impairment. Furthermore, on the day of the test, all 20 speakers passed manual binaural audiometric screening via a Beltone 110 in a sound-attenuated chamber. The audiometric tests demonstrated hearing-threshold levels at audiometric (pulsed) frequencies between 0.125 and 1 kHz at 25 dB or lower—well below the average amplitude of conversational speech.

2. Stimulus generation

In order to determine which F0s we should attempt to elicit from a given speaker and in order to allow us, at a later date, to calculate where those F0s lay within speaker-specific voice ranges, we elicited spoken *tessitures* (vocal ranges) from each speaker. In a double-isolated sound booth, the speaker was instructed to speak, not sing (Titze, 1995), /a/ glissandos as though they were saying the words at a conversational "loudness" to the experimenter, who was seated in the booth approximately one meter away from the speaker. The speaker spoke an /a/ by beginning at a comfortable (self-determined) habitual pitch (see Fairbanks, 1960), then increasing fundamental frequency continuously until modal phonation could no longer be sustained. Multiple rising glissandos of this type were elicited from each speaker until the experimenter was satisfied that he had recorded one smoothly rising, nonsung glissando that included the extreme high end of the speaker's range. Next, a set of falling /a/ glissandos was elicited in a similar manner beginning at a speaker-specific habitual pitch and falling until the speaker was no longer able to sustain phonation at the low end of the range. The number of attempts was typically three but varied from two to eight. During elicitation of spoken glissandos, the speaker was asked to begin again if he or she sensed, or the experimenter judged, that the voice had taken on a sung quality or if the audio signal was clipped or if a vowel token was produced noticeably more quietly than other tokens.

Speaker-specific ranges were calculated from these glissandos using autocorrelation in Praat v4.1 (range=45–900 Hz; 15 maximum candidates), in particular, to provide information about the high end of the *tessiture*. Autocorrelation was supplemented by interactive measurement of the reciprocal of the arithmetic mean of three successive pitch periods. The floor of the spoken *tessiture* was defined as the basal pitch, specifically, the frequency at which periodic F0 was no longer analyzable by autocorrelation or, in dubious cases, identified by direct measurement of three pitch periods. The ceiling of the spoken *tessiture* was defined as the frequency of the first falsetto break extracted from the rising glissando during which nonfalsetto voice quality was sustained at the highest frequency. In clinical practice, falsetto is often included in a normative voice range profile (VRP, also called the " F_0-SPL_{min} voice profile," " F_0/SPL profile,"

“voice field,” “voice area,” or “phonetogram”) in an attempt to assess voice disorders (especially of singers), in which case the falsetto break is often seen as a small notch in intensity (<5 dB) on the loud side of the (normally) oval shape of the profile (Schutte and Seidner, 1983; Heylen *et al.*, 2002). Although falsetto may be used in speech, not just in singing, we excluded falsetto from our speaker-specific ranges in order to increase the difficulty of the ranking task for the listeners (see later). Because we were not interested in the margins of the F0 range, no effort was made to control for variations in extrema within speakers as a function of time of day (see Gelfer, 1989), beyond the collection of multiple ranges from each speaker.

Once speaker-specific ranges had been established, each speaker was asked to sustain a spoken /a/ on at least eight distinct notes spaced roughly evenly within his or her nonfalsetto spoken F0 range. The instruction to speak rather than sing /a/ was met with surprisingly little resistance, perhaps because nonsingers had been recruited by design, some of whom having expressed relief that they were not expected to sing. As was the case with the glissandos, occasional lapses into a sung voice quality also occurred in the production of steady tones, and sung tokens were replaced. In order to help these nonsingers space notes out within their own ranges, they were provided with sinusoidal audio stimuli. Specifically, they heard four 300 ms pure tones per octave (notes c, e, g, and a from 49 to 524 Hz) in which a linear ramp function was applied to the amplitude over the first 100 ms and over the last 100 ms. The experimenters selected at least eight such auditory stimuli within the speaker’s tessiture and presented them over a harman/kardon multimedia speaker system with adjustable output levels. Output was always well above measured auditory threshold levels for the speaker. The talker was asked to respond to each stimulus by attempting to match the pitch of the tone while speaking /a/ at a conversational “loudness.” In order to help the speaker further, we used a Kay Visipitch II running in DOS to provide real-time visual feedback on success of pitch-matching. The participant saw a trace of his or her own pitch along with horizontal guide lines placed at 10 Hz above and 10 Hz below the target pitch. Speakers were asked to hold each tone for four to five seconds, then to inspire (to encourage resetting of the glottis) and to produce at least another two vowels, also separated by a breath. Vowels so produced were also digitized as 44.1 kHz, 16-bit NSP sound files using a near-measurement-quality microphone (Earthworks QTC1) routed to the Visipitch via a hardware high-pass filter (Focusrite ISA220, cutoff=30 Hz, 18 dB/octave rolloff) under speaker-independent input gain. We excluded tokens with noticeable F0 or intensity excursions, as seen in acoustic analysis displays. For each speaker, the eight tokens that were best spread out throughout the speaker’s range were then selected. For each item selected, the first 500 ms containing no noticeable F0 or intensity excursions were extracted from the longer vowel. A linear amplitude ramp was applied to the first and last 100 ms of this extracted segment.

B. Listeners

Twelve native speakers of North American English (6 men, 6 women) participated in the listening task. Ages ranged from 20 to 58. Each listener was asked to respond to a prescreening questionnaire. Answers indicated that none had ever been diagnosed with a communication disorder. Furthermore, on the day of the test, all 12 listeners passed a manual binaural audiometric screening via a Beltone 110 in a sound-attenuated chamber. The audiometric tests demonstrated hearing threshold levels at audiometric (pulsed) frequencies between 0.125 and 1 kHz at 30 dB or lower, well below the lowest amplitude present in the stimulus materials.

C. Procedures

For each stimulus we had recorded, we calculated the achieved F0—not the target F0—as a percentage of the corresponding speaker-specific nonfalsetto tessiture using the formula in Eq. (1), where $F0_{\text{ratio}}$ is the percentage of the individual speaker’s tessiture with which we aimed to correlate listener rankings, $F0_{\text{ach}}$ is the fundamental frequency location actually achieved by the speaker, T_{base} is the lowest sustainable F0 within the speaker’s spoken tessiture, and T_{range} is the tessiture itself.

$$F0_{\text{ratio}} = \frac{F0_{\text{ach}} - T_{\text{base}}}{T_{\text{range}} \cdot 0.01}. \quad (1)$$

Tessitures were based on spoken glissandos, not steady F0s, but highest speakable steady F0s and the top end of the nonfalsetto spoken glissando ranges differed slightly, as reported elsewhere (Reich *et al.*, 1990, but see Zraick *et al.*, 2000). Therefore, for two female speakers, the highest F0 values lay above the speaker’s tessiture, 3% and 14% above for one speaker, and 5% above for the other. Half of the lowest male tokens and half of the lowest female tokens, though they fell within the tessiture, were produced with highly periodic glottal fry. Two instances of the second lowest tones (one male, one female) were also produced with fry. Tessitures for each speaker appear coded by sex in Fig. 1.

Listeners were warned that they would be hearing the voices of different speakers using different parts of their speaking ranges, and asked to identify where within the speaker’s range each token fell. The list of stimuli, consisting of one token of each of eight F0s collected from each speaker ($8 \times 20 = 160$ stimuli), was randomized across speakers and tokens separately for each listener and presented diotically one at a time over headphones. Stimuli were presented at a comfortable output level set by the experimenter and kept constant across listeners. Responses were solicited via a custom MATLAB graphical user interface (GUI) on a flat-panel display. The GUI window accepted input via clickable buttons numbered sequentially and arranged vertically, with the word “high” at the top and “low” at the bottom. Listeners used these buttons to indicate the location of an /a/ token within a speaker’s pitch range on a nine-point scale numbered “1” (“just about as low as they could go”) to “9” (“just about as high as they could go”). A nine-point scale was used so that the eight F0 levels would not be underrepresented. Listeners were instructed to choose “5” if they

FIG. 1. Line chart of tessitures by speaker with high and low values connected. The chart is arranged from lowest falsetto break (left) to highest (right). Male falsetto breaks cluster toward the low end and gradually rise toward the female falsetto breaks with little overlap. Sex-based differences in the location of the low end of the tessiture are less striking. There, ranges bottom out in the high 20s and low 30s for the lowest voices in both sexes, though the 3 highest points are female (594, 563, 581, and 563 Hz) and are measured at over 150 Hz higher than the highest male low end.

thought the pitch was “just normal,” but listeners were told that they would probably need to use all the numbers equally often. They were able to press a “repeat” button to hear a stimulus again, but they were discouraged from listening more than twice. They were also allowed to rest at any point if they wished.

After the task had been completed, listeners were debriefed regarding the perceived difficulty of the task and strategies they believed they had employed. Additionally, all were asked to confirm that they had correctly understood the instruction to indicate where each token lay within its speaker-specific range. All of them did so.

III. RESULTS

A. Correlations by speaker tessitures

A linear regression was run on two variables, with assigned *ranking* of individual tokens (12 listeners) as the dependent variable and, as the independent variable, *F0 location* of the same tokens (calculated as a percentage of the relevant speaker-specific tessiture based on a log base 10 transformation of the high and low F0s from the glissandos). In the scatterplot given as Fig. 2, a relatively dense cluster (a binned range of values) of individual tokens appears as a collection of densely petalled “sunflowers” surrounding a regression line. Correlations were calculated for each listener separately. In all cases r was positive, ranging from 0.587 to 0.789, and $p < 0.001$. In order to render the variance more independent of the population, Fisher’s z transformation was applied to each r (Fisher, 1915). The mean of the resulting z values was calculated and that mean inverted into an r ; this value was 0.721 and indicates a relationship between assigned rankings and location of the tones within speaker-specific tessitures.

FIG. 2. Sunflower scatterplot with regression line between rankings assigned by 12 listeners and log base 10 transformed locations of eight spoken F0s per speaker (20 speakers). Locations are reported as a percentage of speaker-specific spoken F0 ranges. Vowel: /a/. A direct linear relationship is apparent. Each sunflower represents one or more cases that occur very close together on the scatterplot, with each case represented as a sunflower petal. Each sunflower is positioned at the mean of the cluster of cases that it represents. Each dimension of the sunflower cell is 1/15 of the appropriate range.

B. Correlations by speaker tessitures, extrema excluded

In order to exclude the possibility that the correlation reported above was skewed by listener reliance on unusual voice qualities located at range extrema, we ran a further linear regression between assigned rankings from the middle six F0s for each speaker and actual locations of the middle six F0s within speaker-specific tessitures. That is, the high and low F0s for each talker were excluded. Half of these low values were judged by the experimenters to have a creaky voice quality. (Two other tokens that were second lowest were judged to have a creaky quality.) Here also, the scatterplot (see Fig. 3) suggests a linear relationship between ranking and location, and all r values were positive and significant ($p < 0.001$); they ranged from 0.463 to 0.716. The inverse Fisher mean z (calculated as above) was 0.609, which indicates a direct relationship between the variables, though it suggests a weaker relationship than reported above for all eight F0s per speaker. However, a reduction in the strength of the correlation does not necessarily indicate that information around the center of each speaker’s range was not sufficient for the listener. We return to this point in the Discussion.

C. Correlations by generic ranges

To test for the possibility that listeners were actually locating F0 relative to F0 ranges heard elsewhere (and perhaps separately for the two sexes), two further analyses were performed. One assumed that listeners would be able to determine for each stimulus whether a male or a female had uttered the vowel. Listeners are good at doing this based on sentence-length stretches of speech (Lass *et al.*, 1978), and on short segments of speech (Ingemann, 1968). It is also

FIG. 3. Sunflower scatterplot with regression line between rankings assigned by 12 listeners and log base 10 transformed locations of six spoken tones per speaker (20 speakers) with locations reported as a percentage of speaker-specific spoken F0 ranges. The single highest and lowest tone for each speaker have been excluded from the regression, along with corresponding rankings. Vowel: /a/. A direct linear relationship is apparent. Plotting dimensions are as in Fig. 2.

possible to reliably distinguish sex on the basis of the acoustics of vowel segments alone (Childers and Wu, 1991). All of these studies use central F0 values, so it is not clear whether the current listeners would be able to make this distinction throughout the range. Nonetheless, it seemed reasonable to assume that such a distinction might be of perceptual value, so a correlation was calculated as before but using the male or female extreme values as the definition of the range rather than the individual speaker's extremes.

The pattern of correlations is very similar to that found before, so no figure is given. The correlations for the sex-linked estimates were all positive and significant ($p < 0.001$), ranging from 0.611 to 0.901, and the inverse Fisher mean z was again positive (0.830, $p < 0.001$). The magnitude of the correlation was somewhat larger than that for the individual tessitures.

A final analysis used the overall extreme values (low from the lowest male, high from the highest female) as defining the global "tessiture." The correlation coefficients for the global, non-sex-linked range were also positive and significant ($p < 0.001$), ranging from 0.611 to 0.934, with an inverse Fisher mean z of 0.848. These correlations are similar to those found in van Bezoooyen (1984) for mean F0 and the perceived pitch level of her natural speech stimuli (expressing nine emotions plus a neutral reading).

D. Comparison of the two types of ranges

In order to assess the fit between the estimate of the location within range and the ranges based on individual and group tessitures, we have plotted the eight sustained F0s collected from each speaker, superimposing speaker-specific upper and lower tessiture boundaries elicited from spoken glissandos, plotting data according to the value of the bottom of the tessiture (Fig. 4). Colors in the figure represent a continuous gradation based on averaged listener rankings. The figure

allows some comparison of success with the two types of range. Speaker-specific patterns of color updrift across the figure are balanced by global patterns seen in the relative stability of the mid-range bands of color across speakers.

Colored dots tend to expand to fill the tessitures whose boundaries are demarcated by black lines, though there are notable gaps between the lowest or highest F0 attained and the limit of the speaker-specific tessiture. That is, there are steady F0s that were produced and excluded either because eight values had already been obtained from that speaker or because no acceptable token was obtained by our elicitation technique. Those gaps are seen especially, on the low end, in the productions of speakers 6 and 8 among the males and 4, 11, 12, and 17 among the females, and on the high end, in the productions of speakers 2, 3, 6, 9, 18, and 20 among the males and 15 and 16 among the females. The lack of a dark blue dot for the lowest production of speakers 7, 9, 13, and 15 is more consistent with a global interpretation of F0 range fitting, since these attained F0s were close enough to the lower limit of the tessitures that listeners ought to have been able to assign them a ranking of 1 if they were able to locate F0 within individual ranges. Here, just as the correlation analyses show, there is evidence for both specific and general patterns.

IV. DISCUSSION

Significant positive correlations obtain between the assigned ranking and the actual location of tones within individually defined tessitures. However, similar correlations were also found when the F0s were scaled to the ranges of the speakers as a group. Since there was sizable overlap among the F0 ranges of our current talkers, it was not possible to distinguish which factor was more important.

One possible objection to the analysis might be that listeners were biased by the inclusion of extrema in the random presentation of F0s. Therefore, in order to rule out the possibility that ranking of F0 extrema was accurate but ranking of more central F0 values inaccurate, linear regressions on individually defined tessitures were rerun with the top and bottom F0 for each speaker excluded. This test produced slightly lower correlation coefficients (inverse Fisher mean z of 0.609, down from 0.721), but, crucially, the correlation was still positive and significant at $p < 0.001$, even though n was 25% smaller. This test confirms the finding that listeners' successful ranking of pitch did not depend upon identifying peculiarities associated with the extreme high or low F0 values for each speaker.

The fact that listeners are able to locate within a tessiture steady, isolated pitches produced by unfamiliar voices implies some degree of speaker normalization. Although the present results strongly support our hypothesis that parsing of the F0 location does not require context or familiarization, they do not allow us to distinguish between possible models of F0 normalization. Listeners might build models of individual speakers or they might fit individual pitch ranges to previously built prototypes of possible vocal ranges. It is known that factors extrinsic to the signal are implicated in normalization-factors such as the overall formant range (Ladefoged and Broadbent, 1957) or the acoustics of inspi-

FIG. 4. Color-scaled mean rankings (12 listeners) plotted for each of eight sustained frequencies produced by each of 20 speakers. Data are ordered by bottom of glissando-based tessiture. The sex of the speaker is given below the speaker number.

ration, for example (Whalen and Sheffert, 1997). If signal-extrinsic aspects of speech are used in speaker normalization, it stands to reason that signal-intrinsic aspects of speech might also be used as listeners familiarize themselves with the voices of individual vocal tracts or vocal tract types. Voice quality is one such a signal-intrinsic feature.

Extremely low F0 within a speaker's range is often associated with a glottal fry or creaky voice (Ladefoged, 1971; Laver, 1980). Similarly, breathy voice tends to occur with low F0s (Fairbanks, 1960). Thus it may be that creak and breathiness indicate to the listener that the lower portion of the tessiture is being used. At the high end, the mode of vibration of the vocal folds changes dramatically between modal and falsetto voice (Hollien *et al.*, 1971; Laver, 1980). Minimally, therefore, it is likely that listeners can use information about voice quality directly to gauge the location of a steady pitch at the very least at the top and bottom of a speaker-specific range. However, in the present study, listeners appeared to base their rankings on signal-intrinsic (perhaps voice quality) information at or near the extrema as well as throughout the tessitures.

The proposal that listeners rely at least somewhat on voice quality as they locate pitch within a speaker-specific range does not lead naturally to a relational theory of F0 normalization in which pitch is located relative to other pitches via a Fraction-of-Range comparison or Z-Score-around-Mean comparison (e.g., Rose, 1987). In fact, one finding in the present investigation suggests the possibility of

a more direct route to F0 normalization: Listeners performed well throughout a speaker's range, even though F0s were presented randomly. If listeners use information on voice quality intrinsic to the signal to aid in predicting pitch location within the range, no model of speakers is needed, personal or generic. If listeners parse voice quality information and relate F0 information to it, normalization may follow a more direct route. The present findings do not argue conclusively in favor of voice quality as the basis of parsing, but they show clearly that listeners need not depend on sampling the F0s of a speaker before making range judgments. The slight improvement in the correlations when the F0s were coded for the full range of F0s in the experiment suggests that listeners might be calibrating their responses to their experience with typical F0 ranges that they have heard throughout their lives, with or without reference to the intricacies of voice quality changes at different parts of the F0 range. Since our speakers seem to be typical in this regard, such a strategy seems to be a reasonable one. Further tests, in which speakers with less overlapping ranges are selected (if this is possible), would be necessary to sort this out.

In addition to voice quality, there are many sources of information about pitch range available to listeners. However listeners use that information, we can be fairly certain that they do not perform normalization simply by linking speaker pitch location to the perceived size of the speaker. While it appears that vocal tract length in humans depends on skull size, and while it has been shown that vocal tract length, in

turn, directly affects the averaged distance between successive formant frequencies when the cross-sectional area is held constant (Fant, 1960; Fitch, 1997), neither average nor basal pitch (e.g., Cooper and Yanagihara, 1971) correlates directly with adult human vocal tract size. The perhaps common but false supposition of a body size-pitch connection may follow from our more generally correct intuition that large objects resonate at low frequencies, combined with a casual confusion between source and filter properties. Indeed, certain species of birds and mammals “falsely advertise” their body size with disproportionately low calls produced primarily by enlarging the vocal tract (Fitch, 1999; Fitch and Reby, 2001), but actual correlations between body size and the length and mass of the vocal folds have been found to be small in adult humans (e.g., Lass and Brown, 1978; Künzel, 1989) and in other vertebrates more generally (see Fitch, 1997 for a review). In fact, the larynx develops independently of the head and body, and is even hypertrophied in post-pubescent human males (Hollien, 1960). It seems that there is no direct link between larynx size (and thus average or basal F0) and vocal tract length or body size, so pitch normalization cannot proceed from “on-line” (probabilistic) estimation of vocal tract length.

Although F0 does not directly correlate with vocal tract length (or formant distance), a speaker’s sex can be determined reliably from either long (Lass *et al.*, 1978) or short (Ingemann, 1968) segments of typical speech, and automatic techniques are similarly successful with just vowels (Childers and Wu, 1991). It would appear that information regarding speaker sex may be present in what we might generally refer to as source or hybrid source-filter properties. It has been claimed, for example, that information about sex is available to the listener in the absolute value in Hz of some aspect of F0, usually mean or median F0. Peterson and Barney (1952) report male/female differences of around 100 Hz, as does van Bezooeyen (1984). Indeed, Bachorowski and Owren (1999) found that sex was classified correctly 92.4% of the time by discriminant analysis on the basis of formant frequency cues to vocal tract length for 2500 tokens of one vowel produced by 125 subjects. The success of a multivariate statistical technique in classifying speaker sex on the basis of vocal tract length cues alone does not necessarily mean that listeners judge speaker sex in the same way, or that listeners use judgments of speaker sex to normalize pitch at a gross level, but the possibility remains. It has also been claimed that information about sex may be available in spectral tilt. For example, Hanson and Chuang (1999) found the ratio of the amplitude of H1 to that of F3 to be 9.6 dB lower for male than for female speakers, with lower mean values and less variation between male speakers for F1 bandwidth, open quotient, and other measures. However, it is not known whether information about speaker sex is available to the listener in short segments throughout the tessiture. It may be that F0s at the high or low end can be misleading about the sex of the talker, with low values perhaps sounding more typically male and high values, female. This question will be addressed in future research. For now, it is reasonable to assume that the sex of the speaker for at least some of the stimuli could have been perceived in this experiment.

Given the listener’s potential for identifying the sex of the speaker, we might anticipate the following interpretation of our results, namely that listeners rank F0s based on stored templates representing population tessitures for adult male and adult female speakers, respectively. Indeed, correlations based on F0 locations within sex-based population ranges were almost as high as those based on global (sex-independent) ranges. Figure 4 shows evidence for both specific and global trends. If listeners were simply fitting judgments to absolute high- or low-frequency values, the colors of the dots would be expected to appear in straight horizontal bands uniformly throughout the chart; they do not, especially at the high and low ends. Yellow and near-yellow bands in the mid-tessiture range do cluster roughly in the 125–225 Hz range, but so do tessiture midpoints. In other words, where the yellow bands seem too high or too low relative to steady F0s produced by a speaker, they tend to fall roughly on center relative to speaker-specific tessitures. Furthermore, if listeners were simply fitting judgments to male and female (adult) population tessitures, the colors would be expected to band within sex, but plotting them this way (not shown directly) does not reveal any clear difference. In most cases where the lowest F0 within a speaker-specific tessiture does not receive a blue ranking or the highest F0, a red ranking, it is because of gaps in the stimuli. That is, there are steady F0s that, in an ideal world, could have been produced, but were not produced by some of our speakers. Major gaps appear on the low end for speakers 6 and 8 among the males and 4, 11, 12, and 17 among the females, and, on the high end, for speakers 2, 3, 6, 9, 18, and 20 among the males and 15 and 16 among the females. If the reader imagines dark blue and dark red dots in these spaces, respectively, a sex-independent pattern is enhanced. The dark dots simply follow tessiture boundary marks; they do not form bands of a single color family across all speakers of a particular sex. The lack of very high rankings may also be due to our intentional exclusion of falsetto from the stimuli. To the extent that falsetto is part of the speech range, listeners would be correct in not assigning a score of 9 to the highest F0s presented.

Where the F0 literature contains multiple studies of mean or median fundamental frequency as noted above, we focused on the entire range, and found a considerable overlap in tessiture between male and female speakers both in range and location of range. The overlap is especially apparent at the low end, where there is very little in the way of a consistent sex-based F0 difference in the glissando base. What we do see are more gaps for the females, who seem to have had a difficult time sustaining low F0s to which they can indeed glide down in a spoken voice register. At the high end, the highest glissando breaks are achieved by the females, and there is less overlap between sexes. There is some overlap, however, but it is again accompanied by (complementary) high-end gaps in sustained-but-possible F0s by the males. Had listeners here relied on a first-pass discrimination of sex to provide two templates for comparison, they would have misranked far more of these tokens. This pattern is consistent with the evidence for the use of both individual and global ranges.

Whether or not voice quality alone routinely provides

listeners with sufficient information for F0 normalization, it is clear that listeners are sensitive to the location of pitch within a speaker's range, even for isolated utterances. It will take further experimentation to isolate the features that listeners are sensitive to and to explain why listeners are good but not perfect at the task. For example, it would prove useful to test whether varying synthetic voice quality across a range of F0s confounds the listeners' attempts to track F0 values. Another avenue of research suggested by the present study would involve a replication in which the experimenters selected speakers with tessitures located high and low in absolute frequency and with less overlap than seen among the present speakers, if such speakers can be found.

ACKNOWLEDGMENTS

We thank Jeff Weihing for assistance with MATLAB programming and Brook Swainson and Paul De Decker for their assistance with stimulus extraction. We also thank Carol Fowler, Gordon Ramsay, and Yi Xu for their comments and Bob Ladd for a helpful discussion of the data reported here. During the review process, this paper also benefited from a number of insights offered by the Peter Assmann, Tecumseh Fitch and an anonymous reviewer. Any shortcomings in the present research remain our own. This work was supported by NIH Grant No. DC-02717 and NIH Grant No. DC-03782 to Haskins Laboratories and by an equipment loan from the Institute for Voice and Speech.

Perception of aperiodicity in pathological voice

Jody Kreiman^{a)} and Bruce R. Gerratt^{b)}

Los Angeles, California 90095-1794

(Received 20 December 2003; revised 20 December 2004; accepted 22 December 2004)

Although jitter, shimmer, and noise acoustically characterize all voice signals, their perceptual importance in naturally produced pathological voices has not been established psychoacoustically. To determine the role of these attributes in the perception of vocal quality, listeners were asked to adjust levels of jitter, shimmer, and the noise-to-signal ratio in a speech synthesizer, so that synthetic voices matched naturally produced tokens. Results showed that, although listeners agreed well in their judgments of the noise-to-signal ratio, they did not agree with one another in their chosen settings for jitter and shimmer. Noise-dependent differences in listeners' ability to detect changes in amounts of jitter and shimmer implicate both listener insensitivity and inability to isolate jitter and shimmer as separate dimensions in the overall pattern of aperiodicity in a voice as causes of this poor agreement. These results suggest that jitter and shimmer are not useful as independent indices of perceived vocal quality, apart from their acoustic contributions to the overall pattern of spectrally shaped noise in a voice. © 2005 Acoustical Society of America. I. INTRODUCTION

Jitter, shimmer, and noise-to-signal ratios (NSRs) are the cornerstones of acoustic measurement of voice signals, and are often regarded as indices of the perceived quality of both normal and pathological voices. In general, applications of acoustic measures to assess vocal quality derive their validity from the relevance of specific acoustic properties of the signal to auditory perceptions of voice. Researchers typically use correlation or regression techniques to demonstrate the extent to which such measures explain or predict listeners' scalar quality judgments. However, observed associations between acoustic and perceptual measures have varied considerably across studies. For example, correlations between measures of jitter and ratings of both breathiness and roughness have ranged from 0 to about 0.7 (for review see Heiberger and Horii, 1982; Kreiman and Gerratt, 2000). Multidimensional scaling studies (which examine the perceptual dimensions that underlie perceived vocal similarity) have also provided inconsistent results with respect to the role that jitter, shimmer, and the NSR play in determining quality (Kreiman *et al.*, 1990; Kreiman and Gerratt, 1996). Such variability in results has undermined confidence in both the acoustic measures and their perceptual interpretation.

Although hundreds of studies describing, evaluating, and applying measures of noise and acoustic signal perturbation have been published (Buder, 2000), the perceptual salience of these attributes remains poorly understood. A discrepancy exists between the results of early synthesis studies and findings from later investigations examining this association in naturally produced voices (Heiberger and Horii, 1982). Synthesis studies (Wendahl, 1963, 1966a, b; Coleman and Wendahl, 1967) used sawtooth waves with added jitter (± 1 –50 Hz around a mean f_0 of 100 or 200 Hz) or shimmer

(alternate periods reduced in amplitude by 1–6 dB). Near-perfect correlations were observed between the amount of jitter or shimmer and judgments of relative roughness for these nonspeech stimuli. More recently, Hillenbrand (1988) used synthetic vowels to examine the univariate relationships between jitter, shimmer, and noise and ratings of breathiness and roughness. He reported that roughness ratings increased with levels of jitter and shimmer up to about 2% jitter and 2-dB shimmer, after which increasing jitter and shimmer levels did not increase perceived roughness. Similarly, as the NSR increased, so did breathiness ratings.

Several limitations are inherent in these synthesis studies. The synthesis techniques employed in the earliest studies (Wendahl, 1963, 1966a, b) did not include vocal-tract filtering, and used a highly unnatural sawtooth source along with levels of jitter and shimmer (up to $\pm 50\%$) that greatly exceed those usually associated with the human voice (e.g., Andrianopoulos *et al.*, 2001; Munoz *et al.*, 2003). Stimuli lacked pitch contours or formant structure, and varied in only one acoustic dimension at a time. Further, a relatively small number of stimuli differed in relatively large acoustic steps, making it easy for listeners to perform the paired comparison task reliably (Heiberger and Horii, 1982). These factors could account for the high correlations with perceived vocal roughness, and limit the extent to which early studies explain how listeners hear naturally produced voice signals. (Hillenbrand, 1988, also commented that his stimuli sounded somewhat unnatural.) Further, previous studies assessing the role of noise and perturbation in determining voice quality have always assessed quality in terms of specific scales like breathiness, roughness, or hoarseness. However, the reliability of such scales has been repeatedly questioned, and their validity as measures of quality is also questionable (e.g., Jensen, 1965; Kreiman, Gerratt, and Berke 1994; see Kreiman *et al.*, 2005, for review).

A final limitation of previous synthesis studies is the fact

^{a)}Electronic mail: jkreiman@ucla.edu

^{b)}Electronic mail: bgerratt@ucla.edu

that jitter, shimmer, and noise have been manipulated independently of one another, and the perceptual interactions among these three variables have not been investigated. Acoustically, these attributes are obviously related. For example, adding aspiration noise to a signal adds jitter and shimmer; adding jitter also adds shimmer as changes in period length move harmonics toward and away from vocal-tract resonances; and adding jitter and shimmer produces measurable changes in the NSR (Hillenbrand, 1987). Naturally produced voice signals include all these attributes, and separating them analytically has proven difficult (Hillenbrand, 1987; Fukazawa *et al.*, 1988; de Krom, 1993; Titze, 1995; Michaelis *et al.*, 1997; Murphy, 1999).

In contrast to synthesis studies, correlational investigations of jitter, shimmer, and noise perception in naturally produced voices have produced highly variable results. Many low or nonsignificant correlations have been reported (e.g., Martin *et al.*, 1995; de Krom, 1995; Deal and Emanuel, 1978; Prosek *et al.*, 1987). However, correlational approaches are of limited use in resolving the issues surrounding the perceptual importance of vocal aperiodicity, because they cannot provide evidence about cause and effect. Lack of information about how (or whether) an acoustic variable evokes perception of a particular vocal quality leaves researchers and clinicians to make assumptions without evidence about the validity and utility of such measures. For example, it is impossible to determine if statistically significant changes in some parameter are actually perceptually meaningful or not in the absence of a demonstrated cause and effect relationship between an acoustic variable and a perceptual outcome.

In this study, we used a method of adjustment task to examine the perceptual significance of jitter, shimmer, and the NSR. Listeners were asked to manipulate jitter, shimmer, and NSR levels in high-quality synthetic voice stimuli, until the synthetic voices matched naturally produced target voices. This approach avoids the use of verbal rating scales, because listeners compare the stimuli directly in terms of their overall similarity. Further, in the method of adjustment task, subjects manipulate acoustic variables directly, so the association between signal and percept need not be inferred from correlation. Finally, in this task the perceptual importance of acoustic variables is evaluated in the same complex, multidimensional context in which the variables naturally occur. In particular, this study examined the perceptual interactions of jitter and shimmer with noise. A previous study (Gerratt and Kreiman, 2001) found good agreement among listeners for the NSR. It is possible that, because noise comprises jitter and shimmer acoustically, listeners agree about overall levels of noise, but not about the levels of jitter and shimmer present in a voice. On the other hand, if measures of jitter and shimmer are valid indices of perceived vocal quality, then listeners should agree well in the levels of these variables they select in the method of adjustment task.

II. EXPERIMENT 1

A. Rationale

To examine the contributions of jitter, shimmer, and noise to voice quality, listeners in this experiment were asked

to adjust the levels of jitter, shimmer, and/or noise present in a synthetic stimulus until that stimulus matched a naturally produced voice sample as closely as possible. We then examined the extent to which listeners agreed about how much of each variable was necessary for the synthetic and natural voice samples to sound the same, consistent with the ANSI definition of sound quality as “that attribute of auditory sensation in terms of which a listener can judge that two sounds similarly presented and having the same loudness and pitch are dissimilar” (ANSI Standard S1.1.12.9, p. 45, 1960). If jitter, shimmer, and noise contribute independently to the perceived quality of a voice, then listeners should agree well in the values they choose when making their adjustments.

B. Method

1. Voice samples

The voices of 20 speakers with voice disorders (10 males and 10 females) were selected from a large library of samples recorded under identical conditions as part of a clinical voice evaluation. Selection was random except that samples with period doubling or biphonation were excluded because jitter and shimmer are undefined for such signals (e.g., Titze, 1995). Speakers ranged in age from 22 to 78 years (mean=49.8 years; sd=17.2 years) and represented a variety of primary diagnoses, including mass lesions of the vocal folds (7), glottal incompetence (6), chronic laryngitis (4), adductory spasmodic dysphonia (2), and Parkinson disease (1). Severity of vocal deviation was rated by consensus vote of the authors. Ratings ranged from 2–5 on a 5-point scale (where 1=normal quality), and averaged 3.55 (sd =0.97).

During the voice evaluation, speakers sustained the vowel /a/ as steadily as possible. Voice signals were transduced with a 1-in. Bruel & Kjaer condenser microphone held a constant 5 cm off axis. They were then low-pass filtered at 8 kHz and directly digitized at 20 kHz. A 1-s segment was excerpted from the middle of these productions, antialias filtered, and downsampled to 10 kHz for further analysis.

2. Analysis and synthesis methods

Analysis techniques have been described in detail elsewhere (Gerratt and Kreiman, 2001; Gabelman, 2003). Briefly, formant frequencies and bandwidths were estimated using linear predictive coding analysis with a window of 25.6 ms (increased to 51.2 ms when stimulus f_0 was near or below 100 Hz). The glottal volume velocity derivative was estimated by interactively inverse filtering a single glottal pulse from the microphone recordings, using the method described by Javkin *et al.* (1987). The output of the inverse filter was least-squares fit with a modified Liljencrants–Fant (LF) source model (Fant *et al.*, 1985), and the parameters of the best-fitting LF model were used to specify the harmonic component of the voice source in the synthesizer. The shape of the inharmonic part of the voice source (the noise spectrum) was estimated by applying cepstral comb filtering to remove periodic source components following the method described by de Krom (1993). The residual was then inverse filtered to remove the effects of vocal-tract resonances, leav-

FIG. 1. Modeling of jitter, shimmer, and low-frequency modulations of frequency and power (tremors). (A) Output of f_0 analysis algorithm. Solid line shows the low-frequency pitch track, and open circles show deviations about this contour (jitter). (B) Output of power analysis algorithm. Solid line shows the low-frequency power track, and open circles show deviations about this contour (shimmer). Units for power are arbitrary.

ing the inharmonic part of the source, which was fitted with a 25-segment piecewise linear approximation. Finally, f_0 was tracked pulse by pulse on the time-domain waveform by an automatic algorithm. Location of cycle boundaries was verified by the first author. Tremor rates were estimated by visual inspection of smoothed plots of f_0 versus time (Kreiman *et al.*, 2003). Estimated tremor rates averaged 6.45 Hz, with a range of 2 to 10 Hz and a median of 6 Hz.

Variability in f_0 was modeled as follows (Fig. 1). The estimated tremor rate served as a dividing line between slow frequency and amplitude modulations (tremors) on the one hand and fast variations (jitter and shimmer) on the other. To model tremor, the f_0 track was low-pass filtered with the cutoff value equal to the estimated tremor rate, and period lengths were altered to incorporate this slowly varying frequency track [Fig. 1(a)]. Low-frequency amplitude modulations were similarly generated for each voice [Fig. 1(b)], and the power of each cycle was modified to incorporate observed low-frequency modulations in amplitude.¹ Jitter was modeled by altering the duration of each cycle by an amount sampled from a high-pass filtered, normally distributed random sequence whose variance was determined by the desired level of jitter. The filter's cutoff frequency again equaled the estimated tremor value. Shimmer was similarly modeled by altering the power of each cycle of phonation, with power values sampled at random from a normal distribution of values whose variance corresponded to the desired amount of shimmer. (See Gabelman, 2003, for more detail.)

Stimuli were synthesized using a custom formant synthesizer implemented in MATLAB (MathWorks, Natick, MA; Gerratt and Kreiman, 2001).² The synthesizer sampling rate was fixed at 10 kHz. The following procedure was applied to overcome quantization limits on modeling f_0 . Source pulses were synthesized pulse by pulse. A single LF-modeled source pulse was upsampled from 10 to 40 kHz and used as a basis for each pulse in the time series. A plot of the desired f_0 values versus time was generated for the 1-s synthetic sample, taking into account the tremor contour and requested

level of jitter. As the series of pulses was constructed, precise ending times for each LF pulse were tracked, and this curve was interpolated to find f_0 for the next pulse in the series. The basic LF pulse was then time warped (stretched or compressed) to obtain the appropriate period length, and sample points were calculated accordingly. A similar power versus time curve was constructed for the time series, reflecting amplitude tremor and shimmer, and this curve was interpolated to determine the power for each successive cycle in the time series. The overall effect is equivalent to digitizing an analog pulse train with pulses of the exact desired frequencies and amplitudes at the fixed 10-kHz sample rate.

A 100-tap finite impulse response filter was constructed for noise synthesis, with its shape corresponding to the 25-segment piecewise linear approximation fit to the inharmonic part of the voice source derived through comb filtering. A spectrally shaped noise time series was then created by passing white noise through this filter. The jittered, shimmered, and tremored LF pulse train was antialias filtered and down-sampled to 10 kHz, and then added to this noise time series to create a complete source time series. The source was filtered through the vocal-tract model to generate a preliminary version of the synthesized voice. Finally, formant frequencies, bandwidths, and LF parameters were adjusted to provide good perceptual matches to the target voices, and then held constant across experimental conditions.

3. Listening pretest

A listening pretest was used to verify the accuracy of the synthesis. Prior to this pretest, estimated values of the NSR, jitter, and shimmer were adjusted in the synthesizer by the first author as necessary to provide the best possible perceptual match to the natural voice samples, because measurement of jitter, shimmer, and the NSR is difficult and often inaccurate when phonation departs from periodicity (e.g., Titze, 1994; Bielamowicz *et al.*, 1996). Synthetic copies of each of the 20 natural voice samples were then generated,

using the methods described above and these perceptually adjusted levels of jitter, shimmer, and noise. Twenty listeners (UCLA students and staff; 20 to 53 years of age; mean age = 26.4 years; $sd=9.93$ years) heard pairs of voices. On half of the trials, a synthetic voice sample was paired with its natural counterpart, and on the other half stimuli were identical. Each pair was repeated 3 times, for a total of 120 trials/listener.

For each trial, listeners were asked to judge whether the two samples were the same or different, and to rate their confidence in their response on a 5-point scale ranging from “positive” to “wild guess.” Listeners were not allowed to replay the stimuli before responding. Order of voices in “different” pairs was randomized, and the stimulus pairs were rerandomized for each listener. Listeners were tested individually in a double-walled sound suite. To approximate normal listening conditions, stimuli were presented in free field at a comfortable constant listening level. Testing lasted approximately 15 min.

To provide a measure of the average discriminability of the synthetic and natural tokens, responses were pooled across listeners. Overall rates of correct and incorrect “same” responses (hits and false alarms) were calculated for each voice. Hit rates ranged across voices from 85%–98.3% (mean=91.8%; $sd=3.66\%$); false-alarm rates ranged from 51.7%–85% (mean=65.7%; $sd=11.18\%$). The probability of any correct response (“same” or “different”) ranged across voices from 54.2%–70% (mean=63.1%; $sd=5.02\%$).

Same/different responses for each voice were combined with confidence ratings to create a 10-point scale ranging from “positive voices are the same” to “positive voices are different.” For example, “same” responses with confidence equal to 1 (positive) were recoded as “1,” “same” responses with confidence equal to 5 (wild guess) were recoded as “5,” “different” responses with confidence equal to 5 were recoded as “6,” and “different” responses with confidence equal to 1 were recoded as “10.” Receiver operating characteristics (ROCs) consisting of 9 points each (10 recoded response categories minus 1) were constructed from these recoded data following the procedure described by Green and Swets (1966; see also MacMillan and Creelman, 1991). The area under the ROC for each voice was calculated, along with 99% confidence intervals around these values. In all cases, these confidence intervals included the chance value of 0.5. These data, combined with consistently high false-alarm rates, indicate that listeners were unable to consistently distinguish the synthetic copies from the natural samples. We conclude that the synthesis technique is able to model the quality of the natural target voice samples adequately for purposes of the following experiments.

4. Listening task

Seventy listeners participated in experiment 1. They ranged in age from 19–57 years (mean age=26.7 years; $sd=7.83$ years). All reported normal hearing. Listeners were unselected with respect to experience with voice disorders, and most were phonetically- and otolaryngologically naive.

Listeners were tested individually in a sound-treated room. Each listener participated in 20 trials, one for each

voice. Voices were presented to each listener in a unique random order, in free field through two loudspeakers at a constant comfortable listening level (to approximate normal listening conditions). At the beginning of each trial, listeners heard the natural voice sample paired with a copy of that voice synthesized without jitter, shimmer, or noise. They were told that one voice was naturally produced, and that the other was a synthetic copy. They were then asked to adjust the quality of the second voice by moving a sliding cursor or cursors on a computer monitor with a mouse, until the two voices matched on the target dimension or dimensions as closely as possible. These cursors controlled the jitter, shimmer, and NSR levels present in the synthetic voice. Depending on condition, listeners adjusted either one, two, or all three parameters in a given trial. Listeners heard a given voice in a single condition only. Which task a listener performed for a given voice was assigned at random, with the constraint that ten listeners performed each of the seven possible tasks (jitter only; shimmer only; noise only; jitter + shimmer; jitter+noise; shimmer+noise; or jitter+shimmer+noise) for each voice. Listeners were encouraged to play the natural and synthetic stimuli as often as they liked in any order, and could make as many adjustments as necessary to achieve the best possible match to the target voice.

Scale displays were 115 mm in length. The NSR scale ranged from -50 to 0 dB (noise-free to extremely noisy); the jitter scale ranged from 0% to 3% ; and the shimmer scale ranged from 0 to 2 dB. These values were chosen based on measurements of the test voices, on pilot tests, and on data from Hillenbrand (1988), who reported that increasing jitter beyond 2.5% and shimmer beyond 2 dB had little additional effect on perceived vocal roughness. Ranges of values for jitter, shimmer, and the NSR vary widely across previous studies, for both pathological and normal voices, due to differences in measurement techniques, instrumentation, and computational algorithms. In the present research, stimuli were frequency- and amplitude demodulated prior to perturbation analysis to remove the contributions of tremor from measured values. Values of these variables in the synthesizer were also calculated independently of the effects of tremor. For these reasons, the ranges used here for these variables are lower than those reported by some authors (see Buder, 2000, for review). Parameters not being manipulated in a given trial remained set in their “off” position (0% jitter, 0 -dB shimmer, -50 -dB NSR).

Prior to the experiment, the synthesizer was demonstrated and two practice items were presented, so that listeners could become thoroughly familiar with the task and with the sounds of different amounts of jitter, shimmer, and noise, individually and in combination. Practice continued until subjects were satisfied that they understood and could perform the task; it lasted about 15 min on average. The total test session lasted 1.5–2 h. Listeners were encouraged to take breaks during this period as necessary to maintain attention and motivation.

C. Results

Figure 2 shows the distributions of jitter, shimmer, and NSR responses, summed over voices and experimental con-

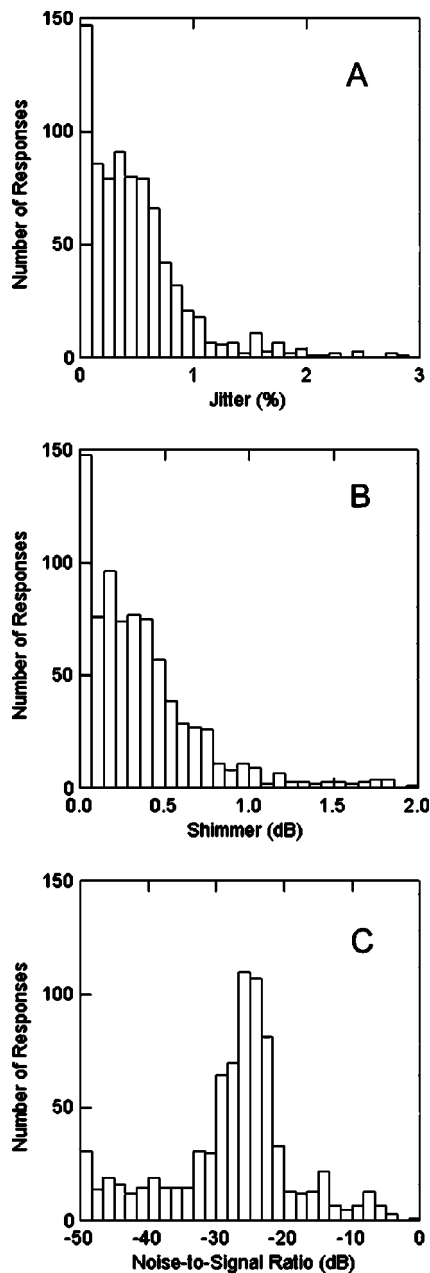

FIG. 2. Distribution of responses for jitter (A), shimmer (B), and the NSR (C), pooled across the 20 stimuli in the method-of-adjustment task in experiment 1.

ditions. Across conditions and voices, listeners used the full range for each of these scales. Responses for jitter and shimmer clustered toward the lower third of each scale, with listeners adding only small amounts of jitter and/or shimmer on most trials. In contrast, NSR responses were approximately normally distributed.

To measure response variability, we calculated the coefficient of variation (the standard deviation divided by the mean) for the jitter, shimmer, and NSR responses for each voice. Figure 3 shows the distribution of variation coefficients for each measure across the 20 stimulus voices. For each of the individual voices, variability of the jitter and shimmer responses exceeded that of the NSR responses. On average, jitter and shimmer responses were more than 5 times more variable than NSR responses, and in one case

FIG. 3. Distribution of coefficient of variation values for the jitter, shimmer, and NSR responses in experiment 1, across experimental conditions and stimuli.

they were over 20 times more variable. These differences were significant across voices [$F(2,297) = 162.12$, $p < 0.01$; Bonferroni *post hoc* comparisons $p < 0.01$].

Jitter and shimmer responses varied significantly with the particular listening task. Listeners used significantly less jitter and shimmer when asked to adjust all three parameters at once than they did when matching jitter or shimmer alone [jitter: $F(3,796) = 4.32$, $p < 0.01$; shimmer: $F(3,796) = 4.14$, $p < 0.01$; Bonferroni *post hoc* comparisons $p < 0.01$]. In contrast, listeners always adjusted the NSR to similar levels, even when they were also adding jitter and/or shimmer to the voice, so no significant effect of response condition on NSR values was observed [$F(3,796) = 1.01$, n.s.]. However, coefficients of variation did not vary significantly by experimental task [jitter: $F(4,95) = 0.288$, $p > 0.01$; shimmer: $F(4,95) = 1.05$, $p > 0.01$; NSR: $F(4,95) = 0.525$, $p > 0.01$].

Variability in NSR responses *decreased* with increasing rated severity of vocal deviation. In other words, the worse the voice sounded, the better the listeners agreed in their NSR responses ($r = -0.64$, $p < 0.01$). No significant relationship between severity of deviation and response variability was observed for jitter or shimmer (jitter: $r = -0.23$, n.s.; shimmer: $r = -0.16$, n.s.). However, variability in jitter and shimmer responses did increase significantly with the NSR (jitter: $r = 0.68$, $p < 0.01$; shimmer: $r = 0.74$, $p < 0.01$). When the NSR was low, listeners' responses rarely exceeded 1% jitter or 1-dB shimmer. However, as the NSR increased, so did response variability, with some listeners adding little or no jitter or shimmer to the synthetic stimuli, and others adding large amounts. This contrasts sharply with NSR responses: The higher the NSR, the better listeners agreed in their responses ($r = -0.66$, $p < 0.01$).

To examine the relationship between response variability and the spectral shape of the harmonic part of the source (Gerratt and Kreiman, 2001), we calculated the difference in the amplitudes of the first two harmonics ($H1-H2$) from FFT spectra of the LF source pulses. This measure provides one index of the source spectral slope, independent of the influence of the vocal-tract transfer function: The larger

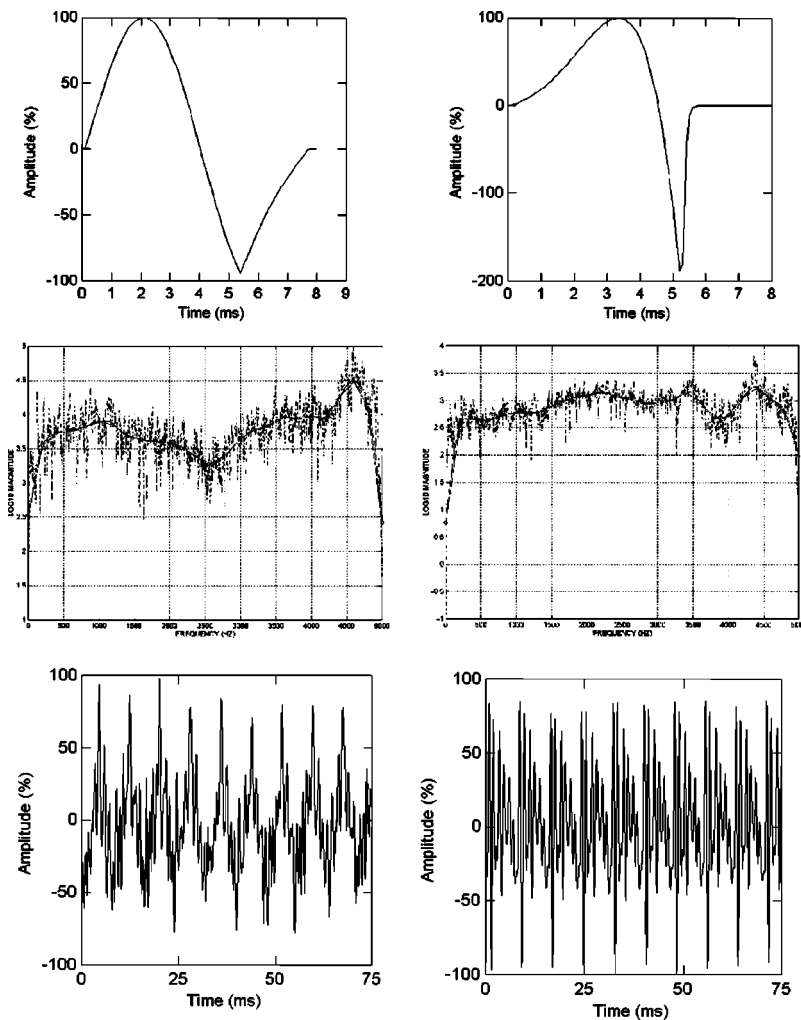

FIG. 4. Sources, noise spectra, and time series waveforms for representative stimuli used in experiment 2. The leftmost three panels represent a voice with a relatively sinusoidal source and a high noise-to-signal ratio (-6.9 dB). The rightmost three panels represent a voice with a nonsinusoidal source and a lower noise-to-signal ratio (-40.4 dB).

$H1-H2$, the more sinusoidal the source. Variability in NSR responses increased as $H1-H2$ decreased ($r = -0.57$, $p < 0.02$). Listeners agreed best in their NSR responses when the harmonic part of the voicing source was near-sinusoidal, as predicted by theory and previous research (Gerratt and Kreiman, 2001). That is, listeners were less sensitive to changes in the NSR when enough energy from the harmonic part of the voice source was also present to provide perceptually salient excitation in the high-frequency part of the voice spectrum. No such relationship was observed between harmonic source characteristics and agreement levels for jitter or shimmer (jitter: $r = 0.29$, n.s.; shimmer: $r = 0.28$, n.s.).

D. Discussion

These data suggest that listeners are relatively sensitive to the overall extent of aperiodicity in the signal, as measured by the NSR. Response variability was relatively low for NSR responses; responses were consistent across experimental conditions, and agreement increased with the amount of noise present. In contrast, the correspondence between jitter, shimmer, and perceived vocal quality appears far less precise. Responses varied widely when listeners were asked to match the amounts of jitter and shimmer present in natural voice signals. Jitter and shimmer responses varied significantly with experimental condition, and variability in re-

sponses increased with increasing aperiodicity. No effect of task on variability was observed, suggesting that listener difficulties were not related to the presence or absence of noise (and corresponding differences in the naturalness of the stimuli).

The dependence of jitter and shimmer responses on experimental condition suggests that listeners judge aperiodicity with respect to the overall amount of noise in the signal, rather than by decomposing aperiodicity into independent, separable aspects. This in turn suggests that listeners' relative insensitivity to the amounts of jitter and shimmer present in a voice signal may be due to their inability to isolate jitter and shimmer within a noisy voice signal. The increasing variability in jitter and shimmer responses as the NSR increased is consistent with this explanation. When the NSR was low, listeners chose (relatively) low values for all aspects of aperiodicity. As the NSR increased, however, variability in jitter and shimmer responses increased, suggesting that listeners as a group could not decide how much of the aperiodicity they heard was jitter or shimmer.

The following experiment tested this hypothesis. We synthesized stimuli with and without noise, and added jitter and shimmer in steps to those stimuli to create several series of voices. If listeners are able to separate the effects of jitter and shimmer from the overall noise pattern, then they should be equally able to detect differences between these stimuli

TABLE I. Stimulus characteristics, experiment 2.

Voice	Speaker sex	Source	NSR (dB)
1	F	-sine	-23.2
2	M	+sine	-6.9
3	F	+sine	-14.9
4	M	-sine	-40.4
5	M	+sine	-24.9
6	F	-sine	-29.2
7	F	+sine	-28.5
8	M	-sine	-29.5

whether noise is absent or present. If listeners are simply grossly insensitive to jitter and shimmer, then they should have difficulty detecting differences whether noise is present or absent. Finally, if listeners can easily distinguish among the variable jitter and shimmer responses from experiment 1, this would implicate difficulties with the multivariate matching task as the cause of the observed variability in responses.

III. EXPERIMENT 2

A. Method

1. Stimuli

Eight voices (four males and four females) were selected from the set of 20 studied in experiment 1. Because sensitivity to the level of noise in a voice may depend on the spectral shape of the harmonic part of the source (Gerratt and Kreiman, 2001), voices were chosen based on the shape of the LF-fitted source pulses (relatively sinusoidal/relatively non-sinusoidal) and on the NSR of the natural voice (relatively high/relatively low) (Fig. 4). Stimuli were chosen so that these parameters varied as orthogonally as possible, given the characteristics of the original voice samples. One male and one female voice were assigned to each source-by-NSR cell (Table I).

Five series of stimuli, each comprising five tokens, were synthesized for each of these eight voices. In two series, the amount of jitter increased across the five tokens in steps. One jitter series was synthesized with the NSR set at a constant value equal to the mean of the levels listeners selected for that voice in experiment 1. The second jitter series was synthesized with the NSR set at -50 dB (no perceptible noise present). Two series of shimmered stimuli were also created, one in which the NSR was set at -50 dB and one with the

NSR set at the mean of the values listeners selected in experiment 1. In both series, the amounts of shimmer present increased across the series in steps, as for the jittered stimuli. The fifth series of stimuli was synthesized with the amount of noise increasing in steps, without any additional jitter or shimmer. Because noise responses were independent of jitter and shimmer responses in experiment 1, additional stimulus series were not created varying noise levels in the contexts of average amounts of jitter and shimmer.

Series endpoints and step sizes were individually determined for each voice (Table II). Endpoints for the jitter series represented the maximum and minimum jitter responses observed for that voice in the condition in experiment 1 in which listeners adjusted jitter only, with noise and shimmer set at -50 and 0 dB, respectively. The three intermediate points in each series were evenly spaced (in acoustic units) between these extremes. Endpoints for the shimmer and noise series were similarly selected based on “shimmer only” and “noise only” response ranges from experiment 1. All other synthesis parameters were held constant for each voice at the values used in experiment 1.

Stimuli were 1 s in duration, and were synthesized with a sampling rate of 10 kHz, using the methods described for experiment 1. They were multiplied by 25-ms onset and offset ramps and scaled for equal peak amplitude prior to presentation to listeners.

2. Listeners and listening task

Eighteen listeners participated in this experiment. All reported normal hearing. For each series of stimuli for each voice, listeners heard all possible pairs of the five synthetic tokens in the series, plus an equal number of pairs where stimuli were the same, for a total of 800 trials/listener (8 voices \times 5 series/voice \times 10 comparisons/series, plus 400 “voices same” trials). They were asked to determine whether the stimuli were the same or different within a pair, and to rate their confidence in their response on a 5-point scale ranging from “positive” to “wild guess.”

Testing took place in a double-walled sound suite in two sessions, each lasting about 45 min. Stimuli were presented in free field at a comfortable constant listening level, and were rerandomized for each listener. Voices within a pair were separated by 350 ms. Listeners controlled the rate at which pairs were presented, but were not allowed to play a pair more than once before responding.

TABLE II. Characteristics of stimulus series for jitter, shimmer, and noise in experiment 2.

Voice	Step sizes for jitter (%)	Jitter continuum endpoints	Step sizes for shimmer (dB)	Shimmer continuum endpoints	Step sizes for NSR (dB)	NSR continuum endpoints
1	0.26	0.018, 1.05	0.18	0, 0.73	1.60	$-27.15, -20.80$
2	0.65	0.15, 2.75	0.39	0.18, 1.75	1.46	$-10.10, -4.25$
3	0.41	0, 1.63	0.45	0, 1.82	0.87	$-16.90, -13.40$
4	0.25	0, 0.98	0.10	0, 0.41	4.68	$-49.20, -30.45$
5	0.47	0.08, 1.94	0.30	0, 1.18	1.97	$-29.20, -21.30$

7	0.23	0, 0.90	0.24	0.09, 1.07	4.17	$-40.20, -23.50$
8	0.70	0, 2.80	0.29	0, 1.16	2.84	$-36.60, -25.25$

FIG. 5. The rate of correct “different” responses versus as a function of the acoustic distance between stimuli. For jitter and shimmer data, stimuli from series that included noise are plotted with stars, and stimuli from series synthesized without noise are plotted with filled circles. For noise data, open circles indicate a voice with a nonsinusoidal source and a high NSR. Regression lines through the two series of data in each panel are plotted with solid lines. The dashed line corresponds to 75% correct discrimination, as described in the text. Top panel: shimmer. Middle panel: jitter. Bottom panel: the noise-to-signal ratio.

3. Results and discussion

Same/different response data were pooled across listeners to estimate overall discrimination performance.³ For each voice and stimulus series, we calculated the percentage of correct “same” responses and the percentage of correct “different” responses. The rate of correct “same” responses was consistent across experimental conditions [$F(4,35) = 0.14, p > 0.05$], ranging from 78.9%–92.8% (mean = 86.5%, $sd = 3.70\%$). Discrimination accuracy (the rate of correct “different” responses) is shown as a function of the acoustic distance between stimuli within a pair in Fig. 5.

Each panel of this figure combines data from the eight individual stimulus voices, pooled across listeners.

Results for jitter and shimmer are shown in panels (A) and (B). In these panels, stimuli from series that included noise are plotted with stars, and stimuli from series synthesized without noise are plotted with filled circles. Regression lines through the two series of data in each panel are plotted with solid lines [Jitter: with noise, $F(1,30) = 9.12, p < 0.01$; no noise, $F(1,30) = 46.39, p < 0.01$. Shimmer: with noise, $F(1,30) = 32.33, p < 0.01$; no noise, $F(1,30) = 83.56, p < 0.01$]. Data in panels (A) and (B) show similar patterns. Discrimination accuracy was significantly better in both cases when noise was absent (filled circles) than when it was present (stars). For jitter, correct discrimination rates averaged 14.95% greater when noise was absent than when it was present [matched pairs $t(31) = 4.37, p < 0.01$]. For shimmer, discrimination accuracy averaged 9.03% more when noise was absent [matched pairs $t(31) = 3.74, p < 0.01$].

Difference limens were estimated by the point of intersection between the regression lines fit to the data and the point at which discrimination accuracy reached 75% (indicated by a dashed line in the figures; e.g., Marks and Algom, 1998). For jitter, averaged across the eight voices, listeners only reliably heard a difference between stimuli that differed by 2.27% or more in jitter when spectral noise was absent. When noise was present, listeners never reliably heard a difference between the stimuli used in this experiment, indicating that stimuli must differ by more than 3% jitter (the maximum range available) for the difference to be reliably perceptible. For shimmer, in the absence of spectral noise listeners could discriminate only among stimuli that differed by at least 1.42 dB in mean shimmer; in the context of spectral noise, a difference of 1.99 dB in mean shimmer (given a maximum range of 2.0 dB) was required for listeners to hear a difference between stimuli 75% of the time.⁴

The pattern is somewhat different for spectral noise [panel (C)]. One voice (number 4) with an extremely high NSR and a harmonic source that provided significant high-frequency excitation was an obvious outlier (plotted with open circles in the figure). When this voice is omitted from the analysis, the function relating discrimination accuracy to differences in noise levels appears curvilinear. This curve was interpolated using a power function rather than a linear function [$F(1,26) = 43.58, p < 0.01$], as shown in the figure, omitting the outlying case. For stimuli to be correctly discriminated 75% of the time required a difference in the NSR of 10.65 dB, a relatively low value given the 50-dB range of the scale. (Recall that listeners used the entire scale for all three measures, so observed differences in the magnitude of the estimated difference limens with respect to the length of the scales are not due to the length of the scales themselves.)

Experiment 2 examined three hypotheses regarding the causes of poor listener agreement in experiment 1. The present results are consistent with two of these hypotheses: Listeners are unable to isolate jitter and shimmer as separate components in the overall pattern of aperiodicity in a voice, and they are also insensitive overall to jitter and shimmer. Listeners were significantly better at discriminating levels of both jitter and shimmer when noise was absent than when it

was present, indicating that listeners do have difficulty decomposing the overall aperiodic component of a voice into independent constituent parts. However, estimated difference limens for jitter and shimmer are large overall, both in the presence and in the absence of spectral noise. These limens are also large relative to jitter and shimmer levels usually considered experimentally or clinically significant. For example, Karnell *et al.* (1995) reported that differences in the jitter measured by different analysis systems averaged 0.01%, while differences in shimmer averaged 0.085 dB. Bielamowicz *et al.* (1996) reported differences between systems in measured jitter of about 0.4%–0.5%; differences between systems in measured shimmer values were less than 0.1 dB. Linville (2000) reported that the voices of old and young men differed in jitter by about 0.6%. Shimmer values for old and young men differed by about 0.4 dB. Hanson *et al.* (1997) found decreases in jitter of about 0.03% after 6–9 weeks of treatment for laryngeal inflammation from gastroesophageal reflux, and claimed that these changes “document the changes in vocal quality with treatment for chronic laryngitis” (p. 284). Shimmer levels for patients with unilateral vocal-fold paralyses differed from those of control patients by about 1 dB (Hartl *et al.*, 2003); and reliable changes in jitter level during a histamine challenge test averaged about 1.5%, leading to the conclusion that “jitter is an objective and repeatable measurement of hoarseness” (Jones *et al.*, 2001, p. 29). Although probable variations in measurement techniques may limit comparisons among studies, estimated difference limens for jitter and shimmer in the present study far surpass these values, and also exceed the measurement precision usually required for such measures (Titze, 1995; Titze *et al.*, 1987).

Finally, the results do not support the hypothesis that listener problems in agreement observed in experiment 1 resulted from difficulties in performing the multivariate method-of-adjustment task. In our previous study using this method (Gerratt and Kreiman, 2001), listener agreement was substantially higher for NSR settings than it was for perceptual ratings of the noisiness of the same stimuli. However, in that study listeners were asked to adjust only a single synthesizer parameter. Similar levels of listener agreement were observed for NSR settings in the present study, when listeners were asked to adjust as many as three parameters simultaneously. Further, NSR ratings remained consistent, whether listeners were adjusting one, two, or three parameters simultaneously. The fact that listener agreement about NSR ratings remained consistently high across tasks suggests that listeners’ inconsistency with each other when matching jitter and shimmer levels was not due to the multivariate task, but instead was related to their auditory insensitivity to these two parameters.

IV. GENERAL DISCUSSION

Acoustic measures of voice derive their importance from the relevance of the acoustic signal to auditory perception of voice, association with some aspect of laryngeal physiology, or both (Catford, 1977). Jitter, shimmer, and noise have many physical sources and may arise at many stages in the speech production process (see, e.g., Titze, 1994, for review).

Because a given measurement value can reflect so many different causes, acoustic measures of aperiodicity are not diagnostically useful as indices of any particular physical state or physiological process. This leaves associations with voice quality as a possible motivation for measuring aperiodicity. This motivation also appears to fail in the cases of jitter and shimmer. Comparisons with published values are difficult because recording techniques, measurement procedures, and computational algorithms vary widely (see Buder, 2000, for review), and authors are not always specific about the methods applied. However, it appears that listeners are insensitive to the amounts of jitter and shimmer present in a voice sample within a range often treated as meaningful, as discussed above. We conclude that the associations between jitter, shimmer, and perceived voice quality are not sufficiently explanatory to justify continued reliance on jitter and shimmer as indices of voice quality.

The case is stronger for the perceptual relevance of NSR measures, because listeners agreed far better in their NSR responses than they did for jitter and shimmer, and the minimum reliably perceptible difference for the NSR was much smaller relative to the range of observations than it was for jitter and shimmer. NSR responses were independent of experimental task, and observed variability could be explained in part by the pattern of high-frequency excitation in a voice. These results indicate that listeners respond perceptually to changes in the NSR in consistent and principled ways, suggesting that the NSR is a significant and reliable determinant of vocal quality.

However, the fact that a measure is perceptually or psychologically important does not mean that researchers can ignore the limits of perceptual resolution on that scale when applying it. Although comparisons to values in the literature are again difficult (differences among computational methods for NSR measures being particularly inscrutable and vexing; see Buder, 2000), many authors’ claims about group differences or treatment effects rest on NSR differences that may be imperceptible. For example, Su *et al.* (2002) found statistically significant differences in pre- and postsurgical NSR values of 0.12 dB; Jotz *et al.* (2002) reported that each increase of 0.01 dB in the NSR doubled the risk of dysphonia in a sample of boys with and without vocal-fold lesions; and Niedzielska (2001) found differences in NSRs between control subjects and various diagnostic groups ranging from 2.7 to 14.2 dB. Further research examining the perceptual interactions between the harmonic and inharmonic parts of the voicing source should contribute to standardizing NSR measures so that they reflect vocal quality as accurately as possible. This will enhance our ability to apply NSR measures appropriately.

Finally, the present data extend our previous findings regarding the reliability of the method of adjustment task from expert listeners (Gerratt and Kreiman, 2001) to naive listeners. Reanalysis of data from our previous experiment, which used a different set of stimulus voices and expert listeners, produced a difference limen for the NSR (the point at which listeners achieved 75% correct discrimination, on average) of 13.4 dB, compared to the value of 10.65 dB for naive listeners in the present study. Expert and naive listeners

have previously been shown to differ significantly in the perceptual strategies they apply when rating pathological voices on traditional scales like breathiness or roughness (Kreiman *et al.*, 1990). However, the similarity in sensitivity levels for expert and naive listeners suggests that this method-of-adjustment task controls the effects of listener experience on perceptual responses, as previously predicted (Kreiman and Gerratt, 2000).

The results reported here may be surprising in light of the hundreds of papers published on these acoustic measures over the last 40 years. These results highlight the importance of applying psychometric methods to the study of voice quality. Descriptive and correlational statistical techniques, including multidimensional scaling and factor analysis, may suggest that a given dimension is perceptually important. However, without confirmatory experimental studies, such associations between signal and percept remain merely suggestive. At a minimum, both theory and application will benefit if investigators verify that listeners are auditorily sensitive to the range of values of interest for a particular acoustic measure to ensure that such measures are in fact determinants of perceived quality.

ACKNOWLEDGMENTS

Norma Antoñanzas and Brian Gabelman wrote the software used in this research. Jason Mallory created the stimuli in experiment 2 and patiently tested many of the listeners in both experiments. Preliminary reports of the results were presented at the 144th and 145th meetings of the Acoustical Society of America. This research was supported by Grant DC01797 from the National Institute on Deafness and Other Communication Disorders.

¹Amplitude modulations did not produce major differences in the quality of most voices, because many so-called “amplitude tremors” are artifacts of frequency modulation (Sundberg, 1995; Kreiman *et al.*, 2003). However, these modulations were important for synthesizing several samples in the present study, especially those from speakers with spasmodic dysphonia.

²Software is available from the authors by request.

³Confidence ratings were not used in analyses of these data.

⁴Difference limens observed here may depend in part on the fact that listeners heard stimuli in free field, and could only hear a pair of voices once before responding. Although results reflect listeners’ discrimination ability under normal listening conditions, they do not necessarily reflect the precise limits of perceptual acuity as measured with headphones and multiple presentations prior to response.

Consonant recognition and the articulation index

Jont B. Allen

ECE Department and the Beckman Institute, University of Illinois, Urbana, Illinois 61801

(Received 1 August 2004; revised 14 December 2004; accepted 15 December 2004)

The purpose of this paper is to provide insight into how speech is processed by the auditory system, by quantifying the nature of nonsense speech sound confusions. (1) The Miller and Nicely [J. Acoust. Soc. Am. **27**(2), 338–352 (1955)] confusion matrix (CM) data are analyzed by plotting the CM elements $S_{i,j}$ (SNR) as a function of the signal-to-noise ratio (SNR). This allows for the robust clustering of perceptual feature (event) groups, not robustly defined by a single CM table, where clusters depend on the sound order. (2) The SNR is then re-expressed as an articulation index (AI), and used as the independent variable. The normalized log scores $\log(1-S_{i,i}(\text{AI}))$ and $\log(S_{i,j}(\text{AI}))$, $j \neq i$, then become linear functions of AI, on log-error versus AI plots. This linear dependence may be interpreted as an extension of the band-independence model of Fletcher. (3) The model formula for the average score for the finite-alphabet case $P_c(\text{AI}, \mathcal{H}) = \sum_{i=1}^N S_{i,i} / N$ is then modified to include the effect of entropy \mathcal{H} . Due to the grouping of sounds with increased SNR (and AI), the sound-group entropy \mathcal{H}_g plays a key role in this performance measure. (4) A parametric model for the confusions $S_{i,j}(\text{AI}, \mathcal{H}_g)$ is then described, which characterizes the confusions between competing sounds within a group. © 2005 Acoustical Society of America.

I. INTRODUCTION

The articulation index (AI) and the confusion matrix (CM), denoted $\mathcal{C}_{i,j}$, are two important measures frequently used to characterize human speech recognition. This paper explores the merging of these two measures by expressing the CM as a function of the AI. The natural grouping of sounds, observed by Miller and Nicely in their classic 1955 experiment, is then explained in terms of a change in each group's entropy \mathcal{H}_g , which is also a function of the AI. A parametric model of the symmetric form of the CM confusions $S_{i,j}(\text{AI}, \mathcal{H})$ is then developed. These parametric models lead to a new formulation of the average score $P_c(\text{AI}, \mathcal{H})$, which accounts for chance. This model provides an accurate fit to the raw data, and provides new insight into Fletcher's *band independence* formulation for the average articulation score (Allen, 1994).

A fundamental building block in the theory of speech communication is the articulation index (AI) model of speech sound recognition (French and Steinberg, 1947; Fletcher and Galt, 1950; Allen, 1994). The AI is a speech audibility measure, averaged across many cochlear frequency bands, of a specific speech-to-noise ratio measure, that takes into account the effects of masking and cochlear filtering (Allen, 1994). The masking can be due either to external noise, when noise is added to the speech at the source, or internal noise, present in the cochlea and auditory nerve. The AI measure is weighted to account for both cochlear critical bands and those frequency regions containing important speech information. Fletcher developed the AI to predict the average nonsense-phone articulation score $P_c(\text{SNR})$, as a function of the speech-to-noise ratio (SNR) (specified over 20 frequency bands), as a way of avoiding expensive and time-consuming listening tests on speech communication equipment. The AI also offers important in-

sights into human speech perception. In this paper the AI is used to provide a new and insightful view of the confusion data of Miller and Nicely (1955).

Many procedures have been developed which claim to predict the phone performance score for noisy and/or filtered channels, several of which are called the “articulation index.” Following the first proposal in 1921 by Fletcher, there is the Bell Labs procedure of FS47 (key abbreviations are provided in Table I), followed by the more extensive version by Fletcher and Galt (1950). Then, Kryter published his simplified method in 1962 (Kryter, 1962a, 1962b), soon followed by the ANSI version. More recently, the STI was proposed to extend the AI procedure when room reverberation is present (Houtgast and Steeneken, 1973; Steeneken and Houtgast, 1980). This was then followed by the new ANSI procedure SII (S3.5-1997, 1997).

The focus on the articulation index provided here is not on predicting the performance of speech communications systems, but rather in understanding and modeling the perception and recognition of human speech sounds. The focus

TABLE I. Table of abbreviations.

Abbreviation	Definition
CV, CVC	Consonant+vowel sounds
intelligibility	Recognition of phonemes
articulation	Recognition of nonsense phones
CM	Confusion matrix
AM	Articulation matrix (CM of nonsense speech)
AI	Articulation index
SNR	Speech-to-noise ratio
rms	Root-mean-squared
events	Perceptual features
MN55	Miller and Nicely (1955)
FS47	French and Steinberg (1947)

here is not on procedures for predicting phone intelligibility, but in gaining leverage from the well-validated AI predictions, to provide insight into nonsense-phone identifications.

At least four fundamental questions are addressed in this presentation.

- (1) What is the relation between the AI and the CM?
- (2) How can one more accurately determine the groups that are present in Miller and Nicely's CM data at certain SNRs?
- (3) What are the limits of Fletcher's *band independence* assumption?
- (4) Can the AI be used to predict the phone score for closed sets (i.e., what are the limits of the AI procedure)?

Subsequent to the Bell Labs articulation studies, and following up work done during WWII, Miller took up the study of speech articulations in much greater detail. As detailed in Miller's (1951) book *Language and Communication*, information and communication theory are the basis for understanding the speech code. One of the basic tools of information theory is the *channel*, the mathematical characterization of a communication link (i.e., a noisy pair of wires, with codecs attached), in terms of discrete input and output symbols from some *alphabet*. One method for characterizing the human speech communication channel is the nonsense-phone confusion matrix (CM), which characterizes the probabilities of nonsense speech sound (the symbols) transmission errors. It is expected that an error analysis of this *articulation matrix* (AM), as a function of the SNR, can give important insight into the speech code.

A second key concept from information theory is that of entropy \mathcal{H} , which is a measure of the compactness of a probability distribution, which in the case of speech represents the distribution of the sound confusions. In his classic 1951 study, Miller *et al.* (1951) (MHL51) showed the effects of symbol alphabet size, and thus the entropy, on word recognition. Four years later, in a second classic study, Miller and Nicely (MN55) showed that as the wideband SNR is raised from -18 to $+12$ dB, *the sounds form perceptual groups*. The formation of a group, as a function of the SNR, also results in a change (reduction) in \mathcal{H} .

In analyzing their confusion matrices, MN55 quantified the grouping effect using a mutual-information (MI) analysis, on assumed groups. An natural advantage of the MI analysis method is its insensitivity to bias, as defined by the skew-symmetric form of the CM. This is at the same time a weakness of the MI, since it may be beneficial to remove the effects of subject bias prior to modeling the confusions. A major disadvantage of mutual information, as used in MN55, is that it gives no insight into the formation of the groups being analyzed.

This paper explores the limits and applicability of Fletcher's band-independence model, applied to the 1955 closed-set consonant articulation data of Miller and Nicely (MN55). Such data do not meet the usual assumptions of the AI audibility measure, of a large, high-entropy open-set corpus. By plotting the confusions as a function of SNR, it is possible to identify the groups in a systematic, logical way, without assuming any predetermined sound ordering. This

leads to an accurate method of identifying the natural sound groups, and allows one to display the complex body of CM data at all SNRs, in a single figure. Once the groups have been identified, one is then free to further explore the relationship of the AM to the AI and \mathcal{H} .

The definitions of mathematical symbols has been summarized in Table II.

II. REPRESENTATIONS OF THE CONFUSION MATRIX (CM)

Figure 1 shows a typical MN55 consonant–vowel (CV) *confusion matrix* or *count matrix* for wideband speech (0.2–6.5 kHz), at a *speech-to-noise ratio* (SNR) of -6 dB (Miller and Nicely, 1955, Table III). The 16 consonants were presented along with the vowel /a/ as in father (i.e., the first three sounds were [pa/,ta/,ka/]). After hearing one of the 16 CV sounds as labeled by the first column, the consonant that was reported is given as labeled along the top row. This array of numbers form the basic CM, denoted $\mathcal{C}_{s,h}$, where integer indices s and h (i.e., “spoken” and “heard”) each run between 1 and 16. For example, /pa/ was spoken 230 times (the sum of the counts in the first row), and was reported heard 80 times ($\mathcal{C}_{1,1}$), while /ta/ was reported 43 times ($\mathcal{C}_{1,2}$). For Table III the mean row count was 250, with a standard deviation of 21 counts.

When the sounds are ordered as shown in Fig. 1, they form groups, identified in terms of hierarchical clusters of *articulatory features*. For example, the first group of sounds 1–7 correspond to unvoiced, group 8–14 are voiced, and 15, 16 are nasal (and also voiced).

At an SNR of -6 dB, the intraconfusions (within a group) are much greater than the interconfusions (between groups). For example, members of the group 1–7 (the unvoiced sounds) are much more likely to be confused among themselves, than between the voiced sounds (8–14), or the nasal sounds (15,16). The nasal are confused with each other, but rarely with any of the other sounds 1–14.

TABLE II. Table of mathematical symbols.

Symbol	Definition	Equation
\mathcal{I}	Intelligibility (meaningful sound recognition)	
\mathcal{C}	Confusion matrix	(2)
\mathcal{A}	Articulation matrix	(1)
S	Symmetric form of \mathcal{A}	(3)
A	Skew-symmetric form of \mathcal{A}	(4), (5)
P_c	Probability correct	(17), (16), (18)
$P_c^{(i)}$	Same as $\mathcal{A}_{i,i}$ and $S_{i,i}$	
\mathcal{H}	Entropy	
AI	Articulation index (AI)	(8)
AI_k	Specific AI in band k	(11)
e	Total error	(12), (13), (20)
e_i	Total error for sound i : $e_i \equiv 1 - P_c^{(i)} = 1 - \mathcal{A}_{i,i}$	(7)
e_{\min}	Minimum error	(15)
e_{chance}	Chance error	(19)
ϵ_k	k th band error	(14)
$e_{\min}^{(i)}$	Minimum error for sound i : $e_i _{AI=1}$	
S_{15}	Shorthand for $S_{15,15}$	
snr_k	Speech-to-noise rms ratio in band k	(9)

FIG. 1. Typical Miller–Nicely frequency of confusions, or count matrix C , from Table III at -6 -dB SNR. Each entry in the matrix $C_{s,h}$ is the subject response count. The rows correspond to the *spoken* CVs, each row representing a different consonant, from $s = 1, \dots, 16$. The columns correspond to the *heard* CVs, each column representing a different consonant, from $h = 1, \dots, 16$. The common vowel /a/, as in “father,” was used throughout. When the 16 consonants are ordered as shown, the count matrix shows a “block-symmetric” partitioning in the consonant confusions. In this matrix there are three main blocks delineated by the dashed lines, corresponding to unvoiced, voiced, and nasal. Within the voiced and unvoiced subgroups, there are two additional symmetric blocks, corresponding to affrication and duration, also delineated with dashed lines.

The MN55 articulatory feature classification scheme is far from perfect. For example, the nasals are voiced in the same sense as those labeled voiced; however, they clearly form a unique cluster. Thus, there is no unique simple articulatory label for sounds 8–14. Groups systematically depend on the SNR, and groups remain unidentified by this scheme. Using the example of Table III (Fig. 1), [ba/,va/,ða/] form a group that is distinct from the nonfricative voiced subgroup. An improved order for sounds 8–14 would be [ba/,va/,ða/], [za/,za/,da/,ga/]. Of course, this example fundamentally breaks the MN55 articulatory feature classification scheme. In fact, the feature space cannot strictly be articulatory feature based.

The MN55 data have been the inspiration for a large number of studies. The sound grouping has been studied using multidimensional scaling, which has generally failed in providing a robust method for finding perceptually relevant groups of sounds, as discussed by Wang and Bilger (1973). Thus, the grouping problem has remained unsolved.

The data in the CM represent a psychological subject response, and therefore need to be represented in terms of *psychological variables* rather than physical (production) measures, as labeled by articulatory features. This could have been the role of *distinctive features*, had they been so defined. Unfortunately, there seems to be some confusion in the literature as to the precise definition of a distinctive feature. For example, are distinctive features production or perception quantities?

To avoid this confusion, I shall use the term *event* when referring to *perceptual features*. Since Miller and Nicely’s confusion data are based on perception, they must be de-

scribed by events. The precise nature of these events may be explored by studying the 15 plots $S_{i,j}$, $i \neq j$, as shown in the lower-left panel of Fig. 2 for the case of $i = 2$.

A. The transformation from CM to AM

The term *articulation* is defined as the probability correct P_c of identifying nonsense-phone speech sounds (consonants and vowels), while *intelligibility* \mathcal{I} is the probability of identifying meaningful speech sounds, such as words and sentences (Fletcher and Galt, 1950).

When normalized as a probability, the consonant confusion matrix is transformed to an *articulation matrix* (AM), denoted \mathcal{A} (script A, Table II), with elements

$$A_{s,h} \equiv \frac{C_{s,h}}{\sum_h C_{s,h}}. \quad (1)$$

This normalization, to an equal probability for each row, is justified because of the small standard deviation of the row sums (i.e., 250 ± 21).

The AM is the empirical conditional probability $P_c(h|s)$ of reporting sound h after speaking sound s , namely

$$A_{s,h} \equiv P_c(h|s), \quad (2)$$

for integer labels s, h (i.e., spoken, heard). In another sense, $A_{s,h}$ for $s \neq h$ is an error probability, since it is the probability of reporting the wrong sounds h after hearing spoken sound $s \neq h$.

Figure 2 shows the probability of responding that the sound $h = 1, \dots, 16$ was reported, following speaking /ta/ ($s = 2$), as a function of the wideband SNR. The upper-left

FIG. 2. This figure shows Miller and Nicely's 1955 wideband row-normalized confusion matrix data $\mathcal{A}_{s,h}(\text{SNR})$ [Eq. (1)] for the sound /ta/ (sound 2) from MN55 Tables I–IV, as a function of the speech-to-noise ratio. The upper-left panel is a plot of the second row of the articulation matrix $[\mathcal{A}_{2,h}(\text{SNR}), h=1,\dots,16]$, corresponding to /ta/ spoken], while the upper-right panel is a plot of the second column $[\mathcal{A}_{s,2}(\text{SNR})]$, corresponding to /ta/ heard]. The matrix is not perfectly symmetric ($\mathcal{A} \neq \mathcal{A}^t$), which explains the small differences between these two plots. The lower-left panel is the symmetric form of the articulation matrix given by Eq. (3), which is the average of \mathcal{A} and its transpose \mathcal{A}^t . The lower-right panel is the skew-symmetric form A [Eq. (4)]. The horizontal dashed line in each figure shows chance performance (i.e., $1/16$).

panel shows the probability $\mathcal{A}_{2,h}(\text{SNR})$ of each heard sound ($h=1,\dots,16$), given /ta/ was spoken. The upper-right panel shows the probability $\mathcal{A}_{s,2}$ of each sound spoken ($s=1,\dots,16$), given that /ta/ was heard. The curve that rises to 1 is the probability of correctly reporting /ta/ $\mathcal{A}_{2,2}(\text{SNR})$, given that it was spoken (left), or spoken given that it was heard (right). The solid-thick curve is the total probability of error $e_2(\text{SNR}) \equiv 1 - \mathcal{A}_{2,2}(\text{SNR})$ of not reporting /ta/, given that it was spoken (left) or heard (right).

Symmetric and skew-symmetric decomposition

The lower-left panel of Fig. 2 is a plot of the second row $S_{2,j}$ of the symmetric form of the AM, defined as

$$S \equiv \frac{1}{2}(\mathcal{A} + \mathcal{A}^t), \quad (3)$$

where \mathcal{A}^t is the transpose of \mathcal{A} , while the lower-right panel is the second row of $A_{i,j}$ of the skew-symmetric form of the matrix, defined as

$$A \equiv \frac{1}{2}(\mathcal{A} - \mathcal{A}^t). \quad (4)$$

It appears that the sampling error (statistical uncertainty) in the measurements, due to the sample size, is about 0.5% (0.005), which is where the measurements become scattered. This variability is determined by many factors, including the number of trials per sound, the smoothing provided by the symmetric transformation, the consistency of the talker, and the mental concentration and number of the observers (four in this case).

From the lower-right panel, it is clear that the AM is close to symmetric, since the skew-symmetric terms are small. A few terms of $A_{2,h}(\text{SNR})$ are as large as 5%, but most are less than 1%. Since the MN55 data are close to symmetric, it is reasonable to force the symmetry, and then to study S and A separately, which is the approach taken here. Note that S is slightly smoother than \mathcal{A} , since each element $\mathcal{A}_{s,h}$ is the average of two similar terms, $\mathcal{A}_{h,s}$ and

$\mathcal{A}_{s,h}$. Using the symmetric form simplifies the analysis of the matrix and gives us access to the skew-symmetric form.

Based on an analysis by Goldstein (1980), the interpretation of the skew-symmetric form is quite different from that of the symmetric form. The most likely explanation of the skew-symmetric matrix is that the subjects have a bias for one sound over another, and are therefore more likely to report the consonant for which they have the bias (Goldstein, 1980).

The largest skew-symmetric sounds in row 2 are /fa/, /θa/, /va/, and /ða/, which have errors approaching 5%, but are always less than chance (1/16). It seems significant that the skew-symmetric form always lies slightly below chance (Fig. 2, lower-right panel). For the rest of the sounds, the error patterns are similar in their nature to those of /ta/, with the largest errors of about 10% in a few places, but with most of the errors being a few percent or less.

There is an interaction between the row normalization [Eq. (1)], and the symmetry transformation Eq. (3), which requires that the row normalization and symmetric computations be iterated. This iteration always converges to the same result, and is always stable for all of the MN55 tables. An entry of "1" in \mathcal{C} represents a single vote for the same utterance, from four listeners who heard that utterance. All 1's were deleted from the matrix before computing S . Once matrix S has been determined, A is computed from

$$A = \mathcal{A} - S. \quad (5)$$

Plotting the symmetric data $S(\text{SNR})$ as a function of SNR, as shown in Fig. 2, provides a concise yet comprehensive summary of the entire set of measurements, and shows the hierarchical grouping, without a need to order the sounds. In the next section it is shown that if $S_{i,j}$ is described as a function of the AI, rather than the SNR, the same data may be quantitatively modeled, and the important effects of chance may be accounted for.

B. Grouping the sounds

Sound clustering in the CM was used by MN55 as the basis for arguing that the sounds break down into distinct groups, which MN55 identified as five discrete *articulatory features*, which they called *voicing*, *nasality*, *affrication*, *duration*, and *place*.

Each symbol in Fig. 2 labels a different articulatory feature. Sounds 1–3 (/pa/,/ta/,/ka/) are shown as circles, 4–7 (/fa/,/θa/,/sa/,/ʃa/) triangles, 8–10 (/ba/,/da/,/ga/) squares, 11–14 (/va/,/ða/,/za/,/ʒa/) upside-down triangles, while the nasal sounds 14 and 15 (/ma/,/na/) are labeled by 5-pointed stars.

The hierarchical clusters are seen as groups that peel away as the SNR increases. The symmetric /ta/ data shown in the lower-left panel of Fig. 2 are a great example: First, all the voiced sounds dramatically drop, starting from chance, as the SNR is raised. Next, the unvoiced-fricatives /fa/, /θa/, /sa/, /ʃa/ (triangles) peel off, after very slightly rising above chance at –12-dB SNR. Finally, the two main competitors to /ta/ (/pa/ and /ka/) peak around –6-dB SNR, and then fall dramatically, as /ta/ is clearly identified at 0-dB SNR and above. In the lower-left panel /pa/, /ta/, and /ka/ (○) are statistically indistinguishable below –6 dB, and approach chance identification of 1/16 at –18 dB. Above about –6 dB, /ta/ separates and the identification approaches 1, while the confusions with the other two sounds (/pa/ and /ka/) reach a maximum of about a 25% score, and then drop monotonically, as the SNR increases.

The MN55 sounds 4–7 (/fa/, /θa/, /sa/, and /ʃa/), like sounds 1–3 (/pa/,/ta/,/ka/), also form a group, as may be seen in the lower-left panel, labeled by Δ. This group also starts from chance identification (6.25%), rises slightly to a score of about 7% at –12 dB, and then monotonically drops at a slightly greater rate than sounds 1 and 3 (symbols ○).

The third group is the remaining sounds 8–16, labeled by the remaining symbols, which show no rise in performance; rather, they steeply drop from the chance level.

At the lowest SNR of –18 dB, the elements in the symmetric form of the AM approach chance performance, which for MN55 is 1/16, corresponding to closed-set guessing. Extrapolating the data of Fig. 2, chance performance corresponds to about –21-dB SNR.

Based on the clustering seen in the AM (e.g., MN55 Tables II and III), it was concluded by MN55 that the three sounds /ta/, /pa/, and /ka/ might be thought of as one group. These three sounds form the unvoiced, non-nasal, nonaffricate, low-duration group, having three different values of place. The details of these groupings depend on the SNR. A detailed analysis of these clusters show that the MN55 *articulatory features* (production feature set) do not always correspond to the *events* (perceptual feature set).

In fact, it would be surprising if it turned out any other way, given that production and perception are fundamentally different things. The details of a scheme that will allow us to make such an analysis of the optimal perceptual feature set, form the remainder of this paper.

1. Formula for the total error

The solid-thick curve in the top two, and bottom-left panels of Fig. 2, are graphs of the total error for /ta/

$$e_2(\text{SNR}) \equiv 1 - S_{2,2}(\text{SNR}). \quad (6)$$

Because each row of $S_{i,j}$ has been normalized so that it sums to 1, the total error for the i th sound is also the row sum of the 15 off-diagonal ($j \neq i$) elements, namely

$$e_i(\text{SNR}) = \sum_{j \neq i} S_{i,j}(\text{SNR}). \quad (7)$$

Since each error term is non-negative, e_i must bound each individual confusion $S_{i,j}$. For the data of Fig. 2, lower-left, the other two circle curves (/pa/ and /ka/), which compete with /ta/, and thereby form a 3-group, are nearly identical. All other error terms are much smaller. Thus, the solid-thick curve, $e_2(\text{SNR})$, is approximately twice the size of the curves for /pa/ and /ka/. All the off-diagonal terms go to zero at +12-dB SNR so for that one point $e_2 = S_{2,j}$, a fluke of the small-number statistics.

Equation (7) says that the total error for the i th sound is linearly decomposed by the off-diagonal errors of the AM. This is a natural decomposition of the total error into its confusions that can help us understand the AI predictions in much greater detail.

For example: *Why does the probability of identification of sounds 1–3 and 4–7 increase even when these sounds are not spoken?* The initial rise for the two sound groups follows from the increase in chance performance due to the decreased entropy, which follows from the reduced size of the group. This conclusion follows naturally from Eq. (7). As the SNR increases, the size of the group exponentially decreases.

As the number of alternatives in a closed-set task decreases, the probability of guessing increases. Given 2 alternatives, chance is 1/2; given 16, chance is 1/16. Thus, grouping and the rise due to the confusion within the group are intimately tied together. In the same manner, as the SNR rises from –18 to –12, the MN55 sounds 4–16 are perceptually ruled out, increasing chance performance for sounds 1–3 from 1/16 to 1/3.

2. The nasals

In Fig. 3 $S_{i,j}(\text{SNR})$ for $i = 15, 16$, corresponding to /ma/ and /na/, are presented. The two nasal sounds are clearly separated from all the other sounds, even at –18-dB SNR. As the SNR increases, the scores rise to $\approx 25\%$, peaking at or near –12-dB SNR, following with the identification rising and the confusion dramatically falling for SNRs at and above –6 dB.

Sounds 1–14 are solidly rejected, even at –18 dB. These scores exponentially drop as the SNR is increased. There is a slight (visual) hint of a rise of a few sounds for the case of /ma/, in some of the rejected sounds in the left panel, and some corresponding grouping, but the effect is small and it would be difficult to tease out. The rejected sounds in the right panel do not show any obvious grouping effect.

The subjects can clearly distinguish the two nasal sounds (sounds 15,16) from all the others (sounds 1–14),

FIG. 3. Plots of the symmetric AM corresponding to the nasals /ma/ and /na/. The curve that rises to 1 is $S_{i,i}(\text{SNR})$ for $i=15$ (left) and $i=16$ (right). The solid thick curve in each panel is e_i [Eq. (7)]. The other curves represent confusions $S_{i,j}(\text{SNR})$ for the remaining sounds $j=1, \dots, 14$.

even at the lowest SNR of -18 dB; however, they cannot distinguish between them until the SNR is greater than -12 dB. The subjects know the sound they hear is nasal, but the question is, which one? This identification of event-nasal leads to a significant increase in chance performance for SNRs between -18 and -6 dB, from $1/16$ to $1/2$.

One may also see this effect in the raw count data at -18 dB, where the confusions are approaching equal chance levels. For example, in MN55 Table I, the raw counts are [25,28;33,32]. At -12 dB, /ma/ and /na/ are significantly confused with each other, but rarely with the other sounds. For example, from MN55 Table II, /ma/ is heard 20 times when /ba/ is spoken [$S_{15,8}(-12) = 6.72\%$ of the time], while /ba/ is heard 11 times when /ma/ is spoken (5.83% of the time).

III. TRANSFORMATION FROM THE WIDEBAND SNR TO THE AI

Miller and Nicely used the wideband SNR, in dB, as their measure of audibility. However, as discussed in the Introduction, there are reasons to believe that the AI(SNR) is a better audibility measure. We shall now demonstrate this for the MN55 data. Our approach is to transform MN55's wideband SNR into an AI, and then to plot the resulting $S_{i,j}(\text{AI})$.

To compute the AI for MN55 one needs to know the *specific* SNR, over articulation bands, denoted snr_k . This requires knowledge of the average speech spectra for five female talkers, and the noise spectra. The spectrum for five female talkers is shown in Fig. 4, while the noise spectra was independent of frequency (i.e., white). The procedure for computing AI(SNR) is described next.

A. Computing the specific AI

The AI is defined by FS47 [their Eq. (8)] as

$$\text{AI} = \frac{1}{K} \sum_k^K \text{AI}_k, \quad (8)$$

namely as a 20-band average over the *specific* AI, denoted AI_k . The specific AI is defined in terms of the speech-to-noise ratio

$$\text{snr}_k \equiv \sigma_{s,k} / \sigma_{n,k}, \quad (9)$$

where the speech power is $\sigma_{s,k}^2$ [Watts/critical band] and the masking noise power is $\sigma_{n,k}^2$ [Watts/critical band], in the k th articulation band. When calculating $\sigma_{s,k}$, the average is over 1/8-s intervals. snr_k is the same as FS47's band sensation

level E. The k th articulation band power-snr *speech detection threshold* may be modeled as

$$\frac{I + \Delta I}{I} \equiv \frac{\sigma_{n,k}^2 + c^2 \sigma_{s,k}^2}{\sigma_{n,k}^2} = 1 + c^2 \text{snr}_k^2, \quad (10)$$

where a frequency-independent *speech detection constant* c is determined empirically from data on the detection of speech in noise (Fletcher and Munson, 1937; French and Steinberg, 1947). The role of c is to convert the speech rms to the speech peaks, which are typically 12 dB above the rms speech level. When snr_k specifies the speech peaks, $c=2$.

Converting to decibels, and scaling by 30, defines the *specific* AI

$$\text{AI}_k = \min\left(\frac{1}{3} \log_{10}(1 + c^2 \text{snr}_k^2), 1\right). \quad (11)$$

Relationship Eq. (11) follows from the detailed discussions of FS47 and Fletcher and Galt (1950), followed by the subsequent analysis by Allen (1994). [See especially (Fletcher, 1995, Eq. (10-3), page 167).]

Between 0 and 30 dB, AI_k is proportional to $\log(\text{snr}_k)$ because the percent of the time the speech is above a certain level is proportional to the dB SL level (*re*: threshold sensation level) (French and Steinberg, 1947; Allen, 1994). The factor of $1/3$ comes from the dynamic range of speech in a given articulation band (French and Steinberg, 1947, Fig. 4,

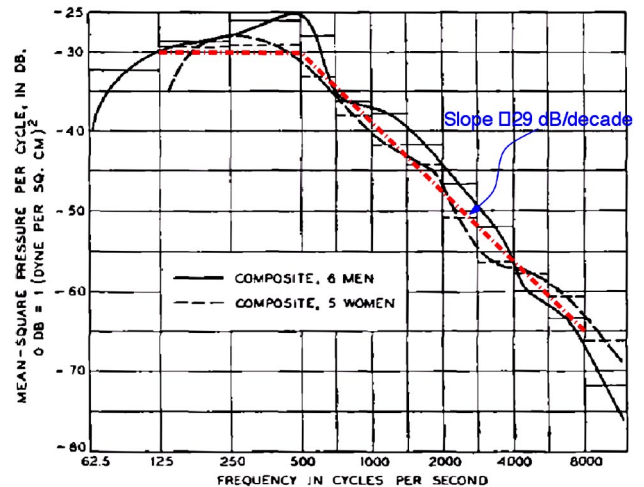

FIG. 4. This figure from Dunn and White, 1940 (their Fig. 10) shows the average power spectrum for six men and five women. The dashed curve, which approximates the power spectrum for the five women, has a slope of 0 from 125 to 500 Hz, and a slope of -29 -dB/decade between 0.5 and 8 kHz.

page 95). As discussed extensively by FS47 (i.e., their Table 12), an empirical *threshold adjustment* must be made, labeled c in Eq. (10). The value of c is chosen such that the speech is just detectable when $\text{snr}_k = 1$, in each cochlear critical band, corresponding to specific AIs of zero (i.e., $\text{AI}_k = 0$). Equation (11) over-predicts the data of FS47 Table V by 3.2% ($c \equiv 1/2$, $\text{snr}_k = E$). A more precise estimation of c would require repeating Fletcher's critical ratio experiment using narrow bands of speech, with a white-noise masker and measuring snr_k at the detection threshold. The $\min(x, 1)$ part of the definition limits the AI on the high end, since for an SNR above 30 dB, the noise has a negligible effect on the articulation (and intelligibility).

The band independence model of the total error

The average sound articulation error e (SNR), in terms of the average sound articulation $P_c(\text{SNR})$, is

$$e(\text{SNR}) = 1 - P_c(\text{SNR}). \quad (12)$$

In 1921 Fletcher showed that the articulation error probability $e(\text{SNR})$ could be thought of as being distributed over K -independent articulation bands. The bandwidth of each of these articulation bands was chosen so that they contribute equally to e [the articulation per critical band is constant from 0.3–7 kHz (Fletcher and Galt, 1950; Allen, 1994, 1996)]. Assuming band independence, the total articulation error may be written as a product over K band articulation errors

$$e = \epsilon_1 \epsilon_2 \cdots \epsilon_k \cdots \epsilon_K. \quad (13)$$

This equation is called the *band independence model*.

Galt established that the articulation bandwidth is proportional to cochlear critical bandwidths (French and Steinberg, 1947, page 93), as measured by the *critical ratio* method and the frequency jnd (Allen, 1994, 1996). Fletcher then estimated that each articulation band was the equivalent of 1 mm of distance along the basilar membrane, thereby taking up the 20-mm distance along the basilar membrane, between 300 to 8 kHz (Allen, 1996). Thus, the AI [Eq. (8)] may be viewed as an average SNR, *averaged over dB units*, of a scaled specific SNR, defined over cochlear critical bands.

As first derived in Allen (1994), the probability of articulation error in the k th band ϵ_k may be written in terms of the specific AI as

$$\epsilon_k = e^{\text{AI}_k / K}, \quad (14)$$

where the constant e_{\min} is defined as the minimum error via the relationship

$$e_{\min} \equiv 1 - \max_{\text{snr}}(P_c(\text{SNR})). \quad (15)$$

This constant e_{\min} depends in general on the corpus, talkers, and subjects. For Fletcher's work, e_{\min} was 1.5% ($\mathcal{H} \approx 11$, i.e., more than 2048 sounds). For the work reported here, a value of 0.254% ($\mathcal{H} = 4$) was used, based on an extrapolation of the MN55 data to $\text{AI} = 1$ and a minimization of the model parameters for a best fit to MN55 data.

It follows from the above relations that

$$P_c(\text{AI}) = 1 - e_{\min}^{\text{AI}}. \quad (16)$$

The total error $e = e_{\min}^{\text{AI}}$ in Eq. (16) was represented by Fletcher as $e = 10^{-\text{AI}/0.55}$. Both expressions are exponential in AI, differing only in the choice of the base ($e_{\min} = 10^{(-1/0.55)}$). Equation (16) only applies to the case of non-sense phones, having the maximum entropy.

Figure 5, left, shows the relative spectrum and noise level corresponding to SNRs of -18 to $+12$ dB, for female speech with a white-noise masker. On the right one may see the resulting $\text{AI}(\text{SNR})$, based on the calculations specified by the equations presented in this section. The final values of the AI were determined with $c = 2$ to be (starting from an SNR of $+12$): $[0.459, 0.306, 0.186, 0.1, 0.045, 0.016]$.

Because the spectrum of the speech and the spectrum of the noise are not the same, the $\text{AI}(\text{SNR})$ cannot be a linear function of SNR. Only for the case where the two spectra have the same shape will $\text{AI}(\text{SNR})$ be linear in SNR. For the case at hand, a white-noise masker, the high frequencies are progressively removed as the SNR decreases, as shown in the left panel of Fig. 5.

B. AM(SNR) to AM(AI)

The left panel of Fig. 6 shows the MN55 consonant identification curves $P_c^{(i)}(\text{SNR}) \equiv S_{i,i}(\text{SNR})$, as a function of the SNR for each of the 16 sounds ($i = 1, \dots, 16$), along with their mean $P_c(\text{SNR})$ (solid curve with circle symbols)

$$P_c \equiv \frac{1}{16} \sum_{i=1}^{16} P_c^{(i)}. \quad (17)$$

It must be mentioned that Eq. (17) only applies to the case at hand, where the *a priori* probabilities of the sounds are equal. In the more general case, a Bayesian formulation would be required.

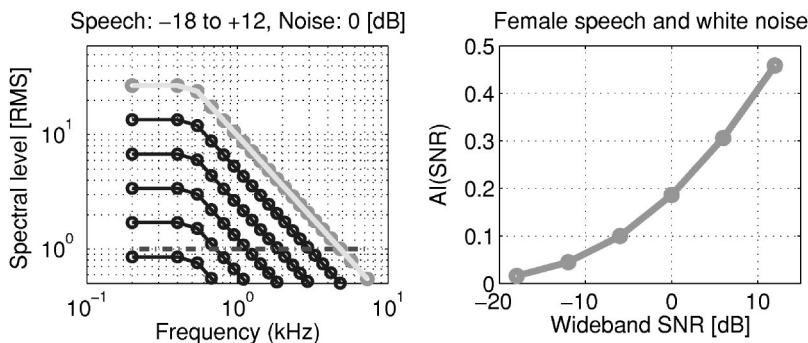

FIG. 5. Using the speech power spectrum given by the dashed line in Fig. 4, and assuming a uniform noise spectral level, the $\text{AI}(\text{SNR})$ was calculated. Each curve shows the relative spectral level of the speech having a peak level at the wideband SNRs used by Miller and Nicely $[-18, -12, -6, 0, 6, 12]$, in units of dB. The top curve shows the $+12$ -dB speech spectrum. The dashed-dot line is the noise spectral level having an rms of 0 dB.

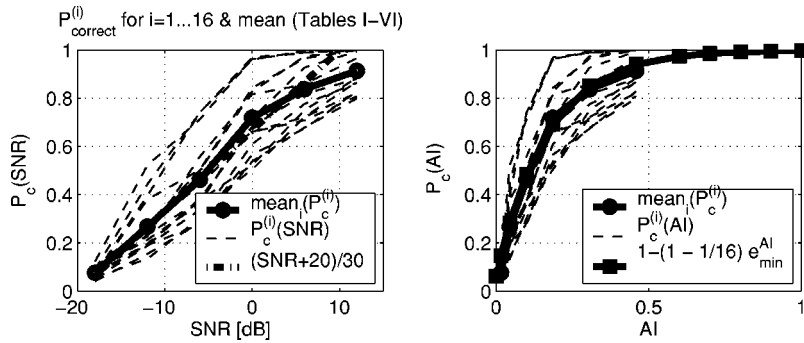

FIG. 6. The light dashed lines are $P_c^{(i)}$ for each of the 16 consonants. On the left the abscissa is the SNR in dB, while on the right, the AI is used as the independent variable. The solid-thick curve (circles) on both the left and right is the average score P_c , Eq. (17). The solid-thick curve (squares) on the right is the average phone prediction given by Eq. (18).

In the right panel the individual scores, along with the average, are shown as a function of the AI. To transform from SNR to AI the values shown in the right panel of Fig. 5 are used.

We also wish to compare the AI model prediction to the measurements shown in Fig. 6. However, it is necessary to modify Eq. (16) so that it accounts for chance (guessing) given by $P_{\text{chance}} = 2^{-\mathcal{H}}$, when $\mathcal{H}=4$ and $\text{AI}=0$. This is done by again assuming independence of the error probabilities. Since chance error for guessing is $e_{\text{chance}} = 1 - P_{\text{chance}}$, the chance-corrected $P_c(\text{AI})$ formula is

$$P_c(\text{AI}, \mathcal{H}) = 1 - e_{\text{chance}}(\mathcal{H})e_{\text{min}}^{\text{AI}}, \quad (18)$$

with

$$e_{\text{chance}}(\mathcal{H}) \equiv 1 - 2^{-\mathcal{H}}. \quad (19)$$

Fletcher's formula Eq. (16) is the limiting case of Eq. (18) when \mathcal{H} becomes large (Fletcher's $\mathcal{H} \approx 11$).

A plot of Eq. (18) is shown in the right panel of Fig. 6 (solid curve, square symbols), with $e_{\text{min}} = 0.254\%$, and $\mathcal{H}=4$. The fit of Eq. (18) to the average of the 16 MN55 curves is excellent.

Discussion

The left panel of Fig. 6 shows that there is an approximately linear relationship between $P_c(\text{SNR})$ and SNR over the range from -18 to 6 dB. The thick dashed-dot line is $(\text{SNR}+20)/30$. This line is useful as a simple reference.

The main deviation from the linear dash-dot curve is due to the strong saturation that occurs for the two nasal sounds and sound 7 [the three curves with the highest $P_c(\text{SNR})$]. Note that each of the sounds has a nearly linear $P_c^{(i)}(\text{SNR})$, with different saturation levels (if they are reached). The saturation point for $P_c(\text{SNR})$ occurs at an SNR of about 30 dB above the threshold, at -20 dB (thick solid line with circles). Note that since the relation $P_c(\text{SNR})$ depends on the noise spectrum, the linear relation observed in the left panel of Fig. 6 can only hold for the white-noise masker, since if the noise spectrum is changed, $P_c(\text{SNR})$ must change, and it is linear for the white-noise case.

In the right panel of Fig. 6 the extended AI model [Eq. (18)] is shown for MN55's data. Each of the 16 curves $P_c^{(i)}(\text{AI})$, $i=1, \dots, 16$, is shown as the light-dashed curves. This average [Eq. (17)] is shown as the solid-thick curve with circles.

The solid-thick line with squares is the extended (chance-corrected) AI model, Eq. (18). The value of e_{min} of

0.254% is one-sixth that used by Fletcher (1.5%). The smaller size could be attributed to the larger amount of training the subjects received over such a limited set size $\mathcal{H}=4 = \log_2(16)$.

As may be seen in the left panel of Fig. 5, since MN55 used white noise, the snr_k for frequency bands larger than about 0.7 kHz have an SNR of less than 30 dB, resulting in an AI of much less than 1. In fact, the AI was less than 0.5 for the MN55 experiment, corresponding to a maximum score of only 90%.

A most interesting and surprising finding is that the extended AI model [Eq. (18)] does a good job of fitting the average data. In fact, the accuracy of the fit over such a small set of just 16 consonants was totally unanticipated. This needs further elucidation.

C. Extended tests of the AI model

If one plots the total error probability $e(\text{AI}) = 1 - P_c(\text{AI})$ in log coordinates, as a function of AI, such plots should approximate straight lines. This follows from the log of Eq. (18)

$$\log(e(\text{AI})) = \log(e_{\text{min}})\text{AI} + \log(e_{\text{chance}}(\mathcal{H})), \quad (20)$$

which has the convenient form $y = ax + b$. The ordinate (y axis) intercept of these curves at $\text{AI}=0$ gives the log chance error [$b \equiv y(0) = \log(e(0)) = \log(e_{\text{chance}}(\mathcal{H}))$], while the ordinate intercept of these curves at $\text{AI}=1$ defines the sum of the log-chance error and the log-minimum error, namely [$a + b \equiv y(1)$, thus $a = \log(e_{\text{min}})$]. In Fig. 7 the log-error probabilities for each of the 16 sounds, along with the average and the AI model, are shown. The sounds have been regrouped so that the log-error plots have similar shapes. The shallow slopes are shown on the left and the steeper slopes on the right.

From Fig. 7, we shall find that the linear relationship [Eq. (20)] holds for 11 of the 16 sounds, with the free parameters $e_{\text{min}}(i)$ and $e_{\text{chance}}(i)$, either depending on the sound, or on a sound group.

The upper two panels show the most linear groups, while the lower panels are the most nonlinear (nonstraight) log-error curves. The curves that are close to linear (the two top panels) are consistent with the AI model, due to Eq. (20).

This observation of a log-linearity dependence for the probability of error of individual sounds is rather astounding in my view. First, there was no *a priori* basis for anticipating that individual sounds might obey Fletcher's band-independence property, Eq. (18). Second, if individual

FIG. 7. This figure shows the probability of error for the i th sound, $P_e^{(i)}(AI) \equiv 1 - P_c^{(i)}(AI)$, as a dashed curve. To reduce the clutter, the sounds have been sorted over the four panels, with the sound number indicated in each panel title. The top two panels are the cases where the individual sound-error curves are close to straight lines. The left-upper panel are those cases where the sound lies above the average, while the right-upper panel shows those cases where the sound lies below the average. The two lower panels correspond to the sounds that violate the exponential rule (are not straight lines on a log-error plot). For reference, each panel contains the average probability of error $P_e(AI) \equiv 1 - P_c(AI)$, shown as the solid curve with circles, and the model error e_{\min}^{AI} , shown as the solid line (squares).

sounds obey equations of the form of Eq. (8), then sums of such equations cannot obey Eq. (8), since the sum of many exponentials, each having a different base, is not an exponential.

The finding that individual CV recognition error is exponential in the AI (the basis of the band-independence hypothesis) therefore extends, and at the same time violates, Fletcher's original fundamental AI hypothesis that the average error is exponential.

It is therefore essential to understand the source of the deviations for the individual sounds from the average, and to critically assess the accuracy of the model for individual sounds. Five sounds (4,8,11,15,16) have a probability of error that deviates from linear, with the most nonlinear and the largest deviations from the mean, being the nasals (15,16), as shown in the lower-right panel. In the next section I explore the reasons for this.

1. Log-error for the nasals

In Fig. 8 the nasal data are shown using the same log-error linear decomposition used in Fig. 3, where the total error (solid-thick curve) is the sum of the errors of the com-

peting sounds [i.e., Eq. (7)]. In the case of the nasals, the confusions for the other sounds is small, namely only /ma/ and /na/ significantly compete.

As a result of plotting the data as a function of AI, for $AI > AI_g = 0.045$ ($SNR \geq -12$), the log-error curves become linear in AI, as predicted (modeled) by Eq. (18). This value of AI_g is shown in the plot with an arrow indicating the point of separation of the target sound from the competing sound. Extrapolating this linear region back to $AI=0$, one finds the chance guessing probability of $1 - 2^{-\mathcal{H}_g} = 1/2$, corresponding to a nasal group entropy of $\mathcal{H}_g = 1$. This is shown on the graph by the dashed line superimposed on the corresponding error curve (stars). In the region $0 \leq AI \leq AI_g = 0.045$, \mathcal{H} depends on AI, since it dramatically drops from 4 to 1.

Thus, the reason that the nasal curves are not linear in Fig. 7 is that chance (the entropy factor) is dramatically changing between $0 \leq AI \leq AI_g$, due to the formation of the perceptual "event-nasal" group.

When the data are plotted as a function of SNR, as in Fig. 3, the log-error linearity is not observed. Also, the shape of the curve will depend on the spectrum of the noise. Clearly, the SNR to AI transformation is an important key to making sense of these data.

2. Log error for /pa/, /ta/, and /ka/

Finally, in Fig. 9 we return to the case of /pa/, /ta/, and /ka/. This 3-group generalizes the /ma/, /na/ 2-group conclusions of Fig. 8. In the middle panel it is clear that for small values of AI less than $0.045 S_{2,2}(\text{AI})$ for /ta/ is equal to the curves for /pa/ and /ka/ [$S_{2,j}(\text{AI}), j=1,3$]. As the AI rises above about 0.1, the three curves (circles) split due to the identification of /ta/ and the rejection of /pa/ and /ka/. The shape and slope of the curves corresponding to the two rejected sounds are identical. The projection of the rejected curves back to AI=0 gives the probability of chance error for a group of 3 (i.e., $1-1/3$), as shown by the dashed line in this middle panel. In the left-most and right-most panels, corresponding to /pa/ and /ka/, the two rejected sounds have very different log-error slopes. However, the two dashed curves still project back to the chance error probability for a group of 3 ($1-1/3$). This change in the slope for the two sounds shows that $e_{\min}(i,j)$ can, in general, depend on the sound in the group. This seems to reflect the more robust nature of /ta/ relative to /pa/ and /ka/ due to /ta/ having more high-frequency energy than its competitors.

Based on the small amount of the data shown in Fig. 8 and Fig. 9, it appears that the band-independence assumption [Eq. (13)] and the band error expression [Eq. (14)] model the individual sound confusions $S_{i,j}(\text{AI})$ more accurately than they model the average band error [Eq. (13)]. The total sound error is more precisely the sum of these off-diagonal confusion terms, as given by Eq. (7). The implications of this model seem quite significant, but without more data it is unwise to speculate further at this time.

IV. CONCLUSIONS

The intent of this paper is to provide a theoretical analysis of the venerable 1955 Miller and Nicely confusion matrix data, which have been difficult to fully appreciate, due to inadequate analysis methods. Replotting the data as a function of the SNR, rather than as confusions at a fixed SNR, provides a novel way of robustly clustering the feature groups. This grouping, not robustly defined in a single CM, is easily determined in such SNR plots. When working with individual CM data at a single SNR, clusters depend on the

sound ordering. When plotted as a function of SNR, sound order is irrelevant, and clusters depend instead on a smoothness, or continuity, across SNR.

A second contribution is the use of the AI as the independent variable. When the PI is plotted as a function of the SNR, the only structure observed are the clusters (Fig. 2). When these same data are plotted as a function of AI (Fig. 8), they become linear functions of AI (they form straight lines on log-error axes), consistent with the band-independence model of Fletcher [Eq. (13)], thereby corroborating Fletcher's AI model equation [Eq. (16)] for the case of single competing consonants. Plots of $S_{i,j}(\text{AI})$ depend on the spectrum of the noise.

A third contribution is the extension (and verification) of Fletcher's articulation model equation for $P_c(\text{AI})$, for the case of small set size [Eq. (18)], by introducing entropy \mathcal{H} into the model [Eq. (16)], thereby accounting for chance (guessing).

As the SNR increases from chance levels (e.g., -21 -dB SNR), sound groups form, forcing the entropy to decrease. The extended model [Eq. (18)] leads us to the conclusion that the entropy must depend on AI. This function, $\mathcal{H}(\text{AI})$, decreases from its maximum value of 4 at AI=0, to $\mathcal{H}_g \equiv \log_2(\text{group size})$ for AI=AI_g, where the group is fully formed. The entropy associated with these groups may be estimated from the clusters in $S_{ij}(\text{AI})$, or from the intercept at AI=0 of the dashed lines of Fig. 8 and Fig. 9. For the nasal sounds the group size is 2 ($\mathcal{H}=1$), leading to an intercept of $1-1/2$. For the [/pa/,/ta/,/ka/] group, the group size is 3 [$\mathcal{H}=\log_2(3)\approx 1.58$]; thus, the intercept is $1-1/3$.

A. Parametric model

In summary, a parametric model of the confusion matrices for the sound groups 1–3 and 15, 16 has been established. Chance, defined by $e_{\text{chance}}(\mathcal{H})$ [Eq. (19)], depends only on the experimental set (alphabet) size, characterized by $\mathcal{H}(0)$, not on the sounds themselves. Each sound may be described by three parameters. The sound-dependent parameters of Eq. (18) are $e_{\min}(i,j)$, $\mathcal{H}_g(i)$ and AI_g(i). The parameter $e_{\min}(i,j)$ appears to be a property of the individual

FIG. 8. Since the log-error plots for /ma/ and /na/ (see the lower-right panel of Fig. 7) show the greatest deviation from linear, they seem to be a “worst case” for the AI model. From this figure it is clear that the reason for the deviation from linear dependence is due to the migration of chance from $1/16$ ($\mathcal{H}=4$) to $1/2$ ($\mathcal{H}=1$), due to the nasal grouping. The rising nasal curves result from the robust grouping of the nasal, resulting in an increase in chance from $1/16$ at AI=0 to $1/2$ at AI ≈ 0.045 . The solid-thick curve is the sum of all the errors (and is $1 - P_c$ for the spoken sound). A dashed line has been drawn from the point (0, 0.5) to (0.31, 0.01). This line fits the error curve (/na/ given /ma/, and /ma/ given /na/) with very little error, for AI=AI_g>0.045, and intercepts the ordinate at $1/2$ for AI=0, as expected for a 2-group ($\mathcal{H}=1$). This further supports the band independence model Eq. (13).

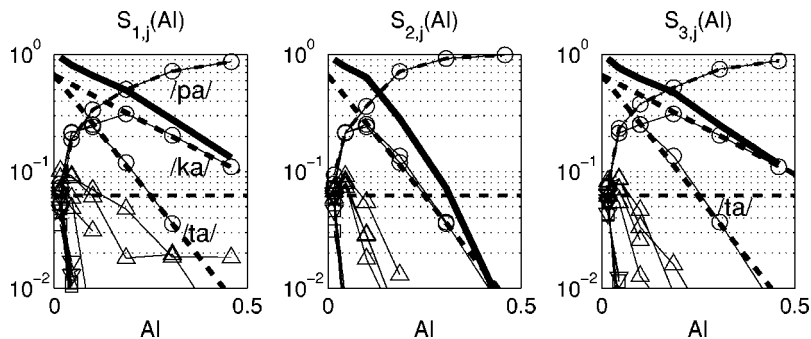

FIG. 9. This figure shows $S_{s,i}(AI)$ for $s=1, 2, 3$ corresponding to the sounds /pa/, /ta/, and /ka/. The dashed lines connect $(0, 1-1/3)$ with $(0.48, 0.1)$ and $(0.442, 0.01)$.

sounds in the group. For example, the value of $e_{\min}(i,j)$ for sounds 1 and 3 are the same, but the value for sound 2 is much smaller (Fig. 9).

The value of e_i is the sum of all the errors of the corresponding off-diagonal values, namely

$$e_i(AI) = \sum_{j \neq i} S_{i,j}(AI). \quad (21)$$

This equation is the same as Eq. (7) except for the independent variable. The total minimum error is given by the average of the row errors, evaluated at $AI=1$

$$e_{\min} = \frac{1}{16} \sum_i e_i(AI) \Big|_{AI=1}. \quad (22)$$

This follows from Eq. (17) and Eq. (7).

Parameter $AI_g(i)$ characterizes the transition from the maximum alphabet entropy [$\mathcal{H}(AI=0)$] to the group entropy \mathcal{H}_g . We have not attempted to find an analytical expression for $H(AI)$, to describe the transition from entropy maximum $\mathcal{H}(0)$ to that of the group $\mathcal{H}(AI_g)$. The hierarchies mentioned in the Introduction each have their own AI_g parameter, each group within the hierarchy having a smaller value of AI_g .

The change in the entropy, from $\mathcal{H} \rightarrow \mathcal{H}_g$, due to the formation of groups as the sounds start becoming identified, accounts for the deviations from linear of the log-error probability.

One might even view the ultimate identification of the sound, as $AI \rightarrow 1$, as a further reduction of the sound's row entropy to zero.

Since the parametric model is based on very little data, there is presently no clue as to how it will generalize.

B. Preprocessing of \mathcal{C}

The confusion matrix \mathcal{C} was transformed to form the articulation matrix \mathcal{A} , by a normalization step [Eq. (1)], and then further transformed by symmetrizing [Eq. (3)]. These two transformations interact and must therefore be iterated to convergence. While these transformation steps are not essential, they are justified, since they reduce sampling noise and remove subject bias. Sampling noise and bias are interesting topics in their own right that deserve further analysis. For example, the skew-symmetric form $A(AI, \mathcal{H})$ [Eq. (4)] should be carefully considered in the future, to characterize and determine the precise nature of the subject bias. This bias should be considered when designing MN55-type experiments.

Once the CM has been preprocessed so that its rows sum to 1, an error decomposition is possible. The equation for this is Eq. (7), which says that the total sound identification error is the sum of the confusions. This expression is useful in those cases where the sounds group, as it uniquely decomposes the error into the group confusions. When plotted as log error (e.g., Fig. 9) one may characterize the sources of the sound errors in a quantitative way [i.e., using the parameters $e_{\min}(i,j)$ and $AI_g(i)$]. This method seems superior to all previous analysis methods of such confusion matrices.

As shown in Fig. 7, the nasals appear to violate Fletcher's independence formula Eq. (13), since the total error is not a straight line on the log-error plot. However, when decomposed by Eq. (7), we see that *individual competing sounds obey band independence*. Thus the total error deviates from a linear log error, due to the dramatic change in \mathcal{H} with AI , from 4 to 1, over the small range of AI between 0 and $AI_g \approx 0.045$ (Fig. 8).

Furthermore, the projection of the straight lines that lie along the log-error curves, back to $AI=0$, gives e_{chance} for the group. This is an important corroboration of Eq. (18). Two examples of these are seen for the nasals, where the group has entropy 1, and the dashed lines of Fig. 8 project back to $1-1/2$, and the 3-group of Fig. 9, where the dashed lines project back to $1-1/3$.

C. Calculating the AI

The procedure for calculating the AI, developed in Sec. III A, has some novel aspects as well. Rather than defining the specific AI in terms of the band SNRs, the modified function of Eq. (11) was used. The justification for Eq. (11) comes from the work of Fletcher as well as French and Steinberg, both of whom promote (but did not use) this detection formulation. The *speech detection constant* c is chosen to characterize the detection of the speech peaks when noise is added to the speech. Even though this formulation of the AI has some important advantages, and is more accurate, it is never referred to in the modern AI literature. This, I feel, is a mistake that needs rectification. Again, this approach was not studied in detail in this paper; however, there is a detailed analysis of Eq. (11) in both of the references, and a deeper analysis here is off topic. It was necessary to introduce Eq. (11) to get reasonable values of $AI(\text{SNR})$ when fitting the model $P_c(AI, \mathcal{H})$, as shown in Fig. 6. This is because the estimates of the SNR as a function of frequency [i.e., $\text{snr}_k(\text{SNR})$], in the left panel of Fig. 5, are strongly affected by this detection model, and on the specific choice of c in

Eq. (10). Without the use of this speech detection parameter ($c=2$), the band SNR values $\text{snr}_k(\text{SNR})$ would be unrealistic for small values of AI.

D. Band independence

Fletcher's band-independence assumption Eq. (13) has proven to be an important tool at the individual sound level. This should come as a surprise, as it was not anticipated by Fletcher's work, or any work following (that I am aware of). On the other hand, the fact that it works at all should lead us to the possibility that it could generalize. It would appear from the analysis provided here that Eq. (13) is more accurate in describing competing sounds than in describing the average probability correct $P_c(\text{AI}, \mathcal{H})$. This statement is supported by the very linear behavior of the off-diagonal confusion terms $S_{i,j}$ in Fig. 8 and Fig. 9. The partial errors are highly linear once the group has formed ($\text{AI} > \text{AI}_g$). It follows from Eq. (7) that the deviations from linear are a result of the groups, which depend on the noise spectrum. The influence of a group formation distorts this basic linear character, and therefore distorts the linearity of the sum over many error terms [i.e., $P_c(\text{AI})$]. Based on the small amount of data we presently have (those shown in this paper), it would be reasonable to conclude that band independence is more a property of individual consonants than it is of the group means, as first proposed (derived) by Fletcher. Much more data and analysis are needed to verify this possibility, which is hardly proved at this time.

E. Implications to ASR

Automatic computer recognition of speech (ASR) could benefit from many of the same considerations as those of MN55. It would be interesting to run similar experiments on modern ASR systems, to characterize their $\mathcal{A}(\text{AI}, \mathcal{H})$ performance. In many cases this might not be practical, due to the limited performance of the ASR front ends, or if the confusion matrices turned out to be skew-symmetric. The ASR language model performance is inhibited when using nonsense speech, since most of these systems depend on some sort of language context for their performance.

ACKNOWLEDGMENTS

The inspiration for this work started with a question by David Nahamoo which I could not answer: "What is the

meaning of e_{\min} ?" I would like to thank my students Suvrat Budhlakoti, Bryce Lobdell, Andrew Lovitt, and especially Sandeep Phatak, and also thank Harry Levitt, for many important insights and critical discussion, and thank Anthony Watkins and two anonymous reviewers, for many insightful comments. Finally, I would especially like to thank George Miller for doing his original 1955 work, for reading the present manuscript, and for the personal encouragement he has provided.

The speech intelligibility index (SII) (ANSI S3.5-1997) provides a means for estimating speech intelligibility under conditions of additive stationary noise or bandwidth reduction. The SII concept for estimating intelligibility is extended in this paper to include broadband peak-clipping and center-clipping distortion, with the coherence between the input and output signals used to estimate the noise and distortion effects. The speech intelligibility predictions using the new procedure are compared with intelligibility scores obtained from normal-hearing and hearing-impaired subjects for conditions of additive noise and peak-clipping and center-clipping distortion. The most effective procedure divides the speech signal into low-, mid-, and high-level regions, computes the coherence SII separately for the signal segments in each region, and then estimates intelligibility from a weighted combination of the three coherence SII values. © 2005 Acoustical Society of America. I. INTRODUCTION

A hearing aid is intended to improve speech intelligibility for the hearing-impaired user, but it is often difficult to predict the amount of benefit that will be obtained in practice. Intelligibility is reduced not only by the hearing loss, but also by ambient noise, room reverberation, and the noise and nonlinear distortion introduced by the hearing aid. The desire to assess speech intelligibility under adverse conditions has led to the development of several measurement and prediction procedures. Some of the problems affecting speech intelligibility, such as additive noise and bandwidth reduction, have been addressed by the speech intelligibility index (SII) (ANSI S3.5-1997), and reverberation has been addressed by the speech transmission index (STI) (Steeneken and Houtgast, 1980; Houtgast and Steeneken, 1985). However, there is no metric that can successfully deal both with noise and with the various types of nonlinear distortion that can occur in a hearing aid or communication system.

An intelligibility-estimation procedure for hearing aids must satisfy several criteria. First, the metric must be applicable to systems, like hearing aids, that have frequency-dependent magnitude and phase transfer functions. A flat frequency response, often assumed in telephony and for digital speech coding systems, cannot be assumed for a hearing aid. Second, in the presence of additive noise without distortion, the metric should yield intelligibility predictions that are consistent with those produced by the SII calculation (ANSI S3.5-1997). Third, the method should be applicable to speech as the test signal; much of the nonlinear signal processing in hearing aids is specifically designed for speech as the input and will respond differently to other types of exci-

tation such as pure tones, multitone complexes, or broadband noise.

The goal of the work reported in this paper is to derive a speech intelligibility metric that generalizes the SII. The specific objectives of the work are twofold: first, the metric should accurately predict the effects of broadband noise and distortion for speech reproduced by hearing aids and other communication systems, and, second, the metric should be accurate for hearing-impaired as well as normal-hearing listeners.

A. Speech intelligibility in normal-hearing listeners

There are several procedures for estimating speech intelligibility in normal-hearing listeners. The best known are the articulation index (AI) (French and Steinberg, 1947; Kryter, 1962), which has been further developed to produce the speech intelligibility index (ANSI S3.5-1997), and the speech transmission index (Steeneken and Houtgast, 1980; Houtgast and Steeneken, 1985). The SII measures the signal-to-noise ratio (SNR) on a dB scale in each frequency band. The calculation procedure then adjusts for auditory threshold and for frequency-domain masking effects and sums the weighted SNR across frequency to produce the intelligibility estimate. The STI uses amplitude-modulated speech-shaped noise as the excitation. Its calculation procedure measures the modulation depth in each frequency band in the listening environment and forms a weighted sum across frequency to give an estimate of the SNR. The STI calculation can also be performed using speech as the stimulus (Payton and Braida, 1999). The SII is effective in stationary additive noise and for filtering that restricts the speech bandwidth, and the STI is also effective in reverberation.

The SII procedure embodies a simplified model of the auditory periphery. The critical band formulation of the SII

^{a)}Electronic mail: jkates@gnresound.dk

^{b)}Electronic mail: kathryn.arehart@colorado.edu

procedure given in Table I of the standard (ANSI S3.5-1997) uses the critical bands of Zwicker (1961), which give a representation of auditory frequency analysis. The auditory threshold for normal and impaired hearing is incorporated into the calculation in Eq. (10) of the standard, and upward spread of masking for normal ears is included in Eqs. (6)–(9) of the standard. Because of this implicit auditory model, the SII procedure can be extended to include conditions not incorporated into the standard as long as the basic physical and perceptual assumptions are not violated.

Examples of previous extensions to the SII are the work of Kates (1987) and Rhebergen and Versfeld (2004). To compute the SII, the speech power spectrum and the noise power spectrum are averaged across the entire duration of the stimulus, and the SII is then calculated using these long-term averages. The SII computed this way is accurate for stationary noise, but is inaccurate for fluctuating noise. Kates (1987) evaluated an adaptive noise-cancellation system by dividing the speech into segments, computing the AI for each segment, and then plotting the change in the AI as a function of time to illustrate the system convergence. Rhebergen and Versfeld (2004) have extended the SII approach to predict the effects of fluctuating noise. They propose dividing the noisy speech into segments, computing the SII for each segment, and then averaging the SII values. The SII assumptions concerning auditory frequency resolution, threshold, and masking are preserved in their procedure, but the analysis adds additional understanding of the effects of signal fluctuations and the ability to listen in the noise valleys.

The principles underlying the SII have also been applied to estimating speech intelligibility and quality for distortion mechanisms such as symmetric peak clipping. Steeneken and Houtgast (1980), for example, show that the modulation transfer function can accurately predict speech intelligibility for peak-clipped speech. Kates and Kozma-Spytek (1994) studied speech subjected to low-frequency or high-frequency amplification followed by symmetric peak clipping. They computed the signal-to-distortion ratio (SDR) from the magnitude-squared coherence (MSC), and then derived a speech-quality metric based on a weighted sum of the SDR across frequency. This metric, which is similar to the frequency-dependent weighting of the SNR used in the SII calculation, was accurate in predicting speech quality for peak clipping even though auditory masking was not included. An extension of this approach (Kozma-Spytek *et al.*, 1996) was accurate in predicting speech quality for peak-clipped speech for hearing-impaired listeners, although some of the hearing-impaired subjects appeared to concentrate more on the low frequencies and other subjects appeared to concentrate more on the high frequencies in making their judgments.

B. Speech intelligibility in hearing-impaired listeners

Speech intelligibility in hearing-impaired listeners has been studied for conditions of bandwidth reduction and additive noise, but only rarely for distortion. For additive noise and bandwidth reduction, the SII (ANSI S3.5-1997) procedure has been found in general to overestimate speech intelligibility for hearing-impaired listeners (Pavlovic, 1984;

Ludvigsen, 1987; Hornsby and Ricketts, 2003). One solution is to apply a desensitization factor to the SII calculation, reducing the estimated intelligibility in proportion to the measured hearing loss (Pavlovic *et al.*, 1986; Magnusson *et al.*, 2001). The desensitization factor does not explain the reason for the discrepancy between the SII and the observed intelligibility, but it does provide an accurate empirical correction. The desensitization factor accuracy can be further improved by applying individually determined frequency-dependent proficiency factors in the SII calculation (Ching *et al.*, 1998).

A second solution to the problem of overestimating the intelligibility for hearing-impaired listeners is to modify the effective signal-to-noise ratio (SNR) used in the SII calculation. For example, the upward spread of masking function used in the SII calculation is based on averaged measurements of normal-hearing subjects. Increasing the spread of masking for the impaired ear reduces the effective signal-to-noise ratio (SNR) above the frequency region of the masker. The reduction in SNR reduces the calculated SII value. Rankovic (1998) used individual frequency-domain masking functions in applying the Fletcher and Galt (1950) calculation procedure to hearing-impaired listeners and found that the individualized calculations improved the accuracy of the intelligibility predictions without needing a desensitization factor. Hornsby and Ricketts (2003) measured pure-tone detection thresholds in speech-shaped noise for each hearing-impaired listener and used these data to increase the effective masking spectrum in the SII calculation. This modification of the SII implicitly includes the increase in spread of masking in the impaired ear and thus reduces the effective SNR. The modification resulted in intelligibility predictions for hearing-impaired subjects, having flat losses, that were comparable in accuracy to those for normal-hearing listeners, again without the need for a desensitization factor.

Crain and Van Tasell (1994) studied speech intelligibility in hearing-impaired subjects for peak-clipping distortion. They found that peak-clipping distortion increased the speech reception threshold (SRT) more for hearing-impaired listeners than for normal-hearing listeners. Crain and Van Tasell compared the SRT for no distortion to the SRT for infinite peak clipping after equating the levels of presentation. They found that the SRT for the hearing-impaired subjects shifted by 5 dB while that for the normal-hearing subjects shifted by only 2 dB. The shift in SRT was also found to be highly correlated with the reduction in the coherence between the input and distorted signals.

C. Test signal

Speech is the desired test signal for most types of hearing-aid processing. In many nonlinear processing systems, such as the noise suppression and multiband compression found in digital hearing aids, the signal processing behavior depends on the characteristics of the signal. For example, replacing speech with the amplitude-modulated speech-shaped noise used in the STI measurement (Steeneken and Houtgast, 1980) or with a synthesized approximation to speech (CCITT, 1986) will result in different frequency- and time-dependent gains than would occur for

real speech. Thus estimating the distortion that will occur for speech in a nonlinear speech-processing system requires the use of speech or, equivalently, a speechlike test signal that has statistics very close to those of real speech.

D. Coherence measurements and hearing aids

Coherence measurements are becoming important in evaluating hearing aids. Coherence measurement procedures using a broadband noise input signal have been developed for hearing aids (Preves *et al.*, 1989; Dyrland, 1989; Preves, 1990; Kates, 1992; Fortune and Preves, 1992; Schneider and Jamieson, 1995; Kates, 2000), and measurement procedures were standardized in ANSI S3.42-1992. The use of a broadband stimulus is essential for determining the response of multi-channel compression hearing aids; in these systems the gain as a function of frequency depends on both the signal amplitude and spectral distribution. Coherence is attractive for determining the nonlinear behavior of such systems because it measures all forms of distortion and not just the harmonic distortion traditionally measured (ANSI S3.22-1996).

An implicit assumption in using coherence to measure the nonlinear system behavior is that equal reductions in coherence will cause equal reductions in intelligibility or sound quality. In dealing with a single distortion mechanism, such as amplifier saturation, a correlation between a reduction in sound quality and a reduction in coherence is often found (Palmer *et al.*, 1995). However, different distortion mechanisms may reduce the MSC by the same amount yet have different perceptual consequences. The relationship between coherence and intelligibility and sound quality has not been investigated for different forms of distortion, and the assumption that equal reductions in MSC are perceptually equivalent has not been tested.

E. Summary of the paper

In this paper the SII approach is extended to estimate intelligibility for peak clipping and center clipping distortion as well as for additive noise. The new procedure is a modified form of the SII procedure wherein the standard speech signal-to-noise ratio estimate is replaced by the signal-to-distortion ratio computed from the MSC. The MSC is used because it is immune to linear transformations of the signal, is reduced by nonlinear distortion as well as by additive noise, and because it is applicable to any excitation signal, including speech. The SII is used as the basis of the metric because of its established accuracy in predicting intelligibility for additive noise and because it includes a model of auditory masking as well as the threshold shift in impaired ears. The new metric is tested with both normal-hearing and hearing-impaired listeners.

The remainder of this paper describes the evaluation and modeling of speech intelligibility scores from normal-hearing and hearing-impaired individuals. The stimuli used in the evaluations are sentences subjected to different forms of noise and distortion. The first experiment uses normal-hearing listeners. The subject intelligibility scores are modeled using a modification of the SII procedure in which co-

herence is used to estimate the effects of the noise and distortion on the speech. It is shown that the predictions using the coherence SII do not adequately model the intelligibility results. A further modification, based on computing the coherence SII separately for low-, medium-, and high-level segments of each sentence, is shown to be much more accurate in predicting the intelligibility scores.

The second experiment uses hearing-impaired listeners. The processed sentence stimuli are the same as used for the normal-hearing subjects. However, the hearing-impaired subjects are provided with amplification to compensate for each individual hearing loss. The intelligibility scores for the hearing-impaired subjects are predicted using the three-level coherence SII procedure with the same weights for the low-, mid-, and high-level segments of the sentences as used for the normal-hearing subjects. The only modification is the inclusion of the individual hearing loss in the coherence SII calculations. The new procedure is shown to be just as accurate in predicting the intelligibility for the hearing-impaired listeners as it is for the normal-hearing listeners.

II. EXPERIMENT I: NORMAL-HEARING LISTENERS

A. Listeners

Thirteen adult listeners with normal hearing (age range 18 to 45 years) participated. All listeners had thresholds of 20 dB HL (ANSI, 1989) or better at octave frequencies from 250 to 8000 Hz, inclusive. Listeners were tested individually in a double-walled sound booth and were compensated \$10/hour for their participation.

B. Test materials

The test materials consisted of the Hearing-in-Noise-Test (HINT) sentences (Nilsson *et al.*, 1994). The sentences were digitized at a 44.1-kHz sampling rate and down-sampled to 22.05 kHz to reduce computation time. There are 25 lists with ten sentences per list, giving a total of 250 sentences. Each test sentence was combined with additive noise or was subjected to symmetric peak-clipping distortion or symmetric center-clipping distortion. The two forms of clipping were chosen as examples of memoryless nonlinearities that have been used in previous investigations (Licklider, 1946). Peak clipping is related to arithmetic, amplifier, and receiver saturation in a hearing aid. Center clipping is related to noise-suppression systems that reduce the amplitude of low-level portions of the signal.

The additive noise was extracted from the opposite channel of the HINT test compact disc. The noise has the same long-term spectrum as the sentences. The signal-to-noise ratio (SNR) was determined by computing the root-mean-squared (RMS) power of each sentence, ignoring the silent intervals at the beginning and end of the sentence, and adjusting the noise power over the same interval to give the desired SNR. The combined signal-plus-noise power over the duration of each sentence was then adjusted to give a presentation level of 65 dB SPL.

The peak-clipping and center-clipping distortion thresholds were set using the histogram of the magnitudes of the signal samples for each sentence. The silent intervals at the

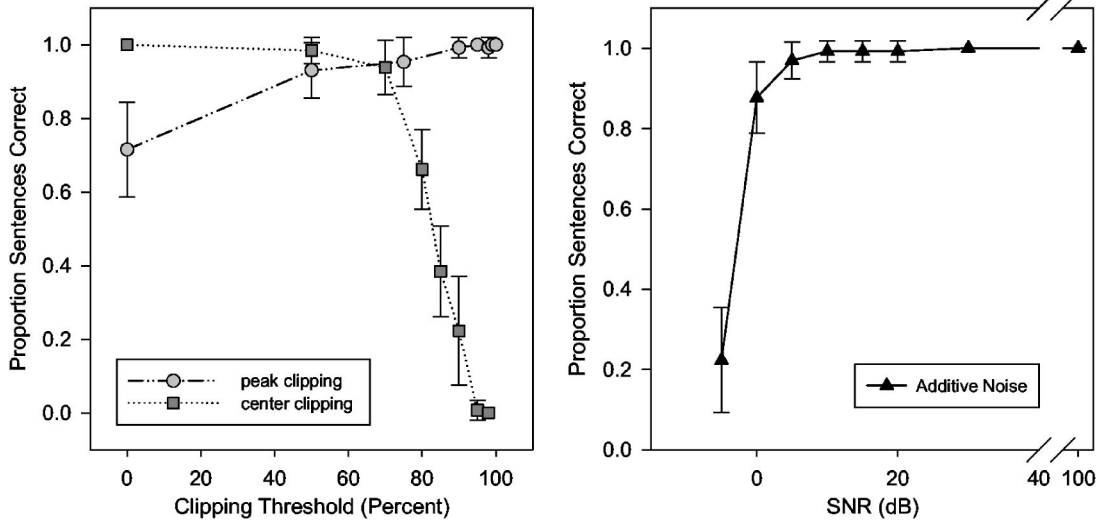

FIG. 1. Average subject intelligibility scores for additive speech-shaped noise (right panel) and peak-clipping and center-clipping distortion (left panel) for the HINT sentence test materials. The error bars show one standard deviation.

beginning and end of each sentence were discarded, and the cumulative distribution of the absolute values of the signal samples was then computed for the sentence. The clipping threshold was set as a percent of the cumulative magnitude histogram for the sentence. For symmetric peak clipping, the clipping operation is given by

$$y(n) = \begin{cases} c, & x(n) > c, \\ x(n), & -c \leq x(n) \leq c, \\ -c, & x(n) < -c \end{cases} \quad (1)$$

where $x(n)$ is the speech input, $y(n)$ is the distorted output, and c is the clipping threshold. The symmetric center clipping operation is given by

$$y(n) = \begin{cases} x(n), & x(n) > c, \\ 0, & -c \leq x(n) \leq c, \\ x(n), & x(n) < -c \end{cases} \quad (2)$$

The distorted sentences were then readjusted to give an average level of 65 dB SPL.

For each individual listener, 24 lists with ten sentences per list were selected for processing, with eight lists randomly selected for each of the three distortion conditions. Eight levels of distortion were evaluated for each distortion type and the distortion levels were randomized within each block. The distortion levels were peak clipping with the clipping threshold set to {0%, 50%, 75%, 90%, 95%, 98%, 99%, 100%} of the cumulative magnitude histogram of each sentence; center clipping with the clipping threshold set to {0%, 50%, 70%, 80%, 85%, 90%, 95%, 98%} of the cumulative magnitude histogram; and additive noise with the SNR set to {-5, 0, 5, 10, 15, 20, 30, 100} dB. Note that the effects of peak clipping are reduced as the clipping threshold is increased, while the effects of center clipping are increased as the clipping threshold is increased.

C. Procedure

Listeners participated in 1-h sessions. During the session, the listeners were presented with three blocks of 80 sentences, with one block in each of the three distortion conditions. The order of presentation of the three distortion conditions was randomized across listeners and across sessions. The order of presentation of sentences within a block was also randomized for each listener. During the sessions, listeners verbally repeated each sentence after it was presented. The tester then scored the proportion of complete HINT sentences that were correctly repeated by the listener.

For listener presentation, the digitally stored speech stimuli went through a digital-to-analog converter (Tucker-Davis Technologies RP2), an attenuator (TDT PA5), and a headphone buffer amplifier (TDT HB7). Finally, the stimuli were presented monaurally to the left ear of each listener through a TDH-49 earphone. All stimuli were presented to the listeners at an equalized-RMS level of 65 dB SPL.

D. Intelligibility scores

The intelligibility scores for the normal-hearing subjects are plotted in Fig. 1. The scores for each listener were first averaged across the ten sentences used for each combination of distortion type and level. The average intelligibility scores for each condition were then averaged across the 13 listeners. The average intelligibility (proportion sentences correct) is plotted as a function of SNR in dB (right panel) and as a function of the clipping threshold expressed as a percent of the cumulative amplitude distribution (left panel). The error bars show the standard deviation across the 13 subjects.

For the additive noise, the intelligibility increases as the SNR increases. The general shape of the curve is consistent with previous intelligibility results for the HINT sentences in additive speech-shaped noise (Nilsson *et al.*, 1994; Eisenberg *et al.*, 1998). The speech intelligibility is a steep function of SNR over the range of -5 to +5 dB; the intelligibility goes from 22% to 97%, giving an average slope of

7.5% per dB. The intelligibility reaches an asymptote of nearly perfect sentence recognition above the 5-dB SNR.

The worst case intelligibility for peak clipping is 72% correct, obtained for infinite clipping (replacing the speech signal samples by their signs). The intelligibility improves as the clipping threshold increases. The high intelligibility for peak clipping indicates that much of the vowel and consonant structure of the speech is preserved even for infinite clipping. For center clipping, the intelligibility remains high for a clipping threshold up to 70%, and then decreases rapidly with increasing clipping threshold. At a clipping threshold of 98% all but the highest peaks of the speech signal have been removed, resulting in an intelligibility of 0%. These results are consistent with previous results for peak-clipped and center-clipped speech (Licklider, 1946).

III. COHERENCE

The coherence function (Carter *et al.*, 1973) is the normalized cross-spectral density given by

$$\gamma(\omega) = S_{xy}(\omega) / [S_{xx}(\omega)S_{yy}(\omega)]^{1/2}, \quad (3)$$

where $S_{xy}(\omega)$ is the cross-spectral density between the two stationary random processes $x(n)$ and $y(n)$ having autospectral densities $S_{xx}(\omega)$ and $S_{yy}(\omega)$, respectively. The magnitude-squared coherence function (MSC) is then given by

$$|\gamma(\omega)|^2 = |S_{xy}(\omega)|^2 / S_{xx}(\omega)S_{yy}(\omega), \quad (4)$$

with $0 \leq |\gamma(\omega)|^2 \leq 1$.

When $x(n)$ is the input to a system and $y(n)$ is the output, the MSC represents the fraction of the output signal power that is linearly dependent on the input at each analysis frequency. The complementary fraction $1 - |\gamma(\omega)|^2$ gives the output power at each frequency that is unrelated to the input at that frequency and thus represents the nonlinear distortion and noise. The signal-to-noise and distortion ratio (SDR) is therefore given by (Carter *et al.*, 1973)

$$\text{SDR}(\omega) = |\gamma(\omega)|^2 / [1 - |\gamma(\omega)|^2]. \quad (5)$$

When $|\gamma(\omega)|^2 = 1$, all of the output is linearly related to the input and the SDR approaches infinity. When $|\gamma(\omega)|^2 = 0$, there is no relationship between the output and the input and the SDR is zero as well.

The MSC is typically estimated using fast Fourier transform (FFT) techniques (Carter *et al.*, 1973). The data sequences $x(n)$ and $y(n)$ are divided into a number M of overlapping windowed data segments. The cross-spectrum and autospectra are computed for each segment using the FFT and are then averaged across segments, and the MSC is computed from the averages. For M data segments, the estimated MSC is given by

$$|\gamma(k)|^2 = \frac{|\sum_{m=0}^{M-1} X_m(k) Y_m^*(k)|^2}{\sum_{m=0}^{M-1} |X_m(k)|^2 \sum_{m=0}^{M-1} |Y_m(k)|^2}, \quad (6)$$

where the asterisk denotes the complex conjugate. $X_m(k)$ and $Y_m(k)$ are the spectra of the m th windowed data segments of $x(n)$ and $y(n)$, respectively, computed using the FFT algorithm where k is the FFT bin index. Typically, a

Hann or Hamming data window and 50% overlap are used for the data segments. The estimated MSC is subject to bias effects due to the finite number of segments used in the FFT procedure and to the interaction of the processing system delay with the segment length. For the greatest accuracy, unbiasing techniques that temporally align the input and output sequences should be used when computing the MSC (Kates, 1992).

The coherence is unaffected by a linear transformation of the signal. A linear filter will increase the gain at each frequency, but the change in gain affects the numerator and denominator of Eq. (6) by equal amounts. Nonlinear transformations, however, will reduce the MSC (Kates, 2000). Thus the MSC is reduced by additive noise, but it is also reduced by nonlinear distortion such as peak clipping, center clipping, and by dynamic-range compression.

IV. THE COHERENCE SII

A. Calculation procedure

The SII standard (ANSI S3.5-1997) allows the SNR to be calculated using the speech and noise spectra measured in octave, one-third octave, or auditory critical bands. The critical-band SII procedure is used in this study, and the filter center frequencies and bandwidths are given in Table I of ANSI S3.5-1997. The critical band filter shapes used in this study are the simplified ro-ex filters suggested by Moore and Glasberg (1983). Let q_j be the center frequency in kHz of the j th critical band, with the band center frequency shifted to match the center frequency of the closest FFT analysis bin. The filter bandwidth from the ANSI Table I is denoted by b_j ; the bandwidths correspond to the classical critical bands (Zwicker and Terhardt, 1980). The ro-ex filter parameter is given by

$$p_j = \frac{4(1000q_j)}{b_j}, \quad (7)$$

where the factor of 1000 converts the filter center frequency to Hz. The simplified ro-ex filter is then given by

$$W_j(f) = (1 + p_j g) \exp(-p_j g), \quad (8)$$

where g is the normalized deviation from the filter center frequency given by

$$g = |1 - f/q_j| \quad (9)$$

and f is the FFT bin center frequency in kHz.

The standard SII calculation assumes that the speech and noise spectra have been measured separately. Let $P(k)$ be the speech power spectrum and $N(k)$ be noise power spectrum computed separately using FFT techniques and where k is the FFT bin index. The SNR for the j th critical band is then given by

$$\text{SNR}(j) = \frac{\sum_{k=0}^K W_j(k) P(k)}{\sum_{k=0}^K W_j(k) N(k)}. \quad (10)$$

In a system that includes distortion, the noise-plus-distortion spectrum is not directly available and must therefore be estimated from the MSC. The speech power spectrum computed using the MSC is given by

FIG. 2. SDR (solid line), SNR (dashed line), and the difference between them (dot-dashed line) as a function of the frequency band number for the concatenated HINT list 1 sentences. Additive noise low-pass filtered at 900 Hz is present at an SNR of 10 dB.

$$\hat{P}(k) = |\gamma(k)|^2 S_{yy}(k) \quad (11)$$

and the noise power spectrum is given by

$$\hat{N}(k) = [1 - |\gamma(k)|^2] S_{yy}(k), \quad (12)$$

where $S_{yy}(k)$ is the output power spectral density estimated using the FFT. The SDR estimated using the MSC is thus

$$\text{SDR}(j) = \frac{\sum_{k=0}^K W_j(k) |\gamma(k)|^2 S_{yy}(k)}{\sum_{k=0}^K W_j(k) [1 - |\gamma(k)|^2] S_{yy}(k)}. \quad (13)$$

The calculation of Eq. (13) uses the output power spectrum and the coherence, and thus requires access to the input and output signals of the system. However, the system under test can be treated as a “black box;” the procedure does not require knowledge of the distortion mechanism or separate measurements of the noise or distortion signals. The standard SII is computed using the procedures of ANSI S3.5-1997 and the SNR estimate of Eq. (10). The coherence-based SII is computed using the same procedures, but with the speech power spectrum replaced by Eq. (11), the noise power spectrum replaced by Eq. (12), and the SNR replaced by the SDR estimate of Eq. (13).

B. Validation for additive noise

The SDR computed using Eq. (13) and the SNR computed using Eq. (10) should agree for additive noise. That is, the SDR should give the same results as the SNR if only additive noise (and no distortion) is present in the system being measured. If the SDR equals the SNR, the standard and coherence approaches for computing the SII will yield identical results for additive noise.

The SDR and SNR are compared for additive low-pass filtered noise in Fig. 2. The input was a concatenation of the ten sentences in the HINT test list 1 (Nilsson *et al.*, 1994) read by a male talker. The gaps between the sentences were removed. The sentences were digitized at a 44.1-kHz sampling rate and down-sampled to 22.05 kHz. The stimulus duration was approximately 18 s. Figure 2 is for the concat-

FIG. 3. Proportion of the HINT sentences identified correctly plotted versus the full-level coherence SII calculation for normal-hearing subjects. The triangles, circles, and squares show the average results for the additive noise, peak-clipping, and the center clipping, respectively.

enated sentences with low-pass filtered (one-pole filter at 900 Hz) noise at a 10-dB SNR. The spectra used a FFT size of 32 ms, which is 706 samples at the 22.05-kHz sampling rate. The FFTs were computed using 706-point segments having 50% overlap and weighted with a Hamming window. A new FFT was thus computed every 16 ms, and the FFT had a frequency resolution of 31.23 Hz.

The SNR and SDR are nearly identical, with the largest difference between the two being less than 0.5 dB. Thus the requirement that the SDR and SNR agree for additive noise is satisfied. The SII values computed using the SDR and SNR are identical, being 0.671 for a signal level of 65 dB SPL.

C. Intelligibility predictions

The proportion of the HINT sentences identified correctly is plotted in Fig. 3 as a function of the coherence SII (CSII) for the noise and distortion conditions. The results for the additive speech-shaped noise are in reasonable agreement with the results of Eisenberg *et al.* (1998); an SII of 0.5 corresponds to approximately 90% sentences correct for both sets of data. A CSII of 0.2 corresponds to approximately 35% correct in the results plotted in Fig. 3, while Eisenberg *et al.* (1998) found that an SII of 0.3 gave approximately the same performance.

The intelligibility for peak-clipped speech is similar to that for the additive noise for the same CSII values. The worst case for peak clipping is infinite clipping, which results in a CSII value of approximately 0.3. But even for this worst case there does not appear to be a significant difference between the additive noise and the peak-clipping intelligibility results. For center clipping, however, the intelligibility is significantly worse than for additive noise or peak clipping at the same CSII values. A possible explanation is that center clipping removes a large fraction of the consonant information in the speech signal, but the CSII calculation is dominated by the more-intense portions of the signal and thus primarily reflects modifications of the vowels. Thus the assumption that equal CSII values will give equal intelligibility

is not valid, and the CSII approach cannot accurately predict speech intelligibility for all forms of distortion and noise.

V. THREE-LEVEL CSII

The goal of the new speech intelligibility metric is to derive a single model that accurately predicts the effects of the additive noise, peak clipping, and center clipping used in the experiment. The coherence SII, as implemented above, is inadequate in representing the effects of all three noise and distortion conditions. More information about how both noise and distortion affect the speech signal is needed to predict the subject intelligibility results. This additional information can be provided by dividing the speech signal envelope into three amplitude regions and performing a separate CSII calculation for each region. The three CSII values are then combined to model the intelligibility scores.

A similar multi-level procedure was proposed for estimating perceived speech intelligibility for voice communication systems (CCITT, 1986). In the CCITT (1986) procedure, a synthetic speech signal is divided into overlapping 32-ms windowed segments. The mean-squared level of each segment is computed, and a histogram constructed from the segment magnitudes. Each segment is then assigned to one of four quartiles of the histogram. For the segments in each quartile, the MSC is computed and used to scale the output power spectrum for the quartile to give the speech and noise power spectral estimates. The noise power spectrum is combined with the auditory threshold to give a masking function, the speech power spectrum is converted to sensation levels, and an intermediate score is computed in a manner similar to the SII. The intermediate scores in each quartile are then summed using a weight of 0.556 for the lowest quartile and weights of 0.148 for the upper three quartiles. The weighted sum is then converted to a mean opinion score (MOS) using a nonlinear transformation consisting of the ratio of two logistic functions. Scores predicted using this approach were found to have an average correlation coefficient of 0.97 with subjective ratings of telephone speech processed through various encoding/decoding procedures, additive circuit noise, and quadratic and cubic distortion mechanisms (CCITT, 1987).

A. Coherence SII calculation

To compute the three-level CSII, the speech input signal envelope is divided into three amplitude regions. The calculation uses a block size of 16 ms with a Hamming window and 50% overlap between windowed segments. The magnitude of the signal in each segment is computed and stored over the duration of the sentence. The root-mean squared (RMS) level of the segments is then computed. The high-level segments are those at or above the overall RMS level. The mid-level segments are those between 0 and 10 dB below the overall RMS level, and the low-level segments are those between 10 and 30 dB below the overall RMS level.

The assignment of sentence envelope samples to the different levels is illustrated in Fig. 4 for the first sentence from HINT list 1. Approximately one-third of the segments fall into each of the three level regions. The high-level segments can be considered to be primarily vowels, the mid-level seg-

FIG. 4. Envelope for a sentence (HINT list 1, sentence 1) showing the level in dB relative to the RMS level. The dashed lines show the boundaries of the high, mid, and low level regions used for computing the CSII.

ments contain vowel-consonant transitions, and the low-level segments are mostly consonants and pauses. In terms of noise and distortion, the high-level segments will be most strongly affected by peak clipping, while the low-level segments will be most strongly affected by additive noise and center clipping.

For the computation, the output and input signals are first time-aligned. The high-level CSII ($CSII_{High}$) value is then computed by applying the coherence SII calculation procedure, including the auditory threshold, to just the high-level input segments and the corresponding output segments. The high-level MSC is computed using Eq. (6), but the summation is only for those segments classified as high-level input segments. The power spectra used in Eqs. (11)–(13) are similarly restricted to the high-level input segments and the corresponding output segments. The procedure is then repeated to give the mid-level CSII ($CSII_{Mid}$) and the low-level CSII ($CSII_{Low}$) values, after which the high-, mid-, and low-level CSII values are combined to give the prediction of speech intelligibility. In comparison with the CCITT (1986) procedure, the three-level CSII procedure is more computationally efficient since it does not require computing the signal magnitude histogram, and it requires spectrum and coherence calculations over three rather than four signal amplitude regions.

The correlations between the three level CSII values and the overall signal CSII and the subject results are presented in Table I. The correlation between the overall signal CSII and the average intelligibility scores is 0.722. The correlations between the low-level CSII and the scores and between the mid-level CSII and the scores are all higher than the correlations between the overall signal CSII and the scores. Thus the overall signal CSII is not the most useful statistic for describing the effects of the noise and distortion used in the experiment. Furthermore, the correlation between the low-level CSII and the overall signal CSII is only 0.703, indicating that the low-level CSII provides information about the noise and distortion that is absent in the overall signal CSII. Thus the combination of low-, mid-, and high-level

TABLE I. Correlations between the level CSII values, the overall signal CSII, and the average subject intelligibility scores.

	Low-level CSII	Mid-level CSII	High-level CSII	Overall CSII	Average Intelligibility
Low-level CSII	1	0.902	0.508	0.703	0.733
Mid-level CSII		1	0.799	0.922	0.818
High-level CSII			1	0.966	0.626
Overall CSII				1	0.722
Average Intelligibility					1

CSII values provides more information about the noise and distortion and should yield a more-accurate prediction of speech intelligibility and quality than provided by the overall signal CSII.

B. Intelligibility model

The speech intelligibility model uses a linear weighting of the low-, mid-, and high-level CSII values. The weighted sum is then transformed using a logistic (or log-sigmoid) function to give the predicted proportion sentences correct (Gordon-Salant and Fitzgibbons, 1995). The weights are constrained to be positive numbers, and a bias term that adjusts the horizontal position of the curve is also included. The optimum fit of the model to the subject intelligibility scores was found using an unconstrained nonlinear minimization procedure (Nelder and Mead, 1965) to minimize the mean-squared error between the model and the average subject intelligibility scores. Let I_3 denote the intelligibility predicted by the model. The optimum solution is given by

$$c = -3.47 + 1.84CSII_{Low} + 9.99CSII_{Mid} + 0.0CSII_{High},$$

$$I_3 = \frac{1}{1 + e^{-c}}. \quad (14)$$

The intelligibility appears to be dominated by the mid-level CSII, with some input from the low-level CSII. The weight for the high-level CSII is zero, so this term has no apparent effect on intelligibility in the context of this model. The high-level segments are predominantly vowel nuclei, which exhibit little variation over time in comparison with many other speech sounds (Greenberg, 2005), and the contribution of these vowel segments to intelligibility appears to be small (Yoo *et al.*, 2004). The most important term in Eq. (14) is the mid-level CSII, which contains much of the information on envelope transients and spectral transitions that indicate place and manner of articulation (Greenberg, 2005). Preserving the integrity of the speech envelope modulation in the mid-amplitude region appears to be important for both intelligibility (Plomp, 1988; Yoo *et al.*, 2004) and speech quality (Knagenhjelm and Kleijn, 1995). The low-level CSII makes a smaller contribution to intelligibility and, as shown in Table I, much of the information in the low-level region is correlated with that in the mid-level region. The bias value of

FIG. 5. Proportion of the HINT sentences identified correctly plotted versus the three-level CSII intelligibility predictions I_3 for the normal-hearing subjects. The triangles, circles, and squares show the average results for the additive noise, peak clipping, and the center clipping, respectively.

–3.47 in Eq. (14) provides a lateral shift of the prediction curve that minimizes the error between the prediction and the observed subject intelligibility scores.

The accuracy of the model predictions is shown in Fig. 5. The average intelligibility scores are plotted as a function of I_3 for additive noise, peak clipping, and center clipping. The model tends to underestimate the intelligibility for additive noise and to overestimate the intelligibility for center clipping. The overall accuracy of the model is high, however, with a correlation coefficient between the intelligibility scores and the model predictions of $r=0.94$.

VI. EXPERIMENT II: HEARING-IMPAIRED LISTENERS

The above results indicate that the three-level coherence SII procedure is accurate for normal-hearing listeners. Since an objective of this work is accurate prediction of intelligibility for hearing aids, the procedure must also be shown to work for hearing-impaired listeners. The intelligibility experiment was therefore repeated for a group of hearing-impaired subjects, and the results analyzed using the same three-level coherence SII technique that was used for the normal-hearing subjects.

A. Methods

Nine adult listeners with hearing loss of presumed cochlear origin (mean age=49 years old; age range =23–81 years) participated in experiment 2. (Audiometric thresholds of the listeners with hearing loss are plotted as part of Fig. 7.) Listeners underwent an audiometric evaluation during their initial visit. All of the listeners with hearing loss demonstrated test results that were consistent with cochlear impairment: normal tympanometry, the absence of excessive reflex decay, the absence of air-bone gap exceeding 10 dB at any frequency, and the absence of otoacoustic emissions in regions of threshold loss. All listeners were native English speakers.

As in experiment 1, the hearing-impaired listeners were tested individually in a double-walled sound-treated booth.

The stimuli were the same HINT sentence materials as were used for the normal-hearing subjects. The additive speech-shaped noise, peak-clipping distortion, and center-clipping distortion levels were set using the same procedures as for the normal-hearing listeners. The corrupted sentences were then equalized in level so that they had the same long-term 65-dB SPL amplitude as the unprocessed stimuli. The corrupted and level-adjusted sentences were then amplified using the NAL-R gain rule (Byrne and Dillon, 1986) computed for each hearing loss at the audiometric frequencies from 250 to 4000 Hz. The gains in dB were interpolated across frequency and used to design a 128-point linear-phase finite impulse response (FIR) filter through which the stimuli were processed. The sentences were presented monaurally to the listener's test ear. The equipment and headphones were the same as for the normal-hearing subjects.

B. Intelligibility scores

The proportion of the sentences identified correctly for the additive noise, peak-clipping distortion, and center-clipping distortion is plotted in Fig. 6 for each of the nine hearing-impaired subjects. The general trend of the data is poorer performance as the amount of noise or distortion is increased, with the spread in the data also increasing as the noise or distortion increases. The speech recognition score for all of the subjects is 80% or better for no noise or distortion, and drops to close to zero for the worst-case noise and center clipping conditions. The overall trends in speech-recognition performance for the hearing-impaired listeners agree with those in the normal-hearing listener data presented in Fig. 1.

In general, the subjects with the greatest hearing loss have the poorest performance. For example, subject V (solid triangles) has a flat loss ranging from 30 dB at 250 Hz to an average of 50 dB above 2000 Hz and has nearly the best performance of the hearing-impaired subjects. Conversely, subject O (open circles) has a steeply sloping loss with over 70 dB of loss above 2000 Hz, and has uniformly poor performance.

C. Hearing-impaired CSII

The predicted intelligibility for the hearing-impaired subjects is given by the same I_3 calculation procedure as used for the normal-hearing subjects. The speech segments are each assigned to one of three level regions, and the coherence computed separately for the groups of low-, mid-, and high-level speech segments. The three coherence values are then combined using the offset and weights given in Eq. (14), followed by the logistic function transformation. The numerical coefficients used in Eq. (14) for the hearing-impaired listeners were exactly the same as those used for the normal-hearing listeners, and the upward spread of masking included in the SII calculation was as specified in the standard procedure for normal ears. The level distortion factor in the SII calculation was not used.

The only difference between the calculations for the normal-hearing and hearing-impaired subjects is that the calculation for the hearing-impaired listeners includes the hear-

FIG. 6. Proportion of the HINT sentences identified correctly plotted for each hearing-impaired subject for the additive speech-shaped noise, peak clipping, and center clipping distortion.

ing loss and the NAL-R amplification. These two adjustments affect the SDR as a function of frequency. The audiogram in the SII calculations is represented as an equivalent internal noise source, so the hearing loss reduces the SDR. The NAL-R amplification increases the signal gain in the regions of hearing loss and thus partly restores the SDR. The amplification, however, provides imperfect compensation; the SDR for all three signal levels is therefore reduced by the hearing loss, with the greatest effect occurring for the low-level CSII. The predicted speech intelligibility is there-

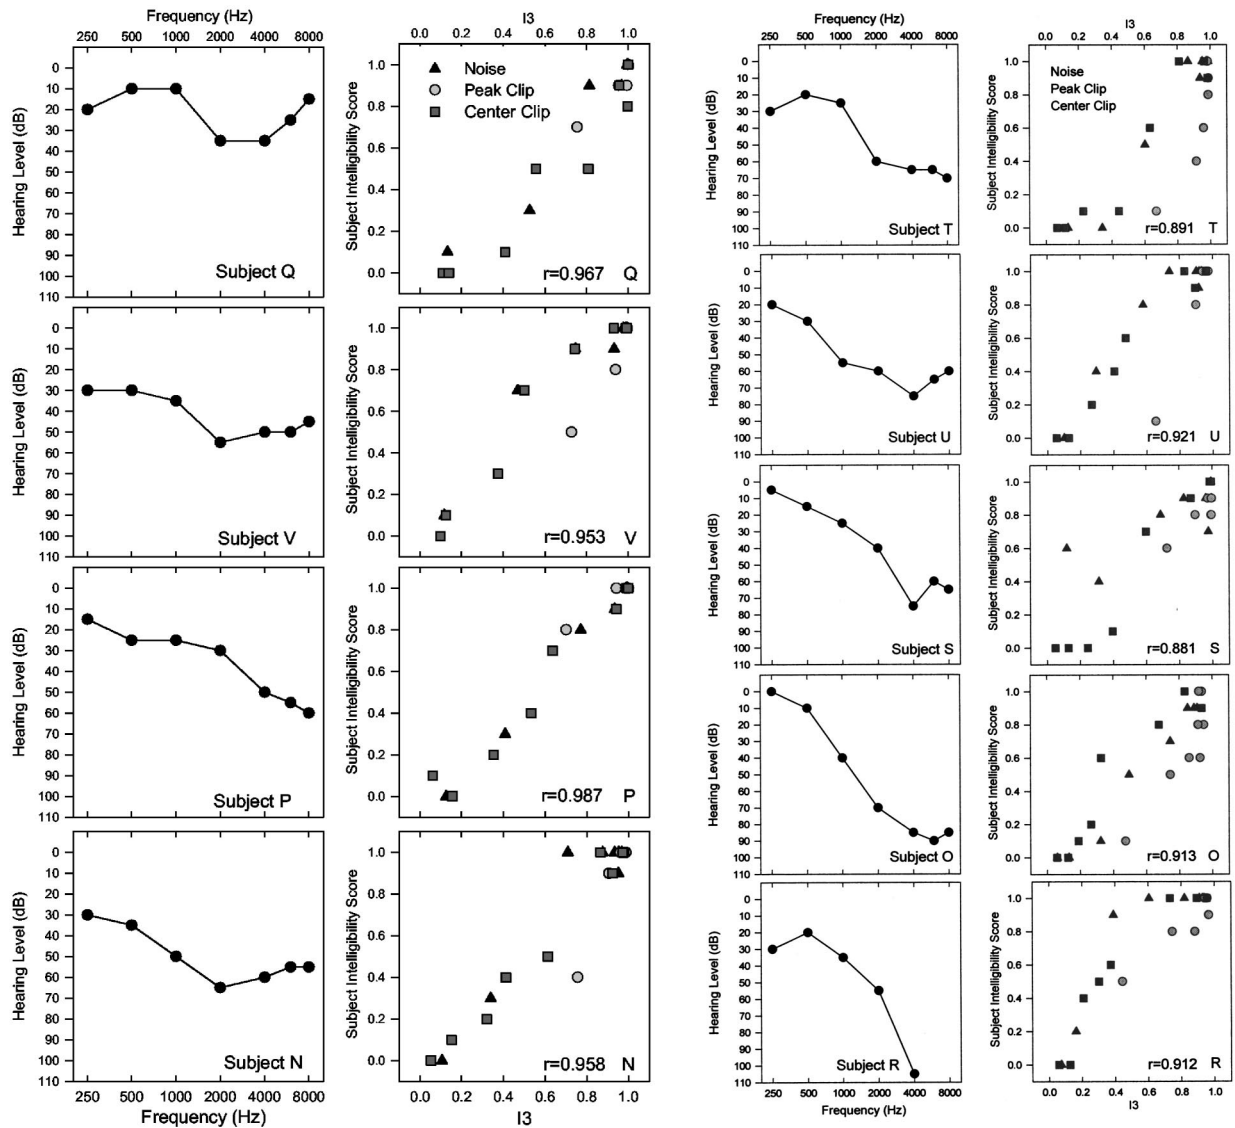

FIG. 7. Audiograms and the three-level CSII intelligibility predictions I_3 for each hearing-impaired subject. The triangles, circles, and squares show the average results for the additive noise, peak-clipping, and the center clipping, respectively.

fore reduced both by the presence of noise and distortion in the signal and by the reduced audibility of speech sounds caused by the hearing loss.

The individual subject results are shown in Fig. 7, where the audiogram is presented for each subject along with the plot of the observed versus predicted intelligibility. The subjects are ordered by increasing severity of the high-frequency hearing loss. As explained above, the predictions for each hearing-impaired subject use the coefficients derived for the normal-hearing subjects in conjunction with the individual audiogram and NAL-R gain. The correlation coefficients between the predicted and observed intelligibility scores range from 0.88 (subject S) to 0.99 (subject P). There appears to be a slight trend of decreasing prediction accuracy with increasing hearing loss, but the I_3 predictions are quite accurate even for the most severe losses included in this study.

In Fig. 8, the average hearing-impaired intelligibility scores are plotted against the average I_3 predictions for each noise or distortion condition. The correlation coefficient between the average predictions and subject scores is 0.98. The

FIG. 8. Average proportion of the HINT sentences identified correctly plotted versus the three-level CSII intelligibility predictions I_3 for the hearing-impaired subjects. The triangles, circles, and squares show the average results for the additive noise, peak-clipping, and the center clipping, respectively.

accuracy of the intelligibility predictions is high for all three forms of noise and distortion used in this experiment despite the widely different distortion mechanisms. Peak clipping predominantly affects the high-level speech sounds, with reduced effects on the mid-level sounds, and noise and center clipping primarily affect the low-level speech sounds, again with reduced effects on the mid-level sounds. Because the I_3 calculation procedure divides the speech into high-, mid-, and low-level regions, it can effectively deal with the reduced audibility of speech information occurring at different speech amplitude levels for the noise and distortion used in this study.

VII. DISCUSSION

The experiments described in this paper deal with two issues. The first issue is extending the SII approach to include distortion as well as noise, and the second is predicting speech intelligibility for hearing-impaired listeners.

A. Distortion

Replacing the SNR in the SII calculation with the SDR computed from the coherence is an intuitively obvious extension of the principles underlying the SII. Authors of papers using coherence to measure distortion in hearing aids (Preves *et al.*, 1989; Dyrland, 1989; Preves, 1990; Kates, 1992; Fortune and Preves, 1992; Schneider and Jamieson, 1995; Kates, 2000) have made the assumption that there is a direct relationship between a reduction in coherence and a reduction in intelligibility. For any one type of noise or distortion, there will be a monotonic relationship between the increase in the amount of distortion and the reduction in the SDR. Thus earlier experiments that looked at just one type of distortion, such as peak clipping (Steeneken and Houtgast, 1980; Crain and van Tasell, 1994; Kates and Kozma-Spytek, 1994), can produce an accurate mapping of the SDR to intelligibility or sound quality for the distortion condition considered in the study. But as shown in this paper, those mappings may not be accurate if more than one type of distortion is considered. It is much more difficult to produce a relationship that is accurate for both center clipping, which most strongly affects the lower signal amplitude regions, and peak clipping, which most strongly affects the higher signal amplitude regions. The three-level coherence SII, on the other hand, combines the effects of the three different noise and distortion mechanisms considered in this paper into a single relationship that is accurate for all of them.

The three-level CSII approach divides the speech into low-, mid-, and high-amplitude regions. The three level CSII calculations provide much more information about the effects of the distortion on the speech than can be obtained by the SNR or the full-level CSII alone. In particular, the high-level CSII, which dominates the full-level CSII, has a weight of zero in the three-level calculation and thus no observed effect on intelligibility even though the high-level CSII is greatly reduced by peak clipping. Most of the speech information appears to be conveyed within a narrow 10-dB dynamic range from the RMS level of the sentence to 10 dB below, with a smaller contribution from the lower speech levels. The three-level CSII approach thus provides enough

information to accurately model the reduction in intelligibility resulting from all three types of noise and distortion considered in this study, and does so in a manner consistent with observations on speech production and perception (Greenberg, 2005; Yoo *et al.*, 2004). Increasing the number of levels to more than three may improve the accuracy of the intelligibility predictions, but it would also increase the number of degrees of freedom in the model and would thus increase the chances of over-fitting (fitting individual data points rather than the overall structure of the data) the limited amount of data available from the experiments.

B. Hearing-impaired listeners

Many researchers have tried to predict speech intelligibility in hearing-impaired listeners. The approaches typically taken in modeling the effects of hearing loss are the addition of a desensitization factor to the SII calculation (Pavlovic *et al.*, 1986; Ching *et al.*, 1998; Magnusson *et al.*, 2001) or the inclusion of increased spread of masking (Ludvigsen, 1987; Rankovic, 1998) or individually measured masking functions (Hornsby and Ricketts, 2003). The desensitization factor is equivalent to a reduction in the SNR used in the SII calculation, with the amount of the reduction based on empirical observations of speech intelligibility in hearing-impaired listeners compared with those having normal hearing. Increasing the masking used in the SII calculation, either through increased spread of masking or the use of individual masking functions, has a similar effect in that it reduces the effective SNR.

The three-level CSII gives an alternative approach to modeling the effects of hearing loss. The CSII calculation for the hearing-impaired subjects requires no modification to the calculation procedure or masking functions; the audiogram and amplification used for the impaired ear are the only necessary inputs, after which the calculation for the hearing-impaired listeners proceeds exactly as for the normal-hearing listeners. The difference is that the three-level CSII incorporates a much more complete model of the effects of hearing loss on the audibility of speech. The low-level CSII is strongly affected by the hearing loss; the low-level speech sounds are much closer to threshold in the impaired than in the normal ear, and the low-level CSII is therefore much lower in the impaired ear even without noise or distortion. The addition of noise or distortion will reduce the low-level CSII even further, thus quickly removing the speech information provided in the low-level signal region. The mid-level CSII will experience similar effects, but with reduced severity given the higher signal level. The high-level CSII is affected the least, but the high-level CSII is not a factor in the I_3 calculation of Eq. (14).

These results indicate that audibility is an important factor in the difference in speech intelligibility between normal-hearing and hearing-impaired listeners. No modifications were made to the auditory filter shapes, upward spread of masking, or the importance functions used in computing I_3 for the hearing-impaired subjects, yet very accurate predictions of intelligibility were obtained over a wide range of hearing losses by incorporating just the audiogram. The SNR used in the standard SII calculation reflects the level of the

noise relative to the speech peaks and gives an imprecise indication of the effects of the noise on the low-level speech components. The desensitization factor or increased masking proposed previously for hearing-impaired listeners can thus be seen as attempts to take an imperfect measure of speech audibility, the full-level SNR, and modify it to reflect the greater loss of audibility of low-level speech information experienced by the impaired ear.

The impaired auditory system exhibits processing deficits in addition to the elevated auditory threshold. These deficits include recruitment (Reger, 1936; Allen *et al.*, 1990), broadened auditory filters (Tyler, 1986; Dubno and Schaefer, 1991), increased spread of masking (Gagné, 1983; Glasberg and Moore, 1986), and poorer temporal resolution (Oxenham and Bacon, 2003). It is possible that some of these effects are subsumed into the three-level coherence SII approach. For example, the loss of information in the low-level signal segments may be highly correlated with the audiogram, and thus predicted by the I_3 calculation, but could still be caused by poor temporal processing or other deficits in the impaired ear. The predictive value of the SII, or of the three-level coherence SII extension, is based on correlations and does not necessarily indicate a causal relationship. It is also possible that certain types of interference that were not considered in this paper, such as temporally fluctuating noise, may cause reductions in intelligibility for hearing-impaired listeners (Festen and Plomp, 1990; Peters *et al.*, 1998) that are not predicted by the three-level coherence SII model.

C. Limitations and extensions

One limitation of the work reported in this paper is that the noise was broadband, and the distortion mechanisms were also applied to the broadband signals. These test conditions are appropriate for many communication systems. In hearing aids, however, frequency-dependent amplification is used, which can result in different amounts of noise or distortion in different frequency regions. Previous results (Kates and Kozma-Spytek, 1994; Kozma-Spytek *et al.*, 1996; Tan *et al.*, 2004) have shown that approaches based on the principle of coherence are accurate in predicting speech quality for frequency-dependent distortion conditions as well as for broadband distortion. However, experimental verification is needed to show that the three-level coherence SII approach is also valid for frequency-dependent distortion. Experiments are also needed to extend the range of noise and distortion conditions considered. Quantization noise can be caused by the digital processing in a hearing aid or communication system, and transducer problems such as displacement limiting and nonuniform driver magnetic fields can also cause distortion. An additional issue is the accuracy of the three-level coherence SII approach for fluctuating noise. Additional experiments are needed to validate and refine the metric for the wide range of noise and distortion conditions that occur in real life.

The three-level CSII approach should also lead to an improved procedure for predicting the quality of distorted speech. There is a strong correlation between intelligibility and sound quality (Preminger and Van Tasell, 1995; Eisenberg *et al.*, 1998), which would lead one to expect a similarly

high correlation between the intelligibility predicted by I_3 and sound quality for comparable noise and distortion conditions. While preliminary results are encouraging (Kates and Arehart, 2004), additional experiments are needed to extend the three-level coherence SII approach to produce an accurate speech quality metric for normal-hearing and hearing-impaired listeners.

VIII. CONCLUSIONS

Speech intelligibility is the primary concern in hearing aids and many communication systems. The SII has been developed and validated for additive noise and for bandwidth reduction, but the output of hearing aids is affected by distortion as well as by noise. The coherence between the input and the output of the device under test provides a tool for calculating the combined effects of noise and distortion in the processed output. It is therefore attractive to modify the SII calculation procedure to use the SDR computed from the coherence instead of the SNR, and thus include distortion along with noise.

Intelligibility was determined for broadband additive speech-shaped noise, peak clipping, and center clipping for normal-hearing and hearing-impaired subjects. A simple modification of the SII, using the SDR in place of the SNR but leaving the remainder of the procedure unchanged, was shown to be inadequate in predicting the intelligibility data for the normal-hearing listeners. The estimated intelligibility for peak clipping was similar to that for noise, but center clipping had much lower intelligibility for the same coherence SII values.

Much better accuracy was obtained by dividing the speech signal segments into three level regions. The high-level region consists of those segments at or above the sentence RMS level. The mid-level region ranges from the RMS sentence level to 10 dB below, and the low-level region ranges from RMS - 10 dB to RMS - 30 dB. The coherence SII is then computed separately for the segments in each level region. A linear combination of the CSII values, followed by a logistic function transformation, models the normal-hearing subject intelligibility scores with a correlation coefficient of 0.94.

The intelligibility experiment was then repeated for a group of hearing-impaired listeners. The distorted speech was amplified using the NAL-R gains computed for each hearing loss, and the three-level CSII calculation was adjusted for the hearing loss by including the audiogram and the NAL-R gain in the constituent CSII calculations. The intelligibility predictions were accurate across the entire range of hearing losses used in the experiment, and the average across subjects for the different noise and distortion conditions had a correlation coefficient of 0.98. The three-level CSII thus appears to be an accurate procedure for estimating intelligibility for the conditions of distortion and noise considered in this paper, and it is as effective for hearing-impaired listeners as it is for those with normal hearing.

Statistical properties of infant-directed versus adult-directed speech: Insights from speech recognition^{a)}

Katrin Kirchhoff^{b)} and Steven Schimmel

Department of Electrical Engineering, Box 352500, University of Washington, Seattle, Washington 98195

(Received 18 April 2004; revised 20 January 2005; accepted 21 January 2005)

Previous studies have shown that infant-directed speech ('motherese') exhibits overemphasized acoustic properties which may facilitate the acquisition of phonetic categories by infant learners. It has been suggested that the use of infant-directed data for training automatic speech recognition systems might also enhance the automatic learning and discrimination of phonetic categories. This study investigates the properties of infant-directed vs. adult-directed speech from the point of view of the statistical pattern recognition paradigm underlying automatic speech recognition. Isolated-word speech recognizers were trained on adult-directed vs. infant-directed data sets and were tested on both matched and mismatched data. Results show that recognizers trained on infant-directed speech did not always exhibit better recognition performance; however, their relative loss in performance on mismatched data was significantly less severe than that of recognizers trained on adult-directed speech and presented with infant-directed test data. An analysis of the statistical distributions of a subset of phonetic classes in both data sets showed that this pattern is caused by larger class overlaps in infant-directed speech. This finding has implications for both automatic speech recognition and theories of infant speech perception. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1869172]

I. INTRODUCTION

Many studies on infant speech perception have analyzed the acoustic-phonetic properties of infant-directed speech (also called "motherese" or "parentese"). It has been observed that infant-directed speech is generally slower in tempo and exhibits increased segmental duration, longer pauses, and more pronounced pitch contours (Grieser and Kuhl, 1988; Fernald *et al.*, 1989; Kuhl *et al.*, 1997). Most importantly, it has been shown that motherese is characterized by overemphasized acoustic-phonetic contrasts: compared to adult-directed (AD) speech, vowels in infant-directed (ID) speech have mean formant values closer to the outermost points of the vowel triangle and are thus acoustically more distinct (Andruski and Kuhl, 1996; Kuhl *et al.*, 1997; Burnham *et al.*, 2002). Infants have been shown to prefer infant-directed over adult-directed speech (Cooper and Aslin, 1994; Fernald and Kuhl, 1987), and a recent study (Liu *et al.*, 2003) has found a correlation (though not necessarily a causal link) between the clarity of mothers' speech as measured by vowel space expansion and infants' phonetic discrimination abilities. It has also been demonstrated that auditory input with overemphasized acoustic-phonetic contrasts is helpful in second-language learning (Protopapas and Calhoun, 2000; Hazan and Simpson, 2000) and that it is more intelligible to individuals with hearing impairments (Picheny *et al.*, 1986; Payton *et al.*, 1994). For these reasons, it has often been suggested that ID-style speech might also be useful for training automatic speech recognition (ASR) systems. It is generally recognized that the amount of train-

ing data is of primary importance in developing good ASR systems; however, a recent study (Moore, 2003) which extrapolates state-of-the-art ASR results to larger training sets suggests that ASR performance would still be far from human performance even if training sets were increased by orders of magnitude. An alternative to simply using more data might be to use "better" data, e.g., more clearly articulated acoustic data. The present study explores this hypothesis by training an isolated word recognizer on adult-directed and infant-directed data sets, respectively, and analyzing its performance under identical versus mismatched test conditions.

In addition to assessing the benefit of ID-style speech for ASR we are interested in exploring the ASR framework as a computational modeling technique for infant speech perception, in particular phonetic category learning. The development of a computational model whose predictions match data gathered from human speech perception experiments could prove valuable in predicting the outcome of future experiments through simulations. A good computational model allows one to observe the effect of adjusting individual experimental variables without having to conduct expensive perceptual studies. The framework of ASR can potentially make a significant contribution towards this goal. First, ASR relies on a suite of statistical modeling techniques that have been fine-tuned to speech (e.g., perceptually inspired signal processing and temporal modeling algorithms) and are more advanced than many of the computational models of speech perception proposed in the past. Second, the ASR community has developed automated methods for collecting, preprocessing and "cleaning" speech data (e.g., high-accuracy automatic segmentation) which enable speech

^{a)}Portions of this work were presented at the 146th Meeting of the Acoustical Society of America, Austin, Texas, November 2003.

^{b)}Electronic mail: katrin@ee.washington.edu

researchers to analyze large speech data sets more rapidly and efficiently.

Previous computational or numerical models of speech perception have mainly focused on predicting experimental data using techniques such as logistic regression and discriminant analysis (e.g., Hillenbrand *et al.*, 1995; Nearey, 1997) or connectionist models (Protopapas, 1999; Damper and Hanard, 2000; Guenther and Bohland, 2002). Recently, the idea of using ASR techniques for modeling human speech perception and language acquisition has attracted increased attention. Scharenborg *et al.*, (2002, 2003), for instance, have investigated the problem of word segmentation in human speech perception using an ASR decoder as a modeling tool. They showed, in a small word discrimination experiment, that the segmentations selected by an ASR decoder matched the outcome of human word segmentation experiments. In de Boer and Kuhl (2003) the learnability of infant-directed and adult-directed speech datasets was investigated using a computer model. A mixture of Gaussians was fitted to samples of the vowels /i:/, /u:/ and /ɒ/ obtained from ID and AD speech, respectively. The resulting means of the learned categories were then compared to the expected means for those vowels. Since the means learned from ID speech matched the reference values more closely, it was concluded that the ID speech has better learnability. However, this study did not evaluate the generalizability of the models by applying them to a separate test set. A fundamental concept of statistical learning, however, is the capability of the trained models to classify unseen samples that are not present in the training set.

The present study investigates the benefit of ID versus AD training data for the formation of phonetic category models which are subsequently applied to unseen instances of those categories. The ability of the trained models to generalize to novel data is measured in terms of their classification error rate. Unlike most previous work, which has focused on the analysis of individual phonetic categories (e.g., vowels), this study also investigates the recognition of entire words.

The remainder of this paper is structured as follows: in Sec. II we give a more detailed explanation of the rationale for this work. The data is described in Sec. III, and experiments and results are presented in Sec. IV. Section V concludes.

II. RATIONALE

In order to assess the potential benefit of ID-style speech for training ASR systems, it is necessary to take a closer look at its properties and view them in light of the standard phonetic classification procedures employed in state-of-the-art ASR systems.

As mentioned above, ID speech is characterized by a greater distance between vowel class means measured in formant space. In addition, the variances associated with individual classes are often greater than in adult-directed speech (Kuhl *et al.*, 1997; de Boer and Kuhl, 2003). These properties have been observed in a number of studies of vowel patterns in ID speech, in American English as well as other languages (Chinese, Swedish and Russian) (Kuhl *et al.*,

1997; Liu *et al.*, 2003). Phonetic overspecification has also been observed for stop consonants in the form of longer voice onset times in ID speech addressed to infants aged 11–14 months (Sundberg, 2001). Most of these studies have focused on monosyllabic content words with stressed vowels. In a study of both content and function words in ID speech, van de Weijer (2001) confirmed the observation of an enlarged vowel space for content words but found the opposite pattern in function words.

Studies of infant speech perception, in particular word segmentation, have shown that infants respond to statistical regularities in the speech input (e.g., Jusczyk *et al.*, 1994; Saffran *et al.*, 1996). The assumption that some form of statistical learning underlies the acquisition of phonetic categories as well (Holt *et al.*, 1998) has recently been demonstrated empirically: Maye *et al.* (2002) showed that infants exposed to speech samples from a bimodal distribution of stops (with the two peaks representing voicedness and voicelessness, respectively) were capable of discriminating new samples from the endpoints of those distributions, whereas infants exposed to a unimodal training distribution were not. The precise nature of such a learning mechanism remains as yet obscure, but it is apparent that spectral discrimination as well as temporal information integration must be involved. However, computational models of infant speech perception that explicitly incorporate temporal information processing are rare. In order to better assess the potential contributions of the ASR framework to this field, we briefly review the statistical models used in present-day ASR systems.

A. Acoustic modeling in automatic speech recognition

Current ASR systems are based on a statistical pattern recognition framework. Recognizers attempt to find the best word sequence W^* given a sequence of acoustic observations O :

$$W^* = \arg \max_W P(W|O) \quad (1)$$

The probability $P(W|O)$ is computed using Bayes' rule:

$$P(W|O) = \frac{P(O|W)P(W)}{P(O)} \propto P(O|W)P(W). \quad (2)$$

The *language model* $P(W)$ gives the prior probability of a word sequence W . Since our focus is on acoustic classification and isolated word recognition, properties of the language model are of no further concern in this study. The *acoustic model* $P(O|W)$ maps acoustic observations first to intermediate phonetic classes (phones/phonemes) and eventually to words. The normalization by the probability of the observation sequence, $P(O)$, can be omitted since it is constant for all W .

The acoustic observations take the form of multidimensional acoustic feature vectors that are extracted from the speech signal at equidistant time intervals, e.g., every 10 ms. Various feature extraction schemes have been devised; the most widely used representation is based on mel-frequency cepstral coefficients (MFCCs), which mimic the nonlinear frequency resolution characteristics of human auditory perception.

The classification of acoustic feature vectors is typically performed by hidden Markov models (HMMs). An HMM λ consists of a set of states $S = s_1, s_2, \dots, s_N$, a set of observation symbols $O = o_1, o_2, \dots, o_M$, and probability distributions governing the transitions between states and the emission of observation symbol from states. Given these parameters, the probability of an observation sequence $O = o_1, \dots, o_T$ given a model λ is computed as

$$P(O|\lambda) = \sum_S \prod_{t=1}^T a(s_t|s_{t-1})b(o_t|s_t) \quad (3)$$

where $a(s_t|s_{t-1})$ denotes the transition probability from state s_{t-1} to s_t , and $b(o_t|s_t)$ is the probability of the t th observation at state t . Thus, the global probability of an observation sequence given an HMM is defined as the product of all transition and observation probabilities over time points $1-T$, summed over all possible state sequences.

Of particular importance for the problem studied in this paper is the way in which the state-conditional observation probabilities, $b(o_t|s_t)$ in Eq. (3), are computed. In practice, the observation probabilities (as opposed to the transition probabilities) contribute most to the final probability score and are thus primarily responsible for acoustic-phonetic classification performance.

The most widespread model used in this context is a Gaussian mixture model, which computes the probability of the continuous acoustic observation vector \mathbf{o} at time t , $P(\mathbf{o}_t|s_j)$, as a weighted sum of M individual Gaussian probability density functions (mixture components):

$$p(\mathbf{o}_t|s_i(t)) = \sum_{m=1}^M c_{mi} \mathcal{N}(\mathbf{o}_t; \mu_{mi}, \Sigma_{mi}) \quad (4)$$

where μ_{mi} and Σ_{mi} are the mean vector and covariance matrix, respectively, of the m th mixture component of state i and c_{mi} is the mixture weight for that component. Each mixture component has the form of a Gaussian or Normal distribution:

$$\mathcal{N}(\mathbf{o}; \mu, \Sigma) = \frac{1}{\sqrt{(2\pi)^d |\Sigma|}} e^{-(1/2)(\mathbf{o}-\mu)' \Sigma^{-1} (\mathbf{o}-\mu)}. \quad (5)$$

where μ is the mean vector and Σ the covariance matrix of the distribution and d is the dimensionality of the feature space. The Gaussian mixture parameters, as well as the transition probabilities in the HMM, are estimated from training data using the expectation-maximization algorithm (Dempster *et al.*, 1977). Typically, HMMs are constructed for individual speech units such as phones, and are concatenated to form words, according to constraints specified in a pronunciation dictionary. The Viterbi algorithm is then used to find the best path through the concatenation of models.

B. Use of infant-directed training data in speech recognition

Given this background, two hypotheses can be made regarding the use of ID-style training data in speech recognition:

TABLE I. Cue words representing the vowels /i:/, /u:/, /ɒ/.

Vowel	Cue words		
/i:/	key	sheep	bead
/u:/	boot	shoe	spoon
/ɒ/	pot	top	sock

- (1) Phonetic classification using Gaussian mixture models is easier and more accurate when individual classes are well separated in the input space, i.e., when the class-conditional distributions overlap as little as possible. In previous experimental studies, the means of acoustic classes have been shown to be better separated in infant-directed than in adult-directed speech. While some researchers have also observed enlarged class variances in ID speech, all studies emphasize the strongly separated class means as the predominant property of ID speech. This suggests that the use of infant-directed training data might indeed be beneficial during training.
- (2) On the other hand, it is well known that matched training and test conditions are of utmost importance in ASR. When test data differ from training data, e.g., due to different recording conditions, presence of noise, or unknown accents, speech recognition performance deteriorates. For this reason, it might be hypothesized that training on infant-directed speech will not be useful for developing a speech recognizer for adult-directed speech, since the training and test conditions will be too different.

In order to test these hypotheses, separate speech recognizers are trained on two different data sets consisting either only of AD speech or only ID speech. Each of them is then tested on an AD data set and an ID data set, reflecting matched versus mismatched test conditions. In order to focus entirely on the contributions of the acoustic modeling component, we perform only isolated word recognition experiments—this serves to eliminate differences in performance that could be attributed to the language model or the vocabulary size (in ID speech, for instance, speakers tend to use a much smaller vocabulary).

III. DATA

The data used for the experiments described in this paper were drawn from a corpus of infant-directed speech provided by the Institute for Learning and Brain Sciences (formerly the Center for Mind, Brain and Learning) at the University of Washington. The corpus consists of 64 conversations by 32 different mothers. Each mother had two conversations, one with an adult experiment facilitator, the other with her infant. The data collection was designed to elicit certain cue words during both conversations, viz. nine monosyllabic words (shown in Table I) containing the vowels /i:/, /u:/, and /ɒ/ (the most distant points in the vowel triangle). Only these words were used for the present study since they had a sufficient number of samples and allow the comparison with previous studies focusing on the same vowels.

TABLE II. Distribution of training and test samples over words in AD and ID speech data sets.

Word	AD		ID	
	train	test	train	test
bead	136	26	196	56
boot	161	43	148	34
key	148	44	125	25
pot	121	25	136	29
sheep	138	41	148	45
shoe	216	54	154	35
sock	148	37	150	44
spoon	135	24	157	41
top	139	42	128	27

During the adult-infant conversations, toys of the same name (sheep, keys, etc.) were provided, which mothers used in interacting with their infants. In the adult-adult conversations, cue words were elicited simply by talking about related topics. Conversations were recorded using a far-field microphone (suspended from the ceiling near speakers' heads). For this reason, the recorded speech is far from studio-quality; rather, it reflects natural listening conditions. First, the use of a far-field rather than a close-talking microphone results in energy fluctuations in the speech signal due to the varying distance of the speaker's mouth to the microphone. Second, much of the speech is overlapped by background noise, such as infants crying or banging toys on the table, people entering and leaving the room, etc. Two infant-directed conversations were discarded *a priori* due to the presence of constant background noise. In addition, the adult-adult conversations contain many instances of speaker overlap or speech overlapped with laughter.

All audio files were time-segmented and transcribed orthographically by phonetically experienced transcribers. The time boundaries of noise events, speaker overlaps, and all instances of cue words were marked. These time marks were double-checked in a second transcription pass, and all instances of cue words were extracted from the audio data. Each instance was categorized by a trained listener with respect to the degree of background noise (on a scale from 1 to 10, with 1 being the lowest and 10 being the highest noise level), and with respect to the presence or absence of pitch-accent on the word (on a scale from 1 to 5, with 1 being the lowest confidence and 5 being the highest). The latter was determined by listening to the word in its context in the original speech file. All samples of cue words that had a noise level higher than three were discarded. Furthermore, only data from those speakers with sufficient instances in both the ID and the AD conversations were selected. As a result, the data from eight speakers could not be used at all, such that the final data set used for the experiments reported below consists of the cue words from 22 different speakers. The remaining samples were randomly assigned to training and test sets. For each speaking mode (ID and AD), there were 1342 training and 336 test samples; every speaker had the same number of training and test samples in both the AD and ID data sets. Table II shows the distributions of samples over training and test sets. Further balancing of the data in

TABLE III. Word accuracy (%) for speech recognizers trained on AD versus ID speech and tested on matched versus mismatched conditions.

		Test

	ID	90.2	93.5

terms of speaker and word identities (e.g., enforcing exactly the same number of samples for each word) would have resulted in sets with too few training samples. Although the data sets are very small by ASR standards, they are larger than the samples used by most other phonetic studies on infant-directed speech.

IV. EXPERIMENTS AND RESULTS

The original recorded data files were sampled at 16 kHz and preprocessed using MFCC analysis. The acoustic front-end consisted of 39 coefficients (12 MFCCs, normalized log energy, and their first and second derivatives), extracted every 10 ms with a window size of 25 ms. Cepstral mean and variance normalization were applied on a per-conversation basis to reduce the effects of recording conditions and speaker variation. Whole-word acoustic HMMs were then constructed for each cue word, with eight emitting states and two Gaussian mixture components per state. In accordance with standard practice in small-vocabulary ASR, whole-word- rather than subword-unit-based HMMs were used in order to achieve better coarticulation modeling. The models had a left-to-right topology without skip transitions, e.g., each state could transition only to itself or the immediately following state; states could not be skipped. Given that most ASR systems use three-state models for phone units (which are on average 30 ms long), the number of states reflects the expected duration of words consisting of three phones. Diagonal covariance matrices were used in each mixture component. The models were trained using three iterations of EM; recognition was performed by one-best Viterbi search. Due to the small size of the data set, more advanced modeling techniques which increase the number of parameters (such as context-dependent models or full covariance matrices) were not used.

A. Experiment I: Baseline study

The performance of the recognizers is measured as word accuracy, i.e., the percentage of correctly recognized samples in the test set. The results (Table III) show that absolute recognition performance is highest on the AD data set when using an AD-trained recognizer (upper left corner of Table III). In both conditions, the recognizer trained and tested on matched sets (the diagonal of the table) performs better than the corresponding recognizer trained on mismatched data. However, systems behave differently with respect to the relative degradation of recognition performance under mismatched conditions. The relative degradation of the AD-trained system on ID speech is 16.5% whereas the ID-trained system applied to AD speech shows a relative loss of 3.3%

FIG. 1. Per-speaker relative degradation (in % word error rate) of AD and ID recognizers on mismatched test data.

accuracy. This difference was statistically significant at the 0.0001 level, using a difference of proportions significance test. The absolute differences in accuracy are on the same scale (loss of 13.9% absolute of AD recognizer on ID speech and 3.3% of the ID recognizer on AD speech).

The relative degradation was also computed on a per-speaker basis. Results are displayed in Fig. 1. For 16 out of 22 speakers, the AD-trained recognizer showed a stronger degradation on ID speech (indicated by the striped bars) than vice versa (black bars). For two speakers, the performance did not change, and four speakers showed a stronger relative degradation on AD than on ID speech. The ID-trained recognizers also showed a better performance on the AD data set than on the ID test set for several speakers (the bars extending into the negative region in Fig. 1). From this we can conclude that the ID-trained recognizers perform more robustly under mismatched training and test conditions. There was no correlation with the amount of training or test data used per speaker.

B. Analysis

An analysis of the recognition errors showed that confusions occurred mainly between words sharing the same vowel (e.g., confusions between *key* and *bead* or *top* and *sock*) and words of the /u:/ and /ɒ/ categories (such as *spoon* and *sock*). Confusions between /i:/ words and the other categories were rare, although some examples of *shoe*–*sheep* confusions did occur, possibly due to strong coarticulation of the /u:/ vowel with the palatal fricative /sh/.

For a more detailed analysis it was necessary to look at individual phonetic segments. In order to automatically extract signal portions corresponding to subword units, we trained individual phone models, using a transcription of words in terms of their constituent phones. The preprocessing of the signals was identical to the recognition experiments described above. The phone models consisted of three emitting states with two Gaussian mixture components each; the topology was left-to-right without any skip transcriptions. The initial model parameters were set to the global mean and variance of the data, i.e., the parameters were computed from all feature vectors, regardless of phonetic class. The models were trained in three iterations of EM and were then used in a forced alignment procedure in order to obtain

FIG. 2. Distribution of vowel classes in normalized formant space in AD speech (a) and ID speech (b).

time boundaries of the constituent phones. During this procedure, the reference transcription was provided to the recognizer, and the Viterbi algorithm was used to identify the globally best time alignment of the model sequence defined by the transcription. The resulting time alignments were then checked for accuracy and the corresponding time segments were extracted. This data was used to analyze the distribution and separability of phonetic classes under different acoustic representations and prosodic conditions, as described in the following sections.

1. Separability of vowel classes

Standard formant-based analysis was applied to the vowel spaces in AD and ID speech. For each vowel segment (as identified by the forced alignment), formant values were obtained using the formant program of the Entropics ESPS package, and they were averaged over the entire length of the vowel. Cross-speaker normalization in the form of mean and variance normalization was applied.

The class distributions in the space defined by the normalized first two formants are shown in Fig. 2. Similar to previous studies which have investigated phonetic discriminability in either speech perception or automatic classification scenarios (e.g., Nossair and Zahorian, 1991; Zahorian and Jagharghi, 1993; Hillenbrand *et al.*, 1995), we computed

TABLE IV. Comparison of within-class distance (V^2), within-class distance (D^2), Fisher ratio (\mathcal{F}) (the ratio of within-class to between-class distance), and average Euclidean distance (E) between class means for AD and ID vowel data. The upper row shows results based on speaker-normalized formant values; the lower row shows results for PCA-mapped mel-frequency cepstral coefficients.

	AD				ID			
	V^2	D^2	\mathcal{F}	E	V^2	D^2	\mathcal{F}	E
Formants	4.98	24.32	0.17	3.96	8.73	20.94	0.29	3.84
MFCCs	1.08	12.72	0.08	3.24	2.70	8.82	0.23	2.89

various numerical measures of class separation. One of these is the Fisher ratio \mathcal{F} (e.g., Schuermann 1996) defined as

$$\mathcal{F} = \frac{V^2}{V^2 + D^2}, \quad (6)$$

where

$$V^2 = \sum_{k=1}^K P_k \text{trace}[\Sigma_k] \quad (7)$$

and

$$D^2 = \frac{1}{1 - \sum_{k=1}^K P_k^2} \sum_{k=1}^K \sum_{j=1}^K P_k P_j (\mu_k - \mu_j)^2 \quad (8)$$

where K is the number of classes, Σ_k is the covariance matrix of the k th class, μ_k is the mean of the k th class, and P_k is the prior probability of the k th class. V^2 measures the within-class variance of the features with respect to the class mean. D^2 denotes the interclass distance, i.e., the distance between class means, weighted by the class priors. \mathcal{F} thus expresses the ratio of within-class distance to the between-class distance and ranges between 0 and 1. A lower \mathcal{F} value indicates better separability. We also computed the average Euclidean distance between the three class means. These measures are shown in Table IV.

The results indicate a slightly better separation of class means in AD speech than in ID speech. Overall class separability is noticeably poorer in ID speech than in AD speech; this is due to a stronger degree of class overlap caused primarily by larger class variances.

In order to eliminate possible effects caused by the automatic segmentation, the analysis was repeated for average formant values computed only over the center third of each vowel. However, no significant difference was found between the results.

Formant values are useful for comparing the present analysis to other phonetic studies of vowel spaces; however, they are not used in the speech recognizers. It is not immediately obvious whether class distributions in formant space can be equated with class distributions in the 39-dimensional MFCC space that defines the recognizer front-end. The above analysis was therefore repeated for the MFCC data. Principal components analysis (PCA) (see, e.g., Duda *et al.*, 2001) was applied to the data and feature vectors, and the feature space was mapped to the coordinate system defined by the first two principal components, in order to be able to display the result graphically. Table IV lists the Fisher ratio

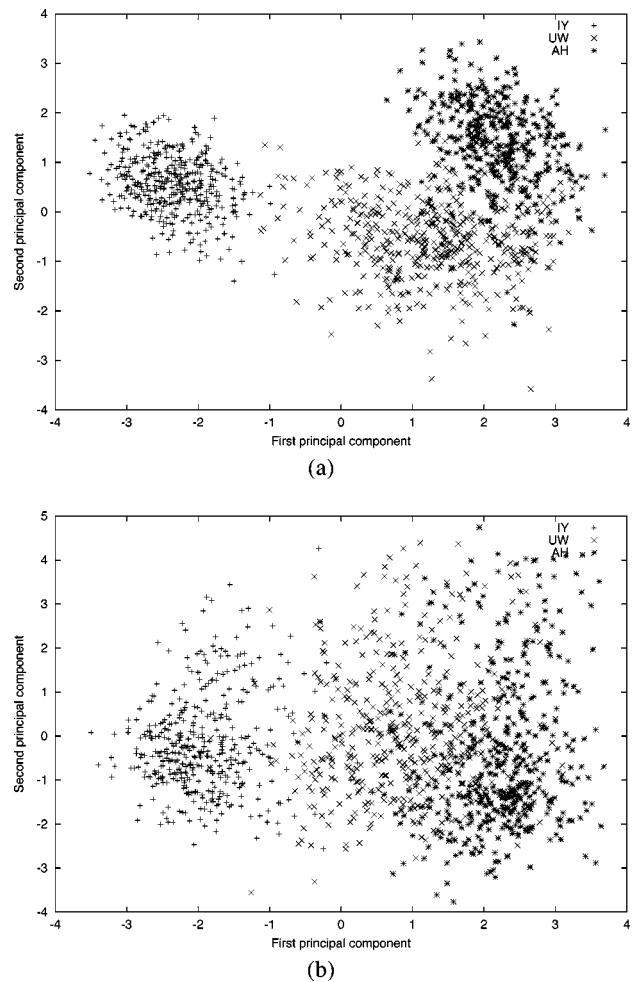

FIG. 3. Distribution of vowel classes in MFCC space mapped to the first two principal components, in AD speech (a) and ID speech (b).

and distance measures computed on this data, and Fig. 3 shows the corresponding distributions. Similar results can be observed: the average distance of class means is slightly larger and class separation is more pronounced in AD speech. Class separability measures computed on the full 39-dimensional feature space showed the same pattern.

One factor contributing to the variability in ID speech may be that no distinction was made between vowels that are typical examples of “motherese,” i.e., vowels that exhibit strong hyperarticulation, and those that are not. Our definition of “infant-directed speech” includes the ensemble of speech used in infant-directed conversations. Although this definition reflects natural listening conditions more faithfully, ID speech is a continuum, and a further distinction can be made between different points within this continuum. To this end, pitch-accented versus non-pitch-accented vowels were considered separately. Vowels bearing linguistic stress or pitch-accent are often articulated more clearly, whereas unstressed or unaccented vowels show a stronger degree of coarticulatory reduction, with a concomitant decrease in the size of the vowel space. This has been verified in a number of experimental and corpus-based studies (e.g., Lindblom, 1963; Sluijter and van Heuven, 1996; Kirchhoff and Bilmes, 1999). Vowels that are more representative of ID speech can be expected to be perceived as pitch-accented. We extracted

TABLE V. Within-class distance (V^2), between-class distance (D^2), Fisher ratio (\mathcal{F}) (the ratio of within-class to between-class distance), and average Euclidean distance (E) between class means for pitch-accented vowels in AD and ID speech.

AD				ID			
V^2	D^2	\mathcal{F}	E	V^2	D^2	\mathcal{F}	E
1.91	8.39	0.19	2.86	3.01	8.11	0.27	2.91

pitch-accented samples according to the manual annotations described above (Sec. II). For each condition, we extracted the 220 vowel samples with the highest pitch-accent values. The analysis measures were then recomputed for these data sets based on PCA-mapped MFCCs. The results are shown in Table V.

In spite of the elimination of non-pitch-accented vowel samples, the pattern observed before still holds: class overlap is greater in ID speech than in AD speech. However, the average mean Euclidean distance is now slightly greater than in ID than in AD speech. These observations confirm results obtained in previous studies (see above Sec. I). Although studies focusing on content words mostly report an expansion of the vowel space, van de Weijer (2001) explicitly compared vowels in content versus function words and found that expansion of the vowel space in ID speech occurred in content words but was reversed in function words, which are presumably not pitch-accented.

2. Separability of consonant classes

Most previous studies of infant-directed speech have focused on the acoustic properties of vowels. Consonants, on the other hand, are less well studied. An exception is Sundberg and Lacerda (1999) and Sundberg (2001), where the effects of infant-directed speech on the voice onset time (VOT) of stop consonants was studied. It was shown that VOT is significantly shorter in infant-directed speech than AD speech for infants in younger infants (three months) but changed to longer, overspecified patterns in older infants (11–14 months).

The error patterns in the recognizer output indicate that word confusions were caused not only by poor separation of vowels, but also by consonant substitutions. Therefore, the class separability measures described above were also applied to consonant distinctions, viz. the stops /b/ vs. /p/ in syllable-initial position, and the fricatives /sh/ vs. /s/ in syllable-initial position. These pairs were chosen because they represent the same broad phonetic class in comparable prosodic contexts; in particular, syllable-initial consonants were chosen because they tend to be less strongly coarticulated than syllable-final consonants. As before, the MFCC space was mapped to two dimensions using PCA. Table VI shows the resulting measurements. Whereas the average class mean distance is fairly similar, the Fisher ratio is again lower in AD speech.

C. Experiment II: Linear discriminant analysis

In pattern recognition, a common technique to enhance acoustic class separability is linear discriminant analysis

TABLE VI. Between-class distance (D^2), within-class distance (V^2), Fisher ratio (\mathcal{F}), and average Euclidean distance (E) between class means for syllable-initial consonant pairs /b/-/p/ and /sh/-/s/.

	AD				ID			
	V^2	D^2	\mathcal{F}	E	V^2	D^2	\mathcal{F}	E
/b/-/p/	1.83	6.83	0.21	1.06	2.05	4.99	0.29	1.04
/sh/-/s/	0.77	3.24	0.19	0.83	1.21	1.63	0.43	0.82

(LDA) (see, e.g., Duda *et al.*, 2001). LDA is a transformation designed to maximize the between-class distance while minimizing within-class distance; it is thus related to the Fisher criterion discussed above. Applying LDA to the infant-directed speech data should reduce the class overlap and produce better recognition results, possibly with the effect of smoothing out differences in performance between the AD and ID recognizer. We used LDA on both the AD and ID data sets. In each case, the transformation parameters were estimated on the training set and were then applied to both the training and the test set. The transformed data was used to train the speech recognizers, using exactly the same modeling procedures as before (see above Sec. IV A). The recognition results, listed in Table VII., show that recognition performance improves for both recognizers under both conditions. The relative improvement compared to the baseline results (Table III) is greatest for the AD-trained recognizer on ID test conditions. As before, however, the relative loss in word accuracy on the mismatched condition is more severe for the AD-trained recognizer than for the ID-trained recognizer; the difference is statistically significant at the 0.001 level.

V. DISCUSSION

Automatic speech recognizers trained on ID and AD speech, respectively, were applied to both matched and mismatched test sets. It was found that, on average, matched conditions produced better results than mismatched conditions, confirming the second of the hypotheses stated in Sec. II B. ID-trained recognizers performed better on AD speech test sets for some but not for most most speakers. However, the relative degradation of ID-trained recognizers on AD speech was significantly less severe than in the reverse case.

An analysis of a subset of phonetic class distributions in ID and AD speech showed that ID speech was characterized by a stronger class overlap, which provides an explanation of the recognition results: models trained on strongly overlapped classes can accommodate well-separated test data, but models trained on well-separated data will fail to correctly

TABLE VII. Word accuracy (%) of AD- and ID-trained speech recognizers under identical and mismatched test conditions, after application of LDA transformations.

		test	
		AD	ID
train	AD	97.4	91.8
	ID	92.9	94.7

classify test samples whose distributions show a stronger overlap. Samples in the intersection of the class decision boundaries may receive equally likely scores from the acoustic models, thus causing more confusions. The use of linear discriminant analysis to enhance class separation improved recognition results in all test conditions.

The automatic classification procedure used here does not claim to be a cognitively adequate model of infant perceptual learning. First, automatic speech recognizers are trained on a limited, well-defined training set, whereas it is, in general, impossible to quantify how much training data infants have previously been exposed to. Data collections where the amount of training data for a particular phonetic contrast can be controlled precisely [as in Kuhl *et al.*, (2003)] might turn out to be an interesting testbed for pattern recognition algorithms. Second, the acoustic representation and/or the statistical modeling techniques used in ASR systems certainly have deficiencies compared to human speech perception, since ASR performance still falls short of human performance. Nevertheless, the analyses presented above highlight interesting research questions for the study of infant speech perception. Previous studies on ID speech have emphasized the greater distance between vowel class means and have concluded that “motherese” might facilitate phonetic category learning. In contrast, it was found here (using comparatively large sets of samples and speakers) that class separability is actually poorer in ID speech. A possible reason is that *all* samples produced from infant-directed conversations were included, whereas previous studies may have focused on samples that are most “motherese-like” and thus occupy extreme positions in the vowel space. The slightly greater separation of the class means of pitch-accented vowels observed above confirms this interpretation. Nevertheless, the stronger class overlap is still present in those sets, suggesting that ID speech is poor training data. This result is in line with earlier studies comparing the intelligibility of speech directed to adults versus speech directed to children of 1–3 years (Bard and Anderson, 1983, 1994). In those studies, isolated words excised from either adult-adult or adult-child conversations had to be identified by adult listeners and young children. In Bard and Anderson (1994) additional context was provided for the tokens. It was found that word intelligibility was inversely related to word predictability: predictable words without their context were actually less intelligible in child-directed than in adult-directed speech. The conclusion drawn from this study was that adults might reduce predictable words more when talking to their infants/children than when talking to adults in order to draw the child’s attention to referents that are new in the discourse or in the extralinguistic environment. The observation made by van de Weijer (2001) that ID speech exhibits an enlarged vowel space in content words but a reduced vowel space in function words (see Sec. I) supports this analysis. It seems plausible that words which are predictable or already given in the discourse are underarticulated in favor of words that are new, some of which may then exhibit the typical motherese effect.

Our observations also pose the question of why infants are able to acquire phonetic categories and generalize to new

test samples in spite of strongly overlapped training data—we may assume that the majority of everyday speech that infants are exposed to consists of predictable function words [see also Cutler (1993)]. Several explanations may be advanced, e.g., that auditory representations in human speech perception are more invariant, that different (distribution-free) classification mechanisms are involved, or that listeners perform some form of data normalization, selection, or variance reduction, similar to the LDA transformation. Not all of these explanations are equally likely—it has been shown experimentally that infants do respond to distributions in auditory training data (Maye *et al.*, 2002). Moreover, although the acoustic representations and normalization techniques used in this study may not model human auditory representations perfectly, it is safe to assume that they are correlated. It seems most plausible that infants make use of perceptual variance reduction techniques. One possible candidate for such a technique is the perceptual magnet effect (Kuhl, 1991; Kuhl *et al.*, 1992). This effect is often described as a perceptual warping in the sense that auditory stimuli close to a “prototypical” representation of the category cannot be distinguished perceptually, thus decreasing within-class variance. Although the existence of this effect as well as the precise nature of the magnet theory have been under much discussion (Lively and Pisoni, 1997; Lotto *et al.*, 1998; Guenther, 2000; Lotto, 2000), it is striking that phonetic category perception does not occur until fairly late in the first year of life, after the emergence of the magnet effect as dated by proponents of this theory. It is unlikely that only the *amount* of speech data encountered by infants is responsible for the onset of categorical perception, or that categories are formed simply by passively processing all available input without some active contribution by the perceptual system: naturally occurring speech data is extremely variable in its distribution, and, as the present study shows, may even be more variable in ID speech than in AD speech. It may be assumed that infants selectively filter the available input, or perform a compaction of stored class representations [see recent evidence from neural imaging (Guenther and Bohland, 2002)]. Filtering might be done by focusing on the most motherese-like items in the speech input, which then become the prototypes of phonetic classes.

In summary, two conclusions can be drawn from this study. First, from an ASR point of view, ID-style speech seems to be of no immediate benefit to present-day ASR systems: matched training data still leads to superior results on AD test data. Furthermore, filtering of the training data in the way suggested above would not be advisable for ASR systems because of the resulting reduction in training material. The second conclusion is that parameters encoding contextual information (either linguistic or extralinguistic) should be explicitly integrated into data selection methods in acoustic-phonetic studies of ID speech, and into actual theories of infant speech perception. It should be noted that the ASR framework provides a tool for quantifying linguistic predictability (in the form of language model perplexity), which can in turn be used in data selection. It thus seems that the main benefits of combining ASR technology and the study of speech perception lie in the use of ASR techniques

for speech data selection and statistical representation as well as for building and testing perceptual models.

ACKNOWLEDGMENTS

(Received 20 July 2004; revised 14 January 2005; accepted 19 January 2005)

A drumlike traditional Japanese instrument, the mokugyo, is experimentally discussed. First, the acoustic characteristics of 176 mokugyos with diameters ranging from 7.5 to 120 cm and three drumsticks were measured. Results show that (a) the sound spectra consist of two common peaks [F_1 (Hz): first peak frequency, F_2 (Hz): second peak frequency] close together, with an average ratio (F_2/F_1) of 1.15, and (b) a drumstick beating the mokugyo is translated into an impact force applied over a period of time from 1 to 6 ms related to the mass and stiffness of the material wrapped around the tip of the drumstick. Second, to evaluate the acoustic response of a mokugyo in the final tuning process, the mechanical and acoustical analogy between the mokugyo and a bass reflex loudspeaker is theoretically and experimentally discussed. Results show that the model can be estimated within a relative error of 0.52% from the mass of wood chips. Finally, from a psychological experiment, the timbre of the mokugyo shows higher scores on psychological scales when the ratio (F_2/F_1) becomes 1.15. © 2005 Acoustical Society of America.

I. INTRODUCTION

In most of the rituals for Buddhism, the sutras are recited to the rhythm created by several percussion instruments such as a mokugyo, a keisu, and a large bowl-shaped gong.¹ A mokugyo is a round drum made of wood used during Zen rituals like the recitation of the sutras. Buddhists recite sutras while striking a mokugyo with a regular rhythm. Most Japanese have been familiar with the mokugyo sound since childhood. The word, “mokugyo,” means “a wooden fish” in Japanese. In Buddhism the fish, which never sleeps, symbolizes wakefulness. It was introduced from China to Japan around the 17th century. From an acoustic engineering standpoint, the mokugyo has never been investigated.

In recent years, physical modeling of the sound production mechanism of percussion instruments like a mokugyo has been studied. For example, Chaigne *et al.*^{2,3} proposed a physical model of xylophone sound production and synthesized xylophone sounds based on the proposed model. They reported that the synthesized sound was close to the real sound of the xylophone, and that the quality of the synthe-

sized sound could be controlled by adjusting the physical structure of the xylophone using the proposed model. L. Rhaoui *et al.*⁴ also proposed a physical model of the kettle-drum and its synthesized sounds from a similar standpoint. On the other hand, Obata *et al.*⁵ investigated acoustic characteristics of a Japanese traditional percussion instrument, the “ôdaiko.” They reported that the fundamental frequency component of ôdaiko sounds involved approximately 25 beats per second. The beats were produced by a coupled vibration between the drumskins on both sides of the body and the enclosed air. In the same way, Ando *et al.*^{6,7} investigated and synthesized the sound of the “tudumi,” and Aoki *et al.*⁸ investigated that of the “washô.”

Figure 1(a) shows the front view of a general mokugyo with a 37.5-cm diameter, (b) shows its side view with a 32.0-cm height, and (c) shows a drumstick with a 43.0-cm length. The body is made of camphorwood with a density of 0.16 g/cm³. Reliefs of dragons or fishes are carved on the body. The sound is produced by striking the contact area with a drumstick. As indicated by the dotted line in Fig. 1(b), the body is carved from a single block of wood to have a large internal cavity, which is quite a feat, given its narrow slit opening (intended to resemble the mouth of a fish). The cavity walls are 2.5 cm thick on average. These components form a Helmholtz resonator system. The handle of the drumstick is made of wood, and the tip is wrapped in rubber.

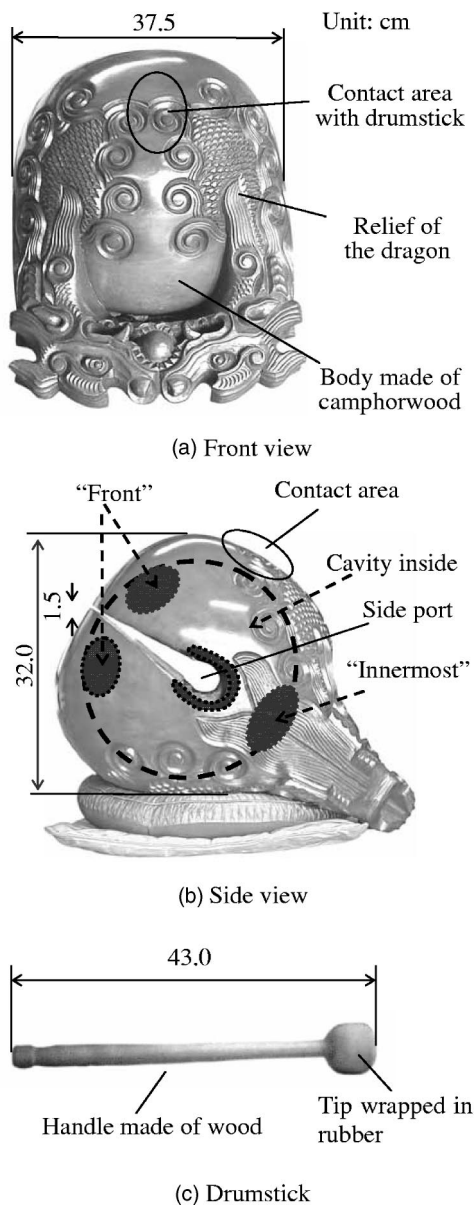

FIG. 1. The mokugyo. (a) Front view. (b) Side view. (c) The drumstick.

Typical drumstick tips are often wrapped in thread, cloth, or leather. The kinds of wrapping materials may be an important factor for producing beautiful timbre, since the timbre varies with the material. Therefore, the artisan making a mokugyo also makes a drumstick exclusively for the mokugyo.

Traditional skills for making mokugyo are endangered, since the number of artisans has decreased. One of the causes is the technical difficulty involved. The most difficult process is the adjustment of the timbre. This is done by chiseling the cavity of the side port little by little based only on the artisan's intuition. This process suggests that the physical characteristics which determine the timbre are affected by various structural elements of the body. If it is possible to control such physical parameters numerically using a physical model, the desired timbre could be produced easily.

In this paper, acoustic characteristics of mokugyos are investigated experimentally, theoretically, and psychoacoustically. In Sec. II, five physical characteristics of the

mokugyo and its drumstick are measured and discussed: mokugyo sound spectrum, vibration of the body, waveform and spectrum of the driving forces of the drumstick, directivity, and sound intensity vector of the acoustic radiation of the mokugyo. In Sec. III, a physical model of the mokugyo is proposed in which it is assumed that the mechanical vibratory section of the body and the Helmholtz resonator system are coupled. The mokugyo sound is simulated in the frequency domain. Parameter values used in the proposed model are estimated by comparing the spectrum of the simulated sound with that of the original sound. In Sec. IV, the proposed model is evaluated. Three areas in the cavity, which are called "front," "innermost," and "side port," are chiseled, and then the difference in the spectrum before and after the chiseling is measured and evaluated. In Sec. V, the relation between favorable timbre and physical characteristics of the mokugyo is experimentally examined with the semantic differential method in order to establish indices for evaluating mokugyo timbre.

II. EXPERIMENTS

In order to investigate the physical and acoustic characteristics of the mokugyo, five characteristics were measured: sound spectrum, vibration of the body, drumstick driving force, directivity, and sound intensity vector.

A. Sound spectrum

1. Experimental method

One hundred seventy-six mokugyos were used for this measurement. The minimum diameter of the mokugyos was 7.5 cm and the maximum was 120 cm with an average diameter of 46 cm. Each mokugyo was struck with a drumstick at the contact area shown in Fig. 1. This experiment was conducted in an anechoic room with a volume of 60 m³. To record the sounds a microphone was set at a distance of 100 cm away from the side port, and the output signals were recorded on DAT (Technics: SV-MD11) with a sampling frequency of 48 000 Hz. The recorded sounds were analyzed using a (fast Fourier transform) (FFT) with a rectangular window of 32 768 samples.

2. Results

Figure 2 shows waveforms and spectra for three mokugyos with typical characteristics. Time scales in the figures are different from each other. The rising edge of the waveform (i.e., when the drumstick contacts the body) is set to "0" in the time scale. The beats were observed for all three waveforms whose periods are (a) 7.2 ms for the mokugyo with a diameter of 9 cm, (b) 46 ms for that with a diameter of 37 cm, and (c) 110 ms for that with a diameter of 90 cm. Three peaks were observed in all sound spectra. The two peaks at lower frequencies are significant. In this paper, the three peaks are defined as the first, second, and third resonance frequencies, F_1 , F_2 , and F_3 (Hz) in increasing order. Each resonance frequency decreases as the diameter increases, and F_1 and F_2 are close. These two close peaks are a general physical characteristic for the sound of the mokugyo, since such peaks were observed for 174 out of 176

FIG. 2. Waveforms and spectra of three kinds of mokugyo: (a) 9 cm in diameter, (b) 37 cm, and (c) 90 cm.

mokugyo. Figure 3 shows a correlation diagram between F_1 and F_2 for these 174 mokugyo. F_1 and F_2 show a linear correlation, and its correlation coefficient is 0.997. The average ratio of F_1 and F_2 (i.e., the average of F_2/F_1) is ap-

proximately 1.15. These results suggest that the period of the beat observed in the waveform is $1000/(F_2 - F_1)$ (ms).

B. Vibration of the body

1. Experimental method

The mokugyo shown in Fig. 2(b) was used in this measurement. The vibration of the driving point of the body was measured using an acceleration pickup (RION: PV-90V) set 2 cm above the contact point for the drumstick along with the surface. The mokugyo was struck with a drumstick at the contact area shown in Fig. 1. The output acceleration signal was converted to a velocity signal via a charge amplifier (SHOWA: 4006).

2. Results

Figure 4 shows the waveform of the vibration velocity of the body, in which the rising edge of the waveform (i.e., when the drumstick contacts the body) is set to "0" in the time scale. A beat was observed in the waveform. The period

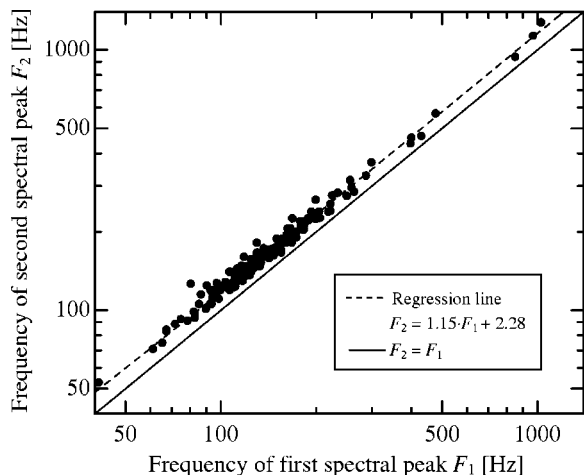

FIG. 3. Correlation between second peak F_2 and first peak F_1 of the sound spectra of 174 mokugyo.

FIG. 4. Vibration velocity of the driving point of the body.

of the beat, 46 ms, is approximately equal to that of the sound wave in Fig. 2(b). As is seen in Fig. 2(b), the phase difference of the beat between the vibration and the sound is 26 ms, which is the sum of half the period of the beat and the propagation time to the observation point. Half the period was 23 ms, and the propagation time was 3 ms since the observation point for the sound was set at a distance of 100 cm away from the mokugyo. These results suggest that the energy of the vibration is exchanged alternately from the body to the Helmholtz resonator system. This energy exchange is caused by the coupled vibration of the two systems with the same eigenfrequency.

C. Effect of impact forces

1. Experimental method

Three kinds of drumsticks were used. Their tips were wrapped in thread, leather, and rubber. The length and mass of the drumstick with the thread tip were 23 cm and 26 g, those of the drumstick with the leather tip were 40 cm and 173 g, and those of the drumstick with the rubber tip were 55 cm and 250 g. The impact force was measured using an impedance head (RION: PF-60) set on a rigid wall. The impedance head was struck with the drumstick by an experimenter. The experimenter kept the driving force at 170 N through all measurements. The output signal was recorded via a charge amplifier (SHOWA: 4006).

Following the measurements of the impact forces, the sound spectra of a mokugyo with a 42-cm diameter were measured using two kinds of drumsticks: a leather-wrapped drumstick and a thread-wrapped drumstick. The method of recording and analyzing the measured sounds was the same as described in Sec. II A.

2. Results

Figure 5(a) shows the impact forces as a function of time. The force duration varies from 1 to 6 ms according to the material wrapped around the tip. Figure 5(b) shows the spectra of the impact forces. The frequency range varies according to the wrapping material.

Figure 6 shows the sound spectra of a mokugyo struck with two kinds of the drumsticks. In the frequency region less than $F_3 = 517$ Hz, the sound spectrum for the drumstick wrapped in thread corresponds to that for the one wrapped in leather. At higher frequencies the spectrum level for the

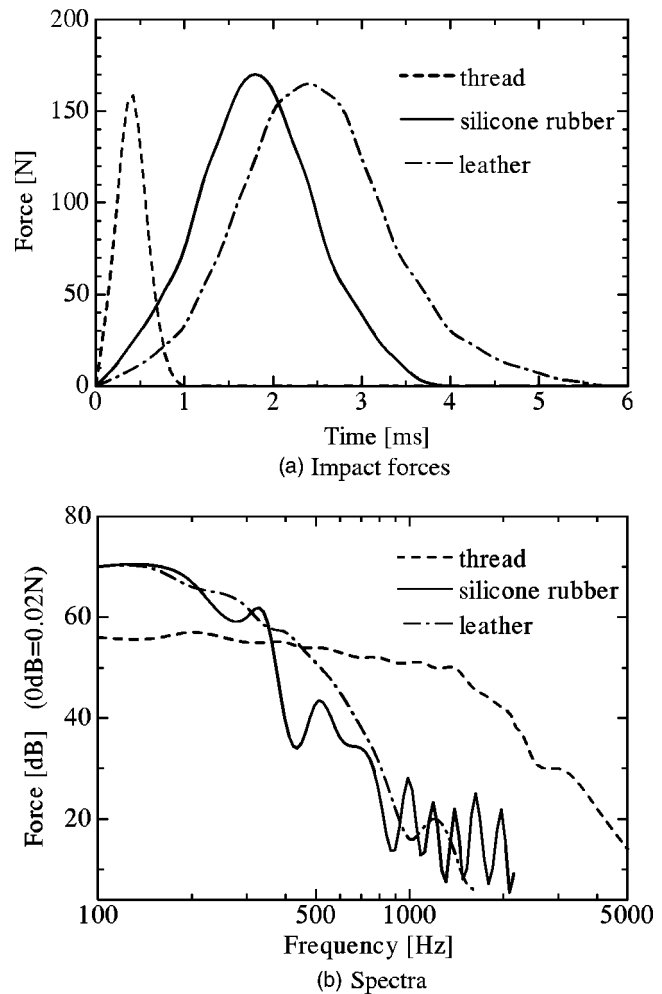

FIG. 5. Waveforms and spectra of impulsive forces from three kinds of drumsticks. (a) Impact forces. (b) Spectra.

drumstick wrapped in leather decreases. The result is consistent with the frequency range of the impact force.

D. Directional response

1. Experimental method

The mokugyo shown in Fig. 2(b) was used in this measurement, and its resonance frequencies are $F_1 = 155$ Hz,

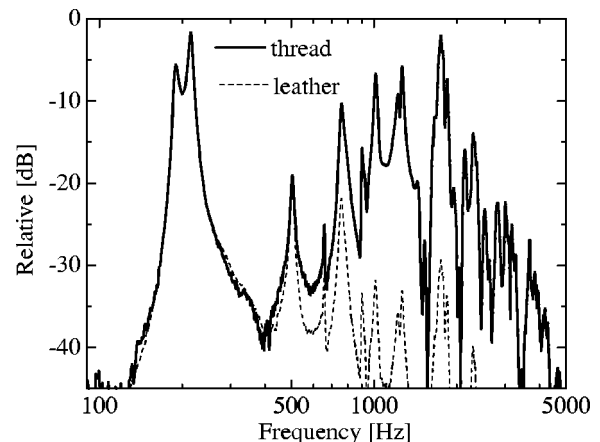

FIG. 6. Sound spectra from two kinds of drumsticks.

FIG. 7. Block diagram of directivity measurement setup.

$F_2 = 177$ Hz, and $F_3 = 402$ Hz. Figure 7 shows the block diagram of the measurement system. The mokugyo was put on a turntable and driven steadily with sinusoidal waves corresponding to each resonance frequency. The sound pressure level was measured as the turntable rotated. The output signal from the oscillator (NF: SY-126) was amplified and transmitted to a vibration exciter (Nikkei Denshi: Golden Tone) whose mass was compensated for by a spring balance. The body of the mokugyo was excited by the vibration exciter fixed on the contact area. A microphone was set at a distance of 100 cm away from the side port at a 45° angle from the horizontal plane. Also, an acceleration pickup (RION PV-90V) was used to investigate the vibration at various points on the surface of the body. This acceleration signal was recorded via a charge amplifier (SHOWA: 4006).

2. Results

Figure 8 shows the directivity for each resonance frequency. F_1 and F_2 are omnidirectional while F_3 shows a figure-8 pattern. This figure-8 pattern of F_3 was caused by the divided vibration of the body since the vibration node, which divides the upper part of the body in two, was observed as shown in Fig. 7.

E. Sound intensity measurement

1. Experimental method

The mokugyo shown in Fig. 2(b) was used. A two-dimensional sound intensity vector was measured by exciting the body using the same method described in Sec. IID. The measurement plane was a vertical one dividing the body in half. One hundred eighty-five measuring points, which were allocated on the measuring plane at 2-cm intervals around the side port, were used. The sound intensity vector was measured using the two rotating microphone method.^{9,10}

FIG. 8. The directional patterns of three resonant frequencies.

2. Results

Figure 9 shows the sound intensity vector around the side port at frequencies F_1 , F_2 , and F_3 . The arrows and their lengths indicate the directions and the levels (dB) of the vectors. The levels shown in Fig. 9(c) are compensated by +30 dB, since these levels are lower than the others.

For $F_1 = 155$ Hz and $F_2 = 177$ Hz, many of the vectors spread radially from the side port, and no vectors spread directly from the body. Therefore, the vibration mode at F_1 and F_2 would be a simple point sound source corresponding to the vibration of the air in the side port. This result is consistent with the directivity shown in Fig. 8. On the other hand, for $F_3 = 402$ Hz, the vectors from the side port are hardly observed, and most of the vectors are radiated from the body. This result suggests that the figure-8 pattern of F_3 shown in Fig. 8 is due to the divided vibration of the body.

III. THEORETICAL ANALYSIS

As shown in Sec. II, the sound of the mokugyo involves two close resonance frequencies, F_1 and F_2 . In this section, the relationship between these two resonance frequencies and the structure of the mokugyo is discussed based on a physical model. This structure composed of the body, cavity, and side port is analogous with that of the bass reflex loudspeaker,^{11,12} and a guitar,¹³⁻¹⁵ since there is coupling between vibrations of plates and the internal air cavity they enclose. An equivalent model of the mokugyo is proposed based on the theory of the bass reflex loudspeaker. Then, the mokugyo with a diameter of 37 cm shown in Fig. 2(b) is simulated acoustically.

A. Model of the mokugyo

Figure 10 shows the physical model of the mokugyo proposed in this paper, and Table I shows the parameters used in this model. The model is composed of two vibration systems: a mechanical vibration system driven by the drumstick and an acoustic vibration system composed of the cavity and the side port. In the mechanical vibration system, the effective vibration part of the body is assumed to be a circular vibratory board with equivalent mass m_m , which is fixed

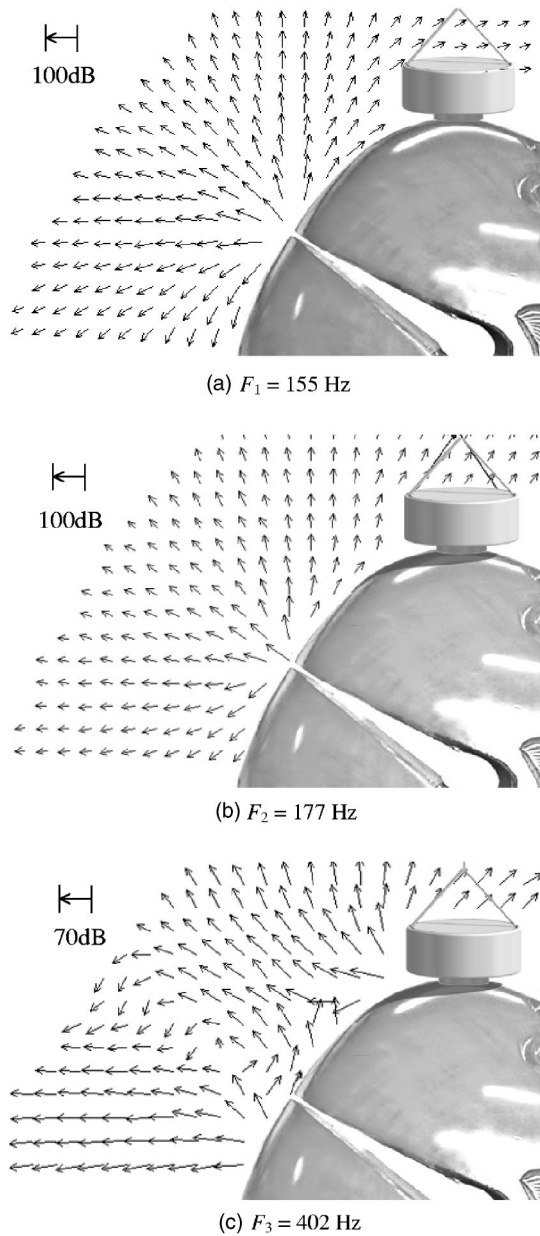

FIG. 9. Sound intensity vectors around the port: (a) $F_1 = 155$ Hz, (b) $F_2 = 177$ Hz, and (c) $F_3 = 402$ Hz.

on a rigid wall. m_m is derived from the sum of the mass of the board, m_d , and an additional mass radiated from the board, m_{ad} . The additional mass m_{ad} is a reaction force from the medium when the board is vibrating, and acts to increase the mass of the board. In this model, furthermore, the deflection forced by the drumstick is modeled using both a spring with equivalent stiffness, s_m , supporting the circular vibratory board and a mechanical resistance, r_m . The board is driven by an external force F due to the drumstick and is vibrated at a velocity v_d . In an acoustic vibration system, the cavity corresponds to the reciprocal of acoustic compliance, i.e., stiffness, s_c . The side port is modeled as a cylindrical hole hollowed out of a rigid wall. The hole is equivalent to the sum of the air mass, m_p , and an additional mass radiated from the side port, m_{ap} . The acoustic resistance of the side port is ignored in this model, since the resistance is much smaller than the mechanical resistance r_m .

FIG. 10. Physical model of the mokugyo.

Figure 11 shows the electrical circuit equivalent to the model in Fig. 10. Coupling between the mechanical and acoustical systems is replaced by a transformer with a turn ratio equivalent to the area ratio of the effective vibration area of the body, S_d , and the cross-sectional area of the side port, S_p . Converting the secondary side (acoustical system) of the transformer into the primary side (mechanical system), the following simultaneous differential equations can be derived:

TABLE I. Parameter values used in the proposed model.

Variable	Symbol	Value
Mechanical system		
Effective vibration area of the board	S_d	0.07 m^2
Radius of the board	a_d	14.9 cm
Mass of the board	m_d	5.48 kg
Additional mass of the board	m_{ad}	0.616 kg
Equivalent mass	m_m	$m_d + m_{ad} = 6.10 \text{ kg}$
Equivalent stiffness	s_m	$6.76 \times 10^6 \text{ N/m}$
Equivalent resistance	r_m	$210 \text{ N} \cdot \text{s/m}$
Vibration velocity of the board	v_d	...
Acoustic system		
Volume of the port	W_p	$1.55 \times 10^{-3} \text{ m}^3$
Cross section area of the port	S_p	$1.50 \times 10^{-2} \text{ m}^2$
Radius of the port	a_p	6.9 cm
Length of the port	l_p	10.3 cm
Mass of the port's air	m_p	$1.87 \times 10^{-3} \text{ kg}$
Additional mass of the port	m_{ap}	$2.36 \times 10^{-3} \text{ kg}$
Equivalent mass converted into the mechanical system	m_1	$(S_d/S_p)^2(m_p + m_{ap}) = 0.092 \text{ kg}$
Volume of the cavity	W_c	$1.80 \times 10^{-2} \text{ m}^3$
Equivalent stiffness of the cavity	s_c	$1.0 \times 10^5 \text{ N/m}$
Particle velocity	v_p	...
Other parameters		
Impact force with the drumstick	F	170 N
Distance from the board to the observation point	r_1	130 cm
Distance from the side port to the observation point	r_2	100 cm
Air density	ρ_0	1.21 kg/m^3
Sound velocity	c	343 m/s

FIG. 11. Equivalent circuit of the physical model.

$$\begin{aligned}
 & m_m \frac{d}{dt} v_d(t) + r_m v_d(t) + s_m \int v_d(t) dt \\
 & + s_c \int \left\{ v_d(t) - \frac{S_p}{S_d} v_p(t) \right\} dt \\
 & = F(t),
 \end{aligned} \tag{1}$$

$$\hat{v}_d(\omega) = \frac{j\omega(s_c - m_l\omega^2)\hat{F}(\omega)}{m_m m_l \omega^4 - (s_c m_m + m_l s_c + m_l s_m)\omega^2 + s_c s_m - j(m_l r_m \omega^3 - s_c r_m \omega)} \tag{4}$$

and

$$\hat{v}_p(\omega) = \frac{j\omega s_c S_d \hat{F}(\omega) / S_p}{m_m m_l \omega^4 - (s_c m_m + m_l s_c + m_l s_m)\omega^2 + s_c s_m - j(m_l r_m \omega^3 - s_c r_m \omega)}, \tag{5}$$

where ω denotes the angular frequency, which is related to the vibration frequency f by $\omega = 2\pi f$. From the results shown in Sec. II E, the mechanical vibration system in the body and the acoustic center of the side port can be assumed to be simple point sound sources. Thus, the complex sound pressure $\hat{p}(\omega)$ at an arbitrary observation point is given by

$$\hat{p}(\omega) = \frac{j\rho_0\omega}{2\pi} \left\{ \frac{\epsilon^{-jkr_1}}{r_1} S_d \hat{v}_d(\omega) - \frac{\epsilon^{-jkr_2}}{r_2} S_p \hat{v}_p(\omega) \right\}, \tag{6}$$

where r_1 denotes the distance from the sound source of the mechanical vibration system, r_2 denotes that from the side port, ρ_0 denotes the density of air, and k denotes the wave constant given by $k = \omega c$. By applying Eqs. (4) and (5) to Eq. (6), the sound pressure at the observation point is given by

$$\hat{p}(\omega) = \frac{-\rho_0 S_d \omega^2 \hat{F}(\omega)}{2\pi} \left\{ \frac{(s_c - m_l\omega^2)\epsilon^{-jkr_1}/r_1 - s_c \epsilon^{-jkr_2}/r_2}{m_m m_l \omega^4 - (s_c m_m + m_l s_c + m_l s_m)\omega^2 + s_c s_m - j(m_l r_m \omega^3 - s_c r_m \omega)} \right\}. \tag{7}$$

B. Measurement of the model parameters

In this section, parameter values for the proposed model in Sec. III A are calculated using a mokugyo with a 37-cm diameter.

1. Model parameters

Table II shows the profile of the mokugyo used. Assuming the shape of the mokugyo is spherical, the surface area of the hemisphere (0.215 m^2) can be calculated from the diameter of the mokugyo. The area of the circular vibratory board, S_d , corresponding to the effective vibration area of the body in the model is supposed to be $\frac{1}{3}$ the surface area of the hemisphere. When $S_d = 0.07 \text{ m}^2$, the radius of the vibratory board, a_d , is 15.1 cm. In the proposed model, since the side

$$m_l \frac{S_p}{S_d} \frac{d}{dt} v_p(t) + s_c \int \left\{ \frac{S_p}{S_d} v_p(t) - v_d(t) \right\} dt = 0,$$

where $v_d(t)$ denotes the vibration velocity of the circular board, $v_p(t)$ denotes the particle velocity of the side port, and m_l denotes the equivalent mass of the side port converted to the mechanical system. m_l is given by

$$m_l = \left(\frac{S_d}{S_p} \right)^2 (m_p + m_{ap}). \tag{2}$$

The initial conditions of Eq. (1) are

$$v_d(0) = v_p(0) = \int_{-\infty}^0 v_d(0) dt = \int_{-\infty}^0 v_p(0) dt = 0. \tag{3}$$

From Eq. (1), the Fourier transforms of $v_d(t)$ and $v_p(t)$, that is, $\hat{v}_d(\omega)$ and $\hat{v}_p(\omega)$, are

port of the body is assumed to be a circular cylinder, its radius, a_p , is 6.9 cm and length, l_p , is 10.3 cm, where the cross section, S_p , of the side port (i.e., the cross section of the circular cylinder) is assumed to correspond to the actual area of the side port opening. The maximum force driven with the drumstick, F_{\max} , is set at 170 N as shown in Fig. 5.

TABLE II. Profile of the mokugyo used in the simulation.

Parameter	Actual measurement
Diameter of the mokugyo	37 cm
Aperture area of the side port	$1.50 \times 10^{-2} \text{ m}^2$
Capacity of the side port	$1.55 \times 10^{-3} \text{ m}^3$
Capacity of the cavity	$1.80 \times 10^{-2} \text{ m}^3$

The distance from each source to observation points r_1 and r_2 , the density of air, ρ_0 , and the sound velocity, c , are set at $r_1 = 130$ cm, $r_2 = 100$ cm, $\rho_0 = 1.21$ kg/m³, and $c = 343$ m/s.

2. Mechanical system parameters

a. *Equivalent mass of the circular vibratory board: m_d .* From the original first resonance frequency of the body, F_1 , and the resonance frequency, F'_1 , produced by fixing an arbitrary additional mass, m'_d , on the surface of the mokugyo, the equivalent mass of the vibratory board, m_d , is given by¹¹

$$m_d = m'_d \frac{F_1'^2}{F_1^2 - F_1'^2}. \quad (8)$$

$F_1 = 155$ Hz was used for the mokugyo as shown in Fig. 2(b). Here, F'_1 was measured and found to be 152.2 Hz, when the additional mass ($m'_d = 0.20$ kg) was experimentally fixed on the driving point of the body. Thus, $m_d = 5.48$ kg was obtained from Eq. (8).

b. *Additional mass of the board: m_{ad} .* The additional mass, m_{ad} , due to the radiation from the board, is derived from the following equation,¹²

$$m_{ad} = \frac{16}{3} \rho_0 a_d^3, \quad (9)$$

which expresses an inductive component of the radiated impedance produced by the circular vibratory board.¹² From Eq. (9), $m_{ad} = 0.3269$ kg.

c. *Equivalent stiffness: s_m .* From F_1 and m_d , the equivalent stiffness of the board s_m (Ref. 11) is

$$s_m = 4\pi^2 F_1^2 m_d. \quad (10)$$

From Eq. (10), $s_m = 6.76 \times 10^6$ N/m.

d. *Equivalent resistance: r_m .* The quality factor Q_1 of the first resonance frequency is 25.4, since Q_1 is $F_1 / \Delta F_Q$,¹¹ where ΔF_Q is the bandwidth when the sound pressure level becomes $1/\sqrt{2}$ times the sound pressure level at F_1 . Thus, the equivalent resistance of the mechanical system r_m (Ref. 11) is

$$r_m = \frac{2\pi F_1 m_d}{Q_1}. \quad (11)$$

From Eq. (11), $r_m = 210$ N·s/m.

3. Acoustical system parameters

a. *Stiffness of the cavity: s_c .* From the volume of the cavity, W_c , the area of the vibratory board, S_d , the sound velocity, c , and the density of air, ρ_0 , the stiffness of the cavity, s_c , is

$$s_c = \frac{\rho_0 c^2 S_d^2}{W_c}. \quad (12)$$

From Eq. (12), $s_c = 3.86 \times 10^4$ N/m.

b. *Air mass in the side port: m_p .* Multiplying the volume of the side port, W_p , by the density of air, ρ_0 , gives $m_p = 1.87 \times 10^{-3}$ kg.

c. *Additional mass of the side port: m_{ap} .* From Eq. (9), $m_{ap} = 2.13 \times 10^{-3}$ kg. This value was obtained in the same way as the additional mass of the vibratory board, m_{ad} .

FIG. 12. Spectra of simulated and actual mokugyo.

C. Simulation

The sound spectrum of the mokugyo was simulated based on Eq. (7). Some of the parameter values, however, may be different from the actual values, since the shapes of the cavity and the side port assumed in the proposed model differ from the actual ones. W_c may also vary when struck by the drumstick. In this simulation, therefore, the additional mass of the vibratory board, m_{ad} , the stiffness of the cavity, s_c , and the additional mass of the side port, m_{ap} , were considered to be variables. These three parameters were optimized so as to match the simulated spectrum to the actual one.

First, the spectrum was calculated using Eq. (7) with the values of m_{ad} , s_c , and m_{ap} calculated in Sec. III B. Second, the optimal values for these three parameters were found by varying the values repeatedly. The convergence criteria were that the simulation error was within 1% for F_1 , F_2 , and the spectrum level difference at these frequencies. Here, $F_1 = 155$ Hz, $F_2 = 177$ Hz, and the level difference was 2.72 dB for the original sound spectrum as shown in Fig. 2(b).

Figure 12 shows the result obtained through the procedure described above. The final characteristics given by this simulation indicate that $F_1 = 155$ Hz, $F_2 = 177$ Hz, and the spectrum level difference is 2.72 dB. The result shows a correspondence between the simulated spectrum and the original one. The convergence values of the three parameters are $m_{ad} = 0.616$ kg, $s_c = 1.0 \times 10^5$ N/m, and $m_{ap} = 2.36 \times 10^{-3}$ kg.

Using these convergence values, the eigenfrequency of the mechanical system f_m is $1/2\pi\sqrt{s_m/m_m} = 167.5$ Hz, and that of the acoustic system f_c is $1/2\pi\sqrt{s_c/m_1} = 165.9$ Hz. These two frequencies are approximately equal. These results suggest that the mechanical vibration of the body and the acoustic vibration of the Helmholtz resonator are robustly coupled with each other, and that the beat of the waveforms shown in Fig. 2(b) is due to the mutual interaction of these two vibration systems.

From these results, the body, cavity, and side port create a structure for producing the two close resonance frequencies F_1 and F_2 . We assume that these two frequencies are the most important for the timbre of the mokugyo.

IV. COMPARISON OF THEORY AND EXPERIMENT

In the final tuning process of the mokugyo, an artisan chisels three areas called “innermost,” “side port,” and

TABLE III. Measured and estimated F_1 and F_2 before and after chiseling.

Part chiseled		“innermost”		“side port”		“front”	
Weight of sawdust		227.6 g		7.29 g		205.5 g	
		F_1 (Hz)	F_2 (Hz)	F_1 (Hz)	F_2 (Hz)	F_1 (Hz)	F_2 (Hz)
Measured	before chiseling	155.0	177.0	154.1	175.4	153.1	174.5
	after chiseling	154.1	175.4	153.1	174.5	153.4	175.1
Simulated	before chiseling	155.0	177.0	154.1	176.1	153.0	175.4
	after chiseling	154.1	176.1	153.0	175.4	153.4	176.0
Relative error		-0.03%	-0.38%	0.06%	-0.52%	0.05%	-0.52%
Main factors		$\Delta s_c = -2.08 \times 10^3$ N/m		$\Delta m_p = +1.49 \times 10^{-5}$ kg		$\Delta m_d = -6.90 \times 10^{-2}$ kg	
				$\Delta m_{ap} = +7.5 \times 10^{-5}$ kg			

“front” shown in Fig. 1. In this experiment, these areas were chiseled by an artisan and the sound spectra were measured before and after chiseling. The accuracy of the simulation with the proposed model described in Sec. III was examined using the results of the measurements during the actual chiseling.

A. Experiment and simulation conditions

1. Measurement experiment method

A mokugyo with a diameter of 37 cm was used for this experiment. The material of the body was camphorwood and its density was 0.16 g/cm³. The experimental procedure was as follows:

- The sound spectrum of the mokugyo was measured by the same method as described in Sec. II A.
- The “innermost” was chiseled by an artisan until he felt that the timbre changed.
- The mass of wood chips chiseled by the artisan and the sound spectrum for the chiseled mokugyo were measured.
- Procedures (a)–(c) were carried out for the “side port” and “front.”

2. Simulation method

The difference between the volume before and after chiseling the “innermost,” $\Delta W_{innermost}$, can be obtained from the mass of the wood chips and the density of the wood. $\Delta W_{innermost}$ is equal to the increase in volume of the cavity, ΔW_c , and the parameter corresponding to ΔW_c in the proposed model is the stiffness of the cavity s_c . Thus, substituting $\Delta W_{innermost}$ into ΔW_c in Eq. (12) gives the variation in stiffness, Δs_c . The simulated value of F_1 and F_2 can be obtained by substituting Δs_c into Eq. (7).

The decrease in volume of the “side port,” $\Delta W_{side\ port}$, can be also obtained from the mass of the wood chips and the density of the wood. $\Delta W_{side\ port}$ is equal to the increase in the volume of the side port, W_p . Thus, the variation of air mass in the side port, Δm_p , can be written as $\Delta W_{side\ port} \times \rho_0$. In addition, the additional mass of the side port, m_{ap} , increases since the cross section S_p of the side port increases due to the chiseling. Assuming that the length of the cylinder of the port l_p remains the same, the increase in the radius of the port, Δa_p , can be calculated, and then the additional mass, Δm_{ap} , can be obtained by using Eq. (9).

Considering the structure of the mokugyo, the mass of the “front” may vary with the decrease in the equivalent

mass, Δm_d , in the mechanical system. It would be difficult, however, to estimate a relationship between Δm_d and the mass of the wood chips from the “front.” Thus, in this simulation, Δm_d is assumed to be a variable parameter whose maximum value is equal to the mass of wood chips. The simulated values of F_1 and F_2 are calculated using Eq. (7). The optimal value of Δm_d is found using the same method as described in Sec. III C.

B. Results and discussion

Table III shows the weight of wood chips, measured and simulated resonance frequencies F_1 and F_2 before and after the chiseling, the relative error, and the main parameters thought to affect F_1 and F_2 . For “innermost” and “side port,” the measured F_1 and F_2 decreased after the chiseling, and the simulated values matched the measured ones well since the relative error was within 0.52%. The chiseling of the “side port” affects F_1 and F_2 significantly in spite of the fact that the mass of the chiseled wood chips, 7.6 g, is only 0.18% of the whole mass of the mokugyo, 4.3 kg. Such significant variations in F_1 and F_2 are due to the variation of the eigenfrequency of the Helmholtz system, which varies according to the variation of the volume of the “side port,” $\Delta W_{side\ port}$, and the mutual interaction of the vibration of the body and the Helmholtz system. In contrast, chiseling the “front” increased F_1 and F_2 , but the simulated values still matched the measured ones well since the relative error was within 0.52%. This seems to indicate that the top and bottom portions of the instrument are moving like the tines of a tuning fork or like portions of a slot drum. The vibrational mode of the wooden shell was not changed at its lowest sound peaks. The optimal value of Δm_d was found to be -6.90×10^{-2} kg, which is about $\frac{1}{3}$ of the mass of the wood chips. The reason why Δm_d becomes $\frac{1}{3}$ of the mass of the wood chips is a topic for further research. These results suggest that the proposed model can estimate ΔF_1 and ΔF_2 using the mass of the wood chips from the three areas selected here.

V. TIMBRE EVALUATION

As described in Sec. II A, beats are observed in the sound waveforms for all mokugyos, and their periods are $1000/(F_2 - F_1)$ (ms). In this section, the effects of F_1 and F_2 on the timbre of four kinds of mokugyos (with 9-, 18-, 37-, and 90-cm diameters) are investigated psychoacoustically with the semantic differential (SD) method. It is desir-

FIG. 13. Block diagram of the simulation synthesis method.

able for timbre evaluation that subjects can play the mokugyo. However, it is difficult to vary the resonance frequencies to arbitrary values by chiseling a real mokugyo. Thus, a system for simulating the sound of the mokugyo was made using a DSP board. This system can reproduce in real time simulated mokugyo sounds based on the model described in Sec. III.

A. Method of the simulation

Figure 13 shows a block diagram for synthesizing the sound using a DSP board (Texas Instruments: C6711DSK). The impact force of a drumstick was simulated as a voltage signal generated by striking a circular PZT board with a real drumstick. This signal was digitized with a sampling frequency of 2000 Hz and was transmitted to the DSP board. The parameter values of the proposed model for four kinds of real mokugyos were obtained by the same method as described in Secs. III B and C. Table IV shows sound characteristics of four real mokugyos and the values of F_1 and F_2 for each synthesized sound. Parameters in the proposed model were selected to match the F_1 and F_2 values shown in Table IV. The transfer function of the mokugyo body, i.e., FIR filter coefficients, was calculated for a sampling frequency of 2000 Hz. Then, the mokugyo sound was synthesized by convolution of the FIR coefficients with the impact force signal of the drumstick. This signal was reproduced by a loudspeaker (Electro Voice: SH15-2) via the D-A converter inside the DSP board.

B. Experiments

The timbre evaluation experiment based on the SD method was conducted in an anechoic room with a volume of 60 m³. Subjects reproduced each sound source with the system described in Sec. V A. The process was repeated until each subject felt that the evaluation was finished. To evaluate the four real mokugyos, the real mokugyos were also struck

TABLE IV. Sound characteristics of four real mokugyos and the values of F_1 and F_2 for the synthesized sounds.

Diameter of mokugyo (cm)	F_1 (Hz)	F_2 (Hz)	Center frequency F_c (Hz)	Values of $\Delta F = F_2 - F_1$ for synthesized sounds
9	984	1098	1041	0–200Hz(in50-Hzsteps)
18	392	427	409.5	0–60Hz(in10-Hzsteps)
37	155	177	166	0–40Hz(in10-Hzsteps)
90	70	80	75	0–20Hz(in 5-Hzsteps)

with a drumstick by the subject. The order of the experiments was randomized. The subjects were ten males and two females with normal hearing. In the experiment, ten rating words for a bipolar scale such as “bright” or “soft,” etc., and six rating words for a monopolar scale such as “like a wooden drum” or “comfortable,” etc., were used. The bipolar scale consists of nine points: -4 , Extremely; -3 , Very; -2 , “Dark” or “Hard,” etc.; -1 , A little; 0 , Midway; $+1$, A little; $+2$, “Bright” or “Soft,” etc.; $+3$, Very; $+4$, Extremely. The monopolar scale consists of seven points: 1 , Not at all; 2 , Not; 3 , Not too; 4 , A little; 5 , Good; 6 , Very; 7 , Extremely.

C. Results and discussion

Figure 14 shows the results of the timbre evaluation using the SD method for the real and the synthesized sounds. In this paper, only results for the mokugyo with a 37-cm diameter are shown. As shown in Figs. 14(a) and (b), the timbre of the real sound is mainly characterized by the rating words: “smooth,” “warm,” “gracious,” “rich,” “like a wooden drum,” and “comfortable.” The results for the synthesized sound with $\Delta F = 20$ Hz, which is closest to that of the real sound ($\Delta F = 22$ Hz), are similar to those for the real sound, that is, the timbre of the synthesized sound is close to that of the real sound. The six words mentioned above and “distinct” show higher scores. Here, $F_2/F_1 = 1.13$. On the other hand, scores for the words “distinct,” “clear,” “bright,” “cold,” and “unpleasant” are significantly higher for the synthesized sound with $\Delta F = 0$ Hz, and the shape of its polygon is significantly different from the real sound. The polygon of the sound for $\Delta F = 40$ Hz also differs from the others.

Figure 15 shows the relationship between F_2/F_1 and the average scores for the two monopolar rating words: (a) “like a wooden drum” and (b) “comfortable.” The results show that each evaluation score varies according to the value of F_2/F_1 . As shown in Fig. 15(a), the maximum scores for “like a wooden drum” are 3.25, 4.41, 4.42, and 3.29. Furthermore, the rates of change from the minimum score to the maximum one are 0.24, 0.54, 0.65, and 0.15 in order of increasing mokugyo size. Thus, the maximum score and the rate of change for 18- and 37-cm mokugyos are higher than those for 9- and 90-cm mokugyos. The values of F_2/F_1 for the maximum scores are 1.16, 1.08, 1.13, and 1.17. These values are close to the slope (1.15) of the regression line described in Fig. 3. The evaluation score of the real sound of the mokugyo with a 37-cm diameter is 4.25, whereas that of the synthesized sound is 4.42. As shown in Fig. 15(b), the

FIG. 14. Timbre evaluation results based on the SD method for a 37-cm mokugyo. (a) Results for a bipolar scale. (b) Results for a monopolar scale.

maximum scores for “comfortable” are 3.38, 4.27, 4.08, and 3.64 in order of increasing mokugyo size. The rates of change from minimum score to maximum one are 0.08, 0.40, 0.44, and 0.09 in order of increasing mokugyo size. Thus, the maximum score and the rate of change for 18- and 37-cm mokugyos are higher than those for 9- and 90-cm mokugyos. The values of F_2/F_1 for the maximum scores are 1.16, 1.08, 1.13, and 1.27. These values are also close to the slope 1.15. These results support our hypothesis that F_1 and F_2 are the most important factors affecting the timbre of a mokugyo. Also, the simulated sound based on the proposed physical model using a DSP board is effective.

VI. CONCLUSIONS

A traditional Japanese instrument, the mokugyo, which is made depending only on an artisan’s intuition, is investi-

FIG. 15. Relationship between the evaluation score and F_2/F_1 : (a) “like a wooden drum” and (b) “comfortable.”

gated experimentally, theoretically, and psychoacoustically from an acoustic engineering standpoint. First, the physical characteristics of the mokugyo and the drumstick were experimentally measured and analyzed, and the following results were obtained:

- The sound of the mokugyo involves two close spectral peaks, F_1 and F_2 , and F_2/F_1 was approximately 1.15.
- The vibration of the driving point of the body shows a beat whose period is equal to the radiated sound wave.
- The duration of the impact force of the drumstick varies from 1 to 6 ms according to the material wrapped around the tip.
- The directivity of the F_1 and F_2 components is omnidirectional.
- The vibration mode of the F_1 and F_2 components is a point sound source.

Second, a physical model of the mokugyo was proposed. Because this model involves three variables which are difficult to measure, these variables are estimated using the real sound of the mokugyo. The proposed model was evaluated using a real mokugyo in the final tuning process. The results

showed that the model can estimate the difference between resonance frequencies before and after chiseling from the mass of wood chips from three areas: “innermost,” “side port,” and “front.”

Finally, the effects of F_1 and F_2 on the timbre of the mokugyo were investigated psychoacoustically using the semantic differential method. The results showed that when F_2/F_1 is approximately 1.15, the evaluation scores for the rating word, “like a wooden drum” or “comfortable,” showed higher scores.

It can be said that a mokugyo whose timbre is evaluated as a favorable sound can be made by controlling the physical characteristics corresponding to the timbre using the proposed model.

Beating frequency and amplitude modulation of the piano tone due to coupling of tones

Bo Cartling^{a)}

Department of Physics, Royal Institute of Technology, SE-106 91 Stockholm, Sweden

(Received 2 June 2004; revised 28 December 2004; accepted 3 January 2005)

The influence on a piano tone from weak coexcitation of damped adjacent tones due to coupling via the bridge is studied. The frequency and amplitude modulation of the sound resulting from coexcitation of one strong and one or two weak tones is analyzed. One weak tone causes frequency and amplitude modulation of the sound, and two weak tones produce beating frequency and amplitude modulation, where the beatings of the two modulations are of opposite phase. By digital recording of the sound of piano tones, the appearance of these phenomena is verified. The audibility of the observed frequency and amplitude modulation is discussed in terms of previously determined detection thresholds. The beating character of both frequency and amplitude modulations, however, distinguishes the phenomena from those previously studied and prompts further psychoacoustic investigations. It is shown that detuning of unison strings may significantly increase the frequency deviation of the frequency modulation in conjunction with affected amplitude modulation. The modulatory effects of coupling to adjacent tones therefore may possibly be utilized in the tuning process. A coupling of tones analogous to the situation in a piano may arise in other stringed musical instruments transferring string vibrations to a soundboard via a bridge. © 2005 Acoustical Society of America. I. INTRODUCTION

Several characteristics of the piano tone have been identified since the scientific study of the acoustics of the piano was initiated by von Helmholtz;¹ see Refs. 2–6 for reviews. The hammer being the distinguishing feature of the piano in relation to its predecessor, the harpsichord, the interaction between the hammer and the string received attention early¹ and has remained an active research area since.^{7–17} This interaction influences, e.g., the spectral and attack characteristics of piano tones. By designing a chromatic stroboscope,¹⁸ Railsback was able to determine the stretching of the equal-tempered scale, sharpening the treble and flattening the bass, consistently practiced by expert aural tuners.^{19,20} The physical rationale behind this was then established to be the inharmonicity of the string vibrations due to the stiffness of strings.^{21,22} The early and late phase of the decay of piano tones, named “prompt sound” and “aftersound,” respectively, were distinguished by Martin.²³ It was observed that expert aural tuners slightly detuned the strings of unisons.^{24,25} A seminal study of the physics of coupled strings by Weinreich^{26–28} revealed several important mechanisms. The prompt sound was ascribed to string vibrations of vertical polarization (in the configuration of a grand piano) with rapid energy transfer to the soundboard via the bridge, in particular symmetric motion of unison strings. The aftersound comes either from antisymmetric motion of unison strings, or from string vibrations of horizontal polarization only weakly coupled to the soundboard and feeding their energy back to the vertical mode of vibration. The aftersound can be affected by slight detunings of unison strings. As

regards coupling of unison strings via the bridge, Weinreich demonstrated that, for plane-polarized motion of two strings, a resistive coupling brings frequencies of the resulting normal modes closer together, whereas a reactive component of the coupling prevents a frequency crossing under adiabatic changes of system parameters. The degree of excitation of the different normal modes is determined by the initial conditions at the strike of the strings by the hammer. Weinreich also suggested that the objective for detuning the strings of unisons is to obtain a consistent aftersound for all tones by compensating for various irregularities in the sound generation by a piano. A recent study²⁹ considers the effect of localized anisotropy in the reactive part of the bridge admittance for a given partial frequency on so-called “false beating,” and suggests that the detuning of unison strings serves to reduce inheritance of false beats between partials of separate strings.

The bridge in a piano may transfer energy from excited string vibrations of a played tone to unstruck strings of adjacent tones. Such an indirect excitation will be weak compared to a direct blow by the hammer. Unless the sustaining pedal is engaged, the excitation will be further reduced by the dampers. The phase of the indirectly excited string vibrations starts out opposite to that of the directly excited string vibrations. The large frequency difference between the directly excited strings and the adjacent strings (5.9% for a semitone step), as compared with those of slightly detuned unison strings, makes the frequencies of the string vibrations less affected by the coupling. Nevertheless, the sound of a piano tone may be influenced by weak coexcitation of adjacent tones, and this is the subject of the present work. Already von Helmholtz¹ analyzed the amplitude variation when two sinusoids of different amplitude are superimposed

^{a)}Electronic mail: boc@kth.se

to produce beats, as well as the accompanying frequency modulation, as recently reviewed by Hartmann.³⁰

In this study, two cases of coexcited tones are first analyzed theoretically. In order to reach a high resolution in time, the analysis is based on the definition of frequency as the inverse of the time interval between successive zero crossings of the signal with the same change of sign. The frequency and amplitude modulation of the sound resulting from a strongly excited tone influenced by a weakly excited tone is first studied. Coexcitation of one strong tone and two weak tones is then shown to produce beating frequency and amplitude modulation of the resulting sound. By digital recording of piano tones, the appearance of these phenomena is verified.

II. COUPLING OF ADJACENT TONES

A. Coexcitation of one strong and one weak tone

Consider a coupling of two tones, such that a strong excitation of one tone causes a weak coexcitation of the other tone, initially at a phase opposite to that of the strongly excited tone. The two frequencies are assumed sufficiently far apart to remain nearly unaffected by the coupling. This situation may arise in a piano where a played tone may weakly coexcite a damped adjacent tone via the bridge. The resulting sound is described by

$$A(t) = \cos(\omega_0 t) + a \cos(\omega_1 t + \pi), \quad (1)$$

where ω_0 and ω_1 are the fundamental angular frequencies of the strong and weak tone, respectively. In a piano, the value of a is determined by both the weak excitation and the damping of the weak tone, making $a \ll 1$. Whereas decay rates of piano tones vary across the scale,²³ adjacent tones will have similar decay rates. Since these rates are much slower than that of the frequency and amplitude modulation to be analyzed here, the decay characteristics of the tones are not included. The implications of a time dependence of the relative amplitude a of the weak tone due to its damping will be discussed in Sec. III A. The frequency of the resulting sound $A(t)$ can be defined as the inverse of the time interval between successive zero crossings with the same change of sign. To determine this frequency, $A(t)$ is rewritten as

$$A(t) = \text{Re}(B(t)), \quad \text{where } B(t) = e^{i\omega_0 t} + a e^{i(\omega_1 t + \pi)}. \quad (2)$$

The summation of the two terms of $B(t)$ in a complex plane is illustrated in Fig. 1. A zero crossing of $A(t)$, from positive to negative sign, occurs at the positive imaginary axis. The presence of the weak tone of angular frequency ω_1 implies that successive zero crossings will occur at times deviating from those determined by only the strong tone of angular frequency ω_0 . Such a deviation is denoted by δt , and since $a \ll 1$, its magnitude satisfies $|\delta t| \ll 2\pi/\omega_0$, which will be utilized throughout the analysis below. The sign of δt depends on the relative phase of the two terms of $B(t)$, which is given by $\Delta\omega_0 t + \pi$, where $\Delta\omega_0 = \omega_1 - \omega_0$, as seen in Fig. 1. The fluctuations between advanced and retarded zero crossings, relative to the ones determined by the strong tone alone, thus give rise to a frequency modulation of the resulting sound $A(t)$ at an angular modulation frequency $|\Delta\omega_0|$.

FIG. 1. An illustration of the superposition of a strong tone (vector of magnitude 1) at angular frequency ω_0 and a weak tone (vector of magnitude a , where $a \ll 1$) at an angular frequency $\Delta\omega_0$ from ω_0 , as described in a complex plane by Eq. (2). The depicted situation corresponds to a zero crossing of the resulting sound at a time δt in advance of a zero crossing of the strong tone alone. Further details are given in Sec. II A.

From Fig. 1, the following relation is obtained:

$$\frac{a}{\sin(\omega_0 \delta t)} = \frac{1}{\sin(\Delta\omega_0 t + \pi - \omega_0 \delta t)}, \quad (3)$$

which yields

$$\delta t = -\frac{1}{\omega_0} \text{atan} \left(\frac{\sin(\Delta\omega_0 t)}{\frac{1}{a} - \cos(\Delta\omega_0 t)} \right). \quad (4)$$

For $a \ll 1$, a simplified expression can be obtained as

$$\delta t \approx -\frac{1}{\omega_0} \text{atan}(a \sin(\Delta\omega_0 t)) \approx -\frac{a}{\omega_0} \sin(\Delta\omega_0 t). \quad (5)$$

To determine the time interval between two successive zero crossings, the following quantity is also defined:

$$\delta t' = -\frac{a}{\omega_0} \sin \left(\Delta\omega_0 \left(t + \frac{2\pi}{\omega_0} \right) \right). \quad (6)$$

The frequency of the resulting sound $A(t)$ can then be obtained as

$$\begin{aligned} \nu(t) &= \frac{1}{\frac{2\pi}{\omega_0} - (\delta t' - \delta t)} \\ &= \frac{1}{\frac{2\pi}{\omega_0} + \frac{2a}{\omega_0} \sin \left(\frac{\Delta\omega_0}{\omega_0} \pi \right) \cos \left(\Delta\omega_0 t + \frac{\Delta\omega_0}{\omega_0} \pi \right)}. \end{aligned} \quad (7)$$

This expression displays a periodic frequency modulation at angular frequency $|\Delta\omega_0|$ and shows that the modulation is not precisely sinusoidal. The expression interpolates between the zero crossings, that on average are separated by $2\pi/\omega_0$ s, corresponding to the crossing of lines through the origin of the complex plane at phase angles other than that of the imaginary axis. The frequency deviation (“amplitude”) $\Delta\nu$ of the frequency modulation, defined as the maximal differ-

FIG. 2. Calculated frequency modulation of the fundamental of the C_4 tone due to weak coexcitation of the B_3 tone -30 dB relative to C_4 . The underlying expressions are derived in Sec. II A.

ence between the instantaneous frequency and the center frequency ν_0 , is obtained as

$$\Delta\nu = \frac{a\omega_0}{2\pi^2} \sin\left(\frac{|\Delta\omega_{01}|}{\omega_0}\pi\right). \quad (8)$$

An example is shown in Fig. 2, in which the strong tone is C_4 at $\omega_0/2\pi = 261.63$ Hz and the weak tone is B_3 at $\omega_1/2\pi = 246.94$ Hz. The value $a = 0.03$, corresponding to excitation of B_3 -30 dB relative to C_4 , is selected to be within the range of observed values, as discussed in Sec. III. The frequency modulation is at frequency $|\Delta\omega_{01}|/2\pi = 14.69$ Hz, and its frequency deviation is $\Delta\nu = 0.44$ Hz.

As evident, e.g., from Fig. 1, the resulting sound $A(t)$ will also be subject to an amplitude modulation with the same temporal characteristics as the frequency modulation, and can be expressed as

$$A(t) = \text{Re}(B(t)) \approx |B(t)| \cos(\omega_0 t - a \sin(\Delta\omega_{01} t)). \quad (9)$$

The amplitude modulation is described by the envelope function $|B(t)|$ of the faster temporal variation and can, for $a \ll 1$, be obtained as

$$|B(t)| \approx 1 - a \cos(\Delta\omega_{01} t). \quad (10)$$

The angular frequency of the amplitude modulation is thus given by $\Delta\omega_{01}$, and the maximal deviation of the amplitude from its average is equal to a . The ratio of the maximal amplitude deviation to the average amplitude is termed the modulation index of amplitude modulation. It is here given by a since the strong-signal amplitude is normalized to 1. The frequency and amplitude modulations are of same phase for $\Delta\omega_{01} > 0$ and of opposite phase for $\Delta\omega_{01} < 0$.

B. Coexcitation of one strong and two weak tones

Next, consider the coexcitation of one strong tone at angular frequency ω_0 and two weak tones at angular frequencies $\omega_1 < \omega_0$ and $\omega_2 > \omega_0$, under the same conditions as specified in Sec. II A. The resulting sound is described by

$$C(t) = \cos(\omega_0 t) + a \cos(\omega_1 t + \pi) + b \cos(\omega_2 t + \pi), \quad (11)$$

where $a, b \ll 1$. The two angular frequency differences are denoted $\Delta\omega_{01} = \omega_1 - \omega_0$ and $\Delta\omega_{02} = \omega_2 - \omega_0$. Based on the analysis in Sec. II A, the following quantities are defined:

$$\delta t_{01} = -\frac{a}{\omega_0} \sin(\Delta\omega_{01} t), \quad (12)$$

$$\delta t_{02} = -\frac{b}{\omega_0} \sin(\Delta\omega_{02} t), \quad (13)$$

$$\delta t'_{01} = -\frac{a}{\omega_0} \sin\left(\Delta\omega_{01}\left(t + \frac{2\pi}{\omega_0}\right)\right), \quad (14)$$

$$\delta t'_{02} = -\frac{b}{\omega_0} \sin\left(\Delta\omega_{02}\left(t + \frac{2\pi}{\omega_0}\right)\right). \quad (15)$$

The frequency of the resulting sound $C(t)$ can then be obtained as

$$\nu(t) = \frac{1}{\frac{2\pi}{\omega_0} - (\delta t'_{01} - \delta t_{01} + \delta t'_{02} - \delta t_{02})}. \quad (16)$$

For simplicity, consider $b = a$. It then follows that

$$\begin{aligned} \delta t_{01} + \delta t_{02} &= \frac{2a}{\omega_0} \cos\left(\frac{|\Delta\omega_{01}| + |\Delta\omega_{02}|}{2} t\right) \\ &\quad \times \sin\left(\frac{|\Delta\omega_{01}| - |\Delta\omega_{02}|}{2} t\right), \end{aligned} \quad (17)$$

and

$$\begin{aligned} \delta t'_{01} + \delta t'_{02} &= \frac{2a}{\omega_0} \cos\left(\frac{|\Delta\omega_{01}| + |\Delta\omega_{02}|}{2} \left(t + \frac{2\pi}{\omega_0}\right)\right) \\ &\quad \times \sin\left(\frac{|\Delta\omega_{01}| - |\Delta\omega_{02}|}{2} \left(t + \frac{2\pi}{\omega_0}\right)\right). \end{aligned} \quad (18)$$

Both Eqs. (17) and (18) include a faster variation at an angular frequency $(|\Delta\omega_{01}| + |\Delta\omega_{02}|)/2$, and a slower variation at an angular frequency $||\Delta\omega_{01}| - |\Delta\omega_{02}||/2$. The frequency of the resulting sound $C(t)$ is consequently periodically modulated at the angular frequency $(|\Delta\omega_{01}| + |\Delta\omega_{02}|)/2$, i.e., the average of the two angular frequency differences. The frequency change of the frequency modulation varies at an angular frequency $||\Delta\omega_{01}| - |\Delta\omega_{02}||$, i.e., the difference between the two angular frequency differences. A phenomenon resembling “beating” (which normally refers to the amplitude modulation caused by partials close in frequency) thus appears in the frequency modulation in this case. For a tone in the equal-tempered scale, the angular beat frequency is 0.33% of ω_0 , assuming that the weak tones are adjacent semitones. An example is shown in Fig. 3, in which the strong tone is C_4 at $\omega_0/2\pi = 261.63$ Hz and one weak tone is B_3 at $\omega_1/2\pi = 246.94$ Hz and the other weak tone is $C_4^\#$ at $\omega_2/2\pi = 277.18$ Hz. For the same reason as in Sec. II A, the values $a = b = 0.03$ are selected, corresponding to excitation of both B_3 and $C_4^\#$ -30 dB relative to C_4 . The frequency differences are given by $|\Delta\omega_{01}|/2\pi = 14.69$ Hz and $|\Delta\omega_{02}|/2\pi = 15.55$ Hz, so that the frequency modulation is at

FIG. 3. Calculated frequency modulation of the fundamental of the C_4 tone due to weak coexcitation of the B_3 and $C_4^\#$ tones -30 dB relative to C_4 . The underlying expressions are derived in Sec. II B.

15.12 Hz and the beat frequency of the frequency modulation is 0.86 Hz. The frequency deviation approximately doubles (for $|\Delta\omega_{01}| \approx |\Delta\omega_{02}|$) compared with the case in Sec. II A.

As for the case of one strong and one weak tone described in Sec. II A, there is also an amplitude modulation of the resulting sound $C(t)$. Denoting the complex quantity corresponding to $C(t)$ by $D(t)$ [in analogy with Eq. (2)] and considering $b = a$, $C(t)$ can be expressed as

$$C(t) = \text{Re}(D(t)) = |D(t)| \cos(\omega_0 t - a \sin(\Delta\omega_{01} t) - a \sin(\Delta\omega_{02} t)). \quad (19)$$

The envelope function $|D(t)|$ describing the amplitude modulation can, for $a \ll 1$, be obtained as

$$|D(t)| \approx 1 - 2a \cos\left(\frac{|\Delta\omega_{01}| + |\Delta\omega_{02}|}{2} t\right) \times \cos\left(\frac{|\Delta\omega_{01}| - |\Delta\omega_{02}|}{2} t\right). \quad (20)$$

The amplitude modulation thus displays a faster variation at an angular frequency $(|\Delta\omega_{01}| + |\Delta\omega_{02}|)/2$ and a slower variation at an angular frequency $||\Delta\omega_{01}| - |\Delta\omega_{02}||/2$, the same two frequencies characterizing the frequency modulation. As for the frequency modulation, the slower variation can be referred to as a beating of the amplitude modulation at an angular frequency $||\Delta\omega_{01}| - |\Delta\omega_{02}||$. The modulation index of the amplitude modulation is given by $2a$, i.e., twice the value for the case in Sec. II A. Defining the relative phase shift between the frequency and amplitude modulations to be positive when the frequency modulation precedes the amplitude modulation, then the relative phaseshift switches from $+\pi/2$ to $-\pi/2$ at the maxima of the frequency-beat envelope and vice versa at the minima. The beatings of the two modulations are of opposite phase. An example of the amplitude modulation is shown in Fig. 4 for the same case as defined for Fig. 3. To fully describe the temporal development of piano tones, their decay characteristics should also be included.

FIG. 4. Calculated amplitude modulation for the same case as in Fig. 3. The underlying expressions are derived in Sec. II B. Decay characteristics of the tones are not included.

III. PIANO TONES

A. Single-string tones

The situations treated in Sec. II, giving rise to frequency and amplitude modulation or beating frequency and amplitude modulation, may apply to piano tones. In the piano, tones other than the played ones are intended to be damped, unless the sustaining pedal is engaged. However, the frequency and amplitude modulation of the resulting sound is quite sensitive to the influence of even weakly excited tones, as demonstrated in Sec. II. A coupling of adjacent tones via the bridge in a piano can generate weakly excited tones along with a strongly excited tone. To investigate this possibility, measurements were performed by digital recording of the sound from an upright piano (Yamaha model M1E) via a microphone. The sampling rate of the recording was 48 kHz and the resolution 16 bits. As mentioned in the Introduction, it is well known that the vibration of a piano string is not perfectly periodic due to inharmonicity, which makes the frequencies of overtones slightly different from precise multiples of the fundamental frequency. To remove contributions to nonperiodicity from overtones, the recorded signal was bandpass filtered around the fundamental frequency of the played tone. This was accomplished by a fast Fourier transform (FFT) followed by an inverse FFT after retaining Fourier components across the desired range. To improve the spectral estimate, a Hann window was applied to the recorded signal before the FFT.³¹ The bandpass filter was realized by a square window of full width $0.2\nu_0$ around ν_0 , where ν_0 denotes the fundamental frequency of the played tone. This width allows the fundamentals of adjacent tones, a semitone step down or up, to contribute while suppressing overtones of the played tone as well as fundamentals of next-nearest semitones. The processed signal was then frequency analyzed in terms of the inverse time interval between successive zero crossings with the same change of sign. The frequency resolution is improved by linear interpolation of the zero crossings and can be estimated at 0.1 Hz for a C_4 tone at about 262 Hz.

FIG. 5. Observed frequency modulation of the fundamental of the C_4 tone recorded from an upright piano. Each of the C_4 , B_3 , and C_4^\sharp tones is generated by a single string. The recorded sound is bandpass filtered around the fundamental of the C_4 tone, and the frequency is determined from successive zero crossings of the signal with the same change of sign. The time interval is 0.1 to 1.9 s from excitation. Further details of the recording and analysis are given in Sec. III A.

Figure 5 shows the result obtained by means of this analysis of the recorded sound of a C_4 tone. The adjacent tones, a semitone step down and up, are B_3 and C_4^\sharp , respectively. In this measurement, two of the three strings of each unison are damped, so that each tone is generated by a single string. To compensate for inharmonicity (“stretched octaves”), as described in the Introduction, the piano was tuned so that the equal-tempered frequencies of these three tones were reduced by 1 cent, i.e., C_4 at $\omega_0/2\pi = 261.47$ Hz, B_3 at $\omega_1/2\pi = 246.80$ Hz, and C_4^\sharp at $\omega_2/2\pi = 277.02$ Hz. The tuning was accomplished by means of a 1-s digital recording of the sound followed by a calculation of a 2001-point spectrum across a frequency interval of 20 Hz around the fundamental frequency by means of a chirp z-transform.³¹ The resolution of the spectrum is thus 0.01 Hz, so that the tuning accuracy is limited by the precision by which the tuning pins can be set, about ± 0.05 Hz. The two frequency differences are $|\Delta\omega_{01}|/2\pi = 14.67$ Hz and $|\Delta\omega_{02}|/2\pi = 15.55$ Hz, so that their average is 15.11 Hz and their difference 0.88 Hz. The figure displays a time interval from 0.1 to 1.9 s of a 2-s recording excluding the initial and final 0.1 s where the signal is strongly reduced by the Hann window applied prior to the FFT, as described above. During the 2-s period, the sound is of the prompt type before the aftersound appears. For a single string, it is vibrations of horizontal polarization that contribute to the aftersound. Figure 5 demonstrates a beating frequency modulation in fair agreement with the predictions from the analysis in Sec. II B of one strongly excited tone and two weakly excited tones. The observed maximal peak-to-peak frequency swing of about 3 Hz corresponds to a frequency deviation of about 1.5 Hz and a value of the a amplitude of about 0.05. (Recall that Figs. 3 and 4 refer to $a = 0.03$.) A time-dependent frequency deviation can be defined as the maximal frequency change from the center frequency ν_0 determined over a modulation period. A decrease of frequency deviation with time may derive from the damp-

FIG. 6. Observed amplitude modulation of the fundamental of the C_4 tone for the same sound, and over the same time interval, as in Fig. 5. The recorded sound is bandpass filtered around the fundamental of the C_4 tone. Further details of the recording and analysis are given in Sec. III A.

ing of the weakly excited tones, i.e., the amplitude a may be a decreasing function of time. To display the amplitude modulation of the sound, the recorded signal was bandpass filtered as above but without the application of a Hann window prior to the FFT. The resulting signal is shown in Fig. 6 over the same time interval as in Fig. 5. Also the amplitude modulation is in fair agreement with the predictions in Sec. II B. Possible sources of deviations from the calculated behavior include a difference of the weak amplitudes a and b in Eq. (11). If one of these amplitudes dominates over the other, then the situation described in Sec. II A is more applicable. Additional time dependence of a and b , apart from their decay due to damping, may also interfere with the beating patterns. Noise affecting amplitude relationships and phase relationships between the component signals will cause irregularities in the frequency and amplitude modulation, in particular the beating patterns. Since the beating frequency is a small difference between larger frequency differences, a small relative change of these larger frequency differences implies a large relative influence on the beating frequency. The estimated amplitude value of the weakly excited adjacent tones may seem large. The excitation of the adjacent tones is, however, presumably linked to the total sound pressure of the played tone. Relating this excitation to the excitation of the fundamental of the played tone results in a larger ratio than that between the total sound pressures of adjacent and played tones.

An influence of the damping of the weak tones on the frequency deviation of the frequency modulation was also confirmed. The frequency deviation is reduced if further damping is imposed on the strings of the adjacent tones, and removal of damping increases the frequency deviation. Figure 7 displays the frequency modulation of the C_4 fundamental when the dampers are lifted off the strings of the adjacent B_3 and C_4^\sharp tones. The maximal peak-to-peak frequency swing increases to about 8 Hz.

One more example is shown in Fig. 8 which refers to the A_4 tone, with adjacent tones one semitone step away G_4^\sharp and

FIG. 7. Same as Fig. 5, but with the dampers lifted off the strings of the B_3 and $C_4^\#$ tones.

$A_4^\#$. As in the previous case, the measurement is performed with each tone generated by a single string. In this range, the piano is tuned according to equal temperament, so that A_4 is at $\omega_0/2\pi = 440.00$ Hz, $G_4^\#$ at $\omega_1/2\pi = 415.31$ Hz, and $A_4^\#$ at $\omega_2/2\pi = 466.16$ Hz. This yields the two frequency differences $|\Delta\omega_{01}|/2\pi = 24.69$ Hz and $|\Delta\omega_{02}|/2\pi = 26.16$ Hz, with an average 25.43 Hz and a difference 1.47 Hz. To ensure the prompt type of sound, the recording is restricted to 1 s. The displayed time interval omits the initial and final 0.1 s, for the same reason as in the previous example. The agreement with predictions is again fair. The observed maximal peak-to-peak frequency swing of about 5 Hz corresponds to a value of the a amplitude of about 0.05. The tones F_3 , F_4 , and C_5 were also measured to study average frequency differences of approximately 10, 20, and 30 Hz, in addition to the approximately 15 and 25 Hz for C_4 and A_4 , and an analogous degree of agreement with predictions was observed. The results obtained therefore indicate that weak co-

FIG. 8. Same as Fig. 5, but for the A_4 tone and the time interval 0.1 to 0.9 s from excitation. Each of the A_4 , $G_4^\#$, and $A_4^\#$ tones is generated by a single string.

FIG. 9. Simulated frequency modulation of the fundamental of the C_4 tone due to weak coexcitation of the B_3 and $C_4^\#$ tones -30 dB relative to C_4 . Each of the tones is generated by three strings detuned -1 , 0 , and 1 cent from the respective fundamental frequency. Further details of the simulation are given in Sec. III B.

excitation of adjacent tones can contribute beating frequency and amplitude modulation to the piano tone.

B. Triple-string tones

All of the tones studied are generated by three unison strings, so that a slight detuning of these, as discussed in the Introduction, may produce up to 18, rather than two, frequency differences between the played tone and adjacent tones. Only nine of these frequency differences are independent, corresponding to the number of strings. To determine the effects of such a multitude of frequency differences on the frequency and amplitude modulation, computer simulations as well as measurements were performed. Figure 9 shows the frequency modulation of the fundamental of the C_4 tone as obtained by a simulation in which each of the three tones involved is generated by the three strings of a unison disregarding coupling effects within a unison. Fundamental frequencies, and the amplitudes of the weak tones, are as described in Sec. II B for Fig. 3. Within each unison, the three strings are detuned -1 , 0 , and 1 cent, respectively, from the fundamental frequency. Such a detuning pattern within the unisons does not cause a significant difference of the resulting frequency modulation from what is obtained for single-string tones, as seen by a comparison of Figs. 3 and 9.

Another detuning pattern of the unisons can, however, produce rather different frequency modulation. Figure 10 shows the result of a simulation of the C_4 tone, where the three strings of the C_4 unison are detuned -1 , 0 , and 2 cents from the fundamental frequency and the strings of the other two unisons involved are detuned -1 , 0 , and 1 cent from the respective fundamental frequency. With this type of detuning within the unisons, the amplitude modulation will be more affected as shown in Fig. 11 for the same case. For detuning patterns that produce zero transitions of the amplitude, rather large frequency deviations may occur at these. However, they will probably not be perceived due to the low amplitude. An example of observations near the latter situation is

FIG. 10. Same as Fig. 9, but with the three strings of C_4 detuned -1 , 0 , and 2 cents from the fundamental frequency. The three strings of each of the B_3 and $C_4^\#$ tones are detuned -1 , 0 , and 1 cent from the respective fundamental frequency.

shown in Figs. 12 and 13, displaying frequency and amplitude modulation, respectively. Just after the recording of this signal, the nine fundamental frequencies involved were determined by the procedure described in Sec. III A for tuning and found to be 261.16 , 261.48 , and 261.51 Hz for the three unison strings of C_4 , 246.63 , 246.78 , and 246.92 Hz for B_3 and 276.88 , 277.09 , and 277.39 Hz for $C_4^\#$. As described in the Introduction, the frequencies of the normal modes that result from bridge coupling of strings in a unison may be different from the values to which the strings are tuned when sounding separately, and the excitation of the normal modes is determined by the initial conditions at the strike by the hammer.^{26–28}

IV. DISCUSSION

Frequency and amplitude modulations are phenomena commonly associated with sinusoidal modulation,³⁰ which produces Fourier components at frequencies deviating from the carrier frequency by positive and negative multiples of

FIG. 11. Simulated amplitude modulation for the same case as in Fig. 10. Decay characteristics of the tones are not included.

FIG. 12. Same as Fig. 5, but with each tone generated by three strings. The figure illustrates an example of detuning pattern generating rather large frequency deviations. The particular frequency values, to which the strings are tuned when sounding separately, are given in Sec. III B.

the modulation frequency (frequency modulation) or plus and minus the modulation frequency (amplitude modulation). In the cases treated in Sec. II, the starting points are rather the spectral decompositions of a signal and the frequency and amplitude modulations are derived. In Sec. II A, a signal that is a superposition of one strong and one weak signal of different frequencies is considered. The modulation frequency of the frequency and amplitude modulations is then given by the frequency difference between the two signals. The modulation index of the amplitude modulation and the frequency deviation of the frequency modulation are determined by the relative amplitudes of the weak and strong signals. The two modulations are of same phase for a weak-signal frequency above the strong-signal frequency, and of opposite phase for the reverse situation. The case of one strong signal and two weak signals is shown in Sec. II B to result in beating frequency and amplitude modulations. The modulation frequency is the average of the two frequency differences between the strong signal and the two weak sig-

FIG. 13. Same as Fig. 6, but for the same sound as in Fig. 12.

nals. It is the difference between these two frequency differences that gives rise to the beating character of the frequency and amplitude modulations and that determines the beat frequency. For weak signals of equal amplitude, the modulation index of the amplitude modulation doubles and the frequency deviation of the frequency modulation approximately doubles, as compared with the case of one strong and one weak signal. The frequency and amplitude modulations have a relative phase shift near $\pm \pi/2$ in between the extrema of the beat envelopes. The relative phase shift between the beatings of the two modulations is π .

By digital recording of the sound of piano tones, beating frequency and amplitude modulations are observed in fair agreement with the derived influence of weakly excited adjacent tones one semitone step down and up, as described in Sec. III. Of immediate interest then is to what extent these phenomena are audible. Detection thresholds for both amplitude and frequency modulations have long been examined.^{32–38} For sinusoidal amplitude modulation, Zwicker^{33–35} studied the threshold value of the modulation index as a function of selected values of carrier frequency, modulation frequency, and sound-pressure level. For a carrier frequency of 1 kHz, a modulation frequency of 15 Hz and a sound-pressure level of 80 dB, the threshold modulation index is about 3%. For the beating amplitude modulation, treated in Sec. IIB, the maximal modulation index is given by $2a$, which is about 10% with the approximate value of a derived from observations described in Sec. IIIA and illustrated in Fig. 5. With respect to sinusoidal frequency modulation, Zwicker^{33–35} reported threshold values of the frequency deviation, again as a function of selected values of carrier frequency, modulation frequency, and sound-pressure level. For a carrier frequency of 250 Hz, a modulation frequency of 4 Hz and a sound-pressure level of 80 dB, the threshold frequency deviation is about 1.6 Hz, i.e., the threshold peak-to-peak frequency swing about 3.2 Hz. This is in fair agreement with a more recent study,³⁶ which also provides individual values for four subjects. For a carrier frequency of 250 Hz, a modulation frequency of 16 Hz and a sound-pressure level of 70 dB, the lowest detectable peak-to-peak frequency swing reported is 2.6 Hz. In frequency discrimination of pulsed pure tones, the detection thresholds are generally lower, about 1 Hz in the frequency range 200–400 Hz at a sound-pressure level of 40 dB.³⁷ From the observations described in Sec. IIIA and illustrated in Fig. 5, the maximal peak-to-peak frequency swing is about 3 Hz. It therefore appears that the audibility criterion is better fulfilled for the amplitude modulation than for the frequency modulation.

It has been observed that mixed amplitude and frequency modulation may be detected, although either of the modulations are below threshold.³⁸ The precise conditions of the two types of modulation are, however, important. In the case studied in the present work, the beating character of both frequency and amplitude modulations, with alternately occurring maxima of the beatings and an intricate phase relationship between the modulations, distinguishes the situation from those previously studied. The modulation and beat frequencies of frequency and amplitude modulation

also vary across the piano scale. The modulatory effects may also vary between different pianos due to different degrees of damping. Whereas the analysis in the present work refers to the fundamentals of tones, the sound of a tone derives from its full spectrum. The spectral composition of a piano tone is influenced by how hard strings are struck and the condition of the hammer.^{7–10,12,13,16,17} For all these reasons, further psychoacoustic investigations will be helpful in determining the possible contribution of the beating frequency and amplitude modulation deriving from coupling of tones to the quality of the piano tone.

The beating frequency and amplitude modulations both exceed the reported thresholds when the damping of the adjacent tones is released by means of the sustaining pedal, as can be concluded from Fig. 7 which refers to a situation with dampers lifted off the strings of the adjacent tones. The modulations can therefore be expected to contribute to the clearly audible difference in tone quality with and without the sustaining pedal being engaged, a difference which may also have other components. The dependence of the frequency and amplitude modulations on the detuning of strings in a unison may possibly serve an aural tuner as a complement to the principal tuning out the beats in obtaining an optimal tone quality. As the example in Fig. 10 demonstrates, even small changes of the detuning of unison strings may have large effects on the frequency modulation and cause large frequency deviations. This may also partly explain the observed preference for limited detunings of unison strings.²⁵ The frequency deviations observed in the present work are also large in comparison with the accuracy that an expert aural tuner can achieve. The latter accuracy has been estimated at ± 2 cents in the middle range of the piano scale,²⁴ which for C₄ is only about ± 0.3 Hz, to be compared with the observed maximal peak-to-peak frequency swing of about 3 Hz (Fig. 5). An even higher accuracy than ± 2 cents is actually required and achieved in tuning, e.g., equal-tempered fifths, for which the narrowing relative to beatless fifths in itself is approximately 2 cents. For electronically assisted tuning, high-resolution frequency meters are often based on the detection of successive zero crossings of the signal. An understanding of the phenomena discussed in the present work may therefore be of interest also in that context. The modulatory phenomena observed in a piano may occur in other stringed musical instruments transferring string vibrations to a soundboard via a bridge.

Generation of longitudinal vibrations in piano strings: From physics to sound synthesis^{a)}

Balázs Bank^{b)} and László Sujbert

Department of Measurement and Information Systems, Budapest University of Technology and Economics, 1521 Budapest, Hungary

(Received 14 December 2004; revised 18 January 2005; accepted 19 January 2005)

Longitudinal vibration of piano strings greatly contributes to the distinctive character of low piano notes. In this paper a simplified modal model is developed, which describes the generation of phantom partials and longitudinal free modes jointly. The model is based on the simplification that the coupling from the transverse vibration to the longitudinal polarization is unidirectional. The modal formulation makes it possible to predict the prominent components of longitudinal vibration as a function of transverse modal frequencies. This provides a qualitative insight into the generation of longitudinal vibration, while the model is still capable of explaining the empirical results of earlier works. The semi-quantitative agreement with measurement results implies that the main source of phantom partials is the transverse to longitudinal coupling, while the string termination and the longitudinal to transverse coupling have only small influence. The results suggest that the longitudinal component of the tone can be treated as a quasi-harmonic spectrum with formantlike peaks at the longitudinal modal frequencies. The model is further simplified and applied for the real-time synthesis of piano sound with convincing sonic results. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1868212]

I. INTRODUCTION

In this paper the generation mechanism of longitudinal vibration in piano strings is investigated. The purpose of this paper is twofold: to explain the experimental results of earlier papers and to provide a guideline for physics-based sound synthesis.

The importance of longitudinal vibration of piano strings was recognized long ago by piano builders. Conklin¹ demonstrated that the pitch relation of the transverse and longitudinal component strongly influences the quality of the tone and described a method to tune these components. Giordano and Korty² found that the amplitude of the longitudinal vibration is a nonlinear function of the amplitude of transverse vibration, confirming the assumption that the longitudinal component is generated by the nonlinearity of the string and not by the “misalignment” of the hammer.

Nakamura and Naganuma³ found a second series of partials in piano sound spectra having one-fourth of inharmonicity compared to the main partial series. They attributed these to the horizontal polarization of the string, but they have actually found the series that later was named “phantom partials” by Conklin. Conklin⁴ pointed out that the phantom partials are generated by nonlinear mixing and their frequencies are the sum or difference of transverse model frequencies. He named “even phantoms” those having double the frequency ($2f_n$), of a transverse mode and “odd

phantoms” those which appear at the sum $f_m + f_n$ or difference $f_m - f_n$ frequencies of two transverse modes. Conklin’s measurements have shown that odd phantoms generally originate from adjacent parents, i.e., can be found at $f_5 + f_6$ rather than at $f_4 + f_7$. Phantom partials have also been found in the spectrum of guitar tones.⁴ In a recent paper about guitar transients, Woodhouse states that the amplitude of the phantom partials seems to be modulated according to the longitudinal modal frequencies.⁵ The present paper gives a theoretical explanation for these experimental results.

In an earlier work⁶ some of the properties of phantom partials and longitudinal modes have been investigated. It was pointed out and it is emphasized here again that longitudinal modes and phantom partials are two different manifestations of the same phenomenon: they are the free and forced response of the same system, respectively. Therefore, in the theoretical treatment of the present paper they are covered jointly. This paper outlines some of the findings of Ref. 6 and provides a more refined theoretical background.

Theoretical works on nonlinear string vibrations that consider longitudinal motion include the papers of Narasimha,⁷ Anand,⁸ Watzky,⁹ and O’Reilly and Holmes.¹⁰ As these papers discuss the nonlinear coupling of the first modes of the two transverse polarizations, the inertial effects of the longitudinal vibration are neglected. This leads to the uniformity of the tension and equals to computing the tension from the relative elongation of the string.⁸ (This is also studied in the Appendix.) The uniform tension approximation (thoroughly discussed by Legge and Fletcher¹¹) often forms the basis for the sound synthesis of nonlinear strings. Papers include tension-modulated string models^{12,13} based on digital waveguides¹⁴ and energy-conserving finite difference schemes.¹⁵ The inertial effects of longitudinal modes have

^{a)}Portions of this work have been presented in “Modeling the longitudinal vibration of piano strings,” Proceedings of the Stockholm Music Acoustics Conference, Stockholm, Sweden, August 2003, and “A piano model including longitudinal string vibrations,” Proceedings of the 7th International Digital Audio Effects Conference, Naples, Italy, October 2004.

been considered in the case of rubberlike strings by Leamy and Gottlieb¹⁶ and by Kurmyshev.¹⁷

However, the results of these earlier papers^{7-11,16,17} cannot be directly applied for the present purposes. This is because the present problem is more complex in the sense that not only the first few but 50 to 100 transverse modes have to be taken into account in the case of a struck piano string. On the other hand, it is simpler in the way that the longitudinal to transverse coupling and the coupling of different transverse modes are not investigated, as the primary interest is on the longitudinal vibration itself. Therefore, in this paper a modal model is developed that computes the spectrum of the longitudinal vibration in the case of arbitrary transverse model frequencies. It turns out that the most important properties of the longitudinal vibration can be explained by this simplified modal approach. The Appendix shows that the uniform tension approximation of earlier papers⁷⁻¹¹ is the special case of the tension computed from the modal model presented here.

The synthesis of the longitudinal components in piano tone is quite a recent topic. In an earlier work⁶ the digital waveguide string model¹⁴ has been extended by an auxiliary digital waveguide for computing the response of the phantom partials and by second-order resonators for modeling the longitudinal free modes. A very efficient method for modeling the phantom partials was proposed by Bensa.¹⁸ The model had a loose connection to physical reality, since in that work spatially uniform tension was assumed. In a recent work¹⁹ a physics-based solution is presented for modeling the longitudinal components jointly (i.e., phantom partials and free modes together), which is able to produce high quality piano sounds. In this model second-order resonators are nonlinearly excited according to the transverse string shape computed by a finite difference model. This paper outlines the above approach and presents an alternative technique having lower computational cost.

The paper is organized as follows: first the differential equations are derived from basic principles in Sec. II. In Sec. III a modal model is presented, which analytically computes the longitudinal vibration under certain assumptions. In Sec. IV the measurements of other authors²⁻⁴ are explained by the results of the proposed model, and some measurement results of the present authors are also given. Section V describes efficient algorithms for the synthesis of piano sound including the longitudinal vibrations. The Appendix relates the uniform tension approximation to the modal model presented in this paper.

II. EQUATIONS FOR ONE PLANE OF VIBRATION

A real piano string is vibrating in two transverse planes, and in the longitudinal direction as well. Principally, piano hammers excite one transverse polarization of the string, while the other two polarizations are gaining energy through coupling. For simplicity, it is assumed in this section that the string is vibrating in one plane, i.e., one transverse and one longitudinal polarization are present. Losses and dispersion are neglected for the time being and they are included later in Sec. III. The differences arising from the incorporation of two transverse polarizations are outlined in Sec. III E. Note

FIG. 1. The string element.

that similar derivations in a different formulation can be found in earlier works, e.g., in the textbook of Morse and Ingard.²⁰ The equations are developed here to make the paper self-explanatory.

When a transverse displacement occurs on the string, the string elongates. This results in a force exciting a longitudinal wave in the string. The longitudinal wave modulates the tension of the string, which influences the transverse vibration.

The element of length dx at equilibrium will have the length ds , as depicted in Fig. 1, which is calculated as follows:

$$ds^2(x,t) \approx [\xi(x+dx,t) - \xi(x,t) + dx]^2 + [y(x+dx,t) - y(x,t)]^2. \quad (1)$$

As dx is infinitesimally small, the differences are substituted by differentials

$$ds = \sqrt{\left(\frac{\partial \xi}{\partial x} + 1\right)^2 dx^2 + \left(\frac{\partial y}{\partial x}\right)^2 dx^2}, \quad (2)$$

where $y = y(x,t)$ and $\xi = \xi(x,t)$ are the transverse and longitudinal displacements of the string with respect to time t and space x . The tension $T = T(x,t)$ of the string (which equals to T_0 at rest) is calculated according to Hooke's law,

$$T = T_0 + ES \left(\frac{ds}{dx} - 1 \right), \quad (3)$$

where E is the Young's modulus and S is the cross-section area of the string. By substituting Eq. (2) into Eq. (3) and neglecting the higher order terms the tension can be approximated as

$$T \approx T_0 + ES \left[\frac{\partial \xi}{\partial x} + \frac{1}{2} \left(\frac{\partial y}{\partial x} \right)^2 \right]. \quad (4)$$

As the segment ds is nearly parallel to the x axis, the longitudinal force on the segment ds can be approximated as the difference of the tension at the sides of the segment

$$F_x \approx \frac{\partial T}{\partial x} dx \approx ES \left[\frac{\partial^2 \xi}{\partial x^2} + \frac{1}{2} \frac{\partial (\partial y / \partial x)^2}{\partial x} \right] dx. \quad (5)$$

Note that the resolution of the force would only introduce a negligible correction term for metal strings (where $T_0 \ll ES$). The force F_x acts on a mass μdx where μ is the mass

per unit length. Accordingly, the longitudinal vibration is approximately described by

$$\mu \frac{\partial^2 \xi}{\partial t^2} = ES \frac{\partial^2 \xi}{\partial x^2} + \frac{1}{2} ES \frac{\partial(\partial y/\partial x)^2}{\partial x}, \quad (6)$$

which is the standard one-dimensional wave equation with an additional force term depending on the transverse vibration. According to Eq. (6), the transverse string motion can only excite the longitudinal vibration if the square of the string slope is significant, i.e., the transverse displacement is relatively large. Note that neglecting the term $\mu(\partial^2 \xi/\partial t^2)$ leads to the uniform tension approximation (see the Appendix).

After similar derivations the wave equation for the transverse motion can be written as

$$\mu \frac{\partial^2 y}{\partial t^2} = T_0 \frac{\partial^2 y}{\partial x^2} + ES \frac{\partial\{(\partial y/\partial x)[\partial \xi/\partial x + \frac{1}{2}(\partial y/\partial x)^2]\}}{\partial x}, \quad (7)$$

which is again a one-dimensional wave equation with an additional force term depending on the product of the transverse slope and the tension variation. Consequently, the longitudinal vibration influences the transverse one if both the transverse and longitudinal displacements are relatively large.

To sum up, both Eqs. (6) and (7) can be considered as standard linear wave equations with additional forcing terms on their right-hand sides. From Eq. (6) it can be concluded that the level of transverse to longitudinal coupling depends on the magnitude of transverse vibration according to a square law. From Eq. (7) it turns out that the amount of longitudinal to transverse coupling is a third-order function of the amplitude of transverse vibration, since ξ is in the order of y^2 [see Eq. (6)].

III. TRANSVERSE TO LONGITUDINAL COUPLING

As the main interest of this paper is to clarify the generation of longitudinal string vibration, a further simplification is made: the longitudinal to transverse coupling is neglected. Moreover, the string termination is assumed to be infinitely rigid. The effects of these assumptions are covered in Sec. III F.

These limitations lead to a model that cannot be in complete quantitative agreement with measurements. On the other hand, its simplicity helps to gain a better understanding of the phenomenon. This simple model is already enough for the qualitative explanation of the measurements of earlier papers,²⁻⁴ as discussed in Sec. IV later. Furthermore, sound synthesis models (see Sec. V) based on these principles produce realistic piano sounds.

A. Excitation force

For the freely vibrating, dispersive, lossy, and rigidly terminated string the transverse displacement for a given position $0 \leq x \leq L$ and time $t \geq 0$ can be written in the following form:²¹

$$y(x, t) = \sum_{n=1}^{\infty} A_n \cos(2\pi f_n t + \varphi_n) e^{-t/\tau_n} \sin\left(\frac{n\pi x}{L}\right), \quad (8)$$

where f_n is the frequency, τ_n is the decay time, A_n is the initial amplitude, and φ_n is the initial phase of the transverse mode n , and L refers to the length of string. This form is of particular interest since the motion of the piano string behaves similarly after the hammer-string contact (typically after 1–2 ms).

As a general case, the transverse displacement of a rigidly terminated string can be described by a similar formula:

$$y(x, t) = \sum_{n=1}^{\infty} y_n(t) \sin\left(\frac{n\pi x}{L}\right), \quad (9)$$

where the time-dependent terms of Eq. (8) are substituted by the series of functions $y_n(t)$, which can be considered as the instantaneous amplitudes of the modes $n=1, \dots, \infty$. This notation is used to obtain simpler formulas in the following derivations.

According to Eq. (6), the transverse to longitudinal excitation-force distribution $F_{t \rightarrow l}(x, t)$ is computed as

$$F_{t \rightarrow l}(x, t) = \frac{1}{2} ES \frac{\partial[\partial y(x, t)/\partial x]^2}{\partial x}. \quad (10)$$

Substitution of Eq. (9) into Eq. (10) yields

$$F_{t \rightarrow l}(x, t) = \frac{1}{2} ES \frac{\partial[\sum_{n=1}^{\infty} y_n(t)(n\pi/L)\cos(n\pi x/L)]^2}{\partial x}, \quad (11)$$

which, after some derivations, takes the following form:

$$F_{t \rightarrow l}(x, t) = -ES \frac{\pi^3}{4L^3} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} y_m(t) y_n(t) mn \times \left[(m+n) \sin\left(\frac{m+n}{L} \pi x\right) + (m-n) \sin\left(\frac{m-n}{L} \pi x\right) \right]. \quad (12)$$

Note that the indices m and n belong to variables of transverse modes throughout the paper. The variables of longitudinal modes are indexed by k .

B. Longitudinal motion

The longitudinal displacement can be written in the same form as Eq. (9), resulting in

$$\xi(x, t) = \sum_{k=1}^{\infty} \xi_k(t) \sin\left(\frac{k\pi x}{L}\right). \quad (13)$$

By applying the derivations of Morse²² (which were originally developed for transverse vibrations), the instantaneous amplitude $\xi_k(t)$ of the longitudinal mode k is obtained as

$$\xi_k(t) = F_{t \rightarrow l, k}(t) * \xi_{\delta, k}(t), \quad (14a)$$

$$F_{t \rightarrow l, k}(t) = \int_0^L F_{t \rightarrow l}(x, t) \sin\left(\frac{k\pi x}{L}\right) dx, \quad (14b)$$

$$\xi_{\delta, k}(t) = \frac{1}{\pi L \mu} \frac{e^{-t/\tau_k'}}{f_k'} \sin(2\pi f_k' t), \quad (14c)$$

where the * sign denotes time-domain convolution and $F_{t \rightarrow 1,k}(t)$ is the excitation force acting on the longitudinal mode k . The time-domain impulse response of longitudinal mode k is denoted by $\xi_{\delta,k}(t)$, where f'_k and τ'_k stand for the frequency and decay time of the longitudinal mode k . Note that the single quote in f'_k and τ'_k is used to distinguish the longitudinal variables from the transverse ones.

The first step in calculating the longitudinal motion is the computation of the excitation force $F_{t \rightarrow l,k}(t)$ by Eq. (14b), which is the scalar product of the excitation-force distribution $F_{t \rightarrow l}(x,t)$ and the longitudinal modal shape. From Eqs. (12) and (14b) it follows that $F_{t \rightarrow l,k}(t)$ is nonzero for $m+n=k$ and $|m-n|=k$ only, since in all other cases the spatial distribution of the excitation $F_{t \rightarrow l}(x,t)$ is orthogonal to the modal shape of mode k .

The two cases can be computed separately by defining $F_{t \rightarrow l,k}(t)$ as a sum of two components, i.e., $F_{t \rightarrow l,k}(t) = F_{t \rightarrow l,k}(t)^+ + F_{t \rightarrow l,k}(t)^-$. The component originating from the transverse modes that satisfy $m+n=k$ is

$$F_{t \rightarrow 1,k}(t)^+ = -ES \frac{\pi^3}{8L^2} \sum_{n=1}^{k-1} y_{k-n}(t) y_n(t) k(k-n)n. \quad (15a)$$

The component coming from $|m-n|=k$ becomes

$$F_{t \rightarrow 1,k}(t)^- = -2ES \frac{\pi^3}{8L^2} \sum_{n=1}^{\infty} y_{k+n}(t) y_n(t) k(k+n)n. \quad (15b)$$

The factor of 2 in Eq. (15b) comes from the fact that there are two equal series $m=k+n$ and $n=k+m$, since both satisfy $|m-n|=k$.

C. Excitation frequencies

For qualitative understanding of the longitudinal components it is useful to look at the spectra of the excitation force series $F_{t \rightarrow l,k}(t)$. The most important question is where the frequency peaks can be found.

To the first approximation, the instantaneous amplitudes $y_n(t)$ are exponentially decaying sinusoidal functions with the frequencies f_n , such as in Eq. (8). By observing Eqs. (15a) and (15b) the frequencies of the mixing terms in $F_{t \rightarrow l,k}(t)$ can be calculated as

Frequencies

$$\begin{aligned} \text{in } F_{t \rightarrow l,k}(t)^+ : & \begin{cases} f_n + f_{k-n} \approx f_k, \\ f_n - f_{k-n} \approx f_{|2n-k|}, \end{cases} \\ \text{in } F_{t \rightarrow l,k}(t)^- : & \begin{cases} f_n + f_{k+n} \approx f_{2n+k}, \\ f_n - f_{k+n} \approx f_k, \end{cases} \end{aligned} \quad (16)$$

where the form f_a refers to the frequency of the transverse mode with mode number a .

1. Harmonic transverse vibration

The approximations in Eq. (16) become equalities if the transverse frequencies f_n are perfectly harmonic, i.e., $f_n = n f_0$, which is the case for string instruments having negligible inharmonicity. In this case, there is a strong peak at the frequency f_k , and a series of partials at f_{2n-1} for odd k and at f_{2n-2} for even k , with $n = 1, \dots, \infty$. This means that the

odd longitudinal modes are excited by components having the same frequencies as the odd transverse modes. Similarly, the even longitudinal modes are excited at the even transverse modal frequencies.

These frequencies form the inputs of the time-domain impulse responses $\xi_{\delta,k}(t)$, which can be considered as second-order resonators [see Eq. (14c)]. The output of a resonator has two types of components: one component is the free response, which is a decaying sinusoid at the frequency f'_k . The other component is the forced response consisting of the frequency series f_{2n-1} or f_{2n-2} with $n = 1, \dots, \infty$. The amplitudes of these spectral lines are amplified around the peak of the resonator f'_k . As the responses of all the longitudinal modes are summed together, the output becomes similar to having formants on a rich harmonic spectrum. In any case, the forced components are indistinguishable from the transverse ones since they are exactly at the same frequencies.

2. Inharmonic transverse vibration

In the case of the piano, due to the stiffness of the string, the transverse partial frequencies do not form a perfect harmonic series but rather obey the equation²³

$$f_n = f_0 n \sqrt{1 + B n^2}, \quad (17)$$

where B is the inharmonicity coefficient and $f_0 \approx f_1$ is the fundamental frequency of the string.

In this case the terms $f_n + f_{k-n}$ and $f_n - f_{k+n}$ do not have the frequency of f_k but form a bunch of peaks around f_k . The peaks at the frequencies $f_n - f_{k-n}$ lie somewhat higher compared to $f_{|2n-k|}$ and the frequencies $f_n + f_{k+n}$ are lower than f_{2n+k} . This means that these peaks depart from the transverse partials in a rate determined by the inharmonicity coefficient B and the longitudinal mode number k . However, it is still true that odd longitudinal modes are excited by an oddlike partial series, while even longitudinal modes are excited by an evenlike one.

The force exciting the first longitudinal mode $F_{t \rightarrow 1,1}(t)$ is displayed in Fig. 2(a) by a solid line, computed by the resonator-based string model (see Sec. VC), which is the discrete-time implementation of the modal model described in Secs. III A and III B. Note that the excitation force has an oddlike partial series. The spectrum of the transverse bridge force is displayed by dots to show the transverse modal frequencies as a reference. The dashed line indicates the Fourier transform of the impulse response of the first longitudinal mode $\xi_{\delta,1}(t)$, amplifying the frequencies around 690 Hz. Figure 2(b) shows the excitation-force spectrum of the second longitudinal mode for the same example. It can be seen that here the excitation spectrum contains even partials only and that the peak of the longitudinal mode (dashed line) is located at a higher frequency (1380 Hz in this case).

The longitudinal motion is the sum of the motion of different modes. This means that spectra similar to Figs. 2(a) and (b) should be superimposed with slightly shifted excitation frequencies and very different longitudinal modal frequencies. The result is similar to formants on a quasi-harmonic spectrum but here the peaks are somewhat smeared as they are made up of many close frequencies. The most

FIG. 2. The force spectrum exciting the first (a) and the second (b) longitudinal modes $[F_{t \rightarrow l,1}(t)$ and $F_{t \rightarrow l,2}(t)]$ computed by the resonator-based string model of Sec. V C (displayed by solid line). The transverse bridge force (dotted line) is displayed to show the transverse modal frequencies. The dashed line shows the frequency response of the first (a) and the second (b) longitudinal modes. The relative levels of the signals are arbitrary.

important difference from the case of harmonic transverse vibration is that these smeared peaks appear between the transverse ones and therefore they can be easily distinguished.

D. Longitudinal force at the bridge

The longitudinal component of the tone is transmitted to the soundboard via the force acting on the bridge in the longitudinal direction. This force equals to the tension [see Eq. (4)] at the termination $x=L$, written as

$$F_l(t) = - \left[T_0 + ES \frac{\partial \xi}{\partial x} \Big|_{x=L} + \frac{1}{2} ES \left(\frac{\partial y}{\partial x} \Big|_{x=L} \right)^2 \right], \quad (18)$$

showing that the force $F_l(t)$ depends not only on the longitudinal motion but on the transverse vibration as well.

The force component coming from the transverse motion have the same sum- and difference-frequency terms as the component arising from the longitudinal motion, but their amplitudes are different. It is an interesting outcome that when the transverse motion of the string contains low frequency components only, most of these terms cancel out and only the double frequency terms remain. This produces the same longitudinal bridge force as what would occur with applying the uniform tension approximation.¹¹ The derivation of this result is included in the Appendix.

E. Extension to two transverse planes

Real strings vibrate in two transverse polarizations. The modal frequencies for these polarizations can be different for the same modes, mostly because of the direction-dependent termination impedance. This produces beating and two-stage decay in piano sound.²⁴ Working out the equations (1)–(6) for the three-dimensional case gives

$$\mu \frac{\partial^2 \xi}{\partial t^2} = ES \frac{\partial^2 \xi}{\partial x^2} + \frac{1}{2} ES \left[\frac{\partial(\partial y / \partial x)^2}{\partial x} + \frac{\partial(\partial z / \partial x)^2}{\partial x} \right], \quad (19)$$

where z is the string displacement in the direction perpendicular to the already considered transverse y and longitudinal x directions.

It follows from Eq. (19) that the excitation-force distribution $F_{t \rightarrow l}(x, t)$ is the superposition of the excitation-force distributions computed for the two transverse planes separately. Accordingly, if two modes vibrate in two planes perpendicular to each other, their sum and difference frequencies do not appear in the excitation force. In reality the vibrating planes are not perfectly perpendicular to each other (the motion is actually not even planar^{7–10}), meaning that mode m vibrating in one plane will mix with mode n vibrating in a different plane.

The modal frequencies $f_{n,1}$ and $f_{n,2}$ of the two transverse polarizations are slightly different for the same mode number n . Accordingly, the excitation components coming from the two transverse modes m and n consist of four different frequencies. For example, the sum-frequency components have the frequencies $f_{m,1} + f_{n,1}$, $f_{m,1} + f_{n,2}$, $f_{m,2} + f_{n,1}$, and $f_{m,2} + f_{n,2}$. The difference-frequency components can be expressed similarly.

F. Validity of the approximation

1. Neglecting the longitudinal to transverse coupling

The assumption of neglecting the longitudinal to transverse coupling is valid until the longitudinal vibration is small compared to the transverse one. However, if one of the excitation frequencies of the longitudinal mode k [see Eq. (16)] is very close to the resonant frequency f'_k of that mode, the longitudinal motion can have extremely large amplitude. This would not happen in reality since the longitudinal motion would diminish the amplitude of those transverse modes from which it originates (the total energy of transverse and longitudinal vibrations cannot increase). This stabilizing effect is not included in our modal model. On the other hand, these coincidences have a small practical significance from the sound synthesis viewpoint since they produce an unpleasant ringing sound even when computed by a finite difference string model (see Sec. V A) having bidirectional coupling. (This fact also implies that these annoying coincidences should also be avoided in real pianos by careful string- and scale design.)

The longitudinal to transverse coupling would also introduce some terms of third order in the amplitude of the transverse vibration, but their contribution is less significant compared to the second-order terms discussed here. To sum up, the frequencies predicted by the model of Sec. III should be in quantitative agreement with the dominant peaks found in real piano spectrum. The amplitude behavior is described properly for those peaks that do not coincide with the resonant frequency of the excited longitudinal mode. (This holds for most of the peaks.)

2. Perfectly rigid termination

The termination of piano strings is not perfectly rigid, contrary to the assumptions made here. As the impedance of the bridge is ca. 1000 times larger compared to the impedance of the string, its main effect is a change in the partial

frequencies f_n and decay time τ_n , which can be easily incorporated in Eq. (8). The modal shapes also change slightly [L is substituted by $L + \delta L$ in Eq. (8), see Ref. 11], meaning that none of the longitudinal modal shapes are completely orthogonal to the modal shapes of the excitation-force distribution. However, it is still true that the dominant force components are those computed by Eqs. (15a) and (15b). This is confirmed by finite difference simulations showing only a small change in the output when a more realistic termination model is applied.

The termination of piano strings can also contribute to the energy transfer between the transverse and longitudinal motion.¹¹ As such a coupling is linear, it does not introduce new terms by itself. The transverse frequencies can appear in the longitudinal motion, and, conversely, the longitudinal frequencies may turn up in the transverse vibration. However, those transverse and longitudinal components that have the same frequency cannot be distinguished in the sound pressure. The coupling through the bridge in combination with the transverse to longitudinal coupling along the string could produce new terms, but they are of fourth order in the amplitude of the transverse vibration.

IV. CONNECTIONS TO MEASUREMENTS

In this section the results of Sec. III are related to the measurements of other authors.²⁻⁴ On the one hand, this confirms the modal model presented in Sec. III. On the other hand, it helps to understand the theoretical reasons underlying the findings of these experimental studies.²⁻⁴

A. Parentage of phantom partials

From the theoretical point of view, phantom partials are the forced motion of longitudinal vibrations. An interesting property of odd phantom partials discovered by Conklin⁴ is that they originate from adjacent parents, i.e., they can be found at frequencies $f_m + f_n$ where $m - n = 1$.

By looking at $F_{t \rightarrow l, k}(t)$ in Eq. (16) it turns out that the frequencies $f_n + f_m = f_n + f_{k+n}$ are quite close to each other for $m + n = p$ (they would actually coincide in the case of a perfectly harmonic transverse vibration having the frequency f_{2n+k}). The question is which $f_m + f_n$ combination has the largest amplitude in the resulting sound. It follows from Eq. (16) that the different $f_m + f_n$ components belonging to the same smeared peak (i.e., $m + n = p$) excite different longitudinal modes. Namely, the frequency $f_m + f_n$ excites the longitudinal mode having the mode number $k = m - n$. Accordingly, that $f_m + f_n$ component results in the largest longitudinal motion which excites the longitudinal mode having a modal frequency f'_k close to the frequency $f_m + f_n$. In other words, if the frequency of a phantom partial group is close to the frequency f'_k of the k th longitudinal mode, it mainly originates from parents having mode number difference of k .

The lower odd phantom partials, which were measured by Conklin,⁴ most probably have frequencies to which the first longitudinal mode is the nearest. In this case the $f_m + f_n$ terms satisfying $m - n = 1$ dominate, which actually originate from adjacent parents f_n and f_{n+1} .

FIG. 3. Spectrum of the first (a) and the second second (b) of a F_1 piano tone. Transverse partials are marked by crosses and the second longitudinal mode is marked by a circle. Two prominent phantom partial groups are indicated by a square and a diamond (the latter is magnified in Fig. 4).

Similar considerations apply for even phantoms, that is, they are generated by parents having mode number difference of 2, 4, 6, etc., depending on the frequency of the phantom partial. However, there is an important difference that double frequency terms $2f_n$ also occur in the spectrum. These $2f_n$ components would arise even when the bandwidth of transverse components was significantly lower than the frequency of the first longitudinal mode, i.e., when the tension was approximately uniform along the string (see the Appendix). In other words, these are the only components that can be explained by the uniform tension approximation of Refs. 7–11, while for the sum- and difference frequency components the inertial effects of longitudinal modes have to be included in the model.

The spectrum of a recorded F_1 piano tone (having only one string) is displayed in Fig. 3. Transverse partials are indicated by crosses and the free response of the second longitudinal mode is marked by a circle. The remaining peaks are the forced response of the longitudinal motion, i.e., phantom partials. Figure 3(a) shows the first second of the tone and Fig. 3(b) displays the second, giving an insight to the evolution of the spectrum. Note that the free response of the longitudinal mode (circle) disappears fast in the noise (the decay time is ca. 0.15 s), while the phantom partials remain significant and their decay rate is comparable to that of the transverse partials. It can be said in general that the highest nontransverse peaks in the long-term spectrum are phantom partials amplified by a longitudinal mode (one prominent example is marked by a square). This suggests that the forced response of the longitudinal motion may have a larger perceptual significance than the free response itself. Most probably the pitch of the longitudinal component is determined by these amplified phantom partials (like the one marked by a square in Fig. 3) and not by the fast decaying free response. The interested reader may listen to the sound examples demonstrating the relative significance of these components.²⁵

The “single” phantom partial marked by a diamond in

FIG. 4. The spectrum of an even phantom partial group in the F_1 piano tone of Fig. 3. Sum frequencies of transverse modes $f_m + f_n$ are marked by circles, and the mode numbers of the parent partials are labeled in the form of $m + n$. The phantom group is displayed by a diamond in Fig. 3.

Fig. 3 becomes a group of partials when plotted at a higher frequency resolution in Fig. 4. In this case the data length is 16 s (705 600 samples at $f_s = 44.1$ kHz), which was zero padded to 2^{22} samples after applying a Hanning window. The most prominent peaks of the phantom group are marked by circles. The label “ $m + n$ ” beside a circle indicate that the circle is located at the sum frequency of the transverse modes m and n (i.e., at $f_m + f_n$). The frequencies of the transverse modes were determined by finding peaks in the spectrum. Note that the same $m + n$ combinations can be found at several peaks: the reason is that the two different frequencies $f_{m,1}$ and $f_{m,2}$ of the two transverse polarizations of mode m mix with the two different frequencies $f_{n,1}$ and $f_{n,2}$ of mode n , as predicted in Sec. III E.

It can be seen in Fig. 4 that the highest peak comes from the 12th and 14th transverse modes and not from the 13th mode itself, although the amplitude of the latter is only 10 dB smaller. Other even phantoms show the same phenomenon: they principally originate from parents having mode-number difference of 2, 4, etc., and not from a single mode by frequency doubling. This contradicts the findings of Conklin⁴ but confirms the analysis of Sec. III.

B. Inharmonicity of phantom partials

Nakamura and Naganuma³ found that the inharmonicity of phantom partials (called “lower series” in Ref. 3) is one-fourth of that of normal transverse partials.

This can be explained by knowing that phantom partials are mainly produced by parents with mode numbers close to each other. This means that even phantoms have an approximate frequency of $f_p = 2f_n$, where $p = 2n$ is the “mode number” of the phantom partial. (See Fig. 4 as an example, where $f_{12} + f_{14} \approx 2f_{13}$.) Writing $f_p = 2f_n$ according to Eq. (17) and expressing the frequencies by the phantom mode number $p = 2n$ gives⁶

$$f_p \approx 2f_n = 2f_0n\sqrt{1 + Bn^2} = f_0p\sqrt{1 + \frac{1}{4}Bp^2}. \quad (20)$$

For even phantoms, the expression is quite accurate. For odd phantoms, $n = p/2$ is not an integer number. However, as the inharmonicity curve is a smooth function, the frequencies of odd phantom partials are also close to the ones predicted by Eq. (20).⁶

C. Amplitude of longitudinal vibration

Giordano and Korty² found that the amplitude of the longitudinal vibration is a nonlinear function of the amplitude of the transverse one. They noted that the nonlinear curve is faster than a simple quadratic function.

Equation (12) shows that a peak in the excitation spectrum of a longitudinal mode is a quadratic function of the overall amplitude of the generating transverse modes m and n . However, the amplitude of longitudinal motion is mostly determined by parents having sum frequencies $f_m + f_n$ around the longitudinal modal frequencies f_k' . The amplitude of these parents (with mode numbers around 10–20 in practice) are a nonlinear function of the overall amplitude of the transverse vibration. This is because of the nonlinear nature of the hammer–string interaction (see, e.g., Ref. 26). The presence of this second kind of nonlinearity explains why Giordano and Korty² could not measure a second-order relationship.

V. SOUND SYNTHESIS

The original motivation of this research was to support the development of physics-based piano models. These physics-based models do not have to describe each part of the instrument precisely. They should be as simple as possible while still producing agreeable sound quality. Therefore these models are often constructed from precise physical descriptions by neglecting those effects that have small perceptual relevance.

A. Finite difference modeling

A straightforward approach of modeling the vibration of piano strings is implementing the simultaneous differential equations (6) and (7) by the finite difference approach. Naturally, these have to be extended by the terms realizing frequency-dependent losses and dispersion. In an earlier work⁶ such a model was developed along the lines of the transverse string model of Chaigne and Askenfelt.^{27,28} However, the computational demand of such an approach is large because high sampling frequency ($f_s \approx 500$ kHz) is required due to the higher propagation speed in the longitudinal direction. Still, this approach can be very useful for experimental purposes. A commercial computer program based on a finite difference string model was written by Bernhard,²⁹ helping piano tuners in scale design.

The inclusion of longitudinal components in the piano model greatly improves the quality of synthesized piano sounds. However, complete finite difference modeling of the string is too demanding for real-time sound synthesis applications. In the following sections two models are presented that overcome this limitation. The composite model of Sec. VB replaces the finite difference model implementing Eq. (6) with the modal description for the longitudinal polariza-

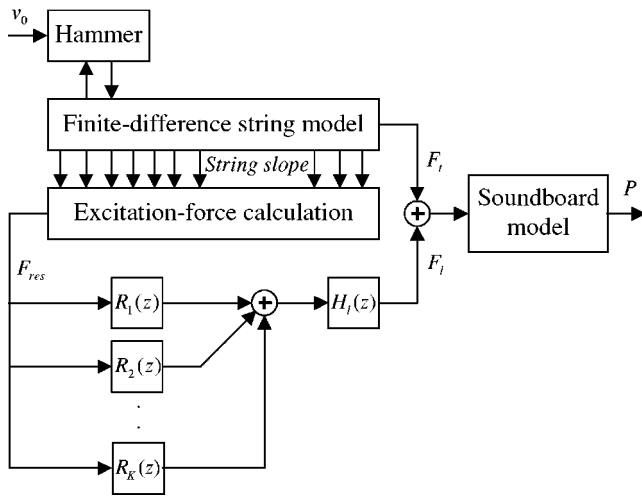

FIG. 5. The composite string model applying finite difference modeling and second-order resonators R_1, \dots, R_K .

tion, while the transverse vibration is computed by a variation of Eq. (7). The resonator-based string model of Sec. V C applies the modal model for both polarizations instead of directly realizing Eqs. (6) and (7).

B. The composite string model

In an earlier work¹⁹ a composite string model was introduced, which computes the longitudinal vibration in a modal form according to the theory presented in Sec. III. The model structure is depicted in Fig. 5. The transverse deflection $y(x, t)$ is computed by a finite difference string model running at audio sampling rate (e.g., $f_s = 44.1$ kHz), which implements the following differential equation:

$$\mu \frac{\partial^2 y}{\partial t^2} = T_0 \frac{\partial^2 y}{\partial x^2} - ES\kappa^2 \frac{\partial^4 y}{\partial x^4} - 2b_1\mu \frac{\partial y}{\partial t} + 2b_2\mu \frac{\partial^3 y}{\partial x^2 \partial t}. \quad (21)$$

Equation (21) is a variation of Eq. (7) where the nonlinear forcing term [the rightmost term of Eq. (7)] is missing, as the longitudinal to transverse coupling is neglected, while it is extended by terms realizing dispersion and losses. This is basically the string model proposed by Chaigne and Askenfelt,^{27,28} except for the last term, which substitutes temporal derivatives with spatial ones. This modification is suggested by Bensa *et al.*,³⁰ leading to a stable system for arbitrary b_2 . The κ parameter in the dispersion term refers to the radius of gyration of the string, and the constants b_1 and b_2 determine the decay rates of the partials. A finite difference hammer model^{27,28} is also attached to the string. The initial velocity of the hammer is denoted by v_0 in Fig. 5.

The excitation-force distribution of the longitudinal motion $F_{\rightarrow l}(x, t)$ is computed according to Eq. (10) from this transverse displacement. Then the excitation force $F_{\rightarrow l, k}(t)$ of each longitudinal mode k is computed by a scalar product with the longitudinal modal shape [see Eq. (14b)]. The instantaneous amplitudes $\xi_k(t)$ of the longitudinal modes are calculated according to Eq. (14a), which is implemented by second-order resonators (R_1, \dots, R_K in Fig. 5).

In order to reduce the computational cost, the same excitation force is used for all the longitudinal modes.¹⁹ This is

FIG. 6. The sound pressure spectrum of the first second of a synthesized G_1 piano tone²⁵ computed by the composite string model of Sec. V B (a) and by the resonator-based string model of Sec. V C (b). Crosses indicate the transverse partials and the second longitudinal mode is marked by a circle in both figures. To be compared with Fig. 3(a).

acceptable from a perceptual point of view because the spectra of the excitation forces $F_{\rightarrow l, k}(t)$ are quite similar. It follows from Eq. (16) that odd phantoms arise from the vibration of odd longitudinal modes and even phantoms from the vibration of even ones. Therefore it is satisfactory to compute the excitation force of one odd and one even longitudinal mode, e.g., the input of the resonators R_1, \dots, R_K can be $F_{\text{res}} = F_{\rightarrow l, 5}(t) + F_{\rightarrow l, 6}(t)$. This way a multiple (or smeared) peak of a phantom partial is substituted by a single, exponentially decaying sinusoid. In order to avoid an unpleasant ringing sound (see Sec. III F 1), the frequencies f'_k of the resonators R_1, \dots, R_K are set in a way that they do not coincide with the peaks of their excitation signal F_{res} . It has been found that using a common excitation force for R_1, \dots, R_K does not impair sound quality, but contributes to large computational savings.

The force signals F_t and F_l in Fig. 5 coming from the transverse and longitudinal polarizations are sent to the soundboard model, which computes the sound pressure P . The soundboard is modeled by a multi-rate filtering algorithm approximating the measured impulse response of a transversely excited piano soundboard.¹⁹ The soundboard responds differently to a longitudinal force than to a transverse one. This difference is modeled by a simple high-pass filter $H_l(z)$ in the longitudinal force path.

The sound pressure spectrum of the first second of a synthesized G_1 note²⁵ is displayed in Fig. 6(a). The phantom partials are clearly visible between the transverse modes, which are emphasized around the longitudinal free mode at 1450 Hz. The circle indicates the component coming from the longitudinal free response, while the crosses show the transverse modal frequencies. It can be seen that the spectrum is similar to that of a real piano tone displayed in Fig. 3. The composite string model produces the same sound quality as the full finite difference method of Sec. V A, while its computational requirements are reduced by an order of a magnitude (to around 10%–15%).

C. The resonator-based string model

The resonator-based string model is the discretization of the equations presented in Sec. III. The string displacement is represented by its modal form [see Eqs. (9) and (13)] for both the transverse and longitudinal polarizations and the instantaneous amplitudes $y_n(t)$ and $\xi_k(t)$ are computed by second-order resonators.

The string is excited by a hammer in the transverse polarization. The hammer is modeled in the same way as in the case of finite difference string models.^{27,28} The string response to the hammer force is calculated by a set of second-order resonators, which have input and output coefficients depending on the hammer position. The outputs of these resonators correspond to the instantaneous amplitudes $y_n(t)$ of the transverse vibration, which can be directly used to compute the excitation force $F_{t \rightarrow l, k}(t) = F_{t \rightarrow l, k}(t)^+ + F_{t \rightarrow l, k}(t)^-$ of the longitudinal modes by using Eqs. (15a) and (15b). From this point, the approach is the same as taken in Sec. VB: the excitation force of one even and one odd longitudinal mode is calculated and summed [e.g., $F_{\text{res}} = F_{t \rightarrow l, 5}(t) + F_{t \rightarrow l, 6}(t)$]. This signal is then fed to the resonators calculating the instantaneous amplitudes $\xi_k(t)$ of the longitudinal modes. The efficiency can be further increased if those components of the excitation signal F_{res} are not computed where the gain of the longitudinal resonator bank is small.

This model is capable of producing the same sound quality as the model of Sec. VB when the number of resonators implementing the transverse modes equals to the number of string elements in the finite difference model. Figure 6(b) displays the sound pressure spectrum of the first second of a G_1 piano tone synthesized by the resonator-based string model.²⁵ It can be seen in Fig. 6 that the resonator-based model produces a similar output compared to the composite model of Sec. VB when the string and hammer parameters are set to be the same. The only difference is that the composite string model generates noiselike peaks between the dominant partials due to computational inaccuracies. However, this is not considered as an advantage because the difference between the output of the two models is almost inaudible.²⁵

An advantage of this approach is that the computational complexity is reduced to less than the half. Moreover, this method is particularly advantageous when the goal is to reproduce a tone which is similar to that of a particular piano since the measured partial frequencies f_n and decay times τ_n can be directly implemented in the model. On the other hand, the resonator-based model is less physical in the sense that the physical parameters of the string (such as string mass and tension) have only indirect connection to the model.

D. Implications to psychoacoustic research

The informal listening tests made during the development of sound synthesis algorithms raised some questions on the perceptual aspects of longitudinal vibrations. It is an important property of the piano sound that the longitudinal component sounds as an inherent part of the tone, while it is still possible to perceive its pitch.²⁵ The present authors be-

lieve that the reason for this is that the distance of the phantom partials reinforces the pitch information originating from the transverse vibration, while the distance of the “formant peaks” leads to the pitch perception of the longitudinal mode. The perceptual effect can be similar to the sound of Touvinian throat- or overtone singers³¹ who can produce two tones simultaneously. Listening tests should be conducted to confirm this conjecture.

VI. CONCLUSIONS

The generation of longitudinal components can be summarized as follows: the longitudinal motion is continuously excited by the transverse vibration along the string (and not only during the hammer-string contact). The forced response to this excitation gives a rise to phantom partials, while the free response produces the components corresponding to the longitudinal modal frequencies. Both of these components develop under the assumption of rigid string terminations, i.e., the piano bridge has a less significant effect on the phenomenon.

According to the modal model presented in Sec. III, each longitudinal mode can be viewed as a second-order resonator, whose input is a quasi-harmonic spectrum, containing terms with sum and difference frequencies of some specific transverse modes. As each longitudinal mode emphasizes the peaks around its modal frequency, the sum of their outputs is similar to having formants on a quasi-harmonic spectrum.

In Sec. IV the experimental results of earlier papers have been explained by the results of the modal model, such as why phantom partials originate from adjacent parents and what the inharmonicity coefficient of the phantom partial series is. Some measurements of the present authors have also been outlined, confirming the results of the theoretical model.

Based on the further simplification of the model, two sound synthesis algorithms have been presented in Sec. V. The first one computes the transverse vibration by a finite difference string model and then calculates the inputs of the resonators, which represent the longitudinal modes. The second approach computes both the transverse and longitudinal vibrations in the modal domain, implemented by second-order resonators. Both models produce convincing piano sounds.²⁵

The present work has examined the main effects arising from the longitudinal vibration of piano strings. Secondary effects coming from the coupling of longitudinal to transverse polarizations and originating from the characteristics of the string termination could be a subject of future research. For these studies the admittance matrix measurement of the piano bridge would be of great significance. Moreover, the radiation properties of the soundboard as a function of longitudinal string force could also be an interesting field of research. As for sound synthesis models, the computational complexity might be lowered by further simplifications based on psychoacoustic criteria. Accordingly, studies on how the longitudinal components are perceived would also be of great importance.

The findings of the paper can be useful not only in the field of piano acoustics but for researchers interested in the analysis or synthesis of other stringed instruments, such as the guitar. Understanding the generation mechanism of longitudinal components (e.g., which transverse partials excite a specific longitudinal mode) can help piano or guitar builders to achieve a better control over the nature of the tone. For the sound synthesis of other string instruments, the tension computed by the modal model might be used to improve the performance of synthesis models that presently apply the uniform tension approximation.

APPENDIX: UNIFORM TENSION AS A SPECIAL CASE

The assumption of spatially uniform tension is often applied in the literature (see the work of Legge and Fletcher¹¹ or Refs. 7–10), since in that case the tension can be computed from the relative elongation of the string by

$$\bar{T}(t) = T_0 + ES \frac{1}{2L} \int_{x=0}^L \left(\frac{\partial y}{\partial x} \right)^2 dx, \quad (\text{A1})$$

where the string tension $T(x, t) = \bar{T}(t)$ is independent of position x . This assumption is based on the fact that when the speed of the longitudinal waves is much larger than that of the transverse ones, the longitudinal inertial effects can be neglected.⁸

In this case the tension contains terms which have double the frequencies of the corresponding transverse modes.¹¹ If the transverse displacement is written in a modal form as in Eq. (9), the tension $\bar{T}(t)$ is obtained as

$$\bar{T}(t) = T_0 + ES \frac{\pi^2}{4L^2} \sum_{n=1}^{\infty} y_n^2(t) n^2. \quad (\text{A2})$$

It is of some interest to see how the results of this formula can be developed as a special case of the modal model presented in this paper. This both confirms the modal model described in Sec. III and helps in finding the limits where the assumption of uniform tension can be applied.

It can be seen in Eq. (4) that the expression of the tension $T(x, t)$ is made up of three terms. By defining T_0 as the tension at rest, $T_l(x, t)$ as the tension component proportional to the longitudinal slope, and $T_t(x, t)$ as the tension component proportional to the square of the transverse slope, the total tension can be written as

$$T(x, t) = T_0 + T_l(x, t) + T_t(x, t). \quad (\text{A3})$$

If the transverse displacement is expressed in the modal form of Eq. (9), the tension component coming from the transverse slope becomes

$$\begin{aligned} T_t(x, t) &= ES \frac{1}{2} \left[\frac{\pi}{L} \sum_{n=1}^{\infty} y_n(t) n \cos\left(\frac{n\pi x}{L}\right) \right]^2 \\ &= ES \frac{\pi^2}{4L^2} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} y_m(t) y_n(t) mn \\ &\quad \times \left[\cos\left(\frac{m+n}{L} \pi x\right) + \cos\left(\frac{m-n}{L} \pi x\right) \right]. \quad (\text{A4}) \end{aligned}$$

The Laplace transform of the time domain impulse response $\xi_{\delta, k}(t)$ in Eq. (14c) of a longitudinal mode k is

$$\mathcal{L}\{\xi_{\delta, k}(t)\} = \frac{2}{L\mu} \frac{1}{s^2 + (2/\tau_k')s + 1/\tau_k'^2 + 4\pi^2 f_k'^2}, \quad (\text{A5})$$

from which the low frequency response ($s \rightarrow 0$ for $f \ll f_k'$) of the resonator can be approximated as

$$\xi_k(t) \approx \frac{2L}{ESk^2\pi^2} F_{t \rightarrow l, k}(t), \quad (\text{A6})$$

which was obtained by writing $f_k' = k\sqrt{ES/\mu}/(2L)$ and assuming $1/\tau_k' \ll f_k'$. The shape of the dashed lines in Figs. 2(a) and (b) confirms that the longitudinal modes have constant gain at low frequencies. Note that this point of the derivation relates to neglecting the inertial effects, i.e., assuming $\mu(\partial^2 \xi / \partial x^2) = 0$ in Eq. (6). (See also Refs. 8 and 9.)

In this case, the component that comes from the longitudinal motion is expressed as

$$\begin{aligned} T_1(x, t) &= ES \frac{\pi}{L} \sum_{k=1}^{\infty} \xi_k(t) k \cos\left(\frac{k\pi x}{L}\right) \\ &= -\frac{2}{\pi} \sum_{k=1}^{\infty} \frac{1}{k} [F_{t \rightarrow l, k}(t)^+ \\ &\quad + F_{t \rightarrow l, k}(t)^-] \cos\left(\frac{k\pi x}{L}\right). \quad (\text{A7}) \end{aligned}$$

Calculating the excitation force $F_{t \rightarrow l, k}(t) = F_{t \rightarrow l, k}(t)^+ + F_{t \rightarrow l, k}(t)^-$ with the help of Eqs. (15a) and (15b) and eliminating k by substituting $m+n=k$ and $|m-n|=k$ gives

$$\begin{aligned} T_1(x, t) &= -ES \frac{\pi^2}{4L^2} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} y_m(t) y_n(t) mn \cos\left(\frac{m+n}{L} \pi x\right) \\ &\quad - ES \frac{\pi^2}{4L^2} \sum_{m=1}^{\infty} \sum_{\substack{n=1 \\ n \neq m}}^{\infty} y_m(t) y_n(t) mn \cos\left(\frac{m-n}{L} \pi x\right), \quad (\text{A8}) \end{aligned}$$

where $n \neq m$ in the second term comes from the fact that the longitudinal mode number $k = |m-n|$ cannot be zero. Note that there is no such constraint for the first term as $k = m+n$ in that case.

If Eqs. (A4) and (A8) are substituted into Eq. (A3), all the terms cancel out, except some with $m=n$ giving

$$T(x, t) = T_0 + ES \frac{\pi^2}{4L^2} \sum_{n=1}^{\infty} y_n^2(t) n^2 \cos\left(\frac{n-n}{L} \pi x\right), \quad (\text{A9})$$

which is the same as Eq. (A2) obtained by assuming uniform tension along the string. Note that the uniform tension approximation does not lead to zero longitudinal displacement. On the contrary, the string elements move in the longitudinal direction in a way that the tension remains uniform along the string. Actually, the tension could not be uniform without longitudinal motion.

The assumption leading to Eq. (A9) is that all the longitudinal modes are excited by frequencies that are considerably smaller than the corresponding longitudinal modal frequency f'_k . Thus, the validity of the uniform tension approximation should be evaluated by comparing f'_k with the excitation frequencies calculated by Eq. (16) for each k . Having small order transverse vibrations in comparison to the ratio of longitudinal and transverse propagation speeds (see, e.g., Ref. 8) is a sufficient, but not a necessary, condition for the applicability of the uniform tension approximation.

As a special case, if the transverse vibration contains only one mode, the uniform tension approximation can be applied. This is because the transverse mode n excites longitudinal mode $k = 2n$, for which Eq. (A6) holds. Note that this is true for all the transverse modes, and not only for the first few. However, when all the transverse partials are present up to a mode number N the assumption of the uniform tension can be applied only if the transverse vibration does not contain significant components around and above $f'_0/2$ (where $f'_0 = f'_1$ is the fundamental frequency of the longitudinal modal series). This is because the excitation force $F_{t \rightarrow 1,k}(t)$ has approximately double the bandwidth compared to the bandwidth of the transverse vibration.

It is important to note that the behavior of the longitudinal vibration changes qualitatively as a function of the transverse modes present on the string. It is an interesting field of future research to evaluate the coupling of transverse modes and the properties of nonplanar string vibrations in the case of realistic transverse components, i.e., when the uniform tension approximation cannot be applied. This would answer the question whether the theoretical and experimental results presented for the first few modes of transverse vibrations^{7–11} can be applied for the qualitative description of the phenomenon in the case of stringed instruments where dozens of transverse partials are generated.

(Received 7 February 2003; revised 27 September 2004; accepted 2 December 2004)

The accordion reed is an example of a blown-closed free reed. Unlike most oscillating valves in wind musical instruments, self-sustained oscillations occur without acoustic coupling. Flow visualizations and measurements in water show that the flow can be supposed incompressible and potential. A model is developed and the solution is calculated in the time domain. The excitation force is found to be associated with the inertial load of the unsteady flow through the reed gaps. Inertial effect leads to velocity fluctuations in the reed opening and then to an unsteady Bernoulli force. A pressure component generated by the local reciprocal air movement around the reed is added to the modeled aerodynamic excitation pressure. Since the model is two-dimensional, only qualitative comparisons with air flow measurements are possible. The agreement between the simulated pressure waveforms and measured pressure in the very near-field of the reed is reasonable. In addition, an aeroacoustic model using the permeable Ffowcs Williams–Hawkings integral method is presented. The integral expressions of the far-field acoustic pressure are also computed in the time domain. In agreement with experimental data, the sound is found to be dominated by the dipolar source associated by the strong momentum fluctuations of the flow through the reed gaps. © 2005 Acoustical Society of America. I. INTRODUCTION

The accordion is based on a very old system: the free metal reed which dates from the third millenium BC. It was used in a Chinese musical instrument, the tcheng. Nowadays, this system can be found in the harmonica and the harmonium, for example. The accordion reed is a thin metal plate riveted at one end to a support plate. There is a rectangular slot in the support plate immediately beneath the reed. The aperture is a bit larger than the reed so that the it freely vibrates as a cantilevered beam and does not strike against the support plate. An air flow is generated by the inward or outward movement of the bellows. With regards to Fletcher's classification,¹ the accordion reed is a valve of type $(-, +)$. In the presence of pre-existing flow in the same direction as the instrument, a steady overpressure applied from the upstream side of the reed tends to close the valve and inversely, a steady overpressure applied from downstream of the reed causes it to open further. Of course, if we consider a steady flow in the opposite direction, the valve is of type $(+, -)$. However, in the instrument, the accordion reed only operates in its blown-closed configuration: the inward movement of the bellows generates an upstream steady overpressure P_0 and the outward movement generates a depression on the downstream side of the reed which is equivalent to an upstream overpressure. The self-sustained oscillation results

from the unsteady pressure difference between both sides of the reed. But unlike most wind instruments such as woodwind and brass,^{2,3} the time-dependent pressure drop is not driven by the oscillation of the air column of a resonator. In the accordion, we can consider that the reed oscillation mechanism and the emitted sound do not depend on the acoustic influence of the upstream and downstream volumes. This kind of oscillating valve can be called a dominant or a strong reed.

In classical reed models^{1,2,4} that have been developed for resonator-coupled reeds, the pressure fluctuation $p_{ac}(t)$ is written from the acoustic response of the resonator excited by an unsteady volume flux $q_{ac}(t)$. By assuming the incompressibility of the flow around the reed, the acoustic volume flux at the resonator inlet is matched to the aerodynamic flux through the reed aperture $q_{ac}(t) := q(t) \propto V(t)x_2(t)L$ where $V(t)$ is the flow velocity, $x_2(t)$ is the reed displacement and L is a characteristic length of the orifice. The aerodynamic velocity—and thus the volume flux—is easily calculated from the steady-state Bernoulli equation with a pressure drop $P_0 - p_{ac}(t)$. This modeling approach implicitly supposes that the pressure of the reed flow at the exit of the reed channel exactly equals the acoustic pressure at the entrance of the resonator. This assumption can be justified⁵ by noting that a jet is formed at the exit of the reed channel because of the large abrupt transition in cross-sectional area from reed channel to instrument mouthpiece. All the kinetic energy of the flow is supposed to be dissipated in the spreading turbulent

^{a)}Current address: 10 avenue Paul Cezanne 78990 Elancourt, France; electronic mail: DenisRicot@aol.com

jet. This hypothesis is also consistent with the modeling of the acoustic source. Indeed, it is clear that only the fluctuating mass is taken for the excitation of the acoustic air column. The fluctuating force associated with the periodic momentum injection can be ignored. Finally, the reed is modeled by a simple mass-spring-damping system. Consequently, a coupled system of three equations (the impedance relation, the Bernoulli equation and the simple harmonic oscillator equation) and three unknown variables [$x_2(t), q(t), p_{ac}(t)$] can be written. With the same approach, the influence of the internal acoustic impedance of the air supply system (the player's lungs, vocal tract and mouth) can be taken into account.¹ Because of the impedance relation, most calculations are performed in the frequency domain.^{1,2} But the frequency-domain approach is not advantageous for strongly nonlinear equations such as the Bernoulli equation. Time-domain solutions^{6,4} and hybrid methods⁷ have also been proposed.

For a constant surface of contact between the flow and the reed, the dynamic excitation force is a combination of acoustic pressure and pressure induced by velocity variation due to the variation in the aperture area. The velocity-induced pressure fluctuations are found by applying the stationary Bernoulli equation which associates a decrease of the pressure with an acceleration of the fluid. But, without other physical mechanisms such as acoustic feedback, these pressure fluctuations cannot induce self-oscillations. For example, if we suppose a constant volume flow through the reed aperture, it is straightforward to show that the force induced by fluid velocity variation is in phase with the displacement. Energy transfer between the constant supply pressure and the reed oscillation is not possible if we consider only the stationary Bernoulli equation. Titze⁸ explained that an asymmetry of the pressure force during the cycle is necessary for reed excitation. In case of resonator-coupled reeds, the pressure asymmetry is provided by the acoustic response of upstream and/or downstream volumes. In case of the accordion reed, there is no acoustic feedback. By supposing that the stationary Bernoulli equation well describes the aerodynamic flow through the reed aperture, other physical mechanisms have been proposed to explain the phase shift of the total force with regard to the reed displacement. For example, a complex evolution of the channel geometry during the cycle can lead to the asymmetry of the total force. This approach is used to model voice production because vocal fold oscillations are not considered to be driven by the acoustic impedance of lungs and vocal tract. Titze⁸ used a wave motion model to describe the movement of the tissues and Pelorson *et al.*⁹ added a second mechanical oscillator: a phase delay of the total pressure force is obtained because the shape variations of the channel are not the same during closing and opening of the glottis.

The effect of separation and reattachment of the flow in the reed channel has also been studied. Indeed, the flow separation at the inlet of the clarinet reed channel leads to a local acceleration of the flow⁵ (vena-contracta effect). Moreover, the total pressure force can also depend on the possible reattachment of the air flow on the reed further in the reed channel. The vena-contracta factor and the location of the reat-

tachment point may vary as a function of the reed position and produce a force in phase with the reed velocity. An example of the modeling of these viscous effects can be found in the study of Pelorson *et al.*⁹ At the outlet of the vocal fold channel, he studied the movement of the point where the air flow separates from the glottis. In this case, the total pressure force fluctuates because the reed surface in contact with the unsteady flow fluctuates. Although the consequences of the flow separation are qualitatively and quantitatively significant, it was not shown whether this phenomenon could induce self-oscillation without the presence of the two-mass model.

The separation points of the accordion reed flow are fixed at the sharp edge of the reed. As shown in Sec. II of this paper, there is no flow reattachment on the other side of the reed, therefore the surface of the reed immersed in the flow is constant. The flow separation/reattachment effects are not a candidate for a possible excitation mechanism of the accordion reed.

If we discard the supposition that the unsteady flow can be described by the stationary Bernoulli equation, it appears that the energy transfer from the flow to a free reed can be obtained by two other physical mechanisms. First, the vortex shedding behind a solid obstacle¹⁰ induces a periodic force on the structure. Thanks to their experimental investigations, Saint Hilaire *et al.*¹¹ concluded that vortex shedding is not responsible for the excitation of his harmonium reed. This result has been also confirmed in a recent study¹² for a blown-open reed.

At last, the inertial effect of the upstream flow has been proposed to be the excitation mechanism of free reeds¹¹ in the absence of acoustic coupling. The verification of this assumption is one of the purposes of the present work. An analysis of the flow around the accordion reed (Sec. II) shows that the flow can be modeled as an unsteady potential two-dimensional flow. In Sec. III, the aerodynamic force which excites the vibration of the reed is calculated under the incompressible flow hypothesis. From aerodynamic data, a model for the calculation of the aeroacoustic source based on an acoustic analogy is proposed (Sec. IV). Flow and aeroacoustic models are solved in the time domain and results are compared with experimental data (Sec. V). Since the attention of this paper is turned to the analysis of the exact nature of both the excitation force and acoustic source, empirical hypotheses or adjustable parameters must not be used. Because of the complexity of flow equations, the calculation of analytical expressions is only possible with a very simplified representation of the accordion reed. Therefore quantitative values of physical variables are not expected to agree with the actual ones. Only waveforms and spectra are compared to measurements.

II. FLUID MECHANICAL DESCRIPTION OF THE FLOW

The geometry of the accordion reed is slightly different from the reed geometry used by Saint Hilaire *et al.*¹¹ in their flow visualizations. The initial distance x_0 between the vibrating reed and the support plate is smaller for the accordion reed than for the Saint Hilaire arrangement. The reed is directly riveted onto the support plate, therefore x_0 is very

FIG. 1. Sketch of the Plexiglas support plate and riveted reed. The flow is from right to left. The mathematical axes used in the model (Secs. III and IV) are also shown.

small and greatly depends on the stationary profile of the reed. In our case, we can suppose that $x_0 \leq 0.4$ mm. The thickness of the support plate is another difference. The slot in the support plate will be called the exhaust channel in the following (see Fig. 1). The length of the exhaust channel in the streamwise direction is equal to the thickness of the support plate. We see that this length is quite large compared to the width of the gaps. Therefore a flow reattachment is expected to occur on the lateral walls of the exhaust channel.

In order to check the validity of Saint Hilaire's conclusions concerning the inability of wake instabilities to excite the reed and to have more details on the flow structure, flow visualizations using dye stream injections have been conducted in water. The experimental arrangement is given in Fig. 2. The accordion reed is mounted on a Plexiglas reservoir of about 800 cm³. The steel reed was $l=32$ mm in length and $b=0.2$ mm in thickness and has a mean width of $h=3.6$ mm. In air, the natural frequency of the reed is $f_0=330$ Hz. The parameter a is the remaining distance between the reed and the exhaust channel walls when the reed

FIG. 2. The experimental setup for water-flow visualizations. This setup is also used for measurements of reed displacement, aerodynamic and acoustic pressures in air flow (Sec. V). The two large arrows indicate the views of the photographs shown in Fig. 3 and Fig. 4.

FIG. 3. Side views (see Fig. 2 and Fig. 5) of the flow pattern for two dye stream injection points situated (a) in front of a reed gap, and (b) in the support plate plane. Only a central part of the reed is shown. The supply cavity is on the right. In the upstream region, the dye is convected along potential streamlines. Downstream of the reed, turbulent mixing and diffusion are visible.

is closed. It means that the width of the exhaust channel is $h+2a$. Generally, a is less than 0.2 mm. The notations for the reed dimensions are given in Fig. 1. The reed mounted on its supply cavity is immersed in a discharge tank. The height of the free surface of water in the discharge tank is maintained constant thanks to an overflow pipe. The water was supplied to the reed cavity through a narrow flexible tube from a large supply tank. The average supply pressure of the reed (the difference between the upstream and the downstream pressures) was simply set by varying the distance between the free surfaces of water of the supply and discharge tanks. A honeycomb flow straightener ensures an even upstream flow. This system is visible in the background of the photography given later in Fig. 4. Visualization of the flow field was accomplished by the injection, via a capillary tube, of a dye stream at various locations upstream of the reed.

For a supply pressure of $P_0=2000$ Pa, self-sustained oscillations of the reed can be observed. The mean velocity \bar{V} of the flow through the reed gaps can be evaluated using the stationary Bernoulli equation. The Reynolds number based on the reed width h is about $Re_h = \bar{V}h/\nu \approx 6000$ where ν is the kinematic viscosity of water. For self-sustained oscillations in air at normal playing pressure, the Reynolds number of the flow is slightly inferior to that observed in water but has the same order of magnitude. Thus, we can suppose that the excitation mechanism and the flow characteristics in water are the same as that in air flow. The frequency of reed oscillation under water flow is 142 Hz. The stroboscopic images that are not reported here clearly show that the reed oscillates on the first mode of the cantilever beam. The great difference between the oscillation frequency and the natural frequency of the reed in air is a consequence of the added mass effect of water (see Sec. III C).

Typical flow patterns are shown in Figs. 3(a) and 3(b). As expected, the upstream flow is laminar. The dye is convected along well-defined streamlines. The dye streams show

FIG. 4. Front view (see Fig. 2 and Fig. 5) of the water flow around the reed if the water discharge tank is empty. The reed also oscillates in this configuration. Water plane-jets are formed from the lateral and tip gaps. The downstream side of the reed (that is visible in the picture) is in a dry region.

that it is consistent to model the upstream flow by potential sinks. Moreover, for injection points far enough from the tip gap, streamlines lie in planes $x_3 = \text{constant}$, where x_i is the coordinate along the axis \mathbf{e}_i (see Fig. 1). Thus, the flow upstream of the reed seems to be two-dimensional. This assumption is used in the proposed flow model to describe the near-field potential flow. The outflow is turbulent. In photographs, we see the mixing and the diffusion of the dye jets downstream of the reed. However, the characteristic sizes of the turbulent structures are small compared to the reed width h . There are no large coherent vortices that could have been responsible for the reed excitation. Because of the very small gap sizes compared to the reed width and to the thickness of the support plate, the downstream flow does not have the characteristics of a wake. In fact, it appears that the jet is attached to the lateral wall of the exhaust channel.

Figure 4 shows the water flow around the reed if the discharge tank is empty so that the downstream fluid is air. Self-oscillations also occur in this configuration. The added mass effect is reduced in comparison with the first configuration because only one side of the reed is immersed in water. Thus, it is not surprising to find a vibration frequency of 206 Hz that is superior to that obtained when the upstream and downstream fluid is water. The flow view of Fig. 4 shows that the downstream flow can be considered as plane jets, which do not interact with the downstream side of the reed. Even though this configuration is unrealistic, it is interesting because it definitively shows that the downstream flow does not take part in the reed oscillation mechanism.

III. AERODYNAMIC EXCITATION AND REED OSCILLATION

A. Dynamics of the potential flow

The flow visualizations in water show that only the upstream face of the vibrating plate is in contact with the moving fluid. Therefore the excitation force must be evaluated by integrating the aerodynamic pressure fluctuation over the upstream face. The flow through the reed gaps can be supposed

FIG. 5. Sketch of the flow patterns through the reed gaps in a plane $x_3 = \text{constant}$. The upstream flow is a potential flow induced by the sinks (the lateral gaps). Downstream of each gap, the flow is a plane wall-jet, and it turns to a turbulent free-jet after separation from the exhaust channel walls.

incompressible because the Mach and Helmholtz numbers are very small. Even if the downstream jets are turbulent at the exit of the exhaust channel, it can be considered to be laminar and irrotational to a certain extent from the gaps. Consequently, potential expressions are used to model the upstream and downstream flows. In this analysis, the inviscid two-dimensional flow is described in a section perpendicular to the length of the reed (plane $x_3 = \text{constant}$). This section is supposed to be far enough from the tip of the reed to avoid three-dimensional effects. Using the superposition property of potential flows,¹³ the total flow could be found by the summation of the identical potential flows created by the two lateral gaps drawn in Fig. 5. However, in order to obtain the most simple mathematical expressions, it is reasonable to suppose that the physics of reed excitation can be described considering simply one-gap flow. This very simplified representation of a blown-closed free reed is shown in Fig. 6.

The width of the gap is $e(t) = \sqrt{x_2^2(t) + a^2}$ if $x_2(t) > 0$ and $e(t) = a$ if $x_2(t) < 0$. The flow past the reed is approximated by assuming that the reed lies in the support plate plane $x_2 = 0$. The potential of the upstream flow is expressed as the sum of a continuous distribution of fluid sinks,¹³

$$\phi_1(x_1, x_2, t) = -\frac{1}{\pi} V(t) \int_0^{e(t)} \ln \left(\frac{\sqrt{(x_1 - u)^2 + x_2^2}}{e(t)/2} \right) du, \quad (1)$$

where $V(t)$ is the velocity of the downstream jet. The jet velocity $\mathbf{V}_2 = -V(t)\mathbf{e}_2$ is supposed to be constant across the gap, along the axis \mathbf{e}_1 . The integral of Eq. (1) can be analytically evaluated. The expressions of $\phi_1(x_1, x_2, t)$ and the velocity $\mathbf{V}_1(x_1, x_2, t) = \mathbf{grad}(\phi_1)$ are given in Appendix A. The logarithmic singularity in the expressions of the potential and velocity at points (0,0) and $(e(t), 0)$ are a classical consequence of the inviscid potential model. At these points, the

C. Reed motion and reciprocal flow

It has been previously shown that the motion of a free reed^{14,15} is almost perfectly sinusoidal. Laser vibrometer system measurements that are not reported here have also been made on our accordion reeds and the results are consistent with the previous observations. Thus the reed can be modeled by a mass-spring-damping single oscillator system. The reed motion leads to a reciprocal fluid current that is not dependent on the main unsteady flow. The contribution of the reed surface vibration to the total pressure can be studied using the radiation impedance of a baffled rectangular piston $Z_m(\omega) = F_2(\omega)/u(\omega)$, where $u(\omega)$ is the normal velocity of the reed and $F_2(\omega)$ is the reaction force of the fluid back on the driving piston for an angular frequency ω . For $\omega l/c_0 \ll 1$, where c_0 is the speed of sound, the largest term in Z_m is its imaginary part, the reactance. Morse and Ingard¹⁶ calculated the expression of the reactance of a baffled rectangular piston for one of its faces,

$$F_2(\omega) = -i\omega m_f u(\omega), \quad \text{with}$$

$$m_f = \frac{8}{9\pi} \rho_0 l h \frac{l^2 + lh + h^2}{l+h}. \quad (9)$$

This force F_2 is in an opposite phase with the reed acceleration and it describes that the fluid entrained by one reed side has an apparent mass of m_f . Consequently, the effective fluid mass $2m_f$ must be added to the accelerated reed mass m in the two-dimensional reed motion equation,

$$\frac{(m+2m_f)}{l} \frac{\partial^2 x_2}{\partial t^2} + \frac{c}{l} \frac{\partial x_2}{\partial t} + \frac{k}{l} (x_2 - x_0) = F_1(t), \quad (10)$$

where c and k are the equivalent damping and stiffness of the reed. The added mass causes a decrease of the natural frequency of the reed. In air, this effect is very small but in a heavier fluid such as water the difference between the intrinsic natural frequency and the measured natural frequency can be very large. The reed oscillator coefficients have been determined by a classical experimental procedure based on static stiffness evaluation and free decay behavior. These measurements are not detailed in this paper. The oscillator mass is determined from the measurement of the natural frequency of the reed in air. The experimental effective mass then includes both the intrinsic mass m and the added mass of air $2m_f$. In fact, the study of the reed-induced reciprocal flow is only useful for the estimation of the near-field resultant pressure that is added to the aerodynamic pressure $P_1(t)$ for comparisons with experimental data (Sec. V). In the near field of the upstream region, the mean fluctuating pressure associated with the reed reactance is

$$P_2(t) = -\frac{1}{lh} m_f \frac{\partial^2 x_2}{\partial t^2}. \quad (11)$$

Moreover, it is worth noting that the reciprocal flow associated with the reed reactance must not be taken into account for the calculation of the far-field acoustic pressure.

In this section, we have written in the time domain the equations of flow and reed motion. If we notice that $V(t)$ and $\partial V/\partial t$ can be expressed as a function of $x_2(t)$ and $q(t)$ and

their time derivative, we see that the model of reed excitation is a differential system of two coupled nonlinear equations (5) and (10) with the unknowns $x_2(t)$ and $q(t)$. A fourth order Runge–Kutta algorithm is used for the numerical system solving. The nonconstant coefficients of the differential system are updated at each step of the Runge–Kutta procedure.

IV. AEROACOUSTIC MODEL

As for other wind instruments, the sound produced by the accordion is a consequence of the unsteady flow through the reed apertures. But unlike resonator-coupled instruments, we cannot deduce the sound from the analysis of the resonator response to the inlet unsteady flux. For the accordion reed, we can consider that the fluctuating fluid flow acts directly as a source of sound on the free acoustic medium. Therefore we neglect in the model all contributions of reflection or diffraction of acoustic waves on the neighboring solid walls.

A. Lighthill's acoustic analogy

The problem of sound production by flow was first investigated by Lighthill¹⁷ in 1952. His theory is based on the comparison between the exact equations of fluid motion with the equations of sound propagation in a medium at rest. The mass and momentum conservation equations are rewritten to form the most general inhomogeneous wave equation,

$$\frac{\partial^2 \rho'}{\partial t^2} - c_0^2 \nabla^2 \rho' = \frac{\partial^2 T_{ij}(\mathbf{y}, t)}{\partial y_i \partial y_j} \quad (12)$$

where $\rho' = \rho - \rho_0$ and $p' = p - P_{\text{atm}}$. The tensor $T_{ij} = \rho u_i u_j + (p' - c_0^2 \rho') \delta_{ij} - \tau_{ij}$ is the Lighthill stress tensor where δ_{ij} is the Kronecker delta and τ_{ij} is the viscous stress tensor. The summation convention on indices i and j is used. For high Reynolds, low Mach number flows and in the absence of thermal sources the Lighthill stress tensor can be reduced¹⁷ to $T_{ij} \approx \rho_0 u_i u_j$. With this simplification, the source term of Eq. (12) expresses the variation of the rate of momentum flux which is induced by turbulent processes. The upstream sink flow is not turbulent and, arguing that the upstream and downstream acoustic waves are the same but with an opposite sign, it becomes evident that the turbulent sources are not important in the generation of an accordion reed sound for both the blowing and drawing notes. However, the physics of aeroacoustic sources can only be analyzed by using the mathematical expressions of the far acoustic field. The far-field acoustic pressure is calculated using the convolution product of Lighthill's source with the free-space Green's function. In this case, the spatial derivatives of Lighthill's tensor with respect to the source position must be rewritten in terms of derivatives with respect to the observer's position. By a careful mathematical analysis^{18,19} of the bounded volume integration of Lighthill's tensor, mass and momentum sources appear as residual terms of the Lighthill tensor flux through the surface that bounds the volume. These monopole and dipole terms on the surface add to the quadrupole source generated by turbulence in the control volume. This analysis was first proposed by Curle,¹⁸ and

Ffowcs Williams and Hawkings²⁰ gave a rigorous mathematical framework in order to take into account solid or fictitious (permeable) control surfaces and moving solid bodies.

B. Application of the permeable Ffowcs Williams–Hawkings integral method

The Ffowcs Williams–Hawkings (FW–H) integral method²⁰ was first used for the calculation of noise generated both by turbulence and moving impenetrable surfaces, but recently the FW–H equation has been validated as an integral formulation with permeable surfaces.^{21,22}

The derivation of the FW–H formulation is based on the mathematical technique of generalized functions. A generalized function is formed with the aid of Heavisides’s function $H(f)$ defined to be unity where $f > 0$ and zero where $f < 0$. The equation $f = 0$ defines the control surface Σ .

The Navier–Stokes equations are written for the generalized density $H(f)\rho'$, momentum $H(f)\rho u_i$, and pressure $H(f)p'$. As for Lighthill’s equation (12), an inhomogeneous wave equation can be expressed from the mass and momentum conservation equations. Details of the derivation of the FW–H equation from conservation laws are given by Brentner and Farassat.²³ For a nonmoving permeable surface, the inhomogeneous wave equation is

$$\begin{aligned} & \frac{\partial^2 \rho' H(f)}{\partial t^2} - c_0^2 \nabla^2 \rho' H(f) \\ &= \frac{\partial^2 T_{ij} H(f)}{\partial y_i \partial y_j} - \frac{\partial}{\partial y_i} \left((\rho u_i u_j + p \delta_{ij} - \tau_{ij}) \delta(f) \frac{\partial f}{\partial y_j} \right) \\ &+ \frac{\partial}{\partial t} \left(\rho u_j \delta(f) \frac{\partial f}{\partial y_j} \right). \end{aligned} \quad (13)$$

Generally, the control surface Σ is supposed to enclose all the volume sources described by Lighthill’s tensor T_{ij} . Then, $T_{ij}H(f) = 0$ for $f \geq 0$. Moreover, as the free-field Green’s function is used for the calculation of the far-field acoustic pressure, all the possible flow/acoustic interactions and acoustic wave reflections on solid walls must be taken into account as flow variables on the control surface. Because of our incompressible approach, all these effects are neglected in the source terms. Finally, neglecting the viscous stress tensor in the second term of the right hand side of the FW–H equation, we see that the acoustic sources can be divided into a monopole Q and a dipole F_i that are calculated on the permeable control surface,

$$\begin{aligned} Q(\mathbf{y}, t) &= \rho u_j \frac{\partial f}{\partial y_j} \approx \rho_0 u_j \frac{\partial f}{\partial y_j}, \\ F_i(\mathbf{y}, t) &= -(\rho u_i u_j + p \delta_{ij}) \frac{\partial f}{\partial y_j} \approx -(\rho_0 u_i u_j + p \delta_{ij}) \frac{\partial f}{\partial y_j}. \end{aligned} \quad (14)$$

The free-field solution of Eq. (13) is the convolution product of the source terms with the free-space Green’s function. After rearrangement of the integral expressions (see Appendix C), the density fluctuations are given by

$$\begin{aligned} \rho'(\mathbf{x}, t) &= \frac{1}{4\pi c_0^2} \frac{\partial}{\partial x_i} \int_{\Sigma} \left[\frac{\rho_0 u_i u_j + p \delta_{ij}}{r} \right] n_j d\Sigma \\ &+ \frac{1}{4\pi c_0^2} \frac{\partial}{\partial t} \int_{\Sigma} \left[\frac{\rho_0 u_j}{r} \right] n_j d\Sigma, \end{aligned} \quad (16)$$

where the square brackets denote that the functions are evaluated at the retarded time $\tau = t - r/c_0$ and n_j are the components of the unit outward normal vector to surface. When $|\mathbf{x}| \ll L \ll \lambda$, where L is a typical dimension of the control surface Σ and λ is a typical wavelength of the sound generated, a classical simplification procedure^{18,17} leads to the final expression of the acoustic pressure,

$$\begin{aligned} p_{ac}(\mathbf{x}, t + |\mathbf{x}|/c_0) &= \frac{1}{4\pi c_0} \frac{x_i}{|\mathbf{x}|^2} \frac{\partial}{\partial t} \int_{\Sigma} (\rho_0 u_i u_j + p \delta_{ij}) n_j d\Sigma \\ &+ \frac{\rho_0}{4\pi |\mathbf{x}|} \frac{\partial}{\partial t} \int_{\Sigma} u_j n_j d\Sigma. \end{aligned} \quad (17)$$

Obviously, the second integral on the right hand side of Eq. (17) is the expression of the total volume flux through the control surface that is evidently equal to $q(t)$. The first source term of Eq. (17) has a dipolar form and its value is evaluated numerically using an adaptive recursive Simpson’s rule.

V. EXPERIMENTS AND MODEL VALIDATION

A. Experimental study in air

The experimental setup for air measurements is similar to that used for water visualizations (Fig. 2). The water supply tank is replaced by a low-impedance pressure source that insures a constant blowing pressure inside the reservoir. A probe microphone measures the aerodynamic pressure at a few millimeters from the upstream face of the reed. A variable capacitance transducer is used for the motion of the reed. This transducer is based on a condenser microphone, the membrane of which is electrically replaced by the reed. A water manometer measures the average supply pressure and a microphone captures the radiated sound. This microphone is located at 25 cm downstream of the reed.

In Fig. 7, displacement, aerodynamic pressure and acoustic pressure are represented for a reed with a natural frequency of $f_0 = 795$ Hz. The characteristic dimensions of the valve are $l = 22.9$ mm, $h = 2.5$ mm, $a = 0.14$ mm, and $x_0 = 0.2$ mm. The supply pressure is $P_0 = 40$ Pa. As expected, we see in Fig. 7(a) that the reed motion is composed of sinusoidal oscillations around a displaced equilibrium position. We note that for low playing pressure, the steady displacement of the reed is small and we can consider that the equilibrium position is about x_0 . Figure 7(b) shows a sharp aerodynamic pressure spike at the moment when the reed enters the slot. Since the equilibrium position is not so far from the plane $x_2 = 0$, the force induced by this strong pressure variation is nearly in phase with the reed velocity. Thus, it provides energy to the oscillator. Similarly at the reed opening, a negative pressure variation occurs but it is less violent. The downstream acoustic signal shown in Fig. 7(c)

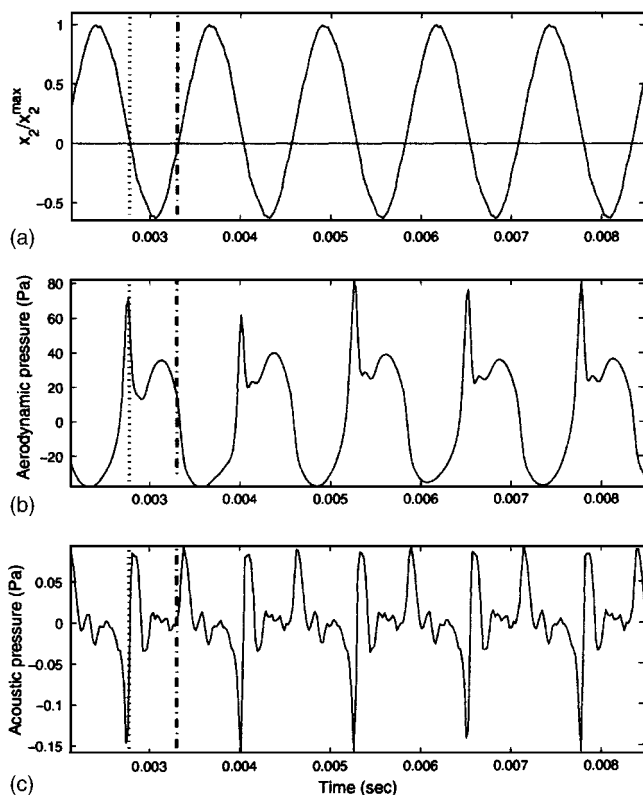

FIG. 7. Experimental measurements in air flow: (a) reed displacement; (b) upstream aerodynamic pressure; (c) downstream acoustic pressure. \cdots , closing of the valve; $-\cdots-$, opening of the valve.

greatly differs from the aerodynamic pressure waveform. This illustrates the complex conversion mechanism of the fluid mechanical energy into acoustic energy. Only the sharp pressure spike associated with the reed closure is common to the two waveforms with an opposite sign. This reverse sign results from the quasi-symmetry of the upstream and downstream flow with regard to the aperture plane. Figure 8 shows the spectrum of the acoustic pressure. In the rich spectral distribution of the reed sound, the odd harmonics are predominant. It is interesting to note that both the waveform and

FIG. 8. Spectrum of the measured acoustic pressure.

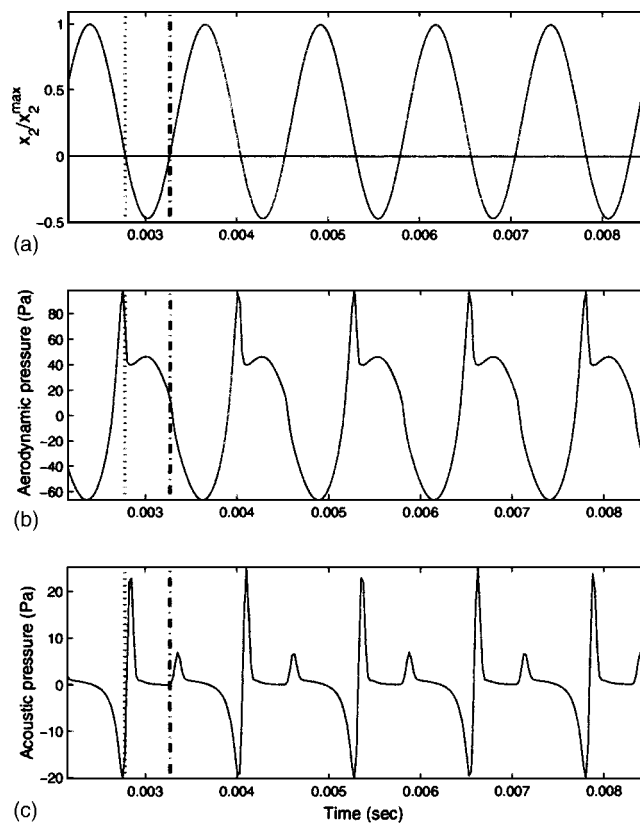

FIG. 9. Results of the model calculation: (a) reed displacement; (b) aerodynamic pressure at point C; (c) reverse of the acoustic waveform at point D. \cdots , closing of the valve; $-\cdots-$, opening of the valve.

spectrum of the acoustic signal compare well with signals extracted from recordings of accordion notes.²⁴

B. Application of the model

For the calculation, the model variables are initialized at zero and the reed position is set to x_0 . The differential equation system, Eqs. (5) and (10), is solved using Eq. (8) for the excitation force. After the transient, self-sustained sinusoidal oscillations are observed at the natural frequency of the reed [see Fig. 9(a)]. Using the computed fluid variables $q(t)$ and $V(t)$, the aerodynamic pressure at point C of Fig. 6 is computed from the Bernoulli equation (3) with the complete expression of the potential derivative, Eq. (A3). For a comparison with the probe microphone signal, the contribution $P_2(t)$ of the reciprocal flow is added to this aerodynamic excitation pressure. The total signal is plotted in Fig. 9(b). The agreement with the measured waveform is good.

Since the downstream flow model is very simplified compared to the actual development of turbulent spreading jets, the acoustic pressure is calculated in the upstream region. The symmetry property of the produced sound is used to compare the calculated signal to the acoustic measurement performed in the downstream region. The modeled acoustic pressure is the external acoustic pressure that would be measured if the reed oscillated in its sucking configuration. The fluid variables calculated on the control surface Σ defined in Fig. 6 are introduced in the integral equation (17). The result is plotted in Fig. 9(c). Even if the pressure spike occurring just after the reed opening is smaller than the measured one,

FIG. 10. Spectrum of the modeled acoustic pressure.

the modeled waveform reproduces quite well the experimental acoustic signal. Moreover, it is shown in Fig. 10 that the odd harmonics of the modeled sound spectrum are more powerful than the even ones, which is a characteristic of the accordion reed sound. Examples of synthesized sounds are available on the IRCAM website.²⁵

C. Analysis of the aerodynamic excitation

From the previous comparisons, we can suppose that the physics of both reed excitation and acoustic emission are well reproduced by the model. The calculation results can be used to highlight some details of the physical mechanisms.

For example, Fig. 11 shows the components of the aerodynamic pressure force $F_1(t)$ associated with the Bernoulli force [the first term of Eq. (8)] and inertial force [second and third terms of Eq. (8)]. This figure clearly demonstrates that the inertial force is a negligible part of the total force. In most reed models,^{1,5,2,4} inertial forces are neglected. This simplification can also be done for the accordion reed model and from Eq. (8), the average excitation pressure on the upstream face of the reed is now

FIG. 11. A comparison of the three terms of the aerodynamic force given by Eq. (8): ---, first term; Δ , second term; +, third term; -, total force.

$$\langle P_1(t) \rangle = -\frac{1}{h} F_1(t) = \frac{\rho_0}{2} V^2(t) (1 - A_1(t)). \quad (18)$$

Replacing the fluid velocity in Eq. (18) by its expression given by Eq. (5), the average pressure becomes

$$\langle P_1(t) \rangle = -\rho_0 K_0(t) (1 - A_1(t)) \frac{\partial q}{\partial t} + P_0 (1 - A_1(t)). \quad (19)$$

As explained before, the contraction effect associated with $A_1(t)$ does not contribute to the excitation mechanism. Thus, the term $P_0(1 - A_1(t))$ on the right hand side of Eq. (19) is not an excitation pressure. Finally, the expression of the excitation pressure is

$$\langle P_1(t) \rangle_{exc} = -\rho_0 K_0(t) (1 - A_1(t)) \frac{\partial q}{\partial t}. \quad (20)$$

This relation looks like an impedance relation giving the pressure as a function of the volume flux. In this case, the impedance is inertial. The value of the equivalent ‘‘acoustic’’ inertia $M(t) = \rho_0 K_0(t) (1 - A_1(t))$ is time-dependent.

Unlike traditional theoretical approaches of oscillating valves¹ based on acoustic impedances of upstream and downstream volumes, Eq. (20) is related to the impedance of the orifice. $M(t)$ can be interpreted as the mass end correction¹⁶ of the upstream side of the gap. The mass end correction depends on the detailed form of the potential flow and gap geometry. Thus, the time dependence of $M(t)$ is due to the variation of gap size. In particular, $K_0(t)$ is related to the total quantity of fluid that takes part in the inertial mechanism. For the calculation presented in this paper, the average value of the parameter K_0 is 4.5. This corresponds to a very large distance of the reference point B where the pressure is supposed to be constant and the fluid velocity is zero. The choice of point B is arbitrary but first applications of the aerodynamic model show that the influence of K_0 on the result becomes small above a certain value that depends on dimensions and characteristics of the simulated reed.

D. Analysis of the sound production

In addition, the presented model allows us to analyze the mechanism of sound production. The monopole and dipole sources of Eq. (17) are represented in Fig. 12. It appears immediately that the sound of the reed is dominated by the dipolar component. This observation is in opposition to the physics of the reed coupled to a resonator. Indeed, as mentioned in the Introduction, the acoustic source exciting the air column of the resonator is modeled as the variation of the volume flux through the reed gaps. In the case of a free reed, the monopolar source associated with unsteady volume flux at the orifice is negligible, the acoustic waves are excited by the violent changes of momentum flux through the orifice.

VI. CONCLUSIONS

In this paper, a simplified representation of a blown-closed reed used, for example, in accordions has been studied. The flow around the reed is described using an incompressible potential flow theory and the excitation force in this

FIG. 12. A comparison of the monopole and dipole terms of the acoustic expression, Eq. (17): Δ , monopole term; $-\cdot-$, dipole term; $-$, total aeroacoustic source.

model is associated with the inertial load of the upstream fluid. The delay in the variation of upstream fluid velocity due to the inertia leads to a velocity fluctuation in the reed opening. Unlike for resonator-coupled reeds, the pressure-velocity relationship is not driven by the impedance of upstream and downstream volumes but by an equivalent inertial impedance of the gaps. One of the difficulties arises from the time-dependence of the orifice geometry which leads to a time-dependent mass inertia.

This work also provides the first model of the source of sound generated by a free reed in the absence of a resonator. Despite the numerous simplifications made in the calculation, the qualitative agreement of the synthesized pressure signal with the measured one in terms of waveform and spectrum is quite good. The model is based on the application of an acoustic analogy that allows the derivation of the acoustic pressure in the far-field as a function of the aerodynamic variables known in the source region. In our case, the acoustic source is calculated in the time domain but it is also possible to perform the calculation in the frequency domain.

ACKNOWLEDGMENTS

The authors wish to thank Agnès Maurel and Philippe Petitjeans of the Ecole Supérieure de Physique et de Chimie Industrielles for helpful discussions about the flow visualization arrangement. We also want to thank Alain Terrier and Gérard Bertrand of IRCAM for their help in the measurements.

APPENDIX A: CALCULATION OF THE UPSTREAM FLOW

In this appendix, the analytical expressions of the flow potential and velocity for the upstream region are given.

1. Flow potential in the upstream region

The upstream potential is given by Eq. (1):

$$\phi_1(x_1, x_2, t) = -\frac{1}{\pi} V(t) \int_0^{e(t)} \ln \left(\frac{\sqrt{(x_1 - u)^2 + x_2^2}}{e(t)/2} \right) du. \quad (\text{A1})$$

The coordinates x_1 and x_2 are given in Fig. 6. $V(t)$ is the fluid velocity through the gap and $e(t)$ is the gap size. After calculations, one can obtain the explicit expression of the potential:

$$\begin{aligned} \phi_1(x_1, x_2, t) = & -\frac{1}{\pi} V(t) \left(\frac{1}{2} e(t) \ln \left(\frac{(x_1 - e(t))^2 + x_2^2}{(e(t)/2)^2} \right) \right. \\ & - \frac{1}{2} x_1 \ln \left(\frac{(x_1 - e(t))^2 + x_2^2}{x_1^2 + x_2^2} \right) + x_2 \left(\arctan \left(\frac{x_1}{x_2} \right) \right. \\ & \left. \left. - \arctan \left(\frac{x_1 - e(t)}{x_2} \right) \right) \right) + \frac{1}{\pi} q(t), \quad (\text{A2}) \end{aligned}$$

where $q(t) = V(t)e(t)$ is the volume flux through the gap.

2. Time derivative of the flow potential in the upstream region

The time derivative of the flow potential given by Eq. (A2) is

$$\begin{aligned} \frac{\partial \phi_1(x_1, x_2, t)}{\partial t} = & \frac{1}{\pi} \frac{\partial V}{\partial t} \left(\frac{1}{2} x_1 \ln \left(\frac{(x_1 - e(t))^2 + x_2^2}{x_1^2 + x_2^2} \right) \right. \\ & \left. - x_2 \left(\arctan \left(\frac{x_1}{x_2} \right) - \arctan \left(\frac{x_1 - e(t)}{x_2} \right) \right) \right) \\ & + \frac{1}{\pi} \frac{\partial q}{\partial t} \left(1 - \ln \left(\frac{\sqrt{(x_1 - e(t))^2 + x_2^2}}{e(t)/2} \right) \right). \quad (\text{A3}) \end{aligned}$$

3. Components of the velocity vector in the upstream region

The two components of the upstream velocity vector are found by calculating the gradient of the potential ϕ_1 [Eq. (A2)]:

$$\begin{aligned} V_{1,x_1}(x_1, x_2, t) = & \frac{\partial \phi_1}{\partial x_1} = \frac{V(t)}{2\pi} \ln \left(\frac{(x_1 - e(t))^2 + x_2^2}{x_1^2 + x_2^2} \right), \quad (\text{A4}) \\ V_{1,x_2}(x_1, x_2, t) = & \frac{\partial \phi_1}{\partial x_2} \\ = & \frac{V(t)}{\pi} \left(\arctan \left(\frac{x_1 - e(t)}{x_2} \right) - \arctan \left(\frac{x_1}{x_2} \right) \right). \quad (\text{A5}) \end{aligned}$$

APPENDIX B: EXPRESSION OF THE AERODYNAMIC FORCE

The total force on the upstream face of the reed is given by integration of the aerodynamic pressure [Eq. (6)] over the reed width h ,

$$\mathbf{F}_1(t) = - \left(\int_{e(t)}^{e(t)+h} P(x_1, 0, t) dx_1 \right) \mathbf{e}_2. \quad (\text{B1})$$

The force then has the form

$$F_1(t) = -h \frac{\rho_0}{2} V^2(t) (1 - A_1(t)) + \rho_0 h^2 A_2(t) \frac{\partial V}{\partial t} - \rho_0 h A_3(t) \frac{\partial q}{\partial t}, \quad (\text{B2})$$

with the parameters

$$A_1(t) = \frac{1}{h \pi^2} \int_{e(t)}^{e(t)+h} \left(\ln \left(\frac{x_1 - e(t)}{x_1} \right) \right)^2 dx_1, \quad (\text{B3})$$

$$A_2(t) = \frac{1}{h^2 \pi} \int_{e(t)}^{e(t)+h} x_1 \ln \left(\frac{x_1 - e(t)}{x_1} \right) dx_1, \quad (\text{B4})$$

$$A_3(t) = \frac{1}{h \pi} \int_{e(t)}^{e(t)+h} \ln \left(\frac{x_1 - e(t)}{e(t)/2} \right) dx_1. \quad (\text{B5})$$

For an analytical calculation of the integrals, we can note that the logarithmic singularities in potential and velocity expressions are integrable.

The final expressions of the parameters A_1 , A_2 , and A_3 are given below.

1. Parameter $A_1(t)$

$$A_1(t) = \frac{1}{\pi^2} \left(\ln^2(h) + \left(1 + \frac{e(t)}{h} \right) \ln(e(t)+h) \right) \times \ln \left(\frac{e(t)+h}{h^2} \right) + \frac{e(t)}{h} \ln(e(t)) \ln \left(\frac{e(t)}{h^2} \right) - 2 \frac{e(t)}{h} \operatorname{dilog} \left(\frac{e(t)+h}{e(t)} \right), \quad (\text{B6})$$

where the dilogarithm function is defined by

$$\operatorname{dilog}(x) = \int_1^x \frac{\ln(u)}{1-u} du. \quad (\text{B7})$$

2. Parameter $A_2(t)$

$$A_2(t) = \frac{1}{2\pi} \left(\ln(h) + \frac{e(t)}{h} (\ln(h^2) - 1) + \frac{e^2(t)}{h^2} \ln(e(t)) - \frac{(e(t)+h)^2}{h^2} \ln(e(t)+h) \right). \quad (\text{B8})$$

3. Parameter $A_3(t)$

$$A_3(t) = \frac{1}{\pi} \left(\ln \left(\frac{2h}{e(t)} \right) - 1 \right). \quad (\text{B9})$$

APPENDIX C: CALCULATION OF THE ACOUSTIC DENSITY FLUCTUATIONS

The free-field Green's function is

$$G(\mathbf{x}, t | \mathbf{y}, \tau) = \frac{1}{4\pi c_0^2 r} \delta(g), \quad \text{with } g = \tau - t + r/c_0, \quad r = \|\mathbf{x} - \mathbf{y}\|. \quad (\text{C1})$$

where \mathbf{y} is a point in the source region and \mathbf{x} is the observer's position. Then the acoustic density fluctuations are

$$\rho'(\mathbf{x}, t) H(f) = \frac{1}{4\pi c_0^2} \int_{\mathcal{R}^3} \int_{\mathcal{R}} \frac{1}{r} \left(\frac{\partial}{\partial y_i} F_i(\mathbf{y}, t) \delta(f) \right) \delta(g) d\boldsymbol{\tau} d\mathbf{y} + \frac{1}{4\pi c_0^2} \int_{\mathcal{R}^3} \int_{\mathcal{R}} \frac{1}{r} \frac{\partial}{\partial t} (Q(\mathbf{y}, t) \delta(f)) \delta(g) d\boldsymbol{\tau} d\mathbf{y}. \quad (\text{C2})$$

The spatial integral of the first term can be developed as

$$\int_{\mathcal{R}^3} \frac{1}{r} \left(\frac{\partial}{\partial y_i} F_i(\mathbf{y}, t) \delta(f) \right) \delta(g) d\mathbf{y} = \int_{\mathcal{R}^3} \frac{\partial}{\partial y_i} \left(\frac{1}{r} F_i(\mathbf{y}, t) \delta(f) \delta(g) \right) d\mathbf{y} - \int_{\mathcal{R}^3} F_i(\mathbf{y}, t) \delta(f) \frac{\partial}{\partial y_i} \left(\frac{1}{r} \delta(g) \right) d\mathbf{y}. \quad (\text{C3})$$

The first integral of the right hand side is zero and noting that $\partial(\delta(g)/r)/\partial y_i = \partial(\delta(g)/r)/\partial x_i$ we can write

$$\int_{\mathcal{R}^3} \frac{1}{r} \left(\frac{\partial}{\partial y_i} F_i(\mathbf{y}, t) \delta(f) \right) \delta(g) d\mathbf{y} = - \frac{\partial}{\partial x_i} \int_{\mathcal{R}^3} \frac{1}{r} F_i(\mathbf{y}, t) \delta(f) \delta(g) d\mathbf{y} = \frac{\partial}{\partial x_i} \int_{\Sigma} \frac{1}{r} (\rho_0 u_i u_j + p \delta_{ij}) n_j \delta(g) d\Sigma, \quad (\text{C4})$$

with

$$n_j = \frac{1}{|\nabla f|} \frac{\partial f}{\partial y_j}. \quad (\text{C5})$$

The second spatial integral of the density fluctuations can be also written as

$$\int_{\mathcal{R}^3} \frac{1}{r} \frac{\partial}{\partial t} (Q(\mathbf{y}, t) \delta(f)) \delta(g) d\mathbf{y} = \frac{\partial}{\partial t} \int_{\Sigma} \frac{1}{r} \rho_0 u_j \delta(g) n_j d\Sigma. \quad (\text{C6})$$

Finally, the temporal integration of the two transformed expressions of the spatial integrals immediately gives the formulation of Eq. (16).

(Received 16 June 2004; revised 17 December 2004; accepted 22 December 2004)

An experiment was conducted to determine the response of the human lung to water-borne sound in the range of 20 to 500 Hz. A small pool inside a hyperbaric chamber was used to simulate four ambient pressure conditions spanning the range of recreational diving depths. Ten subjects were tested on two occasions each using three separate measures to evaluate the response of the subjects' lungs. With some notable exceptions, results were consistent between subjects and between measures. These indicate that human lungs can be reasonably modeled as a lumped single-degree-of-freedom system over the lower portion of the band of interest. Here, the surrounding fluid provides the dominant mass and the dominant stiffness is provided by the entrapped air with a small additional contribution from tissue elasticity. Measured resonances increase with the square root of ambient pressure from an average of 40 Hz with a quality factor of 1.8 at near-surface pressure to 73 Hz with a quality factor of 2.6 at an equivalent depth of 36.4 m. There is evidence of other resonances within or near the band of interest that may be attributable to nonvolumetric chest/lung modes, Helmholtz resonance, and/or resonance of gastrointestinal bubbles. © 2005 Acoustical Society of America. I. BACKGROUND

Advances in low-frequency active (LFA) sonar systems have raised concerns for the safety of divers that may be exposed to the acoustic radiation produced by these systems.^{1–3} Similar concerns have also been raised for the safety of sea mammals.^{1,4–6} Compliance with safe exposure levels for divers and sea mammals can dictate operational parameters for LFA sonar systems beyond the limits imposed by the physics of transduction and acoustic propagation and are therefore of great concern to system operators.⁷ Unfortunately, damage and aversion thresholds for both divers and marine life are not well understood. Physical damage thresholds are based on evidence that is anecdotal or on experiments with small animal models.⁶ Aversion thresholds have been derived from experiments that were conducted under conditions that make an extrapolation of the results to real-world scenarios difficult.^{1,2} To match existing data to these scenarios, it is necessary to develop models for the response of organ systems to incident acoustic signals in the free field. The most significant of these systems, from a predictive standpoint are those that resonate within the frequency range of a particular LFA system such as the US Navy's Surveillance Towed Array Sonar System (SURTASS) LFA. These can either be the most likely organs to be damaged by the incident sound or can act as secondary sources that mediate the exposure level of other organ systems. The SURTASS LFA frequency range is sufficiently low that the organs most likely to resonate are compliant bodies such as the lungs and other gas-filled spaces. The experiment reported here was intended to test the response of gas-filled spaces within the human body that might resonate in the SURTASS LFA fre-

quency range. Although this experiment does not provide underwater-sound-exposure criteria, the information may be of use in the interpretation of exposure criteria for depths other than those that were used in threshold-determination experiments.

II. CONFIGURATION OF THE EXPERIMENT

Ideally, the response of the human body to low-frequency underwater sound should be tested under free-field conditions. These can be simulated at sea, in a very large lake or tank, or in a water tank with effectively anechoic boundaries. The frequencies of interest for the SURTASS LFA problem make either of the latter two schemes impractical if only passive boundaries are considered. These boundaries would need to attenuate signals with wavelengths of up to 75 m at the lowest frequencies of interest. At-sea testing was deemed to be impractical because of cost and logistical constraints, and because of the potential danger to the test subjects. As an alternative to these schemes a configuration was sought in which the nature of the expected response could be used to reduce the scale of the experiment. Because the lungs are much smaller than a wavelength in water at even the highest frequencies of interest ($f = 500$ Hz, $\lambda = 3$ m) it is reasonable to assume that the radiation load imposed on their dilatational motion by the water will be dominantly reactive (i.e., mass-like). Similarly, the load imposed on a uniformly vibrating body within a small tank with soft boundaries will also be mass-like because the water within the tank moves in unison with the surface of the vibrating body, and the radiation resistance must be nearly zero because very little energy can be radiated across the bound-

FIG. 1. Spherically symmetric encapsulated radiator model for the impedance loading imposed by a small water tank.

aries. Given that the radiation impedance on the lung would be mass-like both in the small tank and in a free field, it is reasonable to explore the circumstances under which these two impedances would be effectively identical. The analysis of a simple, related system sheds considerable light on this problem.

If a sphere of radius a oscillates radially at the center of a water-filled spherical enclosure with radius b and a pressure-release outer boundary (as depicted in Fig. 1), then the spherically symmetric Helmholtz equation can be used to describe the acoustic field within the water:

$$\nabla^2 P + k^2 P = \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial P}{\partial r} \right) + k^2 P = 0. \quad (1)$$

Here $P(r)$ is the spatially dependent complex amplitude of the acoustic pressure and k is the wave number in the fluid. Two boundary conditions apply to this equation. The first of these is the pressure-release condition at the outer boundary and the second is a prescribed radial acceleration at the surface of the inner sphere:

$$P|_{r=b} = 0, \quad \nabla P|_{r=a} = -i\omega\rho v_a. \quad (2)$$

Here v_a is the radial velocity of the surface, ρ is the quiescent density of the fluid, and Euler's equation relates the pressure gradient to acceleration. The differential equation and boundary conditions can be satisfied by a spherical standing wave of the form

$$P_{\text{encl}} = \frac{-i\omega\rho v_a a^2}{ka \cos(k(b-a)) + ka \sin(k(b-a))} \times \left[\frac{\sin(kb)\cos(kr) - \cos(kb)\sin(kr)}{r} \right]. \quad (3)$$

In the absence of the outer boundary the Sommerfeld radiation condition would apply and the exterior field would be described by an outward traveling spherical wave of the form

$$P_{\text{ff}} = \left(\frac{-i\omega\rho v_a a^2}{e^{ika}[1 - ika]} \right) \left(\frac{e^{ikr}}{r} \right). \quad (4)$$

The impedance measured at the surface of the radiator ($r = a$) in either of the cases defined in Eqs. (3) and (4) completely defines the fluid loading on the radiator. Taking the ratio of the impedance at the surface of the encapsulated

FIG. 2. Impedance imposed by a tank, computed from the encapsulated sphere model, relative to free field: amplitude (a) and phase (b).

sphere to the surface impedance of the sphere in free field gives the expression

$$\frac{Z_{\text{encl}}}{Z_{\text{ff}}} = \frac{\left[\frac{P_{\text{encl}} \nabla P_{\text{ff}}}{P_{\text{ff}} \nabla P_{\text{encl}}} \right]_{r=a}}{ka \cot(k(b-a)) + 1} = \frac{1 - ika}{ka \cot(k(b-a)) + 1}, \quad (5)$$

where $Z = (P/v)_{r=a}$ for the subscripted scenario.

It is clear from this expression that the impedance of the encapsulated sphere can only approximate the free-field impedance when ka is small so that the numerator is dominantly real and the corresponding free-field impedance is reactive. Physically, this is because the fluid has no mechanism for extracting energy from the encapsulated sphere, but it can radiate away in the free field. It is also clear from Eq. (5) that the cotangent of $k(b-a)$ must be small because the impedance is very far from correct when $ka \cot(k(b-a))$ either has a large magnitude or is close to -1 . Physically, this is equivalent to the statement that resonances of the fluid volume must be avoided. These occur for values of $k(b-a) = n\pi$ for $n=0,1,2,\dots$, and for $kb \sim n\pi$ if ka is assumed to be very small. These conditions can be easily avoided if $kb < \pi/2$ and $a < b$, where the latter is an obvious geometrical requirement. The impedance ratio can be plotted in terms of the nondimensional variables $k(b-a)$ and a/b , as shown in Figs. 2(a) and 2(b). Here, a third physical intuition is reinforced. This is that the impedance is only correct if the encapsulated sphere is much smaller than its enclosure, thus

ensuring that most of the kinetic energy of the free near-field would be contained within the enclosure. Elementary considerations show that, in a free field, the total nonpropagating kinetic energy of the fluid in a spherical shell from radius a out to radius r is given by

$$T(r) = \frac{2\pi\rho a^3 v_a^2 (1 - a/r)}{(1 + k^2 a^2)} \quad (6)$$

Equation (6) approaches the radiation mass of a free-field sphere (which is three times the displaced mass of water if $ka \ll 1$) when $r \rightarrow \infty$. From Eq. (6) it is apparent that 90% of the radiation mass is contributed by fluid within 10 radii of the center of the sphere.

Human lungs have a volume on the order of 4 l. The available pool, which was designed for other hyperbaric-chamber experiments, held approximately 4000 l. Thus a/b for the experiment was about 1/10th ($\sqrt[3]{1/1000}$). The equivalent spherical radii of the lung and pool volumes are about 10 cm and 1 m respectively. Thus, $0.1 < k(b-a) < 2$, so the experiment was conducted in a region depicted in the lower left of Figs. 2(a) and 2(b), where the impedance condition on the lung-like sphere is correct to about 10% in amplitude and 10° in phase at worst. At the low end of the frequency range, where lung resonances were observed, the impedance is much closer to the free-field condition. For small gas bodies such as bubbles in the stomach and intestines, the impedance in the tank is more nearly correct than it is for the lungs. The tank was designed to fit into the hatch of the hyperbaric chamber that housed it rather than being based on the above-mentioned acoustic considerations. In spite of this, it was very nearly ideal for the lung-resonance experiment. Because the lung volume and frequency range were fixed, a significantly larger or smaller tank would have placed the experiment in a region of either a higher $k(b-a)$ or a/b value where impedance conditions are less favorable. The tank was constructed with eight sections of 6.4 mm thick aluminum that were bolted together with soft rubber gaskets. The tank was open at the top and sat inside of the much larger hyperbaric chamber. There was only contact between the tank and the chamber where the bottom of the tank rested on foam tiles on the chamber floor. The interior surfaces of the tank had been covered with a 2.5 cm layer of closed-cell foam. There were no apparent in-band structural resonances of the tank walls that would have violated the assumptions of the spherical impedance model. The combination of the tank's free surface, thin-walled construction, and the surface treatment reasonably mimicked pressure release assumption of the spherical model. The tank was irregularly shaped, but its first mode was not strongly dependent on this geometry and could be predicted by a spherical model. This mode was measured at 950 Hz, an octave above the band of interest for the experiment. More detailed tank models have been developed for measurements at or near tank resonances.⁸ However a more detailed model of the tank was unnecessary for this experiment given that the wavelengths were long in comparison to it and that a detailed model of the lungs was unavailable to embed within such a model. It should be noted that detailed lung models have been developed for other

FIG. 3. Setup of an experimental water tank inside the hyperbaric chamber (chamber not shown).

applications.^{9,10} Unfortunately, these consider excitations and loading conditions inappropriate to the problem under consideration here.

III. EXPERIMENTAL METHODS

For the experiments, each diver was seated with his upper torso in the approximate center of the tank. USRD J-11 electrodynamic transducers¹¹ were suspended in front of and behind the diver at the mid-depth along the longest dimension of the tank. This configuration is shown in Fig. 3. These two transducers were driven with identical signals so that there was coherent summation of the pressure signals and destructive interference of the velocity at the tank's center. In a free-field environment and in the farfield of a source, a subject would be exposed to an incident signal with the acoustic pressure and velocity related by the intrinsic impedance of the fluid ($P/|\vec{v}| = \rho c$). It is not feasible to achieve this condition over a significant volume in a small tank and it is not obvious which orientation of the velocity vector would be appropriate for a worst-case scenario. It is, however, likely that the acoustic pressure rather than the velocity controls lung motion in the free field. This has been shown to be a reasonable assumption in the analysis of the low-frequency response of air bubbles and other compliant scatterers.^{12,13}

Ten subjects were tested in this experiment. All of the subjects were navy divers in good health, ranging from 26 years to 41 years in age and weighing between 64 and 98 kg. There were nine male subjects and one female. Subjects were selected for their availability, willingness to participate, and ability to participate in the experimental protocol.¹⁴ Pulmonary function was tested on all of the subjects. These tests included both vital capacity and lung volume measures. The mean full vital capacity for the subjects was 6.4 l and varied by $\pm 30\%$ over the test group with a weak correlation to the subject's body mass. Residual lung volumes averaged 1 l with a $\pm 55\%$ variability and no obvious correlation to weight. Air was supplied to the subjects by a diving regulator connected to an air supply outside the tank. During the tests, the subjects were instructed to inhale a volume of air with which they were comfortable holding their breath for ~ 20 s

and that permitted them to remain stationary in the focus of an ultrasonic measurement system. Because of this, it is likely that individual preferences overwhelmed physiological differences in determining the lung volumes during the measurements. Each subject was tested twice. Each test was performed at ambient pressures (measured in the hyperbaric chamber, i.e., at the free surface of the water tank) equivalent to 0, 2.1, 17.4, and 35.7 m of seawater (0, 7, 57, and 117 ft \pm 1 ft). The subjects were seated such that their chests were approximately centered at the mid-depth of the tank, which adds an additional 0.7 m to the equivalent depth because this was used as the datum. There was some variation in this because of the differing heights of the subjects. The depths and time at each depth were determined by decompression requirements. The time constraints imposed by decompression were such that higher pressures and other equivalent depths were not practical for these tests.

Sound exposure levels were not considered as a variable of interest in this study. Incident levels were set sufficiently low to ensure the linearity of the lung response and to meet the safe exposure guideline that was in place at the time of the study, which was 160 dB (*re* 1 μ Pa rms) based on pure-tone exposure at any frequency in the range and at any depth. Levels were set sufficiently high to ensure an adequate SNR within the time available for each measurement. Each subject was exposed to a sound pressure level of 150 dB (*re* 1 μ Pa rms) computed over the 16 s duration of the broadband exposure signal. No subjects reported discomfort from this exposure.

Four techniques were used to monitor the response of the subjects' lungs during the experiments. These are depicted in Fig. 3. Two of the measurements were made with B&K™ 8103 miniature hydrophones. One of these was in contact with the subject's abdomen just below the sternum and the other was located 30 cm away in a direction perpendicular to the line determined by the two J-11s. This was midway between the tank's center and the sidewall. The near hydrophone was intended to measure the surface pressure on the subjects' lungs and the further hydrophone was intended to measure the scattered pressure in a way that would integrate over a larger area in the event that lung motion was not uniform. The further hydrophone needed to be located sufficiently far from the tank boundary, which was extremely soft, that a reasonable SNR could be achieved. The third transducer was a PCB™ 352C accelerometer (100 mV/g) that was taped over the subject's fifth intercostal space on the right side and oriented radially. The accelerometer was encapsulated in syntactic foam to make the unit neutrally buoyant. Thus the accelerometer moved in unison with the surrounding fluid, so the tape served only to ensure the location and orientation of the accelerometer rather than to provide mechanical coupling. The fourth transducer was an ultrasonic device that interrogated the motion of the lung surface through the fifth intercostal space on the subject's left. This device employed a pair of 10 MHz transducers: one functioning as a transmitter and the other as a receiver. The received signal was reflected from the lung's surface and phase modulated by the motion of the surface. A similar device has been described by Cox and Rogers.¹⁵ In this implementation

the surface displacement was extracted in real time by demodulation with a phase-lock loop (PLL). This permitted the extraction of phase information that was not possible in the technique employed by Cox and Rogers. The PLL also introduced the dominant noise source into the measurement, which significantly degraded the resolution of the system. Since the experiment reported here, the resolution of this system has been substantially improved by using a direct homodyne demodulation scheme in lieu of the PLL.¹⁶ For each measurement the subject was required to adjust the position of the ultrasonic transducers so that the ultrasonic receive signal was dominated by his lung's reflection. Subjects were aided by a real-time underwater display of the received signal. Some of the subjects proved to be less skilled at this than others and as a result the ultrasonic data are less complete than the data from other measures. Similarly, the failure of two accelerometers under pressure caused the accelerometer datasets to be less complete than the hydrophone data.

IV. DATA ACQUISITION AND PROCESSING

Data were acquired by a direct digitization of the time domain outputs of all four measures during the presentation of each incident signal using a 12-bit digitizer sampled at 8 kHz. Up to ten incident signals were presented to each subject at each depth depending on the available time and the subject's ability to adjust the ultrasonic system to produce a good carrier signal at each depth. Each signal was presented as a series of 16 half-second-long swept-frequency chirps with half-second separation. Although a single chirp of similar duration would have offered a better SNR for measuring a time-invariant response, this mode of presentation offered advantages for the post-processing of the data, including the removal of transients that occurred when the subjects moved or exhausted bubbles. Transients were removed by visual inspection of the data and the remaining signals were averaged. Some noise sources were readily apparent from the raw data. The heartrate of the subjects was apparent in several measures and, in particular, in the ultrasound data. Power line harmonics were also apparent in the data throughout the band of interest (60, 120, and 180 Hz, etc.). These were dealt with by a time-domain subtraction algorithm in which the power line signals were sampled in the quiescent intervals of the raw data. These were then comb filtered, extrapolated across the signal window, and subtracted from the signal before averaging. The averaged signals were converted to the frequency domain by means of a Fast Fourier Transform (FFT) and normalized by incident spectra to form transfer functions. Incident signals were measured at each depth with the subject absent during a compression-decompression cycle that immediately followed the measurement cycle with the subject. This was necessary because J-11 transducers exhibit a depth-dependent resonance at the low end of the band of interest (about 20 Hz when the chamber was at surface pressure).¹¹ At frequencies below this resonance, their output falls sharply, and the two transducers are poorly matched to each other. Incident levels were computed using the manufacturer's calibration constants for the hydrophones. These values were only relevant to the interpretation of the accelerometer and ultrasound data since the same hydrophones

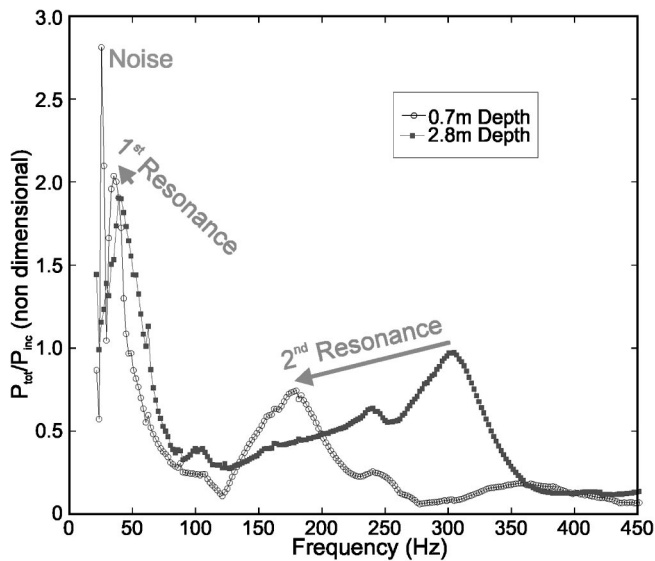

FIG. 4. Magnitude of full bandwidth total-pressure transfer functions at shallow depths from close hydrophone data.

were used for both incident and response measurements. The limited bandwidth of the chirps that were used resulted in a U-shaped noise floor for the measured transfer functions (the actual noise divided by the incident signal spectrum). The J-11s' resonance caused the lower leg of this U to shift upward in frequency with increasing depth. A second problem associated with this resonance was that the poor matching of the J-11's below the resonance frequency caused the incident field to have a significant velocity component that was not accounted for in the lung transfer functions. The amplitude and phase of the pressure associated with the resonant response of the J-11's was normalized out of the lung response when the transfer functions were formed.

Two transfer functions that were measured on a single diver at two different depths are plotted in Fig. 4. These exhibit several features relevant to the further analysis of the data. The low-frequency noise floor can be seen to mimic a resonance (or multiple resonances) in the amplitude of the transfer function. This demonstrates the importance of the inclusion of the measured phase in distinguishing between noise and resonance. There is not a substantial shift in the lower leg of the U-shaped noise floor between the two plotted measurements. The larger low-frequency noise spike associated with the shallower depth (the opposite of the previously mentioned trend) is purely a feature of the noise that was present during that measurement. A higher-frequency resonance is apparent in both transfer functions and it clearly has a stronger depth dependence than the first resonance. This can be partially explained if such resonances are attributed to gas bubbles in the gastrointestinal (GI) tract that shrink in size in addition to increasing their internal pressure and hence their stiffness with depth. An additional effect such as the dissolution of the gas in the bubble or a change in its shape or location must also be postulated to account for the magnitude of the observed changes. It should be noted that a GI bubble need not have achieved equilibrium size for either of these two datasets because gas dissolves over a long time scale and measurements at higher pressures preceded

FIG. 5. A one-degree-of-freedom model used for parameter estimation from the measured lung response near the fundamental frequency.

those that are depicted (the order of measurements was from deepest to shallowest equivalent depths). The lung, in contrast, maintains a constant volume because the subject is supplied with air at his ambient pressure through the diving regulator. The second resonance narrows the band in which the lung's response can be evaluated without the specific inclusion of other gas bodies or another plausible physical mechanism to account for this in the model for lung response. It should be noted that the apparently high quality factor ($Q \sim 6$) of fundamental resonances seen in this figure is not real.¹⁷ This is a combined effect of the U-shaped noise floor and the nature of the total-pressure transfer function that does not follow the displacement resonance curve when the pressure is measured anywhere other than directly on the surface of the lung. These effects were considered in the analysis that follows.

V. PARAMETER ESTIMATION

The lung is modeled as a lumped 1-DOF system with the stiffness (κ), damping (η), mass (M), and force (P) defined per unit of the lungs' surface area. The mass term is dominated by the radiation mass of the surrounding fluid, which would be three times the mass of fluid displaced by the lung if the lung were spherical.¹⁸ This mass may be divided into two rigidly attached masses, as is shown in Fig. 5. Here the *excluded mass ratio* (ζ) is defined as the effective entrained mass of moving fluid between the measurement location and the lungs' surface divided by the total radiation mass. Because the attachment is rigid, the response of the system is unaffected by this construction. The pressure transfer function evaluated at the rigid attachment will contain all of the salient features of the interference between the incident and scattered fields close to the surface provided that an appropriate value for ζ is selected to correspond to the measurement location. It is relatively simple to show that, for a spherical bubble, $\zeta = d/(a+d)$, with d and a the distance from the surface to the measurement point and the bubble radius, respectively. This assumes that $k(a+d) \ll 1$, where k is the wave number in the fluid. No *a priori* knowledge of lung size, shape, or measurement-to-surface standoff is re-

quired for this inversion when ζ is used in lieu of a and d . The model acceleration (7) and pressure (8) transfer functions are as follows:

$$\frac{\ddot{\xi}_{\text{surface}}}{p_{\text{incident}}} = \frac{1}{M_{\text{rad}} - i\eta\omega^{-n} - \kappa\omega^{-2}}, \quad (7)$$

$$\frac{p_{\text{total}}}{p_{\text{incident}}} = \frac{\zeta M_{\text{rad}} - i\eta\omega^{-n} - \kappa\omega^{-2}}{M_{\text{rad}} - i\eta\omega^{-n} - \kappa\omega^{-2}}. \quad (8)$$

Here n determines the damping mechanism: $n = -1, 1,$ or 2 correspond to radiation, viscous, or structural damping, respectively. Equation (7) is unremarkable and appears in different forms in textbooks on dynamics and vibrations.¹⁹ Equation (8), however, has interesting features that should be noted. First, it contains a root (for $\eta \rightarrow 0$) that accurately predicts a range-dependent pressure null in the near field of an air bubble. This null explains the false appearance of an excessively high Q in Fig. 4. Second, there are only three free parameters in (8) because a system under study can be scaled by an arbitrary constant with an identical pressure transfer function. Mathematically, this results from dividing any of the lumped parameters (M_{rad} , κ , or η) through the numerator and denominator of (8). The lumped parameters cannot, therefore, be extracted individually from an inversion of the pressure transfer function as they can from the acceleration transfer function. The third inverted parameter (ζ) describes the measurement location and not the lungs. The lumped parameter model was tested by the inversion of synthetic data generated with a free-field bubble model. An assumption of internal lung-like damping was included in the bubble model (i.e., a complex wave number for air that leads to $Q \sim 2.5$). The inversion yielded resonance frequency and Q within 1% of their true values for synthesized pressure measurements made up to one radius from the surface over a frequency range from dc to three times the fundamental resonance of the idealized bubble.

Lung resonance frequencies and Q 's were obtained by fitting (7) and (8) to the experimentally measured transfer functions over a frequency range from 20 to 120 Hz. Parameter fits were performed numerically by minimization of the rms error using the Nelder–Mead simplex search method implemented with the FMINS m file in MATLAB.^{TM20} The noise floor of the data dictated the lower bound for this band and the upper bound was set at a frequency below most of the observed high-frequency resonances that may have involved GI bubbles. Results were discarded for cases where the search algorithm did not converge, a sensor was known to have failed, a resonance was computed outside the band of the data, or the results were clearly aphysical (such as $M_{\text{rad}} < 0$, $\kappa < 0$, $\eta < 0$, $|\zeta| \geq 1$, or $\zeta < 0$). This occurred most often for datasets with poor signal to noise and was often the result of a noise spike appearing to be a resonance peak. These peaks seldom had a phase consistent with resonance, and erroneous signs of one or more model parameter frequently characterized such noise-contaminated results. The largest number of interpretable results was obtained from the close hydrophone, which was the least noisy measure. Here 76% of the data that were acquired provided meaningful parameter sets:

a total of 205 sets for all subjects and depths. The smallest number of results was obtained from the ultrasonic sensor, which was the noisiest. Here only 20% of the data were interpretable for a total of 54 parameter sets. Ultimately the ultrasonic data was of little use because of its poor signal-to-noise ratios. The second hydrophone and the accelerometer provided 190 and 165 parameter sets, respectively. Representative data and curve fits from a single measurement are shown in Fig. 6. Although this measurement is not noise-contaminated to a degree that would make it uninterpretable, the low-frequency nature of the noise along with its relative magnitude on each of the transducers can be seen. The ultrasound data depicted in Fig. 6 is less noise contaminated than it was for most of the measurements. It has been fit to the model in two ways, both considering and neglecting the phase of the measured velocity. The phase-independent predictions are clearly in closer accord with the other data. This may be indicative of unaccounted-for delays in the PLL circuit, but this effect could not later be reproduced and was not diagnosed at the time of the experiment.

Viscous damping offered the best fit to the data for the three scenarios that were considered (i.e., viscous, structural, and radiation damping). The manipulation of n from Eqs. (7) and (8) shows a degradation in both the mean error of the fit and the standard deviation of the resonances measured at each depth if n is varied fractionally from $n = 1$.

The natural frequencies determined by fitting Eqs. (7) and (8) to all of the data are shown as histograms in Fig. 7. The Q 's of these resonances were found from $Q \cong \sqrt{\kappa M_{\text{rad}}}/\eta$, which is taken from Meirovitch.¹⁹ These are depicted in the histograms shown in Fig. 8. Viewed independently, the mass-normalized damping from the hydrophone data and the damping from the accelerometer measurements showed no obvious depth dependence. This would predict that Q is proportional to ω_n ($\omega_n = \sqrt{\kappa/M_{\text{rad}}}$) and M_{rad} is a constant. It is clear from the figures that Q does not consistently obey this relationship. The reason for this is that the accelerometer and hydrophone predictions are in disagreement over the constancy of M_{rad} and η . Accelerometer data indicate that the depth dependence of the resonance is caused by roughly equal contributions from a stiffness that is monotonically related to depth and a radiation mass that is inversely related to depth in the presence of a depth-independent damping term. In contrast, the pressure measurements indicate that the mass-normalized damping is constant and therefore the radiation mass can only vary in direct proportion to the damping. This is one of several interesting features of the data that point to a second degree of freedom for the lung motion with a natural frequency near this frequency range.

Figure 9 shows a comparison between the fundamental resonances predicted by the 1-DOF model fits and a simple model for their depth dependence. Each of the measures has been plotted separately along with error bars that indicate the standard error of the mean for each of the measures. The agglomeration of the data is an unweighted average of all of the data from the two hydrophones and the accelerometer. The ultrasound data were omitted from this average because of a general bias toward higher frequencies that is a combi-

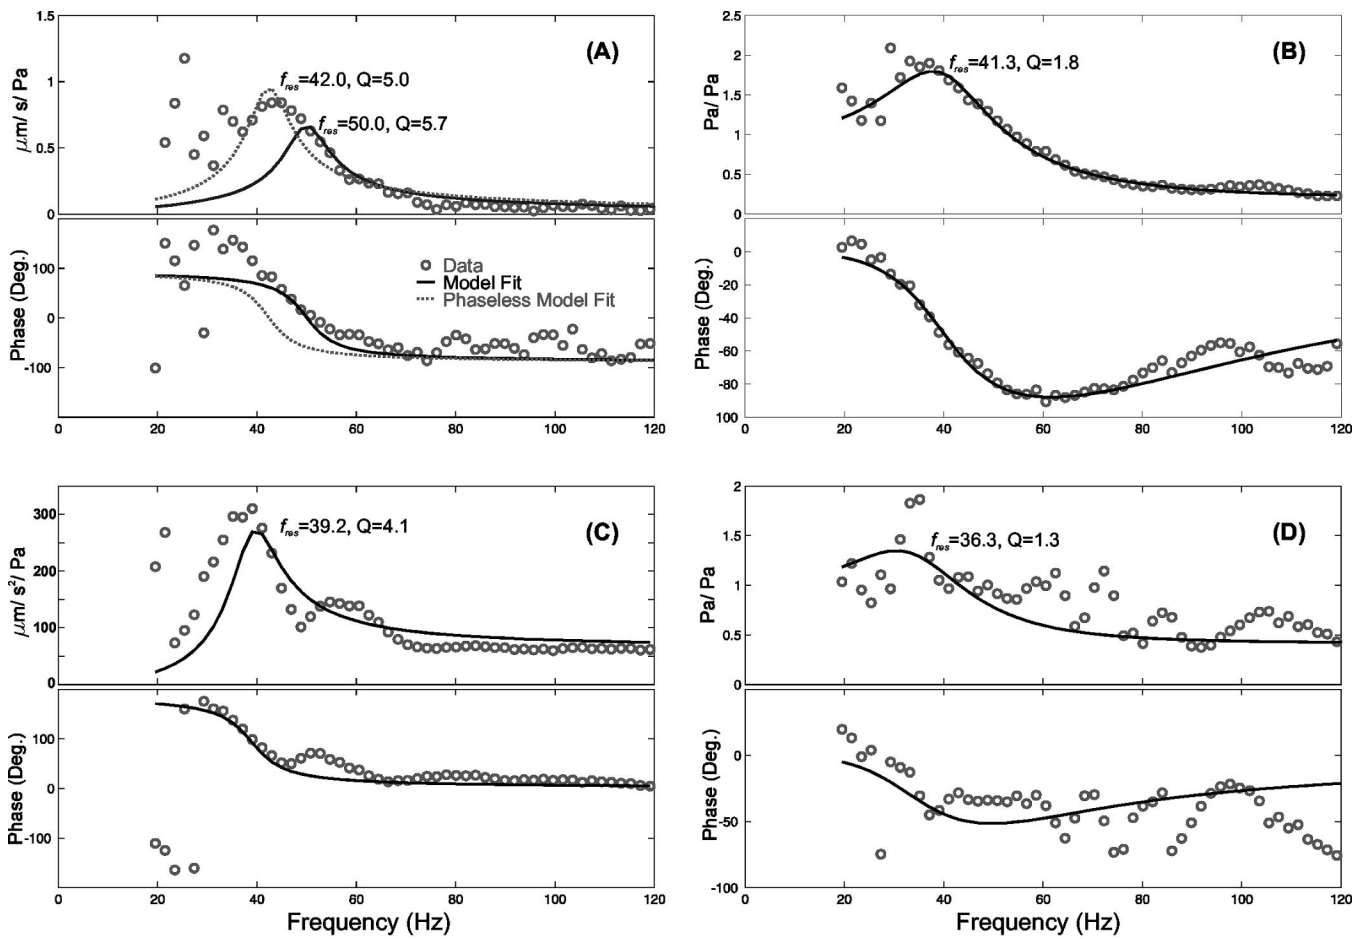

FIG. 6. Full set of transfer functions measured on subject E at 2.8 m equivalent depth: ultrasonic vibrometer (a), close hydrophone (b), accelerometer (c), and far hydrophone (d).

nation of the noise contamination of the data and the phase response of the PLL (as indicated in Fig. 6). The model is based on the assumption of a depth-dependent air spring in parallel with a depth-independent chest-wall stiffness, such that

$$f_{\text{lung}}(z) = f_0 \sqrt{\frac{p(z)}{p(0)}} + \beta, \quad (9)$$

where $f_0 = 31.7$ Hz, $\beta = 0.55$, p is ambient pressure, and z is

depth. f_0 and β were determined from a least-squares fit to the agglomeration of measured resonances. These numbers differ slightly from previously reported results from the same dataset¹⁷ because of the inclusion of additional data and the exclusion of ultrasonic data and aphysical results. In both cases the model fit falls within the error bars for the data to which it is fit. Physically, f_0 represents the natural resonant frequency of the air-spring portion of the lung at atmospheric pressure. β represents the chest wall and body tissue contri-

FIG. 7. Histograms of measured resonance frequencies on all subjects for each equivalent depth.

FIG. 9. Data model fit for depth dependence of lung resonance. Error bars indicate standard errors of the mean for each subset of data.

butions to lung stiffness normalized by the air-spring stiffness. The assumption of a depth-independent radiation mass is implicit in this model. This interpretation is reinforced by comparison of f_0 in Eq. (9), as obtained from the data with the natural frequency of a submerged air-filled spherical bubble with the same (4 l) volume. The theoretical value for the resonance frequency of a spherical bubble of radius a is given by¹³

$$f_{\text{bubble}} = \frac{1}{2\pi a} \sqrt{\frac{3\gamma P}{\rho_{\text{water}}}}, \quad (10)$$

where P is the ambient pressure, γ is the ratio of specific heats (1.4 for air), and ρ_{water} is the density of water. For a 4 l volume at one atmosphere ($P = 1 \times 10^5$ Pa) we obtain $f_{\text{bubble}} = 33.1$ Hz that is close to the empirically obtained estimate for f_0 . Equation (9) is also consistent with Andreeva's model for the resonance of a fish swim bladder as an air-filled sphere embedded in an elastic medium:²¹

$$f_{\text{swim bladder}} = \frac{1}{2\pi a} \sqrt{\frac{3\gamma P + 4\mu_f}{\rho_{\text{water}}}}. \quad (11)$$

Here μ_f is the shear modulus of the surrounding medium. Combining Eqs. (9)–(11) reveals that $\mu_f = 3/4\gamma P(0)\beta$. This predicts a shear modulus of 58 kPa for the material surrounding the lung, which is in reasonable accord with reported values for soft body tissue tissues such as blood vessels²² and slightly lower than values reported for soft rubber²³ ($\mu_f \approx 200$ kPa).

The most pronounced deviations from the model fit shown in Fig. 9 are for the measurements made at low ambient pressures. This is somewhat explainable in terms of the salient features of the corresponding datasets. The U-shaped noise floor causes a bias toward higher frequencies in all of the data. This is most pronounced at low ambient pressures because the lung resonance shows stronger depth dependence than the apparent low-frequency noise, which is amplified by the resonant response of the J-11's. Thus, the data from the close hydrophone, which was the most noise-immune measure, result in the lowest mean resonance at low

ambient pressures. Similarly, the data from the ultrasound system (not depicted in this figure) were, in general, very noisy and yielded the highest mean values for resonance frequency. The consistently lower predictions of resonance frequency from the close hydrophone compared to the other two measures depicted in Fig. 9 are interesting. These may indicate additional degrees of freedom. It is clear from Fig. 9 that an explanation that attributes the error to a single type of measure would require an adjustment to the values of f_0 and β in Eq. (9).

VI. ADDITIONAL DEGREES OF FREEDOM

Evidence that additional degrees of freedom play a significant role in the response of the lungs in the frequency range of interest includes systematic disagreements between predictions from different measures with the 1-DOF model regarding the depth dependence of the radiation mass and of the resonance frequency. There is also an obvious high-frequency resonance in much of the data acquired at low ambient pressures. Two different two-degree-of-freedom (2-DOF) models were used to study these effects.

One of these models considers the lungs as two separate systems that are mass-coupled following the simplified models of Shima²⁴ and Zabolotskaya²⁵ for a two-bubble system. Here a complex stiffness was assumed to approximate the Q 's observed in the measured transfer functions. Because the right and left lung differ in size, the new antisymmetric mode has a net volume velocity and can be excited by incident pressure, although it is likely to be more heavily damped than the fundamental mode. This model was used to generate synthetic results that were then inverted using the 1-DOF model that was used to estimate lung parameters from the experimental data. In general, the estimates were good because the two resonance frequencies were close and the low Q 's tended to smear the effects of the two modes together. The inverted parameters reasonably represented the properties of the two bubbles coalesced. There was, however, a systematic difference between the parameters that were inverted from the displacements of the larger and smaller bubbles. This offers one possible explanation for the observed resonance frequency discrepancy between measures. Confirmation of this conjecture would require additional data (such as separate right and left side measures with good SNR) and a more complicated model that accounted for actual lung geometry, nonuniform excitation, and stiffness coupling through the airways. The two-bubble model was also used to simulate the response of GI bubbles. Curves similar to those shown in Fig. 4 were generated by assuming a 3.5 cm diameter bubble in close proximity to a lung-like 20 cm diam (4.2 L) bubble at atmospheric pressure. The response of the larger bubble was negligibly affected by the presence of the smaller bubble below 120 Hz and its parameters could be inverted from the synthesized data in the 20 to 120 Hz range without consideration of the smaller bubble.

A second 2-DOF model that was considered was a mathematical model without an intrinsic physical basis. Here a second resonance (uncoupled from the fundamental resonance) was assumed to exist, and the measured transfer functions were numerically fit to the model. This resolved the

disagreement between hydrophone and accelerometer predictions regarding the radiation mass without significantly altering the fundamental resonances predicted by the 1-DOF model. The modeled second resonance was below the evaluation band and nearly depth independent. The data are best fit by a second resonance at 18 Hz, although the fit can be substantially improved over the 1-DOF model, even by the assumption of a second resonance well below 1 Hz. Its primary contribution to the transfer function is that it adds a constant-phase term in the band of interest (which is in the mass-controlled region of the conjectured mode). Because its effects are most apparent in the accelerometer data, it is likely that this resonance, if it exists, does not have an associated volume velocity and is therefore excited by the non-uniformity of the incident field. The incident pressure has a significant spatial second derivative at all frequencies and a gradient that becomes pronounced below the resonance of the J-11 transducers, where they are poorly matched to each other. Possible modes of a second lung-related resonance at these frequencies include whole-body translation, a Helmholtz resonance, or shell-like modes of the chest wall to which the entrained air does not contribute stiffness. Only the last two of these are consistent with the previously mentioned 18 Hz result. The second low-frequency resonance is a compelling explanation for the anomalous accelerometer response in that it confirms both intuition and hydrophone measurements in supporting a depth-independent radiation mass and it significantly improves the quality of the model fit. There is, however, not sufficient data to verify this conjecture.

VII. CONCLUSIONS

The frequency response of the submerged human lung was measured *in vivo* at several depths over the frequency range of 20 to 500 Hz. Although the measurements were made in a relatively small volume of water, free-field conditions were reasonably simulated with regard to the fundamental lung resonance. Three different techniques were used for the measurement: pressure was measured in the fluid around the subjects at two locations with hydrophones, chest wall acceleration was measured using an accelerometer, and lung surface motion was measured using a noninvasive ultrasonic technique. Noise problems rendered the ultrasonic data useful only as a proof-of-concept. The measurements are consistent with a lung stiffness that is a parallel combination of the chest wall and the entrained air, a dominant viscous damping mechanism contributed by body tissue, and a depth-independent radiation mass that is dominated by the surrounding fluid. Averaged measurements over ten subjects support the conclusion that lungs resonate at around 40 Hz with a mean Q of 1.8 to 2.2 (depending on assumptions regarding the existence of an additional low-frequency resonance) when normally inspired at an ambient pressure of 1.1 atmospheres. The resonance frequency increases as the square root of the ambient pressure and was measured on average at 71 Hz at a pressure equivalent to a 36.4 m submersion in seawater. At this pressure, Q 's rose to about 2.6 on average. A physical model based on the experimental data predicts that the resonance frequency would remain below

the band of interest for the SURTASS LFA system (i.e., <100 Hz) over the range of diving depths down to 86 m.

Although the analysis presumed that the lung could be characterized as a 1-DOF system, there is evidence to suggest that other modes of vibration play a role in the measured data. The more compelling of these are a depth-independent resonance at or below 18 Hz with little or no associated volume velocity that is open to several interpretations and a strongly depth-dependent resonance well above 120 Hz that may be associated with GI bubbles. Because of the small number of sensors used in the experiment, there is not sufficient data available to confirm or characterize the other modes that have been conjectured.

(Received 9 August 2004; revised 8 January 2005; accepted 18 January 2005)

Dolphins within the Navy Marine Mammal Program use echolocation to effectively locate underwater mines. They currently outperform manmade systems at similar tasks, particularly in cluttered environments and on buried targets. In hopes of improving manmade mine-hunting sonar systems, two instrumentation packages were developed to monitor free-swimming dolphin motion and echolocation during open-water target detection tasks. The biosonar measurement tool (BMT) is carried by a dolphin and monitors underwater position and attitude while simultaneously recording echolocation clicks and returning echoes through high-gain binaural receivers. The instrumented mine simulator (IMS) is a modified bottom target that monitors echolocation signals arriving at the target during ensonification. Dolphin subjects were trained to carry the BMT in open-bay bottom-object target searches in which the IMS could serve as a bottom object. The instrumentation provides detailed data that reveal hereto-unavailable information on the search strategies of free-swimming dolphins conducting open-water, bottom-object search tasks with echolocation. © 2005 Acoustical Society of America. I. INTRODUCTION

Dolphins possess a biological sonar system that is highly effective at submerged object detection and identification, is operational in open water to littoral zones, and is capable of finding buried targets. Due to the ability of the dolphin to out-perform manmade systems at submerged object detection and identification, the United States Navy has placed considerable effort into understanding dolphin biosonar (echolocation).

Past research has investigated the propagation characteristics of echolocation clicks (Au and Snyder, 1980; Au, 1980; Au, 1992), mechanisms of click production and echo reception (Brill, 1991; Bullock and Ridgway, 1972; McCormick *et al.*, 1980; Moore and Pawloski, 1990; Cranford, 2000, Dubrovskii *et al.*, 1991), adaptive production of clicks relative to the echoic task performed (Houser *et al.*, 1999), and performance at object detection and identification (Au and Snyder, 1980; Au and Penner, 1981; Helweg *et al.*, 1996). Dolphin echolocation research is traditionally confined to enclosed pen environments and requires a limitation on dolphin movement and precise placement of the subject to ensure control over the maximum response axis (MRA) of the echolocation beam [see Au (1993) for review of historical studies]. These manipulations are required to manage the complexities of click propagation but impose an artificiality that removes dolphin motion from search strategy analysis, potentially creates a relatively simple echoic task, and minimizes the clutter and reverberation that a dolphin experiences in more naturalistic environments. As such, little quantitative data are available on dolphins conducting free-swimming, open-water acoustic searches.

Prior research conducted in pens or pools is invaluable;

however, it cannot ascertain acoustic interactions with the environment, and the potentially broader variability in response afforded a free-swimming dolphin that conducts an echoic search in a natural, open-water environment. Under such conditions, information obtained on animal movement, click production, echo reception, and reception of clicks at an ensonified target can provide detailed information on dolphin echolocation that can be mined for biosonar search strategies under real-world conditions. Results can be applied to the development of signal-processing algorithms and adaptive search strategies that improve the mine-hunting capability of manmade naval assets (e.g., Au *et al.*, 1995; Gaunaurd *et al.*, 1998; Helweg *et al.*, 1996; Moore *et al.*, 1991; Roitblat *et al.*, 1995).

This paper describes the design of two instruments constructed for free-swimming dolphin echolocation studies in the natural environment. The first instrument, termed the biosonar measurement tool (BMT), permits the movement and echolocation strategy of a target-hunting dolphin to be recorded without hampering the dolphin's motion through the search field. The second instrument, the instrumented mine simulator (IMS), records echolocation clicks at the targeted mine simulator. Collectively, data from the BMT and IMS provide a composite acoustic and visual representation that can be mined for information on dolphin echolocation search strategies.

II. METHODS

A. Biosonar measurement tool (BMT)

The BMT is based on an earlier development effort termed the attitude range monitor (ARM; Sigurdson, 1997). The ARM effort investigated dolphin echolocation during

FIG. 1. Photograph of the BMT with the click detector hydrophone, binaural receivers, velocity sensor, and biteplate identified.

open-water target detection trials, but was constrained by requiring that the animal and recording instrumentation be tethered to a research boat. The BMT is mounted underneath a biteplate that the dolphin carries in its mouth (Fig. 1), thus allowing the animal to freely move throughout a search field. This design was favored over alternatives (such as backpack mounting) for simplicity, safety, and comfort of the dolphin. The dolphin is free at any time to open its mouth and release the instrumentation package. The biteplate configuration also provides a consistent mounting relationship between the dolphin and the acoustic and navigational sensors.

The BMT was developed to record a wide variety of sensor data from a free-swimming dolphin engaged in a target detection task. Sensor data include three-dimensional attitudes and dynamics of the dolphin (heading, pitch, roll, acceleration, angular rates, depth, and velocity) and three channels of passive sonar data (one for recording outgoing echolocation clicks, and two for recording echoes on paired biologically inspired high-gain binaural receivers). A low-risk approach to the development of the BMT electronics was employed through the use of Commercial Off-The-Shelf (COTS) electronics.

1. Underwater navigation

Underwater navigational data were measured using a mixture of three separate passive sensors. These included a pressure sensor (Micron Instruments, Simi Valley, CA) for measuring depth to an accuracy of ~ 8 cm and a nonmagnetic, fiberoptic, propeller-driven velocity sensor (Swoffer Instruments, Seattle, WA). Additionally, an all-attitude Crossbow® solid-state, 9-degree of freedom, Attitude Heading Reference Unit (AHRS) was used. The AHRS computed Euler angles of heading, pitch, and roll, and provided three axes each of magnetic data, acceleration data, and angular rate data. The AHRS angular rate sensors required “zeroing” on a stable platform prior to each power on use. AHRS data were used to reconstruct and analyze the dolphin’s underwater track during a search procedure and to investigate more detailed aspects of dolphin motion, such as tail thrusts (e.g., Johnson and Tyack, 2003). Due to inherent bias and stability errors associated with solid-state accelerometers, a propeller-

driven velocity sensor was required to directly measure velocity. Collectively, AHRS data combined with the depth sensor and velocity sensor data allow for estimates of x , y , and z positional data.

2. Acoustic sensors

Three channels were designed into the BMT to record acoustic data—one low-gain channel for sensing echolocation clicks produced by the dolphin, and two high-gain directional channels for sensing echoes from objects in the environment. All channels of acoustic data were continuously and simultaneously sampled to 16-bit resolution at a sample rate of ~ 314 kHz. Sigma-delta analog to digital oversampling converters were utilized to provide a frequency bandwidth of ~ 150 kHz for each channel. All channels were bandpass filtered at 12 kHz on the low end (to reduce the impact of ambient noise in the bay) and 150 kHz on the high end (for antialiasing).

Outgoing echolocation clicks were detected using a small, omnidirectional hydrophone (Reson TC4013) placed 1 m in front of the animal on the presumed maximum response axis (MRA) for outgoing echolocation clicks (Au *et al.*, 1986). This allowed echolocation clicks to be recorded unsaturated to a ceiling of 215 dB re : 1 μ Pa (peak–peak). Fidelity of data collection was maintained for each collected echolocation click by fixing the hydrophone on the presumed MRA, i.e., click variation due to movement of the recording hydrophone was minimal because the position of the hydrophone relative to the dolphin was controlled by the biteplate mounting.

Two directional hydrophones were mounted on the front of the BMT package to receive ambient acoustic data and echoes from objects ensounded by the dolphin’s echolocation. The directional hydrophones were designed to be biomimetic: the hydrophones had beamwidths comparable to behaviorally measured dolphin receive beam patterns (Au and Moore, 1984), and the spacing between biomimetic receivers, 12.5 cm, approximated the spacing of the dolphin’s auditory bullae as determined through computed tomography. The gain of the biomimetic receiver was set such that digitized data saturated at approximately 155 dB re : 1 μ Pa (peak–peak). Due to the wide dynamic range realized with 16-bit converters, and the relatively short functional range of the sonar system (under 100 m), time-varying gain was not utilized. The higher gain and directivity index associated with the directional receiver allowed for the detection of small target strength targets out to ranges in excess of 60 m. The binaural nature of the receiver permitted coherent-based processing, such as beamforming.

3. BMT controller

COTS electronics were utilized for the control computer, which consisted of a conduction-cooled 6U VME computer board with a Motorola PowerPC processor. The VxWorks Real Time Operating System (RTOS) was used for the software architecture. Another COTS 6U VME analog to digital converter board was utilized for acquiring the three channels of acoustic data. Custom electronics were required for

preamplification and signal conditioning of the acoustic channels and the depth and velocity sensors. A battery pack utilizing 10 D-size cells was used to power the unit via a COTS PC104 dc–dc converter. The converter had a switching frequency of 200 KHz, which is above the highest biosonar frequency of interest and well suited to the analog to digital converters utilized. Total power consumption was approximately 35 watts and the device was capable of running for more than an hour on one battery charge. In excess of 20 target search trials were possible on a single battery charge. The batteries were housed in a set of sealed compartments, physically separating them from the BMT controller electronics and facilitating the changing of the batteries in the field. Following a search trial, a wet mate-able underwater connector was utilized to connect the BMT to a computer on the workboat. Data were uploaded to the workboat computer over a standard 100 BaseT Ethernet connection. Time to upload the maximum amount of data collected per trial (242 MB) was approximately 25 s. The BMT was placed in a standby power mode after data upload and prior to the start of the next trial (i.e., in between data collections).

4. Workboat computer

The workboat computer interfaced to a differential global positioning system (DGPS) and implemented a user “mark” system for logging the position of the boat and targets in the search field. The position of the boat was marked when the dolphin carrying the BMT was sent from the side of the boat to search for a target, and was marked again once the dolphin returned to the boat following completion of the target search. Send and return marks allowed integration of the underwater relative navigational data into the world coordinate system (i.e., latitude/longitude). The workboat computer utilized ONTRAK© navigational software, which could be integrated with uploaded navigational data from the BMT to assess the search path of the dolphin.

B. Instrumented mine simulators (IMS)

The instrumented mine simulators (IMS) used in dolphin bottom-object searches were developed approximately 18 months after initial development of the BMT. These instruments made use of a single omnidirectional receiving hydrophone (Reson TC4013A) to collect echolocation signals produced by the dolphin. The gain on the hydrophone preamplifier was set at 40 dB [incoming clicks saturated at ~ 165 dBre:1 uPa (peak–peak)] so that incoming echolocation signals could be recorded when the dolphin was tens of meters away from the IMS. The same sigma-delta analog to digital converter chips used in the BMT were used in the IMS. However, as the IMS is stationary during trials, it contained a relatively simple COTS heading, pitch, roll sensor and no depth or velocity sensors. A COTS PC104 + Pentium-based control computer and data acquisition boards were used to reduce the footprint and expense of the IMS. A SHARC-based PC104+DSP card was used for acquiring single-channel data at a sample rate of 312.5 kHz. A D-cell alkaline battery pack and PC104 dc–dc converter were utilized to power the IMS.

FIG. 2. A three-dimensional representation of a dolphin target search relative to the start-of-search position. The axes units are in meters relative to the starting position.

The IMS included an acoustically commanded wake/sleep subsystem that allowed the IMS to be placed in the field for weeks at a time; in standby mode, an IMS could stay deployed for up to 3 weeks. Each IMS could be “awakened” before conducting dolphin search trials with a 32-kHz tone. The IMS would then continuously collect acoustic data for 18 min before automatically shutting off. IMS packages stored data on a 20-GB hard drive until they were retrieved from the field. Following recovery, data collected with the IMS were transferred to analysis computers utilizing a 100 BaseT Ethernet link.

III. DATA ANALYSIS AND ANALYSIS TOOLS

A. BMT—underwater navigational data

The collective outputs of the BMT navigational sensors can be used to create three-dimensional paths of a dolphin during an echolocation search. Coupled to acoustic data, these reconstructions permit relationships between echolocation production, target ensonification, and the spatial association between target and dolphin to be analyzed. This information is particularly useful during target-present trials in which the dolphin whistles to signify its finding of the target (see Houser *et al.*, this issue). The whistle, which is recorded by the BMT acoustic sensors, permits the acoustic information potentially processed by the dolphin prior to decision making to be segmented from the data stream. This reduces the amount of data that requires postprocessing if one is investigating the target detection and classification aspects of the dolphin’s echolocation.

Figure 2 provides a three-dimensional plot demonstrating the underwater position of a dolphin during a target search as derived from the AHRS, depth, and velocity sensors. Data corresponding to the start of the trial are referenced to the origin of a three-dimensional Cartesian coordinate system. Additional navigation data may also be plotted with position for finer analysis. Figures 3(a) and (b) demonstrate the velocity of a dolphin during a target search (in m/s), as well as the pitch angle of the animal and its acceleration in the Z dimension. Such information is useful in determining the tail thrust sequences during animal motion as well as when the animal demonstrates angular head motion, i.e., when the animal changes the region of echo inspec-

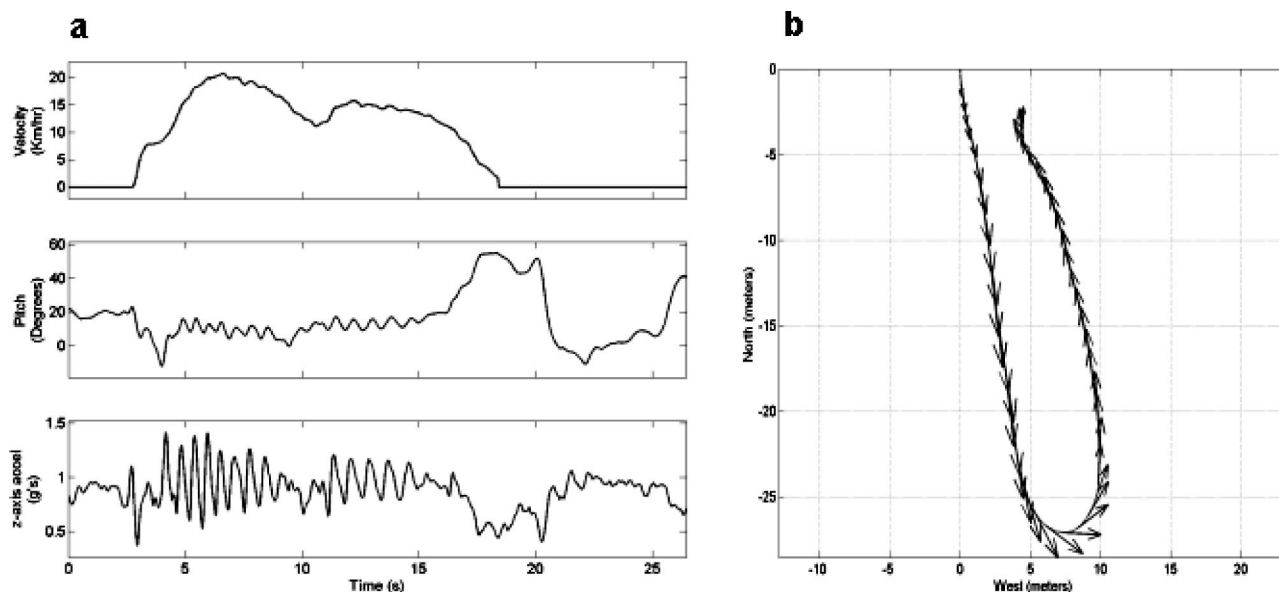

FIG. 3. (a) From top to bottom—velocity in meters/s; middle—pitch angle in degrees; bottom—Z-axis accelerometer in G’s for a dolphin on a correct, target-present trial are shown. A strong effect of tail thrust in the vertical accelerometer (Z axis) can be observed corresponding to the strongest and fastest tail thrusts of the animal in the first 1/3 of the trial. (b) A planar view of travel path in meters with relative velocity demonstrated by vector arrows. The data are from the same trial demonstrated in Fig. 2.

tion without varying the position of the longitudinal axis of its body. Figure 3(b) demonstrates the two-dimensional search of the dolphin and includes velocity information subsampled from the original AHRS data set.

B. BMT—acoustic data

Figure 4 provides an overview of the three acoustic channels of data for the trial presented in Fig. 3 (45-s trial). Figure 5 demonstrates the source level and interclick intervals for all outgoing clicks from a representative short trial.

The trial was a target-present trial and the arrows show where the dolphin whistled to indicate detection of the target. Instantaneous peak source levels are over 205 dB *re*:1 uPa and the interclick intervals (measured as the time between the two pressure peaks of successive clicks) are around 40 ms at the time of the whistle. These graphics demonstrate the utility of the collective data in exploring dolphin echolocation strategies; temporal and spectral characteristics of recorded clicks can be compared with subject attitude and position relative to the target, up to the time that the dolphin whistles to signify target detection.

FIG. 4. Acoustic time-series data for a 45-s trial (same trial as Fig. 3). Data from the outgoing click monitor (a) and binaural high-gain, directional receivers (b) are displayed. Note that saturation of the binaural receivers requires use of the time-aligned click channel to segment echolocation clicks from the echo stream.

FIG. 5. Peak amplitude in dB re: $1 \mu\text{Pa}$ and interclick interval in ms for the target search depicted in Fig. 3. The arrows indicate the point at which the dolphin whistles, indicating detection of the target.

The acoustic and navigation data can be time aligned by correcting for the start of acquisition for each sensor, thus allowing position and acoustic information to be synchronized. Time alignment is essential for segmentation of the outgoing echolocation clicks from the more sensitive binaural receiver channels (see Fig. 4). One can also gain exceptional situational understanding for each trial by coupling scientific visualization techniques with an acoustic replay of the echolocation data. Echolocation signals can be time stretched into the audible range by slowing the replay by a factor of 8. The three-dimensional dolphin position data, target position data, acoustic data streams, and timing information can then be combined to form a four-dimensional acoustic and visual representation of the dolphin search strategy. Visualization can be augmented with bathymetric features to aid in understanding the dolphin's search strategy in relation to the bathymetry and target placement (for example, see Fig. 6). Various modeling languages can be used for this type of visualization, including the VIRTUAL REALITY MODELING LANGUAGE (VRML) used in Fig. 6. VRML is interactively viewable via a Web browser through freely available plug-ins, such as Cosmo Player[®]. Once acoustic and position data are time aligned, analysis typical to echolocation studies (e.g., variation in amplitude and spectral content of clicks, interclick intervals, etc.) can be applied with added contextual information on the movement of the dolphin relative to the target.

Data collected from the binaural receivers allow backscatter produced by the dolphin's echolocation clicks to be observed. Echoes can be analyzed for temporal and spectral cues that may indicate to the dolphin the presence of a target. Because of the interaural time of arrival differences in the binaural model, it also permits beamforming, or bearing estimates, to determine the relative angle to echo sources. Standard cross-correlation techniques or more elaborate adaptive techniques (e.g., BioSAS[®], Chirp Corporation, La Jolla, CA) may also be applied to investigate echoic returns for clues to target detection. Information from these various analyses can be used to determine if a correlation exists between the frequency-dependent energy distributions of click

and echo returns and the animal's searching mode (i.e., search, acquire, confirm).

C. IMS data

Similar to navigation and acoustic data collected with the BMT, acoustic data collected with the IMS can be synchronized to BMT data after accounting for timing offsets between the instruments. This is accomplished by roughly aligning the time of day based upon internal clocks and then correlating interclick intervals recorded at the IMS with interclick intervals recorded from the BMT. Figure 7 provides a sample of acoustic information arriving at an IMS that has been synchronized with BMT data. The upper panel shows

FIG. 6. Interactive four-dimensional representation of the dolphin search depicted in Fig. 3 created using VRML. The viewer used here is CosmoPlayer[®].

FIG. 7. (a) BMT outgoing click synchronization with (b) IMS incoming clicks, both with respect to BMT heading, pitch, and roll data. The pitch and roll data are centered around 0 deg, while the heading data varies from approximately 140 deg down to 40 deg while the dolphin is searching.

the time series for echolocation click production as recorded by the BMT, as well as the simultaneously collected heading, pitch, and roll. Given the known relative position of the target to the dolphin at the beginning of the trial, bearing estimates from the BMT can be used as an additional step in verifying that the dolphin is inspecting the IMS. The lower part of Fig. 7 shows the IMS incoming acoustic data with the same time-aligned BMT heading, pitch, and roll data that appear in the upper panel. In this instance, the IMS is at a true bearing of approximately 50 deg from the location of the BMT at the time of echolocation click reception. The dolphin acoustic search pattern in terms of head motion can be observed as scanning from a 100 deg heading down to 50 deg. The IMS received signals are maximized when the BMT is pointing at a heading of 50 deg. The dolphin then scans back up towards 100 deg and comes back to 50 deg; again, the IMS data show maximal incoming signal as the dolphin scans back onto the IMS target heading. The acoustic search ends at this time.

Acoustic data from the IMS are useful in determining how many of the dolphin's echolocation clicks ensound the target. This information permits the scope of acoustic information analyzed for cues to target detection to be narrowed and provides insight into the attenuation of frequency-specific energy with click propagation. Coupled to the returning echoes recorded at the BMT, a complete acoustic circuit is observed demonstrating the type of acoustic information available to the dolphin and how that information changes as a function of range and angle of target incidence.

IV. CONCLUSION

The BMT and IMS systems permit the study of search strategies by free-swimming, echolocating dolphins operating in real-world environments. Traditionally, echolocation studies relied upon hoop or biteplate stationing to ensure the on-axis collection of echolocation clicks, necessarily con-

straining the potential behaviors of the animal and the complexity of the tasks. The ability to conduct echolocation studies on free-swimming dolphins increases the richness of behavior that can be explored, and permits a more adequate assessment of dolphin search strategies given the limitations imposed by the noise and clutter inherent to a natural environment. Furthermore, such information can be collected without sacrifice of on-axis fidelity of recorded echolocation clicks.

The instrumentation described herein has been designed to provide quantitative data for free-swimming dolphins conducting mine-hunting tasks. Researchers now are capable of having detailed insight into what dolphins actually do when free swimming and hunting for targets. The data allow researchers to better understand how the dolphin effectively accomplishes object detection and identification tasks through acoustic means. Particular to goals of target detection and identification, it allows signal-processing algorithms developed to improve mine-hunting sonar capabilities to be tested on BMT and IMS data. The performance of the algorithms can then be ranked relative to dolphin performance, which is a benchmark for mine hunting in shallow-water and very shallow-water systems (40–200 and 10–40 ft., respectively). To date, data have been collected from two dolphins engaged in free-swimming, bottom-object searches in conjunction with the deployment of both the BMT and IMS systems. Results from the analysis of the BMT data can be found in Houser *et al.* (this issue); however, the richness of the entire data set is unparalleled and requires continued in-depth analysis.

ACKNOWLEDGMENTS

The authors wish to acknowledge the financial support of the Office of Naval Research (Dr. Robert Gisiner, Dr. John Tague, Dr. Doug Abraham, and Dr. Mardi Hastings) and of the Defense Advanced Research Projects Agency (Dr. Alan

Rudolph). The authors also wish to acknowledge San Diego State University students Tim Herrin, Matt Cross, and Andrea Vidal in the development of the BMT and IMS instrumentation and VRML virtual replay capabilities. Thanks go to Robert Floyd of SPAWAR Systems Center San Diego for his consulting on measurements of dolphin echolocation parameters. For the training of difficult behaviors required in this project, the efforts of the SAIC contractor dolphin training crew are particularly appreciated.

A biosonar measurement tool (BMT) was created to investigate dolphin echolocation search strategies by recording echolocation clicks, returning echoes, and three-dimensional angular motion, velocity, and depth of free-swimming dolphins performing open-water target detections. Trial start and stop times, locations determined from a differential global positioning system (DGPS), and BMT motion and acoustic data were used to produce spatial and acoustic representations of the searches. Two dolphins (LUT, FLP) searched for targets lying on the seafloor of a bay environment while carrying the BMT. LUT searched rapidly (< 10 s), produced few clicks, and varied click-peak frequency (20–120 kHz); FLP searched relatively slowly (tens of seconds) and produced many hundreds of clicks with stereotypical frequency-dependent energy distributions dominating from 30–60 kHz. Dolphins amplified target echo returns by either increasing the click source level or reducing distance to the target but without reducing source level. The distribution of echolocation click-peak frequencies suggested a bias in the dominant frequency components of clicks, possibly due to mechanical constraints of the click generator. Prior training and hearing loss accommodation potentially explain differences in the search strategies of the two dolphins. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1867912]

I. INTRODUCTION

Interest in dolphin echolocation is spurred by curiosity over the mechanisms involved, its ecological significance, and its applicability to the improvement of manmade sonar systems (Moore, 1997; Roitblat *et al.*, 1995, 1989). Past research on bottlenose dolphins (*Tursiops truncatus*) has yielded insight into echolocation transmit and receive beam patterns (Au, 1980; Au and Moore, 1984; Au *et al.*, 1986), the time, amplitude, and frequency components of echolocation clicks (Au, 1980; Au *et al.*, 1974; Houser *et al.*, 1999), and the hearing ability of this species (Au *et al.*, 2000; Brill *et al.*, 2001; Jacobs, 1972; Johnson, 1968). Investigations on the effectiveness of echolocation in object detection and identification (Au and Penner, 1981; Helweg *et al.*, 1996; Moore, 1997) and echolocation strategies used in object detection and identification (Houser *et al.*, 1999) have also been performed, but such experiments are typically confined to pen enclosures or utilize stationing techniques to control the position of the dolphin. Such approaches control for the complexities of the acoustic environment and constrain the possible interpretation of the results.

Dolphins move in the vertical dimension of three-dimensional space to a great degree, and their primary sensory modality is acoustic, not visual, thus distinguishing them from most terrestrial mammals (excepting bats). These characteristics make conceptualization of echo-image representation within the dolphin difficult and impede our understanding of dolphin echolocation signal processing. Collecting data on free-swimming, echolocating dolphins can

provide information on how dolphins utilize echolocation in more dynamic and difficult real-world tasks, providing information on the relationship between motion, click projection, and echo reception, the amount of echoic information required for decision making, and the magnitude and types of noise (e.g., clutter echoes) that must be resolved for target detection. Such information can provide insight on mathematical principles underlying the signal processing of the echolocating dolphin that may not be obtainable with experiments confined to pen enclosures or that employ stationing techniques to constrain dolphin movement.

Three-dimensional movement during echolocation increases the complexity of signal-processing tasks necessary for object detection and identification. However, three-dimensional movement should also increase the effectiveness of echolocation; returns from successive sonar pings projected toward a point in space progressively increase information regarding that location if coupled with changes in projector position (particularly for aspect-dependent targets; Altes *et al.*, 2003, 1998). The adaptive value of motion during sonar operations is evidenced by the development of such systems as synthetic aperture sonar (SAS). It is reasonable to assume that a free-swimming dolphin, which has evolved the ability to track and capture mobile prey in a visually limiting environment, capitalizes on dynamic position within the water column while echolocating to optimize useful information contained in returning echoes. It follows that the ability to record outgoing echolocation clicks, returning echoes, and the three-dimensional orientation of a free-swimming echolocating dolphin's head can provide informa-

tion valuable to the development of signal-processing algorithms seeking to emulate dolphin performance. Furthermore, such information might provide insight into the capability and function of echolocation in ecologically important activities such as foraging and navigation.

This paper describes data collected from a hardware system specifically designed for recording echolocation in a free-swimming dolphin and that leverages anatomical knowledge of dolphin auditory system structure into its design (see Martin *et al.*, this issue). The data collection device, termed the biosonar measurement tool (BMT), consists of a recording hydrophone on axis with the echolocation beam of the dolphin, two receivers spatially separated according to the distance between the auditory bullae of the dolphin, and a Crossbow® 9-degree-of-freedom motion sensor (Attitude Heading Reference Unit), pressure sensor, and propeller-drive velocity sensor. The BMT allows for the continuous recording of echolocation clicks, returning echoes, and measurement of the movement of a dolphin's head while the dolphin is engaged in a free-swimming target detection task. This paper characterizes the echolocation strategies of two free-swimming bottlenose dolphins engaged in similar object detection tasks.

The purpose of this research is to gain a better quantitative understanding of how dolphins search for targets in highly cluttered, shallow-water environments, which provide a more difficult setting for echolocation detection tasks than traditional pen-constrained research settings. It seeks to determine the variation or consistency in search strategies between different animals given similar tasks in hopes of finding information useful in advancing signal-processing approaches to target detection and classification in shallow, cluttered environments. The ultimate goal of this research is to improve manmade sonar systems by enabling effective target searches in shallow-water and cluttered environments and to remove the Navy's need to use dolphins in the same capacity.

II. METHODS

A. Instrumentation

Details of BMT hardware design are given elsewhere (Martin *et al.*, this issue). A more general description of design and functionality are given here. The BMT consists of a data acquisition system compartmentalized within a pressurized housing that is backfilled with argon gas. The housing is suspended from a neoprene-covered biteplate that a dolphin uses to carry the unit. The BMT is activated just prior to sending a dolphin on a submerged, target detection task (see subsection B, behavioral task) and it continuously collects data on echolocation production, echo reception, and motion throughout the detection task. Data are collected from each acoustic channel, one "click" channel and two "receive" channels, at ~314-kHz sample rate with 16-bit resolution. Sigma-delta analog to digital oversampling converters are utilized that provide a bandwidth of approximately 150 kHz for each channel. All channels are bandpass filtered at 12 kHz on the low end and 150 kHz on the high end for anti-aliasing purposes. Data collection is manually terminated

when the dolphin returns from the task and reports that a target is either present or absent. Data are then uploaded to a computer through a 100-baseT Ethernet connection. Through interface with a boat-mounted differential global positioning system (DGPS), this computer also records the location of targets and buoys (see subsection B) and the location of the workboat, from which the dolphin begins and ends its search, at the start and termination of a trial. DGPS locations are used to create a map of the search field through ONTRAK® navigational software. The map is used to obtain a larger situational understanding of dolphin movement relative to the location of trials and targets in a session.

B. Behavioral task

Data were collected from two male dolphins that were trained for open-water target searches, LUT (24 years old) and FLP (25 years old). Trials were run between July 2001 and January 2003 and were performed at two open-water sites located within San Diego Bay, San Diego, CA. The test field for LUT was an approximately 132×99-m rectangle which covered a variable range of depths from a maximum of 23.8 m near the bayward boundary to the shallows of the shoreline. The test field for FLP was an approximately 231 × 112-m rectangle which covered a graded range of depths from 14 m at the bayward boundary to the shoreline. The depth grade at this site encompassed a steep upward slope on the shoreward approach from the center of the bay.

Between 4 and 6 search stations were created at each site prior to a session, with an equal number of target present and target absent stations. Each station consisted of a floating buoy alone (target absent) or a floating buoy and a target (target present). Floating buoys were tethered to the seafloor via a weighted clump. The target consisted of an aluminum ball (10-in. diameter, 0.19-in. wall thickness) attached to a short aluminum pipe and mounted on a aluminum base plate (30-in. square, $\frac{1}{2}$ in.). At target present stations, the target was placed 2–30 m away from the base of the weighted clump at arbitrary bearings. Search stations were placed so that the buoys and targets of different search stations were a minimum of 50 m apart. Search stations were rearranged between sessions to prevent memorization of target locations by the dolphins. Varying the search station positions also permitted a variable number of water depths and bottom topographies to be utilized during the trials. Furthermore, natural influx and efflux of sand, mud, vegetation, and false targets (i.e., trash) provided for an environment that varied dynamically with time.

Dolphins were trained to swim a path around the buoy at each station and to search the adjacent areas for the target. If the dolphin detected the target, it whistled, returned to the boat, and reported to a response paddle corresponding to "target present." If the dolphin did not detect the target, it finished the search path around the buoy, returned to the boat, and pressed a response paddle corresponding to "target absent." Dolphins were not required to swim around the buoy if they detected the target prior to reaching the buoy line. Conversely, a correct response on a target-absent trial required that the dolphin swim around the buoy, thus ensur-

ing that he moved through the entire search space within which a target could be placed.

All trials were run from a Boston whaler. Prior to a session, the BMT navigation sensors (angular rate gyros) were zeroed on a stationary cement piling and the BMT was put into standby mode until the start of the trial. Dolphins either swam next to the boat on the way to the test site or were trained to beach themselves on a foam-padded mat within the Boston whaler and were then transported to the test site. Two trainers were utilized for dolphin control and monitoring throughout the session. A third and fourth person were responsible for boat driving and downloading data from the BMT. Prior to the beginning of a search trial, each dolphin was required to station at a trainer's hand on the aft-port side of the boat. The second trainer placed the BMT just below the water surface on the port side of the boat with the biteplate oriented toward the dolphin. The dolphin was then cued to accept the BMT via the biteplate. Once accepted, the BMT was switched to data collection mode and the dolphin was cued to begin the trial.

The Boston whaler was positioned with the port side toward the buoy marker of a search station. Distance between the Boston whaler and buoy varied from 25–60 m. The distance was varied from trial to trial to provide a variable range of areas over which the dolphin was required to search. The ordering of target-absent or target-present trials was determined by consulting a Gellerman series. The series was balanced to provide an equal probability of absent versus present trials within a session but with no more than three trials of the same type in succession.

C. Analysis

Trials were selected for analysis based upon the following criteria: (1) unambiguous animal response; (2) no failure of system hardware during data collection or data upload; and (3) absence of system or environmental noise prohibiting the detection of echolocation clicks. Trials were segregated according to the dolphin's response to the trial. "Correct" trials were those for which the dolphin responded correctly for a target present or target absent, respectively. "Missed" trials were target-present trials that the dolphin incorrectly reported as target absent. "False-alarm" trials were target-absent trials incorrectly reported as having a target present.

Echolocation clicks were detected by using a 1000-point sliding window instantaneous peak-pressure detector with a 175-dB *re*:1- μ Pa threshold. Once detected, echolocation clicks were recorded as a 256-point waveform, with a 32-point buffer prior to the pressure peak. This threshold level occasionally captured other impulsive sounds (e.g., snapping shrimp) or triggered due to other environmental or system noise. Therefore, echolocation data were manually displayed in sequence so a human observer could verify that captured signals were echolocation clicks. Other captured waveforms were discarded from the data set.

Trial start time was defined as the time that the first echolocation click was emitted. Trial end time for target-present trials was defined as the time at which the dolphin whistled, indicating target detection and identification. Trial end time for target-absent trials was determined as the time

that the last echolocation click emitted by the dolphin was recorded by the BMT. Similar criteria were applied to trials in which the animal missed a target or a false alarm occurred; target-absent and target-present definitions for total trial time were applied to each, respectively.

Interclick interval was determined for successive pairs of clicks by measuring the time interval between the instantaneous peak pressures of each click. Interclick intervals greater than 500 ms were eliminated from the interclick interval data set and arbitrarily defined as a termination point of a click train. Each click was transformed to the spectral domain by applying a 256-point FFT, without windowing, thus producing a frequency spectra representation with a \sim 1.2-kHz bin resolution. Peak frequency, instantaneous peak pressure, and 3-dB bandwidth were calculated for each echolocation click.

Echolocation clicks were categorized according to the classification scheme of Houser *et al.* (1999), which is an extension of descriptions presented by Au *et al.* (1995). Briefly, click amplitude spectra were reduced to a number of features and categorized so that categorical analysis of echolocation clicks between trial types could be performed. Rules for click categorization were modified slightly so as to capture the more salient features of the clicks. Previous categorization of dolphin echolocation clicks resulted in a number of clicks being classified as "multimodal" because the classification scheme failed on parameters that were of secondary importance to those that more effectively described the amplitude spectrum (Houser *et al.*, 1999). Specifically, the following modifications to Houser *et al.* (1999) were made:

- (1) Type B and D clicks were eliminated from the classification scheme. These clicks consist of a low-frequency or high-frequency primary peak (within the -3 -dB band) with a secondary peak in the -10 -dB band. These categories were found to seldom occur in previous work (Houser *et al.*, 1999). The remaining categories used in this study consisted of wideband (W), low-frequency unimodal (LFU), high-frequency unimodal (HFU), bimodal (BI) and multimodal (MULTI) clicks.
- (2) Contiguous regions of the amplitude spectrum within the -3 -dB band were not counted as regions unless the bandwidth of the contiguous region exceeded 10 kHz. (For primary peaks to be calculated for a region, the bandwidth of the contiguously bounded region had to exceed 10 kHz.)
- (3) Two adjacent contiguous regions were considered one region if the frequency separation between the adjacent upper and lower frequency limits was less than 5 kHz.
- (4) The frequency considered for categorization was \sim 23–120 kHz.

Target-absent and target-present trials in which correct responses were given by the dolphin were analyzed to determine whether animals demonstrated systematic approaches to click production while performing target searches. Correct target-present trials were further separated into "search" and "acquisition" segments to assess whether click production varied as the dolphin moved from a search mode to an ac-

quisition mode. Data from the receive channels and click channel of the BMT were used to determine times that bound the two segments. The “acquisition” segment was defined as the time that the echo of the target was first detected to the time that the dolphin whistle was detected in the receive channels. The search segment was defined as the time from the production of the first echolocation click to the time that the acquisition phase began. Returning echoes from the insonified target were detected by application of a whitened and match-filtered (WMF) detector. The WMF detector was implemented by convolving the received signal with the time-reversed transmit replica. The output was half-rectified and filtered via a Hanning window. A signal level was calculated on a 32-sample frame, slipped 50%, as 10 log of the variance of the filtered output. This result was then compared to an adaptive noise level estimator and, when the signal level to adaptive noise level ratio exceeded a threshold value of 8 dB, detection was declared. A human observer with experience in identifying echoes from the specific target employed visually verified detections as originating at the target. Even with a trained observer, verification of the target echo was difficult on many trials, so only those trials for which the target echo could be verified were kept for segment analysis.

The complete number of raw detections was recorded for each animal on each trial to assess the amount of clutter that dolphins encountered during searches. Raw detections were clustered by grouping detections in the receive channel within a time frame that was equivalent to the amount of time required for sound to travel 1 m through ocean water, i.e., range clustered to 1 m, which corresponds to the maximum length of the target of interest considered for this task.

Animal movement was plotted in three dimensions by utilizing the yaw, pitch, and roll information from the Crossbow® 9-degree-of-freedom (9-DOF) motion sensor. Depth information was obtained from a pressure sensor and velocity information was obtained from a propeller-driven velocity sensor (Martin *et al.*, this issue). The pressure sensor was used for actual depth determination, and comparisons were made with the depth profiles calculated using the integrated output of the angular rate and acceleration sensors. Furthermore, it permitted the determination of continued descent by the dolphin during periods where the dolphin was descending but looking upward in the water column. (The 9-DOF sensor is essentially fixed with respect to the animal’s head as a result of biteplate mounting. This allows accurate measurement of where echolocation clicks are directed and the reception of echoic information similar to what the dolphin receives. However, the dolphin often moves in a direction which does not correspond to the direction the head is pointed; e.g., the dolphin can look left or right while traveling in a straight line.)

Three-dimensional track information was combined with known depth values for the test site and known DGPS locations of the boat, buoys, and targets on each trial. Collectively, these data were used to create a virtual representation of the dolphin search using the VIRTUAL REALITY MODELING LANGUAGE (VRML; Martin *et al.*, this issue). The VRML representations were used for three purposes: (1) to allow the

researcher to review the dolphin trial with unparalleled situational understanding (i.e., by allowing echolocation to be listened to while simultaneously observing dolphin motion in three dimensions); (2) to quickly identify interesting sections of a trial for more detailed analysis; and (3) to validate spatiotemporal matching of acoustic data (echolocation clicks and target echoes) with positional data (DGPS and underwater positions of the dolphin relative to the target). VRML representations were particularly useful on target-present trials in which the dolphin detected the target since they allowed the position of the dolphin to be compared to the position of the target at the time the dolphin whistled.

D. Statistical analyses

Several statistical analyses were performed to investigate whether the subjects demonstrated consistency in search strategy between target-present and target-absent trials and between search and acquisition segments of target-present trials. Only trials in which the animals correctly responded to either target presence or absence were used for statistical analysis. Significant differences between the peak sound-pressure levels of emitted clicks, interclick intervals, and the number of clicks emitted during different segments of target-present trials and between target-present and target-absent trials were assessed via t-test. Where data proved heteroscedastic, a t-test for unequal variances was used. Significance tests were run with $p=0.05$. (All statistical values reported for the remainder of the paper are means \pm 1 standard deviation.)

The occurrence of clicks was summed across target-absent trials according to the click taxonomy, i.e., the number of clicks belonging to each taxonomic category was determined for each target-absent trial and then summed across all target-absent trials. This process was repeated for target-present trials and then repeated once more using only search or acquisition segments of target-present trials. Summed occurrences were used to test whether certain categories of clicks were produced more often on target-absent trials than target-present trials, or on search segments than acquisition segments. Since the duration of trials was not a controlled factor, and more clicks of any given type could be produced on long trials or segments relative to short ones, the proportional production of each click by category was calculated to normalize the data sets to time. Proportions were arc-sine transformed according to a modification of the Freeman and Tukey (1950) transformation (Zar, 1984). This procedure corrected for the bimodal distribution of proportional data and is the recommended procedure for proportional data that approach either 0 or 1. Two-way analysis of variance (ANOVA) was applied to the data sets utilizing both segment and click category as factors, and trial type (target absent or present) and click category as factors. Homoscedasticity was assessed through application of the Bartlett–Forsythe test (Brown and Forsythe, 1974). When data were not homoscedastic, the Welch ANOVA was applied. Multiple *post hoc* comparisons were performed with either Tukey’s “honestly significantly different” test (HSD; when data were homoscedastic) or the Kruskal–Wallis rank sum test (when data were

FIG. 1. Demonstration of the search strategy used by FLP relative to an arbitrary starting position. The circle corresponds to the buoy, the square corresponds to the bottom target, and the triangle and diamond correspond to the start and end of the trial, respectively. Individual echolocation clicks are denoted with crosses along the track line. Note that during bouts of echolocation, the density of clicks produced by FLP produces a thickening of the track line.

heteroscedastic) to specify differences in the proportional use of click types. All statistical tests were run with $p = 0.05$.

Categorized clicks were used to construct transition matrices to determine whether bouts of clicks were consistently produced in sequence as part of a consistent search strategy. Click bouts were defined as one or more clicks in sequence that belonged to the same click category. Any categorical change between sequential clicks defined the end of a bout and the beginning of a new bout. (It should be noted that this process potentially overestimates the contribution of certain click types that may have occurred as single transitional clicks between differing click bouts.) The proportion of time that one bout transitioned to another was then tabulated and presented as a confusion matrix.

III. RESULTS

Data collection occurred between July 2001 and January 2003. Collections with FLP were interrupted due to animal health issues, resulting in a much smaller data collection effort with this animal. A total of 431 trials was completed with LUT, while 26 trials were performed with FLP. Application of the criteria used to select trials for further analysis resulted in the following number of trials analyzed for FLP: 7 correct target-present trials, 8 correct target-absent trials, and 6 missed trials. FLP did not report any false positives

FIG. 2. Demonstration of the search strategy used by LUT relative to an arbitrary starting position. Symbols correspond to those identified in Fig. 1. The panel in the upper right of the figure is a magnification of the search trial, permitting a better view of when echolocation clicks were produced during the trial. Note the much smaller distance traveled relative to FLP.

TABLE I. Comparison of interclick intervals (ICI) between individual dolphins for correct target absent and target present trials and for search and acquisition phases of correct target present trials. Values are means \pm 1 standard deviation and sample size (n).

	FLP		LUT	
	ICI (ms)	n	ICI (ms)	n
Target absent	35.9 \pm 21.9	4437	58.3 \pm 55.1	9412
Target present	38.9 \pm 19.0	2151	61.1 \pm 26.5	2832
Search	38.7 \pm 14.5	1383	66.1 \pm 29.5	652
Acquire	39.3 \pm 25.0	768	56.2 \pm 14.2	407

prior to exclusion from the study. Application of the selection criteria resulted in the following number of trials analyzed for LUT: 96 correct target-present trials, 92 correct target-absent trials, 31 missed trials, and 53 false positive trials. The inability to identify and track target echoes within the receive channels further reduced the number of target positive trials used for categorical comparisons of clicks between search and acquisition segments to 39 for LUT and 7 for FLP.

To characterize the success of the search strategy employed by each dolphin, the probability of detection (P_D) and probability of false alarm (P_{FA}) were calculated for each. P_D was calculated as the ratio of the number of correct responses to target-present trials to the total number of target-present trials. P_{FA} was calculated as the ratio of the number of false alarms to the total number of target-absent trials. FLP had a $P_D=0.60$ but never false alarmed ($P_{FA}=0.00$); in contrast, LUT had a $P_D=0.78$ and $P_{FA}=0.36$.

Differences between animals were noted with respect to the amount of time spent searching during a trial and the movement of the dolphin through the search field. Mean trial time was 24.6 \pm 7.3 s for FLP and 6.5 \pm 3.0 s for LUT on target-present trials. Mean trial time was 38.3 \pm 5.4 s for FLP and 17.6 \pm 5.2 s for LUT on target-absent trials. FLP demonstrated a stereotypical search pattern that consisted of an immediate descent to a depth just above the benthos followed by a thorough and methodical search of the region in the path surrounding the buoy (Fig. 1). In contrast, LUT minimized the distance traveled from the workboat (Fig. 2) and only circled the buoy when a target was not detected. Distance moved away from the workboat on target present trials in which the target was detected was typically 2–3 m for LUT, but was on the order of tens of meters for FLP.

The number of clicks produced per trial, the instantaneous peak pressure of clicks, and the interclick interval significantly varied between target-absent and present trials conducted by both FLP and LUT. FLP produced an average of 312.6 \pm 102.9 clicks per trial on correct target-present trials and 563.8 \pm 83.7 clicks per trial on correct target-absent trials. Click production by LUT was economical by comparison; LUT produced an average of 30.6 \pm 14.7 clicks per trial on correct target-present trials and 108.9 \pm 51.3 clicks per trial on correct target-absent trials. Slight but significantly longer duration interclick intervals were observed during target present trials both for FLP [$F(1,4859)=32.1$, $p<0.001$] and for LUT [$F(1,9937)=13.7$, $p<0.01$; Table I]. Similarly, the peak pressure of clicks emitted on target-

TABLE II. Comparison of click-peak pressure level (dB *re*: 1 uPa) between dolphins for correct target-present and target-absent trials and for search and acquisition phases of correct target-present trials. Values are means \pm 1 standard deviation and sample size (n).

	FLP		LUT	
	dB <i>re</i> : 1 uPa	n	dB <i>re</i> : 1 uPa	n
Target absent	195.2 \pm 8.4	4510	197.5 \pm 6.7	10017
Target present	197.5 \pm 6.8	2188	198.9 \pm 7.3	2942
Search	197.1 \pm 7.4	1412	196.1 \pm 7.7	692
Acquire	198.1 \pm 5.4	776	202.5 \pm 3.7	407

present trials was slightly but significantly greater than the peak pressure of clicks emitted on target absent trials [FLP: $F(1,5208)=138.0$, $p<0.001$; LUT; $t=-9.5$, $df=12957$, $p<0.001$; Table II].

Click production between search and acquisition phases demonstrated less variation between phases for FLP than was observed for LUT. Significantly fewer clicks were emitted by LUT ($t=-2.191$, $df=76$, $p=0.03$) during the acquisition segment (12.3 \pm 6.6 clicks, $n=39$ trials) than during the search segment (15.9 \pm 7.9 clicks, $n=39$ trials) of target-present trials. No significant differences were noted between the number of clicks emitted during search and acquisition segments conducted by FLP (search: 148.9 \pm 55.1 clicks, $n=7$ trials; acquisition: 163.7 \pm 119.9, $n=7$ trials). Interclick intervals ($t=-6.3$, $df=1057$, $p<0.001$) were significantly shorter during acquisition segments than search segments for LUT, but no such relationship was observed for FLP (Table I). The peak pressure of emitted clicks was significantly greater during acquisition segments both for FLP [$F(1,2028)=13.1$, $p<0.01$] and LUT [$F(1,1063)=344.4$, $p<0.0001$; Table II].

ANOVA performed on proportions of taxonomic click types indicated no effect from search or acquisition segment or from the overall trial type, but did indicate a predominant use of wideband clicks throughout the searches conducted by both animals. Results of the Kruskal–Wallis rank sum test are presented in conjunction with the mean and standard deviations of the arc-sine transforms both for FLP (Fig. 3; Kruskal–Wallis SE=84.4, $q_{(0.05,\infty,5)}=3.858$) and for LUT

FIG. 3. Arc-sine transforms of the proportional use of specific click types for FLP. Statistically significant differences in the production of click types are denoted above a click category according to the following: H=high frequency, unimodal; L=low frequency, unimodal; B=bimodal; W=wideband; M=multimodal.

FIG. 4. Arc-sine transforms of the proportional use of specific click types for LUT. Statistically significant differences in the production of click types are denoted above a click category according to the following: H=high frequency, unimodal; L=low frequency, unimodal; B=bimodal; W=wideband; M=multimodal.

(Fig. 4, Kruskal–Wallis $SE=3722.6$, $q_{(0.05,\infty,5)}=3.858$). Wideband clicks were utilized to a significantly greater extent by LUT than any other type of click. Wideband clicks were utilized to a significantly greater extent by FLP for all but the low-frequency unimodal clicks. Transition between click bouts reflected a similar trend and indicated that high-frequency unimodal clicks were never transitioned to from low-frequency unimodal clicks (Tables III and IV; note that these tables only show results for target-absent trials but that similar results were also obtained on target-present trials).

The cumulative distribution of echolocation click peak frequencies was notably different between the two dolphins. Considering both target-present and target-absent trials, only 3.6% of all clicks produced by FLP contained peak frequencies greater than 60 kHz. In contrast, LUT produced clicks with peak frequencies above 60 kHz 20.4% of the time. The clicks of both animals demonstrated a bias towards particular groupings of peak frequencies; when plotted against the peak pressure level of the clicks, the groups clustered into bands. Clicks generated by LUT had a greater tendency to have peak frequencies of ~38, 54, and 69 kHz (Fig. 5). When peak frequencies occurred at higher frequencies, clustering was still notable but less defined. Peak frequencies of clicks emitted by FLP had a tendency to occur at 25, 35, and 40 kHz (Fig. 6). Although clicks produced by FLP occasionally had higher peak frequencies, a bias toward any specific peak frequencies above 60 kHz was not evident.

Raw detections, which provide an indication of how much clutter each animal encounters during its search, were overall greater for FLP than for LUT, though the number of clustered and raw detections experienced by LUT was more

FIG. 5. Distribution of echolocation click-peak frequency as a function of click-peak pressure for LUT. Note the distinctive clustering around 38, 54, and 69 kHz.

variable (Fig. 7). Both animals experienced thousands of raw detections during target searches, and hundreds to in excess of a thousand detections when detections were range clustered within a 1-m range extent (i.e., consistent with multiple reflections from an object 1 m in diameter).

IV. DISCUSSION

Data collected from two dolphins, LUT and FLP, demonstrate differences in target detection strategies involving whole animal locomotion, the number of echolocation clicks produced, and the frequency content of those clicks. However, certain limitations to the data collection and methodology must be considered when interpreting the results.

First, statistical analysis of the instantaneous peak pressure of echolocation clicks is biased by the maximum level at which clicks could be recorded (peak sound-pressure level of 209 dB *re:1* μ Pa) and the threshold level accepted for analysis (peak sound-pressure level of 175 dB *re:1* μ Pa). Occasional clicks saturated the system and were excluded from analysis. Clicks produced below the threshold level likely occurred but were ignored as an acceptable trade-off between lost data and the minimization of detections due to noise. Consideration must also be given when comparing the analysis of echolocation clicks from target-present and target-absent trials, since the latter includes some amount of echolocation for the purpose of returning to the workboat from which the animal was sent. Furthermore, search and acquisition segments were defined by algorithmic detection

TABLE III. Transition probability matrix for click bouts according to their taxonomic classification for FLP during target-absent trials. Click taxonomy corresponds to the following: W (wideband), LFU (low frequency, unimodal), HFU (high frequency, unimodal), BI (bimodal), MULTI (multimodal).

	W	LFU	HFU	BI	MULTI
W		0.75	0.00	0.06	0.19

and human verification of target echoes. This does not imply that the dolphin detection capability is equivalent; without a doubt the ability of the dolphin to detect and identify target echoes is superior to this approach. Finally, there are errors inherent in GPS-determined locations and in the onboard underwater navigation system of the BMT. Attempts to qualify and control these errors have been made through virtual reality playbacks and acoustic refinement of dolphin positions relative to targets. A certain degree of error is acceptable, particularly since movement patterns are only topically discussed here. However, this issue must eventually be addressed to permit more accurate localization of the dolphin and targets in three-dimensional space.

The search strategy of FLP can be grossly described as conservative. FLP demonstrated a stereotypical search pattern that consisted of descent to a point immediately above the benthos followed by a methodical search of the region around the search buoy. Click intervals and the number of clicks emitted were comparable between search and acquisition segments, and FLP swam within close proximity of the target prior to reporting it as present. Echolocation was stereotypical with search patterns typified by slow swim speeds and more distance traveled during positive trials (the animal typically swam around targets). In contrast, LUT was economical in click production, and on target-present trials traveled no more than a couple of meters from the boat prior to reporting target detection. This dolphin appeared to abide by the “law of least effort” in that energy spent to receive a

FIG. 6. Distribution of echolocation click-peak frequency as a function of click-peak pressure for FLP. Note the distinctive clustering around 25, 35, and 40 kHz.

food reward was minimized. Swimming around the buoy marker, 25–60 m away from the workboat, was only performed when no target was observed in the area and the dolphin had to complete the search pattern circuit to receive a reward. LUT echolocated more near the workboat at the start of the trial; relatively few clicks were produced in transit to the buoy, contrasting FLP in which copious numbers of clicks were produced throughout target present and absent trials.

Differences in the search strategies of the two dolphins are possibly explained by previous training histories and individual hearing ability. FLP was previously trained for open-water target searches in which targets, once found, were inspected again for verification prior to marking the identified target. In this study, reporting that a target is present only when in close proximity of the target may have resulted from integration of the previously acquired target marking behavior into this search strategy. In contrast, LUT was a naive animal with little experience in open-water target detection tasks. LUT may have developed a more economical strategy because no prior experience existed to im-

FIG. 7. Mean (\pm s.d.) of the number of detections received by FLP and LUT. Detections are presented as individual detections within the receive data stream, and detections clustered to a temporal run-out beyond the first detection equivalent to 1 m of travel time in the water (i.e., assuming a target of approximately 1-m diameter).

pact strategy development. Alternatively, recent hearing tests on FLP suggest that FLP has profound hearing loss above 50 kHz (Moore *et al.*, 2004). A reduction in hearing sensitivity may explain the reduced search range (shorter interclick intervals), predominant use of wideband clicks with low-frequency peaks, and more abundant click production. Similar characteristics have been observed in dolphins that have known hearing losses performing simpler target detection tasks (Houser *et al.*, 1999). Collectively, hearing ability and experience may have contributed to FLP evolving a conservative search strategy in which no false alarms were committed but correct detections were reduced.

Both LUT and FLP increased the source level of echolocation clicks during target acquisition segments. Although significant in both cases, the increase was smaller (~ 1 dB *re*: $1 \mu\text{Pa}$) for FLP than for LUT (~ 6 dB *re*: $1 \mu\text{Pa}$). Prior work by Au *et al.* (1988) suggests that the dolphin ear may act as an energy detector in the processing of echolocation clicks, and that multiple echoes of equivalent amplitude which do not fall within a critical time interval do not appear to impact detection thresholds for phantom echoes of similar frequency content. However, evidence from wild dolphins suggests that the pressure amplitude of emitted clicks may vary as $20 \log(R)$, where R is the distance to a target(s) that emits echoes as volume reverberation, as in a school of fish (Au and Benoit-Bird, 2003). Such variation is suggestive of time-varying gain controlled through source level variation. Unlike wild animals that vary click source level as a function of distance to a volume reverberant target, dolphins in this study searched for a target that is more like a point source and increased the echo level during acquisition of the target, prior to positive identification. Depending upon the subject, this was achieved by different means. In the case of FLP, an increase in the amplitude of echo returns was primarily achieved by decreasing the distance between the click source and the target. In contrast, LUT did not approach targets once detected, but increased the source level of his echolocation clicks prior to reporting detection. Although approached differently, these behaviors increase the amplitude of returning echoes and likely decrease the threshold for correct identification of a target through accentuation of echo highlights.

The tendency for echolocation clicks to have certain peak frequencies suggests either a preference for the use of certain frequencies or a resonant response of the click generating structures. The former possibility seems unlikely as most clicks produced by both animals were wideband, having -3 -dB bandwidths in excess of 85 kHz. However, separation between clusters of peak frequencies below 70 kHz is nearly harmonically related. Values for LUT are separated by ~ 15 kHz and the same is true for the lowest and highest values for FLP. Clustering at higher frequencies is evident, though difficult to quantify for LUT, and is absent for FLP. The separation in clusters is consistent with the idea of two sources for click generation, i.e., a pair of phonic lips (Cranford, 2000; Cranford *et al.*, 1996), if each set of lips has a different set of resonant frequencies resulting from its geometry and composition. This proposition is consistent with previous anatomical work that has demonstrated asymmetry in

the phonic lips of delphinid species (Cranford *et al.*, 1996). Furthermore, if FLP were constrained by hearing loss above 50 kHz, selective use of one set of phonic lips could allow the hearing loss to be accommodated by preferentially echolocating at frequencies at which there is functional hearing.

Both FLP and LUT demonstrated effective clutter rejection. The bathymetry over which the dolphins performed their searches was uneven, composed of heterogeneous sediment, and contained a number of clutter items, many of which were likely manmade. The ability of the animals to find and discriminate the search target via echoic means in the presence of many hundreds of reflective surfaces is a testament to their echolocation ability. The mechanism by which the dolphin excludes clutter is of interest to the sonar community, as replication of such capability would provide substantial improvement to current sonar detection and classification systems. It is uncertain whether the dolphins in this study learned the echo structure of the target and applied an exclusionary rule while searching (i.e., if not a , then reject), or whether an acoustic image of the total area searched is formed. Further research is required to answer such questions.

In summary, the use of remote acoustic and navigational recording devices carried by free-swimming dolphins in open water has provided new insight into dolphin echolocation search strategies. Data collected with new instrumentation (Martin *et al.* this issue) demonstrates that dolphins, with different hearing abilities and different training histories, are capable of finding targets in reverberant and cluttered environments but with a degree of success that varies as a function of distinct search strategies. The overwhelming occurrence of particular click-peak frequencies in the echolocation clicks of both dolphins is suggestive of structural resonances within two asymmetric click-producing structures. A lack of high-frequency peaks in one animal may indicate reliance upon a single set of structures for echolocation, the use of which may accommodate hearing loss above 50 kHz. Increasing the echo amplitude of targets during acquisition phases of a target search task was achieved by both dolphins through an increase in the source level of echolocation clicks and/or a reduction in the distance between target and dolphin without a reduction in click source level. Future experiments utilizing remote recording devices such as the BMT should provide an increasing body of knowledge on echolocation in freely swimming animals. By comparison to more traditional pen and pool work, a better understanding of how echolocation signals and strategies are varied in noisy, real-world environments will be obtained.

Quantifying the acoustic repertoire of a population: The vocalizations of free-ranging bottlenose dolphins in Fiordland, New Zealand

Oliver Boisseau

Department of Marine Science, University of Otago, 310 Castle Street, Dunedin, New Zealand

(Received 1 June 2004; revised 28 December 2004; accepted 30 December 2004)

Quantification of the vocal repertoire of a species is critical for subsequent analysis of signal functionality, geographical variation, social relevance, and transmission. While signal repertoires have been documented for numerous animal species, detailed descriptions for the cetaceans are rare. This study describes the vocalizations of free-ranging bottlenose dolphins resident to the waters of Fiordland, New Zealand. The field recordings presented in this paper were made using both audio band and broadband apparatus. Subsequent classification of vocalizations using multivariate parameters enabled a quantification of the entire vocal output of the focal animals. These results were used to propose a meaningful repertoire of signals employed by this species. A total of 12 individual signal types were described, comprising four broad structural classes: “tonal,” “single bursts,” “click bursts,” and “repeat bursts.” The proposed repertoire will allow subsequent investigation into vocal behavior. It appears that the successful description of a species’ repertoire is dependent on the use of appropriate recording systems, a high number of representative recordings with good signal-to-noise ratio, and subsequent validation of the original classification system. © 2005 Acoustical Society of America. I. INTRODUCTION

Quantifying the signals produced by a species is a fundamental first step in the investigation of their functionality, geographical variation, social relevance, and cultural transmission. Signaling acts may include physical displays, pheromone release, and vocalizations (Herman and Tavolga, 1980). The vocal repertoires of numerous vertebrate species have been described, including such diverse taxa as the anurans (Grafe *et al.*, 2000), songbirds (Kroodsma and Henri, 1982), ungulates (Budde and Klump, 2003), carnivores (Volodina, 2000), and primates (Fischer and Hammer-schmidt, 2002). The cetaceans comprise an extremely vocal mammalian order [see Herzing (2000) for a recent review] and numerous aspects of their sound production and auditory systems have been described in detail. Surprisingly, thorough descriptions of vocal repertoires are rare amongst the cetacea. For the baleen whales, for example, a comprehensive repertoire description has been provided for a population of southern right whales *Eubalaena australis* (Clark, 1982) including vocal and nonvocal calls. A clustering technique has been applied to the signals of humpback whales *Megaptera novaeangliae* to derive an objective classification of calls (Chabot, 1988).

Amongst the toothed whales, perhaps the best documented communication system is that of the beluga *Delphinapterus leucas*, in which 80% of calls may be pulsive (Sjare and Smith, 1986; Recchia, 1994). Click-based repertoires from two other odontocete species have also been documented: the Hector’s dolphin *Cephalorhynchus hectori* (Dawson and Thorpe, 1990) and the sperm whale *Physeter macrocephalus* (Gordon, 1987). The repertoire of resident killer whales *Orcinus orca* has been described in some detail and is

based principally upon clicks, pulsed calls, and whistles (Ford, 1989). Vocalizations from false killer whales *Pseudorca crassidens* have been described along a continuum with clicks and whistles representing extreme cases (Murray *et al.*, 1998a). Spinner dolphin *Stenella longirostris* calls have been categorized as burst pulses or whistles, with some further division within these categories (Brownlee and Norris, 1994). Calls produced by Risso’s dolphins *Grampus griseus* have been divided into seven categories (Corkeron and Van Parijs, 2001), the calls of Irrawaddy dolphins *Orcaella brevirostris* into six (Van Parijs and Corkeron, 2001), and calls of the tucuxi *Sotalia fluviatilis* into four (Monteiro and Monteiro, 2001). A number of other studies (e.g., Lilly and Miller, 1961; Caldwell and Caldwell, 1967; Ridgway, 1983) have classified vocalizations under the three broad structural classes of whistles (narrow-band, tonal signals), clicks (broadband pulses with rapid onset/offset), and burst pulses (sequences of impulsive sounds).

Almost all of the vocal repertoires proposed for the cetaceans are based on classification of aural and spectrographic properties. While useful in reducing the complexity of a dataset, there is often no subsequent testing of the validity of the proposed categories. Notable exceptions include the work on right whales (Clark, 1982), humpback whales (Chabot, 1988), Hector’s dolphins (Dawson and Thorpe, 1990), and beluga (Recchia, 1994) and false killer whales (Murray *et al.*, 1998b).

Another pitfall in the categorization of signaling systems is the equipment used for recordings. Many cetaceans produce vocalizations within the human audio range (below 20 kHz) and even solely ultrasonic species may be audible at lower frequencies through an artifact of click repetition rate (Watkins *et al.*, 1977). However, significant energy may ex-

TABLE I. Synopsis of signal types proposed in this study in relation to other studies of bottlenose repertoire. Context for signals inferred from surface behavior (Boisseau, 2005). Signal prevalence is the percentage of all 875 recordings that contain each signal type.

tend into higher frequency ranges (i.e., above 20 kHz). The equipment required for recording these higher frequencies is often expensive and/or cumbersome. As such, only investigations into echolocation clicks have tended to use broadband systems [see Herzing (2000) for review]. Quantitative broadband analyses of vocalizations that are not solely echolocatory are restricted to the Hector's dolphin (Dawson, 1991), spinner dolphin (Brownlee and Norris, 1994), spotted dolphin (Lammers *et al.*, 2003), and white-beaked dolphin (Rasmussen and Miller, 2002).

Bottlenose dolphins (*Tursiops truncatus*) are extremely vocal and numerous studies have been made of their acoustic behavior. The majority of these studies have concerned the echolocation system in captive contexts (see Au, 1993 for a review). Of the studies based upon free-ranging animals, most emphasis has been placed on whistles. Whistles are tonal signals that appear to be used as contact calls between individuals in some situations (e.g., Sayigh *et al.*, 1999; Smolker and Pepper, 1999; Janik, 2000a; Jones and Sayigh, 2002). These vocalizations may be recorded readily in the field in high numbers with good signal-to-noise ratios. The presence of numerous other signals within the repertoire of

bottlenose dolphins has long been acknowledged and many appear universal (some are summarized in Table I). However, these vocalizations have received much less attention for various reasons. Some are produced far less frequently than whistles and clicks, and thus require high levels of study effort to build up large samples. These signals may be produced with low amplitude levels, and hence must be recorded from animals at close quarters. Any overlapping or intergrading of signals may create an obstacle for meaningful classification. A broad range of physical descriptions has been applied to pulsed bottlenose vocalizations, yet many of these descriptions may refer to fundamentally similar sounds. Many of these classifications are subjective, based on differences perceived by human observers. They are thus unquantified and mostly unrepeatabe.

Amid the abundant literature pertaining to bottlenose dolphins, there are no descriptions of complete vocal repertoires for closed populations, either in captivity or the wild. Descriptions of various signal types exist (e.g., Connor and Smolker, 1996; dos Santos *et al.*, 1995; Herzing, 1996; McCowan and Reiss, 1995; Schultz *et al.*, 1995), but little mention has been made of the individuality or overlap of these

vocalizations. The most comprehensive review of bottlenose vocal activity is that of Caldwell and Caldwell (1967) and was largely based on two small captive groups. Likewise, there is a dearth of information on the broadband properties of the non-echolocatory signals of bottlenose dolphins. Broadband results from captive studies have been published for one example of a whistle (Lilly and Miller, 1961), as well as 26 cases of a “jaw pop” vocalization and 17 cases of nonvocal breaches and tail slaps (Finneran *et al.*, 2000). For free-ranging dolphins, an extremely brief mention has been made of broadband recordings of “pop” trains (Connor and Smolker, 1996).

The waters of Fiordland in the southwest of New Zealand’s South Island are home to three separate resident populations of bottlenose dolphin. Data from two of these populations are presented in this paper. The fiords present ideal study sites for work on free-ranging dolphins. The steep rock walls create shelter from prevailing weather patterns. The dolphins tend to follow predictable seasonal patterns and these waterways effectively provide conditions of “natural captivity.” Individuals from Doubtful Sound rarely leave the fiord (Schneider, 1999) while the home range of the Milford Sound population encompasses seven northern fiords, several bays, and one lake system (Dave Rundgren, personal communication). The aims of this paper are (i) to compare vocalizations of free-ranging bottlenose dolphins using both audio band and broadband apparatus, (ii) to quantify the entire vocal output of the focal animals, (iii) to classify the vocalizations using multivariate parameters, and (iv) to propose a meaningful repertoire for subsequent investigations in to vocal behavior.

II. METHODS

Recordings of bottlenose dolphins were made between August 2000 and June 2003 from two resident populations in Fiordland, southwest New Zealand. Surveys for dolphins were conducted from a 4.8-m aluminum research vessel, with a 50-hp Yamaha 4-stroke engine. Acoustic recordings were made while drifting ahead of dolphin groups with the engine off. Recordings were made using a Sonatech 8178 mono element hydrophone (30 Hz to 180 kHz \pm 3 dB) on 10 m of cable connected to an on-board preamplifier with a linear frequency response (dc—300 kHz). For recordings made within the human audio range, a Sony TCD D8 digital audio tape recorder was used with a calibrated frequency response of 10 Hz to 22 kHz \pm 1 dB (sampling at 48 kHz). For broadband recordings, an analog Racal Store 4DS recorder was used at a speed of 30 ips, for which the calibrated frequency response is 120 Hz to 150 kHz \pm 0.5 dB. For lower frequencies the DAT recorders are far superior to the Racal, offering a broader dynamic range (>85 vs. 40 dB) and excellent fidelity to infrasonic frequencies (10 Hz).

A. Tape transcription

All DAT and Racal recordings made in the field were reviewed at a later date to avoid observer bias. Acoustic emissions were transcribed by noting the time and the type of signal. All recorded vocalizations belonged to one of four structural classes: “tonal” (narrow-band, frequency-

modulated signals), “single burst” (short impulsive emissions with most energy below 5 kHz), “click burst” (broadband pulses with rapid onset/offset time), and “repeat burst” (sequences of single bursts). Within these classes, 15 signal types were initially transcribed: *buzz*, *click train*, *creak*, *choke*, *cough*, *hiccup*, *laughter*, *long styro*, *orca*, *quack*, *ratchet*, *short styro*, *splash*, *squeal*, and *whistle*. Signal categorization was based in part on previously reported vocalizations and partly on novel interpretation. Although qualitative categorization of this kind is extremely subjective, it allows a division and reduction of the data for later analysis. Efforts were made to transcribe every individual vocalization heard, with the exception of clicks. As echolocation clicks were present in almost all recordings, often in overwhelming numbers, it was not possible to define individual click trains.

B. Digitization of vocalizations

For subsequent analysis, vocalizations were randomly sampled from all seasons for all three years of data to control for seasonal variation. The target sample size was arbitrarily set at 10 signals per season per year for each proposed signal type for both Doubtful and Milford Sounds. Thus for any given signal type, a maximum of 10 (samples) \times 4 (seasons) \times 3 (years) \times 2 (fiords) = 240 samples would be available. To limit repeated sampling of individual dolphins, selected samples were at least a day apart when possible. As higher frequency signals may be highly directional, only vocalizations with relatively high amplitude were digitized in an effort to enhance the likelihood of measuring on-axis signals. Vocalizations were deemed suitable for analysis if their mean square (rms) amplitude was more than 10 dB above background noise. Vocalizations were digitized from DAT tapes with a sample rate of 44.1 kHz via a 24 bit RME Digi96/8 digital sound card. To avoid aliasing, signals were filtered using a Kemo VBF8 filter set at 22 kHz with 96 dB/oct attenuation. Wideband Racal recordings were digitized at an effective sampling rate of 352.8 kHz ($\frac{1}{8}$ record speed at 44.1 kHz; 16 bit). Measurements were taken from digitized vocalizations using Canary 1.2.4. (Cornell Laboratory) on a 933-MHz G4 Macintosh computer.

C. Comparison of broadband recordings with DAT recordings

Of the 875 recordings made in both fiords, 25 were made using the broadband system during periods of high vocal activity. From these recordings, all vocalizations with suitable signal-to-noise ratio were digitized and measured using Canary’s automatic measurement function. Peak frequencies were measured and compared to similar values from DAT recordings using a Student’s *t*-test. All measurements were log-transformed to approximate the normal distribution. As the sample size for the Racal system was markedly smaller than for the DAT system, vocalizations were only tested if a suitable sample size was available using the following iterative rule:

$$n = \frac{s^2 t_{\alpha(2), (n-1)}^2}{d^2},$$

where s^2 is the sample variance, t is the two-tailed critical value of Student's statistic, d is the half width of the desired confidence interval, and $1 - \alpha$ is the confidence level for the confidence interval (Zar, 1998). In addition, nine long recordings were made on separate occasions using both systems simultaneously. The spectrograms from these "duets" were compared for evidence of ultrasonic components.

D. Quantitative measurement of signal parameters

Signal parameters were measured from waveform, spectrogram, and point spectrum windows. Spectrographic information was obtained using fast Fourier transformation (FFT) with a Hamming window function. The FFT procedure has an inherent trade-off between time resolution and frequency resolution (Bradbury and Vehrencamp, 1998). As a wide variety of signal types were measured in this study, a window size of either 256 or 512 points was selected on a file by file basis to allow the measurement of time-frequency parameters from each vocalization. The parameters measured from each vocalization were dictated by its structure. However, from the diverse range of signals recorded, six parameters could be measured from all vocalizations. The first of these, "peak frequency," was defined as the frequency at which a signal has the highest energy. The time of this peak intensity ("peak time") was also measured along with "center time" (the point at which the collective intensity of a signal is half the total). Both these values were measured as proportions of "total signal duration." Interpeak interval ("IPI") was measured as the time between successive pressure peaks in a vocalization. "Duty cycle" was measured for each vocalization and is defined as the percentage of time a signal is "on" in relation to its total length (Murray *et al.*, 1998a).

E. Spectrographic cross-correlation

The spectrographic cross-correlation (SPCC) procedure performs quantitative comparisons between spectrograms by incrementally sliding spectrograms past each other and calculating correlation coefficients at successive time offsets. Thus SPCC can provide a quantitative measure of vocal similarity that is both automated and repeatable. As the similarity is being measured between spectrograms that may be radically different in length, peak correlation is of interest rather than time offset. The SPCC procedure was employed using Canary's batch correlator function. Start and end times of individual signals were determined by close inspection of spectrograms and waveforms. During SPCC evaluation, the signals being compared were normalized to ensure the maximum amplitudes of both signals were the same. Spectrograms were derived using the same settings (FFT and frame length 512 points; filter bandwidth 350 Hz; 75% overlap; Hamming function). Each spectrogram in the dataset was compared with every other spectrogram in turn. This process provided a measure not only of the similarity between individual signals, but also between signal types (*whistle* versus *buzz*, etc.). Hierarchical cluster analysis was conducted on the resulting distance matrix. Ward's linkage method was used to amalgamate vocalizations based on increasingly dis-

similar SPCC values. This method tends to produce compact groups (Ward, 1963).

F. Principal component analysis of signal type

Principal component analysis (PCA) is of use when *reducing* the number of variables (by removing highly correlated variables) and *detecting structure* between variables. The principal components method finds linear combinations of variables (components) that account for as much variation in the original variables as possible. Usually, a few components will account for most of the variation, and these components can be used in place of the original variables during subsequent analysis (Stevens, 2001). Principal components were extracted using a variance maximizing (varimax) rotation that maintains the cumulative percentage of variation explained by the extracted components but spreads it more evenly over the components. Thus the rotated component matrix is easier to interpret than the unrotated matrix. The PCA scores for each vocalization were used in discriminant function analysis (DFA) to investigate differences between signal types. DFA is used as a descriptive technique to determine which variables discriminate between two or more naturally occurring groups. The accuracy of the DFA model was tested using cross validation, a process that classifies each case while leaving it out from the model calculations.

III. RESULTS

Over the 3-year study period, 875 recordings were made of bottlenose dolphins in Fiordland. From 49 hours of recorded vocal output, approximately 50 000 separate vocalizations were categorized aurally into four broad structural classes—"tonal," "single burst," "click burst," and "repeat burst." These classes incorporated 15 discrete signal types. Two of the signal types (the single burst *laughter* of Doubtful Sound and the triple-burst *long styro* of Milford Sound) were fiord specific. The calls in the proposed repertoire were also segregated to a certain extent by behavioral context (Boisseau, 2005).

A. Description of signal types

Mean spectral and structural qualities were calculated for each of the proposed signal types (Table II). For the majority of vocalizations recorded, most energy was below 22 kHz (i.e., the upper frequency limit of the DAT system). However, certain vocalizations had significant ultrasonic energy, typically the click-based signals and the harmonics of *whistles*. Some vocalizations, such as *laughter* and the *styro*s, seem to possess low-frequency narrow-band components, which (in the case of the *styro*s) oscillated rhythmically with broadband pulses.

"Tonal" signals are comprised of two separate types. *Whistles* are narrow-band frequency-modulated signals that are typically longer than 500 ms and have most energy between 7 and 26 kHz. *Squeals* are also narrow-band signals

TABLE II. Summary of the properties of all 15 proposed signal types. Values are means ($\pm 95\%$ confidence limits). Duty cycle generally increases moving down the table. The occurrence of each signal type is measured as a percentage of all 49 222 transcribed calls.

	% of all calls	Total duration (ms)	Peak frequency (Hz)	IPI (ms)	Duty cycle	Max. harmonic interval	Max. frequency (kHz)	No. of repeated elements	Burst length (ms)	Inter-burst interval (ms)	Interrepeat interval (ms)

^aCounts of individual *click trains* are excluded due to the problems associated with identifying discrete trains.

but differ from *whistles* in that they are shorter (usually less than 300 ms) and of lower frequency (most energy below 5 kHz). *Squeals* also tend to be upsweeps (i.e., the fundamental frequency increases).

The rest of the proposed repertoire is pulse based. Vocalizations in the “single burst” class are intrinsically short. *Splash* is the shortest vocalization in the proposed repertoire (less than 50 ms) and is composed of a single large pulse with rapid onset and offset. *Choke* is structurally similar to *splash* yet has an additional noisy broadband element that follows the initial pulse and thus increases signal duration (~ 135 ms). *Cough* and *quack* are of similar duration (~ 135 ms), but *cough* is generally a noisy signal with very low fundamental frequency (700 Hz) while *quack* is almost sinusoidal in nature, with higher fundamental frequency (1250 Hz).

The remaining pulsed vocalizations consist of repeated bursts of pulses. The “click bursts” are composed of regular broadband clicks and are structurally similar but differ mostly in interburst interval (IBI), i.e., the time between successive clicks. *Click trains* have the highest IBI (90 ms) and

also tend to be relatively long (upwards of 2000 ms). *Ratchets* have lower IBIs (75 ms) and are composed of clicks with strong emphases on lower frequencies. *Creaks* have still lower IBI values (30 ms) and tend to be broadband in nature. *Buzzes* have such low IBI values (4 ms) that consecutive clicks start to overlap and results in a single tone to the human ear. *Orcas* have the lowest IBI of the click bursts (3 ms) and also sound tonal to a human listener. *Orcas* tend to be shorter than *buzzes* (320 and 1000 ms, respectively). In many ways *orcas* may be seen as intermediaries between the click bursts and the single bursts.

The final structural subclass of the pulsed vocalizations is the “repeat bursts.” These signals are low in frequency (typically below 2 kHz) and have repeated elements, but do not possess the broadband nature of click bursts. The simplest of these repeat bursts is the *hiccup*, a short vocalization (310 ms) composed of two separate burst trains (essentially a double *cough*). *Laughter* is similar in structure to *hiccup* but is composed of numerous *coughlike* bursts (typically 15, although examples with over 120 repeats have been recorded). *Short styro* is formed of repetitive cycles (usually six) and

FIG. 1. Example of consecutive “duet” recording (broadband Racal spectrogram above narrowband DAT spectrogram). Arrows denote two solely ultrasonic *buzzes*. Note boat noise apparent during the DAT recording but absent from the RACAL spectrogram due to differences in dynamic range. Individual vocalizations are represented as b=*buzz*, cl=*click train*, cr=*creak*, r=*ratchet*, and w=*whistle*.

each cycle is composed of two variable burst trains. *Long styro* is similar although each cycle is formed by three variable burst trains. As the number of repeated elements forming *laughter* and the *styros* is highly variable, the durations of these sequenced vocalizations are also highly variable (from 100 ms to 120 s).

B. Comparison of broadband recordings with DAT recordings

Few of the proposed signal types exhibited a greater emphasis in the ultrasonic range than the audible range. The only vocalizations that seemed to contain minimal energy in the DAT range (i.e., below 24 kHz) were *click trains*. Comparisons between consecutive DAT and Racal recordings suggest only *click trains* and *buzzes* may ever be exclusively ultrasonic. For example, the sequence portrayed in Fig. 1 comes from a longer recording containing 110 separate vocalizations of which only 2 are ultrasonic (both *buzzes*). This

is in keeping with the other eight “duet” recordings, for which solely ultrasonic vocalizations typically represent less than 2% of all signals recorded.

Of the parameters measured from each vocalization, peak frequency is the measurement most likely to be underestimated by DAT recordings. To investigate this misrepresentation, the peak frequencies of vocalizations were measured from both DAT and Racal recordings. The lower frequency limit of the DAT system is below that of the Racal system (30 and 120 Hz, respectively, using a Sonatech hydrophone). As approximately 3% of peak frequencies measured from the DAT tapes were below 120 Hz, these values were excluded from analysis. Log transformed values from Racal recordings were significantly higher than DAT recordings for *buzz*, *hiccup*, *quack*, *short styro*, *splash*, *squeal*, and *click trains* (Student *t*-test; all $p < 0.01$). However, all mean values were below 22 kHz (the upper DAT limit) except for the *click trains* (Fig. 2). Only in the click-based categories (*click trains*, *creak*, *buzz*, and *orca*) were peak frequencies

FIG. 2. Summary of mean peak frequencies for all proposed signal types. Error bars represent standard errors of the mean. Dotted line represents upper frequency limit of DAT system. *Long styro* excluded due to low number of broadband samples. (**) represents significant *t*-test differences at the 99% level. (n/a) represents those signals with too few RACALS samples to conduct Student's *t*-test.

measured above 22 kHz. Recordings made with the DAT system seem to be representative of all signal types except broadband *click trains*. It must be noted that the sample size of Racal recordings is low and thus the *t*-tests have relatively low statistical power.

C. Quantitative measurement of signal parameters

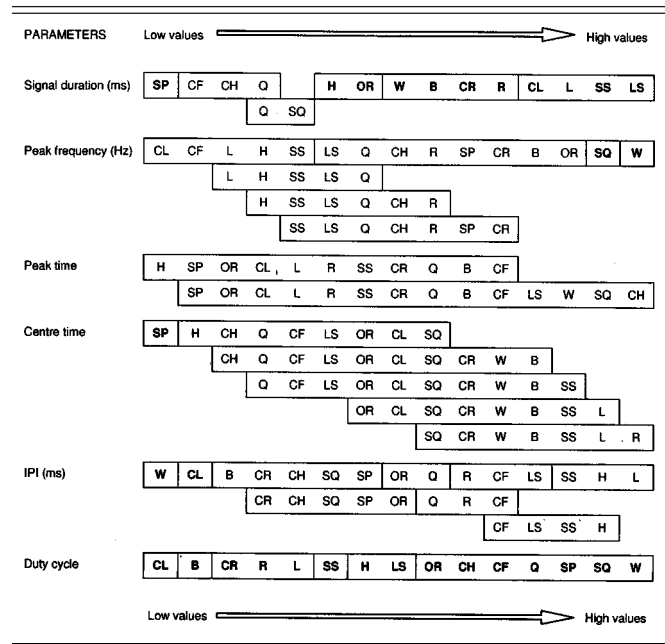

A dataset of 1959 individual vocalizations was extracted from the 49 h of recordings. These samples represented 3 years of data from both fiords, incorporating all 12 seasons in that period. To compare signal types a one-factor ANOVA was conducted on the log-transformed data. For each of the six common parameters, significant differences existed between the 15 proposed signal types (all $p < 0.01$). High *F* values (> 100) for “signal duration,” “peak frequency,” and “duty cycle” suggest variation in these parameters is much greater between groups than within groups. Tukey's range test was subsequently used to identify homogenous subsets of signal types (Table III).

D. Spectrographic cross-correlation

Spectrograms were produced for all 1959 vocalizations in the dataset and were subjected to spectrographic cross-correlation (SPCC). When comparing signal types, the mean peak correlation values were lowest for *splash*, *long styro*, *short styro*, and *click trains*, suggesting the spectrograms of these vocalizations were relatively distinct. A dissimilarity matrix was derived from the SPCC matrix and a dendrogram formed using hierarchical cluster analysis (Fig. 3). The dendrogram reveals two main clusters that may broadly be described as repetitive (composed of repeated bursts) and non-repetitive (composed of single bursts). Notable exceptions to these clusters are *whistle*, *orca*, and *hiccup*. *Whistle* forms a

cluster with some of the click-based signals (*buzz*, *creak*, and *ratchet*). These click-based vocalizations all have energy covering a broad range of frequencies. As the peak frequencies of *whistles* tend to be higher than most other vocalizations (Fig. 2), it is likely that any given *whistle* contour will have a high correlation with broadband vocalizations. *Orca* and *hiccup* are both repetitive vocalizations, *orca* being composed of rapid clicks and *hiccup* being composed of twin

TABLE III. Summary of Tukey's *posthoc* range tests for one-factor ANOVA. Vocalizations contained within the same rectangle are not significantly different from each other at the 95% level. Rectangles that do not overlap (in bold) are significantly distinct from all others. See Fig. 4 for vocal abbreviation key.

FIG. 3. Dendrogram derived from hierarchical cluster analysis (Ward's method). Based on dissimilarity matrix of SPCC scores.

burst pulses. Nevertheless, they appear in the nonrepetitive cluster. These two vocalizations form the strongest cluster in the dendrogram with a linkage distance of 0.27, perhaps reflecting their repetitive nature. *Orca* and *hiccup* also form a tight group with *squeal*. Despite being a tonal signal, *squeal* is aurally very similar to *orca* and this similarity is reflected in the tight clustering of these signals.

E. Principal component analysis of signal type

There was some correlation between the six parameters common to all 1959 vocalizations, and the use of PCA was therefore appropriate. The eigenvalues for the first three components were all greater than one, a value expected by chance alone for each variable. The resulting principal components accounted for 71% of the original variation, suggesting that the complexity of the data set can be reduced to three components with a 29% loss of information. This process formed separate clusters for *whistle*, *splash*, and *click train* (Fig. 4). The remaining signals form two general data clouds: the single bursts and those vocalizations with repeated elements.

Component 1 is most closely correlated with the variables “center time” and “peak time.” This component readily distinguished *splash* from the other vocalizations, and to a certain extent *ratchet*. *Splash* is a loud, broadband signal that seems to be produced nonvocally, typically through aerial activity and rapid movements of a dolphin's tailstock (personal observation). After a rapid onset, the energy produced during a *splash* degrades slowly, presumably due to surface echo and multipath effects. Thus the energy distribution in a typical *splash* is negatively skewed, with a

relatively low center time and peak time. Conversely, *ratchets* have high PC1 scores as they tend to increase in amplitude between successive clicks and are thus positively skewed. Component 3 readily distinguishes *whistles* from the other signal types and is strongly correlated with “peak frequency” (positively) and “interpeak interval” (negatively). Interpeak interval is a measure of the wavelength of a signal (i.e., the time offset between successive pressure peaks) and so, as wavelength decreases, frequency increases. *Whistles* have correspondingly high component 3 scores. Component 2 is strongly correlated with total signal duration and PC2 scores for the sequenced sounds (*laughter*, *short styro*, and *long styro*) are all very high. Many of these vocalizations are

FIG. 4. Mean scores for first three principal components for each proposed signal type.

TABLE IV. Stepwise formation of an increasingly condensed repertoire. The final four categories represent fundamentally different structural classes (“tonal,” “single pulse,” “click bursts,” and “repeat bursts”).

Stepwise no. of signal types	% correct		Merging process	
	Observed	Expected	Candidate	Merged with
15	37.6	6.7		
14	38.6	7.1	long styro	short styro
13	40.9	7.7	cough	quack
12	43.9	8.3	laughter	long styro+short styro
11	45.3	9.1	choke	cough+quack
10	48.5	10.0	buzz	creak
9	47.5	11.1	orca	buzz+creak
8	55.3	12.5	ratchet	orca+buzz+creak
7	55.5	14.3	hiccup	laughter+long styro+short styro
6	62.6	16.7	splash	choke+cough+quack
5	65.7	20.0	clicks	ratchet+orca+buzz+creak
4	73.8	25.0	squeal	whistle

particularly long—for example, one bout of *laughter* used in this analysis was audible for 38 s and consisted of 130 bursts. Although not included in this analysis, some bouts may last longer than 2 min. As a result, these sequenced sounds form a subcluster along the PC2 axis. *Whistles* are separated from other vocalizations along this axis as they also tend to be long signals (the maximum duration in this data set was 3.3 s).

The first three principal component scores for all 1959 cases were used in discriminant function analysis (DFA). PCA scores were used in lieu of raw data to ensure variables were not correlated. The mean values for the three components differed significantly between signal types (ANOVA; all $F > 15$, all $p < 0.01$). It may therefore be assumed that all three components contribute to the discriminant model. To test the efficacy of the classification scheme, all 1959 cases were cross-validated. As there were 15 proposed signal types, a correct classification rate of approximately 7% would be expected by chance alone. The DFA process classified 37% of cases to the correct signal type. *Whistles* were most reliably allocated to the correct category (94% correct). *Splash* was also relatively well discriminated (77%), while *hiccup*, *laughter*, *orca*, *ratchet*, and *squeal* were also considered fairly distinct (all over 40% correct). The remaining vocalizations were poorly discriminated, with values ranging from 10% to 30% correct. *Long styro* had no correct classifications, and tended to be mistaken for the other sequenced vocalizations *laughter* and *ratchet*.

F. Condensation of signal repertoire

The results of the various multivariate techniques suggest that the variation of the measured parameters did not accurately capture the proposed repertoire. There was a great deal of overlap between some of the subjectively defined signal types and a clear need to reduce redundancy in the proposed repertoire. The results from the various multivariate techniques were used to construct a hierarchy of vocalizations that could be condensed with others in a stepwise process to gradually reduce the 15 initial groups to the four structural classes of “tonal,” “single pulse,” “click bursts,” and “repeat bursts” (Table IV). For each step the ratio between observed and expected classification accuracy was calculated.

A plot of these ratios against category number revealed a gradual increase followed by a plateau between 12 and 15 categories (Fig. 5). A plateau of this nature represents repertoire redundancy, as an increase in category number gives little net increase in classification success. Thus the 12 category repertoire appears to have maximal classification success and minimal redundancy.

The first step in the 12-signal repertoire was merging the two *styro* categories. The two categories had proved very hard to distinguish statistically. Indeed, during DFA no cases of *long styro* were correctly assigned. The second step was to join *cough* and *quack* into a new category defined as the

FIG. 5. Increase in correct classification (ratio of observed to expected values) with increasing number of signal types. Dotted line indicates the ratio of a 12-signal repertoire.

short bursts. These two vocalizations generally have very similar parameters and often clustered together during testing. The last step was to merge *laughter* with the *styros* into the category *sequenced signals*. Although these vocalizations were structurally different (i.e., single, double, and triple repeats), they were often confused during multivariate ordination. The 12-signal repertoire had a correct classification rate of 44% compared to 8.3% expected by chance (giving an observed to expected ratio of 5.3).

IV. DISCUSSION

The acoustic repertoire of the Fiordland dolphins is extremely diverse. Many of the vocalizations reported are structurally similar to signals reported elsewhere (Table I). *Whistles* and *click trains*, for example, have been reported from all acoustic studies of the *Tursiops* genus. Conversely, some vocalizations reported in other areas are not heard in the fiords, such as the low-frequency narrow-band calls recorded off eastern Australia (Schultz *et al.*, 1995). It would appear there is a geographical element to vocal repertoire that may in turn be based on differences in social structure and habitat type.

Broadband studies of cetacean repertoire are rare, particularly for free-ranging populations. High-frequency recordings of bottlenose dolphins in this study suggest that extreme broadband energy is restricted to click-based vocalizations and whistle harmonics. The click-based vocalizations may be important for echolocation, while the lower frequency vocalizations may have more communicative significance. The nature of sound is such that decreasing wavelength allows finer resolution of echoes reflected from small targets (Au, 1993). Hence echolocation clicks typically encompass higher frequencies, presumably for detecting and tracking small prey items. Conversely, lower frequency signals attenuate less energy and are more suited for long-range transmission of information during interspecific communication. In general, high frequencies are less ubiquitous for the Fiordland dolphins than for other species for which ultrasonic signals have been quantitatively described [e.g., Hector's dolphin (Dawson and Thorpe, 1990); harbour porpoise (Verboom and Kastelein, 1997); spinner and spotted dolphins (Lammers *et al.*, 2003)]. This difference may relate to relative body size. The four species mentioned are all small odontocetes, typically less than 2 m in length. The bottlenose dolphins in this study are significantly larger, with asymptotic body length conservatively predicted at 3.2 m (Schneider, 1999).

Categorization of vocalizations within a species' repertoire is essential in order to facilitate insight into functionality, social relevance, and geographical variation. Historically, dolphin vocalizations have been categorized as either tonal or pulsed (e.g., Herman and Tavolga, 1980). Some studies have further divided the pulsed category into "click trains" and "burst pulses" (Lilly and Miller, 1961; Caldwell and Caldwell, 1967; Ridgway, 1983). Results from this study are in broad agreement, with "tonal signals," "single bursts," and "click bursts" considered structurally different. However, a fourth division, "repeat bursts," is also suggested to further discriminate the pulsed vocalizations. This division is

based on the relative distinctiveness of these signals during multivariate testing combined with the growing evidence of sequenced signals from other bottlenose populations. It appears that the acoustic repertoire of bottlenose dolphins lies on a continuum with *clicks* at one extreme and *whistles* at the other. As interburst interval increases, *click trains* become *creaks*, *creaks* become *buzzes*, and so on. As consecutive pulses overlap to a greater and greater extent, the waveform becomes sinusoidal and eventually results in a *whistle*. Within the four structural classes further subdivision is possible. The initial repertoire of 15 signals was subsequently condensed to 12 based on various classification techniques. Throughout these ordinations, *whistles* were found to be uniformly different from all other signals, even the related *squeals*. Surprisingly, *splash* was also unique despite having similar aural properties to the *chokes*. Perhaps less surprising were the numerous differences between the *clicks* and all other vocalizations. The sequenced signals also tended to cluster together as might be expected. The other proposed signal types were less obviously demarcated. Condensation within the "single burst" and "repeat burst" classes provided a simplification of the repertoire with minimal change in accuracy.

Animal species tend to have small repertoires of signal units. A species' total repertoire for all sensory modalities is typically 40 to 45 units (Smith, 1969). Small repertoire size promotes the evolution of context-dependent communication. Within the cetaceans this is most obvious in those species limited to click-based vocalizations—the physeteridae (Gordon, 1987), the phocoenidae (Mohl and Andersen, 1973), and the genus *Cephalorhynchus* (Dawson, 1991). A similar scenario is played out in the repertoire of bottlenose dolphins. The click-based vocalizations have historically been associated with echolocation for navigation, orientation, and prey detection. Recent studies, however, suggest click-based vocalizations may also be socially important, such as the "pops" and "genital buzzes" produced by male dolphins during consortship [Connor and Smolker (1996) and Herzing (1996), respectively]. Thus the small repertoire of 12 signals proposed in this study may have expanded relevance in differing behavioural context. For example, a *buzz* produced in a foraging bout may represent the detection of prey during a rapid approach. The same vocalization produced in a social setting may be used for genital stimulation during sexual interactions.

The various classification techniques used in this study had different strengths, and thus often gave conflicting results. The SPCC process, for example, while providing a quantitative and repeatable comparison measure without subjective influence, has a number of weaknesses. Studies on the vocal output of songbirds suggest that as the background noise of recordings increase, between-group similarity also increases. This in turn leads to a reduction in SPCC accuracy (Terry *et al.* 2001). The SPCC technique also seems less reliable when comparing signals of different duration (Cortopassi and Bradbury, 2000). In general, SPCC techniques appear most useful when comparing similar signals, such as whistle contours. For the multivariate techniques, a drawback of typical PCA methods is that they are least squares

estimation techniques. Hence they are sensitive to outliers, which are common in realistic training sets (Kendall, 1980). In this study, the PCA process built upon quantitative measures taken automatically by the *Canary* software. As such, it was based upon subjectively selected parameters that were deemed important to human observers. However, problems of this kind are largely insurmountable. For example, the vocalizations in this study had wildly differing durations ranging from the most diminutive *splash* (0.02 s) to the most extravagant sequenced signal (120 s). This is the fundamental nature of these vocalizations and will always make classification difficult. The repertoire of vocalizations described in this paper was classified using a combination of human interpretation and multivariate ordination. However, the acoustic criteria important for signal representation in the dolphin auditory cortex remain unclear. Nevertheless, the 12-signal repertoire proposed in this study may provide the basis for subsequent analyses of geographical variation, functional importance, spatial and temporal patterns, and call sequencing.

ACKNOWLEDGMENTS

Heartfelt thanks are extended to all the volunteers who gave generously of their time to help in the field. The assistance and thoughtful suggestions of David Lusseau, Susan Lusseau, Dave Rundgren, and Steve Dawson were of particular importance. This work was made possible through the support of the New Zealand Whale and Dolphin Trust, New Zealand's Department of Conservation, the University of Otago and Real Journeys Ltd. Constructive comments were provided by two reviewers and greatly improved the original manuscript.

Information theory analysis of patterns of modulation in the advertisement call of the male bullfrog, *Rana catesbeiana*^{a)}

Dianne N. Suggs and Andrea Megela Simmons^{b)}

Department of Psychology, Brown University, Providence, Rhode Island 02912

(Received 7 October 2004; revised 10 January 2005; accepted 11 January 2005)

Male bullfrogs often amplitude modulate the envelopes of the individual notes (croaks) in their multinote advertisement calls. These amplitude modulations change the envelope of the note from smooth and unmodulated to one with varying numbers of modulations. A Markov analysis shows the pattern of change in the envelope to be highly ordered, but not completely so (semi-Markovian). Three simple rules govern the presence or absence of modulations in individual notes. These rules are (1) all calls begin with an unmodulated note; (2) the first note to be modulated will contain only one modulation; and (3) when a change in modulation occurs from one note to the next, it does so with an increase or a decrease of one modulation only. The addition of modulations is correlated with an increase in note duration. Physiologically, the presence of modulations might increase the precision of temporal coding of note periodicities in the central auditory system. © 2005 Acoustical Society of America. I. INTRODUCTION

Animals use acoustic signals of different form and complexity to communicate such messages as species identification, individual identification, advertisement of social status, advertisement of biological fitness, sexual motivation, and aggressive motivation. Some species have evolved large, complex repertoires to communicate these different messages, while others use a more limited repertoire. A fundamental question in the study of acoustic communication concerns how animals are able to convey multiple, biologically relevant messages with a limited number of signals. The acoustic behavior of anuran amphibians (frogs and toads) has been extensively studied as a model of a communication system consisting of a relatively small repertoire (Wells, 1977; Gerhardt and Huber, 2002). In some species, separate notes in a call communicate distinct messages to different receivers (Narins and Capranica, 1978), while in other species, the same notes may send simultaneous, different messages to different receivers (Capranica, 1965). The incorporation of different messages within a limited repertoire may be achieved by varying the complexity as well as the degree of stereotypy of the signal (Gerhardt and Huber, 2002).

The male bullfrog (*Rana catesbeiana*) emits a harmonically complex advertisement call that is important for regulating both male–male territorial and male–female attractive interactions (Emlen, 1968; Wiewandt, 1969). The spectral and temporal structure of this vocalization has been described in several publications (Capranica, 1965; Wiewandt, 1969; Bee and Gerhardt, 2001; Bee, 2004; Simmons, 2004). The advertisement call consists of a series of 1–12 individual notes (croaks). The one-note call has been categorized as having a territorial or aggressive function (Capranica, 1965),

but the communicative function of the variation in number of notes beyond one has not been definitively established. Each note consists of a number of harmonically related frequencies, extending from about 200 to about 2000 Hz, with a missing or attenuated fundamental frequency around 100 Hz. There is considerable interindividual variability in acoustic properties of individual notes (Bee and Gerhardt, 2001; Bee, 2004). Males may be able to use these differences to discriminate neighbors from strangers, and near neighbors from far neighbors (Davis, 1987; Boatright-Horowitz *et al.*, 2000; Bee and Gerhardt, 2001). Which features female bullfrogs use to choose particular males in a chorus has not been established.

The purpose of this study is to describe and analyze a feature of the male bullfrog's advertisement call that has not as yet been addressed in the literature. Whereas the envelope, or overall shape, of the individual notes has typically been represented as smooth and unmodulated (Capranica, 1965; Bee and Gerhardt, 2001; Bee, 2004; Simmons, 2004), this is frequently not the case. Rather, males often add extra modulations to the envelopes of the individual notes in their calls. The effect of these extra modulations is to change the shape of the envelope so that visually it contains partial gaps, or repetitive valleys. Human listeners perceive these gaps as slight hesitations or pauses (“stutters”). Using analyses based on information theory (Shannon and Weaver, 1949), we characterize the pattern of change in the envelope of individual notes in the advertisement call. Our data show that modulations are added to individual notes in a highly ordered fashion. The robustness of the pattern suggests that these modulations may serve some communicative function.

II. MATERIALS AND METHODS

A. Field sites

Recordings of the calling activity of male bullfrogs from 1994 ($N=10$) and 2003 ($N=10$) were used to analyze the

presence of modulations in individual notes in their advertisement calls. In July 1994 spontaneous chorusing was recorded at a natural bullfrog breeding pond (80×35 m) located in eastern Rhode Island (41°44'34"N,71°20'14"W); analysis of the vocal interactions between males in this chorus has been published previously (Boatright-Horowitz *et al.*, 2000). Air and water temperatures were measured to an accuracy of 0.5 °C during each recording session and ranged between 21 and 25 °C. Chorus density varied from eight to ten vocalizing males each night.

In June and July 2003, spontaneous chorusing was recorded (as part of a larger experiment, results of which will be presented separately) at three breeding sites in Rhode Island and Massachusetts. The location of the 1994 recordings served as site 1 in the 2003 recording sessions. Chorus density varied between six and eight vocalizing males. Site 2, located in central Massachusetts (42°25'47"N, 71°49'35"W), is a permanent pond approximately 100 m in length and 30 m wide. Chorus density ranged from six to ten vocalizing males. Site 3, located in northwestern Rhode Island (41°45'00"N,71°45'00"W), is a permanent pond approximately 90 m long and 25 m wide. Chorus density was lower at this site, ranging from three to five calling males per night. Air and water temperatures of the three sites were measured to an accuracy of 0.5 °C and ranged between 17 and 26 °C.

B. Data collection

During 1994, spontaneous chorus activity was recorded on 3 nights between the hours of 22.00 and 00.15 h. Male advertisement calls were recorded using a battery-powered Marantz cassette recorder (model PMD430: frequency response 0.05–14 kHz, ±3 dB) and a Bionic Ear microphone (frequency response 0.1–14 kHz, ±3 dB) positioned on a Styrofoam platform placed in the water 1 m from an actively calling male. In 2003, chorus activity was recorded on 10 nights between the hours of 21.00 and 01.00 h using a Midnight Blue MB2000L (frequency response 0.06–15 kHz, ±3 dB) or Sennheiser ME66 (frequency response 0.05–20 kHz, ±3 dB) microphone, positioned on a Styrofoam platform about 1 m from individual frogs, and recorded onto the Marantz cassette recorder. Recording sessions lasted between 30 min and 3 h depending on the activity of the chorus. Individual males within each chorus were identified through field notes and visual and auditory inspection of each individual's calls. Such identification is possible due to the small amount of variation in fundamental and dominant frequencies within an individual's calls, whereas significant variability can be detected between the calls of individual frogs (Bee and Gerhardt, 2001). In addition, calling males maintained relatively fixed territorial positions during a single night's chorus and were easily identified by spatial location.

C. Data analysis

Spontaneous vocalizations were converted to 44.1-kHz, 16-bit WAV-format sound files using COOLEEDIT 2000. Figure 1 is an oscillogram of an advertisement call recorded during the summer of 1994. This particular call consist of six indi-

FIG. 1. Oscillogram of a male bullfrog's call recorded at site 1 in 1994. This particular call is made up of six individual notes or croaks. Arrows point to modulations or gaps seen in individual notes. The first note contains no modulations; notes two through six contain 1, 2, 3, 2, and 2 modulations, respectively. Time-domain waveform was exported from COOLEEDIT 2000.

vidual notes. The first note has a smooth, unmodulated envelope, while the envelopes of the other five notes contain modulations. For each call, the numbers of notes and the number of modulations within each note were determined in COOLEEDIT by visual and auditory inspection. The frequency of modulation, the fundamental frequency, and the frequency spectrum of each note were analyzed by a custom-written MATLAB v 6.5 (MathWorks, Natick, MA) script. Duration of individual notes was measured using COOLEEDIT (1-ms resolution) and analyzed using SPSS v. 11.5 statistical packages.

To analyze any pattern in the incorporation of modulations within notes, all advertisement calls with no modulations in any notes were eliminated. Calls whose individual notes could not be completely analyzed due to overlap by calls of neighboring males or interference by nonbiological sources of noise were eliminated as well. The remaining calls were analyzed using UNCERT, a program that examines serial dependencies in sequences of events using Markov chain analysis (Hailman and Hailman, 1993). The program calculates frequencies and probabilities of occurrence of a series of events, the frequencies and probabilities of transition from one event to another, and the uncertainties associated with the events and their transitions. These analyses can be used to evaluate the organizational complexity of, for example, a signal repertoire (McGowan *et al.*, 1999). In our data set, the sequence of events is the number of modulations within consecutive notes in a call. The hypothesis tested is that the number of modulations changes in a systematic way from note to note.

The diversity in the series of events is represented by an uncertainty value, a logarithmic measure (Hailman and Hailman, 1993) based on communication theory (Shannon and Weaver, 1949). To find the maximum amount of uncertainty in a data set, the following formula is applied: $U_m = \log_2 K$, where U_m measures the diversity of events within a sample, \log_2 is the logarithm to the base 2, and K denotes the number of different kinds of events involved. Consider, for example, an animal's repertoire consisting of just one kind of event. The maximum uncertainty would be calculated as $U_m = \log_2(1) = 0$. This makes intuitive sense, because with only one event in a repertoire, there would be absolutely no uncertainty as to what kind of event would follow. Zero-order uncertainty (U_0) is a measure of the probabilities of each of

TABLE I. Bullfrog advertisement calls collected during 1994 and 2003 by date and site. The number of calls, number of calls with modulations (mods), and number of one-note calls are indicated for each recording session. More than 80% of the modulated calls conform to the two patterns identified.

7/14/03	3	163	72	97.2	100	60	0

the kinds of events and thus the complexity of the repertoire. Within each data set of events, each individual event (i) has its own frequency of occurrence (F_i). The total number of events of all kinds is the sum of the total frequencies (N). This means that the probability that event i (or P_i) will occur equals the frequency of i (or F_i) divided by the total frequencies of all events (N). If all events are equally probable, $U_0 = U_m$. First-order uncertainty (U_1) measures the dependencies between first and second events, and second-order uncertainties (U_2) measure the transitional probabilities between event pairs and third events in sequences (Hailman and Hailman, 1993). Although higher measures of uncertainties exist, our data do not exhibit the complexity that would warrant application of them.

III. RESULTS

A. General patterns

A total of 5567 bullfrog calls was collected from 17 recording sessions. Of these calls, 2599 consisted of single- and multinote calls that contained no modulations. Within the remaining 2968 calls, 432 could not be completely analyzed due to interference or call overlap and were eliminated from further analysis. This left a total of 2536 calls made up of 13 081 individual notes that were further analyzed for any pattern in the presence of modulations. Results of analysis of these calls listed according to date and sampling site are shown in Table I.

All single-note calls ($N = 1455$) had unmodulated envelopes. On any recording night, between 27%–72% of all calls (mean 30.4%) contained at least one note with modulations. Between 81.9%–100% of calls that contained any notes with modulations began with one unmodulated note. The mean percent of calls conforming to this “addition of modulations begins with 1 modulation” rule was 91.46%

$\pm 5.1\%$. When the number of modulations increased or decreased between successive notes within a call, it did so by just one modulation in 91.2%–100% of the calls. A mean of $97.5\% \pm 2.5\%$ of calls followed the “modulation increases or decreases by one” rule.

The number of modulations overall varied from 1 to 6 in separate calls, with modulation frequencies all below 12 Hz. One animal produced 5 notes with 7, 8, or 9 modulations, but this occurred so rarely that these notes were excluded from analyses with UNCERT.

B. Uncertainty analyses

The data set was categorized into seven different kinds of events based on the number of modulations (0 to 6) observed in call notes. Based upon the analysis performed by UNCERT, Table II reveals the frequencies and probabilities of the occurrences of each of the seven kinds of events. Maximum uncertainty (U_m) as computed on seven events is 2.81 bits/event and zero-order uncertainty (U_0) is 2.03 bits/event. A bit is a contraction of computer language’s “binary digit” and is considered the basic unit of information. What this means is that the number of bits is the power to which the number 2 must be raised in order to give the number of

equiprobable messages in a signal or a system (Lewis and Gower, 1980). Table III shows a matrix depicting the frequencies of the events as they transition either to the following event or as a repetition of themselves. To obtain a Markovian chain analysis, the frequencies in Table III were converted to probabilities to give a clearer picture of the pattern of insertion of modulations. Based upon those probabilities, U_1 is calculated as 1.31 bits/events, and U_2 as 1.27 bits/event.

Individual graphs for each event are shown in Fig. 2. For each of the graphs, the initial state (S) is identified by the number in the upper-right corner. The probability of the next event is illustrated for each of the seven possibilities (0 through 6). For example, the event state S-0 is followed by a repetition of itself with a probability of 0.42, by S-1 with a probability of 0.53, and by S-2 with a probability of 0.05. Event state S-1 is followed by S-0 with a probability of 0.04, by a repetition of itself by 0.39, by S-2 with a probability of 0.56, and by S-3 with a probability of 0.01. Inspection of the individual graphs shows the increased probabilities of an event being followed by itself, by the preceding event, or by the following event. This pattern is precisely predicted by the “number of modulations increases or decreases by one” rule.

This pattern of transition can be graphically represented through the use of kinematic graphing. Kinematic graphs represent the temporal or sequential ordering of events. Because a system can only be in one state at a time, each state must exclude all other states. In addition, the states must be discrete and easily discriminated from one another (Sustare, 1978). The present data follow these rules perfectly. A male bullfrog can produce only one event state (a single note) at one time, and each event state within its call is discernible from all others (zero through 6 modulations in individual notes). In our kinematic diagram (Fig. 3), circles are used to represent individual events. Events are categorized and labeled according to the number of modulations contained within a note, beginning with S-0 (unmodulated), S-1 (one modulation), S-2 (two modulations), and so forth up to and including S-6 (six modulations). Each time one state ends and is followed by another state, a transition is said to occur.

When a transition occurs, it is depicted by an arrow between the two state events. The direction of the arrow shows the temporal sequence of the events—always pointing away from the initial state and towards the following state. Recurrent arrows, which point from one state back to itself, represent a temporal repetition of that state. When all arrows are

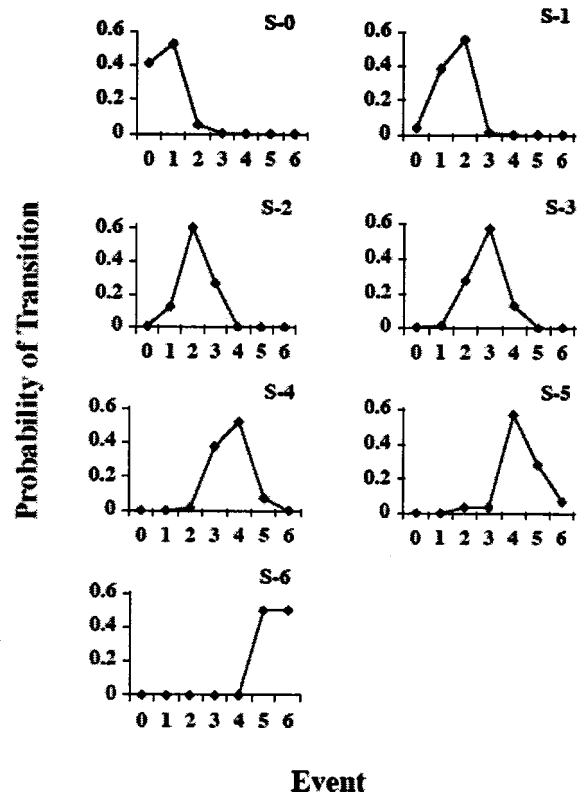

FIG. 2. Probabilities of transition from each of the seven kinds of events (S-0 to S-6, upper right corner in each graph) to each of the events (0 through 6 on x axis). For example, a note containing zero modulations (upper-left graph) is followed by another note with no modulations with a probability of 0.42, by a note with one modulation with a probability of 0.53, by a note with two modulations with a probability of 0.002, by a note with 4 modulations with a probability of 0.0005, and by a note with 5 or 6 modulations with a probability of 0.

FIG. 3. Kinematic diagram of first-order Markov chain analysis. Events are represented by circles (S-0 through S-6, depending upon number of modulations contained within the note). Transitions between events are depicted by arrows pointing away from an initial event and towards a following event. Recurrent arrows represent repetitions of initial events. Probabilities of transitions are found next to arrows.

included in the kinematic graph, a complete picture of the behavior of the system results. Beginning with event S-0, 41.7% of the total S-0 events are recurrent (repeating); 52.9% transition to event S-1; 5.1% transition to event S-2; and very small fractions transition to events S-3 and S-4 (0.021% and 0.005%, respectively). Due to the relatively small amounts of information these transitions add to the system, coupled with the attempt to maintain clarity in the diagram, they are not represented by arrows in the kinematic graph. Moving through the graph, the same observations can be made for each of the event states (S-1 through S-6), with the frequencies of transitions emanating from each of the event states totaling 100%.

C. Correlation with other acoustic parameters

The addition of modulations to the envelope of individual notes is correlated with an increase in note duration.

FIG. 4. Relationship between note duration and number of modulations per note in the spontaneous vocalizations of one male recorded at site 1 in 1994. The curved line is the best-fitting regression through the data.

This trend is shown in Fig. 4 for an individual male. Data are best fit by a cubic regression ($r^2=0.83, P<0.01$). Over all males, the relationship between note duration and number of modulations is statistically significant ($\rho=0.63, P<0.001$). In contrast, in advertisement calls with no modulated notes, there is no significant relationship ($\rho=0.12$) between note duration and its position within the call (that is, later notes do not have longer durations than earlier notes). The change in duration between successive notes thus is related to the insertion of modulations, not to note position.

Although the insertion of modulations into successive notes followed the patterns described for all males, there was individual variability in the extent to which males added modulations to their calls. Individual variability was determined for the ten males recorded in 1994, during sessions in which each male was recorded for periods of about 3 h. The percent of calls that included any modulations varied from 0% to 100% between individuals. There was no significant relationship ($r^2=-0.06$) between the percent of calls that included modulations and fundamental frequency of unmodulated notes in an individual's calls. From this analysis, we infer that the insertion of modulations may be related to chorus dynamics or to female choice rather than to male body size (which is correlated with fundamental frequency; Bee and Gerhardt, 2001).

D. Variation over chorus time

The numbers of calls containing modulations in any notes as a percent of total calls for all males from site 1 in 2003 are shown in Fig. 5(A). The percent of calls with modulations is low on the first recording day (which was the first day males were vocally active at that site), rises to a maximum of about 50% on the second day, and levels off around 40% until the end of the calling season at that site. Data from an individual male on one night, recorded at site 1 in 1994, are shown in Fig. 5(B). The number of notes with modulations (regardless of the number) given by this male varies over the entire chorusing bout, with a peak between calls 40 and 50. Notes with modulations are not restricted to either the beginning or the end of the calling bout, but occur throughout and seem to alternate with unmodulated calls.

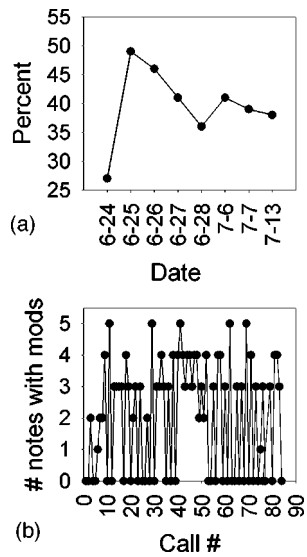

FIG. 5. (A) Percent of calls containing any modulations as a function of all calls in the spontaneous vocalizations of male bullfrogs recorded at site 1 in 2003. (B) Number of notes with modulations in the spontaneous calling of one male recorded at site 1 in 1994.

IV. DISCUSSION

Individual notes in the advertisement call of male bullfrogs often contain extra envelope modulations that visually appear as gaps within an individual note and which acoustically to human listeners resemble pauses or “stutters.” There appear to be three simple rules that govern the pattern of incorporation of these modulations within individual notes in an advertisement call. First, all calls begin with an unmodulated note. Second, the first note to contain a modulation contains only one. Third, the number of modulations changes systematically between notes, with an increase or a decrease of one modulation only. Adherence to these rules is exceedingly robust. Of the 2536 calls analyzed, 100% began with a note containing no modulations, 91.5% followed the “modulation begins with one” rule, and 97.5% followed the “plus or minus one modulation” rule. This pattern is consistent between individual males, as well as across choruses and breeding sites. The regularity of the pattern suggests that it serves some biological significance in the communication behavior of the bullfrog.

A. Markov chains, properties, and processes

Markov chain analyses were developed as a way of determining if events that occur in sequence are independent of one another. A crucial feature of these analyses is the concept of uncertainty (or entropy), which is calculated using the number of events that occur in a particular sequence. When such events are completely independent of one another (i.e., the previous event has absolutely no influence on the immediately following event), the data are described as exhibiting the Markov property. At the other end of the spectrum are previously occurring events that absolutely determine the appearance of the following event. These types of data are termed Markov processes. In a Markov process, knowing which event occurs first will completely predict which event will follow. Animal behavior often falls between these two

extremes and is therefore labeled semi-Markovian (Fagen and Young, 1978). This simply means that the last event the animal engages in may be a good predictor, albeit not a perfect one, of the next event to follow. Because different sets of data vary in their degree of approach to true Markov processes, information theory (Shannon and Weaver, 1949) can be used to estimate how much uncertainty occurs in a sequence of events, and thus provide an estimate of the amount of redundancy or diversity in a particular data set. This kind of analysis has become a powerful quantitative tool for examining and analyzing animal communication systems in diverse species and across a range of modalities. Information theory has been used to categorize the whistle signals of dolphins (McGowan *et al.*, 1999, 2002) and the call repertoires of Mexican chickadees (Ficken *et al.*, 1993), and to analyze aggressive communications in mantis shrimp (Dingle, 1969) and hermit crabs (Hazlett and Bossert, 1965). It has also been applied to analysis of intermale behavior of grasshoppers (Steinberg and Conant, 1974), the study of brood recognition in Mexican free-tailed bats (Beecher, 1989), and the mutually symbiotic relationship between goby fish and snapping shrimp (Preston, 1978). It is this generality of application that makes information theory so useful in examining the capacity, structure, and organization of animal repertoires.

Uncertainty analyses reveal that the appearance of modulations in bullfrog advertisement calls follows a semi-Markovian, deterministic pattern. This is shown in the sizable drop in uncertainty that occurs between U_0 and U_1 , with less of a drop between U_1 and U_2 . The drop between U_m and U_0 shows that knowing the relative frequencies of the seven events in the data set has decreased the amount of uncertainty, and the drop from U_0 to U_1 has established the existence of a pattern. The low value of U_1 is consistent with the “plus or minus 1” rule, since knowing how many modulations (x) the first note has strongly implies the next note will contain x , $x + 1$, or $x - 1$ modulations. The analyses suggest that information transfer is occurring based upon the ordered frequencies between successive events.

B. Mechanisms of production

Calling is an energetically costly behavior for frogs, with an oxygen demand that exceeds that occurring during forced exercise (Taigen and Wells, 1985). In *Hyla*, the trunk muscles are specialized for high-power output, but are highly susceptible to fatigue (Girgenrath and Marsh, 1999). It is possible that the pattern of insertion of modulations reported here reflects fatigue of the vocal musculature. For example, the production of modulations in a series of successive notes might indicate that the male was simply running out of breath. Such a fatigue hypothesis implies that bullfrogs would incorporate more modulations in their calls at the end than at the beginning of a nightly chorus, and that the aggregate chorus would show more modulations at the end than near the beginning of the calling season. Our behavioral data do not show such a simple trend.

In *Bufo*, amplitude modulation of vocalizations is produced by both active (pattern of contraction of the thoracic musculature) and passive (vibration of the arytenoid carti-

lages) mechanisms (Martin, 1971). Which mechanism best accounts for the pattern of modulation seen here cannot be determined from the present data. One possibility is that the production of longer call notes might passively engage the arytenoid cartilages, thus producing modulations. The positive relationship between note duration and number of modulations supports this hypothesis. Inserting modulations might also allow the male to extend the length of the individual notes in his calls while reducing the amount of air exchange needed. This in turn implies that longer duration notes have a different perceptual significance than shorter duration ones. Male bullfrogs do not respond readily to playbacks of short-duration notes outside the normal range of variability in note duration, but they respond equally vigorously to playbacks of modal duration and long-duration notes, showing patterns of generalization rather than discrimination for this acoustic feature (Simmons, 2004). These data suggest that the insertion of modulations *per se* might not have a perceptual significance to other males in the chorus. On the other hand, female bullfrogs, like female frogs of other species (Gerhardt and Huber, 2002), may prefer notes with longer rather than shorter durations, and use note duration as an indicator of male quality. This hypothesis has not been tested directly.

C. Physiological relevance of envelope modulation

Envelope periodicity is an important feature mediating vocal interactions in many anuran species (Gerhardt and Huber, 2002). In playback experiments, male bullfrogs respond differentially to synthetic advertisement calls with unmodulated and modulated notes, when these envelope differences are produced by changes in either the phase structure or the harmonic structure of the signal (Hainfeld *et al.*, 1996; Simmons and Bean, 2000). Although these experiments did not explicitly test responses to signals that resemble the modulation pattern described here, they predict that modulation is a salient perceptual cue for these animals. Physiological experiments show that the 100-Hz periodicity of unmodulated synthetic notes and the envelope fluctuations produced by changes in phase structure are encoded in the bullfrog's eighth nerve by a neural code based on phase-locked discharges (Schwartz and Simmons, 1990; Simmons *et al.*, 2001). This temporal code seems to weaken in the central auditory system, such that, in the auditory midbrain (torus semicircularis, TS), only a relatively small number of neurons respond with phase-locked discharges to modulations in the 90–100-Hz range (Simmons *et al.*, 2000). Yet, strong phase-locked activity continues to occur even in the TS in response to signals with amplitude modulations of 20–50 Hz (Bibikov and Nizamov, 1996; Simmons *et al.*, 2000). The modulated notes described in this study have low-frequency modulations of 12 Hz or less. Although such low frequencies have not been tested in studies of modulation coding in the frog's auditory midbrain, we predict that these stimuli would produce strong phase locking, thus retaining a temporal code for processing of the advertisement call in the central auditory system.

(Received 6 August 2004; revised 6 January 2005; accepted 11 January 2005)

The general approach to estimate the displacement of rounded objects (specifically, gas bubbles and solid spheres) in elastic incompressible media in response to applied acoustic radiation force is presented. In this study, both static displacement and transient motion are analyzed using the linear approximation. To evaluate the static displacement of the spherical inclusion, equations coupling the applied force, displacement, and shear modulus of the elastic medium are derived. Analytical expressions to estimate the static displacement of solid spheres and gas bubbles are presented. Under a continuously applied static force, both the solid sphere and the initially spherical gas bubble are displaced, and the bubble is deformed. The transient responses of the inclusions are described using motion equations. The displacements of the inclusion in elastic incompressible lossless media are analyzed using both frequency-domain and time-domain formalism, and the equations of motion are derived for both a solid sphere and a gas bubble. For a short pulsed force, an analytical solution for the equations of motion is presented. Finally, transient displacement of the gas bubble in viscoelastic media is considered. © 2005 Acoustical Society of America.

I. INTRODUCTION

Recent research on acoustic radiation force has shown great promise for several applications including biomedical ultrasound. For example, shear waves may be induced in tissue by the radiation force of a focused ultrasonic beam and provide shear wave imaging.¹ Another application offers remote palpation using a radiation force method to get information about the local mechanical properties of tissue.^{2–4} In these applications the acoustic radiation force generates localized tissue displacement that depends on its mechanical properties. The radiation force in tissue-like media is determined by the absorption and reflection of ultrasound from inhomogeneities. Lesions or other targets (like gas bubbles or solid spheres) can be considered as inhomogeneities.

A few studies utilizing the radiation force acting on a gas bubble⁵ and a solid sphere⁶ have been reported recently. Erpelding *et al.*⁵ described how the acoustic radiation force was applied to a gas bubble (generated by femtosecond laser pulses focused in the volume of tissue-mimicking gels). Bubble displacements in gelatin phantoms of different concentrations were measured and the maximum displacement reached was several hundreds of micrometers.⁵ Furthermore, it was shown that the bubble displacement depended on the elastic (Young's or shear) modulus of the gel.

In a study by Chen *et al.*, the response of a solid sphere, embedded into an otherwise homogeneous gelatin phantom, was measured.⁶ The mechanical excitation of the sphere was produced using a low-frequency radiation force. The velocities of vibrating spheres of different radii were measured in both liquid (water) and elastic (gelatin) medium. Calculations were performed using the analytical model based on

Oestreicher's theory as developed for the oscillations of a rigid sphere in a viscoelastic medium.⁷ The results of the study demonstrate that mechanical response of the sphere under radiation force is related to viscoelastic properties of the surrounding medium and can be used to determine the local material properties.⁶

Three methods to estimate the radiation force \mathbf{F}_r in acoustic field are often used. The first method is based on the equation derived for a bubble pulsating in liquid^{8,9}

$$\mathbf{F}_r = -\langle V \nabla p_a \rangle, \quad (1)$$

where V is the bubble volume, ∇p_a is a gradient of the acoustic pressure in a medium, and $\langle \rangle$ denotes an average with respect to time.

The second method commonly used is based on conservation of momentum.¹⁰ Assuming that the bubble radius is much smaller than an acoustic wavelength, the scattered wave is nearly spherical and does not carry away a momentum, so the momentum of the incident wave is changed due to absorption and bubble radiation by the amount W_r/c_0 per unit time (W_r is the total radiated and absorbed acoustic power, c_0 is the speed of sound.) Neglecting the absorption and applying the equation for the pressure in far field $p_r = \rho \ddot{V}/4\pi r$ presented in Ref. 11, the radiated power yields

$$W_r = \frac{4\pi r^2}{\rho c_0} p_r^2 = \frac{\rho}{4\pi c_0} \dot{V}^2, \quad (2)$$

where \ddot{V} is the second derivative of the bubble volume with respect to time. It is worth noting that Eq. (2) can be applied to bubble oscillations of both small and finite amplitude.¹¹ The acoustic radiation force is

$$F_r = \frac{W_r}{c_0} = \frac{\rho}{4\pi c_0^2} \langle \ddot{V}^2 \rangle. \quad (3)$$

The third method reviewed here is as follows. The radiation pressure on the target can be estimated by integrating the acoustic field in the surrounding medium with respect to the target surface. For example, Hasegawa and Yosioka used this method to calculate the radiation force on a solid elastic sphere in a plane progressive sound field in liquid.¹²

These approaches have been developed to evaluate the radiation force in liquids, but they can also be applied to estimate the radiation force in tissue-like media. Rigorous verification of the last statement will be presented in our next publication. In the analysis presented here, the radiation force is assumed to be given.

In this paper, the static displacement and transient motion of a gas bubble and a rigid sphere in a viscoelastic medium is estimated and discussed. The current study is focused on developing a theoretical model to describe both static and transient displacements of a target in soft elastic media in response to the externally applied radiation force. The analysis is performed in the linear approximation.

The static displacements of a sphere and a gas bubble in elastic media are considered first. In this case, the pushing force is considered to be given and constant, and the elastic medium is assumed to be isotropic, homogeneous, incompressible, and inviscous. A technique similar to the one applied to estimate Stokes' drag of a solid sphere in viscous incompressible liquid is used here. The transient motions of the sphere and the gas bubble in the elastic, incompressible, inviscous medium are investigated in response to a time-varying force. Both monochromatic and impulse forces are considered. Finally, the transient motion of the bubble in the viscoelastic incompressible media is analyzed. The paper concludes with discussion of the results. Results of this study were partly presented at the 147th Meeting of the Acoustical Society of America.¹³

II. STATIC DISPLACEMENT

Static displacement of an object that can be a rigid sphere or a gas bubble in an elastic medium is estimated in the linear approximation. The applied force is assumed to be constant, i.e., not varying with time. While in a liquid the object is displaced as long as the force is applied, in an elastic medium the displacement is constrained by the elastic properties of the medium. In our analysis the elastic medium is assumed to be isotropic, homogeneous, incompressible, and inviscous. The technique used here is similar to Stokes' formula derivation for the drag of a solid sphere in viscous, incompressible liquid.

For small Reynolds numbers, the Stokes' force, F_s , acting on a solid sphere moving with velocity v in viscous incompressible liquid is (see, for example, Ref. 14)

$$F_s = 6\pi\eta Rv, \quad (4)$$

where R is a solid sphere radius, and η is the viscosity coefficient of liquid. The starting point of Stokes' formula deri-

vation is the equation for the velocity of incompressible viscous liquid¹⁴

$$\eta\nabla^2\mathbf{v} = \nabla p, \quad (5)$$

and the continuity equation

$$\nabla \cdot \mathbf{v} = 0, \quad (6)$$

where \mathbf{v} is a relative velocity between the sphere and surrounding liquid, and p is the pressure in the liquid.

In the elastic medium only finite displacement of the bubble or the sphere from an initial position takes place. The balance equation for stress tensor σ_{ik} in an incompressible isotropic elastic medium is^{15,16}

$$\frac{\partial \sigma_{ik}}{\partial x_k} = 0. \quad (7)$$

Taking into account that the stress tensor in incompressible elastic medium is

$$\sigma_{ik} = -p\delta_{ik} + 2\mu u_{ik}, \quad (8)$$

and the strain tensor u_{ik} in linear approximation is

$$u_{ik} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i} \right), \quad (9)$$

Eq. (7) can be reduced to the equation

$$\mu\nabla^2\mathbf{u} = \nabla p. \quad (10)$$

Here, \mathbf{u} is a displacement vector, μ is the shear modulus of the elastic incompressible medium, and p is the isotropic part of a stress tensor. Incompressibility of the elastic medium in the linear approximation requires

$$\nabla \cdot \mathbf{u} = 0. \quad (11)$$

Equations (10) and (11) for displacement in an elastic incompressible medium are identical to Eqs. (5) and (6) for velocity in viscous incompressible liquid. Therefore, the technique developed to solve Eqs. (5) and (6), presented in detail in Ref. 14, can be used to solve Eqs. (10) and (11).

The solution of Eqs. (10) and (11) can be presented in the form

$$\mathbf{u} = \nabla \times (\nabla f \times \mathbf{e}) = \nabla \times \nabla \times (f\mathbf{e}). \quad (12)$$

Here, $f = f(r)$ is a scalar function

$$f(r) = ar + \frac{b}{r}, \quad (13)$$

and \mathbf{e} is a unit vector along the displacement, and constants a and b are determined by boundary conditions on the object surface.

If the polar axis of the spherical system of coordinates is along the displacement vector (i.e., an angle θ is between a radius vector and displacement), the equations for the components of the displacement vector \mathbf{u} are

$$u_r = \frac{2}{r^2} \left(-ar + \frac{b}{r} \right) \cos \theta, \quad u_\theta = \frac{1}{r} \left(a + \frac{b}{r^2} \right) \sin \theta. \quad (14)$$

From Eq. (10) the pressure gradient created by the displaced object is

$$\nabla p = \mu \nabla^2 \mathbf{u} = \mu \nabla^2 [\nabla \times \nabla \times (f\mathbf{e})]. \quad (15)$$

Following the derivations presented in Ref. 14, the pressure is

$$p = p_0 + \mu \nabla^2 [\nabla \cdot (f\mathbf{e})] = p_0 + \mu (\mathbf{e} \cdot \nabla) \nabla^2 f, \quad (16)$$

where p_0 is an integration constant that describes the pressure far away from the object. The force on the displaced solid sphere or bubble in the elastic medium is¹⁴

$$F = \int (-p \cos \theta + \sigma_{rr} \cos \theta - \sigma_{r\theta} \sin \theta) dS. \quad (17)$$

Here, dS is an element of the sphere surface, and σ_{rr} and $\sigma_{r\theta}$ are components of a stress tensor given by

$$\sigma_{ik} = \mu \left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i} \right). \quad (18)$$

Due to the symmetry of the problem, Eq. (17) should be integrated with respect to θ only

$$F = 2\pi R^2 \int_0^\pi (-p \cos \theta + \sigma_{rr} \cos \theta - \sigma_{r\theta} \sin \theta) \sin \theta d\theta. \quad (19)$$

Consequently, the stress tensor components written in the spherical system of coordinates are

$$\sigma_{r\theta} = 2\mu u_{r\theta} = \mu \left(\frac{\partial u_\theta}{\partial r} - \frac{u_\theta}{r} + \frac{1}{r} \frac{\partial u_r}{\partial \theta} \right), \quad (20)$$

$$\sigma_{rr} = 2\mu u_{rr} = 2\mu \frac{\partial u_r}{\partial r}. \quad (21)$$

In the following sections, the displacements of the solid sphere and the gas bubble in the elastic medium are considered.

A. Static displacement of the solid sphere

The boundary conditions at the surface of the rigid solid sphere of radius R displaced by a vector \mathbf{u}_0

$$u_r(R, \theta) = u_0 \cos \theta, \quad u_\theta(R, \theta) = -u_0 \sin \theta, \quad (22)$$

allow us to find the constants a and b

$$a = -\frac{3Ru_0}{4}, \quad b = -\frac{R^3u_0}{4}. \quad (23)$$

Therefore, Eqs. (14) can be rewritten

$$u_r(r, \theta) = u_0 \left(\frac{3R}{2r} - \frac{R^3}{2r^3} \right) \cos \theta, \quad (24)$$

$$u_\theta(r, \theta) = -u_0 \left(\frac{3R}{4r} + \frac{R^3}{4r^3} \right) \sin \theta.$$

The function f in this case is

$$f = ar + \frac{b}{r} = -\frac{Ru_0}{4} \left(3r + \frac{R^2}{r} \right). \quad (25)$$

Calculating $\nabla^2 f$ and substituting into Eq. (16) yields

$$p = p_0 - \frac{3\mu Ru_0}{2} (\mathbf{e} \cdot \nabla) \frac{1}{r} = p_0 + \frac{3\mu Ru_0}{2r^2} \cos \theta. \quad (26)$$

The necessary stress tensor components are then

$$\sigma_{r\theta} = \frac{3\mu u_0}{2r^4} R^3 \sin \theta, \quad (27)$$

$$\sigma_{rr} = -\frac{3\mu u_0}{r} \left(\frac{R}{r} - \frac{R^3}{r^3} \right) \cos \theta. \quad (28)$$

On the surface of the sphere ($r=R$), the radial component of the stress vanishes ($\sigma_{rr}=0$). Substituting Eqs. (26) and (27) into Eq. (19) and integrating yields

$$F = -6\pi\mu Ru_0. \quad (29)$$

Equation (29) is similar to Stokes' formula presented here by Eq. (4), where the viscous coefficient η is replaced by the shear modulus μ , and velocity v is replaced by the displacement u_0 . Equation (29) accounts for the force acting on the spherical particle displaced by the vector \mathbf{u}_0 in the elastic medium. If an external force (i.e., the radiation force) is applied to the sphere, the sign should be changed

$$F_r = 6\pi\mu Ru_0, \quad (30)$$

and the displacement of the sphere is

$$u_0 = \frac{F_r}{6\pi\mu R}. \quad (31)$$

Therefore, the displacement of the solid sphere in the elastic medium is proportional to the applied force and inversely proportional to the shear modulus of the medium and the radius of the sphere.

Equation (31) can be applied to estimate displacements of nonspherical targets.

B. Static displacement of a gas bubble

Static displacement of a gas bubble in the elastic medium is estimated with the same equations but the boundary condition is different. The boundary condition at the surface of the gas bubble ($r=R$) is

$$\sigma_{r\theta} = 0. \quad (32)$$

The stress tensor component $\sigma_{r\theta}$ can be evaluated using Eq. (20), where u_r and u_θ are given by Eqs. (14)

$$\sigma_{r\theta} = \mu \left(\frac{\partial u_\theta}{\partial r} - \frac{u_\theta}{r} + \frac{1}{r} \frac{\partial u_r}{\partial \theta} \right) = -\frac{6\mu}{r^4} b \sin \theta. \quad (33)$$

The boundary condition requires that $b=0$. Therefore, the components of the displacement vector are

$$u_r = -\frac{2a}{r} \cos \theta, \quad u_\theta = \frac{a}{r} \sin \theta, \quad (34)$$

and $\nabla^2 f$ is

$$\nabla^2 f = \frac{2a}{r}. \quad (35)$$

The pressure is calculated using Eq. (16)

$$p = p_0 + 2\mu a(\mathbf{e} \cdot \nabla) \frac{1}{r} = p_0 - \frac{2\mu a}{r^2} \cos \theta. \quad (36)$$

The component of the stress tensor σ_{rr} is

$$\sigma_{rr} = 2\mu \frac{\partial u_r}{\partial r} = \frac{4\mu a}{r^2} \cos \theta. \quad (37)$$

The value a in Eq. (37) is estimated using the equilibrium equation

$$p - \sigma_{rr} + p_r = p_g, \quad (38)$$

when pressure outside the bubble (including the pressure in the medium p , the normal stress σ_{rr} acting on the bubble, and the acoustic radiation pressure p_r) is in equilibrium with the internal gas pressure in the bubble p_g . The radiation pressure p_r here is the external force per unit area acting on the bubble surface. Since the radiation force changes with θ , the pressure p_r is also a function of θ

$$p_r = p_r^{(0)} \cos \theta, \quad (39)$$

where $p_r^{(0)}$ is the pressure for $\theta=0$, and its value is defined by the equation for the radiation force

$$F_r = 2\pi R^2 \int_0^\pi (-p_r \cos \theta) \sin \theta d\theta. \quad (40)$$

Integration of Eq. (40) yields

$$p_r^{(0)} = -\frac{3F_r}{4\pi R^2}. \quad (41)$$

Substituting Eqs. (36), (37), (39), and (41) into Eq. (38) and setting $r=R$ as well as $p_0=p_g$ gives

$$a = -\frac{F_r}{8\pi\mu}. \quad (42)$$

The displacement components of the bubble surface are then given by

$$\begin{aligned} u_r &= \frac{F_r}{4\pi\mu R} \cos \theta = \alpha R \cos \theta, \\ u_\theta &= -\frac{F_r}{8\pi\mu R} \sin \theta = -\frac{\alpha R}{2} \sin \theta, \end{aligned} \quad (43)$$

where new notation α is introduced

$$\alpha = \frac{F_r}{4\pi\mu R^2}. \quad (44)$$

The dimensionless parameter α is the ratio between the externally applied force and the value associated with elastic property of the medium.

It is easy to show that the bubble changes its shape during displacement. Indeed, the initial shape of the bubble is assumed to be spherical and, in Cartesian coordinates, can be expressed as

$$x = R \cos \theta, \quad y = R \sin \theta. \quad (45)$$

Here, x coincides with a polar axis of a spherical coordinate system and, therefore, the angle θ is an angle from the x axis.

FIG. 1. Displacements and shapes of the bubble for different ratio of the applied force and medium stiffness: the parameter $\alpha = F_r/4\pi\mu R^2$ takes values 0; 0.5; 1; 1.5. The curve for $\alpha=0$ is initial bubble shape and position: the bubble center is located at $x=0$, $y=0$. The curve for $\alpha=0.5$ corresponds to the relatively weak force, the bubble is displaced and remains almost spherical. The curve for $\alpha=1$ is $F_r=4\pi\mu R^2$; the bubble is displaced and loses the spherical form. The curve for $\alpha=1.5$ corresponds to the relatively strong force; the bubble displacement is greater and its deformation is much stronger.

The relationship between Cartesian and spherical coordinates is

$$x = r \cos \theta, \quad y = r \sin \theta. \quad (46)$$

During the bubble displacement, the coordinates x and y changes incrementally by δx and δy

$$\delta x = \delta r \cos \theta - r \sin \theta \delta \theta, \quad \delta y = \delta r \sin \theta + r \cos \theta \delta \theta. \quad (47)$$

Taking into account that

$$\delta r = u_r, \quad r \delta \theta = u_\theta, \quad (48)$$

the shape of the displaced bubble can be presented in the form

$$\frac{x}{R} = \cos \theta + \frac{\alpha}{4} (3 + \cos 2\theta), \quad \frac{y}{R} = \sin \theta + \frac{\alpha}{4} \sin 2\theta. \quad (49)$$

For $\theta=0$, Eqs. (49) yield

$$\frac{x}{R} = 1 + \alpha. \quad (50)$$

It is clear from Eq. (50) that parameter α has a simple physical interpretation—it characterizes the ratio between the displacement of the bubble surface at $\theta=0$ and the bubble radius.

Displacements and shapes of the bubble for the different forces (different parameters α) are plotted in Fig. 1. As expected, the bubble displacement becomes greater with increasing the parameter α , and for $\alpha \geq 1$ bubble deformation is getting noticeable. Although the results presented in Fig. 1 are reasonable, they should be used with caution. The problem has been formulated in linear approximation, assuming that the displacements are small compared to the bubble radius.

Since the influence of surface tension is pretty clear and the procedure to take it into account is known, we have not considered the surface tension here and note only that the surface tension reduces the effect described above, especially

for small bubbles. Surface tension makes the small bubble behave like a solid particle. The influence of surface tension on the bubble displacement and its shape will be discussed in detail in our future publications.

III. TRANSIENT DISPLACEMENT

We will now consider the displacements of solid sphere and gas bubble in the elastic incompressible medium when the external force depends on time. Since the problem is analyzed in linear approximation, force dependence on time is taken as monochromatic, i.e., proportional to $\mathbf{e}^{-i\omega t}$.

Again, the technique used here is very close to the method presented in Ref. 14 where the oscillatory motion of a sphere in viscous incompressible liquid is considered, and the drag force is estimated. If the periodic force is applied to the object, then its movement has an oscillatory character. The equation for sphere motion in the elastic medium is

$$-\rho\omega^2\mathbf{u} = \mu\nabla^2\mathbf{u} - \nabla p, \quad (51)$$

where ρ is elastic medium density and ω is a frequency of sphere oscillations induced by monochromatic force.

The solution of Eq. (51) is formally given by Eq. (12), where the function $f(r)$ is defined as

$$f(r) = \frac{\tilde{a}\mathbf{e}^{ikr}}{ikr} - \frac{\tilde{b}}{r}. \quad (52)$$

Here, \tilde{a} , \tilde{b} are complex constants that are determined by the boundary conditions and k is a wave number for a shear wave of frequency ω

$$k^2 = \frac{\omega^2}{c_t^2} = \frac{\rho\omega^2}{\mu}. \quad (53)$$

The components of the displacement vector \mathbf{u} in this case are

$$u_r = -\frac{2}{r^2} \left[\tilde{a}\mathbf{e}^{ikr} \left(1 - \frac{1}{ikr} \right) + \frac{\tilde{b}}{r} \right] \cos \theta, \quad (54)$$

$$u_\theta = -\frac{1}{r^2} \left[\tilde{a}\mathbf{e}^{ikr} \left(1 - ikr - \frac{1}{ikr} \right) + \frac{\tilde{b}}{r} \right] \sin \theta. \quad (55)$$

The pressure gradient is determined by

$$\nabla p = \mu\nabla[\nabla^2 + k^2](\nabla \cdot \mathbf{f}\mathbf{e}), \quad (56)$$

and the equation for pressure is

$$p = p_0 + \mu(\mathbf{e} \cdot \nabla)(\nabla^2 f + k^2 f), \quad (57)$$

where p_0 is an integration constant corresponding to pressure far away from the object.

A. Transient displacement of a solid sphere

The boundary conditions for the solid sphere are the same as in the static case and are given by Eq. (22). The constants \tilde{a} and \tilde{b} calculated using Eq. (22) are

$$\tilde{a} = -\frac{3Ru_\omega}{2ik}\mathbf{e}^{-ikR}, \quad \tilde{b} = -\frac{R^3u_\omega}{2} \left(1 - \frac{3}{ikR} - \frac{3}{k^2R^2} \right), \quad (58)$$

where u_ω are spectral components of a displacement.

Equation (52) for the function f allows one to calculate $\nabla^2 f + k^2 f$, that is

$$\nabla^2 f + k^2 f = -\frac{k^2\tilde{b}}{r}. \quad (59)$$

Substitution of Eq. (59) into Eq. (57) and elimination of \tilde{b} using Eqs. (58) yields

$$p = p_0 - \frac{\mu k^2 R^3 u_\omega}{2r^2} \left(1 - \frac{3}{ikR} - \frac{3}{k^2 R^2} \right) \cos \theta. \quad (60)$$

The components of the stress tensor on the surface of the sphere are

$$\sigma_{r\theta} = \frac{3\mu u_\omega}{2R} (1 - ikR) \sin \theta, \quad \sigma_{rr} = 0. \quad (61)$$

Ultimately, spectral components of the force calculated using Eq. (19) are

$$F_\omega = -6\pi\mu R u_\omega (1 - ikR - \frac{1}{9}k^2 R^2). \quad (62)$$

The equation that couples the solid sphere displacement and the external periodic force $F_\omega^{(\text{ext})}$, for example, the radiation force, is

$$\begin{aligned} F_\omega^{(\text{ext})} &= -M\omega^2 u_\omega - F_\omega \\ &= -M\omega^2 u_\omega + 6\pi\mu R u_\omega (1 - ikR - \frac{1}{9}k^2 R^2), \end{aligned} \quad (63)$$

where M is a mass of the solid sphere.

Equation (63) has simple interpretation: it is an equation for solid sphere motion in the elastic incompressible medium written in frequency domain. Indeed, the term $6\pi R^2 \mu u_\omega ik$ takes into account damping of sphere's oscillations due to radiation of shear waves, and the term $2\pi R^3 \mu u_\omega k^2/3$ accounts for motion of the medium around the sphere. As $k = \omega/c_t$ and $c_t = (\mu/\rho)^{1/2}$, the last term in Eq. (63) can be written in the form

$$-\frac{2}{3}\pi R^3 \mu u_\omega k^2 = -\frac{2}{3}\pi R^3 \rho \omega^2 u_\omega = -m\omega^2 u_\omega. \quad (64)$$

Here, $-\omega^2 u_\omega$ is the spectral presentation of the second derivative of the displacement $u(t)$, and m , the so-called induced mass

$$m = \frac{2}{3}\pi R^3 \rho, \quad (65)$$

determines the mass of the elastic medium involved in motion. It is worth noting that the induced mass is equal to half of the sphere mass with radius R and density ρ . The term $-6\pi R^2 \mu u_\omega ik$ in Eq. (63) also can be presented in the form

$$-6\pi R^2 \mu u_\omega ik = -6\pi R^2 \mu c_t^{-1} i\omega u_\omega, \quad (66)$$

where $-i\omega u_\omega$ is the spectral presentation of the first derivative of the displacement. Equation (66) describes the dampening force that is proportional to the velocity of the solid sphere.

Equation (63) for solid sphere motion can be written in the time domain. In dimensionless variables

$$U = \frac{u(t)}{R}, \quad \tilde{F}_{\text{ext}} = \frac{F_{\text{ext}}(t)}{6\pi\mu R^2}, \quad (67)$$

the time-domain equation is

FIG. 2. Responses of solid spheres with different densities (the parameter β takes values 0; 1.5; 3) to the short pulsed force calculated with Eq. (68): the external force is taken as a δ function, $\tau = tc_t/R$ is dimensionless time.

$$U + \dot{U} + \frac{1}{9}(1 + 2\beta)\ddot{U} = \tilde{F}_{\text{ext}}, \quad (68)$$

where dots above the function U denote the derivatives with respect to dimensionless time τ , and parameter β is solid sphere density ρ_s normalized by medium density

$$\tau = \frac{tc_t}{R}, \quad \beta = \frac{\rho_s}{\rho}. \quad (69)$$

The equations for solid sphere displacement in the elastic medium—Eq. (63) in the frequency domain and Eq. (68) in the time domain—can be solved analytically or numerically for any external force applied to the sphere.

The responses of the solid sphere with different densities to the short pulsed force taken as a δ function have been calculated with Eq. (68). The results are presented in Fig. 2. There are no oscillatory displacements for the empty sphere $M=0$ and for the relatively light sphere, while the heavier spheres may exhibit a few oscillations. The empty sphere is included here for late comparison with gas bubble.

Results presented above have been obtained for incompressible elastic media. Compressibility of the elastic medium can be also included. In this case, the equation for sphere motion is

$$-\rho\omega^2\mathbf{u} = \mu\nabla^2\mathbf{u} + (\lambda + \mu)\nabla(\nabla \cdot \mathbf{u}), \quad (70)$$

where λ is a Lamé parameter. Equation (70) replaces Eq. (51), which has been used for incompressible media. A solution of Eq. (70) consists of two parts: an incompressible one

$$-\rho\omega^2\mathbf{u}_s = \mu\nabla^2\mathbf{u}_s, \quad (71)$$

and a compressible (potential) part $\mathbf{u}_p = \nabla\varphi$, where φ satisfies the equation

$$-\rho\omega^2\varphi = (\lambda + 2\mu)\nabla^2\varphi. \quad (72)$$

The solution of Eqs. (71) and (72) in spherical geometry, presented in Ref. 17, in our notations takes the form

$$u_r = -\frac{2}{r^2} \left[\tilde{a}\mathbf{e}^{ikr} \left(1 - \frac{1}{ikr} \right) + \frac{\tilde{b}}{r} \mathbf{e}^{i\tilde{k}r} \left(1 - i\tilde{k}r - \frac{1}{2}\tilde{k}^2r^2 \right) \right] \cos\theta, \quad (73)$$

$$u_\theta = -\frac{1}{r^2} \left[\tilde{a}\mathbf{e}^{ikr} \left(1 - ikr - \frac{1}{ikr} \right) + \frac{\tilde{b}}{r} \mathbf{e}^{i\tilde{k}r} (1 - i\tilde{k}r) \right] \sin\theta, \quad (74)$$

where $\tilde{k} = \omega/c_l$, $c_l^2 = (\lambda + 2\mu)/\rho$ is a speed of acoustical waves.

Comparison of Eqs. (73) and (74) for displacement components in compressible media with Eqs. (54) and (55) for incompressible media shows that influence of compressibility reduces to the correction of Eqs. (54) and (55), and this correction is on the order of $\tilde{k}R$. So, the relative correction is $\tilde{k}/k = c_t/c_l \sim 10^{-2} - 10^{-3}$ for media-like tissues that can be considered as incompressible. Therefore, Eq. (63) with precision on the order of $10^{-2} - 10^{-3}$ can be used to describe the displacement of the solid sphere in soft tissues.

B. Transient displacement of a gas bubble

The difference between the solid sphere and bubble displacement analysis is the boundary conditions. The boundary condition for the static bubble displacement given by Eq. (32) is also valid for transient displacement. Equations (54) and (55) for displacement components are used to calculate $\sigma_{r\theta}$, which at the bubble surface $r=R$ is equal to

$$\sigma_{r\theta} = -\frac{\mu}{R^3} \sin\theta \left[\tilde{a}\mathbf{e}^{ikR} \left(3ikR + k^2R^2 - 6 + \frac{6}{ikR} \right) - \frac{6\tilde{b}}{R} \right] = 0. \quad (75)$$

In this case \tilde{b} is

$$\tilde{b} = \tilde{a}\mathbf{e}^{ikR} R \left(\frac{1}{2}ikR + \frac{1}{6}k^2R^2 - 1 + \frac{1}{ikR} \right), \quad (76)$$

and the bubble surface displacement components estimated with Eqs. (54) and (55) are

$$u_r = u_\omega \left(1 - \frac{1}{3}ikR \right) \cos\theta, \quad (77)$$

$$u_\theta = -\frac{u_\omega}{2} \left(1 + \frac{1}{3}ikR \right) \sin\theta. \quad (78)$$

The variable u_ω introduced here can be interpreted as low-frequency displacement

$$u_\omega = -\frac{ik}{R} \tilde{a}\mathbf{e}^{ikR}. \quad (78)$$

The radial component of the stress tensor σ_{rr} at the bubble surface is

$$\sigma_{rr} = -\frac{2\mu}{R} u_\omega (1 - ikR) \cos\theta. \quad (79)$$

Using Eq. (57) for the pressure and Eq. (59) for $\nabla^2 f + k^2 f$, and \tilde{b} defined in Eq. (76), the pressure in the medium around the moving bubble is

$$p = p_0 + \frac{\mu}{R} u_\omega \left(1 - ikR - \frac{1}{2}k^2R^2 + \frac{1}{6}ik^3R^3 \right) \cos\theta. \quad (80)$$

Equation (19) accounts for the force on the bubble oscillating in the elastic medium

$$F_\omega = -4\pi\mu R u_\omega \left(1 - ikR - \frac{1}{6}k^2R^2 + \frac{1}{18}ik^3R^3 \right). \quad (81)$$

When the external force $F_\omega^{(\text{ext})}$ (i.e., the radiation force) is applied to the bubble, Eq. (81) describes the bubble movement where $F_\omega^{(\text{ext})} = -F_\omega$

$$4\pi\mu R u_\omega (1 - ikR - \frac{1}{6}k^2 R^2 + \frac{1}{18}ik^3 R^3) = F_\omega^{(\text{ext})}. \quad (82)$$

Equation (82) describes bubble oscillations induced by the external force. In the time domain the equation for bubble oscillations looks like

$$U + \dot{U} + \frac{1}{6}\ddot{U} + \frac{1}{18}\dddot{U} = \tilde{F}_{\text{ext}}. \quad (83)$$

Equation (83) is written in dimensionless variables: U is the displacement normalized R , \tilde{F}_{ext} is the dimensionless external force, and dots above the function U denote the derivatives with respect to dimensionless time τ

$$U = \frac{u(t)}{R}, \quad \tilde{F}_{\text{ext}} = \frac{F_{\text{ext}}}{4\pi\mu R^2}, \quad \tau = \frac{tc_t}{R}. \quad (84)$$

Equations (82) and (83) derived for bubble displacement in incompressible media can be modified to take compressibility into account. As shown above, however, the correction is on the order of 10^{-2} – 10^{-3} . In addition, inclusion of compressibility makes the equation in the frequency domain very bulky and does not allow one to rewrite it in the time domain.

Equation (83) can be solved by combining a general solution of the homogeneous equation with a particular solution of the inhomogeneous equation. We take the general solution as

$$U = C_1 e^{\lambda_1 \tau} + C_2 e^{\lambda_2 \tau} + C_3 e^{\lambda_3 \tau}. \quad (85)$$

Here

$$\begin{aligned} \lambda_1 &= -1.133\,176, & \lambda_2 &= -0.933\,412 - 3.874\,701i, \\ \lambda_3 &= -0.933\,412 + 3.874\,701i, \end{aligned} \quad (86)$$

are roots of the algebraic equation

$$\lambda^3 + 3\lambda^2 + 18\lambda + 18 = 0, \quad (87)$$

and C_1 , C_2 , C_3 are constants. Since all three roots of the characteristic equation have negative real parts, the displacements are decreasing with time. The general solution, however, can be determined by variations of C_1 , C_2 , and C_3 .

The special case when the external force $\tilde{F}_{\text{ext}}(t)$ is a δ function is considered here. Therefore, C_1 , C_2 , and C_3 are the constants determined by initial conditions

$$\frac{1}{18}\ddot{U} = 1; \quad \dot{U} = 0; \quad U = 0. \quad (88)$$

The normalized solution of Eq. (83) is plotted in Fig. 3 (solid line). The external force in Eq. (83) is taken as a δ function. The bubble displacement has oscillatory character.

For comparison, the displacement of the weightless solid sphere (dashed line) is also shown in Fig. 3—there are no oscillations.

As discussed in the previous section, the bubble changes its shape during displacement. In process of transient displacement, the bubble shape is also changed. Equations (77) show that both components u_r and u_θ of bubble surface displacement as well as u depend on frequency since k is frequency dependent. Therefore, bubble deformation is more

FIG. 3. Responses of the bubble (solid line) and the solid sphere (dashed line) to the short pulse force taken as a δ function, $\tau = tc_t/R$ here is dimensionless time.

complicated during transient displacement compared to the static case. For example, consider displacement of points on the bubble surface that correspond to $\theta = 0$. These points move back and forth along the r axis, which goes through the bubble center in direction of the force. Their displacement is characterized by \tilde{u}_r

$$\tilde{u}_r = (1 - \frac{1}{3}ikR)u_\omega. \quad (89)$$

The points on the bubble surface with $\theta = \pi/2$ also move, and their displacement is \tilde{u}_θ

$$\tilde{u}_\theta = (1 + \frac{1}{3}ikR)u_\omega. \quad (90)$$

Dependence of $u(t)$, as well as r and θ components of displacement in time representation $u_r^{(t)}$ and $u_\theta^{(t)}$ on dimensionless time in the elastic incompressible inviscous medium, are plotted in Fig. 4.

The response of the small bubble to the short pulsed force will be similar to the solid sphere response as the small bubble shape is stabilized by the surface tension. Additional investigation should be done to determine when the surface tension starts playing an important role.

IV. BUBBLE DISPLACEMENT IN VISCOELASTIC MEDIA

In order to determine the displacement of the solid sphere or the gas bubble in the real elastic media, the viscosity of the medium should be taken into account. This can be done by using the approach developed for the solid sphere in tissue.⁷ In our procedure the shear modulus μ should be replaced by $(\mu - i\omega\eta)$, where η is a shear viscosity coefficient. For displacements of the gas bubble in the viscoelastic medium, Eq. (82) takes the form

FIG. 4. Dependence of u , $u_r^{(t)}$ and $u_\theta^{(t)}$ on dimensionless time $\tau = tc_t/R$ in an inviscous medium.

FIG. 5. Responses of the bubble to the short pulse force in the different viscoelastic media; the dimensionless parameter $\varepsilon = c_t \eta / R \mu$ takes value 0; 0.1; 0.2; 0.3.

$$4\pi(\mu - i\omega\eta)Ru_\omega(1 - ikR - \frac{1}{6}k^2R^2 + \frac{1}{18}ik^3R^3) = F_\omega^{(\text{ext})}, \quad (91)$$

where k is

$$k = \frac{\omega}{c_t \sqrt{1 - i\omega\eta/\mu}}. \quad (92)$$

Equation (91) allows for the estimation of the bubble response to the external force in the viscoelastic medium. Here, Eq. (91) is used to estimate bubble displacement when the external force $F_{\text{ext}}(t)$ as a δ function is applied. Since F_ω^{ext} is const for the δ function, it is easy to calculate u_ω using Eq. (91) and then apply inverse Fourier transform to get the bubble response to very short pulse. The bubble responses to the short pulsed force in different media are shown in Fig. 5. The calculations are performed in the frequency domain with inverse Fourier transformation. The number of harmonics in calculations has been equal to 1024. Normalization for t is the same as earlier and is given by Eq. (84). The dimensionless parameter ε is introduced to characterize the ratio between viscosity and elasticity

$$\varepsilon = \frac{c_t \eta}{\mu R}. \quad (93)$$

The results shown in Fig. 5 have an obvious interpretation: under the short impulse force the gas bubble displacement in the medium with no viscosity has oscillatory character. Viscosity eliminates oscillations in bubble displacement and reduces the maximum value of displacement.

Dependence of the variables u , $u_r^{(t)}$, and $u_\theta^{(t)}$ on dimensionless time in the viscoelastic medium with $\varepsilon=0.2$ is shown in Fig. 6. Comparison of the plots in Figs. 6 and 4

FIG. 6. Dependence of u , $u_r^{(t)}$, and $u_\theta^{(t)}$ on dimensionless time in the viscoelastic medium, the external force is a δ function and dimensionless parameter $\varepsilon=0.2$.

shows that there are no oscillations of u , $u_r^{(t)}$, and $u_\theta^{(t)}$ in the viscoelastic medium for up to $\varepsilon=0.2$, and the peak values of all variables in Fig. 6 are less than the ones in Fig. 4.

V. DISCUSSION AND CONCLUSIONS

Previously, the equilibrium shape of an acoustically levitated bubble in liquid has been investigated theoretically.¹⁸ In that case, the acoustic radiation pressure on the bubble surface counteracts gravity, and there is no dipole pressure and bubble deformation caused by the quadrupole term in pressure. In the problem considered here, the bubble shape changes due to the dipole term in pressure.

For transient displacement of solid sphere, our approach agrees with those presented earlier.⁷ Indeed, Eq. (63) couples the applied force and the displacement, while the relationship between pressure and velocity was derived for an oscillating sphere.⁷ The derived formula for impedance coincides with $F_\omega^{(\text{ext})}/u_\omega$ obtained from Eq. (63) if the elastic medium is incompressible, frictionless, and only induced mass is taken into account.

In this paper a general approach is developed to estimate the static displacement of a solid sphere and a gas bubble induced by an external force in elastic incompressible media. The method is similar to a Stokes' force derivation in viscous incompressible liquid. Displacement of the solid sphere is given by Eq. (31) and components of bubble displacement are determined by Eq. (43). Calculations show that the bubble is not only displaced by the applied force but also changes its shape. The initially spherical bubble has a shape described by Eq. (49) after displacement.

For transient displacement of a solid sphere as a bubble in elastic media induced by a time-dependent force, the motion equations are derived in the frequency domain as well as in the time domain. The motion equations for a rigid sphere in an inviscous elastic medium are Eq. (63) in the frequency domain and Eq. (68) in the time domain. They can be solved analytically or numerically for any external force applied to the solid sphere. Here, the solution is presented for the external force as a short pulse.

The transient bubble displacement in elastic media is described by Eq. (82) in the frequency domain and Eq. (83) in the time domain. Equation (83) has been solved analytically and presented in Fig. 3 showing oscillatory behavior in response to a short impulse force.

Since the effect of viscosity on a solid sphere is more or less known, only bubble displacement in the viscoelastic medium is considered here. Analysis is performed in the frequency domain by applying an inverse Fourier transform method. The result is viscosity eliminates oscillations in bubble response to a short impulse force and reduces the maximum value of bubble displacement.

In the future, nonlinear displacement of a solid sphere as well as a gas bubble in elastic media and influence of inhomogeneity of the elastic material will be studied.

(Received 20 September 2004; revised 21 January 2005; accepted 28 January 2005)

This paper is motivated by possible medical applications of focused ultrasound in the minimally invasive treatment of a variety of musculoskeletal disorders that are responsive to thermal treatment. A model-based analysis of the interaction of high-intensity focused ultrasound with biological materials is carried out in an effort to predict the path of the sound waves and the temperature field in the focal region. A finite-element-based general purpose code called PZFlex is used to determine the effects of nonlinearity and geometrical complexity of biological structures. It was found that at frequencies of interest in therapeutic applications, the nonlinear effects are usually negligible and the geometrical complexities can be handled through a substructuring procedure. An approximate analytical method with acceptable accuracy is developed as an alternative to the purely numerical approach used in PZFlex. The mechanical and thermal effects in two-layered fluid material systems induced by high-frequency focused ultrasound are calculated through this analytical method. The results are compared with those obtained using PZFlex as a benchmark. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1873372]

I. INTRODUCTION

The interaction between ultrasound and biological tissues has been the subject of numerous investigators for over three decades (Bilgen and Insana, 1996; Fry and Johnson, 1978; Hutchinson and Hynynen, 1996; Lele and Pierce, 1973; Rivens *et al.*, 1996; Sanghvi *et al.*, 1996; Seip *et al.*, 1996; Wall *et al.*, 1951; Zaneli *et al.* 1994). The application of focused ultrasound as a minimally invasive surgical tool has been demonstrated experimentally (Fry and Johnson, 1978), explained theoretically (Lele and Pierce, 1973; Robinson and Lele, 1972; Damianou, 1997), and practiced clinically (Hallaj *et al.*, 2001). Although the number and scope of the therapeutic applications of high-intensity focused ultrasound have grown in recent years, the technique is still far from being widely accepted by the clinical community. Since the target area is usually quite small, the focal spot generated by the ultrasound transducer needs to be small (Hynynen, 1991). Moreover, in order to avoid damage to neighboring healthy tissues, an effective control of the path of the ultrasound beam and the identification of the location of the focal spot is essential in clinical applications. Thus further progress in the noninvasive or minimally invasive use of ultrasound for clinical applications will require advances in a number of enabling technologies, such as phased array fab-

rication and other techniques of controlling the beam shape, as well as a better understanding of the interaction of focused ultrasound with various types of tissues.

The thermal and mechanical interaction of focused ultrasound with biological tissues and structures is considered in this paper. Since experimental studies using living tissue are difficult and costly, theoretical simulation of the problem can be extremely useful in providing a firm scientific basis for future clinical investigations of focused ultrasound. In previous studies (Mal and Feng, 2002, 2003), relatively complex geometrical and acoustic properties of human tissues have been considered by using the finite-element-based software called PZFlex (2001) in an effort to obtain quantitative information on the interaction between high-energy ultrasound and biological structures. A result of these studies is that the nonlinear effects in the focal region are negligible in the frequency and pressure ranges of interest. However, a number of difficulties were encountered in this purely numerical approach. A major difficulty encountered was the extremely high storage requirement and runtime needed to compute the ultrasound field in the required frequency range and geometrical properties of the model.

Several approximate analytical solutions of the problem of acoustic wave radiation from sources in a homogeneous ideal fluid are available in the literature (King, 1934; O'Neil, 1949; Williams and Labaw, 1945; Williams, 1946, 1947). Williams and O'Neil evaluated the radiated pressure field by computing the Rayleigh integral on the curved surface of the

^{a)} Author to whom correspondence should be addressed. Electronic mail: ajit@seas.ucla.edu

radiator. For a planar source the Rayleigh integral is the exact formulation of the Huygens principle (Morse and Feshbach, 1953). Due to the planar nature of the surface, the spherical waves emitted by all these secondary sources do not interact with the surface itself. However, if the surface is curved, then the spherical waves are diffracted by the surface. Consequently, the amplitude of one spherical wave at one source point depends not only on the initial wave loaded on the local surface, but also on all other diffracted waves reaching that point.

Another interesting analytical method was presented by Killer (1989) and Coulouvrat (1993). It is based on two expansions of the pressure field in spherical harmonics in conveniently chosen domains that are connected by an artificial boundary. This method is “exact” in the sense that it explicitly considers the actual boundary conditions on the real curved surface; approximations only arise from the numerical discretization.

In this paper, an approximate analytical method is developed as an alternative to the purely numerical approach. The method is applicable to cases where the wavelength of the ultrasound is small compared to the geometrical features of the biological structure of interest. The method is based on the approach presented by Killer (1989) and Coulouvrat (1993), and can be considered to be a generalization of their methods to damped multilayered systems. The approach is used to determine the mechanical and thermal fields in a homogenous viscous fluid and in a two-layered material system with planar interfaces. The method can be extended to deal with curved interfaces and multilayered media in a straightforward manner. The developed method is sought to support the increasing application of focused ultrasound to perform minimally invasive medical treatment of musculoskeletal disorders (Bar-Cohen *et al.*, 1999), as well as cancer (Ter Haar *et al.*, 1989).

II. THE APPROXIMATE ANALYTICAL METHOD

A conceptual focused ultrasound system is sketched in Fig. 1 where a spherical cap transducer is used as the source located in a sealed chamber containing a coupling fluid. A thin membrane at the bottom of the chamber separates the fluid from the biologic tissue. An axisymmetric analog problem shown in Fig. 2 is extracted from the therapeutic problem of Fig. 1 for theoretical treatment. Here P is the observation point, and Γ_S is the spherical cap transducer with transverse diameter, $2a$, focal length, f , and aperture angle, β . A stiff baffle, Γ_B , is assumed to be located on the horizontal plane outside the lens. The fluid (e.g., water) occupies the domain, $\Omega = \Omega_i \cup \Omega_o$, and a biological material (e.g., muscle) is in the domain Ω_H with a plane interface, Γ_I , separating it from the fluid. The top of the spherical cap, O , is chosen as the origin of a cylindrical coordinate system, (R, φ, z) . The point O' is the geometrical focus of the lens (i.e., $f = OO'$), and h is the height of the lens. The point C is at the intersection between the baffle plane and the acoustic axis Oz . The inner and outer domains, Ω_i and Ω_o , are separated by an imaginary hemisphere, Γ_A , of the radius, a , centered at the origin C . A spherical coordinate system, (r, θ, ϕ) is introduced with the origin at the point C .

FIG. 1. A conceptual focused ultrasound system for therapeutic application. Note: The wave path shown in this figure is a straight line with no refraction due to the assumption that the wave speed in the tissues is the same as in water.

The solution of the two-layered material problem is realized in two steps. The first step is to calculate the pressure and temperature fields in a fluid occupying the domain $(\Omega_i \cup \Omega_o \cup \Omega_H)$ mathematically but with the original boundary conditions of the model in Fig. 2. In the second step the pressure, velocity, and temperature fields in the biological material in the two-layered model of Fig. 2 are evaluated by applying the boundary conditions at the interface, Γ_I , which are derived from the first step with suitable modifications to account for reflection and transmission at the interface.

A. Homogeneous material

The fluid in the domain $\Omega_i \cup \Omega_o \cup \Omega_H$ is assumed to be homogeneous, isotropic, and viscous. As indicated earlier,

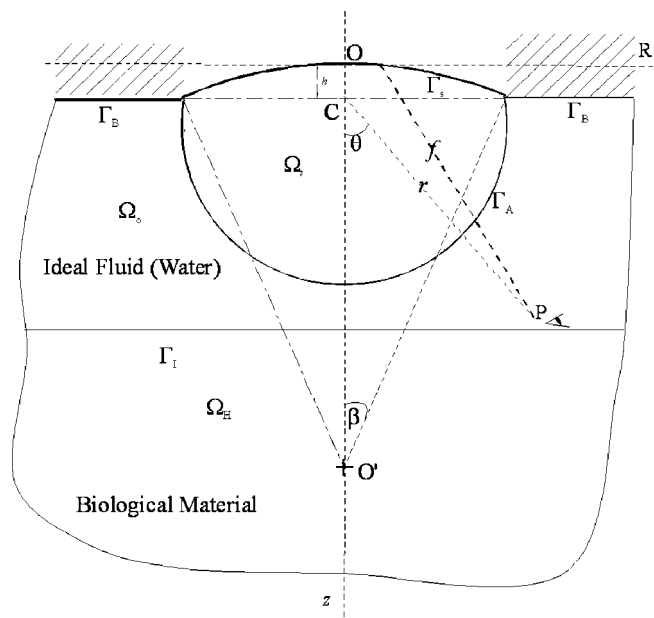

FIG. 2. Geometry of the bimaterial problem.

^aAt 1 MHz.

nonlinear effects can be neglected in most applications considered here so that the time harmonic pressure field, p , in the fluid satisfies the Helmholtz equation,

$$\nabla^2 p + k^2 p = 0 \quad (1)$$

in Ω where $k = \omega/c$, ω is the circular frequency, and k is the wave number. Here as in all subsequent equations the time-dependency factor $e^{i\omega t}$ is omitted.

The general solution for the pressure field in spherical coordinates can be expressed in terms of the spherical Hankel functions $h_n^{(1)}(kr)$ and $h_n^{(2)}(kr)$ (Morse and Feshbach, 1953) in the outer domain $\Omega_o \cup \Omega_H$ as

$$p^{(o)} = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \{ [a_{1m} \sin(m\phi) + a_{2m} \cos(m\phi)] P_n^m(\cos \theta) [b_{1n} h_n^{(1)}(kr) + b_{2n} h_n^{(2)}(kr)] \} \quad (2)$$

and in terms of the spherical Bessel functions $j_n(kr)$ and $n_n(kr)$ in the inner domain Ω_I as

$$p^{(i)} = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \{ [a_{1m} \sin(m\phi) + a_{2m} \cos(m\phi)] P_n^m(\cos \theta) [b_{1n} j_n(kr) + b_{2n} n_n(kr)] \}. \quad (3)$$

In Eqs. (2) and (3), P_n is the n th-order Legendre polynomial, and a_{1m} , a_{2m} , b_{1n} , and b_{2n} are unknown constants to be determined from the boundary conditions.

Taking into account the axial symmetry of the problem, the boundary condition on the baffle plane Γ_B , the boundedness condition in the interior domain, and the radiation condition in the outer domain, the pressures $p^{(i)}$ and $p^{(o)}$ can be simplified as

$$p^{(i)} = \sum_{n=0}^{\infty} \alpha_n^{(i)} j_n(kr) P_n(\cos \theta) \quad \text{in } \Omega_i, \quad (4)$$

$$p^{(o)} = \sum_{n=0}^{\infty} \alpha_n^{(o)} h_n^{(2)}(kr) P_n(\cos \theta) \quad \text{in } \Omega_o \cup \Omega_H, \quad (5)$$

where $\alpha_n^{(i)}$ and $\alpha_n^{(o)}$ are unknown inner and outer coefficients. Applying the continuity conditions on the artificial boundary at a finite number of collocation points (Coulouvrat, 1993), the pressure field in a homogenous fluid material can be obtained through the solution of the linear system

$$\mathbf{S}\mathbf{x} = \mathbf{b} \quad (6)$$

in which $[\mathbf{S}]$ is a known matrix, $\{\mathbf{x}\}$ is a column vector containing the unknown inner coefficients, ($x_n = \alpha_n^{(i)}$), and $\{\mathbf{b}\}$ is

the column vector describing the known applied pressure field at the collocation points. It should be noted that in general the vectors $\{\mathbf{b}\}$ and $\{\mathbf{x}\}$ are complex and the matrix $[\mathbf{S}]$ is, in general, full, nonsymmetric, and complex. The dimension of the system (6) depends on the number of collocation points.

Generally, the phase velocity or the wave number of a material can be assumed to be a complex number for time harmonic wave propagation problems involving materials with dissipation. As an example, the particle motion, $A(x)$, associated with a plane wave propagating along the positive x -direction in a dissipative material can be obtained by simply replacing the wave number k in the motion equation in a perfect fluid with a complex number $k_r + ik_i$:

$$A(x) = A_0 e^{-ikx} = A_0 e^{-ik_r x} \cdot e^{-\alpha x}, \quad (7)$$

where A_0 is the amplitude, $k = k_r - i\alpha$, and α is the attenuation coefficient, which must be positive to represent the exponential decay in the amplitude of the wave. The attenuation of the waves is often described by decibels (dB) in acoustics:

$$\text{dB} = 20 \log_{10} \left(\frac{A_0}{A(x)} \right). \quad (8)$$

Thus

$$\alpha = \frac{\text{dB}}{20 \log_{10} e} = \frac{\text{dB}}{8.686}. \quad (9)$$

The solution of any time harmonic plane wave propagation problem in a dissipative medium can be obtained from that for a nondissipative medium by simply replacing k by $k - i\alpha$. As an example, to calculate the wave field in a muscle material at 100 kHz, the related material properties are given in Table I and the frequency dependence of α is given in the following equation (Duck, 1990).

$$\alpha = a f^b, \quad (10)$$

where a and b are material constants and f is normalized frequency with the center frequency (Duck, 1990). Thus $\alpha = 0.576$ and $k = 399.95 - 0.576i$. The pressure field in a dissipative medium can be obtained by substituting this value of k in Eq. (6), solving for the unknown coefficients, and evaluating the expressions (4) and (5).

One purpose of focused ultrasound in the clinical applications is to deliver controlled heat to the pathological tissue, and the shrinkage of the pathological tissue caused by the controlled heat can, in appropriate cases, restore the tissue to its original state. The most important tasks in the modeling

FIG. 3. Simplified subproblems.

study are to predict the location and extent of the focal zone, the temperature distribution, and, in particular, the highest temperature in the focal zone.

The average energy dissipation, dE , in a cycle per unit length of a plane wave (O'Neil, 1949) can be expressed in the form

$$dE = \text{Re} \left[\frac{p\bar{v}}{2} \right] dx dy, \quad (11)$$

where p is the pressure, \bar{v} is the complex conjugate of the velocity, v , and "Re" implies the real part of the expression. The average energy loss, E_{loss} , in a cycle per unit volume is

$$E_{\text{loss}} = \alpha \text{Re}[p\bar{v}]. \quad (12)$$

Then the modified heat transfer equation is

$$\rho C_p \frac{\partial T}{\partial t} = \nabla \cdot (k_h \nabla T) + q, \quad (13)$$

where ρ is the density of the material, C_p is its specific heat, T is the temperature, t is the current time, k_h is the heat conductivity, and q is the acoustic energy dissipation per volume in unit time, which can be identified as E_{loss} defined in (12). Since the temperature field is only considered in a short time, the heat conduction effect is small enough to be ignored. Thus the temperature rise associated with the energy loss can be approximated as

$$T = \frac{\alpha \text{Re}[p\bar{v}]}{\rho C_p} t. \quad (14)$$

The above equation is the basis for calculating the thermal effects in a viscous fluid. It has been verified through numerical calculations using PZFlex that heat conduction results in small errors in the temperature field in the pressure and temperature ranges of interest here. The mechanical and thermal fields calculated by the present approximate approach will be validated by comparing them with the corresponding results using PZFlex.

B. Two-layered material model

The two-layered (water/muscle) model shown in Fig. 2 is considered next. The original model is separated into two submodels as sketched in Fig. 3. The first submodel shown in Fig. 3(a) is identical with the single material model, in this case water, discussed in the previous section. Dissipation in

water is ignored in the calculations. The imaginary surface shown as a dashed line in Fig. 3(a) is at the same location as the real interface, Γ_I , between two materials (Fig. 2). The pressure, p_o , and velocity, v_{in} , at the imaginary interface can be determined using the method presented in the previous section where p_o is the same as the pressure in the incident wave from water to the real interface in the two-layered model. The corresponding interfacial pressure, p_i , at the real interface Γ_I is determined by an approximate theory.

The calculation of the interfacial pressure p_i is based on the assumption that an infinitesimal region is locally subjected to an incident plane wave (Fig. 4). The reflection and transmission pressures and velocities at each collocation point on the interface Γ_I are evaluated through plane wave theory, after the local incident pressure and velocity at each collocation point are obtained from the first submodel. The interface conditions for the plane wave theory are

$$p_i(R, 0) = (1 + R_w) p_o(R, z_0), \quad (15)$$

$$p_i(R, 0) = T p_o(R, z_0), \quad (16)$$

in which T and R_w are transmission and reflection coefficients given by (see, e.g., Mal and Singh, 1991)

FIG. 4. Plane wave at the interface.

FIG. 5. FEM model for the therapeutic application.

$$T = \frac{2\rho_2 c_2 \cos \gamma}{\rho_2 c_2 \cos \gamma + \rho_1 c_1 \cos \psi},$$

$$R_w = \frac{\rho_2 c_2 \cos \gamma - \rho_1 c_1 \cos \psi}{\rho_2 c_2 \cos \gamma + \rho_1 c_1 \cos \psi},$$
(17)

where γ and ψ are incident and transmitted angles, ρ_i and c_i ($i=1,2$) are the densities and phase velocities of waves in the upper and lower medium, respectively.

The interfacial pressure, p_i , given by (15) or (16) is applied as the boundary condition in the second submodel shown in Fig. 3(b), which involves only one material (muscle) with damping. Then, the same procedure as for the single material model is used to characterize the mechanical and thermal fields of the second submodel. The pressure field is determined from the solution of Eq. (6) and then the thermal field is calculated approximately by Eq. (14).

III. ANALYTICAL RESULTS AND COMPARISON WITH THE FEM MODEL

A. Mechanical and thermal effects in a homogenous fluid

1. Mechanical effect and energy loss

The purpose of this study is to develop an analytical method to efficiently and accurately predict the sound field radiated by an acoustic lens (spherical cap), and to compare the results of computation with the FEM model by PZFlex (Fig. 5). Figures 6(a) and (b) show the comparison of the axial pressure and velocity (V_z) amplitudes assuming that the material is muscle with properties given in Table I, for a focal length of $f=0.3$ m and frequency of 100 kHz. It can be seen that the two results are indistinguishable in the plots. These results are confirmed by the results on the plane z

FIG. 6. (a) Pressure and (b) velocity (V_z) amplitudes along the axis, obtained by FEM and analytical method.

$=0.15$ m, shown in Figs. 7(a) and (b), showing excellent agreement, except at points very close to the source. The calculated energy losses in a cycle ($10 \mu s$) along the axis on $z=0.15$ m at the frequency 100 kHz are compared in Figs. 8(a) and (b). Again, the agreement is excellent except at field points near the lens. The reason for the discrepancies near the source is not completely clear, but they are probably caused by an insufficient number of elements in the FEM model.

These above results indicate that the analytical method

FIG. 7. (a) Pressure and (b) velocity (V_z) amplitude along the plane $z = 0.15$ m, obtained by FEM and analytical method.

FIG. 8. Energy loss in one cycle (10 ms) along (a) the axis and (b) R direction at $z=0.15$ m.

can provide excellent results in a very short computing time, generally 2–5 s, as compared to FEM calculations that often take several hours (12 or more) to accomplish the same task. The mechanical effects in a dissipative material, such as muscle, can be calculated efficiently and accurately by the analytical method.

2. Analysis of focal zone

The dependence of the focal region on the frequency of the incident wave and the radius of the lens is determined by

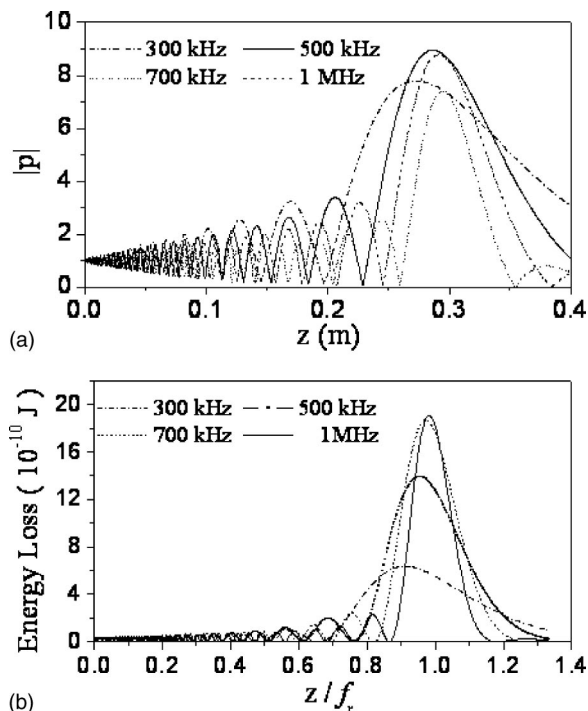

FIG. 9. Focus of pressure and energy loss at different frequencies.

FIG. 10. Maximum pressure and energy loss at different frequencies.

the approximate analytical method for the single material (muscle) model. The pressure and energy loss (or temperature rise) along the lens axis at different frequencies are plotted in Figs. 9(a) and (b), respectively. They show that the focal region, where the pressure and temperature are the highest, becomes more localized (i.e., narrower) at higher frequencies. The maximum pressure and maximum energy loss in the focal region are plotted as functions of frequency in Figs. 10(a) and (b), respectively. The results indicate that the highest pressure and temperature occur at driving frequencies in the range of 700–1000 kHz.

The pressure field generated by a spherical lens in a material with damping exhibits different characteristics from those in a nondissipative material in which the pressure in the focal zone increases monotonously with frequency. Since the attenuation coefficient α is generally a function of frequency, the amplitude of the particle motion subjected to a plane wave decreases with increasing ultrasound frequency. But for a converging spherical wave in a dissipative material, the amplitude increases with propagation distance and increasing frequency due to the geometrical effect of focusing (nondamping effects) while it decreases with increasing distance and frequency due to energy loss in the material

FIG. 11. Temperature fields at frequency 700 kHz by (a) analytical method and (b) FEM.

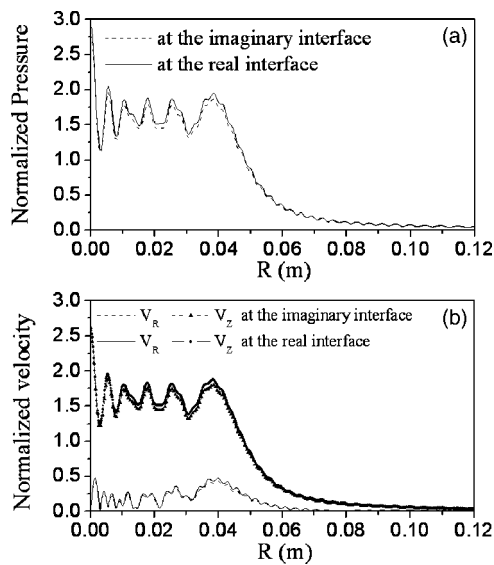

FIG. 12. (a) Pressure and (b) velocity at the interface between water and muscle (system I).

(damping effects). Thus, in a dissipative material the maximum pressure occurs at different spatial locations at different frequencies, as shown in Fig. 10(a). At high frequencies, the amplitude of pressure becomes negligibly small within a short distance away from the source (Mal *et al.*, 2003).

3. Temperature field

In order to calculate the temperature field, the uniform pressure of 0.25 MPa is assumed to be applied on the surface of the lens without loss of generality. The focal length of the lens is assumed to be 0.15 m. Typical results for the temperature fields obtained by the analytical method and FEM with an incident wave of frequency 700 kHz are compared at the end of 5-s exposure in Fig. 11.

The spatial temperature profiles are very similar for both solutions. The highest temperatures predicted in the muscle are 50.1 °C by the analytical method and 48.3 °C by the FEM. However, if a smaller value of the thermal conductivity (e.g., $k_h = 10^{-5}$ W/m K) is used for the material in the FEM calculation, a highest temperature of 49.2 °C is obtained. The difference between these two solutions is caused by the fact that heat conduction is ignored in the analytical method. The results are close enough for therapeutic applications. However, the computational needs are very different for these two methods—PZFlex requires over 10 h, while the analytical method needs only a few seconds to complete the calculations. Considering the tradeoff, the analytical method is clearly more useful for real-time clinical applications.

FIG. 13. (a) Pressure and (b) velocity at the interface between water and the imaginary material (system II).

B. Mechanical and thermal effects in a two-layered fluid material system

1. Interfacial pressure

As mentioned previously, in the two-step method, the interfacial pressure and velocity must be determined after solving the first subproblem. In this section, the results for the calculated pressure and velocity at the interface between water and muscle are plotted in Figs. 12(a) and (b). In this calculation, the focal length of the lens is 0.15 m and the depth of water is 0.075 m (the distance between the aperture plane of the lens and the interface). The driving frequency is 500 kHz and the (uniform) pressure on the surface of the lens is 0.25 MPa. It should be noted that since the wave impedances of water and muscle are very close, the plane wave transmission coefficient is close to 1, and the pair of curves in Fig. 12 are almost identical. In order to demonstrate the accuracy of the present method for two materials with large difference in their wave impedance, another pair (water and an imaginary material) described in Table II is used. The pressure and velocity distributions at the interface between water and the imaginary material are given in Figs. 13(a) and (b), in which the two curves are quite different due to the large mismatch in their wave impedances.

After the interfacial pressure and velocity have been obtained, we can now solve the second subproblem to determine the mechanical and thermal effects in the lower medium.

TABLE II. Mechanical and thermal properties in material system II.

Material	ρ (g/cc)	c_p (mm/ms)	c_s (mm/ms)	a (dB/cm)	b	C_p (J/kg K)	k_h (W/m K)

Lower ^a	1500	3000	0	40 ^b	1.0	3720	0.54

^aAn imaginary material.

^bAt 0.75 MHz.

FIG. 14. The pressure distributions along the z direction in (a) system I and (b) system II obtained by FEM and the analytical method.

2. Two-layered material systems

In the next simulation, the mechanical and thermal effects in two material systems are calculated using the two-step method. One system (I) involves water and muscle, and the other (II) involves those listed in Table II. The focal length of the lens is 0.15 m, the water depth is 0.075 m, the frequency is 750 kHz, and the uniform pressure on the surface of the lens is 0.25 MPa.

In the previous section, the interfacial pressure and velocity have been determined. We can use our program to evaluate the mechanical and thermal effects in the second layer, representing the biomaterial. The validity of the approximate analytical method is demonstrated by comparison with the pressure along the z direction with that obtained from the FEM analysis (Fig. 14). The temperature fields in the two material systems will be compared in a contour plot with those obtained by the analytical method.

Figures 15 and 16 show the temperature fields in the lower material in these two systems. Again, the temperature distributions obtained by the two methods are very similar to each other. The maximum temperatures at the focus are I (55.3 °C and 53.7 °C) and II (51.7 °C and 53.0 °C) calculated from the approximate analytical method and FEM, respectively. However, the runtime for PZFlex is around 12 h or

FIG. 15. The temperature fields in muscle (system I) obtained by (a) FEM and (b) analytical solutions.

FIG. 16. The temperature fields in the imaginary material (system II) obtained by (a) FEM and (b) analytical solution.

more, but the analytical method needs only 3–5 s on the same computer.

The two black lines in Figs. 15 and 16 represent the top and bottom borders of the efficient heating region in the z direction. The profiles of the heated regions simulated by both methods are very similar to each other. Since heat transfer is considered in the FEM model, the width of the heating region is somewhat larger than that obtained from the analytical method.

IV. CONCLUDING REMARKS

A model-based analysis of the interaction of high-intensity focused ultrasound with biological materials was carried out in an effort to predict the path of the sound waves and the temperature field in the focal region. A novel approximate analytical approach has been developed as an alternative to the FEM code in an effort to improve the computational efficiency and accuracy of the simulations. The major features of the approach are (1) extension of the artificial boundary method developed by Coulouvrat (1993) to calculate mechanical and thermal effects in one homogeneous fluid with damping and (2) development of a two-step method using a local plane wave approximation to evaluate the mechanical and thermal effects in two-layered material systems. This analytical method works for any combination of fluidlike material and it can be extended to multilayered fluid and solid media with planar or curved interfaces.

The results presented here show that the approximate analytical method can be used to calculate the mechanical and thermal effects of focused ultrasound in two-layered material systems in real time. The calculated energy loss along the axis of the lens (z axis) shows that the input frequency not only determines the size and the temperature in the focal zone, but also the position of the focus which must coincide with the location of the pathological tissue in clinical applications. The analytical method can effectively and accurately evaluate the mechanical and thermal effects in the second layer in which the pathological tissues are likely to be located. In addition, the code based on the approximate analytical method is much more efficient than the FEM and provides results that are accurate to within 4%–5%, an acceptable error in clinical applications.

1aAA1. Implications of the road traffic and aircraft noise exposure and children's cognition and health (RANCH) study results for classroom acoustics. Stephen A Stansfeld, Charlotte Clark, and on behalf of the RANCH Study Team (Ctr. for Psychiatry, Barts and the London, Queen Marys School of Medicine and Dentistry, Mile End Rd., London, E1 4NS, UK)

Studies in West London have found associations between aircraft noise exposure and childrens' cognitive performance. This has culminated in the RANCH Study examining exposure-effect associations between aircraft and road traffic noise exposure and cognitive performance and health. The RANCH project, the largest cross-sectional study of noise and childrens health, examined 2844 children, 9–10 years old, from 89 schools around three major airports: in the Netherlands, Spain and the United Kingdom. Children were selected by external aircraft and road traffic noise exposure at school predicted from noise contour maps, modeling and on-site measurements. A substudy indicated high internal levels of noise within classrooms. Schools were matched for socioeconomic position within countries. Cognitive and health outcomes were measured by standardized tests and questionnaires administered in the classroom. A parental questionnaire collected information on socioeconomic position, parental education and ethnicity. Linear exposure-effect associations were found between chronic aircraft noise exposure and impairment of reading comprehension and recognition memory, maintained after adjustment for mothers education, socioeconomic factors, longstanding illness and classroom insulation. Road traffic noise exposure was linearly associated with episodic memory. The implications of these results for childrens' learning environments will be discussed. 1aAA2. The probability of young children understanding their teacher in everyday teaching situations. John S. Bradley and Hiroshi Sato (Inst. for Res. in Construction, Natl. Res. Council, Montreal Rd., Ottawa, Canada K1A 0R6)

This paper examines the probability of grades 1, 3, and 6 students understanding their teacher in a normal teaching activity. The results of speech intelligibility tests in 34 enclosed classrooms were analyzed to relate childrens' ability to understand speech to measured signal-to-noise ratios (as well as Speech Transmission Index and useful-to-detrimental sound ratios) for each age group. Measurements of speech and noise levels during a normal teaching activity were used to determine the distribution of signal-to-noise

ratios in normal teaching situations. Combining these two sets of data shows that while 51% of the grade 6 students experienced near-to-ideal acoustical conditions only 9% of the grade 1 students had close-to-ideal conditions in these apparently good classrooms. Estimates of ideal goals for classroom signal-to-noise ratios for each age group will be presented. [Work supported by CLLRnet.]

8:35

1aAA3. Speech intelligibility tests with real and simulated classroom noise sources. Bumjun Kim and Gary Siebein (Univ. of Florida School of Architecture, P.O. Box 115702, Gainesville, FL 32607)

Speech intelligibility tests using the MRT stimuli were administered to 13 college age students in actual classroom spaces in the presence of noise sources identified in a survey of 41 elementary school classrooms in 7 schools. Twenty two different noise sources were identified during the survey of schools in a local school district. A-weighted, C-weighted, octave band and 1/3 octave band measurements of 182 individual noise sources were recorded in the sampled rooms. Noise sources were categorized as students speaking, HVAC equipment, other building equipment, water running in sinks, computers, lighting fixtures, A/V equipment, and miscellaneous sources. The noise source measurements provide a useful data base for future classroom acoustical studies. Five noise levels (35, 45, 55, 65, and 75 dBA) of 4 different types of noise were tested in the rooms. The speech intelligibility tests found significant effects (at the 0.01 level) from level, spectra, type, content, and annoyance caused by the different noise sources. A predictive model based on these variables had an R2 of 0.90 for speech intelligibility under the extremely diverse set of conditions tested.

8:55

1aAA4. Auralization study of optimum reverberation for speech intelligibility for normal and hearing-impaired listeners. Wonyoung Yang, Murray Hodgson (School of Occupational and Environ. Hygiene, Univ. of British Columbia, 3rd Fl., 2206 East Mall, Vancouver, BC, Canada V6T1Z3), and Maki Ezaki (Central West Health Co. Speech-Lang. Pathol. and Audiol., Grand Falls-Windsor, NF, Canada A2A 2E1)

Reverberation and signal-to-noise level difference are two major factors affecting speech intelligibility. They interact in rooms. Past work has accounted for noise using a constant received background-noise level. Noise is actually generated by sources, and varies, and affects speech intelligibility differently, throughout the classroom, depending on where the sources are located. Here, a speech-babble noise source located at different positions in the room was considered. The relative output levels of the speech and noise sources, resulting in different signal-to-noise level differences, were controlled, along with the reverberation. The binaural impulse response of a virtual idealized classroom model was convolved with the Modified Rhyme Test (MRT) source and babble-noise signals in order to find the optimal configuration for speech intelligibility. Speech-intelligibility tests were performed with normal and hard-of-hearing subjects in each of 16 conditions which were combinations of reverberation time, signal-to-noise level difference, and speech- and noise-source locations. For both normal and hearing-impaired subjects, when the speech source was closer to the listener than the noise source, the optimal RT was zero. When the noise source was closer to the listener than the speech source, the optimal RT was generally non-zero. This agrees with theoretical results.

9:15

1aAA5. Optimal speech level for speech transmission in a noisy environment for young adults and aged persons. Hayato Sato, Ryo Ota, Masayuki Morimoto (Environ. Acoust. Lab., Kobe Univ., Nada, Kobe 657-8501, Japan, hayato@kobe-u.ac.jp), and Hiroshi Sato (Natl. Inst. of Adv. Industrial Sci. and Technol., Tsukuba, Ibaraki 305-8566, Japan)

Assessing sound environment of classrooms for the aged is a very important issue, because classrooms can be used by the aged for their lifelong learning, especially in the aged society. Hence hearing loss due to aging is a considerable factor for classrooms. In this study, the optimal speech level in noisy fields for both young adults and aged persons was investigated. Listening difficulty ratings and word intelligibility scores for familiar words were used to evaluate speech transmission performance. The results of the tests demonstrated that the optimal speech level for moderate background noise (i.e., less than around 60 dBA) was fairly constant. Meanwhile, the optimal speech level depended on the speech-to-noise ratio when the background noise level exceeded around 60 dBA. The minimum required speech level to minimize difficulty ratings for the aged was higher than that for the young. However, the minimum difficulty ratings for both the young and the aged were given in the range of speech level of 70 to 80 dBA of speech level.

9:35

1aAA6. Acoustics and sociolinguistics: Patterns of communication in hearing impairing classrooms. William McKellin, Kimary Shahin (Dept. of Anthropology and Sociology, Univ. of British Columbia, Vancouver, BC, Canada V6S 1Z1), Janet Jamieson (Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z1), Murray Hodgson (UBC Acoust. and Noise Res. Group, SOEH, Vancouver, BC, Canada V6T 1Z3), and Kathleen Pichora-Fuller (Univ. of Toronto at Mississauga, Mississauga, ON, Canada L5L 1C6)

In elementary school classes, noise during student led activities is often taken as evidence of successful interaction and learning. In this complex social environment of elementary school classrooms, acquisition of complex language and social skills—the focus of activities in early education—is expected to take place in hearing-hostile environments. Communication and language processing in these contexts requires interactive strategies, discourse forms, and syntactic structures different from the educationally desired forms used in acoustically advantageous environments. Recordings were made of the interaction of groups of students in grades 1–3, 5, and 7 during collaborative group work in their regular classrooms. Each student wore microphones at the ear level and head-mounted video cameras. Each group as a whole was also audio- and videotaped and noise level readings were recorded. Analysis of the acoustical and phonological properties of language heard by each student has demonstrated that the language variety used in these noisy and reverberant settings is similar to that of individuals with hearing impairments. This paper reports similarities between the syntactic structures and pragmatic strategies used by hearing impaired children and normally hearing children in noisy contexts. [Work supported by Peter Wall Institute for Advanced Studies, University of British Columbia.]

1aAA7. Social and academic implications of acoustically hostile classrooms for hard of hearing children. Janet R. Jamieson (Faculty of Education/ECPS, Univ. of British Columbia, 2125 Main Mall, Vancouver, BC, Canada V6T 1Z4)

The correlation between lowered academic achievement and classroom noise has been demonstrated for normally hearing children (Shield and Dockrell, 2003). However, the implications of poor classroom acoustics on the socialization and academic performance of children who are hard of hearing have not been examined. Eleven hard of hearing students in one school district, ranging from kindergarten to grade 7, were the foci of the present study. Acoustic measurements of each of the 11 classrooms in both unoccupied and occupied conditions revealed that all classrooms were acoustically challenging for the hard of hearing students, particularly at transition times, when ventilation was operational, and in the primary grades, when language learning needs are greatest. Interviews with parents and teachers underscored the difficulty these students experienced in comprehending teacher instructions and participating in group work. The students seldom initiated conversation or seatwork independently, but, rather, followed the lead of their peers. The hard of hearing students experienced difficulties in understanding or participating in informal peer-to-peer conversations in the classroom, and parents and teachers attributed the children's frequent social isolation and withdrawal at school to the combined effects of poor hearing abilities and hostile classroom acoustics. [Work supported by Hampton Research Fund.]

1aAA8. Classroom acoustics: Three pilot studies. Joseph J. Smaldino (Northern Illinois Univ., De Kalb, IL 60115)

This paper summarizes three related pilot projects designed to focus on the possible effects of classroom acoustics on fine auditory discrimination as it relates to language acquisition, especially English as a second language. The first study investigated the influence of improving the signal-to-noise ratio on the differentiation of English phonemes. The results showed better differentiation with better signal-to-noise ratio. The second studied speech perception in noise by young adults for whom English was a second language. The outcome indicated that the second language learners required a better signal-to-noise ratio to perform equally to the native language participants. The last study surveyed the acoustic conditions of preschool and day care classrooms, wherein first and second language learning occurs. The survey suggested an unfavorable acoustic environment for language learning.

10:50

1aAA9. Classroom noise and children learning in a second language. Peggy Nelson, Kathryn Kohnert, Sabina Sabur (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 164 Pillsbury Dr. SE, Minneapolis, MN 55455), and Daniel Shaw (Jefferson Community School, Minneapolis, MN 55405)

The presence of background noise affects children more negatively than adults. Understanding speech in noise is a skill that continues to develop well into a child's adolescent years. Children's experience with a specific language also may affect their ability to make sense of incoming speech. Research suggests that even for adults the presence of background noise negatively affects the ability to listen in a second language. Two studies were conducted to investigate the effects of classroom noise on attention and speech perception in native Spanish-speaking second graders learning English as their second language (L2), as compared to English-only speaking peers (EO). In Study 1 we measured childrens' on-task behavior during instructional activities with and without soundfield amplification. In Study 2 we measured the effects of noise (+10 dB signal-to-noise ratio) using an experimental English word-recognition task. Findings indicate although there were no effects of amplification on on-task behavior, word-recognition performance declined significantly for both EO and L2 groups in the noise condition. In particular, the impact of the noise was disproportionately greater for the L2 group. Children learning in their L2 appear to be at a distinct disadvantage when listening in rooms with typical noise and reverberation.

11:10

1aAA10. Effects of road traffic and aircraft noise upon children's academic attainments. Bridget Shield (Dept. of Eng. Systems, Faculty of Eng., Sci. and Built Environment, London South Bank Univ., London SE1 0AA, UK), Julie Dockrell (London Univ., London WC1H 0AA, UK), and Gael Vilatarsana (London South Bank Univ., London SE1 0AA, UK)

The effects of environmental noise upon the academic performance of children aged 7 and 11 years in primary schools in London (UK) have been investigated. Noise surveys were carried out to measure levels of environmental noise during the school day outside 175 schools across London. The majority of the schools were in densely populated areas within 5 miles of central London, where road traffic was the dominant noise source. Thirty three of the schools were in a less densely populated area to the west of London near Heathrow Airport, and were subject to predominantly aircraft noise. The noise levels measured outside each school have been correlated with the results of standard tests in Reading, Writing, Mathematics, English, and Science, which are taken by all children aged 7 and 11 in England and Wales. Significant negative correlations were found between noise levels and many of the test scores, the correlations being stronger in the central London areas than in the schools around Heathrow. These results show that environmental noise has a detrimental effect upon childrens' academic performance, the effect remaining apparent when data were corrected for socio-economic factors such as social deprivation.

11:30

1aAA11. Acoustic environment challenges for the unique communication conditions in group learning classes in elementary school classrooms. Louis Sutherland (27803 Longhill Dr., Rancho Palos Verdes, CA 90275), David Lubman (Westminster, CA 92683), and Karl Pearsons (Woodland Hills, CA 91364)

Unlike the traditional “sage-on-the-stage” configuration of many K–12 classrooms, the group learning or “guide-on-the-side” configuration does not involve communication between a teacher in front of a seated class of 20 to 30 students. Instead, it can involve, most of the time, communication between the teacher and each of several small groups of students interacting, aurally, with each other. To maintain the desired 15 dB signal-to-noise ratio intended as the rationale for the ANSI standard, S12.60-2002 on classroom acoustics, the “noise” heard by participants in one of the groups is likely to include the speech levels generated by the participants in the other groups as well as the background noise in the unoccupied classroom. Thus, specification of the speech level within (i.e. the “signal”), and between (i.e. part of the “noise”) the learning groups, must be considered. Data available to evaluate these speech levels are reviewed and possible models considered to account for the Lombard effect for voice levels of both the teacher and the students. Some of the gaps in these data are suggested as a challenge to stimulate further studies on speech levels of teachers and students in a wide range of communication conditions.

11:45

1aAA12. Hearing impaired speech in noisy classrooms. Kimiry Shahin (Dept. of English Lang. & Translation, Effat College of Al-Faisal Univ., Jeddah 21478, Saudia Arabia), William H. McKellin, Janet Jamieson, Murray Hodgson (Univ. of British Columbia, Vancouver, Canada V6T 1Z3), and M. Kathleen Pichora-Fuller (Univ. of Toronto, Mississauga, Canada L5L 1C6)

Noisy classrooms have been shown to induce among students patterns of interaction similar to those used by hearing impaired people [W. H. McKellin *et al.*, GURT (2003)]. In this research, the speech of children in a noisy classroom setting was investigated to determine if noisy classrooms have an effect on students’ speech. Audio recordings were made of the speech of students during group work in their regular classrooms (grades 1–7), and of the speech of the same students in a sound booth. Noise level readings in the classrooms were also recorded. Each student’s noisy and quiet environment speech samples were acoustically analyzed for prosodic and segmental properties (f_0 , pitch range, pitch variation, phoneme duration, vowel formants), and compared. The analysis showed that the students’ speech in the noisy classrooms had characteristics of the speech of hearing-impaired persons [e.g., R. O’Halpin, *Clin. Ling. and Phon.* **15**, 529–550 (2001)]. Some educational implications of our findings were identified. 8:05

1aAO1. Fisheries management applications of riverine hydroacoustics: 30 years’ experience with applied technology in the practical arena. Michael F. Lapointe (Pacific Salmon Commission, 600-1155 Robson St., Vancouver, BC, Canada V6E 1B5, lapointepsc.org)

Some examples of the successes and challenges encountered by the Pacific Salmon Commission in the application of riverine hydroacoustics to fisheries management of Fraser River sockeye salmon are reviewed. Riverine hydroacoustics estimates have been an integral part of the fisheries data collected by the Pacific Salmon Commission for over 30 years. Real time estimates of fish passage provide intra-seasonal feedback on the progress toward escapement targets and information about changing total abundance levels. This information has allowed managers to adjust fisheries schedules and improved their ability to meet catch and escapement objectives. Despite these successes, application of technology has encountered a number of challenges including: (1) the interpretation of acoustics data in determining fish targets, (2) quantification of accuracy of hydroacoustic estimates in large rivers, (3) misperceptions about estimation methods by the public, and (4) inevitable comparisons with estimates from other sources and their effect on perceived accuracy of the hydroacoustic estimates. Lessons learned from the Pacific Salmon Commission experience are summarized with the objective of helping others engaged in the application of riverine acoustics technology to fisheries management problems.

8:35

1aAO2. A retrospective on hydroacoustic assessment of fish passage in Alaskan rivers. Debby Burwen, Steve Fleischman, Suzanne Maxwell, and Carl Pfisterer (Alaska Dept. of Fish and Game, 333 Raspberry Rd., Anchorage, AK 99518)

The Alaska Department of Fish and Game (ADFG) has enumerated fish stocks in rivers for over 30 years using a variety of acoustic technologies including single-, dual-, and split-beam sonar. Most recently, ADFG has evaluated a relatively new sonar technology at several sites in Alaska to determine its applicability to counting migrating fish in rivers. The new system, called a Dual

frequency IDentification SONar (DIDSON), is a high-definition imaging sonar designed and manufactured by the University of Washington's Applied Physics Lab for military applications such as diver detection and underwater mine identification. Results from experiments conducted in 2002–2004 indicate that DIDSON provides significant improvements in our ability to detect, track, and determine the direction of travel of migrating fish in rivers. One of the most powerful uses of the DIDSON has been to combine its camera-like images of fish swimming behavior with corresponding split-beam data. These linked datasets have allowed us to evaluate the effects of fish orientation and swimming behavior on echo shape parameters that have proven useful in the classification of certain fish species.

9:05

1aAO3. Split-beam sonar observations of targets as an aid in the interpretation of anomalies encountered while monitoring migrating adult salmon in rivers. George M. W. Cronkite (Dept. of Fisheries and Oceans, Pacific Biological Station, 3190 Hammond Bay Rd., Nanaimo, BC, V9T 6N7, Canada, cronkiteg@pac.dfo-mpo.gc.ca), Hermann J. Enzenhofer (Cultus Lake Res. Lab., Cultus Lake, BC, V2R 5B6, Canada), and Andrew P. Gray (Pacific Salmon Commission, Vancouver, BC, V6E 1B5, Canada)

The experiments described in this paper relate known target configurations under controlled conditions to acoustic characteristics of multiple moving fish. This was done to increase the understanding of the interactions between targets and the effects these interactions have on the measurement of the number of salmon migrating in rivers. Multiple targets in various configurations were passed through a horizontally oriented 4×10 beam from a split-beam echo sounder. The effects on measurements of target strength, detection probability and target location in the beam are presented. There was a reduction in target detection due to the single-target selection criteria implemented by the hydroacoustic system. The conditions in a river were mimicked to demonstrate how a close range fish target may modify the beam geometry allowing detection of previously undetected targets. The effects of moving targets into radial alignment were demonstrated along with shadowing conditions that can cause extinction of target echoes.

9:25

1aAO4. Acoustic measurement of the behavioral response of Arctic riverine fish to seismic sound. Eric Gyselman and John Jorgenson (Fisheries and Oceans Canada, 501 Univ. Crescent, Winnipeg, MB, Canada, gyselmane@dfo-mpo.gc.ca)

Renewed interest in oil and gas development in the Canadian Arctic has led to proposals to conduct seismic surveys along the entire length of the Mackenzie River. However, little is known about the effects of seismic sound (air guns) on fish in riverine environments. In 2004, Fisheries and Oceans Canada carried out a study to look at the effects of seismic sound on the physiology and behavior of fish in the Mackenzie River. The behavioral component used a split-beam acoustic system to measure the response of fish to varying levels of seismic sound. Targets were tracked with SonarDats Echoview Tracking Module. Two experiments were carried out. In the first, the acoustic launch was anchored over a concentration of fish while the seismic barge approached. This experiment simulated the conditions proposed for the actual seismic survey. During the second, the acoustic launch was allowed to drift over concentrations of fish. The seismic barge was stationary. When individual fish were seen in the acoustic beam, the air guns were fired. This experiment measured the overt flight response of fish to the seismic sound. Initial results from both studies indicate that fish show no direct behavioral response to the seismic sound.

Contributed Paper

9:45

1aAO5. Innovative techniques for analyzing the three-dimensional behavioral results from acoustically tagged fish. Tracey W. Steig and Mark A. Timko (Hydroacoustic Technol., Inc., 715 N.E. Northlake Way, Seattle, WA 98105)

Acoustic tags were used to monitor the swimming patterns of downstream migrating salmon smolts approaching various dams on the Columbia River, USA. Downstream migrating yearling chinook (*Oncorhynchus tshawytscha*), steelhead (*Oncorhynchus mykiss*), sockeye (*Oncorhynchus nerka*), and sub-yearling chinook smolts were surgically implanted with acoustic tags. Fish were tracked in three-dimensions as they approached

and passed into the turbine intakes, spillways, and surface bypass channel entrances at the dams during the 2004 spring and summer outmigrations. A number of advances in the analysis techniques and software have been made over the past few years. Some of these improvements include the development of various fish density algorithms, stream trace modeling analysis, and advances of three-dimensional animation programs. Three-dimensional tracks of fish approaching the turbine intakes, spillways, and surface bypass channel entrances will be presented. Concentrations of fish passage will be presented as three-dimensional fish densities superimposed over dam structures. Stream trace modeling animation will be presented showing predicted fish passage routes.

10:00–10:15 Break

Invited Paper

10:15

1aAO6. Salmon enumeration in the Fraser River with the dual-frequency identification sonar (DIDSON) acoustic imaging system. John A. Holmes, George Cronkite (Fisheries and Oceans Canada, Pacific Biological Station, 3190 Hammond Bay Rd., Nanaimo, BC, V9T 6N7, Canada), and Hermann J. Enzenhofer (Fisheries and Oceans Canada, Cultus Lake, BC V2R 5B6, Canada)

Reliable data on the number of salmon entering tributaries of the Fraser River to spawn (escapement) is needed for Pacific salmon management. Existing escapement techniques are costly and the number of populations requiring assessments has risen because of stock rebuilding efforts. The efficacy of a DIDSON acoustic imaging system for salmon stock assessment was investigated. Sixteen potential sites within the Fraser watershed were surveyed and based on channel morphology, bottom morphology, flow pattern, fish behavior and location relative to spawning grounds, ten sites in six rivers meet the needs of fisheries managers and the DIDSON

system for escapement estimates. Fish count data from the DIDSON were compared to data from a counting fence (used as a standard) using regression techniques, resulting in relationships with slopes ranging from 0.98 to 1.02. The precision of DIDSON counts >50 (measured by CV) among three readers was 1.7%. This work supports the conclusion that the DIDSON system can deliver escapement estimates whose accuracy, precision and scientific defensibility is consistent with or better than existing escapement techniques and at a lower operating cost to assessment programs. [Work supported by the Southern Boundary Restoration and Enhancement Fund of the Pacific Salmon Commission.]

1aAO7. Survey of dual frequency identification sonar (DIDSON) applications in fisheries assessment and behavioral studies. Edward O. Belcher (Sound Metrics Corp., 6824 NE 160th St., Kenmore, WA 98028)

The Dual Frequency Identification Sonar (DIDSON) is a forward-looking sonar that operates in shallow riverine environments with rocky, uneven substrates and near concrete structures such as dams. This allows a number of fisheries applications in environments previously too hostile for reliable sonar operation. Currently 35 DIDSONs have been obtained by 16 groups to accomplish a variety of fish assessment and behavioral studies. This paper surveys the work of these groups and highlights novel assessments allowed by this new acoustic tool. The groups include Alaska Department of Fish and Game, U.S. Fish and Wildlife Service, NOAA, USGS, Bureau of Reclamation, California Department of Water Resources, Pacific Northwest National Laboratories, Nez Perce Tribal Fisheries, Puyallup Tribal Fisheries, Department of Fisheries and Oceans Canada, and Fisheries Engineering Japan. Assessments include: (1) Counting fish migrating up rivers of various sizes, bottom substrates, turbidity, and velocity; (2) Analysis of fish behavior at (A) prototype fish protection devices on dams, (B) irrigation intakes along muddy rivers, (C) intakes of trawl nets; and (3) Detection and measurement of redds in alluvial riverbeds. [Work for the survey supported by Sound Metrics Corp.]

10:50

1aAO8. Differentiating fish targets from non-fish targets using an imaging sonar and a conventional sonar: Dual frequency identification sonar (DIDSON) versus split-beam sonar. Yunbo Xie, Andrew P. Gray, and Fiona J. Martens (Pacific Salmon Commission, 600-1155 Robson St., Vancouver, BC, Canada V6E 1B5, xie@psc.org)

A key requirement in applying acoustic techniques to estimating fish abundance is the removal of non-fish targets from the database. In a riverine environment, debris, entrained air bubbles, bottom objects are common ambient targets which can effectively scatter the probing sound from a fisheries sonar system, and cause strong echoes for the system. A conventional sonar system provides limited and highly simplified information for a detected target, which results in difficulty in separating fish from other targets. Recently developed DIDSON sonar utilizes imaging sonar technology to provide photo-quality images of underwater objects, making possible the visual interpretation of targets. A DIDSON system was deployed in the Fraser River at Mission, British Columbia during the salmon migration in 2004. Data were collected simultaneously from the DIDSON sonar and from a 200-kHz split-beam sonar. These data allow for comparisons of estimates of upstream salmon flux acquired concurrently by the imaging and the split-beam sonar systems.

11:05

1aAO9. Echoview software for tracking and counting fish detected with a dual frequency identification sonar (DIDSON) imaging sonar: A flexible approach to signal enhancement and object detection prior to target tracking. Ian Higginbottom (SonarData Pty Ltd., G.P.O. Box 1387, Hobart, Tasmania 7001, Australia)

The data from the DIDSON (Dual frequency IDentification SONar) are of startling resolution, and show swimming fish in unprecedented detail. Although the fish objects are visually striking, object detection must be achieved in post processing and is a challenge when compared with conventional split beam systems. Data processing can be applied to automatically remove static objects and noise and to enhance the signal from moving objects in DIDSON data. Moving objects are then detected as targets within individual DIDSON frames and converted to $X-Y-Z$ -time position data suitable for input to a tracking algorithm. The initial data manipulation for noise removal and object detection is achieved through the application of successive modular operators. The results of each operation can be viewed as a "virtual variable" enabling each step to be scrutinized and optimized by the operator. This modular approach to data manipulation, target detection, and fish tracking will enable the rapid development of new techniques and tools. It is a "future-proof" data processing solution.

11:20

1aAO10. Integrating new technologies into split-beam riverine sonar systems. James Dawson (BioSonics, Inc., 4027 Leary Way NW, Seattle, WA 98107)

While development has continued on both acoustic hardware and data processing software, parallel development has involved integration of other technologies. Users may now access and control acoustic systems over the Internet or phone lines. Smart system software can perform self-diagnostics, alert remote users of system status, and automatically adjust operational and physical parameters (such as transducer orientation) during autonomous operation. In addition, advanced remote and autonomous systems are capable of real-time analysis and decision-making functions enabling near real-time decisions and automated interactions with a variety of devices, such as modems, Ethernet adapters, motor controls, and on-site electro-mechanical devices. Details and benefits of these advances are presented in a variety of case studies.

Biomedical Ultrasound/Bioresponse to Vibration and Physical Acoustics: Tissue Response to Shock Waves I

Michael R. Bailey, Cochair

Applied Physics Lab., Center for Industrial and Medical Ultrasound, 1013 NE 40th St., Seattle, WA 98105

Reiner Schultheiss, Cochair

*SWS Shock Wave Systems AG, Wilen 4, 8574 Illighausen, Switzerland***Chair's Introduction—8:00****Invited Papers****8:05****1aBB1. Extracorporeal shock wave therapy for non-unions and delayed fracture healing.** Wolfgang Schaden, Andreas Fischer, Andreas Sailler, and Ender Karadas (Landstrasser Hauptstrasse 83, Vienna 1030, Austria, ismst@aon.at)

Although the primary management of fractures is highly developed in Central Europe 1% of fractures develop a non-union. After successful pilot studies the Traumacenter Meidling started in December 1998 to treat non-unions regularly with shock wave therapy. From December 1998 to August 2004, 1153 patients with non-union and delayed healing fractures were treated. The results of 755 patients are available up to September 2004. The patients consisted of 250 (33%) female and 505 (67%) male. The mean age was 44.1 years (10; 90). The mean age of the non-union was 15.5 months. In 74 (10%) osteomyelitis was present before shockwave therapy. Out of 755 non-unions 593 (79%) achieved bony healing. As expected, the subgroup of 284 delayed unions (shockwave therapy 3–6 months after the trauma or the last surgery concerning the bone) showed the best results. 245 (86%) healed. Out of 471 non-unions being older than 6 months 348 (72%) achieved bony healing. Because of the efficacy and the lack of complications as well as the economic advantage in comparison to surgery, shockwave therapy is considered as therapy of first choice in the treatment of non-union and delayed healing fractures.

8:20**1aBB2. The effect of shock wave treatment at the tendon-bone interface.** Ching-Jen Wang (Chang Gung Memorial Hospital at Kaohsiung, Taiwan, 123, Ta Pei Rd., Niao Sung Hsiang, Kaohsiung 833, Taiwan)

This study was performed to investigate the effect of shock wave treatment on the healing at tendon-bone interface. Thirty-six New Zealand White rabbits were used in this study. The anterior cruciate ligament was excised and replaced with the long digital extensor. The right knees (study group) were treated with 500 impulses of shock waves at 14 kV, while the left knees (control group) received no shock waves. Twenty-four rabbits were sacrificed at 1, 2, 4, 8, 12 and 24-week intervals. The specimens were studied with histomorphological examination and immunohistochemical stains for neovascularization and angiogenic growth factors. Twelve rabbits were sacrificed at 12 and 24 weeks for biomechanical analysis. The results demonstrated that the study group showed significantly more trabecular bone around the tendon and better bonding between bone and tendon as compared with the control group. The expressions of angiogenic growth factors were significantly higher in the study group than the control group. The tensile strength of the tendon-bone interface was significantly higher in the study group than the control group. In conclusion, shock wave treatment significantly improves the healing of the tendon-bone interface in a bone tunnel in rabbits. The effect of shock waves appears to be time-dependent.

8:35**1aBB3. Extracorporeal shock wave therapy in orthopedics, basic research, and clinical implications.** Joerg Hausdorf, Volkmar Jansson, Markus Maier (Orthopedic Dept., Ludwig-Maximilians-Univ. Munich, Marchioninstr. 15, 81377 Munich, Germany, joerg.hausdorf@med.uni-muenchen.de), and Michael Delius (Ludwig-Maximilians-Univ. Munich, 81377 Munich, Germany)

The molecular events following shock wave treatment of bone are widely unknown. Nevertheless patients with osteonecrosis and non unions are already treated partly successful with shock waves. Concerning the first indication, the question of the permeation of the shock wave into the bone was addressed. Therefore shockwaves were applied to porcine femoral heads and the intraosseous pressure was measured. A linear correlation of the pressure to the intraosseous distance was found. Approximately 50% of the pressure are still measurable 10 mm inside the femoral head. These findings should encourage continued shock wave research on this indication. Concerning the second indication (non union), osteoblasts were subjected to 250 or 500 shock waves at 25 kV. After 24, 48, and 72 h the levels of the bone and vascular growth factors bFGF, TGFbeta1, and VEGF were examined. After 24 h there was a significant increase in bFGF levels ($p < 0.05$) with significant correlation ($p < 0.05$) to the number of impulses. TGFbeta1, and VEGF showed no significant changes. This may be one piece in the cascade of new bone formation following shock wave treatment and may lead to a more specific application of shock waves in orthopedic surgery.

1aBB4. Experience with extracorporeal shock wave therapy (ESWT) in the United States. John P. Furia (SUN Orthopedics and Sports Medicine, 900 Buffalo Rd., Lewisburg, PA 17837)

The purpose of this presentation is to summarize the literature and to report on single treatment, high-energy ESWT for the treatment of chronic plantar fasciitis and lateral epicondylitis. Fifty-three patients (60 heels) were treated with 3800 shock waves. Sixteen patients (19 heels) were active, 21 (22 heels), were moderately active, and 16 (19 heels) were sedentary. Twelve weeks post treatment, mean visual analog scores (VAS) for the entire group improved from 9.2 to 2.4 ($p < 0.05$), RAND-Physical Functioning score improved from 40.4 to 91.5 ($p < 0.05$), and RAND-Pain score improved from 33.3 to 90 ($p < 0.05$). Fifty heels (83.3%) were assigned an excellent or good result. Thirty-six patients with chronic lateral epicondylitis were treated with 3200 shock waves. There were 9 workers compensation and 27 non-workers compensation patients. Twelve weeks post treatment, the mean VAS for the entire group improved from 8.0 to 2.5 ($p < 0.05$), and the mean RAND-Physical Functioning score improved from 65.6 to 88.0 ($p < 0.05$). Twenty-eight elbows (77.8%) were assigned an excellent or good result. In both trials, outcome was similar for each subgroup. There were no significant complications in either trial. Using the therapeutic parameters applied, ESWT is a safe and effective treatment for chronic plantar fasciitis and lateral epicondylitis.

1aBB5. Adverse effects of shock waves and strategies for improved treatment in shock wave lithotripsy. James A. McAteer, Andrew P. Evan, Bret A. Connors, James C. Williams, Jr. (Dept. of Anatomy and Cell Biol., Indiana Univ. School of Medicine, 635 Barnhill Dr., Indianapolis, IN 46202-5120, mcaateer@anatomy.iupui.edu), and Lynn R. Willis (Indiana Univ. School of Medicine, Indianapolis, IN 46202-5120)

Lithotripter SWs rupture blood vessels in the kidney. This acute trauma, accompanied by a fall in renal function, can lead to significant long-term effects such as profound scarring of the kidney cortex and renal papillae permanent loss of functional renal mass. SWL has been linked to new-onset hypertension in some patients, and recent studies suggest that multiple lithotripsies can actually alter a patient's stone disease leading to formation of stones (brushite) that are harder to break. Cavitation and shear appear to play a role in stone breakage and tissue damage. Progress in understanding these mechanisms, and the renal response to SWs, has led to practical strategies to improve treatment. Slowing the SW-rate, or initiating treatment at low kV/power both improve stone breakage and reduce the number of potentially tissue-damaging SWs needed to achieve comminution. The observation that SWs cause transient vasoconstriction in the kidney has led to studies in pigs showing that a pre-conditioning dose of low-energy SWs significantly reduces trauma from subsequent high-energy SWs. Thus, SWs can induce adverse effects in the kidney, but what we have learned about the mechanisms of SW action suggests strategies that could make lithotripsy safer and more effective. [Work supported by NIH-DK43881, DK55674.]

1aBB6. In vitro comparison of shock wave lithotripsy machines. Joel M. Teichman (St. Paul's Hospital, Burrard Bldg. C307, 1081 Burrard St., Vancouver, BC, Canada V6Z 1Y6, jteichman@providencehealth.bc.ca), Patricia P. Ceconi (Univ. of Texas Health Sci. Ctr., San Antonio, TX 78229), Margaret S. Pearle (Univ. of Texas Southwestern Medical Ctr., Dallas, TX), and Ralph V. Clayman (Univ. of California, Irvine, CA)

We tested the hypothesis that shock wave lithotripsy machines vary in the ability to fragment stones to small size. Calcium oxalate monohydrate, calcium phosphate, cystine and struvite calculi were fragmented *in vitro* with the Dornier HM3, Storz Modulith SLX, Siemens Lithostar C, Medstone STS-T, HealthTronics LithoTron 160, Dornier Doli S and Medispec Econolith lithotriptors. Stones were given 2000 shocks or the FDA limit. Post-lithotripsy fragment size was compared. Struvite calculi were completely fragmented by all devices. The mean incidence of calcium phosphate dihydrate, calcium oxalate monohydrate, and cystine stones rendered into fragments greater than 2 mm was 0% for the HM3, Modulith SLX and Lithostar C, 10% for the STS-T, 3% for the LithoTron 160, 29% for the Doli and 18% for the Econolith ($p = 0.04$); 0% for the HM3, Modulith SLX, Lithostar C, STS-T and LithoTron 160, 4% for the Doli and 9% for the Econolith ($p = 0.15$); 1% for the HM3, 0% for the Modulith SLX, 1% for the Lithostar C, 10% for the STS-T, 14% for the LithoTron 160, 3% for the Doli and 9% for the Econolith ($p = 0.44$), respectively. Shock wave lithotriptors vary in fragmentation ability.

1aBB7. Shock wave lithotripsy at 60 or 120 shocks per minute: A randomized, double-blinded trial. Kenneth Pace, Daniela Ghiculete, Melanie Harju, and R. John Honey (St. Michael's Hospital, Univ. of Toronto, 61 Queen St. E, Ste. 9-106, Toronto, ON, Canada M5C 2T2)

Rate of shock wave administration is a factor in the per-shock efficiency of SWL. Decreasing shock wave frequency from 120 shocks per minute (s/m) may improve stone fragmentation. This study is the first to test this hypothesis *in vivo*. Patients with previously untreated radio-opaque kidney stones were randomized to SWL at 60 or 120 s/m and followed at 2 weeks and 3 months. Primary outcome was success rate, defined as stone-free or asymptomatic fragments 5 mm in size 3 months post-treatment. 111 patients were randomized to 60 s/m and 109 to 120 s/m. The groups were comparable on age, gender, BMI, stent status, and initial stone area. Success rate was higher for 60 s/m (75% versus 61%, $p = 0.027$). Patients with stone area 100 mm² experienced the greatest benefit: success rates were 71% for 60 s/m versus 32% ($p = 0.002$), and stone-free rates were 60% versus 28% ($p = 0.015$). Repeat SWL treatment was required in 32% treated at 120 s/m versus 18% ($p = 0.018$). Fewer shocks were required (2423 versus 2906, $p = 0.001$), but treatment time was longer (40.6 versus 24.2 minutes, $p = 0.001$). SWL treatment at 60 s/m yields better outcomes than 120 s/m, particularly for stones 100 mm².

1aBB8. Cavitation, membrane transfer, and molecular response. Michael Delius and Gerhard Adams (Inst. for Surgical Res., Klinikum Grosshadern, 81366 Munich, Germany)

Two topics are discussed in the following. First, red cell lysis and membrane transfer are primarily caused by cavitation since they are suppressed by excess hydrostatic pressure in the exposure vessel. It was additionally proposed that shock waves destroyed red blood cells directly at excess pressure above 10 MPa when cavitation was absent. When this was re-examined with a different pressure chamber with 10 and 20 MPa excess pressure, there was no increased red cell lysis and no direct action of shock waves was found. Second, it was long thought that the transfer of fluorescein dextran into cells was a good method to co-transfer another molecule. Dextran and the other substance had to be dissolved well in a defined molecular ratio and cells with a defined number of dextran molecules recovered by flow sorting contained also a defined number of the other molecule. The attempt to apply this approach for various numbers of molecules of a ribosome inactivating protein revealed, however, an inconclusive result.

1aBB9. The disruption of tissue structure using high intensity pulsed ultrasound. J. Brian Fowlkes (Dept. of Radiol., Univ. of Michigan, Kresge III R3315, Ann Arbor, MI 48109-0553, fowlkes@umich.edu), Jessica E. Parsons, Zhen Xu, Michol Cooper, Binh C. Tran, Timothy L. Hall, William W. Roberts, and Charles A. Cain (Univ. of Michigan, Ann Arbor, MI 48109-0330)

Recent investigations of pulsed ultrasound at high acoustic intensities have revealed a regime in which significant breakdown of tissue structure can be achieved. This therapeutic modality, which might be termed histotripsy, is dependent on the presence of highly active cavitation evidenced by significant temporal fluctuations in acoustic backscatter. In the presence of tissue interfaces, erosion can result yielding, for example, well-defined perforations potentially useful in creating temporary shunts for the treatment of hypoplastic left heart syndrome. When applied in bulk tissue, the process results in a near emulsification with little structural integrity remaining or chance of cellular survival. In each case, the process is dependent on acoustic parameters of the field to not only produce damage for a given pulse but also to sustain the cavitation nuclei population for subsequent pulses. Fluctuations in acoustic backscatter indicate both initiation and extinction of the appropriate cavitation activity during application of therapeutic ultrasound, which leads to a potential feedback mechanism to minimize acoustic exposure. This presentation will discuss the observed tissue damage as affected by acoustic parameters and the ability to monitor the presence of cavitation activity expected to be responsible for these effects. 1aBB10. Observation of cavitation during shock wave lithotripsy. Michael R. Bailey, Lawrence A. Crum (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105), Yuri A. Pishchalnikov, James A. McAteer, Irina V. Pishchalnikova, Andrew P. Evan (Indiana Univ. School of Medicine, Indianapolis, IN 46202-5120), Oleg A. Sapozhnikov (M.V. Lomonosov Moscow State Univ., Moscow, 119992, Russia), and Robin O. Cleveland (Boston Univ., Boston, MA 02215)

A system was built to detect cavitation in pig kidney during shock wave lithotripsy (SWL) with a Dornier HM3 lithotripter. Active detection, using echo on B-mode ultrasound, and passive cavitation detection (PCD), using coincident signals on bifocal, orthogonal receivers, were equally sensitive and were used to interrogate the renal collecting system (urine) and the kidney parenchyma (tissue). Cavitation was detected in urine immediately upon SW administration in urine or urine plus X-ray contrast agent, but in tissue, cavitation required hundreds of SWs to initiate. Localization of cavitation was confirmed by fluoroscopy, sonography, and by thermally marking the kidney using the PCD receivers as high intensity focused ultrasound sources. Cavitation collapse times in tissue and native urine were about the same but less than in urine after injection of X-ray contrast agent. Cavitation, especially in the urine space, was observed to evolve from a sparse field to a dense field with strong acoustic collapse emissions to a very dense field that no longer produced detectable collapse. The finding that cavitation occurs in kidney tissue is a critical step toward determining the mechanisms of tissue injury in SWL. [Work sup

ported by NIH (DK43881, DK55674, FIRCA), ONRIFO, CRDF and NS-BRI SMS00203.]

1aBB11. Detecting cavitation *in vivo* from shock-wave therapy devices. Thomas J. Matula, Jinfei Yu, and Michael R. Bailey (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

Extracorporeal shock-wave therapy (ESWT) has been used as a treatment for plantar fasciitis, lateral epicondylitis, shoulder tendonitis, non-unions, and other indications where conservative treatments have been unsuccessful. However, in many areas, the efficacy of SW treatment has not been well established, and the mechanism of action, particularly the role of cavitation, is not well understood. Research indicates cavitation plays an important role in other ultrasound therapies, such as lithotripsy and focused ultrasound surgery, and in some instances, cavitation has been used as a means to monitor or detect a biological effect. Although ESWT can generate cavitation easily *in vitro*, it is unknown whether or not cavitation is a significant factor *in vivo*. The purpose of this investigation is to use diagnostic ultrasound to detect and monitor cavitation generated by ESWT devices *in vivo*. Diagnostic images are collected at various times during and after treatment. The images are then post-processed with image-processing algorithms to enhance the contrast between bubbles and surrounding tissue. The ultimate goal of this research is to utilize cavitation as a means for optimizing shock wave parameters such as amplitude and pulse repetition frequency. [Work supported by APL internal funds and NIH DK43881 and DK55674.]

1aBB12. Secondary shock wave emissions from cavitation in lithotripsy. Parag V. Chitnis and Robin O. Cleveland (Aerosp. and Mech. Eng. Dept., Boston Univ., 110 Cummington St., Boston, MA 02215)

We investigate the role of secondary shock waves (SSWs) generated by cavitation in lithotripsy. Acoustic pressure was measured with a fiber optic probe hydrophone and cavitation using a dual passive cavitation detector (PCD) consisting of two confocal transducers. An artificial stone (~7 mm diameter and ~9 mm length) was placed at the focus of an electrohydraulic lithotripter. The fiber was inserted through a hole drilled through the stone so that the tip was at the proximal surface. SSWs were

identified by matching the time of arrival to that of the inertial collapse signature acquired by the PCD. Measurements of SSWs were obtained for 50% of SWs fired at 20 kV and 1 Hz. The peak positive pressure for the SSW was $p^+ = 33.7 \pm 14.8$ MPa, which was comparable to the pressure induced by the incident SW ($p^+ = 42.6 \pm 6$ MPa). The peak pressure in water was $p^+ = 23.2 \pm 4.4$ MPa. The PCD also recorded acoustic emissions from forced collapse of pre-existing bubbles caused by the incident SW. We propose that both the reflection from the semi-rigid stone boundary and SSW from the forced collapse contribute to the observed increase in the peak pressure of the incident SW in presence of a stone. 1aPP1. Psychoacoustic evaluation of a low-parameter modal model for synthesizing impact sounds. Robert A. Lutfi, Eileen Storm, Joshua M. Alexander (Dept. of Communicative Disord. and Waisman Ctr., Univ. of Wisconsin, Madison, WI 53706, ralutfi@wisc.edu), and Eunmi Oh (Samsung AIT, Suwon, Korea 440-600)

Three experiments were conducted to test the viability of a low-parameter modal model for synthesizing impact sounds to be used in commercial and psychoacoustic research applications. The model was constrained to have 4 physically-based parameters dictating the amplitude, frequency and decay of modes. The values of these parameters were selected by ear roughly to match the recordings of 10 different resonant objects suspended by hand and struck with different mallets. In Exp. 1, neither 35 professional musicians nor 187 college undergraduates could identify which of the 2 matched sounds was the real recording with better than chance accuracy, though significantly better than chance performance was obtained when modal parameters were selected without the previously imposed physical constraints. In Exp. 2, the undergraduates identified the source corresponding to the recorded and synthesized sounds with the same level of accuracy and largely the same pattern of errors. Finally, Exp. 3 showed highly-practiced listeners to be largely insensitive to changes in the acoustic waveform resulting from an increase in the number of free-parameters used in the modal model beyond 3. The results suggest that low-parameter, modal models might be meaningfully exploited in many commercial and research applications involving human perception of impact sounds.

8:20

1aPP2. Reliable but weak voice-formant cues to body size in men but not women. Drew Rendall, John R. Vokey, Christie Nemeth, and Christina Ney (Dept of Psych., Univ. of Lethbridge, Lethbridge, AB, Canada, d.rendall@uleth.ca)

Whether voice formants provide reliable cues to adult body size has been contested recently for some animals and humans and the outcome bears critically on theories of social competition and mate choice, language origins, and speaker normalization. We report two experiments to test listeners' ability to assess speaker body size. In Experiment 1, listeners heard paired comparisons of the same short phrase spoken by two adults of the same sex paired randomly with respect to height and indicated which was larger. Both sexes (M=20; F=22) showed an equal but modest ability to identify the larger male (mean correct=58.5%; $T=31.5$, $P<0.001$) that correlated with the magnitude of their height difference but could not pick the larger female (mean correct=52.0%; $T=1.05$, $P=0.305$) regardless of the height difference. Experiment 2 used single word comparisons, focused only on male voices, and controlled F_0 while manipulating F_1-F_4 between speakers. When F_0 was equal but F_1-F_4 predicted the height difference between speakers, both sexes (M=12; F=18) correctly chose the taller male (80%). When F_1-F_4 values of the shorter male were reduced below those of the taller male (or vice versa), subjects shifted to pick the shorter male as being larger.

8:35

1aPP3. Formant frequencies as indicators of body size in red deer roars. David Reby, Karen McComb, Chris Darwin (Dept. of Psych., Univ. of Sussex, Brighton, BN2 9QH, UK), and W. Tecumseh Fitch (Univ. of St. Andrews, St. Andrews, KY16 9JU, UK)

Recent studies of animal vocal communication have emphasized the potential for vocal tract resonances to encode information on the size of callers and the need for receivers to attend to this information, in particular in the context of intra-sexual competition and inter-sexual mate choice. Our recent work on red deer roaring, a classical example of a sexual communication signal, is reviewed here. A combination of anatomical analyses of the vocal apparatus, acoustical analyses, and playback experiments using re-synthesized calls has enabled us to show that: (i) red deer and fallow deer males have a descended and mobile larynx, an anatomical innovation that was previously believed to be uniquely human and that enables callers to modulate their formants during vocalizing; (ii) minimum formant frequencies provide an honest indication of body size in red deer roars and (iii) stags use rivals' minimum formant frequencies in assessment during male-male contests, and adjust the formants of their own replies in relation to what they hear.

8:50

1aPP4. Extracting a carrier-independent version of the syllabic message: The principles. Roy D. Patterson, Thomas C. Walters (Ctr. for the Neural Basis of Hearing, Physio. Dept., Univ. of Cambridge, Downing St., Cambridge, CB2 3EG, UK, rdp1@cam.ac.uk), and Toshio Irino (Wakayama Univ., 930 Sakaedani Wakayama 640-8510, Japan)

At the heart of each syllable of speech is a vowel; the wave consists of a stream of glottal pulses, each with a resonance attached. The vowel contains three important components of the information in the larger communication: the glottal pulse rate (the pitch), the resonance shape (the message), and the resonance scale (the vocal tract length). Recent experiments on the perception of vowels show that variability in glottal pulse rate and vocal tract length has surprisingly little effect on the humans ability to recognise the vowel or discriminate speaker size, despite the variability it imparts to the spectra of these sounds. We appear to have an automatic normalization process to scale vowels and extract the message independent of the carrier. Many animal calls are like syllables in form and duration, and normalization is essential here as well if animals are to correctly identify the species of the sender and not be confused by changes in pulse rate and resonance scale that simply indicate a size difference. This talk describes how neural firing patterns produced by vowels and animal calls could be normalized to produce a carrier independent version of the message of the syllable. [Work supported by UK MRC.]

9:05

1aPP5. The stabilized, wavelet-Mellin transform for analyzing the size and shape information of vocalized sounds. Toshio Irino (Faculty of Systems Eng., Wakayama Univ., 930 Sakaedani, Wakayama 640-8510, Japan) and Roy Patterson (Univ. of Cambridge, Cambridge, CB2 3EG, UK)

We hear vowels produced by men, women, and children as approximately the same although there is considerable variability in glottal pulse rate and vocal tract length. At the same time, we can identify the speaker group. Recent experiments show that it is possible to identify vowels even when the glottal pulse rate and vocal tract length are condensed or expanded beyond the range of natural vocalization. This suggests that the auditory system has an automatic process to segregate information about shape and size of the vocal tract. Recently we proposed that the auditory system uses some form of Stabilized, Wavelet-Mellin Transform (SWMT) to analyze scale information in bio-acoustic sounds as a general framework for auditory processing from cochlea to cortex. This talk explains the theoretical background of the model and how the vocal information is normalized in the representation. [Work supported by GASR(B)(2) No. 15300061, JSPS.]

9:20

1aPP6. Manipulating the pulse rate and resonance scale in speech and animal calls. Hideki Kawahara (930 Sakaedani, Wakayama, 640-8510, Japan)

A large proportion of the sound in speech and animal calls is voiced, and thus, periodic in nature. The sounds are generated by repetitive pulsed stimulations and each pulse produces a resonant response. This repetitive structure in the sounds can be interpreted as a time-frequency sampling process that provides a stream of information about the size, shape, and structure of the resonators in the vocal tract. This perspective has enabled us to develop a system, referred to as STRAIGHT, that can analyze, manipulate, and resynthesize vocal sounds. It is based on an extended pitch synchronous spectral estimation algorithm that recovers the underlying smooth time-frequency representation representing physical information on resonators. Ideally, this process removes stimulation related structure from the time-frequency representation, and thus, it should follow the same scaling laws as the physical dimensions of the resonating body. One problem is that speech sometimes contains multiple stimulations within one pitch period. This type of stimulation introduces a spectral deformation that has the same scaling laws as for the fundamental frequency (reciprocal of the repetition rate). The effects of this dual scaling and the problems of joint normalization will be discussed. [Work supported by MEXT Japan.]

9:50

1aPP7. Relationship between fundamental and formant frequencies in speech perception. Peter F. Assmann (School of Behavioral and Brain Sci., Univ. of Texas at Dallas, Box 830688, Richardson, TX 75083), and Terrance M. Nearey (Univ. of Alberta, Edmonton, Alberta, Canada T6E 2G2)

In natural speech, there is a moderate correlation between fundamental frequency (F_0) and formant frequencies, associated with differences in larynx and vocal tract size across talkers. We have manipulated these properties using the Kawahara's STRAIGHT vocoder to determine their contribution to sentence intelligibility, vowel identification accuracy, perceived gender, and naturalness judgments by human listeners. The results of these experiments, together with predictions from a pattern recognition model, suggest that frequency-shifted speech is more intelligible and perceived as more natural when the natural co-variation of F_0 and formant frequency is preserved, even when frequency shifts exceed the range found in human speech.

10:05

1aPP8. Perception of speaker size and sex of vowel sounds. David R. R. Smith and Roy D. Patterson (CNBH, Dept. of Physiol., Cambridge Univ., Downing St., Cambridge CB2 3EG, UK, david.smith@mrc-cbu.cam.ac.uk)

Glottal-pulse rate (GPR) and vocal-tract length (VTL) are both related to speaker size and sex—however, it is unclear how they interact to determine our perception of speaker size and sex. Experiments were designed to measure the relative contribution of GPR and VTL to judgements of speaker size and sex. Vowels were scaled to represent people with different GPRs and VTLs, including many well beyond the normal population values. In a single interval, two response rating paradigm, listeners judged the size (using a 7-point scale) and sex/age of the speaker (man, woman, boy, or girl) of these scaled vowels. Results from the size-rating experiments show that VTL has a much greater influence upon judgements of speaker size than GPR. Results from the sex-categorization experiments show that judgements of speaker sex are influenced about equally by GPR and VTL for vowels with normal GPR and VTL values. For abnormal combinations of GPR and VTL, where low GPRs are combined with short VTLs, VTL has more influence than GPR in sex judgements. [Work supported by the UK MRC (G9901257) and the German Volkswagen Foundation (VWF 1/79 783).]

10:20

1aPP9. Identification of “size-modulated” vowels sequences: Effects of modulation periods and speaking rates. Minoru Tsuzaki (Kyoto City Univ. of Arts, 13-6 Kutsukake-cho, Oe, Nishikyo-ku, Kyoto, 610-1197 Japan, minoru.tsuzaki@kcuu.ac.jp), Toshio Irino (Wakayama Univ., Wakayama, Wakayama 640-8510, Japan), and Roy Patterson (Univ. of Cambridge, Cambridge, CB2 3EG, UK)

We investigated the temporal dynamics of auditory normalization and size perception by measuring vowel recognition performance using sequences of vowels in which vocal tract length was modulated during the sequence. The modulation of speaker size was achieved by scaling the frequency axis of the transfer function of vocal tract. The temporal modulation pattern was sinusoidal with a period of 16, 32, 64, 128, 256, 512, 1024, 2048, or 4096 ms. Listeners identified sequences of six vowels from four response alternatives. Although the listeners had no experience with size-modulated speech, the percentage of correct responses was never less than 90% for any modulation period. This suggests that the auditory system has an automatic size-normalizing mechanism which does not require training. The listeners had most difficulty with the 256-ms modulation period, independent of the speaking rate of the sequence. This might indicate a limitation of the processing speed for size-normalization. A simulation using Mellin Images did not reveal any obvious reason for the dip in performance with the 250 ms period, which suggests that the limitation is not in the image construction stage. [Work supported by GASR(A)(2) No. 16200016, JSPS.]

10:35

1aPP10. The perception of size in musical instrument sounds. Ralph van Dinter and Roy D. Patterson (CNBH, Dept. of Physiol., Univ. of Cambridge, Downing St., Cambridge CB2 3EG, UK, ralph.van-dinter@mrc-cbu.cam.ac.uk)

There is size information in natural sounds. For example, as humans grow in height their vocal tract increases in length, and this produces a predictable decrease in formant frequency. Recent studies have shown that listeners can judge the relative size of two individuals with considerable precision, and they can recognize vowels scaled well beyond the range normally experienced. This paper reports two psychophysical studies designed to extend the research to musical instrument sounds. The first showed that listeners can discriminate the relative size of instruments reliably, although not quite as well as for voices. The second showed that listeners can recognize instrument sounds scaled in size and pitch well beyond the range of normal experience. The research supports the hypothesis that the auditory system applies some kind of active normalization to all input sounds. [Work supported by the U.K. Medical Research Council (G9901257, G9900362), and ONRIFO (Grant N00014-03-1-1023).]

11:05

1aPP11. The neural processing of musical instrument size information in the brain investigated by magnetoencephalography. Andre Rupp (Section of Biomagnetism, Dept. Neurology, Univ. of Heidelberg, Im Neuenheimer Feld 400, 69120 Heidelberg, Germany), Ralph van Dinther, and Roy D. Patterson (Cambridge Univ., UK)

The specific cortical representation of size was investigated by recording auditory evoked fields (AEFs) elicited by changes of instrument size and pitch. In Experiment 1, a French horn and one scaled to double the size played a three note melody around $F3$ or its octave, $F4$. Many copies of these four melodies were played in random order and the AEF was measured continuously. A similar procedure was applied to saxophone sounds in a separate run. In Experiment 2, the size and type of instrument (French horn and saxophone) were varied without changing the octave. AEFs were recorded in five subjects using magnetoencephalography and evaluated by spatio-temporal source analysis with one equivalent dipole in each hemisphere. The morphology of the source waveforms revealed that each note within the melody elicits a well-defined $P1-N1-P2$ AEF-complex with adaptation for the 2nd and 3rd note. At the transition of size, pitch, or both, a larger AEF-complex was evoked. However, size changes elicited a stronger $N1$ than pitch changes. Furthermore, this size-related $N1$ enhancement was larger for French horn than saxophone. The results indicate that the $N1$ plays an important role in the specific representation of instrument size.

11:20

1aPP12. Voices of athletes reveal only modest acoustic correlates of stature. Michael J. Owren and John D. Anderson IV (Dept. of Psych., Cornell Univ., Ithaca, NY 14853)

Recent studies of acoustic cues to body-size in nonhuman primate and human vocalizations have produced results varying from very strong relationships between formant frequencies and length/weight in rhesus monkeys to weak correlations between formants and stature in humans. The current work attempted to address these discrepancies by compiling a database of naturally occurring speech with a large number of vocalizers of maximally varying size. To that end, fundamental frequency ($F0$) and formant frequencies were measured in both running speech and filled pauses (i.e., “ah” and “um”) produced by male athletes during televised same-day interviews. Multiple-regression analysis of data from 100 male athletes showed that these acoustic measures accounted for at most 17% of variance in height over a 37-cm range. Analyses of filled speech pauses produced by a subset of 48 athletes could account for up to 36%. These outcomes fall within the range of previously reported outcomes, indicating that while speech acoustics are correlated with body-size in human adult males, the cues provided are quite modest.

1aSC1. Language acquisition after cochlear implantation of congenitally deaf children: Effect of age at implantation. Mario Svirsky and Rachael Holt (Indiana Univ. School of Med., 699 West Dr., RR-044, Indianapolis, IN 46202)

Evidence shows that early implantation of congenitally deaf children is beneficial. However, infants as young as 6 months of age have started to receive cochlear implants (CIs) in the USA. Such early implantation may be associated with higher risks, including anesthetic risk as well as the increased possibility of a false positive in the diagnosis of profound deafness. On the other hand, delaying implantation may be associated with the risk of missing windows of opportunity or sensitive periods for the development of communication skills. In this study, speech perception and language skills in children who received CIs in the first, second, third, or fourth year of life were compared. Participants were tested at regular 6-month intervals after implantation. The effects of several potential confounds were considered. In general, children implanted earlier outperformed those implanted later, with one exception: infants implanted at 6–12 months showed similar outcomes to children implanted at 12–24 months, at least through 2 to 2-1/2 years of age. This preliminary result may be associated with the difficulty of choosing appropriate stimulation parameters for infants, and its potential influence on the quality of the stimulation patterns delivered by the CI.

9:00

1aSC2. Phonological systems of pediatric cochlear implant users: The acquisition of voicing. Steven B. Chin (Dept. of Otolaryngol., Indiana Univ. School of Medicine, 699 West Dr., RR044, Indianapolis, IN 46202-5119, schin@iupui.edu), Eric N. Oglesbee, Andrew K. Kirk (Indiana Univ., Bloomington, IN), and Joseph E. Krug (Indiana Univ. School of Medicine, Indianapolis, IN)

Although cochlear implants are primarily auditory prostheses, they have also demonstrated their usefulness as aids to speech production and the acquisition of spoken language in children. This presentation reports on research currently being conducted at the Indiana University Medical Center on the development of phonological systems by children with five or more years of cochlear implant use in English-speaking environments. Characteristics of the feature [voice] will be examined in children with cochlear implants and in two comparison groups: adults with normal hearing and children with normal hearing. Specific aspects of voicing to be discussed include characteristic error patterns, phonetic implementation of the voicing contrast, and phonetic implementation of neutralization of the voicing contrast. Much of the evidence obtained thus far indicates that voicing acquisition in children with cochlear implants is not radically different from that of children with normal hearing. Many differences between the systems of children with cochlear implants and the ambient system thus appear to reflect the children's age as much as their hearing status. [Work supported by grants from the National Institutes of Health to Indiana University: R01DC005594 and R03DC003852.]

1aSC3. Source reconstruction of sensory and cognitive evoked potentials. Curtis W. Ponton (Compumedics Neuroscan, 7850 Paseo del Norte, El Paso, TX 79912)

Cortical activity reflected in auditory-evoked potentials (AEPs) is often evaluated using only a small subset of all the recorded data. Conclusions based on this approach can be misleading, with no utility in identifying the underlying neural generators of the scalp recorded activity. Techniques that make use of all of the AEP data range from relatively simple methods, such as global field power, to more advanced approaches including independent components analysis (ICA), dipole modeling, and current density reconstruction. The objective of this presentation is to describe analysis of the component-structure of AEPs using these advanced techniques. Results of the ICA analysis will be used to generate spatial filters characterizing the specific scalp distribution associated with each ICA pattern. The cortical origin of each ICA scalp distribution will then be determined using current density reconstruction. The analysis will be applied to standard AEPs as well as the mismatch negativity in normal hearing and cochlear implant users. The results will demonstrate the unique suitability of neuroimaging based on AEPs for understanding the effects of cochlear implant use on cortical activity associated with cognitive processing in children and in adults.

10:05

1aSC4. Auditory plasticity in deaf children with bilateral cochlear implants. Ruth Litovsky (Waisman Ctr., Univ. of Wisconsin, Madison, WI 53705, litovsky@waisman.wisc.edu)

Human children with cochlear implants represent a unique population of individuals who have undergone variable amounts of auditory deprivation prior to being able to hear. Even more unique are children who received bilateral cochlear implants (BICIs), in sequential surgical procedures, several years apart. Auditory deprivation in these individuals consists of a two-stage process, whereby complete deafness is experienced initially, followed by deafness in one ear. We studied the effects of post-implant experience on the ability of deaf children to localize sounds and to understand speech in noise. These are two of the most important functions that are known to depend on binaural hearing. Children were tested at time intervals ranging from 3-months to 24-months following implantation of the second ear, while listening with either implant alone or bilaterally. Our findings suggest that the period during which plasticity occurs in human binaural system is protracted, extending into middle-to-late childhood. The rate at which benefits from bilateral hearing abilities are attained following deprivation is faster for speech intelligibility in noise compared with sound localization. Finally, the age at which the second implant was received may play an important role in the acquisition of binaural abilities. [Work supported by NIH-NIDCD.]

10:30

1aSC5. Learning on auditory discrimination tasks in normal-hearing listeners: Implications for hearing rehabilitation. Beverly A. Wright (Dept. of Commun. Sci. and Disord., 2240 Campus Dr., Northwestern Univ., Evanston, IL 60208-3550, b-wright@northwestern.edu)

Hearing rehabilitation extends beyond simply fitting a hearing aid or cochlear implant. To improve the benefit of these devices, it must be established which auditory abilities can be improved with training. Toward this end, learning in normal-hearing listeners was examined on five auditory discrimination tasks: frequency, intensity, interaural-time-difference (ITD), interaural-level-difference (ILD), and duration. Because the same training regimen was used throughout, any differences in the learning patterns across these trained discriminations likely reflect differences in the plasticity of the underlying mechanisms, at least for that regimen. The influence of training was assessed by comparing the improvements in discrimination threshold on trained and untrained conditions between listeners who were given multiple-hour practice on a single discrimination condition and those who were not. Learning on the five tasks followed one of two general patterns. For ITD and intensity discrimination, multiple-hour practice did not lead to greater learning than that seen in untrained listeners. In contrast, for ILD, duration, and frequency discrimination, such practice yielded greater learning, but only on a subset of conditions. The differences in the plasticity across these auditory tasks in normal-hearing listeners imply that cochlear-implant users may benefit more from training on some tasks than others. [Work supported by NIH.]

1aSC6. Hair cell regeneration: Look to the future. Edwin W. Rubel (Virginia Merrill Bloedel Hearing Res. Ctr., Univ. of Washington, M.S. 357923, Seattle, WA 98195)

Less than 2 decades ago it was discovered that birds can regenerate hair cells in the auditory and vestibular parts of the inner ear after the native hair cells are destroyed by exposure to excessive noise or by mechanical trauma of aminoglycoside antibiotics. This discovery issued in a new era of hearing research—it suggested that some day it may be possible to actually restore hearing in people with congenital or acquired hearing loss due to the degeneration of sensory cells or supporting cells in the inner ear. Fifteen years is a very short time in the history of science. Consider the fact that we have actively sought chemical treatments to prevent or cure cancers for well over a half century and the “war on Cancer,” resulted in enormous public and private support. Progress has been great, and some forms of cancer can be treated with great success, but the overall 5-year survival rates have only risen from about 50% to 63%. Progress will continue and many more forms of cancer will be cured and prevented during the next half century. Similarly, during the first 15 years of hair cell regeneration research enormous progress has been made, and we now know that postnatal mammalian ears have the capacity to produce new hair cells. We are indeed a long way from restoring hearing through hair cell regeneration, but the future is pretty clear. I will review the progress of this field with an eye toward the future and what it means for treatments of today. In particular, I will address the potential cost versus benefits of bilateral implantation when applied to babies and young children.

11:20

1aSC7. Preliminary comparison of infants speech with and without hearing loss. Richard S. McGowan (CReSS LLC, 1 Seaborn Pl., Lexington, MA 02420), Susan Nittrouer (Utah State Univ., Logan, UT 84322), and Karen Chenausky (Speech Technol. & Appl. Res., Bedford, MA 01730)

The speech of ten children with hearing loss and ten children without hearing loss aged 12 months is examined. All the children with hearing loss were identified before six months of age, and all have parents who

wish them to become oral communicators. The data are from twenty minute sessions with the caregiver and child, with their normal prostheses in place, in semi-structured settings. These data are part of a larger test battery applied to both caregiver and child that is part of a project comparing the development of children with hearing loss to those without hearing loss, known as the Early Development of Children with Hearing Loss. The speech comparisons are in terms of number of utterances, syllable shapes, and segment type. A subset of the data was given a detailed acoustic analysis, including formant frequencies and voice quality measures. [Work supported by NIDCD R01 006237 to Susan Nittrouer.]

1pAA1. Assessing the future of green building. Raymond J. Cole (UBC School of Architecture, 6333 Memorial Rd., Vancouver, BC V6T 1Z2, Canada, raycole@arch.ubc.ca)

As the realities of resource depletion and global environmental degradation become more evident, we can anticipate a maturing and strengthening of the public's concern and knowledge on environmental issues. This will translate into an expectation for greater environmental responsibility and, as with other sectors, the building industry will be increasingly scrutinized for its environmental actions. The adoption of environmental strategies has been accelerated by the emergence of building environmental assessment methods that have provided both a definition and common language for green buildings as well as a means of communicating performance improvements. Whereas the current focus is on “green” design—reducing or mitigating the environmental consequences of buildings—the future concerns will embrace mitigation, adaptation to the new conditions and restoring previous adversely impacted regions and human settlements. This presentation will provide an overview of the evolution of green building practices to set a context for understanding emerging issues in building acoustics. Since the adoption of green building practices is a function of the context that shapes political and public priorities, the presentation compares and contrasts several short and long-term scenarios some certain, others more speculative and their direct and indirect consequences for environmental progress building design.

1:35

1pAA2. Integrated building design. Jennifer Sanguinetti (Keen Eng., 116-930 West First St., North Vancouver, BC, Canada V7P 3N4, Jennifer.Sanguinetti@keen.ca)

For many years, building design has been a very linear process with owners speaking to architects who then design building shells that they pass along to sub-consultants who must fit their systems into the allotted spaces. While this process has some advantages, it provides little opportunity to optimize systems based on such factors as energy use or occupant comfort. This presentation will focus on the evolution and implications of integrated building design, a method that has provided greater opportunities for interaction between design disciplines and with building users early on in the design process. Integration has resulted in buildings that are more sustainable than typical buildings and that can respond better to the needs of the owner and users. Examples of the application of the process and the resulting buildings will be presented from the view of a design engineer with experience of both processes. Specifically, the potential contribution of an acoustical consultant in the integrated process will be explored.

2:05

1pAA3. Post-occupancy evaluation and acoustics in green buildings. Rosamund Hyde (Keen Eng., 116-930 West First St., North Vancouver, BC, Canada V7P 3N4, Rosie.Hyde@keen.ca)

Post-occupancy evaluation is a process for discerning whether completed buildings are delivering to their occupants and owners the benefits which were set as goals in the design process. Both resource consumption and occupant satisfaction are assessed. Evaluations of seven green buildings in British Columbia have been carried out, including buildings with a range of occupancies and climates. These studies have highlighted acoustics as an area where occupant satisfaction could be improved. This presentation will address three questions. First, what have we learned about acoustics from post-occupancy evaluation of green buildings? Results of the seven post-occupancy evaluations of green buildings will be discussed. Second, what questions do designers have about decisions related to acoustics in green buildings? Third, how can we improve post-occupancy evaluation processes to better address those questions?

2:35

1pAA4. Green buildings: Implications for acousticians. Michael R. Noble (BKL Consultants Ltd., 308-1200 Lynn Valley Rd., North Vancouver, BC, Canada V7J 2A2, noble@bkla.com)

This presentation will deal with the practical implications of green design protocols of the US Green Building Council on interior acoustics of buildings. Three areas of particular consequence to acousticians will be discussed. Ventilation Systems: reduced energy consumption goals dictate reliance on natural cooling and ventilation using ambient air when possible. The consequent large openings in the building envelope to bring fresh air into rooms, and similar sized openings to transfer the mixed air out, can severely compromise the noise isolation of the rooms concerned. Radiant Cooling: the heavy concrete floors of buildings can be used as a thermal flywheel to lessen the cooling load, which forces the concrete ceilings to be exposed to the occupied rooms for heat transfer, and strictly limits the application of acoustical absorption on the ceilings. This challenges the room acoustics design. Green Materials: the LEED protocols require the elimination of potentially harmful finishes, including fibrous materials which may impact air quality or contribute to health problems. Since the backbone of sound absorption is glass and mineral fibres, this further challenges provision of superior room acoustics. Examples and commentary will be provided based on current and recent projects.

3:05–3:20 Break

Contributed Papers

3:20

1pAA5. A comparative study of varying fan noise mitigation techniques in relation to sustainable design goals. Cornelis Overweg (Acentech, 1429 E. Thousand Oaks Blvd., Ste. 200, Thousand Oaks, CA 91362) and Jeff L. Fullerton (Acentech Inc., Cambridge, MA 02138)

Green building design promotes effective use of materials and energy, improved indoor environmental quality (IEQ), and enhanced occupant comfort. These “green” goals can occasionally conflict with common acoustical approaches used for fan noise control. A design striving for low noise levels from the ventilation system to benefit occupant comfort can inadvertently introduce elements that are contradictory to other green building objectives. For example, typical fan noise control devices introduce higher energy consumption or less beneficial indoor environmental quality. This paper discusses the acoustical, mechanical, environmental, and relative cost impacts of various fan noise control techniques.

3:35

1pAA6. Acoustical case studies of three green buildings. Gary Siebein (Univ. of Florida School of Architecture, P.O. Box 115702, Gainesville, FL 32607), Robert Lilkendey, and Stephen Skorski (Siebein Assoc., Inc., Consultants in Architectural Acoust., Gainesville, FL 32607)

Case studies of 3 green buildings with LEED certifications that required extensive acoustical retrofit work to become satisfactory work environments for their intended user groups will be used to define areas where green building design concepts and acoustical design concepts require reconciliation. Case study 1 is an office and conference center for a city environmental education agency. Large open spaces intended to collect daylight through clerestory windows provided large, reverberant volumes with few acoustic finishes that rendered them unsuitable as open office space and a conference room/auditorium. Case Study 2 describes one of the first gold LEED buildings in the southeast whose primary design concepts were so narrowly focused on thermal and lighting issues that they often worked directly against basic acoustical requirements re-

sulting in sound levels of NC 50–55 in classrooms and faculty offices, crosstalk between classrooms and poor room acoustics. Case study 3 is an environmental education and conference center with open public areas, very high ceilings, and all reflective surfaces made from wood and other environmentally friendly materials that result in excessive loudness when the building is used by the numbers of people which it was intended to serve.

3:50

1pAA7. An acoustic window for sustainable buildings. Jian Kang, Martin Brocklesby, Zheming Li (School of Architecture, Univ. of Sheffield, Western Bank, Sheffield S10 2TN, UK, j.kang@sheffield.ac.uk), and David J. Oldham (Univ. of Liverpool, L69 3BX, UK)

Encouraging the use of natural ventilation is an important tendency in the green building movement, but opening windows can often cause noise problems. This research develops a window system which allows natural ventilation while reducing noise transmission. The core idea is to create a ventilation path by staggering two layers of glass and using micro-perforated absorbers (MPA) along the path created to reduce noise. The MPA are made from transparent materials so that daylighting is relatively unaffected. Starting with a brief introduction of the MPA theory and its application in ducts, the paper presents a series of numerical simulations using finite element method based software FEMLAB, and experiment results measured between a semi-anechoic chamber and a reverberation chamber. Performance in acoustics, ventilation and daylighting are all taken into account. A basic window configuration is first considered, studying the effectiveness of various window parameters. A number of

strategic designs are then examined, including external hoods and louvers in the sound path. There is generally a good agreement between simulation and measurement, and the noise reduction can be as good as a single glazing, with air movement to achieve occupant comfort, rather than just for minimum air exchange. [Work supported by EPSRC.]

4:05

1pAA8. Modeling the acoustical and airflow performance of natural ventilation inlet and outlet units. David J. Oldham (School of Architecture, Univ. of Liverpool, Liverpool, L69 3BX, UK, djoldham@liv.ac.uk), Jian Kang, and Martin Brocklesby (Univ. of Sheffield, Western Bank, Sheffield S10 2TN, UK)

One aspect of the trend towards designing green buildings has been the increasing use of natural ventilation for buildings which otherwise might have required mechanical ventilation or even full air conditioning. However, the pressure differentials available to drive the natural ventilation process are small and hence relatively large inlets and outlets with low resistance to flow are required. These apertures constitute significant acoustic weak points on building facades and hence need to be treated to reduce noise ingress. Although there are a number of natural ventilation units available they have frequently been designed from the application of simple principles without any attempt to optimise both their airflow and acoustical performance. In this paper the results of a series of computer modeling exercises are described using acoustic FEM and BEM plus Computational Fluid Dynamics (CFD) which seeks to establish recommendations for the optimum design of natural ventilation inlet and outlet devices for both acoustical and airflow performance.

Invited Paper

1:20

1pAOa1. New single echo detection methods for shallow water fishery acoustics. Helge Balk, Torfinn Lindem, and Jan Kubecka (Dept. of Phys., PB1048 Blindern 0316 Oslo, Norway, helge.balk@fys.uio.no)

Acoustic target detection is commonly carried out with parametric single echo detectors. These detectors test one ping at a time and look for echoes fulfilling a set of criteria such as echo duration and shape. In shallow water, noise phenomena can distort echoes from fish and false fish echoes can be generated. This causes the parametric detector to produce fractionated tracks from fish surrounded by numerous noise detections. Parametric detectors utilize only small portions of the information available in a split beam echogram. By including information from more than one ping and from the background reverberation, a more robust fish detector has been designed. This detector, called the Cross Filter Detector (CFD), has now been further improved by applying the variance in the angle measurements.

1:40

1pAOa2. Echo characteristics of two salmon species. Patrick A. Neilson (School of Aquatic and Fishery Sci., Univ. of Washington, Box 355020, Seattle, WA 98195-5020), John K. Horne (Univ. of Washington, Seattle, WA 98195-5020), and Debby L. Burwen (Alaska Dept. of Fish and Game, Anchorage, AK 99518-1599)

The Alaska Department of Fish and Game relies on split-beam hydroacoustic techniques to estimate Chinook salmon (*Oncorhynchus tshawytscha*) returns to the Kenai River. Chinook counts are periodically confounded by large numbers of smaller sockeye salmon (*O. nerka*). Echo target-strength has been used to distinguish fish length classes, but was too variable to separate Kenai River chinook and sockeye distributions. To evaluate the efficacy of alternate echo metrics, controlled acoustic measurements of tethered chinook and sockeye salmon were collected at 200 kHz. Echo returns were digitally sampled at 48 kHz. A suite of descriptive metrics were collected from a series of 1,000 echoes per fish. Measurements of echo width were least variable at the -3 dB power point. Initial results show echo elongation and ping-to-ping variability in echo envelope width were significantly greater for chinook than for sockeye salmon. Chinook were also observed to return multiple discrete peaks from a single broadcast echo. These characteristics were attributed to the physical width of chinook exceeding half of the broadcast echo pulse width at certain orientations. Echo phase variability, correlation coefficient and fractal dimension distributions did not demonstrate significant discriminatory power between the two species. [Work supported by ADF&G, ONR.]

1:55

1pAOa3. Alaskan river environmental acoustics. Peter H. Dahl (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105-6698), Carl Pfisterer (Alaska Dept. of Fish & Game, Fairbanks, AK), and Harold J. Geiger (Alaska Dept. of Fish & Game, Douglas, AK)

Sonars are used by the Alaska Department of Fish and Game (ADF&G) to obtain daily and hourly estimates of at least four species of migratory salmon during their seasonal migration which lasts from June to beginning of September. Suspended sediments associated with a river's sediment load is an important issue for ADF&G's sonar operations. Acoustically, the suspended sediments are a source of both volume reverberation and excess attenuation beyond that expected in fresh water. Each can impact daily protocols for fish enumeration via sonar. In this talk,

results from an environmental acoustic study conducted in the Kenai River (June 1999) using 420 kHz and 200 kHz side looking sonars, and in the Yukon River (July 2001) using a 120 kHz side looking sonar, are discussed. Estimates of the volume scattering coefficient and attenuation are related to total suspended sediments. The relative impact of bubble scattering and sediment scattering is also discussed.

2:10

1pAOa4. Echo integration of nonuniform fish densities. Robert Kieser (Dept. of Fisheries and Oceans, Pacific Biological Station, 3190 Hammond Bay Rd., Nanaimo, BC, Canada V9T 6N7) and John Hedgpeth (Tenera Environ., San Luis Obispo, CA 93401)

Echo integration is a well recognized method for measuring backscatter intensity and for estimating fish density. EI is appropriate for high and low fish densities as long as the target distribution is uniform across the beam. This is generally the case in mobile applications that use a downward looking transducer. However uniform fish distribution across the beam cannot be assumed in riverine applications that use a stationary side looking system. Observed distributions are often very nonuniform especially when migrating fish are surface or bottom oriented. EI may still be possible if the relative vertical fish distribution is known and reasonably constant over time. *A priori* estimates of the vertical fish density distribution could be from split-beam observations when densities are lower or from video observations. A model for the EI of nonuniform fish densities is developed, typical results are simulated to test the model and its application is discussed.

2:25

1pAOa5. Acoustic quantification of fish in the riverine environment: Challenges. Kenneth G. Foote (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

Quantifying fish acoustically in rivers presents many challenges. Some are common to other aquatic environments, but are exacerbated in rivers. Acoustic issues of particular concern are reviewed. These include the backscattering cross section of fish, sampling volume, and both volumetric and surface reverberation. Advantages of methods based on multiple observations of the same fish, such as Doppler analysis, target-tracking, and sensing the angular dependence of fish scattering, or on correlation analysis, given sufficient bandwidth, are emphasized. The need for calibration of involved acoustic devices is mentioned.

1pAOB1. Measurements of the sound created by single bubbles fragmenting in turbulence. Grant Deane (Mail Code 0238, Scripps Inst. of Oceanogr., UCSD, La Jolla, CA 92093-0238)

One of the long-standing problems in wave noise is to understand the link between small-scale physical processes occurring in breaking wave crests and radiated noise. It has been known since the late 1980s that a broad-band component of wind-related noise comes from individual and collective bubble oscillations, but little progress has been made in quantitative calculations of noise levels from whitecaps using first-principles physics. Recent theoretical and laboratory studies have demonstrated that at least part of the wave noise spectrum (from a few hundred hertz up to a few kilohertz) is generated by bubbles fragmented by the turbulent fluid flow in the wave crest. Results from some laboratory studies of the sound radiated by isolated bubbles fragmenting in a turbulent jet as a simplified model for fragmentation in whitecaps will be presented and discussed. [Work supported by ONR.]

3:15

1pAOB2. Could animals detect the approaching tsunami? Srinivasan Jagannathan, Nicholas Makris (MIT, 77 Massachusetts Ave, 5-435, Cambridge, MA 02139, jsrini@mit.edu), and Purnima Ratilal (Northeastern Univ., Boston, MA 02115)

A number of sources report the phenomenon of animals running to safety well before the recent southeast Asian tsunami struck. The phenomenon was apparently observed on both sides of the Bay of Bengal, from Thailand to Sri Lanka. The latter is far from the epicenter of the earthquake. Did the earthquake supply the only warning or is it possible that the tsunami radiated seismo-acoustic signals of sufficient amplitude and frequency for animals to detect and interpret it long before it struck shore? This possibility is quantitatively investigated by solving the coupled hydrodynamic-acoustic equations with a tsunami driving term in a range-dependent ocean acoustic waveguide. Cases where the tsunami is in deep water and on the continental shelf are considered. [The general topic of this research follows from a suggestion made by Herman Medwin.]

3:30

1pAOB3. Estimation of bubble density with subharmonic acoustic wave in bubbly water. Byoung-Nam Kim, Kang Il Lee, Suk Wang Yoon (Dept. of Phys., SungKyunKwan Univ., Suwon 440-746, Republic of Korea, swyoon@skku.ac.kr), and Bok Kyoung Choi (Korea Ocean Res. and Development Inst., Republic of Korea)

Bubble density was estimated with a subharmonic acoustic wave generated in bubbly water. The subharmonic acoustic wave can be easily generated due to the nonlinearity of bubbly water if the frequency of primary acoustic wave is double of the bubble resonance frequency and the driving acoustic pressure amplitude exceeds a certain threshold value. The frequency of primary acoustic wave was varied from 200 kHz to 500 kHz while the bubble resonance radius at subharmonic frequency was from 12 μm to 28 μm . The pressure level of the subharmonic acoustic wave linearly increased as the driving acoustic pressure amplitude increased. With the subharmonic pressure level, the bubble density was estimated from nonlinear bubble oscillation equation [Yu. A. Ilinskii and E.

A. Zabolotskaya, J. Acoust. Soc. Am. **92**, 2837–2841 (1992)]. The estimated bubble densities were also compared with those from a linear conventional acoustic bubble sizing method. Bubble sizing with subharmonic acoustic wave seems to be easily utilized for the diagnosis of sandy sediment with bubbles.

3:45

1pAOB4. Acoustical estimation of scatterer population from total scattering measurements. Stephane G. Conti (Southwest Fisheries Sci. Ctr., 8604 La Jolla Shores Dr., La Jolla, CA 92037), Philippe Roux (Marine Physical Lab., La Jolla, CA 92093-0205), and David A. Demer (Southwest Fisheries Sci. Ctr., La Jolla, CA 92037)

Multifrequency backscattering measurements are more and more frequently used to estimate the populations of scatterers from echosounders data, and to separate the echoes from different species. Such analysis is based on the projection of the backscattered spectral data on the theoretical scattering spectra of the scatterers. Beside the accuracy of the theoretical predictions, the results of the inversion are conditioned by different parameters such as the ambient noise, the number of frequencies available, and the differences between the spectra for each scatterer. Here, we propose to evaluate the possibility of estimating the populations of scatterers from wide bandwidth total scattering cross section spectra measured in a reverberant media. The influences of the different parameters on the evaluated populations are investigated using simulations and experiments. Simulations were run either for similar spheres of different size, or different spheres of the same size. The experiments were performed in a reverberant tank with scatterers of different shapes having the same average total scattering cross section over the bandwidth.

4:00

1pAOB5. Modeling coherent Doppler sonar in fisheries acoustics. Cristina D. S. Tollefsen and Len Zedel (Dept. of Phys. and Phys. Ocean., Memorial Univ. of Newfoundland, St. John's, NL, Canada A1B 3X7, cristina@physics.mun.ca)

A computer model was developed to simulate the operation of a 250-kHz coherent Doppler sonar used to detect fish movements. The backscattered signal was constructed by summing contributions from many point targets. That signal was then detected and analyzed using the same method as used in the actual Doppler system. The model results reproduce predictions for the standard deviation of Doppler velocity estimates from volume backscatter based on the standard theoretical model of coherent pulse processing [Zrnic, IEEE Trans. Aerosp. Electron. Syst. **AES-13**, 344–354 (1977)]. However when the signal is modified to simulate the backscatter from a swimming fish (a single strong target among many weaker targets) the modeled standard deviation is 2 to 4 times lower than predicted by theory. Furthermore, the unusually low modeled standard deviations agree with laboratory and field observations. The model results confirm that the theoretical treatment used to predict the performance of Doppler measurements of current flow, blood flow, and atmospheric phenomena does not apply to the backscatter resulting from a single strong target such as a fish.

1pAOB6. Fish population dynamics revealed by instantaneous continental-shelf scale acoustic imaging. Purnima Ratilal (Northeastern Univ., 409 Dana Res. Ctr., Boston, MA 02115), Deanelle Symonds, Nicholas C. Makris (MIT, Cambridge, MA 02139), and Redwood Nero (Stennis Space Center, MS 39529)

Video images of fish population densities over vast areas of the New Jersey continental shelf have been produced from acoustic data collected on a long range bistatic sonar system during the Acoustic Clutter 2003 experiment. Areal fish population densities were obtained after correcting the acoustic data for two-way transmission loss modeled using the range-dependent parabolic equation, spatially varying beam pattern of the array, source level and mean target strength per fish. The wide-area fish density images reveal the temporal evolution of fish school distributions, their migration, as well as shoal formation and fragmentation at 50 s interval. Time series of the fish population within various density thresholds were made over the period of a day in an area containing millions of fish that at some instances formed a massive shoal extending over 12 km. The analysis shows that fish population in the area can be decomposed into a stable ambient population from lower-fish-density regions and a time-varying population composed from higher-density regions. Estimates of the differential speed between population centers of various shoals show that the average speed is on the order of a slow-moving surface vessel or submarine.

1pAOB7. Estimating biomass of densely populated fish schools from low-frequency acoustic scattering. Thomas R. Hahn (Rosenstiel School of Marine and Atmospheric Sci./AMP, Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149)

Fish schools of sufficient size and density can be efficient scatterers of low-frequency sound. This results from the large response of the fishes' swim bladders to incoming acoustic waves at frequencies at or close to their natural resonance frequencies. Acoustically, these fish schools can be viewed as a single object with acoustic bulk parameters determined from the properties of the individual fish. This effective medium approach incorporates the acoustical coupling of all fish due to multiple scattering and works for a wide range of fish-sizes, -numbers and -densities. If the contrast between the effective medium and the surrounding water is large enough, resonant enhancement occurs. These modes of collective oscillations have been conclusively observed by many authors in the context of bubble clouds. A study of the analytical structure of the effective-medium scattering amplitude reveals simple expressions relating the center frequencies and widths of low-frequency collective resonances to the overall size and fish number density of the fish school. If observed, these resonances might yield stable information that together with the mean resonance frequency of individual fish could lead to simple and practicable estimates of the total school biomass.

1pBB1. Acoustic regulation of extracorporeal shock wave (ESW) therapy devices in the U.S. Subha Maruvada and Gerald R. Harris (Food and Drug Administration, Ctr. for Devices and Radiological Health, 12725 Twinbrook Pkwy., Rockville, MD 20852, subha.maruvada@fda.hhs.gov)

The focused, large amplitude pressure fields produced by ESW lithotripsy devices were shown in the early 1980s to provide an efficient means for fragmenting urinary tract calculi. More recently, orthopedic applications of intense pressure pulses for pain relief and fracture healing have been developed. Under the US Medical Device Amendments of 1976, ESW therapy devices were deemed Class III, meaning that a pre-market application typically would be supported by both pre-clinical and clinical studies. This classification still applies, except for ESW lithotripters indicated for fragmenting kidney and ureteral calculi. These devices were reclassified to Class II in 2000, resulting in a simpler path to market in which a demonstration of substantial equivalence to a currently marketed device is sufficient. As part of its regulatory responsibility to address the safety and effectiveness of these devices, particularly with regard to acoustic output, the US Food and Drug Administration has recognized two International Electrotechnical Commission (IEC) standards for ESW lithotripters, one covering field measurements (IEC 61846) and the other dealing with labeling and other safety aspects (IEC 60601-2-36). Although these standards were designed primarily for lithotripsy, the FDA has used them where applicable in the regulatory analysis of other ESW therapy devices.

1:45

1pBB2. The acoustic fields of shock wave therapy devices. Robin O. Cleveland and Parag V. Chitnis (Dept of Aerosp. and Mech. Eng., Boston Univ., Boston, MA 02215, robinc@bu.edu)

We report measurements of a number of different shock wave therapy (SWT) devices. Two devices were electrohydraulic (EH): one had a large shock source (HMT Ossatron) and the other was a small hand-held source (HMT Evotron). The other device was a pneumatically driven device (EMS Swiss Dolorclast) and two different hand pieces were measured, one with an "unfocused" head and the other with a "focused" head. We found that the EH sources generated focused shock waves with a positive phase about 1 microsec long and peak pressure around 40 MPa, however, the acoustic output of the HMT Evotron appeared to be independent of the power setting of the machine. For the pneumatic source the duration of the positive phase was greater than 4 microsec and the peak pressure about 7 MPa. There was no clear shock front present and the waveform had a complex tail structure that was dependent on the power setting of the machine. We found that the focused hand-piece did not generate a focused acoustic field. The results are compared to reports of measurements from electromagnetic SWT devices. We contrast measurements made with different hydrophone systems: fiber-optic probe hydrophone, PVDF membrane hydrophone and PVDF bullet-shaped hydrophone.

2:00

1pBB3. Different shock front characteristics for non-urological treatments. Reiner Schultheiss (SWS Shock Wave Systems AG, Wilen 4, 8574 Illighausen, Switzerland)

Focused shock waves: Concrement disintegration and stimulation of Pseudarthroses gaps request the shock wave energy at limited spatial areas. High pressure amplitudes and energies need to exceed certain thresholds of stone material for mechanical disintegration work. Accordingly the generation of fractures within the medullar bone explained the stimulation of healing proportional to the acoustic energy. Recent clinical findings reveal identical or even better outcomes at low number of shocks. Biological model: Accepting the biological model as promoted by W. Schaden, the peak pressure and the energy density of the shock waves might be lowered dramatically. Activation of the body's healing mechanisms will be seen by ingrowth of new blood vessels and the release of growth factors. Unfocused shock wave sources: The biological model motivated the design of sources with low pressure amplitudes and energy densities. First: spherical waves generated between two tips of an electrode; and second: nearly even waves generated by generalized parabolic reflectors. Third: divergent shock front characteristics are generated by an ellipsoid behind $F2$. Unfocused sources are preferably designed for extended two dimensional areas/volumes like skin. Detailed acoustical parameters might be presented.

2:15

1pBB4. Tissue response to modified shock wave profiles. Pei Zhong, Yufeng Zhou, Franklin H. Cocks (Dept. of Mech. Eng. and Mat. Sci., Duke Univ., Box 90300, Durham, NC 27708), Charles Marguet, Glenn M. Preminger (Duke Univ.), and John Madden (Duke Univ.)

We have upgraded the original Dornier HM-3 lithotripter with a reflector insert to modify the lithotripter pulse profile and a piezoelectric annular array (PEAA) generator to produce microsecond tandem pulse lithotripsy. In this talk, we will present results from in vivo animal experiments using a swine model with or without surgically implanted artificial stones in the renal pelvis. Using this animal model, we have compared in vivo stone comminution and tissue injury, respectively, produced by the original versus the upgraded HM-3 under clinically relevant output settings. It was found that the upgraded HM-3 could produce significantly improved stone comminution with substantially reduced tissue injury, compared to the original HM-3. The underlying mechanisms that may contribute to the improved performance and safety of the upgraded HM-3 will be discussed. [Work supported by NIH DK52985 and DK58266.]

2:30

1pBB5. Reorganization of pathological control functions of memory—A neural model for tissue healing by shock waves. Othmar Wess (Storz Medical AG, Unterseestrasse 47, CH 8280 Kreuzlingen, Switzerland)

Since 1980 shock waves have proven effective in the field of extracorporeal lithotripsy. More than 10 years ago shock waves were successfully applied for various indications such as chronic pain, non-unions and, recently, for angina pectoris. These fields do not profit from the disintegration power but from stimulating and healing effects of shock waves. Increased metabolism and neo-vascularization are reported after shock wave application. According to C. J. Wang, a biological cascade is initiated, starting with a stimulating effect of physical energy resulting in increased circulation and metabolism. Pathological memory of neural control patterns is considered the reason for different pathologies characterized by insufficient metabolism. This paper presents a neural model for reorganization of pathological reflex patterns. The model acts on associative memory functions of the brain based on modification of synaptic junctions. Accordingly, pathological memory effects of the autonomous nervous system are reorganized by repeated application of shock waves followed by development of normal reflex patterns. Physiologic control of muscle and vascular tone is followed by increased metabolism and tissue repair. The memory model may explain hyper-stimulation effects in pain therapy.

2:45

1pBB6. The mechanism of shock wave treatment in bone healing. Ching-Jen Wang (Chang Gung Memorial Hospital at Kaohsiung, Taiwan, 123, Ta Pei Rd., Niao Sung Hsiang, Kaohsiung 833, Taiwan)

The purpose of this study was to investigate the biological mechanism of shock wave treatment in bone healing in rabbits. A closed fracture of the right femur was created with a three-point bend method and the fracture was stabilized with an intra-medullary pin. Shock waves were applied one week after the fracture. Twenty-four New Zealand white rabbits were randomly divided into 3 groups.

1p MON. PM

Group 1 (the control) received no shock waves; group 2 received low-energy; and group 3 high-energy shock waves. The animals were sacrificed at 24 weeks, and a 5-cm segment of the femur bone including the callus was harvested. The specimens were studied with histomorphological examination, biomechanical analysis and immunohistochemical stains. The results showed that high-energy shock waves improved bone healing with significant increases in cortical bone formation and the number neovascularization in histomorphology, better bone strength and bone mass in biomechanics, and increased expressions of angiogenic growth markers including BMP-2, eNOS, VEGF and PCNA than the control and low-energy shock wave groups. The effect of shock wave treatment appears to be dose-dependent. In conclusion, high-energy shock waves promote bone healing associated with ingrowth of neovascularization and increased expressions of angiogenic growth factors.

3:00

1pBB7. Working mechanism of extracorporeal shockwave therapy in non-urological disciplines. Wolfgang Schaden (Landstrasser Hauptstrasse 83, Vienna 1030, Austria, ismst@aon.at)

For 32 years of extracorporeal shockwave lithotripsy (ESWL) only the mechanical strength of shockwaves were of clinical interest. For use in orthopaedics, the absence of dangerous long term effects (malignant degeneration, etc.) is the only important message. The mechanical model tries to explain the effect of shock waves by the provocation of microlesions in the tissue stimulating repairing processes. First doubts on this mechanical model came up when Schaden (2001) could show, that less energy is more efficient in the treatment of non-unions. Due to the basic research of the last years knowledge increased about the microbiological effects. Under the influence of shock waves the change of permeability of cell membranes and the liberation of free radicals was reported. Also the production of nitric oxide (NO) and different growth factors like vascular endothelial growth factor (VEGF), bone morphogenetic proteins (BMP), transforming growth factor-beta 1 (TGF-b1), insulin-like growth factor-I (IGF-I) etc. was observed. The biological model tries to explain the effect of shock waves by stimulating the ingrowth of blood vessels and liberation of growth factors. Under the influence of shock waves, biological tissues seem to be able to produce important substances to initiate healing processes.

Contributed Papers

3:15

1pBB8. Effects of shock waves on growth of endothelial cells *in vitro*. Masaaki Tamagawa, Masanobu Kitayama, and Seiya Iwakura (Grad. School of Life Sci. and Systems Eng., Kyushu Inst. of Technol., Kitakyushu, Fukoka 808-0196, Japan, tama@life.kyutech.ac.jp)

Recently shock wave phenomena in living tissues are being widely applied in the fields of medical and chemical engineering, such as extracorporeal shock wave lithotripsy, bioprocess for environmental protection and tissue engineering. In the field of tissue engineering, the bone therapy to regenerate the bone by extracorporeal shock waves shows the possibility for new therapy. In this paper, to investigate the effects of shock waves on the endothelial cells *in vitro*, the cells by plane shock waves are observed by microscope and the growth rate and others are measured by image processing. The peak pressure works on the endothelial cells in water at the test case is 0.4 MPa. After working shock waves on suspended cells and fixed cells, the disintegration, shape and growth are investigated. It is found that the younger generation cells have small differences of shape index, and the growth rate of the shock-worked cells from 0 to 4 h are clearly high compared with control ones. It is concluded that once shock waves worked, some of them are disintegrated, but the other has capacity to increase growth rate of cell culture *in vitro*.

3:30

1pBB9. Study of a tissue protecting system for clinical applications of underwater shock wave. S. H. R. Hosseini and Kazuyoshi Takayama (Nanomedicine Div., Tohoku Univ., Biomed. Eng. Res. Organization, 2-1-1 Katahira, Aoba, Sendai 980-8577, Japan)

Applications of underwater shock waves have been extended to various clinical therapies during the past two decades. Besides the successful contribution of extracorporeal shock waves, tissue damage especially to the vasculature has been reported. These side effects are believed to be due to the shock wave-tissue interaction and cavitation. In the present research in order to minimize shock wave induced damage a shock wave attenuating system was designed and studied. The attenuating system consisted of thin gas packed layers immersed in water, which could attenuate more than 90% of shock waves overpressure. Silver azide micro-pellets (10 mg) were ignited by irradiation of a pulsed Nd:YAG laser to generate shock

waves. Pressure histories were measured with fiber optic probe and PVDF needle hydrophones. The strength of incident shock waves was changed by adjusting the distance between the pellets and the layers. The whole sequences of the shock wave attenuation due to the interaction of shock waves with the dissipating layers were quantitatively visualized by double exposure holographic interferometry and time resolved high speed photography. The attenuated shock had overpressure less than threshold damage of brain tissue evaluated from histological examination of the rat brain treated by shock waves.

3:45

1pBB10. Investigations on stone fragmentation in different extracorporeal shock wave lithotripsy sound fields *in vitro*. Thomas Dreyer, Marko Liebler, and Rainer Riedlinger (Universitaet Karlsruhe, IHE-Akustik, Kaiserstr. 12, D-76131 Karlsruhe, Germany, Thomas.Dreyer@ihe.uka.de)

The mechanism of stone fragmentation in ESWL applications is still under investigation. Devices showing a wide focal area and comparably low focal pressure amplitudes have been reported to disintegrate stones more efficiently as current clinical devices with high amplitudes and small focal areas. From this the question is raised whether the underlying different physical mechanisms or treatment issues, like stone localization and movement, are responsible for these results. In this paper fragmentation experiments *in vitro* with different stone types (e.g., HMT and BegoStone, 15 mm diam.) under different sound fields are presented. A self focusing piezoelectric transducer with a small focal area and peak pressure amplitudes of up to 125 MPa is used. The number of pulses was counted until a complete fragmentation through a 2 mm wire mesh is reached. In order to simulate wide-focus low-pressure conditions, the stones were placed in the prefocal region. Fragmentation results are compared to the case of focal placement. Initial breakage occurs earlier in the prefocal region for the HMT stones, whereas complete fragmentation is reached significantly earlier in the focus for all stone types.

1pBB11. A model for damage of microheterogeneous kidney stones. Andrew J. Szeri, Tarek I. Zohdi (Dept. of Mech. Engr., UC Berkeley, Berkeley, CA 94720-1740, Andrew.Szeri@Berkeley.edu), and John R. Blake (U. Birmingham, UK)

In this paper, a theoretical framework is developed for the mechanics of kidney stones with an isotropic, random microstructure—such as those comprised of cystine or struvite. The approach is based on a micromechanical description of kidney stones comprised of crystals in a binding matrix. Stress concentration functions are developed to determine load sharing of the particle phase and the binding matrix phase. As an illustration of the theory, the fatigue of kidney stones subject to shock wave lithotripsy is considered. Stress concentration functions are used to construct fatigue life estimates for each phase, as a function of the volume fraction and of the mechanical properties of the constituents, as well as the loading from SWL. The failure of the binding matrix is determined explicitly in a model for the accumulation of distributed damage. Also considered is the amount of material damaged in a representative non-spherical collapse of a cavitation bubble near the stone surface. The theory can be used to assess the importance of microscale heterogeneity on the comminution of renal calculi and to estimate the number of cycles to failure in terms of measurable material properties.

1pBB12. A mechanistic analysis of stone comminution in lithotripsy. Adam D. Maxwell (Ctr. for Industrial and Medical Ultrasound, APL, Univ. of Washington, Seattle, WA, 98105), Oleg A. Sapozhnikov (Moscow State Univ., Moscow, Russia), Michael R. Bailey, Brian MacConaghy, and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

In vitro experiments and an elastic wave model were employed to isolate and assess the importance of individual mechanisms in stone comminution in lithotripsy. Cylindrical U-30 cement stones were treated in an HM-3-style research lithotripter. Baffles were used to block specific waves responsible for spallation, squeezing, or shear. Surface cracks were added to stones to simulate the effect of cavitation, then tested in water and glycerol (a cavitation suppressive medium). Each case was simulated using the elasticity equations for an isotropic medium. The calculated location of maximum stress compared well with the experimental observations of where cracks naturally formed. Shear waves from the shock wave in the fluid traveling along the stone surface (a kind of dynamic squeezing) led to the largest stresses in the cylindrical stones and the fewest SWs to fracture. Reflection of the longitudinal wave from the back of the stone—spallation—and bubble-jet impact on the proximal and distal faces of the stone produced lower stresses and required more SWs to break stones. Surface cracks accelerated fragmentation when created near the location where the maximum stress was predicted. [Work supported by NIH DK43881, NIH-Fogarty, NSBRI SMS00203, RFBR, and ONRIFO.]

1pEAa1. Seismic landmine detection using microphones as near-ground sensors. Gregg D. Larson, James S. Martin (Georgia Inst. of Technol., School of Mech. Eng., Atlanta, GA 30332), and Waymond R. Scott, Jr. (Georgia Inst. of Technol., Atlanta, GA 30332)

Seismic landmine detection systems interrogate the near-surface layers of the ground by propagating Rayleigh surface waves through the region of interest and remotely detecting surface displacements. However, in handheld or robotic applications, commercial microphones could be utilized as near-ground sensors. The primary surface wave for landmine detection is the Rayleigh surface wave, which propagates at subsonic speeds in typical soils. Therefore, the acoustic wave generated in the air by the Rayleigh wave is evanescent. In general, the Rayleigh waves acoustic pressure can only be accurately measured well within a seismic wavelength of the surface. As ambient acoustic noise and reverberation tend to decrease the signal-to-noise ratio, several techniques have been investigated to improve the measurements. The signal-to-noise ratio of microphone measurements is significantly improved by decreasing the microphone's height above the soil surface or by improving the coupling of the microphone to the evanescent field with a horn. Planar near-field acoustic holography has also been used to back-propagate these signals and calculate surface displacements; this can potentially enhance the performance by preferentially amplifying the effects of the Rayleigh wave. Measurements with microphones have detected both anti-personnel and anti-tank landmines and compare well with radar sensor measurements.

1pEAa2. Design and analysis of a silicon condenser microphone. Jin H. Huang (Dept. of Mech. and Comput.-Aided Eng., Feng Chia Univ., Taichung 407, Taiwan) and Han Kao (Penn State Univ., State College, PA 16804)

The design and analysis of a capacitive microphone is presented in this paper. Capacitive microphone with considerably higher sensitivity and low power consumption offers the innovative design for sound pressure micro-sensors. Polysilicon with smooth surfaces and incredible low residue stress is used for diaphragm of the capacitive microphone. Two methods—equivalent circuit method and finite element method—have been applied in this research to achieve the highest sensitivity of capacitive microphone. Optimal diaphragm edge width, thickness, and air gap have been determined through analyzing and simulating sound pressure micro-sensors, understanding the variation of geometry dimensions parameters between diaphragm and air gap distance, and dissecting the impact among sensitivity, nature frequency and electric field. Consequently, the valuable design model is able to be provided for the best choice of sound pressure micro-sensors among different materials. In addition, the results can improve and control the performance and dimensions of this microsensor. Furthermore, the microphone is fabricated using a combination of surface and bulk micromachining techniques which has favorable integrated capability of CMOS (Complementary Metal-Oxide Semiconductor). These device and techniques are promising for the future production.

2:05

1pEAa3. Mass loading effect of shock accelerometers. Lixue Wu, George S. K. Wong, Peter Hanes, and Won-Suk Ohm (Inst. for Natl. Measurement Standards, Natl. Res. Council Canada, Bldg. M-36, 1200 Montreal Rd., Ottawa, ON, Canada K1A 0R6)

Mass loading affects the sensitivity of an accelerometer. The mass loading effect can be corrected using mass loading correction curves published by manufacturers. These curves, however, are only applicable to the sinusoidal acceleration below 500 m/s². The mass loading effect on the sensitivity of an Endevco 2270 accelerometer in shock calibration, from 500 m/s² and up, was investigated using a laser vibrometer. A new method for conversion of a velocity signal to an acceleration signal was developed. With this method, the sensitivities of the above accelerometer for different mass loads at different shock levels were measured. The mass loading effect in shock calibration for this accelerometer was then obtained. The limitations of the sensitivity measurements were also studied. The variance of the measured sensitivity was mainly due to the resolution limitation (8-bit) of the A/D converter in the digital oscilloscope. A correlation matching algorithm was then developed that utilizes the similarity between the measured acceleration signal and that converted from the velocity signal to further improve the resolution of the digital oscilloscope.

2:20

1pEAa4. Characterization of a small moving-magnet electrodynamic linear motor for use in a thermoacoustic refrigerator. Jin Liu and Steven L. Garrett (Grad. Program in Acoust., Penn State, State College, PA 16804)

The mechanical and electrodynamic parameters of a small, potentially inexpensive, moving-magnet electrodynamic linear motor are determined experimentally. Employing the formalism introduced by Wakeland [J. Acoust. Soc. Am. **107**, 827–832 (2000)], these parameters are used to predict the electromechanical efficiency of the motor. The transduction coefficient Bl was observed to be a function of position. As will be shown analytically, the variation in Bl with position has a reduced effect on the

drivers output power because Bl is largest around the equilibrium position where the piston velocity is also largest. By mechanical co-linear joining of the armatures of two such motors, an electrodynamic load (dynamometer) is created. Motor efficiency is then measured as a function of electrical energy dissipated in resistors placed in series with the motor which acts as the alternator in the pair. The measured efficiencies are shown to be in good agreement with the predictions if a position-averaged effective transduction coefficient is introduced. Based on these results, this linear motor is judged to be an attractive power source in small electrically driven thermoacoustic refrigerator applications. [Work supported by the Applied Research Laboratory Exploratory and Foundational Research Fund and Ben and Jerrys with motors donated by Bose Corporation.]

1pEAa5. Radiated fields of thin and flexible high frequency loudspeakers. David A. Hutchins, Andrew P. Medley, and Duncan R. Billson (School of Eng., Univ. of Warwick, Coventry CV4 7AL, UK, D.A.Hutchins@warwick.ac.uk)

Thin and flexible electrostatic loudspeakers have been constructed, which can be curved into different shapes. This allows some interesting geometries to be explored, at frequencies in the range 10 kHz to 100 kHz. The research has compared the radiated fields measured experimentally with those predicted using established theory. The theoretical approach uses a new geometrical formulation to more efficiently predict radiated field patterns, where the curved surface is considered as a series of elements at specific angles to the beam axis. These elements can be of increased width compared to previous methods, making the approach computationally efficient. It is also a more robust approach than the traditional impulse response methods, in situations where the source size is comparable to the radiated wavelengths in air. Predictions could be made for both continuous and transient excitation. A comparison between theory and experiment has demonstrated that interesting field patterns can be generated. For instance, focussed sound fields can be produced using concave shapes, with predictable focal positions which are not at the center of curvature. These and other geometries will be described.

Engineering Acoustics: Ducts, Barriers and Transmission Loss Testing

Stephen C. Thompson, Chair

Knowles Electronics Inc., 1151 Maplewood Dr., Itasca, IL 60143

Chair's Introduction—3:10

Contributed Papers

3:15

1pEAb1. Application of barrier in industrial noise control. Jonathan Chui, Yong Ma, and Salem Hertil (ATCO Noise Management, 1243 McKnight Blvd. NE, Calgary, AB, Canada)

Noise barriers have been widely used in environmental noise control, such as traffic and railway noise. Actually they are also cost-effective mitigation measures in industrial noise control. In this paper, the applications of noise barrier in power plant are introduced. Types of barrier and

barrier materials are briefly summarized and compared. A case study of noise barrier implement in a 50 MW power plant is presented. The plant is a natural gas-fired simple-cycle peaking facility, and consists of two opposed gas combustion turbine directly connected through a coupling to a single generator. Some residences are located around the facility. A noise barrier wall was designed and installed surrounding the facility to control the noise impact of the plant on the residences. The acoustic modeling software Cadna/A was used to predict the noise insertion loss of the barrier. The prediction results were also compared with the site measurements.

1pEAb2. Developing a procedure for transmission loss testing of noise control blankets. Corjan Buma (Dept. of Mech. Eng., Univ. of Alberta, Edmonton, AB, Canada T6G 2G8, bumacj@superiway.net)

The ASTM E90 test method allows variations of the basic procedure to accommodate diverse products (e.g., build a filler wall to test windows or doors). This paper describes the procedure developed to obtain a sound transmission loss rating for a line of noise-control blankets. The subject blankets are normally attached to an engine housing or used as a pipe lagging. It was originally intended to use the E90 procedure to see the increase in STC rating for a metal substrate without and with the blanket(s). However, this did not provide meaningful data. The sheet-metal substrate and the filler-wall test-opening were modified. Useful 1/3-octave band TL-data were then generated. Review of information publicly available for competitive products disclosed a distinct lack of useful acoustical data. The experience obtained in the study described could serve to further augment the E90 (or other) test procedure.

1pEAb3. A selected history of duct mode synthesis. Joe Posey (NASA Langley Res. Ctr., Hampton, VA 23681)

Attempts to attenuate noise propagating down a duct, with or without flow, must recognize that wall boundary conditions permit only certain spatial wave patterns (modes) to exist. The aircraft noise research community began building mode synthesizers at least thirty years ago in order to study duct propagation and radiation phenomena in a laboratory environment. Lockheed Georgia built a spinning mode synthesizer (SMS) for NASA in the 1970s. NASA used its SMS in a circular flow-duct to validate predictions of mode propagation through constrictions, lined sections, and inlets of various shapes. In the mid-1970s, Penn State created a mode synthesizer as part of a demonstration of active noise control in a circular, no-flow duct. NASA sponsored a series of studies in the 1990s aimed at maturing active control technology for ducted fan noise. Each of these active control systems was essentially a mode synthesizer coupled with a control system to cancel fan-generated noise. NASA is currently building a new mode synthesizer in a rectangular duct to study the effects of high-speed flow and curvature of the duct axis on advanced noise suppression technology. The evolution of mode-generation schemes will be discussed.

1pEAb4. Theoretical and experimental study of sound propagation in ducts with spatially periodic area changes. J. Ryan Nesbitt, Pavel V. Danilov, and Donald B. Bliss (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27705, dbb@duke.edu)

Sound propagation of one-dimensional waves through a tube with spatially periodic area changes is studied theoretically and experimentally. The resulting wave behavior is similar to that observed for periodic structures, with Bloch waves, pass-bands and stop-bands. The feasibility of this configuration is studied as a method to reduce sound radiation from noise sources having harmonics that fall in the stop bands. The performance of two such periodic passageways in series, each having different properties, is also studied. This approach to noise reduction is shown to give substantial attenuation. The bandwidth of the stop bands makes the design robust so that careful tuning is not required. Performance for broadband sound reduction is also evaluated. The relationship between area change parameters and the location and width of stop-bands is discussed. Experimental measurements show reasonable agreement with theoretical predictions as long as the actual geometry is accurately modeled.

1pEAb5. Usage of acoustical filters in transmission line enclosures as a replacement of fiber absorber. Onur Ilkorur, Ismail Yuksek, and Emre Omurlu (Yildiz Tech. Univ., Barbaros Bulv. 34349, Yildiz, Istanbul, Turkey)

The need for small-size loudspeaker enclosures is gaining importance, as the dimensions of the modern houses are getting smaller. Transmission line loudspeaker enclosures need more space than most other loudspeaker enclosures because of their design basics. In many commercial transmission line enclosures, fiber material is used for damping of the standing waves inside the line, resulting in a large size enclosure with a loss in sensitivity. However, their low frequency response is regarded as superior to some other enclosure types. In this paper, the frequency response of a transmission line enclosure is examined by replacing the fiber absorber with axial acoustical filters. It has been shown that, axial acoustical filters can perform as fiber absorber, requiring less space and improving the sensitivity. The other advantage of axial acoustical filters over fiber absorber is the simplicity of their electro-acoustic model. Measurements are performed using a Clio Standard System for fiber and axial acoustical filters. Electro-acoustic model and the measurement results are compared. The advantages of using axial acoustical filters are represented.

Chair's Introduction—1:00

Invited Papers

1pED1. Future directions in musical acoustics education. Thomas D. Rossing (Phys. Dept., Northern Illinois Univ., DeKalb, IL 60115, rossing@physics.niu.edu)

The desire to understand sound production by musical instruments, transmission of musical sound to the listener, and the perception of musical sound has been a strong motivator for students to learn acoustics, and will no doubt continue to be. We briefly describe past and present practices in teaching musical acoustics and attempt to predict how the subject may develop in the future.

1:25

1pED2. The future of acoustics distance education at Penn State. Karen P. Brooks, Victor W. Sparrow, and Anthony A. Atchley (Penn State Grad. Program in Acoust., 217 Appl. Sci. Bldg., University Park, PA 16802)

For nearly 20 years Penn State's Graduate Program in Acoustics has offered a graduate distance education program, established in response to Department of Defense needs. Using satellite technology, courses provided synchronous classes incorporating one-way video and two-way audio. Advancements in technology allowed more sophisticated delivery systems to be considered and courses to be offered to employees of industry. Current technology utilizes real time video-streaming and archived lectures to enable individuals anywhere to access course materials. The evolution of technology, expansion of the geographic market and changing needs of the student, among other issues, require a new paradigm. This paradigm must consider issues such as faculty acceptance and questions facing all institutions with regard to blurring the distinction between residence and distance education. Who will be the students? What will be the purpose of education? Will it be to provide professional and/or research degrees? How will the Acoustics Program ensure it remains attractive to all students, while working within the boundaries and constraints of a major research university? This is a look at current practice and issues with an emphasis on those relevant to constructing the Acoustics Programs distance education strategy for the future.

1pED3. Acoustics in mechanical engineering undergraduate core courses: Challenges and opportunities. M. G. Prasad (Dept. of Mech. Eng., Stevens Inst. of Technol., Hoboken, NJ 07030, mprasad@stevens.edu)

Generally in an undergraduate curriculum of mechanical engineering, acoustics is not included as a core course. The major core courses deal with mechanics, design, dynamics of machinery, etc. However, engineering aspects of acoustics or noise can be included through elective courses. Given the limited slots for elective courses in a curriculum, it is difficult to run elective courses in acoustics regularly with a required number of students. The challenge is to find innovative ways to include acoustics into core courses so that all students are exposed to the field and its applications. The design and analysis of machine elements such as cams, gears, etc. are always part of core courses. It is in these contexts that the acoustics through noise aspects including multimedia can be introduced. Acoustics as an effect due to vibration as cause can be included in vibration analysis. A core course on system modeling can include acoustics. The integration of acoustical topics not only strengthens the core courses but also prepares the graduating engineer to deal with real problems better. Thus, it is important for academic acousticians to bring acoustics into the core courses. This paper presents some efforts to include the acoustics material in some core courses.

1pED4. Acoustics for the musically-gifted at Berklee College of Music. Anthony K. Hoover (Cavanaugh Tocci Assoc., Inc., 327 F Boston Post Rd., Sudbury, MA 01776)

Berklee College of Music has offered an undergraduate course in applied acoustics for eighteen years, and a growing number of students have chosen a career in acoustics. This paper will summarize some of the approaches used to convey meaningful information and methods, while also encouraging interest in acoustics, to a creative and energetic student population that traditionally avoids math and science. This paper will review the textbook developed for this class, the Acoustical Society At Berklee, and the annual Berklee Teachers On Teaching.

2:25

1pED5. Medical ultrasound education for bioengineers. Shahram Vaezy (Bioengineering and Appl. Phys. Lab., Box 355640, Univ. of Washington, Seattle, WA 98195)

The widespread adoption of ultrasound technologies in medicine has necessitated the development of educational programs to address the growing demand for trained expertise in both academia and industry. The demand has been especially great in the field of therapeutic ultrasound that has experienced a significant level of research and development activities in the past decade. The applications cover a wide range including cancer treatment, hemorrhage control, cardiac ablation, gene therapy, and cosmetic surgery. A comprehensive educational program in ultrasound is well suited for bioengineering departments at colleges and universities. Our educational program for students in Bioengineering at the University of Washington includes a year-long coursework covering theory and practice of ultrasound, conducting research projects, attending and presenting at weekly seminars on literature survey, presentations at scientific meetings, and attending specialized workshops offered by various institutions for specific topics. An important aspect of this training is its multi-disciplinary approach, encompassing science, engineering, and medicine. The students are required to build teams with expertise in these disciplines. Our experience shows that these students are well prepared for careers in academia, conducting cutting edge research, as well as industry, being involved in the transformation of research end-products to commercially viable technology.

2:45

1pED6. The elements of a comprehensive education for future architectural acousticians. Lily M. Wang (Architectural Engr. Prog., Univ. of Nebraska-Lincoln, 200B PKI, Omaha, NE 68182-0681, lwang4@unl.edu)

Curricula for students who seek to become consultants of architectural acoustics or researchers in the field are few in the United States and in the world. This paper will present the author's opinions on the principal skills a student should obtain from a focused course of study in architectural acoustics. These include: (a) a solid command of math and wave theory, (b) fluency with digital signal processing techniques and sound measurement equipment, (c) expertise in using architectural acoustic software with an understanding

of its limitations, (d) knowledge of building mechanical systems, (e) an understanding of human psychoacoustics, and (f) an appreciation for the artistic aspects of the discipline. Additionally, writing and presentation skills should be emphasized and participation in professional societies encouraged. Armed with such abilities, future architectural acousticians will advance the field significantly.

1pED7. Meeting the textbook needs of modern acoustic courses. Daniel R. Raichel (Eilar Assoc., Encinitas, CA; and CUNY Grad. Ctr., NYC; 2727 Moore Ln., Fort Collins, CO 80526, draichel@comcast.net)

A truly modern textbook constitutes an essential tool for both the instructor and students of acoustics or, for that matter, of almost any other technological subject. Thus, a newer edition of an acoustics text for upper science/engineering undergraduates and graduate students should not only thoroughly cover the fundamentals (including the derivations of the wave equation for both solids and fluids—a feature, unfortunately, still lacking in many fundamental texts) but also include a coverage of the latest applications such as medical and industrial uses of ultrasound, computer programs for mapping noise contours and solving architectural acoustics problems, introduction to nonlinear acoustics, acousto-optics, sonoluminescence, voice recognition devices, surround-sound systems and newer means of sound reproduction such as iPod, advances in sound measurement equipment and prosthetic hearing devices, and so forth. While the metric system prevails throughout the world, the use of the British system of units in the example problems in a text still may be essential to U.S. students who are likely to work with architects or deal with non-SI units in U.S. industry and the military.

3:35

1pED8. Acoustics in the elementary classroom. Uwe J. Hansen (Indiana State Univ., Terre Haute, IN 47809)

The need for increased science exposure at all educational levels continues to be acute. Science is almost universally perceived as difficult, and its ability to raise the quality of life in the presence of apparently insurmountable social problems is increasingly suspect. Over the past 15 years we have conducted teacher workshops, visited classrooms, have organized hands-on demonstration sessions, judged science fairs, and mentored high school students in research efforts, all in an attempt to raise the level of enthusiasm for science. A look ahead suggests that the need continues. Elementary school teachers all too often limit their own science skills to plants and animals, and thus physics concepts do not get the exposure needed to generate the necessary excitement for the physical sciences. Workshops for Elementary grade teachers will be described, which are aimed at preparing teachers to use music as a vehicle to introduce basic physics concepts in the upper elementary grades.

1pED9. The elastodynamic Poynting vector bridges the gap in student understanding of complex wave phenomena. Cleon E. Dean (Phys. Dept., P.O.B. 8031, Georgia Southern Univ., Statesboro, GA 30460-8031, cdean@GeorgiaSouthern.edu) and James P. Braselton (Georgia Southern Univ., Statesboro, GA 30460-8093)

The advent of powerful graphic desktop computers and software allows the modern physics or engineering student to be shown dynamic physical processes formerly considered too complicated to present at the introductory level. For some time now desktop computers have been capable of showing intricate patterns of time evolving physical systems. As a simple example, students can be shown the energy flux of surface guided waves in both time averaged and time animated forms. Both vacuum and fluid loaded examples in various geometries are considered as examples. In an introductory wave phenomena class that considers electromagnetic, acoustic, and elastodynamic waves, a consistent approach using the Poynting vector field serves to bridge the gap between understanding of wave behavior for the three different types.

4:10

1pED10. Field studies in architectural acoustics using Tablet PCs. Daniel Boye (Phys. Dept., Davidson College, Davidson, NC 28035-7133)

Core requirements for the sciences within the liberal arts curriculum challenge students to become directly involved in scientific study. These requirements seek to develop scientifically literate leaders and members of society. Formal laboratory periods are not usually associated with these courses. Thus, conceptual discovery and quantitative experimentation must take place outside of the classroom. Physics 115: Musical Technology at Davidson College is such a course and contains a section dealing with architectural acoustics. Field studies in the past have been an awk-

ward and cumbersome activity, especially for non-science majors. The emerging technology of Tablet PCs overcomes many of the problems of mobile data acquisition and analysis, and allows the students to determine the locations of the rooms to be studied. The impulse method for determining reverberation time is used and compared with calculations based on room size and absorption media. The use of Tablet PCs and the publicly available freeware Audacity in field studies investigating architectural acoustics will be discussed. [Work supported in part by the Associated Colleges of the South through their Technology Fellowship program.]

1pED11. Developing technologies for bioacoustic vocal profiling as a viable component of integrative medical diagnostics and treatment. Sharry K. Edwards (Sound Health Res. Inst., Inc., Albany, OH 45710 and Capital Univ. of Integrative Medicine, Washington, DC)

Over the past 20+ years the pioneering field of Human Bioacoustics, which includes voice spectral analysis, has begun to model the frequencies and architecture of human vocalizations to identify the innate mathematical templates found within the various system of the human body. Using the idea that the voice is a holographic representation of health and wellness, these non-invasive techniques are being advanced to the extent that a computerized Vocal Profile, using a system of Frequency Equivalents, can be used to accurately quantify, organize, interpret, define, and extrapolate biometric information from the human voice. This information, in turn, provides the opportunity to predict, direct, and maintain intrinsic form and function. This novel approach has provided an accumulation of significant data but until recently has been without an efficient biological framework of reference. The emerging Mathematical Model being assembled through Human Bioacoustic research likely has the potential to allow Vocal Pro-

filing to be used to predict and monitor health issues from the very first cries of a newborn through the frequency foundations of disease and aging.

4:40

1pED12. Teaching sonar methods and technologies using a practical, real-life research environment. Tom Fedenczuk and Patricia Fryer (SOEST/HIGP, Univ. of Hawaii, 1680 East-West Rd., Honolulu, HI 96822)

The results and current developments of an educational outreach website and CD-ROM which allows students and instructors to follow the day-by-day progress of an ocean research expedition aboard the R/V Thomas G. Thompson are presented. Sonar concepts, techniques, and technologies are explained through daily updates, science objectives, data results, and lesson outlines. As the greatest source of data collected on the expedition, sonar technologies play a large role in the outreach effort. Students are exposed to hullmounted bathymetry data collection instrumentation that includes the EM300 and Hydrosweep, multibeam sonar systems. The concept of deep towed, side scan-sonar is introduced through the DSL-120 system (WHOI). Students are also introduced to sonar technologies incorporated into remotely operated vehicles like Jason II/Madea. These include the Imagex 855 scanning sonar, the RDI bottom-

tracking Doppler velocity logger, as well as navigational transponders. Each instrument and educational concept is detailed using video, Quick Time Virtual Reality, html text, and/or images. Using a Marisat satellite link, students are able to ask the researchers questions about their work and findings. [Work supported by a supplement to NSF/OCE-0002584 project: Collaborative Research: Studies of Deep-sourced Mud Volcanism in the Mariana Forearc: A DSL120, Jason ROV, and Coring Program.]

1pMU1. The impact of variation in low-frequency interaural cross correlation on auditory spatial imagery in stereophonic loudspeaker reproduction. William Martens (Faculty of Music, McGill Univ., 555 Sherbrooke St. W., Montreal, QC, Canada H3A 1E3)

Several attributes of auditory spatial imagery associated with stereophonic sound reproduction are strongly modulated by variation in interaural cross correlation (IACC) within low frequency bands. Nonetheless, a standard practice in bass management for two-channel and multichannel loudspeaker reproduction is to mix low-frequency musical content to a single channel for reproduction via a single driver (e.g., a subwoofer). This paper reviews the results of psychoacoustic studies which support the conclusion that reproduction via multiple drivers of decorrelated low-frequency signals significantly affects such important spatial attributes as auditory source width (ASW), auditory source distance (ASD), and listener envelopment (LEV). A variety of methods have been employed in these tests, including forced choice discrimination and identification, and direct ratings of both global dissimilarity and distinct attributes. Contrary to assumptions that underlie industrial standards established in 1994 by ITU-R. Recommendation BS.775-1, these findings imply that substantial stereophonic spatial information exists within audio signals at frequencies below the 80 to 120 Hz range of prescribed subwoofer cutoff frequencies, and that loudspeaker reproduction of decorrelated signals at frequencies as low as 50 Hz can have an impact upon auditory spatial imagery. [Work supported by VRQ.]

1:55

1pMU2. Loudspeaker and listener positions for optimal low-frequency spatial reproduction in listening rooms. David Griesinger (Lexicon, 3 Oak Park Dr., Bedford, MA 01730-1441)

This paper will briefly describe the physical and physiological mechanisms that enable low-frequency externalization and spatial reproduction in listening rooms. These mechanisms depend on reproducing a time-varying interaural time difference at the listening position through interference between symmetric and asymmetric room modes. The effect works successfully when the symmetric and

asymmetric room modes are driven by independent portions of a multi-channel signal, typically the in-phase and the anti-phase component of a two-channel recording. The paper will describe how this overlap can be optimized by adjusting the loudspeaker and listener positions for a variety of playback rooms. The results show that certain common room shapes yield low spatiality regardless of loudspeaker and listener positions.

2:20

1pMU3. Subjective comparison of single channel versus two channel subwoofer reproduction. Todd S. Welti (Harman Intl. Industries Inc., 8500 Balboa Blvd., Northridge, CA 91329)

Bass management has many advantages for surround sound listening, however there is still a question regarding audibility of two channel versus single channel bass reproduction. Many previous investigations have lacked rigor or been preliminary in nature. The study presented here includes strict control of nuisance variables and significance testing of results. A test is described wherein trained listeners compared four different subwoofer configurations in controlled listening tests, using a very sensitive triangle test, in a typical listening room. Methods of controlling nuisance variables are discussed. These include double blind testing, equalizing all responses flat below 120 Hz, and allowing pre-training for the listening test. Critical selection of audio test loops using low frequency decorrelation is discussed. Results are presented.

2:45

1pMU4. Physiological and content considerations for a second low frequency channel for bass management, subwoofers, and low frequency enhancement (LFE). Robert E. (Robin) Miller III (Filmmaker Technol., 606 W. Broad St., Bethlehem, PA 18018)

Perception of very low frequencies (VLF) below 125 Hz reproduced by large woofers and subwoofers (SW), encompassing 3 octaves of the 10 regarded as audible, has physiological and content aspects. Large room acoustics and vibrato add VLF fluctuations, modulating audible carrier frequencies to >1 Hz. By convention, sounds below 90 Hz produce no interaural cues useful for spatial perception or localization, therefore bass management redirects the VLF range from main channels to a single (monaural) subwoofer channel, even if to more than one subwoofer. Yet subjects claim they hear a difference between a single subwoofer channel and two (stereo bass). If recordings contain spatial VLF content, is it possible physiologically to perceive interaural time/phase difference (ITD/IPD) between 16 and 125 Hz? To what extent does this perception have a lifelike quality; to what extent is it localization? If a first approximation of localization, would binaural SWs allow a higher crossover frequency (smaller satellite speakers)? Reported research supports the Jeffress model of ITD determination in brain structures, and extending the accepted lower frequency limit of IPD. Meanwhile, uncorrelated very low frequencies exist in all tested multi-channel music and movie content. The audibility, recording, and reproduction of uncorrelated VLF are explored in theory and experiments.

1pMU5. The influence of low frequency energy on listener envelopment. Gilbert A. Soulodre (Adv. Audio Systems, Commun. Res. Ctr., Ottawa, Canada K2H 8S2, gilbert.soulodre@crc.ca)

The importance of low frequencies to the perception of spatial impression in concert halls and multi-channel surround systems is well established. The present paper reports the results of a series of subjective tests that demonstrate the influence of low frequency lateral energy on the perception of listener envelopment. The results show that the laterally-arriving low frequency energy contributes significantly to listener envelopment, and new objective measures of listener envelopment are derived that account for this effect. The effect of the spatial distribution of low frequency energy on the perception of Bass is also discussed.

3:45

1pMU6. Modeling auditory localization in the low-frequency range. Jonas Braasch, William L. Martens, and Wieslaw Woszczyk (CIRMMT, Sound Recording Area, Faculty of Music, McGill Univ., Montreal, QC, Canada H3A 1E3, jb@music.mcgill.ca)

Binaural recordings were made for subwoofer reproduction of octave-band noise bursts at 31.5-Hz, 63-Hz and 125-Hz center frequencies, and these low-frequency responses were analyzed using a binaural model simulating human perception. As expected, the interaural level differences remained nearly constant for different sound source positions within this low-frequency range. On the basis of interaural time differences, however, the model was able to predict the left/right position of the sound source on the interaural axis. In order to visualize the cross-correlation peak at low frequencies in the ITD range from -1.5 ms to $+1.5$ ms, the cross-correlation functions were decompressed by taking them to the power of 40. At these low-frequencies, the range of phase difference does not vary much with different sound positions although the ITDs are on the same order as for higher frequencies (≈ -1.0 ms to 1.0 ms), but the human ability to resolve very small phase differences already has been shown in previous investigations. The predictions of the model simulation were verified in a listening test. The repetition of the experiment in a second more reverberant space showed similar reductions in performance for both the human listeners and the model. [Work supported by VRQ.]

4:10

1pMU7. The effects of acoustical treatment on lateralization of low-frequency sources. Timothy J. Ryan, William L. Martens, and Wieslaw Woszczyk (CIRMMT, Sound Recording Area, Faculty of Music, McGill Univ., Montreal, Canada)

Recently, the standard of using a single low-frequency driver in stereophonic sound reproduction systems has come into question. Though it is accepted that lateral discrimination and localization of signals is possible well into the subwoofer frequency range, the use of multiple subwoofers in small reverberant rooms remains of questionable value. While inter-aural level differences (ILDs) are negligible at low frequencies, source lateralization is possible at low frequencies by virtue of inter-aural time differences (ITDs). But when such reproduction is attempted in small rooms, strong early reflections and resonances associated with room modes can cause erroneous ITD information to be detected by a listener, thereby compromising a listener's ability to accurately locate the source of a low-frequency sound. Acoustical treatment can be employed to reduce the level of early reflections and low-frequency ringing associated with sharp resonant modes in small rooms. Such acoustical treatment often results in more accurate reproduction of ITDs, which enables more accurate localization of sound sources in the horizontal plane. This study investigated changes in measured interaural phase differences after a treatment scheme using both diaphragmatic and Helmholtz-style absorbers. The results show the viability of using multiple low-frequency drivers given adequate acoustical treatment of the reproduction space.

4:25

1pMU8. A variable passive low-frequency absorber. Niels Werner Larsen, Eric R. Thompson, and Anders Christian Gade (Acoust. Tech., Oersted DTU, Tech. Univ. of Denmark, Bldg. 352, DK-2800 Kgs. Lyngby, Denmark, nielswerner@enghavepark.dk)

Multi-purpose concert halls face a dilemma. They can host classical music concerts, rock concerts and spoken word performances in a matter of a short period. These different performance types require significantly different acoustic conditions in order to provide the best sound quality to both the performers and the audience. A recommended reverberation time for classical music may be in the range of 1.5–2 s for empty halls, where rock music sounds best with a reverberation time around 0.8–1 s. Modern rhythmic music often contains high levels of sound energy in the low frequency bands but still requires a high definition for good sound quality. Ideally, the absorption of the hall should be adjustable in all frequency bands in order to provide good sound quality for all types of performances. The mid and high frequency absorption is easily regulated, but adjusting the low-frequency absorption has typically been too expensive or requires too much space to be practical for multi-purpose halls. Measurements were made on a variable low-frequency absorber to develop a practical solution to the dilemma. The paper will present the results of the measurements as well as a possible design.

4:40

1pMU9. Sensitivity to intermodal asynchrony between acoustic and structural vibrations. Kent Walker and William L. Martens (McGill Univ., Faculty of Music, Sound Recording, 555 Sherbrooke Ouest, Montreal, QC, Canada, H3A 1E3, kent.walker@mail.mcgill.ca)

The purpose of this study was to discover the attributes of musical stimuli which facilitate sensory integration in bi-modal music reproduction systems incorporating sound and whole-body vibration. It was hypothesized that subjective judgments regarding bimodal synchrony would vary depending on the spectral, temporal, and spatial properties of the stimuli. To test this hypothesis, musical instruments with significant low frequency energy and a variety of spectra-temporal envelopes were recorded. These stimuli were then reproduced with varying intermodal delay and overlap in frequency content between displayed vibratory and acoustic components. The air-born component of the bimodal stimuli was presented via a multichannel loudspeaker array, with a direct sound component, as well as a reproduced indirect sound arriving from all around the observer. Psychometric functions were constructed for time order judgment (TOJ) over a range of intermodal delay values. Changes in the slope and intercept of the transformed psychometric functions gave a clear picture of the influence of spectra-temporal and spatial parameters of the multimodal stimuli, the most striking results being the decreased tolerance for intermodal asynchrony associated with instruments recorded in reverberant environments. [Work supported by a Grant from VRQ of the Government of Quebec.]

4:55

1pMU10. Low-frequency interaural cross correlation discrimination in stereophonic reproduction of musical tones. Sungyoung Kim and William L. Martens (Faculty of Music, McGill Univ., 555 Sherbrooke St. West, Montreal, QC, Canada H3A 1E3, sungyoungk@hotmail.com)

By industry standard (ITU-R. Recommendation BS.775-1), multichannel stereophonic signals within the frequency range of up to 80 or 120 Hz may be mixed and delivered via a single driver (e.g., a subwoofer) without significant impairment of stereophonic sound quality. The assumption that stereophonic information within such low-frequency content is not significant was tested by measuring discrimination thresholds for changes in interaural cross-correlation (IACC) within spectral bands containing the lowest frequency components of low-pitch musical tones. Performances were recorded for three different musical instruments playing single notes ranging in fundamental frequency from 41 Hz to 110 Hz. The recordings, made using a multichannel microphone array composed of five DPA 4006 pressure microphones, were processed to produce a set of stimuli that varied in interaural cross-correlation (IACC) within a low-frequency band, but were otherwise identical in a higher-frequency band. This correlation processing was designed to have minimal effect upon other psychoacoustic variables such as loudness and timbre. The results show that changes in interaural cross correlation (IACC) within low-frequency bands of low-pitch musical tones are most easily discriminated when decorrelated signals are presented via subwoofers positioned at extreme lateral angles (far from the median plane). [Work supported by VRQ.]

1pPA1. From seismology to oceanography: Locating the sources of the Earth's hum. Barbara Romanowicz and Junkee Rhie (Berkeley Seismological Lab., 215 McCone Hall, Berkeley, CA 94720)

The observation of continuously excited free oscillations of the Earth, in the absence of earthquakes, was first made by Japanese scientists in 1998. Since then, attention has focused on elucidating the physical mechanism responsible for them. The mechanism must be shallow, as fundamental modes appear to be preferentially excited and it shows seasonal variability. An array-based method has been developed to detect and locate sources of very long period surface wave energy, utilizing the dispersive properties of Rayleigh waves and data from two large aperture arrays of very long period seismometers, in California and in Japan. It is shown that, for each array, there is a well defined preferential direction, which is stable over one season but changes significantly from winter to summer. The fluctuations as a function of time of the maximum stack amplitudes are correlated across the two arrays and point to the northern Pacific Ocean in the northern hemisphere winter and the southern oceans in the summer, correlating with the distribution of maximum wave height. It is inferred that the background oscillations originate primarily in the oceans, and are caused by a non-linear coupling mechanism involving the atmosphere (winds), the oceans (infragravity waves) and the seafloor.

1:30

1pPA2. Correlation in ambient seismic noise and the reconstruction of Green function. Michel Campillo, Laurent Stehly (Observatoire de Grenoble, BP 53, 38041 Grenoble, France, Michel.Campillo@ujf-grenoble.fr), Nikolai Shapiro, and Mike Ritzwoller (Univ. of Colorado, Boulder, CO)

Cross-correlations between long continuous records of ambient seismic noise at distant stations are investigated. The dominant part of the Green function, namely Rayleigh waves, are reconstructed in a broad period range. This property reminds of the fluctuation-dissipation theorem that relates the random fluctuations of a linear system and the system's response to an external force. Ambient seismic noise is indeed not a thermal noise but it can be considered as a random and isotropic wave field both because the distribution of the ambient sources responsible for the noise randomizes when averaged over long periods and because of scattering from heterogeneities that occur within the Earth. The dispersion curves of Rayleigh waves for the paths between the stations are measured from the correlations. On paths where direct measurements between earthquake and station are available, we show that they are in good agreement with those deduced from noise correlation. The measurement of correlation along paths crossing different geological structures allows to differentiate them, opening the way for a passive imaging of the Earth structure. The dispersion measurements are applied to seismic tomography at the regional scale. They make it possible to image crustal structures with a resolution higher than conventional techniques.

1:55

1pPA3. Seismic interferometry, with applications in passive reflection imaging. Kees Wapenaar and Deyan Draganov (Dept. of Geotechnology, Delft Univ. of Technol., P.O. Box 5028, 2600 GA Delft, The Netherlands, c.p.a.wapenaar@citg.tudelft.nl)

Seismic interferometry is the process of generating new seismic responses by crosscorrelating seismic observations at different receiver locations. A first version of this principle was derived in 1968 by Claerbout, who showed that the reflection response of a horizontally layered medium can be synthesized from the autocorrelation of its transmission response. Later he conjectured a similar principle for crosscorrelations of 3-D wave fields. In a similar fashion, Schuster (2001) introduced the principle of interferometric imaging, i.e., forming an image of the subsurface from crosscorrelated seismic traces. In this paper we first discuss the theory of seismic interferometry for arbitrary 3-D inhomogeneous media (deterministic or random). Starting with the Rayleigh-Betti reciprocity theorem and the principle of time-reversal, we derive a number of relations that form the basis for seismic interferometry (amongst others these relations prove Claerbout's conjecture). Despite the difference in assumptions, these relations show a close resemblance with those of Weaver and Lobkis (2001) for the retrieval of the Greens function from diffuse wave field correlations. Next we discuss a number of applications, like passive seismic reflection imaging, surface wave reconstruction, improving sparse data sets and interferometric imaging for different geometries.

1pPA4. Interferometric imaging and the principle of stationary phase. Roel Snieder (Ctr. for Wave Phenomena, Colorado School of Mines, Golden, Co 80401-1887)

Interferometric imaging where the Green's function is constructed using the correlation of complex wavefields recorded at two receivers is a rapidly emerging field. The methodology has been justified based on assumptions of equipartitioning of the normal modes of the system, as well as on various versions of the representation theorem applied to time-reversed waves. I will present another point of view that is based on stationary phase arguments. This complementary formulation of interferometric imaging gives insight in the physics of the emergence of the Green's function, and of the limitations that are encountered when applying this technique to data. Issues that will be covered are the relation between ensemble averaging and time averaging, and interferometric imaging of reflected waves. This example is of particular interest for exploration seismology since it shows that interferometric imaging may introduce spurious multiple reflections. Given the recent effort in "multiple suppression" in exploration seismology, the introduction of spurious multiple reflections is an undesirable artifact.

1pPA5. Diffuse fields in open systems and the emergence of the Green's function. Richard Weaver (Dept. of Theoretical and Appl. Mech., Univ. of Illinois, Urbana, IL 61801)

As is now well known, the relation between diffuse field correlations and the Green's function follows directly from a definition of a diffuse field as an uncorrelated smooth spectral superposition of normal modes. Such a definition is, however, inapplicable in most open structures, the earth in particular. A preferable definition might be that of room acoustics:

a diffuse field is an uncorrelated isotropic superposition of plane waves. But that definition is inapplicable to heterogeneous structures, or near boundaries. Here, a definition of a local diffuse field applicable to open heterogeneous systems is proposed. A local diffuse field is taken to be one in steady-state equilibrium with the field in a homogeneous region having an uncorrelated isotropic superposition of incident plane waves. This definition is applicable to both heterogeneous and open systems, and is shown using a reciprocity argument to lead to the familiar identity between the local Green's function of the structure and the diffuse fields correlations.

3:20

1pPA6. Phase statistics of multiply scattered ultrasonic waves in dynamic mesoscopic systems. John H. Page, Michael L. Cowan^{a)} (Dept. of Phys. and Astron., Univ. of Manitoba, Winnipeg, MB, Canada R3T 2N2), and Bart Van Tiggelen (CNRS/Universite Joseph Fourier, 38042 Grenoble, France)

In weakly scattering materials, detecting motion by measuring the change in phase of reflected ultrasonic waves forms the basis of the well-known technique of Doppler ultrasound. In strongly scattering media, these methods break down and the technique of diffusing acoustic wave spectroscopy (DAWS) was developed [Cowan *et al.*, Phys. Rev. Lett. **85**, 453 (2000)]. To explore the use of phase information to investigate the dynamics of multiply scattering media, the temporal fluctuations in the phase of ultrasonic waves transmitted through a time-varying mesoscopic sample have been measured. We have compared phase statistics and correlations to detailed theoretical predictions based on circular Gaussian ($C1$) statistics [Genack *et al.*, Phys. Rev. Lett. **82**, 412 (1999)]. So far, excellent agreement is found. The cumulative phase is found to undergo a Brownian type process, described by a phase diffusion coefficient. A fundamental relationship between the variance in the phase of the transmitted waves and the fluctuations in the phase of individual scattering paths is predicted theoretically and verified experimentally. This relationship not only gives deeper insight into the physics of the phase of multiply scattered waves, but also provides a new, mesoscopic way of probing the motion of the scatterers in the sample. ^{a)}Currently at Department of Physics, University of Toronto, Toronto, ON, Canada M5S 3E3

1pPA7. Evolution of diffuse fields in heterogeneous slabs. Joseph A. Turner and Goutam Ghoshal (Dept. of Eng. Mech., Univ. of Nebraska-Lincoln, Lincoln, NE 68588)

Fundamental studies of elastic wave scattering in heterogeneous media are applicable for problems at several length scales from ultrasonic to seismic waves. The intermediate scattering regime that lies between the single scattering and the diffusion limits is perhaps the least understood. In this presentation, both the steady-state and time dependent scattering problems are examined for this regime within the context of radiative transfer theory. The focus here is on slab geometries for which the scattering medium lies between two parallel boundaries separated by a distance investigated over a range from several to tens of mean free paths. The spatial distribution, temporal evolution, and partitioning of the diffuse longitudinal and shear energies are studied as a function of direction and frequency for several types of microstructure including polycrystalline metals, concrete, porous media, and geophysical media. The longitudinal and shear flux reflected from and transmitted through the slab are also discussed due to their importance for experimental materials characterization. Finally, comparisons are made with direct numerical scattering simulations for some of the microstructures considered. The results are anticipated to shed insight on this important intermediate scattering regime. [Work supported by NSF and DOE.]

1pPA8. The transition to equipartitioning and its relation to scattering strength. Alison E. Malcolm, John A. Scales (Colorado School of Mines, Golden, CO 80401, amalcolm@dix.mines.edu), and Bart A. van Tiggelen (CNRS/Université Joseph Fourier-Grenoble, France)

In a coarse-grained rock scattering plays a dominant role in determining the characteristics of the ultrasonic wavefield. Immediately after a pulse excites waves in such a sample energy propagates away from the source as a packet. As this packet travels, the individual grains scatter its energy in all directions. This scattering process continues until there are equal amounts of energy propagating in all directions. If the scattering is strong enough, this transition is completed before the signal strength has relaxed to the ambient level. By collecting a dense data set on several rock samples we are able to watch this transition and see the influence of grain size on the wavefield. More quantitatively we show, with noncontacting laboratory data, how this transition can be tracked using the symmetry of the advanced and retarded Green functions. These Green functions are estimated by cross-correlating the signal recorded at two detectors; the two Green functions have equal amplitude only when equal amounts of energy are propagating in all directions. 1pPA9. Convergence rates for diffuse field-field correlations. Richard Weaver (Dept. of Theoretical and Appl. Mech., Univ. of Illinois, Urbana, IL 61801)

A model of diffuse fields in open structures is taken to be that resulting from a Gaussian random distribution of sources spread over all space. It is shown, consistent with recent literature, that this ensemble of fields gives rise to a field-field correlation function R between two points that has

expectation $\langle R \rangle$ equal to the Green's function between those points. It is furthermore found that this model lends itself to calculations of the variance of R , and thus to estimates of the degree to which an R calculated using finite amounts of data will conform to the Green's function. The model indicates, in accord with observations, that such conformation is strongest at low frequencies. Ray arrivals are detectable only if sufficient data has been collected; the amount of data needed scales with the square of the source-receiver separation, and the square of the frequency. Applications to seismology are discussed.

1pPP1. Fear conditioning facilitates rats gap detection measured by prepulse inhibition of the startle reflex. Dan Zou, Xihong Wu, and Liang Li (Dept. of Psych., Natl. Key Lab. on Machine Percept. Speech and Hearing Res. Ctr., Peking Univ., Beijing, 100871 China)

A low-intensity acoustic event presented shortly before an intense startling sound can inhibit the acoustic startle reflex. This phenomenon is called prepulse inhibition (PPI), and is widely used as a model of sensorimotor gating in both humans and animals. Particularly, it has been used for evaluating the aging effect on the mouse's ability to detect a silent gap in otherwise continuous sounds. The present study extended this model to the emotional modulation of gap detection. The results show that a silent gap embedded in each of the two broadband noise sounds (55 dB SPL), which were delivered by two spatially separated loudspeakers, could inhibit the startle reflex that was induced by a loud sound presented from the third loudspeaker 50 ms after the gap. The inhibitory effect largely depended on the duration of the gap, with the mean duration threshold around 11 ms across 18 rats tested. Pairing the gap with foot shock in a temporally specific manner, but not in a temporally random

manner, significantly reduced the duration threshold. Thus this study established a new animal behavioral model both for studying auditory temporal processing and for studying auditory signal-detection plasticity induced by emotional learning.

1pPP2. Hearing levels in US adults aged 20–69 Years: National Health and Nutrition Examination Survey 1999–2002. William J. Murphy, Christa L. Themann, and John R. Franks (Hearing Loss Prevention Team, NIOSH, MS C-27, 4676 Columbia Pkwy., Cincinnati, OH 45226-1998)

The National Health and Nutrition Examination Survey (NHANES) is a nationally representative, population-based survey designed to assess the health and nutritional status of the civilian, non-institutionalized US population. Data were collected through a personal interview regarding health history and through physical examination. Earlier NHANES surveys were conducted on a periodic basis; however, in 1999, NHANES began collecting data on a continuing, annual basis. During NHANES I, which ran from 1971–1975, audiometric testing was conducted on adults aged 25–74

years. No subsequent testing of adults was conducted in the NHANES program until 1999, when NHANES began audiometric testing of adults aged 20–69 years. This report examines the hearing levels for adults in the United States and compares them with the hearing data from NHANES I. Hearing levels are grouped by age and are grouped by ethnicity and gender.

1pPP3. Application of musical timbre discrimination features to active sonar classification. Victor W. Young, Paul C. Hines, and Sean Pecknold (Defence R&D Canada–Atlantic, P.O. Box 1012, Dartmouth, NS, Canada B2Y 3Z7, victor.young@drdc-rddc.gc.ca)

In musical acoustics significant effort has been devoted to uncovering the physical basis of timbre perception. Most investigations into timbre rely on multidimensional scaling (MDS), in which different musical sounds are arranged as points in multidimensional space. The Euclidean distance between points corresponds to the perceptual distance between sounds and the multidimensional axes are linked to measurable properties of the sounds. MDS has identified numerous temporal and spectral features believed to be important to timbre perception. There is reason to believe that some of these features may have wider application in the disparate field of underwater acoustics, since anecdotal evidence suggests active sonar returns from metallic objects sound different than natural clutter returns when auralized by human operators. This is particularly encouraging since attempts to develop robust automatic classifiers capable of target-clutter discrimination over a wide range of operational conditions have met with limited success. Spectral features relevant to target-clutter discrimination are believed to include click-pitch and envelope irregularity; relevant temporal features are believed to include duration, sub-band attack/decay time, and time separation pitch. Preliminary results from an investigation into the role of these timbre features in target-clutter discrimination will be presented. [Work supported by NSERC and GDC.]

1pPP4. Frequency-time dispersion products revisited. William S. Hellman (Dept. of Phys. and Hear. Res. Ctr., Boston Univ., Boston, MA 02115, hellman@buphy.bu.edu) and H. Steven Colburn (Hear. Res. Ctr. and Dept. Biomed. Eng., Boston, MA 02115)

The interaction of bandwidth and duration is an important aspect of signal choice in psychophysical experiments. The traditional measures yield frequency-time dispersion products which have a lower bound of 0.25. Gabor [J. Inst. Elect. Eng. Part III **93**, 429–457 (1946)] argued that the measures for the standard deviation and mean in the frequency domain do not yield formulas in agreement with intuition when applied to the calculation of frequency dispersions for real signals $f(t)$. Gabor's prescription for correcting the problem was to limit the integrations in frequency statistic calculations to the positive frequency domain and, for consistency, use the analytic signal corresponding to $f(t)$ to calculate time dispersions. A more recent statement of this prescription can be found in L. Cohen [*Time-Frequency Analysis*, (Prentice Hall, 1995)]. However the elimination of the negative frequencies introduces difficulties which have not been fully addressed in the literature. It is shown here, that unless the Fourier transform of the signal vanishes at zero frequency, a linear divergence will appear in the time dispersion derived from the analytic signal. In such instances, $f(t)$ must be used to calculate the time dispersion. However the restriction to positive frequencies can generate frequency-time dispersion products which fall below the expected lower limit of 0.25.

1pPP5. Diotic and dichotic discrimination of binary sequences. Stanley Sheft, William A. Yost, and Raymond H. Dye (Parmlly Hearing Inst., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626, ssheft@luc.edu)

Binary-sequence discrimination was compared for diotic and dichotic stimuli. Sequences consisted of 4 to 32 wideband-noise pulses with pulse duration ranging from 8 to 32 ms. Diotic sequences were distinguished by pulse-amplitude pattern, while dichotic patterns differed by their sequence

of ear of presentation. Discrimination was measured as a function of the number of pattern elements that differed between the standard and comparison sequences with temporal location of the altered pulses randomly selected on each trial. Additional fringe pulses bracketed the target sequences to avoid onset and offset cuing. Neither diotic nor dichotic performance was monotonic with the ratio of the number of altered to sequence pulses, with greater exception noted in the dichotic results. Except at the shortest pulse duration, diotic performance was significantly better than that obtained in the dichotic condition with similar pulse duration and numbers of altered and sequence pulses. For the range of stimulus parameters used, sequence discrimination often relied on a global percept rather than processing of individual pulse attributes with timbre differences cuing diotic discrimination. Though exhibiting fine resolution, results suggest poorer ability of the binaural than monaural system at extracting a global percept to cue sequence discrimination. [Work supported by NIDCD.]

1pPP6. Spatial release from masking for amplitude modulated and non-modulated noise stimuli. Norbert Kopčo (Hearing Res. Ctr., Boston Univ. and Tech. Univ., Košice, Slovakia) and Barbara G. Shinn-Cunningham (Boston Univ.)

The ability to hear a target sound (T) masked by another sound (M) improves when the T and M are spatially separated, a phenomenon known as spatial release from masking (SRM). Target detectability is also influenced by temporal characteristics of T and M (e.g., by the presence or absence of amplitude modulation). The current study examines how SRM is influenced by amplitude modulation. Detection thresholds were measured for a broadband noise target (T) temporally and spectrally centered within a broadband noise masker (M). Thresholds were measured for all combinations of five spatial configurations of T and M and five modulation conditions (all combinations of T and M modulated and unmodulated; when both T and M were modulated, the modulation could either be equal or pi out of phase). In all cases, the amplitude modulation, if present, had a rate of 40 Hz and depth of 0.5. Modulation had a complex effect on detection threshold. Thresholds improved by as much as 6 dB (relative to the no-modulation control) in some spatial configurations, but were nearly unaffected in others. These results have important implications for understanding the processes involved in the perception of simultaneous complex signals. [Work supported by NSF and NAS.]

1pPP7. Loudness estimation in the presence of vertical vibrations. Etienne Parizet and Benjamin Marpe (LVA–Insa Lyon 25 bis, avenue Jean Capelle F-69621 Villeurbanne Cedex, France)

The goal of the study was to check whether vibrations submitted to a subject can modify his loudness evaluation. For that purpose, the subject was seated on a rigid chair vertically moved by a shaker, at the frequency of 28 Hz and at 6 different levels. He was also exposed to a pure sound: either a 28 Hz tone produced by a subwoofer, or a 1000 Hz tone produced by headphones. For each combination of sound and vibration levels, the subject had to estimate the magnitude of the loudness of the tone, as compared to a reference tone, heard without any vibration excitation. He also had to evaluate the magnitude of vibration using a 10 point scale. Twenty subjects participated in the experiment. The results showed that vibrations did not influence loudness estimation. On the other hand, the estimation of vibration level was significantly influenced by the level of the 28 Hz pure tone, which can indicate an interaction between the perception of sound by the body and the perception of vibrations.

3:35

1pPP8. Temporal and spectral interaction in loudness perception. Benjamin Pedersen and Wolfgang Ellermeier (Sound Quality Res. Unit, Dept. of Acoust., Aalborg Univ., Fredrik Bajers Vej 7 B5, DK-9220 Aalborg, Denmark)

An experiment was conducted to investigate how changes in spectral content influence loudness judgments. Six listeners were asked to discriminate sounds, which were of one second duration and changing in level every 0.1 s. In one condition the first half of the sound was low-pass filtered and the second half high-pass filtered. In a second condition the opposite order was used. In a third condition no filtering was applied and the frequency spectrum was simply white noise. The results were analyzed using a statistical method, which assigns relative weights to the ten temporal segments. In this way individual weighting curves were obtained for each condition. Listeners tended to emphasize the beginning of the sound in their loudness judgments. When the frequency spectrum changed in the middle of the sound, however, the weighting of the onset of the new spectral content was emphasized as well. This outcome is inconsistent with overall temporal integration, and argues for a cognitive mechanism allocating attention to changes in an event sequence.

3:50

1pPP9. Spectral resolvability of iterated rippled noise. William A. Yost (Parmly Hearing Inst., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626)

A forward-masking experiment was used to estimate the spectral ripple of iterated rippled noise (IRN) that is possibly resolved by the auditory system. Tonal signals were placed at spectral peaks and valleys of IRN maskers for a wide variety of IRN conditions that included different delays, number of iterations, and stimulus durations. The differences in the forward-masked thresholds of tones at spectral peaks and valleys were used to estimate spectral resolvability, and these results were compared to estimates obtained from a gamma-tone filter bank. The IRN spectrum has spectral peaks that are harmonics of the reciprocal of the delay used to generate IRN stimuli. As the number of iterations in the generation of IRN stimuli increases so does the difference in the spectral peak-to-valley ratio. For high number of iterations, long delays, and long durations evidence for spectral resolvability existed up to the 6th harmonic. For all other conditions spectral resolvability appeared to disappear at harmonics lower than the 6th, or was not measurable at all. These data will be discussed in terms of the role spectral resolvability might play in processing the pitch, pitch strength, and timbre of IRN stimuli. [Work supported by a grant from NIDCD.]

1pPP10. Searching for sources of variance in speech recognition: Young adults with normal hearing. Charles S. Watson and Gary R. Kidd (Dept. of Speech and Hearing Sci., Indiana Univ., Bloomington, IN 47405)

In the present investigation, sensory-perceptual abilities of one thousand young adults with normal hearing are being evaluated with a range of auditory, visual, and cognitive measures. Four auditory measures were derived from factor-analytic analyses of previous studies with 18–20 speech and non-speech variables [G. R. Kidd *et al.*, *J. Acoust. Soc. Am.* **108**, 2641 (2000)]. Two measures of visual acuity are obtained to determine whether variation in sensory skills tends to exist primarily within or across sensory modalities. A working memory test, grade point average, and Scholastic Aptitude Test scores (Verbal and Quantitative) are also included. Preliminary multivariate analyses support previous studies of individual differences in auditory abilities (e.g., A. M. Surprenant and C. S. Watson, *J. Acoust. Soc. Am.* **110**, 2085–2095 (2001)) which found that

spectral and temporal resolving power obtained with pure tones and more complex unfamiliar stimuli have little or no correlation with measures of speech recognition under difficult listening conditions. The current findings show that visual acuity, working memory, and intellectual measures are also very poor predictors of speech recognition ability, supporting the independence of this processing skill. Remarkable performance by some exceptional listeners will be described. [Work supported by the Office of Naval Research, Award No. N000140310644.]

4:20

1pPP11. Temporal and spectral resolution of hearing in patients with precipitous hearing loss: Gap release of masking (GRM) and the role of cognitive function. Martin D. Vestergaard^{a)} (Tech. Univ. of Denmark, Ørsted-DTU Acoust. Technol., DK-2800 Lyngby, Denmark and Res. Ctr. Eriksholm, Kongevejen 243, DK-3070 Snekkerten, Denmark)

The purpose of this experiment was to measure temporal acuity and spectral resolution of hearing in new hearing-aid users over a period of time post-fitting, and to demonstrate the extent to which performance might change over time. For one-octave wide maskers with and without spectral and temporal gaps, masking was measured repeatedly over 3 months post-fitting. GRM was characterized as the release from masking under the gap conditions. The cognitive skills of the participants were assessed with two tests for measuring working memory capacity and lexical vigilance. The results showed that while the masking by one-octave wide noise maskers without any gaps was constant over time, GRM increased over time for maskers involving a temporal gap. Moreover, at low frequencies where the subjects had normal hearing-threshold levels, they performed as hearing-impaired for the spectral-gap condition. For the temporal-gap condition, they performed as normally hearing at both low and high frequencies. These results suggest that patients with precipitous hearing loss do not maintain normal spectral resolution through the low-frequency region, in which the hearing threshold levels are otherwise normal. Surprisingly, the results also showed moderate though highly significant correlation between lexical vigilance and GRM. 1pPP12. Simulated phase-locking stimulation: An improved signal processing strategy for cochlear implant. Xihong Wu, Hongwei Qu, Jing Chen, Tianshu Qu (Nat. Key Lab. on Machine Percept. Speech and Hearing Res. Ctr., Dept. of Psych., Peking Univ., Beijing 100871, China), and Liang Li (Peking Univ., Beijing 100871, China)

Electrical stimulation of the auditory pathway produces different patterns of neural activity than those acoustically elicited. Traditional signal-processing strategies for cochlear implant usually do not utilize phase information contained in sound waves. Here, to evaluate potential advantages of introducing phase information to cochlear implant devices, a new signal processing method, so called simulated phase-locking stimulation (SPLS), was developed. To convey phase information of sound signals to the auditory nerve, electrical stimulation pulses were delivered at the zero-crossing time of sine waves of frequency bands after band-pass filtering and envelope extraction. The advantages of the SPLS method over the method of Continuous Interleaved Sampling (CIS+) were demonstrated by both objective evaluations, such as the spectro-temporal modulation index (STMI), and subjective evaluations, such as recognition of processed Chinese speech by normal hearing listeners under either noise (energetic) masking or speech (informational) masking conditions. The results suggest that the SPLS method is able to improve the function of cochlear devices by extracting and transferring fine-structure signals, which are important for cochlear-implant listeners to perceive tonal speech and music.

Session 1pSC**Speech Communication: Vowel Systems and Language Learners (Lecture/Poster Session)**

Linda Polka, Cochair

McGill Univ., School Communication Sciences and Disorders, 1266 Pine Ave., West, Montreal, QC H3G 1A8, Canada

Ocke-Schwen Bohn, Cochair

*English Dept., Aarhus Univ., Aarhus DK-8000, Denmark***Chair's Introduction—1:00*****Invited Papers*****1:05****1pSC1. Diversity of vowel systems.** Ian Maddieson (Dept of Linguist., Univ. of California, Berkeley, CA 94720)

Systems of vowels vary greatly across the world's languages while nonetheless conforming to certain general structural patterns. All languages have at least two qualitative distinctions between vowels based on the major parameters of height, backness and rounding, but probably none has more than 15 or so, and the modal number is 5. Generally these basic vowel qualities respect dispersion principles, but deviations can be considerable. When additional parameters, such as nasalization, length, phonation type and pharyngealization are included, the total number of vowel distinctions may easily exceed 40. These "additive" features never occur with a larger number of vowel qualities than those occurring in a "plain" series. Languages may differ markedly in the distributional patterns of their vowels as well as in their inventory. Some languages have different (usually reduced) vowel inventories in unstressed or other non-prominent positions; others constrain vowel sequences in (phonological) words through vowel harmony limitations. Co-occurrence patterns between vowels and consonants also vary greatly, as does the degree of coarticulation between vowels and neighboring segments. Learners must master all of these factors to speak an individual language fluently. Constraints that are universal or shared may be expected to facilitate this task.

1:30

1pSC2. Natural referent vowels guide the development of vowel perception. Linda Polka (School of Commun. Sci. and Disord., McGill Univ., Montreal, QC, Canada, linda.polka@mcgill.ca), Ocke-Schwen Bohn (Aarhus Univ., Denmark), and Monika Molnar (McGill Univ., Montreal, QC, Canada)

Certain vowels are favored across languages of the world. This selection bias has received a great deal of attention in linguistic theories seeking to explain vowel system typologies. In comparison, the role that specific vowels might play in the ontogeny of vowel perception has been more implicit. In this talk we will summarize recent findings that elucidate the functional significance of peripheral vowels in the development of vowel perception. Data from cross-language studies of infant vowel discrimination and vowel preference will be presented. This work shows that peripheral vowels have a perceptual priority for young infants and that this bias is independent of the phonemic status of the vowels presented in the perceptual task. Findings from cross-language experiments with adults reveal that language experience builds on the natural vowel biases observed in infancy. Adult data suggest that the natural bias remains in place in mature listeners unless the perceiver needs to override the bias to optimize perception of functional vowel differences. These findings support our proposal of a Natural Reference Vowel hypothesis as a framework for understanding the development of vowel perception and production. Specific avenues of research needed to elaborate this framework will be outlined. [Work supported by NSERC.]

1:55

1pSC3. Production-perception relationships during speech development. Lucie Menard (UQAM, Departement de linguistique, CP 8888, succ. Ctr.-Ville, Montreal, Canada H3C 3P8, menard.lucie@uqam.ca), Jean-Luc Schwartz, Louis-Jean Boe (Universite Stendhal, 38031 Grenoble Cedex 1, France), and Jerome Aubin (UQAM, CP 8888, succ. Ctr.-Ville, Montreal, Canada H3C 3P8)

It has been shown that nonuniform growth of the supraglottal cavities, motor control development, and perceptual refinement shape the vowel systems during speech development. In this talk, we propose to investigate the role of perceptual constraints as a guide to the speakers task from birth to adulthood. Simulations with an articulatory-to-acoustic model, acoustic analyses of natural vowels, and results of perceptual tests provide evidence that the production-perception relationships evolve with age. At the perceptual level, results show that (i) linear combination of spectral peaks are good predictors of vowel targets, and (ii) focalization, defined as an acoustic pattern with close neighboring formants [J.-L. Schwartz, L.-J. Boe, N. Vallee, and C. Abry, *J. Phonetics* **25**, 255–286 (1997)], is part of the speech task. At the production level, we propose that (i) frequently produced vowels in the baby's early sound inventory can in part be explained by perceptual templates, (ii) the achievement of these perceptual templates may require adaptive articulatory strategies for the child, compared with the adults, to cope with morphological differences. Results are discussed in the light of a perception for action control theory. [Work supported by the Social Sciences and Humanities Research Council of Canada.]

1pSC4. The influence of different native language systems on vowel discrimination and identification. Diane Kewley-Port (Dept. Speech and Hearing Sci., Indiana Univ., Bloomington, IN 47405, kewley@indiana.edu), Ocke-Schwen Bohn (Aarhus Univ., Denmark), and Kanae Nishi (Indiana Univ., Bloomington, IN 47405)

The ability to identify the vowel sounds of a language reliably is dependent on the ability to discriminate between vowels at a more sensory level. This study examined how the complexity of the vowel systems of three native languages (L1) influenced listeners perception of American English (AE) vowels. AE has a fairly complex vowel system with 11 monophthongs. In contrast, Japanese has only 5 spectrally different vowels, while Swedish has 9 and Danish has 12. Six listeners, with exposure of less than 4 months in English speaking environments, participated from each L1. Their performance in two tasks was compared to 6 AE listeners. As expected, there were large differences in a linguistic identification task using 4 confusable AE low vowels. Japanese listeners performed quite poorly compared to listeners with more complex L1 vowel systems. Thresholds for formant discrimination for the 3 groups were very similar to those of native AE listeners. Thus it appears that sensory abilities for discriminating vowels are only slightly affected by native vowel systems, and that vowel confusions occur at a more central, linguistic level. [Work supported by funding from NIHDCD-02229 and the American-Scandinavian Foundation.]

1pSC5. Cross-language comparisons of contextual variation in the production and perception of vowels. Winifred Strange (Ph.D. Program in Speech and Hearing Sci., CUNY-Grad. Ctr., 365 Fifth Ave., New York, NY 10016-4309, strangepin@aol.com)

In the last two decades, a considerable amount of research has investigated second-language (L2) learners problems with perception and production of non-native vowels. Most studies have been conducted using stimuli in which the vowels are produced and presented in simple, citation-form (lists) monosyllabic or disyllabic utterances. In my laboratory, we have investigated the spectral (static/dynamic formant patterns) and temporal (syllable duration) variation in vowel productions as a function of speech-style (list/sentence utterances), speaking rate (normal/rapid), sentence focus (narrow focus/post-focus) and phonetic context (voicing/place of surrounding consonants). Data will be presented for a set of languages that include large and small vowel inventories, stress-, syllable-, and mora-timed prosody, and that vary in the phonological/phonetic function of vowel length, diphthongization, and palatalization. Results show language-specific patterns of contextual variation that affect the cross-language acoustic similarity of vowels. Research on cross-language patterns of perceived phonetic similarity by naive listeners suggests that listener's knowledge of native language (L1) patterns of contextual variation influences their L1/L2 similarity judgments and subsequently, their discrimination of L2 contrasts. Implications of these findings for assessing L2 learners perception of vowels and for developing laboratory training procedures to improve L2 vowel perception will be discussed. [Work supported by NIDCD.]

Contributed Papers

All posters will be on display and all authors will be at their posters from 3:20 p.m. to 4:30 p.m.

1pSC6. Perceptual assimilation and categorial discrimination of American vowels by Japanese listeners. Miwako Hisagi, Winifred Strange (Dept. of Speech and Hearing Sci., CUNY-Grad.-Ctr., 365 Fifth Ave., New York, NY 10016, mhisagi@hotmail.com), Reiko Akahane-Yamada, and Rieko Kubo (Adv. Telecommunications Res. Inst. Intl., 2-2-2 Hikaridai, Seika-cho, Soraku-gun, Kyoto 619-0288, Japan)

Best's Perception Assimilation Model predicts that relative difficulty discriminating non-native (L2) contrasts is predictable from perceived similarity of L2 segments and native (L1) segments. Japanese listeners performed a categorial discrimination task in which 9 vowel pairs (6 adjacent height pairs, 3 front-back pairs) involving 6 tokens (2 speakers/3 repetitions) of each of 8 American vowels /i, i, e, æ, a, ʌ, u, u/ were tested in the context of hVba disyllables. In a second task, listeners were asked to categorize all stimuli with respect to which Japanese vowel they were most similar, and to rate their goodness on a 9-point Likert scale. Overall error rates on height pairs ranged from 1 percent to 29 percent, and on front/back pairs, from 1 percent to 18 percent. The most difficult height contrasts were /u-u/ and /a-ʌ/; perceptual assimilation patterns showed that these pairs were assimilated to the same Japanese vowels (Single Category or Category Goodness pattern) although /a-ʌ/ were assimilated to 2-mora versus 1-mora Japanese /a/, respectively. The most difficult front/back contrast was /æ-a/. Surprisingly, American /i-i/ was discriminated very well and were assimilated to different Japanese vowels /i, e/, respectively. In general, perceptual assimilation patterns predicted discrimination accuracy quite well. [Work supported by NIDCD.]

1pSC7. A signal detection theory-based analysis of American English vowel identification and production performance by native speakers of Japanese. Stephen Lambacher (Ctr. for Lang. Res., Univ. of Aizu, Aizu-Wakamatsu, Fukushima-ken, Japan 965-8580, steeve@u-aizu.ac.jp), William Martens (McGill Univ., Montreal, QC, Canada H3A 1E3), and Kazuhiko Kakehi (Chukyo Univ., Kaizu-cho, Toyota, 470-0393, Japan)

The identification and production performance by two groups of native Japanese of the American English (AE) vowels /æ/, /a/, /ʌ/, /ɔ/, /ɜ/ was measured before and after a six-week, identification training program. A signal detection theory (SDT) analysis of the confusion data, as measured by d' , revealed that all five AE vowels were more identifiable by the experimental trained group than the control untrained group. The d' results showed that /ʌ/ was less identifiable than /ɔ/ in the pretest, even though the percentage identification rate for /ʌ/ was slightly greater than that for /ɔ/. Both groups productions of a list of CVCs, each containing one of the target AE vowels, were presented to a group of native AE listeners in a series of identification tasks. The d' results revealed that the AE listeners could more sensitively identify the experimental groups post-test vowel productions than they could the control groups. SDT analysis also clarified an additional potentially confusing result: /ʌ/ was somewhat less identifiable than /ɜ/, despite the fact that the percentage identification rate for /ʌ/ was higher. Overall, the SDT-based analysis served to change the pattern of results observed for L2 vowel identification and influenced the interpretation of the data.

1pSC8. Training Japanese L2 learners to perceive difficult American vowel contrasts. Mieko Sperbeck (Dept. of Linguist., City Univ. of New York–Grad. School and Univ. Ctr., 365 Fifth Ave., New York, NY 10016-4309), Winifred Strange, and Kikuyo Ito (City Univ. of New York–Grad. School and Univ. Ctr., New York, NY 10016-4309)

This study compared two methods to improve perception of three vowels ae, ah, uh and examined generalization of training to new vowels eh, awe and to trained vowels by new speakers in new consonantal contexts and in real words. One training protocol began with hVba disyllables (sessions 1–4) and then introduced sentence-length utterances with vowels in gabVpa/gadVda trisyllables (sessions 5–9). The other protocol used sentence materials in all 9 sessions. Twenty-four participants were divided into the two training conditions; half of each group were relatively inexperienced while the others were more experienced. Identification pretests on the 5 vowels in sentence materials showed no differences in overall accuracy for inexperienced (51% correct) and experienced groups (54% correct). Post-tests showed that perception of trained vowels improved in both trained and non-trained trisyllable/sentence materials (65% correct for both training groups). There were no significant differences in amount of improvement for inexperienced and experienced participants. Training also led to improvement on trained vowels by new speakers in new contexts and to real words. However, performance on non-trained vowels did not improve (actually decreased for eh) suggesting a response bias in post-test identification performance. [Work Supported by NIH.]

1pSC9. Within- and across-language spectral and temporal variability of vowels in different phonetic and prosodic contexts: Russian and Japanese. Yana D. Gilichinskaya, Miwako Hisagi, Françoise F. Law II, Shari Berkowitz, and Kikuyo Ito (CUNY–Grad. Ctr., Dept. of Speech and Hearing Sci., 365 Fifth Ave., New York, NY 10016)

Contextual variability of vowels in three languages with large vowel inventories was examined previously. Here, variability of vowels in two languages with small inventories (Russian, Japanese) was explored. Vowels were produced by three female speakers of each language in four contexts: (Vba) disyllables and in 3-syllable nonsense words (gaC1VC2a) embedded within carrier sentences; contexts included bilabial stops (bVp) in normal rate sentences and alveolar stops (dVt) in both normal and rapid rate sentences. Dependent variables were syllable durations and formant frequencies at syllable midpoint. Results showed very little variation across consonant and rate conditions in formants for /i/ in both languages. Japanese short /u, o, a/ showed fronting ($F2$ increases) in alveolar context relative to labial context (1.3-2.0 Barks), which was more pronounced in rapid sentences. Fronting of Japanese long vowels was less pronounced (0.3 to 0.9 Barks). Japanese long/short vowel ratios varied with speaking style (syllables versus sentences) and speaking rate. All Russian vowels except /i/ were fronted in alveolar vs labial context (1.1-3.1 Barks) but showed little change in either spectrum or duration with speaking rate. Comparisons of these patterns of variability with American English, French and German vowel results will be discussed.

1pSC10. Reading skills and the discrimination of English vowel contrasts by bilingual Spanish/English-speaking children: Is there a correlation? Sandra Levey (Dept. of Speech-Lang.-Hearing Sci., Lehman College of the City Univ. of New York, 250 Bedford Park Blvd. W., Bronx, NY 10468)

This study examined the discrimination of English vowel contrasts in real and novel word-pairs by 21 children: 11 bilingual Spanish/English- and 10 monolingual English-speaking children, 8–12 years of age ($M = 10; 6$; $Mdn = 10; 4$). The goal was to determine if children with poor reading skills had difficulty with discrimination, an essential factor in reading abilities. A categorical discrimination task was used in an ABX discrimination paradigm: A (the first word in the sequence) and B (the second word in the sequence) were different stimuli, and X (the third word in the sequence) was identical to either A or to B. Stimuli were produced

by one of three different speakers. Seventy-two monosyllabic words were presented: 36 real English and 36 novel words. Vowels were those absent from the inventory of Spanish vowels. Discrimination accuracy for the English-speaking children with good reading skills was significantly greater than for the bilingual-speaking children with good or poor reading skills. Early age of acquisition and greater percentage of time devoted to communication in English played the greatest role in bilingual children's discrimination and reading skills. The adjacency of vowels in the $F1$ - $F2$ acoustic space presented the greatest difficulty.

1pSC11. English vowel learning by speakers of Mandarin. Ron I. Thomson (Dept. of Linguist., Univ. of Alberta, 4th Fl. Assiniboia Hall, Edmonton, AB, Canada T6G 2G5, rit@ualberta.ca)

One of the most influential models of second language (L2) speech perception and production [Flege, *Speech Perception and Linguistic Experience* (York, Baltimore, 1995) pp. 233–277] argues that during initial stages of L2 acquisition, perceptual categories sharing the same or nearly the same acoustic space as first language (L1) categories will be processed as members of that L1 category. Previous research has generally been limited to testing these claims on binary L2 contrasts, rather than larger portions of the perceptual space. This study examines the development of 10 English vowel categories by 20 Mandarin L1 learners of English. Imitation of English vowel stimuli by these learners, at 6 data collection points over the course of one year, were recorded. Using a statistical pattern recognition model, these productions were then assessed against native speaker norms. The degree to which the learners' perception/production shifted toward the target English vowels and the degree to which they matched L1 categories in ways predicted by theoretical models are discussed. The results of this experiment suggest that previous claims about perceptual assimilation of L2 categories to L1 categories may be too strong.

1pSC12. Vowel space development in a child acquiring English and Spanish from birth. Jean Andruski, Sahyang Kim (ASLP, Wayne State Univ., 581 Manoogian Hall, 906 W. Warren, Detroit, MI 48202), Geoffrey Nathan (Wayne State Univ., Detroit, MI 48202), Eugenia Casielles, and Richard Work (Wayne State Univ., Detroit, MI 48202)

To date, research on bilingual first language acquisition has tended to focus on the development of higher levels of language, with relatively few analyses of the acoustic characteristics of bilingual infants' and children's speech. Since monolingual infants begin to show perceptual divisions of vowel space that resemble adult native speakers' divisions by about 6 months of age [Kuhl *et al.*, *Science* **255**, 606–608 (1992)], bilingual children's vowel production may provide evidence of their awareness of language differences relatively early during language development. This paper will examine the development of vowel categories in a child whose mother is a native speaker of Castilian Spanish, and whose father is a native speaker of American English. Each parent speaks to the child only in her/his native language. For this study, recordings made at the ages of 2;5 and 2;10 were analyzed and $F1$ – $F2$ measurements were made of vowels from the stressed syllables of content words. The development of vowel space is compared across ages within each language, and across languages at each age. In addition, the child's productions are compared with the mother's and father's vocalic productions, which provide the predominant input in Spanish and English respectively.

1pSC13. Acoustic properties of vowels in clear and conversational speech by female non-native English speakers. Chi-Nin Li and Connie K. So (Dept. of Linguist., Simon Fraser Univ., Burnaby, BC, Canada V5A 1S6)

Studies have shown that talkers can improve the intelligibility of their speech when instructed to speak as if talking to a hearing-impaired person. The improvement of speech intelligibility is associated with specific

acoustic-phonetic changes: increases in vowel duration and fundamental frequency (F_0), a wider pitch range, and a shift in formant frequencies for F_1 and F_2 . Most previous studies of clear speech production have been conducted with native speakers; research with second language speakers is much less common. The present study examined the acoustic properties of non-native English vowels produced in a clear speaking style. Five female Cantonese speakers and a comparison group of English speakers were recorded producing four vowels (*i u ae a*) in /bVt/ context in conversational and clear speech. Vowel durations, F_0 , pitch range, and the first two formants for each of the four vowels were measured. Analyses revealed that for both groups of speakers, vowel durations, F_0 , pitch range, and F_1 spoken clearly were greater than those produced conversationally. However, F_2 was higher in conversational speech than in clear speech. The findings suggest that female non-native English speakers exhibit acoustic-phonetic patterns similar to those of native speakers when asked to produce English vowels clearly.

1pSC14. Greek perception and production of an English vowel contrast: A preliminary study. Václav J. Podlipský (Dept. of English and American Studies, Palacky Univ., Krizkovskeho 10, Olomouc, 77180, Czech Republic, vaclavjonaspodlipsky@centrum.cz)

This study focused on language-independent principles functioning in acquisition of second language (L2) contrasts. Specifically, it tested Bohn's Desensitization Hypothesis [in *Speech perception and linguistic experience: Issues in Cross Language Research*, edited by W. Strange (York Press, Baltimore, 1995)] which predicted that Greek speakers of English as an L2 would base their perceptual identification of English /i/ and /I/ on durational differences. Synthetic vowels differing orthogonally in duration and spectrum between the /i/ and /I/ endpoints served as stimuli for a forced-choice identification test. To assess L2 proficiency and to evaluate the possibility of cross-language category assimilation, productions of English /i/, /I/, and /e/ and of Greek /i/ and /e/ were elicited and analyzed acoustically. The L2 utterances were also rated for the degree of foreign accent. Two native speakers of Modern Greek with low and 2 with intermediate experience in English participated. Six native English (NE) listeners and 6 NE speakers tested in an earlier study constituted the control groups. Heterogeneous perceptual behavior was observed for the L2 subjects. It is concluded that until acquisition in completely naturalistic settings is tested, possible interference of formally induced meta-linguistic differentiation between a "short" and a "long" vowel cannot be eliminated.

1pSC15. Diphthongs in the repopulated vowel space. Anna Bogacka (Adam Mickiewicz Univ., Poznan, Poland and Bielefeld Univ., Germany, abogacka@ifa.amu.edu.pl)

The study examined 8 British English diphthongs produced by Polish learners of English, testing the diphthongs' quality, duration, nasalization, and occurrence of glottal stops before the diphthongs. There were twelve conditions in which the diphthongs were tested: word-initial, word-final, before a voiced obstruent, before a voiceless obstruent, before a nasal consonant, and before a nasal consonant followed by a fricative, and each of these conditions was tested in a stressed and unstressed position. The diphthongs were tested in real words, embedded in sentences, controlled for the stress position, rhythmic units, and length. The sentences were read by 8 female and 8 male Polish learners of English and control subjects. The aim of the phonetic analysis done with Praat, and employing the methodologies used by Flege (1995) for SLA and Peeters (1991) and Jacewicz, Fujimara, and Fox (2003) for diphthongs, is to examine the shape of the restructured vowel space (Liljencrants and Lindblom 1972; Stevens 1989). The approach taken here is termed Vowel Space Repopulation to emphasize that the vowel space of Polish speakers of English is re-structured by new categories in complex ways which are not adequately captured by traditional notions such as "transfer," "interference," or "interlanguage."

1pSC16. Training Japanese listeners to identify American English vowels. Kanae Nishi and Diane Kewley-Port (Dept. of Speech and Hearing Sci., Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405)

Perception training of phonemes by second language (L2) learners has been studied primarily using consonant contrasts, where the number of contrasting sounds rarely exceeds five. In order to investigate the effects of stimulus sets, this training study used two conditions: 9 American English vowels covering the entire vowel space (9V), and 3 difficult vowels for problem-focused training (3V). Native speakers of Japanese were trained for nine days. To assess changes in performance due to training, a battery of perception and production tests were given pre- and post-training, as well as 3 months following training. The 9V trainees improved vowel perception on all vowels after training, on average by 23%. Their performance at the 3-month test was slightly worse than the posttest, but still better than the pretest. Transfer of training effect to stimuli spoken by new speakers was observed. Strong response bias observed in the pretest disappeared after the training. The preliminary results of the 3V trainees showed substantial improvement only on the trained vowels. The implications of this research for improved training of L2 learners to understand speech will be discussed. [Work supported by NIH-NIDCD DC-006313 & DC-02229.]

1pSC17. The development of vowel spaces in English- and Korean-learning infants' speech. Soyoung Lee (Univ. of Wisconsin at Milwaukee, P.O. Box 413, Milwaukee, WI 53201)

A previous study (Yang, 1996) revealed that the vowel spaces of adult speech differ between English and Korean. This study longitudinally investigated whether vowel spaces of English- and Korean-learning infants' speech demonstrated similar patterns to their ambient languages. Speech samples of English- and Korean-learning infants were collected at 12 and 24 months and transcribed by either native English- or Korean-speakers, respectively. First and second formants of each vowel were measured using LPC, spectral peak value, and spectrographic formant mid points. The vowel spaces between the two groups displayed similar patterns at 12 months although the frequency of occurrence of each vowel differed (e.g., [i] occurs more frequently in English than in Korean). However, the vowel spaces showed different patterns at 24 months. F_2 values for front vowels [i, e] were higher in English-learning infants' speech than those in Korean. [a] in Korean was located at a central position of vowel space while it was located at a back position in English. These patterns were similar to the adult vowel space of Korean and English. This study suggests that infants form vowel space similar to their own languages at around 24 months.

1pSC18. Spanish listeners' perceptual patterns for English /i/ and /I/. Geoffrey Stewart Morrison (Dept. of Linguist., Univ. of Alberta, Edmonton, AB, Canada, T6G 2E7, gsm2@ualberta.ca)

Spanish has five monophthongs which differ only in spectral properties. General Canadian English has ten monophthongs which differ in steady-state spectral properties and duration, and many nominal monophthongs have substantial diphthongization. Unlike Spanish, Canadian English also uses duration as a cue to postvocalic obstruent voicing. The present study investigates L1-English and L1-Spanish L2-English listeners perception of a Canadian English /bit, bit, bid, bid/ continuum varying in steady-state spectral values and duration. Several patterns emerge in the L1-Spanish listeners data, including a contrary pattern in which duration is used in the same direction as L1-English listeners but spectral properties in the opposite direction. With respect to /i/ and /I/ perception, these patterns are generally consistent with the stages of learning proposed by Escudero [Unpublished Masters Thesis, Edinburgh University, 2000]: L1-Spanish listeners cannot initially perceive the difference, next they use duration properties, later they begin to use spectral properties, and finally they have L1-English-like primary use of spectral properties and secondary use of duration. Production data adds additional insight into the relationship of the perceptual patterns to the stages of learning.

1pSC19. The acquisition of Taiwan Mandarin vowels by native American English speakers. Cyun-jhan Lin (NCTU Dept. of Foreign Lang. and Lit., Ta-Hsueh Rd. 1001, Hsinchu 300, Taiwan, moyal1980.fg92g@nctu.edu.tw)

Previous work on the production of English and French phones by native American English speakers indicated that equivalence classification prevent L2 learners from approximating L2 phonetic norms of similar phones and that learning French would not affect English speakers' production of L1 similar phone /u/ (Flege, 1987). In this study, there were five subjects, including 2 advanced native American English learners of Taiwan Mandarin, 2 basic native American English learners of Taiwan Mandarin, and 1 monolingual Taiwan Mandarin speaker. The corpus were 12 English words "heed, who'd, hod; leak, Luke, lock; beat, suit, bot; peat, suit, pot," and 12 Mandarin words [i, u, a; li, lu, la; pi, pu, pa; phi, phu, pha]. Both advanced and basic learners' production of English and Mandarin words and monolingual Taiwan Mandarin speaker's production of Mandarin words were directly recorded onto a PC. Vowel formants were taken from spectrograms generated by Praat. Preliminary results showed the vowel space of advanced learners between Taiwan Mandarin [i] and [u] was larger than that of basic learners, and closer to the Taiwan Mandarin norms. Besides, the vowel space between English [i] and [u] by basic learners was dramatically smaller than that of American English norms.

1pSC20. Evolution of the speech intelligibility of prelinguistically deaf children who received a cochlear implant. Marie-Eve Bouchard, Henri Cohen (Cognit. Neurosci. Ctr., Univ. of Quebec at Montreal, Montreal, QC, Canada, H3C 3P8), and Marie-Therese LeNormand (Robert Debre Hospital, Paris, France)

The 2 main objectives of this investigation are (1) to assess the evolution of the speech intelligibility of 12 prelinguistically deaf children implanted between 25 and 78 months of age and (2) to clarify the influence of the age at implantation on the intelligibility. Speech productions videorecorded at 6, 18 and 36 months following surgery during a standardized free play session. Selected syllables were then presented to 40 adults listeners who were asked to identify the vowels or the consonants they heard and to judge the quality of the segments. Perceived vowels were then located in the vocalic space whereas consonants were classified according to voicing, manner and place of articulation. 3 (Groups) \times 3 (Times) ANOVA with repeated measures revealed a clear influence of time as well as age at implantation on the acquisition patterns. Speech intelligibility of these implanted children tended to improve as their experience with the device increased. Based on these results, it is proposed that sensory restoration following cochlear implant served as a probe to develop articulatory strategies allowing them to reach the intended acoustico-perceptual target.

1pSC21. A comparison of vowel formant frequencies in the babbling of infants exposed to Canadian English and Canadian French. Karen Mattock, Susan Rvachew, Linda Polka, and Sara Turner (School of Commun. Sci. & Disord., McGill Univ., 1266 Pine Ave. West, Montreal, QC, H3G 1A8 Canada, karen.mattock@mail.mcgill.ca)

It is well established that normally developing infants typically enter the canonical babbling stage of production between 6 and 8 months of age. However, whether the linguistic environment affects babbling, either in terms of the phonetic inventory of vowels produced by infants [Oller & Eiler (1982)] or the acoustics of vowel formants [Boysson-Bardies *et al.*

(1989)] is controversial. The spontaneous speech of 42 Canadian English- and Canadian French-learning infants aged 8 to 11, 12 to 15 and 16 to 18 months of age was recorded and digitized to yield a total of 1253 vowels that were spectrally analyzed and statistically compared for differences in first and second formant frequencies. Language-specific influences on vowel acoustics were hypothesized. Preliminary results reveal changes in formant frequencies as a function of age and language background. There is evidence of decreases over age in the $F1$ values of French but not English infants vowels, and decreases over age in the $F2$ values of English but not French infants vowels. The notion of an age-related shift in infants attention to language-specific acoustic features and the implications of this for early vocal development as well as for the production of Canadian English and Canadian French vowels will be discussed.

1pSC22. Perception of vowels by learners of Spanish and English. Mariche Garcia-Bayonas (Univ. of North Carolina-Greensboro, 321 McIver Bldg., UNCG, Greensboro, NC 27402-5001, megarcia@uncg.edu)

This study investigates the perception of English vowels /i I/, /u U/, and /e E/ and Spanish /i u e/ by native-speakers (NS) and learners (L) and compares these two sets of vowels cross-linguistically. Research on the acquisition of vowels indicates that learners can improve their perception with exposure to the second language [Bohn and Flege (1990)]. Johnson, Flemming, and Wright (1993) investigated the hyperspace effect and how listeners tended to choose extreme vowel qualities in a method of adjustment (MOA) task. The theoretical framework of this study is Fleges (1995) Speech Learning Model. The research question is: Are vowels selected differently by NS and L using synthesized data? Spanish learners ($n=54$) and English learners ($n=17$) completed MOA tasks in which they were exposed to 330 synthetically produced vowels to analyze spectral differences in the acquisition of both sound systems, and how the learners vowel system may vary from that of the NS. In the MOA tasks they were asked to select which synthesized vowel sounds resembled the most the ones whose spelling was presented to them. The results include an overview of the vowel formant analysis performed, and which vowels are the most challenging ones to learners.

1pSC23. Perception of steady-state vowels and vowelless syllables by adults and children. Susan Nittrouer (Ctr. for Persons with Disabilities, Utah State Univ., 6840 Old Main Hill, Logan, UT 84322)

Vowels can be produced as long, isolated, and steady-state, but that is not how they are found in natural speech. Instead natural speech consists of almost continuously changing (i.e., dynamic) acoustic forms from which mature listeners recover underlying phonetic form. Some theories suggest that children need steady-state information to recognize vowels (and so learn vowel systems), even though that information is sparse in natural speech. The current study examined whether young children can recover vowel targets from dynamic forms, or whether they need steady-state information. Vowel recognition was measured for adults and children (3, 5, and 7 years) for natural productions of /dæd/, /dud/ /æ/, /u/ edited to make six stimulus sets: three dynamic (whole syllables; syllables with middle 50-percent replaced by cough; syllables with all but the first and last three pitch periods replaced by cough), and three steady-state (natural, isolated vowels; reiterated pitch periods from those vowels; reiterated pitch periods from the syllables). Adults scored nearly perfectly on all but first/last three pitch period stimuli. Children performed nearly perfectly only when the entire syllable was heard, and performed similarly (near 80%) for all other stimuli. Consequently, children need dynamic forms to perceive vowels; steady-state forms are not preferred.

1eID1. Automatic speech recognition. Carol Espy-Wilson (Univ. of Maryland, Elect. & Comp. Eng. Dept., A. V. Williams Bldg., College Park, MD 20742)

Great strides have been made in the development of automatic speech recognition (ASR) technology over the past thirty years. Most of this effort has been centered around the extension and improvement of Hidden Markov Model (HMM) approaches to ASR. Current commercially-available and industry systems based on HMMs can perform well for certain situational tasks that restrict variability such as phone dialing or limited voice commands. However, the holy grail of ASR systems is performance comparable to humans—in other words, the ability to automatically transcribe unrestricted conversational speech spoken by an infinite number of speakers under varying acoustic environments. This goal is far from being reached. Key to the success of ASR is effective modeling of variability in the speech signal. This tutorial will review the basics of ASR and the various ways in which our current knowledge of speech production, speech perception and prosody can be exploited to improve robustness at every level of the system.

2aAA1. Survey of conditions in New Zealand primary school classrooms and research on mechanisms influencing speech perception for children. George Dodd (School of Architecture, Univ. of Auckland, Private Bag 92019, Auckland, New Zealand, g.dodd@auckland.ac.nz)

A survey of 122 classrooms in New Zealand supports the need for low reverberation time and low background noise if classrooms are to be satisfactory. The RT of “poor” and “good” classrooms was found to be 0.6 s and 0.4 s respectively. Six “poor” classrooms were modified to reduce their RT to 0.4 s which changed them to “good” as judged by the users. The need for this low RT may result from children having a small integration time. A novel technique of reversed-segmented speech has verified that this is significantly smaller for children compared with adults. Activity noise in classrooms exhibits the cafe effect—a rising noise level as children compete to be heard—and we suggest this is caused by the Lombard effect. Values of the Lombard effect that we measured in a cohort of primary school children predict classroom levels similar to those observed. Present theory does not predict that reducing the RT from 0.6 to 0.4 s should significantly influence the cafe effect. Further work is planned to refine the theory and to identify if there are mechanisms not accounted for.

8:35

2aAA2. Auralization studies to develop a classroom questionnaire. Christian Nocke, Catja Hilge (Akustikbuero Oldenburg, Alte Raad 20a, D-26127 Oldenburg, Germany, info@akustikbuero-oldenburg.de), and Markus Meis (Hoerzentrum Oldenburg GmbH, D-26129 Oldenburg, Germany)

Modern, computer-based room acoustic modeling software allows apart from the calculation and visualization of sound fields also the auralization of room acoustic conditions. By these means the listening conditions in (virtual) class rooms can easily be modeled and modified. Furthermore, for each listening position a full set of room acoustical parameters is available. Corresponding measurements in real class rooms would require much effort; well-defined changes could only be reached by interior works in the building. So, computer modeling offers a larger variety of well-defined acoustic conditions. This contribution reports on the auralizations carried out for the development of a questionnaire for subjective evaluations in real class rooms. For this purpose six different virtual class rooms have been modeled. In each of the six situations auralizations at two different listening positions for male and female speakers have been deduced. The auralizations have been presented to 80 test persons. The objective room acoustic parameters have been correlated with the subjective judgements. The questionnaire has been used by Meis *et al.* in real life experiments on the subjective evaluation of listening conditions. Results of these experiments will be presented in another contribution to this session by M. Meis (2pAAa1).

8:55

2aAA3. Subjective and objective assessments in classrooms following acoustical renovation. Arianna Astolfi (Dept. of Energy Technologies, Politecnico di Torino, Corso Duca degli Abruzzi, 24, 10129, Torino, Italy)

The effectiveness of an expensive acoustical intervention in an old Italian high school building has been assessed in this work. The school building has fifty classrooms, the majority of which were acoustically renovated. A subjective survey and measurements were performed in both the renovated and non renovated classrooms. With the competence of some psychologists from Turin University, a questionnaire was set up for the subjective analysis. The questionnaire, validated after numerous pilot tests, was submitted to all the students and the teachers in two periods of the year. The questions on acoustical features included questions on annoyance from room noise, reverberation, speech comprehension, overall acoustical satisfaction and the consequences of bad acoustical conditions. Apart from the acoustics, other aspects of environmental quality, such as the thermal and visual environmental features and IAQ were investigated. The statistical analysis of the subjective answers allowed aggregated information to be obtained on the users and different data to be correlated. The aim of the statistical correlation was to determine any significant relationships between the objective and subjective data, and between the overall satisfaction scores and the different environmental factors. The effects of bad environmental conditions and their influence on learning capacity were also examined.

9:15

2aAA4. Questionnaire study of perceived listening quality in renovated university classrooms. Murray Hodgson and Hugh Davies (UBC School of Occ. & Env. Hygiene, 3rd Fl., 2206 East Mall, Vancouver, BC, Canada V6T 1Z3)

The research reported here investigated the effect of renovations on student perception of the listening environment in university classrooms. It involved four large classrooms at the University of British Columbia which were studied before and after acoustical renovation. Details of the renovations were identified. Measurements of reverberation time, background-noise level and sound propagation were made in each case. Room-average Speech Transmission Indices were calculated as a physically-based summary quality measure, and their changes on renovation were determined. Questionnaires designed to determine student and instructor perception of the listening environment, as well as the personal, academic and environmental factors that might affect it, were administered to a large number of students taking classes in each classroom, and their instructors, before and after renovation. A summary Perceived Listening Ease (PLE) score, measuring student perception of the quality of the listening environment, was calculated for each questionnaire from the responses. Room-average PLE scores, and the changes on renovation, were then calculated. These results were related to the physical measurement results. Physical, personal, academic and environmental factors affecting the changes in PLE score were investigated. The implications of the results for classroom design were considered.

9:35

2aAA5. Acoustical conditions for speech communication in active elementary school classrooms. Hiroshi Sato (Inst. for Human Sci. & Biomed. Eng., Natl. Inst. of Adv. Industrial Sci. and Technol., 1-1-1 Higashi, Tsukuba, Japan) and John Bradley (Inst. for Res. in Construction Natl. Res. Council, Ottawa, Canada K1A 0R6)

Detailed acoustical measurements were made in 34 active elementary school classrooms with typical rectangular room shape in schools near Ottawa, Canada. There was an average of 21 students in classrooms. The measurements were made to obtain accurate indications of the acoustical quality of conditions for speech communication during actual teaching activities. Mean speech and noise levels were determined from the distribution of recorded sound levels and the average speech-to-noise ratio was 11 dBA. Measured mid-frequency reverberation times (RT) during the same occupied conditions varied from 0.3 to 0.6 s, and were a little less than for the unoccupied rooms. RT values were not related to noise levels. Octave band speech and noise levels, useful-to-detrimental ratios, and Speech Transmission Index values were also determined. Key results included: (1) The average vocal effort of teachers corresponded to louder than Pearsons Raised voice level; (2) teachers increase their voice level to overcome ambient noise; (3) effective speech levels can be enhanced by up to 5 dB by early reflection energy; and (4) student activity is seen to be the dominant noise source, increasing average noise levels by up to 10 dBA during teaching activities. [Work supported by CLLRnet.]

2aAA6. Investigation of noise issues at U-Hill Elementary School. Natalie York and Murray Hodgson (UBC Acoust. and Noise Res. Group, SOEH, 3rd Fl., 2206 East Mall, Vancouver, BC, Canada V6T 1Z3, nlyork@interchange.ubc.ca)

University Hill Elementary School (U-Hill) has a reputation amongst its teachers, staff and parents as being a noisy school. The present work is an assessment of the acoustical environment at U-Hill with a focus on evaluating how various noise sources contribute to the total noise levels measured in four classrooms. A questionnaire was completed by several of U-Hill's teachers to determine their reactions to the school's acoustical environments and what they perceived to be the prevalent noise sources. Standard physical measurements of classroom background noise and reverberation time were made and compared to existing acceptability criteria. Measurements of sound propagation and transmission were made to determine how noise propagates in the hallway, as well as into and between adjacent learning spaces, and the effect of open doors and door grates. Dosimeters were used to monitor sound levels at various hallway source locations and received in the four classrooms studied. Octave-band measurements of typical noise-source levels, such as children walking in the hallways and entering through school doors were made. The measurement data was used to estimate the contributions to total noise levels in the four classrooms of the various noise sources inside and outside the classrooms.

2aAA7. Acoustical conditions of typical classrooms in Hong Kong. Kai Ming Li and Coriolanus C. L. Lam (Dept. of Mech. Eng., The Hong Kong Polytechnic Univ., Hung Hom, Hong Kong)

This paper presents measurement results of the acoustical environments of local schools in Hong Kong. In the measurements, several acoustical aspects that affect verbal communication in classrooms have been studied. These conditions include outdoor and indoor ambient noise levels, signal-to-noise ratios, reverberation time and the speech transmission index. Typical classrooms in many different schools and other higher-education institutions have been selected in the present study. Experimental results are compared with such national standards as USA (ANSI S 12.60 V 2002), Australian/New Zealand (AS/NZS 2107:2000), China (GB/T 15508 V 1995) and other national and industrial standards. This study will form the basis of devising acceptable standards for use in Hong Kong. 2aAA8. Acoustic and social design of schools—ways to improve the school listening environment. Mechthild Hagen (Education Dept., Ludwig-Maximilians-Univ. of Munich, Leopoldstr. 13, D-80802 Muenchen, Germany, m_hagen@primedu.uni-muenchen.de)

Results of noise research indicate that communication, and as a result, teaching, learning and the social atmosphere are impeded by noise in schools. The development of strategies to reduce noise levels has often not been effective. A more promising approach seems to be to pro-actively support the ability to listen and to understand. The presentation describes the approach to an acoustic and social school design developed and explored within the project “GanzOhrSein” by the Education Department of the Ludwig-Maximilians-University of Munich. The scope includes an analysis of the current “school soundscape,” an introduction to the concept of the project to improve individual listening abilities and the conditions for listening, as well as practical examples and relevant research results. We conclude that an acoustic school design should combine acoustic changes in classrooms with educational activities to support listening at schools and thus contribute to improving individual learning conditions and to reducing stress on both pupils and teachers.

11:10

2aAA9. New schools design: Acoustics as main target. Luigi Maffei and Paola Lembo (Dispama, Faculty of Architecture, Second Univ. of Naples, Via S. Lorenzo, 81031 Aversa (Ce), Italy)

The effects of poor intelligibility and high background noise levels on the cognitive development of school children and on the dissatisfaction of teachers has been largely investigated. National standards have been implemented and attempts to harmonize these standards in international guidelines are ongoing. All these activities have led to the awareness that design of new schools must be centered on the achievement of a good acoustic environment. At this point a strong research effort to study and implement best solutions must be conducted, in collaboration, by architects, acousticians, pedagogues, psychologists, builders and acoustic materials producers. Recently an international competition for the planning of new primary schools in Rome, Italy has been announced. The aim of the competition is to study new architectural and running features of primary schools to obtain, among other parameters such as lighting, low cost energy solutions and air quality, the control of reverberation time, sound insulation and mechanical equipments noise. In these school buildings, as innovative requirement, children must be also able to elaborate interpretative hypothesis of physical phenomena such as sound emission and perception and be aware of their influence on these phenomena. Different possible solutions are presented.

2aAA10. Speech intelligibility metrics in small unoccupied classrooms. Matthew E. Cruikshank, Melinda J. Carney, and Dominique J. Cheenne (Dept. of Audio Arts & Acoust., Columbia College Chicago, Chicago, IL 60605)

Nine small volume classrooms in schools located in the Chicago suburbs were tested to quantify speech intelligibility at various seat locations. Several popular intelligibility metrics were investigated, including Speech Transmission Index (STI), %Alcons, Signal to Noise Ratios (SNR), and 80 ms Useful/Detrimental Ratios (U80). Incorrect STI values were experienced in high noise environments, while the U80s and the SNRs were found to be the most accurate methodologies. Test results are evaluated against the guidelines of ANSI S12.60-2002, and match the data from previous research.

11:45

2aAA11. The prediction of speech intelligibility in classrooms using computer models. Stephen Dance and Roger Dentoni (Dept. of Eng. Systems, London South Bank Univ., Borough Rd., London, UK)

Two classrooms were measured and modeled using the industry standard CATT model and the Web model CISM. Sound levels, reverberation times and speech intelligibility were predicted in these rooms using data for 7 octave bands. It was found that overall sound levels could be predicted to within 2 dB by both models. However, overall reverberation time was found to be accurately predicted by CATT 14% prediction error, but not by CISM, 41% prediction error. This compared to a 30% prediction error using classical theory. As for STI: CATT predicted within 11%, CISM to within 3% and Sabine to within 28% of the measured value. It should be noted that CISM took approximately 15 seconds to calculate, while CATT took 15 minutes. CISM is freely available on-line at www.whyverne.co.uk/acoustics/Pages/cism/cism.html

Session 2aAB

Animal Bioacoustics: Methodology for Measurements of Auditory Evoked Potentials in Aquatic Mammals I

Mardi C. Hastings, Chair

*Office of Naval Research, ONR 341, 800 North Quincy St., Arlington, VA 22217***Chair's Introduction—8:00****Invited Papers****8:05****2aAB1. Conditions for evoked-potential audiometry in odontocetes.** Alexander Ya. Supin (Inst. of Ecology and Evolution, Russian Acad. of Sci., 33 Leninsky Prospect, 119071 Moscow, Russia)

Currently auditory brainstem evoked potentials (ABR) become widely used for audiometry in odontocetes. Depending on the goal, the ABR technique differs with respect of (i) electrode positions, (ii) stimulus parameters, and (iii) threshold evaluation procedure. (I) Optimal electrode positions are vertex (for binaural responses), lateral (for monaural responses), or pharyngeal (for some express investigations). (II) The shorter the stimulus and the wider its spectrum, the more robust the response. Thereafter, narrow-band stimuli provoke low-amplitude ABR with a short dynamic range, but the goal of investigation often requires keeping the stimulus spectrum narrow. Sinusoidally amplitude modulated (SAM) sounds have narrow spectra, thereby provoking low amplitude envelope-following response (EFR); however, EFR can be extracted from noise by Fourier analysis. Modulation rate for SAM sounds must fit a spectrum peak of the ABR waveform. High-frequency sounds are more effective to provoke ABR and EFR than low-frequency ones, so ABR technique is better applicable for measurements in high-frequency ranges. (III) For precise threshold evaluation, low-amplitude responses must be extracted from noise. Apart from the averaging procedure, cross-correlation (for single ABR) or Fourier (for EFR) analysis is helpful to extract and measure low response amplitudes. [Work supported by Russian Basic Research Foundation, Russian President Grant, ONR.]

8:35**2aAB2. Auditory evoked potential measurement methodology for odontocetes and a comparison of measured thresholds with those obtained using psychophysical techniques.** Paul E. Nachtigall, Michelle Yuen, T. Aran Mooney, and Kristen Taylor (Marine Mammal Res. Program, Hawaii Inst. of Marine Biol., Univ. of Hawaii, Honolulu, HI 96822)

Most measurements of the hearing capabilities of toothed whales and dolphins have been taken using traditional psychophysical procedures in which the animals have been maintained in laboratory environments and trained to behaviorally report the sensation or difference of acoustic stimuli. Because of the advantage of rapid data collection, increased opportunities, and new methods, Auditory Evoked Potentials (AEPs) have become increasingly used to measure audition. The use of this new procedure calls to question the comparability of the established literature and the new results collected with AEPs. The results of behavioral and AEP methods have been directly compared with basic audiogram measurements and have been shown to produce similar (but not exactly the same) values when the envelope following response procedure has been used and the length of the stimulus is taken into account. The AEP methods allow possible audiometric opportunities beyond those available with conventional psychophysics including: (1) the measurement of stranded dolphins and whales that may never be kept in laboratories, (2) the testing of stranded animals for hearing deficits perhaps caused by overexposure to noise, and (3) passive testing of hearing mechanisms while animals actively echolocate. [Work supported by the Office of Naval Research and NOAA-NMFS.]

9:00**2aAB3. Auditory evoked potential measurements with cetaceans.** David Mann, Mandy Cook (USF College of Marine Sci. & Mote Marine Lab., 140 7th Ave. S., St. Petersburg, FL 33701, dmann@marine.usf.edu), Gordon Bauer (New College of Florida & Mote Marine Lab., Sarasota, FL 34243), Wendi Fellner (Walt Disney World, Lake Buena Vista, FL), and Randy Wells (Chicago Zoological Society and Mote Marine Lab., Sarasota, FL 34236)

Auditory evoked potentials (AEPs) allow researchers to measure the hearing abilities of animals that would be difficult or impossible to train for behavioral measurements of hearing. The hearing abilities of live-stranded cetaceans and wild dolphins can only be made with AEP techniques. In these situations, time with the animal is often restricted to an hour or less, and there is often little control over the acoustic environment in which the tests are performed. AEP measurements may be made while the animals are in air or in shallow pools. For cetaceans in air, sounds are typically presented with a suction cup jawphone. For cetaceans in water, sounds may be presented in a direct field (with the transducer located at some distance from the test subject) or with a jawphone. In each of these situations it is important to understand how thresholds derived from AEP measurements compare with behavioral hearing measurements. Examples of AEP measurements from wild and live-stranded cetaceans are presented to illustrate their usefulness and the constraints under which these measurements must be made. AEP measurements from bottlenose dolphins in air and in water are also compared with their behavioral audiograms.

9:25

2aAB4. Narrow band pulses as stimuli in an auditory brain stem recording study with a harbor porpoise. Kristian Beedholm and Lee A. Miller (Inst. of Biol., Univ. of Southern Denmark, Campusvej 55, DK-5230 Odense M, Denmark, lee@biology.sdu.dk)

We have studied several aspects of hearing by a harbor porpoise using the ABR method with pulsed stimuli. Experiments were conducted on a male porpoise in collaboration with Fjord and Baelt, Kerteminde, Denmark. The animal had suction cups containing silver electrodes placed near the blowhole and near the dorsal fin. When fitted with the electrodes he moved to an underwater listening post where his outgoing sonar signal could be used to trigger a phantom echo. EEG signals were amplified differentially and averaged over a variable number of presentations depending on trial duration and experiment. For studying the frequency/intensity response, narrow band pulsed stimuli were generated and presented in several ways. One way was to use the impulse response of a B&K 1/3 octave filter bank (set to 80, 100, 125, or 160 kHz) as a stimulus. This stimulus was presented in both a passive hearing task, when a signal generator triggered the echo, and in an active experiment, where the echo was time locked to the animals emitted signal. Our results show the best response at 125 kHz and indicate a slight, but significantly higher response in the active mode. The latter has a methodological explanation. [Work supported by ONR.]

9:50

2aAB5. Auditory evoked potentials (AEP) methods for population-level assessment of hearing sensitivity in bottlenose dolphins. Dorian Houser (BIOMIMETICA, 7951 Shantung Dr., Santee, CA 92071) and James Finneran (Space and Naval Warfare Systems Ctr., San Diego, CA 92152)

A portable system for recording auditory evoked potentials (AEP) was developed to rapidly assess the hearing sensitivity of dolphins in air. The system utilizes a transducer embedded in a silicone suction cup to deliver amplitude modulated tones to the dolphin through the lower jaw. Frequencies tested range from 10–150 kHz and testing of both ears is completed within 90 min. AEP-determined thresholds from one subject were benchmarked against that subject's direct field behavioral audiogram to quantify variation between the two methods. To date, AEP audiograms have been obtained from over 30 bottlenose dolphins. Considerable individual variation in frequency-specific hearing sensitivity was observed. Some high-frequency hearing loss was observed in relatively young (early 20s) and old (35+ years) animals; conversely, age was not necessarily related to hearing loss as several animals greater than 40 years of age had good hearing sensitivity across the range of tested frequencies. Profound hearing loss typically occurred at higher frequencies. Decline in sensitivity was rapid in all cases and began between 50–60 kHz. Increased sample size of hearing sensitivity in dolphins suggest that the use of audiometric functions from single animals as representative of population level audiometry might be misleading.

10:15–10:30 Break

10:30

2aAB6. Electrophysiological methods for hearing assessment in pinnipeds. Colleen Reichmuth Kastak, David Kastak (Univ. of California Santa Cruz, Long Marine Lab., 100 Shaffer Rd., Santa Cruz, CA 95060, coll@ucsc.edu), James J. Finneran (SPAWARSSYSCEN San Diego, San Diego, CA 92152), Dorian S. Houser (BIOMIMETICA, Santee, CA 92071), and Alexander Supin (Inst. of Ecology and Evolution, 119071 Moscow, Russia)

Studies of auditory sensitivity in marine mammals generally rely on behavioral psychophysical methodologies. While these studies are the standard for hearing assessment in marine mammals, data are limited to only a few individuals representing a small proportion of species. Accumulating research on dolphin auditory physiology has resulted in the refinement of electrophysiological methods appropriate for odontocete cetaceans and an increase in available audiometric information. Electrophysiological methods have also been used with pinnipeds, but there are significant gaps in our understanding of pinniped auditory physiology that must be addressed before such approaches can be broadly applied to investigations of pinniped hearing. We are taking a bottom-up approach to developing suitable methods for evoked potential audiometry in pinnipeds, including technology transfer from studies of cetaceans and other mammals, mapping of response amplitude with respect to recording positions on the skull, characterization of responses in relationship to various stimulus types and presentation parameters, and determination of whether useful frequency-specific data can be reliably obtained using electrophysiological methods. This approach is being taken with representative pinniped species including California sea lions (*Zalophus californianus*), harbor seals (*Phoca vitulina*), and northern elephant seals (*Mirounga angustirostris*) using both training and chemical immobilization techniques. [Work supported by NOPP.]

10:55

2aAB7. Ground-truthing evoked potential measurements against behavioral conditioning in the goldfish, *Carassius auratus*. Randy J. Hill (College of Marine Sci., Univ. of South Florida, 140 7th Ave. S., St. Petersburg, FL 33701) and David A. Mann (Univ. of South Florida, St. Petersburg, FL 33701)

Auditory evoked potentials (AEPs) have become commonly used to measure hearing thresholds in fish. However, it is uncertain how well AEP thresholds match behavioral hearing thresholds and what effect variability in electrode placement has on AEPs. In the first experiment, the effect of electrode placement on AEPs was determined by simultaneously recording AEPs from four locations on each of 12 goldfish, *Carassius auratus*. In the second experiment, the hearing sensitivity of 12 goldfish was measured using both classical conditioning and AEP's in the same setup. For behavioral conditioning, the fish were trained to reduce their respiration rate in response to a 5 s sound presentation paired with a brief shock. A modified staircase method was used in which 20 reversals were completed for each frequency, and threshold levels were determined by averaging the last 12 reversals. Once the behavioral audiogram was completed, the AEP measurements were made without moving the fish. The recording electrode was located subdermally over the medulla, and was inserted prior to classical conditioning to minimize handling of animal. The same sound stimuli (pulsed tones) were presented and the resultant evoked potentials were recorded for 1000–6000 averages. AEP input–output functions were then compared to the behavioral audiogram to compare techniques for estimating behavioral thresholds from AEP data.

2aAB8. Electrophysiological responses to vibratory stimulation in the brainstem of the tadpole. Andrea M. Simmons, Aimee Two, and Seth S. Horowitz (Dept. Psych. and Neurosci., Brown Univ., Providence, RI 02912, Andrea_Simmons@brown.edu)

Maturation of saccular responses to vibratory stimuli in 3 axes was measured in the *Rana catesbeiana* tadpole across metamorphic development. The animal was suspended in a water-filled circular aluminum dish attached to a shaker table system consisting of 5 vibration exciters producing sinusoidal, translational movements in the *x*, *y*, and *z* planes. Multi-unit responses were recorded from the medulla with tungsten or platinum-iridium microelectrodes. Recording sites were electrolytically marked to verify electrode placement. Data were collected from 16 animals in late larval stages, before onset of metamorphic climax. Most recording sites were sensitive to vibrations in the *z* (vertical) direction, indicating a saccular origin of the response. Vibration frequencies of 40 Hz or below produced the strongest activity, with thresholds below a displacement of 10 nm. Secondary sensitivity was sometimes observed to either *x* (body-longitudinal) or *y* (body-lateral) directions of movement. Although some sites produced strong phase-locked activity to the stimulation, others showed more diverse temporal patterns of response. Active recording sites were found in the medial vestibular nucleus, lateral vestibular nucleus, reticular gray, and dorsal superior olivary nucleus. These data suggest that tadpole saccule is functional early in larval development, with sensitivity similar to that observed in adult bullfrogs.

2aAO1. Initial results from the Pacific Ocean Shelf Tracking System: A permanent continental-scale acoustic tracking array for fisheries research. David W. Welch (Chief Scientist, Census of Marine Life Project POST, Kintama Res. Corp., 4737 Vista View Crescent, Nanaimo, BC, Canada V9V 1N8)

The Census of Marine Life is developing POST, a seabed acoustic array for tracking marine animals. The long-range plan involves the deployment of 30 or more cross-shelf monitoring lines forming a permanent continental-scale array, each consisting of autonomous seabed nodes spaced at roughly 1 km intervals. Nodes would be modular and use an acoustic modem to periodically communicate with an overhead ship, which would upload data and download new programming. 2004 was a large-scale test of the tracking array component using 135 km of listening lines and 1050 acoustically tagged juvenile salmon (12–15 cm long). Detection rates for individual fish crossing 20 km long acoustic lines were approximately 91%, and precise measurements of migration timing, speed of movement and survival were obtained for both the freshwater and early marine phases. In subsequent years we plan to include additional oceanographic sensors to provide detailed data on changes in bottom temperature, salinity, and currents over time and implement acoustic modems to allow remote data upload from a visiting boat. These data could then be meshed with the fish movement data to describe how animals move relative to changes in the three dimensional structure of the ocean that they are migrating through.

9:25

2aAO2. Autonomous underwater vehicle networks as integrated acoustic observation systems. Henrik Schmidt (MIT, 77 Massachusetts Ave., Cambridge, MA 02139)

Autonomous Underwater Vehicles (AUV) are rapidly being transitioned into operational systems for national defense, offshore exploration, and ocean science. However, the use the robotic platforms as components of integrated acoustic sensing systems is still at an early stage. Thus, for example, with recent advances in underwater navigation and communication, and collaborative robotics, networks of AUVs may have significant potential as moving tomographic networks for optimally and adaptively providing in-situ environmental estimates. Such concepts are important to the development and operation of environmenatally adaptive, autonomous littoral surveillance systems by providing environmental inversion specifically emphasizing the parameters significant for the actual platform configuration. Also such multi-AUV concepts have significant potential for subbottom characterization in the deep ocean, of increased importance in the offshore industry. For such systems to be operationally feasible, the limited underwater communication bandwidth makes it necessary for such systems to involve significant on-board processing, in turn requiring the acoustic sensing to be fully integrated with an onboard modeling capability and the platform navigation and control. The development of such new nested, distributed processing concepts, autonomously integrating sensing, modeling and control, is a significant challenge to the acoustics community. [Work supported by ONR.]

2aAO3. Communications performance of an undersea acoustic large-area network. Hannah A. Kriewaldt (Phys. Dept., Naval Postgrad. School, Monterey, CA 93943, hakesle@nps.edu) and Joseph A. Rice (SSC San Diego, Naval Postgrad. School, Monterey, CA 93943)

The U.S. Navy is developing Seaweb acoustic networking capability for integrating undersea systems. Seaweb architectures generally involve a wide-area network of fixed nodes consistent with future distributed autonomous sensors on the seafloor. Mobile nodes including autonomous undersea vehicles (AUVs) and submarines operate in the context of the grid by using the fixed nodes as both navigation reference points and communication access points. In October and November 2004, Theater Anti-Submarine Warfare Exercise (TASWEX04) showcased Seaweb in its first fleet appearance. This paper evaluates the TASWEX04 Seaweb performance in support of networked communications between a submarine and a surface ship. Considerations include physical-layer dependencies on the 9–14 kHz acoustic channel, such as refraction, wind-induced ambient noise, and submarine aspect angle. [Work supported by SSC San Diego.]

10:05–10:25 Break

10:25

2aAO4. Acoustic navigation for ultra-precise seafloor mapping. Donald M. Hussong and J. Grant Blackinton (Fugro Seafloor Surveys, Inc., 2727 Alaskan Way, Seattle, WA 98121)

Numerous autonomous underwater vehicles (AUVs) are operating with very precise swath bathymetric mapping systems in ocean depths to 3 000 m and greater. Although these systems acquire data from positions known to a few centimeters accuracy with respect to the vehicle position, the positioning of the AUVs is generally no better than tens of meters at great depths. Although not yet assembled into an operational system, the technology now exists to acoustically navigate an AUV to within a 10 cm in x , y , and z . This begins by establishing active reference positions on the seafloor, known to within a few centimeters absolutely, using acoustic mirror transponders that transmit and receive streams of pulse coded signals from an accurately navigated surface vessel. These bottom reference positions can then be the core of a long baseline acoustic navigation system which, when coupled with constant monitoring of oceanographic conditions to calculate pressure corrections for depth measurements, will provide 10-cm navigation accuracy for the mapping AUV. Implementation of this technology will enable observational mapping of highly seismic areas where frequent earthquakes can cause many meters of deformation of the seafloor, and can generate massive tsunamis.

10:45

2aAO5. NEPTUNE Canada—status and planning. Brian D. Bornhold (NEPTUNE Canada, P.O. Box 1700, STN CSC, Univ. of Victoria, Victoria, BC, Canada V8W 2Y2, bornhold@uvic.ca)

Stage 1 of the joint Canada-U.S. NEPTUNE seafloor observatory has been funded by the Canada Foundation for Innovation and the British Columbia Knowledge Development Fund with an overall budget of \$62.4 million. The network is designed to provide as close to real-time data and images as possible to be distributed to the research community, government agencies, educational institutions and the public via the Internet. Covering much of the northern segment of the Juan de Fuca Plate, this first phase of the NEPTUNE project is scheduled to be installed, with an initial suite of “community experiments”, in 2008. As part of the planning, NEPTUNE Canada held a series of three workshops to develop the science plans for these “community experiments”; these experiments have a budget of approximately \$13 million. The experiments will cover the gamut of oceanographic science themes including various aspects of: ocean climate and marine productivity, seabed environments and biological communities, fluids at ocean ridges, gas hydrates and fluids on continental margins, plate tectonics processes, associated earthquakes and tsunamis. The next three years will be spent developing and testing the necessary instrumentation for deployment on the network.

11:00

2aAO6. Ambient sound budgets. Jeffrey A. Nystuen and Bruce M. Howe (Appl. Phys. Lab., 1013 NE 40th St., Seattle, WA 98105)

The underwater ambient sound field contains a lot of information about geophysical, biological and anthropogenic activities in the ocean. Identification and quantification of these signals will complement more traditional measurements collected on future ocean observatories, including systems cabled to shore and remote mooring arrays. Long-term ambient sound measurements using a low duty cycle recorder are reported from remote deep ocean moorings, coastal shelf moorings, inland waterways and even a deep, quiet fresh water lake. Identifiable geophysical signals

include accurate measurements of wind speed and rainfall over a wide range of wind speeds and rainfall rates. The character and temporal patterns of biological activity, shipping and recreational boating are monitored. The overall ambient sound budgets will be reported for these different environments. Acoustic monitoring is available from sub-surface moorings, remote locations and under severe weather conditions where and when other ocean instrumentation is likely to fail. [Work supported by ONR Ocean Acoustics.]

11:15

2aAO7. The role of ocean observatories in monitoring for potential effects of man-made sound on the marine environment. David L. Bradley (Appl. Res. Lab., Penn State Univ., P.O. Box 30, State College, PA 16804), Gerald L. D’Spain (Scripps Inst. of Oceanogr., La Jolla, CA 93940-0701), James H. Miller (Univ. of Rhode Island, Narragansett, RI 02882), and George V. Frisk (Florida Atlantic Univ., Dania Beach, FL 33004-3023)

An important question is whether or not man-made sounds have an adverse long-term impact on the ocean environment. Clear evidence exists that an impact has occurred on some individual animals in a few cases. However, according to the 2003 National Academy of Sciences report, the degree of impact on any marine mammal population or on ocean ecosystems as a whole is unknown. An essential component of an approach to addressing this question is an ocean noise/marine ecosystem monitoring system. The monitoring regions should be global in extent and include biologically sensitive areas. The effort should be sustained so that long-term trends in ocean noise levels can be evaluated. An important aspect of the data collection effort is the type and quality of ancillary information. Ancillary data on the marine ecosystems allows determination of any impacts and data on the sources of marine noise and marine environmental properties which are required to develop metrics for evaluating and predicting the characteristics of the noise field. The ocean observatory system presently being contemplated could play an important role in establishing

an ocean noise monitoring capability. [Work supported through the National Ocean Partnership Program, with sponsorship from ONR, NOAA, NSF, and USGS.]

11:30

2aAO8. A nearshore observatory for Antarctic krill: Analysis of the spatial variability in their distribution and abundance. Joseph D. Warren (Southampton College, 239 Montauk Hwy, Southampton, NY 11968, joe.warren@liu.edu) and David A. Demer (Southwest Fisheries Sci. Ctr., La Jolla, CA 92037)

Annual surveys of the distribution and abundance of Antarctic krill are conducted by the United States Antarctic Marine Living Resources Program in order to assist fishery managers in conserving this economic and

ecologic resource. These surveys utilize a large vessel which does not sample close (within 10 km) to the South Shetland Islands. These islands are home to many krill predators (fur seals and penguins) who often forage in these nearshore waters. In order to better understand the abundance and distribution of the krill in these waters and to determine the physical and biological factors affecting the krill, a nearshore observatory has been created that combines multiple sensors and platforms to provide improved spatial and temporal coverage of the nearshore region of Livingston Island. This study utilizes a large research vessel, a small inflatable vessel, an array of instrumented buoys, and a pilot project involving an Autonomous Underwater Vehicle. This presentation will discuss acoustic backscatter measurements made from both large and small vessels. Results from the most recent field season (Jan–Feb 2005) will be presented as well as data from previous years (2002, 2004). [Work supported by the NSF Office of Polar Programs and NOAA.]

Invited Papers

8:00

2aBB1. Opening the blood-brain barrier with ultrasound. Pierre Mourad (APL/Neurosurgery, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, pierre@apl.washington.edu)

The blood-brain barrier (BBB) constitutes a unique anatomical structure within the brain that prevents many therapeutic chemicals within the blood from entering the brain. Research at the University of Washington has shown that it is possible to transiently disrupt the BBB without damage in an intra-operative setting, as verified by the flux of vital dyes from the blood-stream into the brain. This talk will review the research we have done to date on this subject, and discuss potential applications of this approach to BBB disruption.

8:20

2aBB2. Feasibility of noninvasive ultrasound delivery for tumor ablation and targeted drug delivery in the brain. Kullervo Hynynen, Nathan McDannold, Greg Clement, Jason White (Dept. of Radiol., Brigham and Women's Hospital, 75 Francis St., Boston, MA 02115), Lisa Treat, Xiangtao Yin, Ferenc Jolesz, Nikolai Sheikov (Brigham and Women's Hospital, Boston, MA 02115), and Natalia Vykhodtseva (Brigham and Women's Hospital, Boston, MA 02115)

The objective of our research during the past few years has been to develop multichannel ultrasound phased arrays for noninvasive brain interventions. We have been successful in developing methods for correcting the skull induced beam distortions and thus, are able to produce sharp focusing through human skulls. This method is now being tested for thermal ablation of tumors, with results from animal studies demonstrating feasibility. In addition, the ability of ultrasound to open the blood-brain barrier (BBB) locally has been explored in animal models. The results suggest that the transcranial ultrasound exposures can induce BBB opening such that therapeutic agents can be localized in the brain. This tool is especially powerful since the beam can be guided by MR images, thus providing anatomical or functional targeting. This talk will review our current status in this research, which ultimately aims for the clinical use of this methodology.

8:40

2aBB3. Transcranial power M-mode Doppler ultrasound for diagnosis of patent foramen ovale. Mark Moehring and Merrill Spencer (Spencer Technologies, 701 16th Ave., Seattle, WA 98122, mm@spencertechnologies.com)

Patent foramen ovale (PFO) is a right-to-left shunt (RLS) which communicates blood from the right to left atrium of the heart. PFO has been associated with stroke and, more recently, with migraine headache. Diagnosis of RLS can be accomplished effectively with transcranial power M-mode Doppler ultrasound (PMD). PMD is a modality which can be performed without the sedation

required by the more invasive diagnostic technique using transesophageal echocardiography. PMD for this application consists of 2 MHz pulse Doppler ultrasound with placement of sample gates at 2 mm intervals along the single-transducer beam axis, and 8 kHz pulse repetition rate (PMD100M, Spencer Technologies). Doppler power versus depth is constructed every 4ms, using 33 sample gates. Bubble microemboli injected in the venous system and moving across a PFO present as high intensity tracks on a PMD image, as emboli transit from the heart to the brain and through the observed cerebral vasculature. Use of PMD in this context has been reported in the clinical literature [M. P. Spencer, M. A. Moehring, J. Jesurum *et al*, *J. Neuroimaging* **14**, 342–349 (2004)]. This talk surveys the basic technical features of PMD for sensing PFO-related showers of bubble microemboli, and how these features provide clues to the severity of PFO.

2aBB4. Frequency-dependent ultrasound transmission through the human skull. P. Jason White, G. T. Clement, and Kullervo Hynynen (Dept. of Radiol., Brigham and Women's Hospital, Harvard Med. School, Boston, MA 02115)

The development of large-aperture multiple-source transducer arrays for ultrasound transmission through the human skull has demonstrated the possibility of controlled acoustic energy delivery into the brain parenchyma. The individual control of acoustic parameters from each ultrasound source allows for the correction of distortions arising from transmission through the skull bone and also opens up the possibility for electronic steering of the acoustic focus within the brain. To determine the efficacy of frequency modulation with such a device, this study examines the frequency dependence of ultrasound transmission in the range of 0.6–1.4 MHz through a series of seven points on each of three *ex vivo* human calvaria. Using broadband pulses, it is shown that the reflected spectra from the skull reveal information regarding the transmission energies at specific frequencies. In fact, there exists an inverse correlation between the reflected pressure amplitude and the transmitted pressure amplitude such that, for the frequency range under examination, approximately three local minima in the reflection spectra with the corresponding three peaks in transmission are observed. A noninvasive determination of the most efficient transmission frequency for a localized spatial region on a skull can yield an improvement of up to 3.5-dB in ultrasound intensity transmission.

2aBB5. Numerical simulation of ultrasound thermotherapy of brain with a scanned focus transducer. Sohrab Behnia, Farzan Ghalichi, Amin Jafari, and Ashkan Bonabi (Dept. of physics, IAU, Univ. of Ourmi, Iran, s.behnia@iaurmia.ac.ir)

Brain tumors are one of the most difficult ones to treat. The margin between destruction of the tumor and damage to the surrounding tissue is narrow in the brain. Ultrasound could be an effective treatment because of its ability to propagate deep in tissue and induce temperature rise at the focus while leaving the surrounding tissue intact. This study investigates whether using a fix-focus transducer could destroy brain tumor cells, in a cost effective manner which reduces the treatment time significantly. In this work an appropriate fix-focus transducer was designed considering effective parameters and limitations which are dominant in this case. Then a real 2-D brain model was constructed from a MR image. A piece of the skull bone has been removed to allow ultrasound to propagate into the brain. The resultant pressure field and the temperature rise were calculated by Rayleigh integral and bio-heat equation on the model. The obtained results were promising indicating that toxic temperatures could be obtained in short treatment times. This could be of great advantage especially in treating primary brain tumors.

2aBB6. Ultrasound-accelerated thrombolysis using microbubbles. William Culp (Interventional Radiol., Univ. of Arkansas for Medical Sci., Little Rock, AR 72205-7199, CulpWilliamC@uams.edu)

Current thrombolytic therapy for ischemic stroke reaches less than 3% of cases and is only moderately successful. Numerous studies have demonstrated increased thrombolytic activity when ultrasound is delivered to clot in the presence of tissue plasminogen activator. Initial human reports using trans-cranial Doppler technology (2 MHz) to deliver continuous ultrasound to intracranial clot are very promising with improved clot lysis and no increase in symptomatic bleeding. However, another human study using low-frequency therapeutic ultrasound resulted in excessive bleeding and was discontinued. Microbubble augmented ultrasound clot lysis has proven successful in several studies ranging from lysis of very small peripheral clots in rabbits to very large clots in dialysis grafts in dogs. Early human studies of thrombosed dialysis grafts show success and no adverse events. Intracranial clot lysis in pigs has been successful with both intra-arterial and intravenous microbubble techniques. Better definition of possible combination therapies and of efficacy and safety is still required in animal models, but human studies should be designed to avoid some of the complications of current therapy. This presentation will review the subject, present recent advances, and define some requirements for successful clot destruction in peripheral vessels and intracranial vessels.

9:50

2aBB7. Ultrasound enhanced thrombolysis: Clinical evidence. Andrei V. Alexandrov (The Univ. of Texas–Houston Med. School, MSB 7.044, 6431 Fannin St., Houston, TX 77030)

Phase II CLOTBUST randomized clinical trial (Houston, Barcelona, Edmonton, Calgary) evaluated patients with acute ischemic stroke due to intracranial occlusion and treated with intravenous tissue plasminogen activator (TPA) within 3 h of symptom onset. Randomization: monitoring with pulsed wave 2 MHz transcranial Doppler (TCD) (Target) or placebo monitoring (Control). Safety: symptomatic bleeding to the brain (sICH). Primary end-point: complete recanalization on TCD or dramatic clinical recovery by the total NIHSS score <3, or improvement by >10 NIHSS points within 2 hours after TPA bolus. All projected 126 patients were randomized 1:1 to target (median NIHSS 16) or control (NIHSS 17). sICH: 4.8% Target, 4.8% Controls. Primary end-point was achieved by 31 (49%, Target) versus 19 (30%, Control), $p < 0.03$. At 3 months, 22 (42% Target) and 14 (29% Control) patients achieved favorable outcomes. Continuous TCD monitoring of intracranial occlusion safely augments TPA-induced arterial recanalization, and 2 MHz diagnostic ultrasound has a positive biological activity that aids systemic thrombolytic therapy. For the first time in clinical medicine, the CLOTBUST trial provides the evidence that ultrasound enhances thrombolytic activity of a drug in humans thereby confirming intense multi-disciplinary experimental research conducted worldwide for the past 30 years.

10:30

2aBB8. The effect of 40 kHz ultrasound on tissue plasminogen activator-induced clot lysis in three *in vitro* models. Marlien Pieters, Rob T. Hekkenberg, Marrie Barrett-Bergshoeff, and Dingeman C. Rijken (TNO Prevention and Health, Leiden, Netherlands)

In previous work from the same laboratory, high-frequency ultrasound (US) (3 MHz) was shown to promote *in vitro* fibrinolysis through enhanced supply of plasminogen to the clot surface. The application of high-frequency US is limited *in vivo* due to tissue heating. Low-frequency US, however, has less tissue heating and improved penetration. Internal plasma clot lysis and external lysis with compacted and non-compacted plasma clots were used to determine the magnitude of the effect of low-frequency US (40 kHz; 0.5 W/cm²) on tissue plasminogen activator-induced lysis and to elucidate the mechanisms behind the effect. Ultrasound enhanced lysis in all three models, with the largest effects (4-fold) in the external lysis model with compacted plasminogen-poor clots. The acceleration effect of ultrasound in this model decreased with increasing *t*-PA—and decreasing plasminogen concentrations. Ultrasound had a much smaller effect in this model when compacted plasminogen-rich clots were used. In the external lysis, non-compacted clot model, ultrasound resulted in consistently higher lysis rates. The acceleration effect of lysis, increased slightly (1.3 to 1.8-fold) with increasing *t*-PA—and decreasing plasminogen concentrations. Plasminogen supply to the clot surface was again shown to be an important contributor to ultrasound-enhanced lysis. [M. Pieters, R. T. Hekkenberg, M. Barrett-Bergshoeff, and D. C. Rijken. *Ultrasound in Med & Biol* **30**, 1545–1552 (2004).]

2aBB9. Confocal microscopy movies of fibrin clots during ultrasound-accelerated thrombolysis. E. Carr Everbach (Swarthmore College, Swarthmore, PA 19081, ceverba1@swarthmore.edu), Irina N. Chernysh, and John W. Weisel (Univ. of Penn School of Med, Philadelphia, PA 19104)

Blood clots made of human purified fibrin (white clots) were insonified with 1 MHz pulsed ultrasound during observation by fluorescence confocal microscopy. A deconvolution microscope allowed extremely thin sheets (0.2 μm) of fibrin to be viewed at a resolution of 0.2 μm per pixel, and the clot microstructure visualized. Acoustic pressure amplitudes from 0.1 to 0.8 MPa (peak-to-peak) were inferred using the image blur of 0.6- μm -diameter polystyrene spheres coated with FITC fluorescent label present in the clots. Acoustic pulse widths of 1 ms and pulse repetition frequencies of 125 Hz reduced clot heating to less than 3°C during each 30-minute exposure. Still 100 μm by 100 μm images were recorded every 10 seconds during pauses in insonification, to produce time-lapse movies that are compared with movies made during sham ultrasound exposures.

11:05

2aBB10. Acousto-mechanical and thermal properties of clotted blood. Volodymyr M. Nahirnyak (Dept. of Phys., Univ. of Cincinnati, Cincinnati, OH 45221-0511), S. Wang Yoon, and Christy K. Holland (Univ. of Cincinnati, Cincinnati, OH 45267-0586)

The efficacy of ultrasound-assisted thrombolysis as an adjunct treatment of ischemic stroke is being widely investigated. In order to determine the role of ultrasound hyperthermia in the process of blood clot disruption, the thermal and acousto-mechanical properties of clotted blood were measured *in vitro*. Whole blood clots were prepared from either fresh porcine or human blood by aliquoting 1.5 or 2.0 ml into 10 ml glass tubes (BD Vacutainer™, Franklin Lakes, NJ), immersing the tubes in a 37°C water bath for three hours and storing the clots at 5°C for at least three days prior to assessment of the properties, which ensured complete clot retraction. Direct calorimetric measurements using calibrated *E*-type thermocouples (Omega Engineering, Inc., Stamford, CT) were performed to determine the heat capacity and thermal conductivity of the human and porcine thrombi against a standard fluid, saline [0.9%]. The amplitude coefficient of attenuation of the clots was determined from 120 kHz to 3.5 MHz with a calibrated hydrophone (TC4038, RESON, Inc., Goleta, CA) in a 20±2°C water bath using the substitution method. The experimentally measured values of heat capacity, density, and thermal conductivity of porcine clotted blood are 3.23±0.46 J/g·K, 1.058±0.014 g/cm³, and 0.52±0.14 W/m·K. The attenuation coefficient ranged from 0.10 to 0.30 Nepers/cm over 120 kHz to 3.5 MHz. Measurements of the acousto-

mechanical and thermal properties of clotted blood can be helpful in theoretical modeling of ultrasound hyperthermia in ultrasound-assisted thrombolysis.

11:20

2aBB11. Measurements of the effect of haemolysis on speed of sound and attenuation through suspensions of red blood cells at 15 MHz. Nicola Z. Hobbs and Constantin-C. Coussios (Dept. of Eng. Sci., Univ. of Oxford, Parks Rd., Oxford OX1 3PJ, U.K.)

When blood flows through an artificial environment for prolonged periods of time, the red blood cells are gradually destroyed due to the high shear stresses to which they are exposed. The ability to measure the degree of haemolysis accurately and in real time is becoming increasingly important, especially in the context of organ preservation and of the implantation of heart-assist devices as a long-term method for treating heart failure. A recent study indicated that the backscattering coefficient (BSC) of red cell suspensions containing damaged red blood cells is significantly higher than the BSC of suspensions containing exclusively healthy cells. Using a specially designed acoustic chamber, suspensions containing different proportions of healthy and damaged cells were exposed to 15-MHz ultrasound. A thin tungsten wire immersed in each suspension was used to quantify the speed of sound and attenuation through increasingly haemolyzed suspensions. It is intended to utilize a combination of measurements of speed of sound, attenuation and backscattering in order to solve the inverse problem and to develop an on-line, non-invasive device for quantifying the degree of haemolysis in artificial circuits.

11:35

2aBB12. Lytic efficacy of apoli protein E2 (ApoE2) and recombinant tissue plasminogen activator (rt-PA) treatment with 120 kHz ultrasound in an *in-vitro* human clot model. Jason M. Meunier, Jason Y. Cheng (Dept. of Emergency Medicine, Univ. of Cincinnati, 231 Albert Sabin Way, Cincinnati, OH 45267, meuniejn@uc.edu), Joseph F. Clark (Univ. of Cincinnati Medical Ctr., Cincinnati, OH 45267), and George J. Shaw (Univ. of Cincinnati, Cincinnati, OH 45267)

Currently, the only FDA approved therapy for acute ischemic stroke is recombinant tissue plasminogen activator (rt-PA). However rt-PA has substantial side effects such as hemorrhage. This has led to interest in other potential therapies. For example, ultrasound (US) increases the lytic efficacy of rt-PA. Also, apolipoprotein E2 (ApoE2) increases rt-PA activity. This suggests combining US, ApoE2 and rt-PA to improve thrombolysis, but the efficacy is not known. Here, the lytic efficacy of apoE2, rt-PA and 120 kHz US is measured in a human clot model. Whole blood was obtained from volunteers, after local institutional approval. Clots were formed in 1.7 mm micropipettes, and placed in a water tank that allowed microscopic video imaging during US and thrombolytic exposure. Clots

were treated with rt-PA ($[rt-PA]=3.15 \mu\text{g/ml}$), rt-PA and apoE2 ($[apoE2]=9.8 \mu\text{g/ml}$), or rt-PA, apoE2 and 120 kHz US (0.35 MPa, PRF=1667 Hz, 80% duty cycle) for 15 min at 37°C in human plasma. Clot lysis was visually recorded and the lysis depth (LD) determined from these data using an image analysis algorithm. LD was linear with time for all treatments ($R^2 \geq 0.81$), allowing the determination of a lytic rate (LR).

LR was found to be 0.35 ± 0.03 , 1.55 ± 0.11 , and $0.75 \pm 0.04 \mu\text{m/min}$ for the rt-PA, rt-PA and apoE2, and US treated groups respectively. The thrombolytic efficacy of rt-PA is enhanced by ApoE2. The interaction of 120 kHz with apoE2 and rt-PA showed a reduced lytic efficacy compared with rt-PA and apoE2 treatment alone. It is possible that US interferes with the ApoE2-mediated activation of rt-PA.

Session 2aED

Education in Acoustics: Hands-On Experiments for High School Students

Uwe J. Hansen, Chair

Physics Dept., Indiana Univ., Terre Haute, IN 47809 10:00

Students and senior scientists will staff approximately 20 experiment stations for local high school students who will perform the experiments. These students will thus be exposed to a variety of acoustics principles and get some practical hands-on experience with a number of research tools. Regular ASA meeting participants are welcome to the session, as long as their participation does not interfere with student hands-on activities.

2aMU1. A physical model and experimental testbed for real-time simulation of flute-like instruments. Patricio de la Cuadra (Ctr. for computer research in music and acoustic, CCRMA, Stanford Univ., CA 94305-8180), Benoît Fabre (Univ. Paris 6, 75252 Paris Cedex 05, France), Jonathan S. Abel (Universal Audio, Inc., Santa Cruz, CA 95060), and Julius O. Smith III (Stanford Univ., CA 94305-8180)

In the last decades, a wealth of experimental data has been gathered concerning sound production in flute-like instruments. These data have driven the development and fine tuning of analytical models for the physical processes involved. Here, a number of these results are integrated into a real-time physical model of a flute-like instrument. The model proposed is one-dimensional and driven by a single input pressure. The system was designed in the spirit of a laboratory testbed, where geometric and performance parameters can be controlled in real time, and in which important physical quantities can be viewed in real time, either in the time domain or frequency domain. In this way, the user may observe and validate the behavior of variables that would otherwise be hidden in the feedback loop. Additionally, the system was designed in a modular fashion, so as to allow independent substitution and adjustment of any of the model blocks. So as to allow real-time implementation and parameter control, a novel time-varying jet filter has been developed which not only closely matches measured jet oscillation amplitudes as a function of jet geometry and frequency, but may be rapidly slewed in response to quickly changing performance parameters.

8:55

2aMU2. A unified digital waveguide (infra)structure for synthesizing wind instrument sounds. Gary Scavone (Music Technol., Faculty of Music, McGill Univ., 555 Sherbrooke St. West, Montreal, QC, Canada H3A 1E3)

Virtual acoustic models provide researchers a means for testing and verifying their scientific understanding of physical systems. As well, they allow explorations in a world free from physical constraints. A digital waveguide structure is presented which implements a generalized air column, or resonator, model for wind instrument sound synthesis. This system has a physical inspiration and interpretation, a “blowed string,” but is an otherwise impossible reality. The structure produces harmonic resonant modes at integer multiples of a fundamental, with controls to vary harmonic content. It is useful for simulating both cylindrical and conical air columns of such instruments as clarinets, saxophones, flutes, oboes, and trumpets. Further, this structure robustly interconnects with several different non-linear “reed” models to produce a rich variety of wind instrument sounds. The result is a highly efficient computational algorithm that can be used to perform real-time sound synthesis on consumer-grade computers. [Work supported by the Canadian Foundation for Innovation.]

9:20

2aMU3. Complete geometric computer simulation of a classical guitar. Rolf Bader (Inst. of Musicology, Neue Rabenstr. 13, 20354 Hamburg, Germany)

The aim of formulating a complete model of a classical guitar body as a transient-time geometry is to get detailed insight into the vibrating and coupling behavior of the time-dependent guitar system. Here, especially the evolution of the guitars initial transient can be looked at with great detail and the produced sounds from this computer implementation can be listened to. Therefore, a stand-alone software was developed to build, calculate, and visualize the guitar. The model splits the guitar body into top plate, back plate, ribs, neck, inclosed air, and strings and couples these parts together including the coupling of bending waves and in-plane waves of these plates to serve for a better understanding of the coupling between the guitar parts and between these two kinds of waves. The resulting waveforms are integrated over the geometry and the resulting sounds show up the different roles and contributions of the different guitar body parts to the guitar sound. Here cooperation with guitar makers is established, as changes on the guitars geometry on the resulting sound can be considered as computer simulation and promising new sound qualities can then be used again in real instrument production.

9:45

2aMU4. An allpass filter design method with application to piano string synthesis. Jonathan S. Abel (Universal Audio, Inc., Santa Cruz, CA 95060), Julius O. Smith III (Stanford Univ., Stanford, CA 94305), and Julien Bensa (Universite Pierre et Marie Curie, Paris, France)

A nonparametric allpass filter design method for matching a desired group delay as a function of frequency is presented. The technique is useful in physical modeling synthesis of musical instruments exhibiting dispersive wave propagation in which different frequency bands travel at different speeds. While current group delay filter design methods suffer from numerical difficulties except at low filter orders, the technique presented here is numerically robust, producing an allpass filter in cascaded biquad form, and with the filter poles following a smooth loop within the unit circle. The technique was inspired by the observation that a pole-zero pair arranged in allpass form has 2π total group delay when integrated around the unit circle, regardless of the pole location. To match a given group delay characteristic, the method divides the frequency axis into sections containing 2π total group delay, and assigns a pole-zero allpass pair to each. In this way, the method incorporates an order selection technique, and by adding a pure delay to the desired group delay, allows the trading of increased filter order for improved fit to the frequency-dependent group delay. Results are presented for modeling the group delay of a stiff piano string under several computational constraints.

10:20

2aMU5. Music and science meet at the micro level: Time-frequency methods and granular synthesis. Barry Truax (School of Commun., Simon Fraser Univ., Burnaby, BC, Canada V5A 1S6)

Musical research over the last century has become increasingly entwined with the areas of acoustics, psychoacoustics, and electroacoustics. One of the most striking results has been to push the frontiers of models of sound and music to the micro level, what is generally termed microsound. At this level, concepts of frequency and time are conjoined by a quantum relationship, with an uncertainty principle relating them that is precisely analogous to the more famous uncertainty principle of quantum physics. A class of methods of sound synthesis and signal processing known as time-frequency models have their basis at this quantum level such that changes in a signal's time domain result in spectral alterations and vice versa. One such method, granular synthesis and the granulation of sampled sound, produces results by the generation of high densities of acoustical quanta called grains. Such a radical shift has profound implications for not only our models of sound design, but also for the compositional methods that emerge as well as the role of the composer in guiding complex processes. The paper will argue that these models are examples of a class of complex systems exhibiting emergent form that create a new form of virtual music instrument.

10:45

2aMU6. Control of diffusion in digital waveguide reverberators. Patty Huang (CCRMA, Dept. of Music, Stanford Univ., Stanford, CA 94305)

Variable diffusion has been incorporated into many room acoustics models, which allows for the representation of materials with different scattering properties. By simulating the scattering of sound waves off surfaces in an acoustical enclosure, a more realistic sound field is produced. Due to constraints on the algorithm architecture and a preference for late reverberation which approaches decaying gaussian noise, it is less common for diffusion to be featured as an adjustable parameter in artificial reverberators. However, parameterized diffusion can be a tool for tailoring the character and density of the reverberant tail, enabling the generation of a greater variety of reverbs. This paper will present methods for implementing and controlling diffusion in artificial reverberation models based on digital waveguides. Sound examples will be given during the presentation.

11:10

2aMU7. Acoustics of the Intonarumori. Stefania Serafin (Medialogy, Aalborg Univ. Copenhagen, Lautrupvang 15, 2750 Ballerup, Denmark)

The Intonarumori were a family of musical instruments invented by the Italian futurist composer and painter Luigi Russolo. Each Intonarumori was made of a wooden parallelepiped sound box, inside which a wheel of different sizes and materials was setting into vibration a catgut or metal string. The pitch of the string was varied by using a lever, while the speed of the wheel was controlled by the performer using a crank. At one end of the string there was a drumhead that transmitted vibrations to the speaker. Unfortunately, all the original Intonarumori were destroyed after a fire during World War II. Since then, researchers have tried to understand the sound production mechanism of such instruments, especially by consulting the patents compiled by Russolo or by reading his book "The art of noise." In this paper we describe the acoustics of the Intonarumori. Based on such description, we propose physical models that simulate such instruments. The intonarumori's string is modeled using a one dimensional waveguide, which is excited either by an impact or a friction model. The body of the instrument is modeled using a 3-D rectangular mesh, while the horn is considered as an omnidirectional radiator.

2aMU8. Guidophone: A handheld virtual music instrument combining vocal tract geometry and hand gestures. Ryan Cassidy, Rodrigo Segnini, and Yi-Wen Liu (Ctr. for Comput. Res. in Music and Acoust., Stanford Univ., Stanford, CA 94305)

Vocal sounds provide an intuitive and appealing basis for virtual instruments. The former aspect allows most people to engage in a musical activity simply by repetition of a heard sound. Physical models in speech synthesis attempt, among other objectives, to approximate the geometry of the vocal tract required to produce specific sounds. Cook has developed one such model [Perry Cook, Identification of Control Parameters in an Articulatory Vocal Tract Model with Applications to the Synthesis of Singing, Stanford University, 1990], where the vocal tract is divided into tube sections that govern the transmission and reflection of acoustic energy at the junctions between sections. Tube section radii provide the model parameters. This paper explores the feasibility of using hand gestures to control those parameters. To that end, the problem of mapping hand gestures to the parameters of Cook's vocal synthesis model, with attention paid to transitions between successive phonemes, is explored. The physical basis of the model is reviewed. Next the relationship between the geometries implied by Cook's tract model and those determined by experiment is investigated. A means for mapping a number of parameters less than the degrees of freedom inherent in the model is presented. Finally, the details of a virtual instrument, controlled by a mechanical device recently developed for the work, are presented.

11:50

2aMU9. SCUBA: The Self-Contained Unified Bass Augmenter. Juan Pablo Cceres, Gautham J. Mysore, and Jeffrey Trevio (Ctr. for Comput. Res. in Music and Acoust., Stanford Univ., The Knoll, 660 Lomita, Stanford, CA 94305)

The Self-Contained Unified Bass Augmenter (SCUBA) is a new augmentative OSC (Open Sound Control) controller for the tuba. SCUBA allows new expressive possibilities by adding onboard continuous and discrete sensors to provide user-controlled parametric data for the processing of the instruments natural sound in Pd. SCUBA endows acoustic instruments with parametric control of virtual instruments and provides a means of integrating the output of a virtual instrument with the natural sound of the tuba. The user sends controller data from the augmented tuba interface to the virtual instrument via FSRs (Force-Sensitive Resistors) and buttons mounted on the existing instrument interface. An AVRMini microcontroller converts raw sensor data to OSC (Open Sound Control) messages, which are mapped in Pd to control virtual instrument parameters. Virtual instrument output is integrated into the solo instrument interface via satellite speakers mounted in the bell; this allows for mixing of the instruments natural sound with that of the virtual instrument to create the impression of a single instrument. This integration is the goal of the SCUBA project: by providing a flexible but unified control interface and acoustic output, traditional acoustic instrument interfaces can be augmented and paired with virtual musical instruments. [We would like to thank Michael Gurevich, Max Matthews, Bill Verplank, Pascal Stang, and classmates from Music 250 (Fall 04) for assistance in the realization of this project.]

Session 2aNS**Noise and Physical Acoustics: Urban Sound Propagation**

Jian Kang, Cochair

Univ. of Sheffield, School of Architecture, Western Bank, Sheffield S10 2TN, United Kingdom

Ning Xiang, Cochair

*Rensselaer Polytechnic Inst., Architecture, 110 8th St., Troy, NY 12180***Chair's Introduction—8:00*****Invited Papers*****8:05****2aNS1. Experimental study of sound propagation in a street.** Judicaël Picaut (Section acoustique routière et urbaine, LCPC, route de Bouaye, BP 4129, 44341 Bouguenais Cedex, France)

This paper presents an experimental study of the sound propagation in a street, performed during July 2002, in order to measure impulse responses at numerous locations in a street canyon, and, for several positions of the sound source. A specific attention has been paid on the processing of the experimental data, in order to obtain accurate values of the reverberation time and the steady-state sound pressure level, including also the compensation of the atmospheric attenuation. In total, 11592 useful data have been collected during this experiment, and are available by contacting the author. Reverberation times and sound levels, in the narrow street, are then analyzed and compared, for the 4 source positions in the street. This experimental study gives interesting results on the behavior of the sound field in the street.

8:30**2aNS2. A scale model study of parallel urban street canyons.** Maarten Hornikx, Jens Forssen, and Wolfgang Kropp (Dept. of Appl. Acoust., Chalmers Univ. of Technol., S-412 96 Göteborg, Sweden)

The access to quiet areas in cities is of increasing importance. Recently, the equivalent sources method for a two dimensional situation of parallel urban street canyons has been developed. One canyon represents a busy road, whereas the other is one without traffic; the quiet side. With the model, the transfer function between the two canyons can be calculated, as well as the influence of diffusion, absorption, and atmospheric turbulence on the transfer function. A scale model study of two parallel canyons has now been executed. A scale of 1:40 has been chosen and the maximum length sequence technique has been applied using the MLSSA system. Results of the scale model study have been compared to calculations with the equivalent sources method. The difference between a two-dimensional and a three-dimensional quiet side, between a coherent and an incoherent line source and the influence of absorption and diffusion has been investigated. The scale model study also gives insight in the evolution of the sound field in the time domain. [Work supported by the Swedish Foundation for Strategic Environmental Research (MISTRA).]

8:55**2aNS3. The effect on sound propagation in streets of the distribution of acoustic scatterers on facades.** David J. Oldham and Mostafa R. Ismail (School of Architecture, Univ. of Liverpool, Liverpool, L69 3BX, UK, djoldham@liv.ac.uk)

Until recently street noise propagation models assumed that faade reflections were either totally specular or totally diffuse. However, the characteristics of building facades are such that some energy will be reflected specularly and some diffusely. Many current models, therefore, use a scattering coefficient to characterize the diffuse reflection characteristics and the assumption is made that a fraction of the sound energy falling on any point on the facade will be scattered to the same degree. From observation it can be seen that facades are not homogeneous but consist of surfaces which are planar in nature but feature discontinuities such as windows, doors, ledges, etc. which will tend to act as distributed scattering centers. The effect of distributions of scattering centers on the propagation of sound in streets is examined using a combined image source and randomly scattered sound rays. Computer generation of street models using an object based approach enables the study of many different configurations using RAYNOISE software. Results are compared with those obtained assuming a homogeneous distribution of facade scattering using both RAYNOISE and a technique proposed by the authors. The results of a scale model experiment to investigate the effect of distributed scatters are presented.

9:20**2aNS4. Recent advances in modeling the propagation noise in high-rise cities.** Kai Ming Li (Dept. Mech., The Hong Kong Polytechnic Univ., Hung Hom, Hong Kong)

In the past few decades, we have witnessed a rapid growth in mechanized transport and transportation systems. We live in a transport-dominated society which has led to a marked improvement in dispersal of land use and to the increased opportunity for the separate development of residential, commercial, and industrial areas. In dense and high-rise cities, various modes of land transpor-

tation are the primary source of noise. The problem of transportation noise is not confined by political or social frontiers. It affects the rich who may live in a quiet residential area but who must make full use of transport to maintain their affluent existence, as well as the less fortunate who must live close to a highway, a major road, or an elevated railway line. A systematic development of the capability for accurate predictions of the propagation of land transportation noise in dense high-rise cities is highly desirable. This paper summarizes the current models for predicting sound fields in urban environments and gives an overview of the recent advances of various numerical models to predict the sound field in urban environments. [Work supported by the Research Grants Council of the Hong Kong SAR Government and the Hong Kong Polytechnic University.]

10:00

2aNS5. Acoustic pulse propagation in an urban environment. Donald G. Albert (USA ERDC-CRREL, 72 Lyme Rd., Hanover, NH 03755-1290) and Lanbo Liu (USA ERDC-CRREL, Hanover, NH 03755-1290)

Experimental measurements conducted in a full-scale artificial village show that complex signatures are formed by multiple reflections and diffractions from buildings along the propagation path. A two-dimensional finite difference time domain (FDTD) simulation running on a personal computer allows this wave interaction to be studied in detail. Time reversal processing to locate a sound source in an urban area is investigated using this simulation method. The results demonstrate that as few as three non-line-of-sight sensors are sufficient to determine the source location, and that errors on the order of a meter in the building or sensor locations still allow the correct source location to be determined. 2aNS6. Sound field simulation and acoustic animation in urban squares. Jian Kang and Yan Meng (School of Architecture, Univ. of Sheffield, Western Bank, Sheffield S10 2TN, UK, j.kang@sheffield.ac.uk)

Urban squares are important components of cities, and the acoustic environment is important for their usability. While models and formulae for predicting the sound field in urban squares are important for their soundscape design and improvement, acoustic animation tools would be of great importance for designers as well as for public participation process, given that below a certain sound level, the soundscape evaluation depends mainly on the type of sounds rather than the loudness. This paper first briefly introduces acoustic simulation models developed for urban squares, as well as empirical formulae derived from a series of simulation. It then presents an acoustic animation tool currently being developed. In urban squares there are multiple dynamic sound sources, so that the computation time becomes a main concern. Nevertheless, the requirements for acoustic animation in urban squares are relatively low compared to auditoria. As a result, it is important to simplify the simulation process and algorithms. Based on a series of subjective tests in a virtual reality environment with various simulation parameters, a fast simulation method with acceptable accuracy has been explored. [Work supported by the European Commission.]

10:50

2aNS7. Modeling the characteristics of wheel/rail rolling noise. Wai Keung Lui, Kai Ming Li (Dept. of Mech. Eng., The Hong Kong Polytechnic Univ., Hung Hom, Hong Kong), and Glenn H. Frommer (MTR Corp. Ltd., Kowloon Bay, Hong Kong)

To study the sound radiation characteristics of a passing train, four sets of noise measurements for different train operational conditions have been conducted at three different sites, including ballast tracks at grade and railway on a concrete viaduct. The time histories computed by the horizontal radiation models were compared with the measured noise profiles. The measured sound exposure levels are used to deduce the vertical directivity pattern for different railway systems. It is found that the vertical directivity of different railway systems shows a rather similar pattern. The vertical directivity of train noise is shown to increase up to about $30\times$ before reducing to a minimum at 90° . A multipole expansion model is proposed to account for the vertical radiation directivity of the train noise. An empirical formula, which has been derived, compares well with the experimental data. The empirical model is found to be applicable to different train/rail systems at train speeds ranging up to 120 km/h in this study. 2aNS8. Microscopic traffic modelling in urban noise assessment. Bert De Coensel, Dick Botteldooren, Tom De Muer (Acoust. Group, Dept. of Information Technol., Ghent Univ., St. Pietersnieuwstraat 41, B-9000 Ghent, Belgium), Bert Peeters, and Gijsjan van Blokland (M+P Raadgevende Ingenieurs, NL-5260 CB Vught, The Netherlands)

The temporal structure of the urban soundscape can be rather complex, due to the presence of many screening and reflecting surfaces and many different sound sources, of which traffic noise is the most dominant. From the point of view of soundscape research, the background level as well as the time structure of noise peaks are important. However, these indicators

cannot be estimated easily by current noise prediction models, based on static traffic flows. Therefore, a dynamic traffic noise model was used, based on a microscopic traffic simulation. This way, individual vehicles can be traced, each having an associated set of noise sources that can depend on vehicle properties such as speed and acceleration, as well as on road properties such as the surface type. The model further consists of an ISO 9613 based propagation component, which can account for multiple reflections and diffractions. Maps of statistical noise levels, but also of more complicated measures reflecting the time structure of the soundscape, can be produced. This way, the soundscape contribution of single vehicles can be traced, as well as the influence of more general vehicle properties, such as the contribution of vehicle acceleration noise to the soundscape at junctions.

11:30

2aNS9. Increased damping in irregular resonators. Bernard Sapoval (Laboratoire de Physique de la Matière Condensée, Ecole Polytechnique, 91128 Palaiseau, France), Mark Asch (Université de Picardie Jules Verne, 80039 Amiens, France), Simon Felix, and Marcel Filoche (Ecole Polytechnique, 91128 Palaiseau, France)

The relation between shape and damping of shallow acoustical cavities has been studied numerically in the case where the dissipation occurs only on the cavity walls. It is first found that whatever the type of geometrical

irregularity, many, but not all the modes are localized. It is shown that the localization mechanism is what is called weak localization. The more irregular, the smaller the quality factors are found. However this effect is very different for the non-localized and the localized modes. For non-localized modes the damping increases roughly proportionally to the cavity surface. The localized modes are even more damped. These results generalize the results already obtained both numerically and experimentally on prefractal acoustical cavities. [B. Sapoval, O. Haeberle, and S. Russ, *J. Acoust. Soc. Am.* **102**, 2014–2019 (1997); B. Hebert, B. Sapoval, and S. Russ, *ibid.* **105**, 1567–1576 (1999)].

2aPA1. Infrasound associated with the 2004 Sumatra megathrust earthquake and tsunami. Milton Garces, Pierre Caron, and Claus Hetzer (Infrasound Lab., Univ. of Hawaii, Manoa, 73-4460 Queen Kaahumanu Hwy., #119, Kailua-Kona, HI 96740-2638)

Multiple infrasound arrays in the Pacific and Indian Oceans that are part of the International Monitoring System (IMS) observed three distinct waveform signatures associated with the December 26, 2004 Sumatra earthquake and tsunami. Infrasound station in Palau, Diego Garcia, Madagascar, and Kenya observed (1) seismic arrivals (P , S and surface) from the earthquake, (2) T -phases, propagated along SOFAR channel in the ocean, and coupled back to the ground, and (3) infrasonic arrivals associated with either the tsunami generation mechanism or the motion of the ground above sea level. All signals were recorded by the pressure sensors in the arrays. The seismic and T -phase recordings are due to the sensitivity of the MB2000 microbarometers to ground vibration, whereas the infrasound arrivals correspond to dispersed acoustic waves propagated through atmospheric waveguides. It appears that the arrival of the tsunami, as well as oceanic infragravity waves following the tsunami, were not observed by the infrasound stations. We show the prominent features of the arrivals, present source location estimates, discuss the absence of a signal associated with the tsunami arrival, and consider the potential for using infrasound as a discriminant for tsunami genesis.

8:20

2aPA2. Acoustic surveillance for hazardous eruptions (ASHE). David McCormack (Geological Survey of Canada, 7 Observatory Crescent, Ottawa, ON, Canada K1A 0Y3, cormack@seismo.nrcan.gc.ca), Henry Bass (Univ. of Mississippi, University, MS 38677), Milton Garces (Univ. of Hawaii, Manoa, Kailua-Kona, HI 96740-2638), and Hugo Yepes (Escuela Politcnica Nacional, Casilla 17-01-2759, Quito, Ecuador)

The potential of using infrasound to rapidly identify explosive volcanic eruptions has been discussed in the environmental acoustics and aviation safety communities for some time. The ability of sounds in the 0.01–10 Hz range to propagate for long distances with little attenuation suggests broad-area regional monitoring with a modest number of observing sites is possible. The ASHE experiment tests both the practical utility of infrasound as a regional-scale volcanic eruption detection tool, and the feasibility of using such an infrasound system to provide timely operational alerts to aviation through Volcanic Ash Advisory Centres (VAACs). Several infrasound arrays are deployed in a volcanic region, sending data in real time to a central detector, and onward to participating VAACs for comparison with existing warning systems. The ASHE experiment will determine if infrasound can complement both seismic and satellite observations to improve monitoring of volcanic hazard. Continuous acoustic surveillance can reduce the ambiguity between eruptive and purely seismic activity in an active volcano and provide additional estimates for the onset time of an eruption. The onset time estimates can be used as triggers for ash transport models.

8:40

2aPA3. Estimation of bolide energy using observed infrasound signals. Wayne N. Edwards (Dept. of Earth Sci., Univ. of Western Ontario, London, ON, Canada N6A 5B7), Peter G. Brown (Univ. of Western Ontario, London, ON, Canada N6A 3K7), and Douglas O. ReVelle (Los Alamos Natl. Lab., Los Alamos, New Mexico, 87545)

The acoustic amplitude-yield relationships including formal errors for a population of large and well-observed (greater than 0.05 kton) bolide events have been investigated. Using various signal measurements as a function of range, these data have been calibrated against optical yield estimates from satellite measurements. A correction for the presence of stratospheric winds has also been applied to the observations and is found to greatly improve the relationship correlation, remaining scatter may be due to variations amongst the fireball population such as differing burst altitudes, greater or lesser amounts of fragmentation or the variability in the magnitude of stratospheric winds, which can during certain times of the year be comparable to or exceed the strength of the winds themselves. Comparison to point source, ground-level nuclear and high explosive airwave data with similar yields shows that observed bolide infrasound is consistently lower in amplitude. This downward shift relative to nuclear and HE data is interpreted as due in part to increased weak nonlinearity during signal propagation from higher altitudes. This is a likely explanation, since mean estimates of the altitude of maximum energy deposition along the bolide trajectory was found to be between 20–30 km altitude for this fireball population.

9:00

2aPA4. Numerical acoustic wave propagation in the atmosphere. Lars Ceranna (BGR, B3.11, Hannover, Germany) and Alexis Le Pichon (CEA/DASE, Bruyeres-le-Chatel, France)

A method is presented which simulates the acoustic wave-field in the atmosphere using a Chebyshev pseudo spectral approach. The aero-acoustic equation of motion is solved in spherical coordinates. The computational time is significantly reduced by applying a rotationally symmetric approximation. Since the complete wave-field is calculated for the two-dimensional model the solution provides pictures of the pressure propagation from the source to the receiver. These images make it possible to study two effects in detail: How the sound and wind profiles affect the synthetic barograms for a fixed source, and in which way the source in space and time is reflected in the synthetic recordings for a stationary elastic model. Examples for both applications are shown where measured data are compared with synthetics. The recording at the German IMS station I26DE of the September 21, 2001, chemical explosion in Toulouse is considered as a benchmark for synthetic barograms calculated for two-dimensional profiles based on NRL-G2S and MSISE/HWM. In the second example the estimation of the source functions of super-sonic moving bodies is demonstrated. The synthetic waveforms are compared with the signals of two bolides recorded at the French IMS station I24FR at Tahiti from the December 1, 2003.

9:20

2aPA5. Contribution of infrasound monitoring for atmospheric investigations. Alexis Le Pichon (CEA/DASE, BP12, Bruyeres-le-Chatel 91680, France) and Doug Drob (Naval Res. Lab., Washington, DC 20375)

The French NDC currently receives data from a number of IMS-type infrasound stations. Continuous automatic processing of the data is being performed in the [0.02–4] Hz frequency band in order to detect and characterize coherent infrasonic waves. Known and quasi permanent infrasonic sources are needed to evaluate and improve upper-wind models. Microbaroms are detected throughout the year on a global scale. Their monitoring reveals clear periodic trends in the detected bearings, providing further confirmation that long-range propagation strongly depends on the atmospheric conditions, primarily on the seasonal variability of the zonal winds. Infrasounds generated by active volcanoes also offer a unique opportunity for atmospheric studies. Recent observations in Vanuatu (New-Hebrides Islands) covering one full year show a maximal peak-to-peak azimuth deviation of ~15. Infrasound observations are used as input of an inversion procedure to evaluate more precisely the vertical structure of the wind above the stratosphere in a range of altitude inaccessible to ground based or satellite measurements. With the increasing number of IMS stations being deployed, continuing systematic investigations into infrasonic signals from volcanoes will certainly help to advance the development of operational infrasound monitoring, and significant contributions to the understanding of atmospheric propagation could be expected.

9:40

2aPA6. Detecting and characterizing infrasound signals with optical fiber infrasound sensors. Kristoffer Walker, Mark Zumberge, Jonathan Berger, Michael Hedlin (Inst. of Geophys. and Planetary Phys., Scripps Inst. of Oceanogr., Univ. of California, San Diego, La Jolla, CA 92093-0225), and Stephen Arrowsmith (Univ. of California, San Diego, La Jolla, CA 92093-0225)

Optical Fiber Infrasound Sensors (OFIS) are long compliant tubes wrapped with two optical fibers that interferometrically measure the differential pressure variation along the length of the tube. Because each sensor averages spatially along the length of the tube, the frequency response of the recorded pressure variation is a function of the orientation of the OFIS sensor relative to the back azimuth and incidence angle of the incoming wave. We have exploited this property to investigate the ability of various OFIS geometries to determine the back azimuth of infrasound signals. We have found that an OFIS comprised of two orthogonal 89-m-long arms having their centers separated by 63 m can resolve the back azimuth of most infrasound signals with a good signal-to-noise ratio. We find a good match between the back azimuths determined with our technique and those determined for the same signals recorded on the co-located pipe array I57US with the Progressive Multichannel Cross-Correlation technique. Based on these results and additional synthetic tests, we have built and are testing a larger OFIS with several arms that will be able to resolve signals from all directions and with small signal-to-noise ratios.

2aPA7. Listening to shower meteors with infrasound. Wayne N. Edwards (Dept. of Earth Sci., Univ. of Western Ontario, London, ON, Canada N6A 5B7), Peter G. Brown (Univ. of Western Ontario, London, ON, Canada N6A 3K7), Pavel Spurny (Astronomical Inst. of the Acad. of Sci. of the Czech Republic, Czech Republic), and Douglas O. ReVelle (Los Alamos Natl. Lab., Los Alamos, NM 87545)

Observations of the Leonid and Perseid meteor showers over the last few years in Europe using multiple camera systems, including the European Fireball Camera Network, have shown several bright meteors (abs. magnitudes -8 to -16) passing nearby to the IMS infrasound array in Freyung, Germany (I26DE). Subsequent checks of I26DE data show that these meteors were also detected infrasonically. This combination of optical location of the meteor in flight and microbarometer array beamforming has provided an excellent opportunity to delimit the altitudes at which these infrasound signals are being generated. UKMO temperature and wind data from the UARS satellite has been combined with MSIS and HWM models to reconstruct the acoustic velocity conditions present during observations. Using the reconstructed conditions, geometric ray tracing indicates that the source altitudes lie between approximately 80 to 105 kilometers; array back-azimuths appear to confirm this conclusion. This is extraordinary since meteoroids of this size, at these altitudes in the atmosphere, are in the transitional region from free-molecular flow to continuum flow. With these observations there is now confirmed infrasound from three separate meteor showers; the Leonids, Geminids and Perseids, meaning that meteor shower infrasound is much more common than previously thought.

10:45

2aPA8. Infrasound remote sensing of the upper atmosphere. Douglas Drob, Micheal Picone (E.O. Hulburt Ctr. for Space Res., Naval Res. Lab., 4555 Overlook Ave., Washington, DC 20375), and Robert Meier (School of Computational Sci., Fairfax, VA 22030)

We investigate the prospects for utilizing infrasound signals from geophysical sources to improve our knowledge of upper atmospheric winds and temperatures. We present results from numerical experiments designed to quantify the statistical performance of an idealized infrasonic upper atmospheric remote sensing network over a range of propagation modeling assumptions, source types, and geophysical variables. For a series of hypothetical events, infrasonic observables are calculated with a spherical 3-D ray tracer and series of atmospheric profiles spanning the range of geophysical parameters. These synthetic measurements are then inverted to estimate the original atmospheric background fields. A nonlinear least-squares estimation procedure that accounts for uncertainties in both the dependent and independent variables is used. The retrieved atmospheric profiles are represented by a set of truncated empirical orthogonal functions to incorporate *a priori* knowledge of atmospheric structure and reduce the number of parameters. Our numerical experiments indicate that it is indeed possible to make meaningful estimates of upper atmospheric environmental profiles with today's infrasound networks. [Work supported by the Office Naval Research.]

11:00

2aPA9. Scattering of sound and infrasound waves by internal gravity waves in the atmosphere. Vladimir E. Ostashev (NOAA/ETL 325 Broadway, Boulder, CO 80305 and Phys. Dept., New Mexico State Univ., Las Cruces, NM 88003), Igor P. Chunchuzov (Obukhov Inst. of Atmospheric Phys., Moscow, Russia), and D. Keith Wilson (U.S. Army Engineer Res. and Development Ctr., Hanover, NH 03755)

Internal gravity waves (IGW) propagating in the atmosphere produce highly anisotropic fluctuations in temperature and wind velocity that are stretched in a horizontal direction. These fluctuations can significantly affect sound propagation in a night-time boundary layer and infrasound

propagation in the stratosphere. In this paper, 3-D spectra of temperature and wind velocity fluctuations due to IGW, recently derived in the literature for the limiting case of large wave numbers, are generalized to account for small wave numbers. The generalized 3-D spectra are then used for development of a theory of sound propagation through and scattering by IGW. First, the sound scattering cross-section due to IGW is calculated. It is shown that the dependence of this scattering cross-section on parameters of the problem (the scattering angle, sound frequency, etc.) is qualitatively different from that for the case of sound scattering by isotropic turbulence. Second, the mean sound field and the transverse coherence function of a plane sound wave propagating in the atmosphere with IGW are calculated and compared with those for sound propagating through isotropic turbulence. [Work supported by ARO, Grant DAAD19-01-1-0640, and RFBR, Grant 03-05-04001.]

11:15

2aPA10. Parabolic equation (PE) model approximations and implications for infrasound. David E. Norris (BBN Technologies, 1300 N. 17th St., Ste. 400, Arlington, VA 22209, dnorris@bbn.com)

The continuous-wave parabolic equation (PE) model is widely used in the prediction of atmospheric propagation. In this study, the effects of several PE approximations are evaluated in the context of long-range infrasonic propagation. Specifically, the focus is on quantifying: phase errors resulting from different split-step Fourier (SSF) implementations, solution stability with respect to step size, and prediction sensitivity to the choice of reference sound speed. The tradeoff between improved performance gain and increased computational loading will also be considered. The study will include comparison of PE waveform predictions with measurements from infrasonic events. These comparisons are of interest in assessing the PE modeling performance, applicability, and limitations. Waveform predictions are made by integrating the continuous-wave PE model into a Fourier-synthesis Time-domain PE (TDPE).

11:30

2aPA11. Modeling volcanic infrasound propagation using the parabolic equation. Geoffrey F. Edelmann, Douglas P. Drob, Joseph F. Lingeitch, Michael D. Collins (Naval Res. Lab., 4555 Overlook Ave. SW, Washington DC, 20375), and Alexis Le Pichon (CEA/DASE BP12, 91680 Bruyeres-le Chatel, France)

Infrasound originating from volcanic sources in the 1–4 Hz range is detectable at long ranges by remote monitoring stations. The effects of wind, in addition to the atmospheric sound speed, is non-negligible for the propagation of these signals. Recent developments in parabolic equation (PE) methods are applicable to infrasonic propagation where both wide-angles and high-Mach number atmospheric flows are important. We apply this model to infrasonic data measured from volcanoes in the Archipelago of Vanuatu in Oceania (e.g., LePichon *et al.*, 2005), as well as other potentially active volcanoes. The diurnal variations and seasonal variations in measured pressure amplitudes are modeled in the context of recent multi-year observations of volcanic infrasound. The significance of upper atmospheric tidal amplitudes, range dependence, and prevailing gravity waves structure in these calculations are also considered. [Work supported by ONR.]

11:45

2aPA12. Use of improved propagation models to investigate novel infrasound signals. Joydeep Bhattacharyya and Robert Gibson (BBN Technologies, 1300 N. 17th St., #400, Arlington, VA 22209, joydeep@bbn.com)

The recent availability of improved infrasound propagation modeling tools and the installation of infrasound arrays in regions of sparse cover-

age provide new opportunities for analysis of rare signals. Analyses are presented resulting from recent natural and manmade events, and insights are discussed. Events of interest include the train explosion in Iran of February 18, 2004 and the South Asian tsunami event of December 26, 2004. Using near-real-time environmental profiles and infrasound propa-

gation models, it is shown that the predicted travel times, azimuth deviation and signal duration closely match the observed values. As the dataset of such events is small, predictive modeling can be a valuable tool in developing detection strategies for such events and may ultimately lead to a decreased incidence of false alarms in global monitoring.

2aPP1. Spectral integration in speech and non-speech sounds. Ewa Jacewicz (Dept. Speech and Hearing Sci., Ohio State Univ., Columbus, OH 43210-1002)

Spectral integration (or formant averaging) was proposed in vowel perception research to account for the observation that a reduction of the intensity of one of two closely spaced formants (as in /u/) produced a predictable shift in vowel quality [Delattre *et al.*, *Word* **8**, 195–210 (1952)]. A related observation was reported in psychoacoustics, indicating that when the components of a two-tone periodic complex differ in amplitude and frequency, its perceived pitch is shifted toward that of the more intense tone [Helmholtz, *App. XIV* (1875/1948)]. Subsequent research in both fields focused on the frequency interval that separates these two spectral components, in an attempt to determine the size of the bandwidth for spectral integration to occur. This talk will review the accumulated evidence for and against spectral integration within the hypothesized limit of 3.5 Bark for static and dynamic signals in speech perception and psychoacoustics. Based on similarities in the processing of speech and non-speech sounds, it is suggested that spectral integration may reflect a general property of the auditory system. A larger frequency bandwidth, possibly close to 3.5 Bark, may be utilized in integrating acoustic information, including speech, complex signals, or sound quality of a violin.

9:25

2aPP2. The dispersion-focalization theory of sound systems. Jean-Luc Schwartz, Christian Abry, Louis-Jean Boë, Nathalie Vallée (Institut de la Commun. Parlée, UMR 5009 CNRS, INPG, Université Stendhal, 46 Av. Félix Viallet, 38031 Grenoble Cedex 1, France), and Lucie Ménard (Univ. du Québec à Montréal, Montréal, Canada H3C 3P8)

The Dispersion-Focalization Theory states that sound systems in human languages are shaped by two major perceptual constraints: dispersion driving auditory contrast towards maximal or sufficient values [B. Lindblom, *J. Phonetics* **18**, 135–152 (1990)] and focalization driving auditory spectra towards patterns with close neighboring formants. Dispersion is computed from the sum of the inverse squared inter-spectra distances in the (F_1 , F_2 , F_3 , F_4) space, using a non-linear process based on the 3.5 Bark critical distance to estimate F_2' . Focalization is based on the idea that close neighboring formants produce vowel spectra with marked peaks, easier to process and memorize in the auditory system. Evidence for increased stability of focal vowels in short-term memory was provided in a discrimination experiment on adult French subjects [J. L. Schwartz and P. Escudier, *Speech Comm.* **8**, 235–259 (1989)]. A reanalysis of infant discrimination data shows that focalization could well be the responsible for recurrent discrimination asymmetries [J. L. Schwartz *et al.*, *Speech Comm.* (in press)]. Recent data about children vowel production indicate that focalization seems to be part of the perceptual templates driving speech development. The Dispersion-Focalization Theory produces valid predictions for both vowel and consonant systems, in relation with available databases of human languages inventories.

9:45

2aPP3. Exploring the role of spectral integration in the perception of vowel sounds. Randy L. Diehl (Dept. of Psych. and Ctr. for Perceptual Systems, Univ. of Texas, Austin, TX 78712)

Building on the important work of Chistovich and Lublinskaya [Hearing Res. **1**, 185–195 (1979)], Syrdal [Speech Commun. **4**, 121–135 (1985)] proposed that vowel category boundaries tend to occur in quantal regions corresponding to a 3.5 Bark bandwidth of spectral integration. This proposal was shown to be consistent with acoustic distributions of certain American English vowels. Some initial perceptual results [K. A. Hoemeke and R. L. Diehl, *J. Acoust. Soc. Am.* **96**, 661–674 (1994)] also tended to support the role

of a 3.5 Bark integrator in determining major perceptual boundaries among vowel categories. However, other evidence, reviewed here, raises doubts about the generality of Syrdal's proposal. The negative evidence includes both within- and cross-language variation in the location of vowel category boundaries assumed to be governed by the 3.5 Bark integrator and the absence of elevated discriminability in putative quantal regions corresponding to the spectral limit of integration. [Work supported by NIDCD.]

10:05–10:20 Break

10:20

2aPP4. Similarities and differences in the perception of formant frequency transitions and center-of-gravity glides. Valentina Lublinskaja (Pavlov Inst. of Physiol., Russian Acad. of Sci., Makarova nab. 6, St.-Petersburg, 199034, Russia, valub@infran.ru)

In Lublinskaja (1996) the spectral “center-of-gravity” (COG) effect was observed in the identification of synthetic vowels in which the amplitude ratio of F_2 and F_3 was gradually changed in time, formant frequencies being constant. The stimuli with such virtual formant transitions (VT) were perceived as diphthong-like Russian vowels when $F_3 - F_2 < 4.5$ Bark. Within this $F_3 - F_2$ frequency separation, the stimuli with the dynamic perceptual formant (F_2^*) were identified as their equivalent vowels with real F_2 and F_3 transitions (FT). But the perception of both types of transitions was not identical. Generally, the VT signals were less salient than FT. Within smaller $F_2 - F_3$ separations ($F_2^* = 1.68$ Bark), the VT signals were first identified with 100%-accuracy as diphthong-like vowels and with larger F_2^* the glide transitions were gradually less perceptible. With separations $F_3 - F_2 > 4.5$ Bark the VT stimuli were identified as stationary vowels, and listeners' decisions were based on terminal values of F_2^* . Reduced salience of VT glides relative to FM tones was also reported for non-speech signals [Dawson and Feth, ARLO 5, 95–99 (2004)]. The talk will discuss possible mechanisms for why VT signals are less perceptually prominent than FT sounds.

10:40

2aPP5. Spectral integration in the processing of dynamic place cues for stops. Robert Allen Fox and Marc Smith (Dept. Speech and Hearing Sci., Ohio State Univ., Columbus, OH 43210-1002)

Chistovich and her colleagues have proposed the spectral “center-of-gravity” (COG) hypothesis suggesting that for static signals (such as steady-state vowels) spectral integration of two or more formant peaks may occur over a range of 3.5 Bark. More recently, studies have examined dynamic COG effects by modifying the amplitude of formants in time in order to create diphthong percepts. This presentation will review data demonstrating the COG effect in the processing of dynamic cues to place of articulation in stops in both voiced [da]-[ga] and voiceless [ta]-[ka] series. By changing only the amplitudes over time of a pair of sinewaves (in [da]-[ga]) or a pair of narrow band noise signals (in [ta]-[ka]) a “virtual F_3 glide” can be created which can serve to signal the alveolar-velar place distinction. If these signals are played to listeners without being inserted into a base token, they are heard simply as frequency glides and not as two separate tones. Listener identification and discrimination responses to CV tokens with virtual and real F_3 frequency transitions show similar overall patterns, but virtual transitions are less salient place cues than real transitions. An auditory model incorporating the dynamic COG effect will be described.

11:00

2aPP6. Auditory spectral integration of dynamic signals. Lawrence Feth (Dept. of Speech and Hearing Sci., Ohio State Univ., Columbus, OH 43210, feth.1@osu.edu), Ashok Krishnamurthy, and Daniel Hack (Ohio State Univ., Columbus, OH 43210)

Auditory spectral integration often refers to the ability of the auditory system to sum information across a wide frequency range to improve the detectability of a supra-critical bandwidth signal in a masking experiment. However, in other paradigms, the spectral components of these broad bandwidth signals can be resolved by auditory system. These findings lead to a resolution versus integration paradox for the frequency domain similar to the resolution versus integration paradox in the time domain that led to the multiple-looks hypothesis [N. F. Viemeister and G. H. Wakefield, J. Acoust. Soc. Am., 90, 858–865 (1991)]. In speech, spectral integration refers to finding that two or more resonance peaks in a synthetic vowel can be approximated by a single peak located at the spectral center-of-gravity (COG). In 1996, Lublinskaja demonstrated that changing the COG of a two-resonance signal over time leads listeners to hear a virtual frequency transition that follows the dynamic COG. Dynamic signals may require the auditory system to take multiple looks in both time and frequency. This talk will present a series of psychoacoustic experiments using dynamic signals and a computational model that incorporates peripheral auditory processing and a modification of the PSC model.

11:20

2aPP7. Difference between diotic and dichotic presentations on audiovisual synchronization. Rie Nakamura and Kiyooki Aikawa (School of Media Sci., Tokyo Univ. of Technol., 1404-1 Katakuracho, Hachioji, Tokyo 192-0982, Japan, aik@media.teu.ac.jp)

Significant differences were found between diotic and dichotic presentations of auditory stimuli on audiovisual synchronization. Two types of moving sphere were used for visual stimuli; (a) a sphere moved straight from left to right at a constant velocity, and (b) it moved up and right and then turned down and right at the midpoint. Auditory stimuli included (1) a continuous pure tone (1000 Hz), (2) a sequence of two short tones of 30

ms (1000 Hz), (3) a sweep tone (500 Hz → 1500 Hz), and (4) a Frequency-Modulated tone (500 Hz → 1500 Hz → 500 Hz). The duration of these stimuli was 240 ms each. Visual stimuli were presented on a Liquid-Crystal Display. Auditory stimuli were presented by headphones. The time difference between auditory and visual stimuli was changed between –360 ms and +360 ms. The sound source linearly moved from left to right in case of dichotic presentation. Subjective tests, using the forced-choice of synchronized or not, clarified the significant differences between diotic and dichotic presentations when the auditory stimulus (1) or (4) was presented with the visual stimulus (b). No significance was obtained for other combinations of auditory and visual stimuli. [Work supported by NTT.]

2aPP8. Frequency band-importance functions for auditory and auditory-visual speech recognition. Ken W. Grant (Walter Reed Army Medical Ctr., Army Audiol. and Speech Ctr., Washington, DC 20307-5001)

In many everyday listening environments, speech communication involves the integration of both acoustic and visual speech cues. This is especially true in noisy and reverberant environments where the speech signal is highly degraded, or when the listener has a hearing impairment. Understanding the mechanisms involved in auditory-visual integration is a primary interest of this work. Of particular interest is whether listeners are able to allocate their attention to various frequency regions of the speech signal differently under auditory-visual conditions and auditory-alone con-

ditions. For auditory speech recognition, the most important frequency regions tend to be around 1500–3000 Hz, corresponding roughly to important acoustic cues for place of articulation. The purpose of this study is to determine the most important frequency region under auditory-visual speech conditions. Frequency band-importance functions for auditory and auditory-visual conditions were obtained by having subjects identify speech tokens under conditions where the speech-to-noise ratio of different parts of the speech spectrum is independently and randomly varied on every trial. Point biserial correlations were computed for each separate spectral region and the normalized correlations are interpreted as weights indicating the importance of each region. Relations among frequency-importance functions for auditory and auditory-visual conditions will be discussed.

TUESDAY MORNING, 17 MAY 2005

REGENCY D, 8:00 A.M. TO 12:00 NOON

Session 2aSC

Speech Communication: Language Acquisition, Bilingual Studies and Category Learning (Poster Session)

Murray J. Munro, Chair

Dept. of Linguistics, Simon Fraser Univ., 8888 University Dr., Burnaby, BC V5A 1S6, Canada

Contributed Papers

All posters will be on display from 8:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:00 a.m. to 10:00 a.m. and contributors of even-numbered papers will be at their posters from 10:00 a.m. to 12:00 noon.

2aSC1. L1 literacy affects L2 pronunciation intake and text vocalization. Martin Walton (Dept. Langues, Université Montesquieu Bordeaux 4, Ave. Léon Duguit, 33608 PESSAC Cedex, France)

For both deaf and hearing learners, L1 acquisition calls on auditive, gestural and visual modes in progressive processes over longer stages imposed in strictly anatomical and social order from the earliest pre-lexical phase [Jusczyk (1993), Kuhl & Meltzoff (1996)] to ultimate literacy. By contrast, L2 learning will call on accelerating procedures but with restricted input, arbitrated by L1 literacy as can be traced in the English of French-speaking learners, whether observed in spontaneous speech or in text vocalization modes. An inventory of their predictable omissions, intrusions and substitutions at suprasegmental and syllabic levels, many of which they can actually hear while unable to vocalize in real-time, suggests that a photogenic segmentation of continuous speech into alphabetical units has eclipsed the indispensable earlier phonogenic module, filtering L2 intake and output. This competing mode analysis hypothesizes a critical effect on L2 pronunciation of L1 graphemic procedures acquired usually before puberty, informing data for any Critical Period Hypothesis or amounts of L1 activation influencing L2 accent [Flege (1997, 1998)] or any psychoacoustic French deafness with regard to English stress-timing [Dupoux (1997)]. A metaphonic model [Howell & Dean (1991)] adapted for French learners may remedially distance L1 from L2 vocalization procedures.

2aSC2. Lexical representation of novel L2 contrasts. Rachel Hayes-Harb (Dept. of Linguist., Univ. of Utah, 255 S. Central Campus Dr., Rm. 2328, Salt Lake City, UT 84112-0492, hayes-harb@linguistics.utah.edu) and Kyoko Masuda (Georgia Inst. of Technol., Atlanta, GA 30332-0375)

There is much interest among psychologists and linguists in the influence of the native language sound system on the acquisition of second languages (Best, 1995; Flege, 1995). Most studies of second language

(L2) speech focus on how learners perceive and produce L2 sounds, but we know of only two that have considered how novel sound contrasts are encoded in learners' lexical representations of L2 words (Pallier *et al.*, 2001; Ota *et al.*, 2002). In this study we investigated how native speakers of English encode Japanese consonant quantity contrasts in their developing Japanese lexicons at different stages of acquisition (Japanese contrasts singleton versus geminate consonants but English does not). Monolingual English speakers, native English speakers learning Japanese for one year, and native speakers of Japanese were taught a set of Japanese nonwords containing singleton and geminate consonants. Subjects then performed memory tasks eliciting perception and production data to determine whether they encoded the Japanese consonant quantity contrast lexically. Overall accuracy in these tasks was a function of Japanese language experience, and acoustic analysis of the production data revealed non-native-like patterns of differentiation of singleton and geminate consonants among the L2 learners of Japanese. Implications for theories of L2 speech are discussed.

2aSC3. L2 use and stimulus complexity in perceived accent ratings. Astrid Zerla Doty, Ruth Huntley Bahr (Dept. of Commun. Sci. and Disord., Univ. of South Florida, PCD 1017, 4202 E. Fowler Ave., Tampa, FL 33620, rbahr@chuma1.cas.usf.edu), and Judith Becker Bryant (Univ. of South Florida, Tampa, FL 33620)

Listener perception of accentedness has been shown to be influenced by experience with L2 (measured by length of residence in US). However, frequency of L1 use and degree of linguistic complexity (defined by the number of non-native phonetic features targeted) may provide more insight into the role of experience in the perception of accentedness. Three groups of listeners (monolingual English and Spanish [L1] speakers divided into two groups of high and low use of English [L2]) rated the accentedness of bilingual speakers who spoke with varying degrees of accentedness. The speakers read sentences adapted from Magan (1998) to

include linguistic aspects likely to be difficult for native Spanish speakers. Listeners performed similarly in rating speakers degree of accent. Amount of daily L1 use only influenced the ratings of the slightly accented group; the high-use bilingual group rated these speakers as more accented than the native English group, regardless of level of linguistic difficulty. These results suggest that the high-use groups lack of L2 experience made them less perceptually sensitive to certain phonetic features of English. Because speakers did not make the predicted target errors, the listener groups may have based their ratings on features not targeted in this investigation.

2aSC4. Training for learning Mandarin tones: A comparison of production and perceptual training. Xinchun Wang (Dept. of Linguist., California State Univ., Fresno, 5245 N. Backer Ave., M/S PB 92, Fresno, CA 93740)

Mandarin Chinese lexical tones pose difficulties for non-native speakers whose first languages contrast or do not contrast lexical tones. In this study, both tone language and non-tone language speaking learners of Mandarin Chinese were trained for three weeks to identify the four Mandarin lexical tones. One group took the production training with both visual and audio feedback using Kay Sona Speech II software. The target tones produced by native Mandarin speakers were played back through a pair of headphones and the pitch contours of the target tones were displayed on the computer screen on the top window to be compared with the trainees productions which appear in real time in the bottom window. Another group of participants took the perceptual training only with four-way forced choice identification tasks with immediate feedback. The same training tokens were used in both training modes. Pretest and post test data in perception and production were collected from both groups and were compared for effectiveness of training procedures.

2aSC5. Production quality of /r/ and /l/ liquids among Cantonese and Mandarin ESL learners. Donald Derrick (Dept. of Linguist., Univ. of British Columbia, 1866 Main Mall, Buchanan E270, UBC, Vancouver, BC, Canada V6T 1Z1, dderrick@interchange.ubc.ca)

Perceptual interference theories suggest L2 language learners produce phonemes based on their native language phonology (Iverson *et al.*, 2004, Cognition). This present study investigated the impact of differing native language segmental inventories on the acquisition of the English r/l contrast. Northern Mandarin dialects exhibit coda /r/ similar to the English bunched /r/, while Cantonese exhibits no r-like liquids (Gick *et al.*, 2003, under review). The Mandarin segmental inventory provides more of a basis for acquiring the English r/l contrast than the Cantonese inventory. It is therefore predicted that Mandarin speakers will acquire the r/l contrast with a lower level of experience with English than the Cantonese speakers. One Cantonese and two Mandarin ESL learners produced r/l sounds in minimally contrastive English words in simple and complex onset, coda, and intervocalic positions. The data were analyzed in two ways. Four native English listeners were asked to judge for each word whether the target consonant was /r/ or /l/. Also, ultrasound tongue images were analyzed for component /r/ and /l/ gestures. Results provided partial support for the hypothesis. Implications for theories of second language acquisition will be discussed.

2aSC6. Native and non-native perception of phonemic length contrasts in Japanese: Effects of speaking rate and presentation context. Amanda Wilson, Hiroaki Kato (ATR Human Information Sci. Labs., Kyoto 619-0288, Japan, kato@atr.jp), and Keiichi Tajima (Hosei Univ., Tokyo 102-8160, Japan)

Japanese words can be distinguished by the length of phonemes, e.g., “chizu” (map) versus “chiizu” (cheese). Perceiving these length contrasts is therefore important for learning Japanese as a second language. The present study examined native English listeners’ perception of length contrasts at different speaking rates and in different contexts. Stimuli con-

sisted of 20 Japanese word pairs that minimally contrasted in vowel length, and 10 synthesized nonwords. The nonwords were created by modifying the duration of the second vowel of the nonword “erete” along a continuum (from “erete” to “ereete”). Stimuli were presented with or without a carrier sentence at three rates (fast, normal, slow). Rate was either fixed or randomized trial by trial. Sixteen native English and 16 native Japanese listeners participated in a single-stimulus, two-alternative forced-choice identification task. Results suggest that native Japanese listeners’ identification boundaries systematically shifted due to changes in speaking rate when the stimuli were in the context of a sentence with mixed rates of presentation. In contrast, native English listeners show a shift in the opposite direction, suggesting that they did not follow the variation in speaking rate. These results will be discussed from the viewpoint of training second-language phoneme perception. [Work supported by JSPS.]

2aSC7. Children’s abilities to distinguish novel languages. Z. S. Bond and Verna Stockmal (Dept. of Linguist., Ohio Univ., Athens, OH 45701)

When adults hear spoken samples of a language which they do not know, they can often identify it and discriminate between languages even when produced by the same talkers. Children have much less experience making metalinguistic judgments. How do children respond to languages which they do not know? We have conducted three experiments examining the abilities of 4-year old and 8-year old children to discriminate between spoken samples of different languages produced by bilingual talkers. We constructed listening tests from 5-second phrases excerpted from fluent reading provided by the talkers. In the three experiments, we progressively simplified the response mode employed by the children as well as the cognitive load of the task. Even in the simplest version, only a third of the 4-year-olds could do the task while the 8-year old children performed above chance in all three experiments. The younger children tended to respond different more than same, as if their criterion for same was identify.

2aSC8. Innovative /ye/ and /we/ sequences in recent loans in Japanese. Timothy Vance and Yuka Matsugu (Univ. of Arizona, East Asian Studies, P.O. Box 210105, Tucson, AZ 85721-0105)

The GV sequences /ye/ and /we/ do not occur in Japanese except perhaps in recent loans. Katakana spellings of the relevant loans in authoritative dictionaries are inconsistent, and it is not clear whether native speakers treat them as containing the GV sequences /ye/ and /we/ or as containing the VV sequences /ie/ and /ue/. Native speakers of Japanese with minimal exposure to spoken English were recorded producing some relevant loans in response to picture prompts. The same speakers were also recorded producing some native words containing uncontroversial /ie/ and /ue/ sequences. All the productions are being analyzed acoustically to determine whether they show the expected contrast between GV and VV sequences. A VV sequence is disyllabic (and bimoraic) and should therefore have greater duration and more gradual formant movements than a monosyllabic (and monomoraic) GV sequence. Utterance-initially, a VV sequence should have a LH pitch pattern and should be preceded by a nondistinctive glottal stop, whereas a GV sequence should have a H pitch pattern and should have smooth onset.

2aSC9. Categorization of speech sounds by Norwegian/English bilinguals. Audny T. Dypvik and Elzbieta B. Slawinski (Psych. Dept., Univ. of Calgary, 2500 University Dr., Calgary, AB, Canada T2N 1N4, atdypvik@ucalgary.ca)

Bilinguals who learned English late in life (late bilinguals) as opposed to those who learned English early in life (early bilinguals) differ in their perception of phonemic distinctions. Age of acquisition of a second language as well as depth of immersion into English is influenced by perceptual differences of phonemic contrasts between monolinguals and bilin-

guals, with consequences for speech production. The phonemes /v/ and /w/ are from the same category in Norwegian, rendering them perceptually indistinguishable to the native Norwegian listener. In English, /v/ and /w/ occupy two categories. Psychoacoustic testing on this phonemic distinction in the current study will compare perceptual abilities of monolingual English and bilingual Norwegian/English listeners. Preliminary data indicates that Norwegian/English bilinguals demonstrate varying perceptual abilities for this phonemic distinction. A series of speech sounds have been generated by an articulatory synthesizer, the Tube Resonance Model, along a continuum between the postures of /v/ and /w/. They will be presented binaurally over headphones in an anechoic chamber at a sound pressure level of 75 dB. Differences in the perception of the categorical boundary between /v/ and /w/ among English monolinguals and Norwegian/English bilinguals will be further delineated.

2aSC10. Perception of coarticulated tones by non-native listeners.

Tessa Bent (2016 Sheridan Rd., Evanston, IL 60208, t-bent@northwestern.edu)

Mandarin lexical tones vary in their acoustic realization depending on the surrounding context. Native listeners compensate for this tonal coarticulation when identifying tones in context. This study investigated how native English listeners handle tonal coarticulation by testing native English and Mandarin listeners discrimination of the four Mandarin lexical tones in tri-syllabic sequences in which the middle tone varied while the first and last tones were held constant. Three different such frames were tested. As expected, Mandarin listeners discriminated all pairs in all contexts with a high degree of accuracy. English listeners exhibited poorer discrimination than Mandarin listeners and their discrimination accuracy showed a high degree of context dependency. In addition to assessing accuracy, reaction times to correctly discriminated different trials were entered into a multidimensional scaling analysis. For both listener groups, the arrangement of tones in perceptual space varied depending on the surrounding context suggesting that listeners attend to different acoustic attributes of the target tone depending on the surrounding tones. These results demonstrate the importance for models of cross-language speech perception of including contextual variation when characterizing the perception of non-native prosodic categories. [Work supported by NIH/NIDCD]

2aSC11. Plasticity in speech production and perception: A study of accent change in young adults.

Bronwen G. Evans and Paul Iverson (Dept. of Phonet. and Linguist., Univ. College London, Wolfson House, 4, Stephenson Way, London, NW1 2HE, UK bron@phon.ucl.ac.uk)

This study investigated plasticity in speech production and perception among university students, as individuals change their accent from regional to educated norms. Subjects were tested before beginning university, 3 months later and on completion of their first year of study. At each stage they were recorded reading a set of test words and a short passage. They also completed two perceptual tasks; they found best exemplar locations for vowels embedded in carrier sentences and identified words in noise. The results demonstrated that subjects changed their spoken accent after attending university. The changes were linked to sociolinguistic factors; subjects who were highly motivated to fit in with their university community changed their accent more. There was some evidence for a link between production and perception; between-subject differences in production and perception were correlated. However, this relationship was weaker for within-subject changes in accent over time. The results suggest that there were limitations in the ability of these subjects to acquire new phonological rules.

2aSC12. Articulatory settings of French-English bilingual speakers.

Ian Wilson (Dept. of Linguist., Univ. of British Columbia, 1866 Main Mall, Buchanan E270, Vancouver, BC, Canada V6T 1Z1, ilwilson@interchange.ubc.ca)

The idea of a language-specific articulatory setting (AS), an underlying posture of the articulators during speech, has existed for centuries [Laver, *Historiogr. Ling.* 5 (1978)], but until recently it had eluded direct measurement. In an analysis of x-ray movies of French and English monolingual speakers, Gick *et al.* [Phonetica (in press)] link AS to inter-speech posture, allowing measurement of AS without interference from segmental targets during speech, and they give quantitative evidence showing AS to be language-specific. In the present study, ultrasound and Optotrak are used to investigate whether bilingual English-French speakers have two ASs, and whether this varies depending on the mode (monolingual or bilingual) these speakers are in. Specifically, for inter-speech posture of the lips, lip aperture and protrusion are measured using Optotrak. For inter-speech posture of the tongue, tongue root retraction, tongue body and tongue tip height are measured using optically-corrected ultrasound. Segmental context is balanced across the two languages ensuring that the sets of sounds before and after an inter-speech posture are consistent across languages. By testing bilingual speakers, vocal tract morphology across languages is controlled for. Results have implications for L2 acquisition, specifically the teaching and acquisition of pronunciation.

2aSC13. Paired variability indices in assessing speech rhythm in Spanish/English bilingual language acquisition.

Richard Work, Jean Andruski, Eugenia Casielles, Sahyang Kim (Wayne State Univ., Detroit, MI 48202), and Geoff Nathan (Wayne State Univ., Detroit, MI 48202)

Traditionally, English is classified as a stress-timed language while Spanish is classified as syllable-timed. Examining the contrasting development of rhythmic patterns in bilingual first language acquisition should provide information on how this differentiation takes place. As part of a longitudinal study, speech samples were taken of a Spanish/English bilingual child of Argentinean parents living in the Midwestern United States between the ages of 1;8 and 3;2. Spanish is spoken at home and English input comes primarily from an English day care the child attends 5 days a week. The parents act as interlocutors for Spanish recordings with a native speaker interacting with the child for the English recordings. Following the work of Grabe, Post and Watson (1999) and Grabe and Low (2002) a normalized Pairwise Variability Index (PVI) is used which compares, in utterances of minimally four syllables, the durations of vocalic intervals in successive syllables. Comparisons are then made between the rhythmic patterns of the child's productions within each language over time and between languages at comparable MLUs. Comparisons are also made with the rhythmic patterns of the adult productions of each language. Results will be analyzed for signs of native speaker-like rhythmic production in the child.

2aSC14. Recognition of function words in 8-month-old French-learning infants.

Rushen Shi and Bruno Gauthier (Dept. of Psych., Univ. of Quebec in Montreal, C.P. 8888, Succ. Ctr.-Ville, Montreal, QC, Canada H3C 3P8)

Previous work has shown that German-learning 7-9-month-old infants recognize function words (Hoehle and Weissenborn, 2003). English-learning infants recognize function words around 10.5-11 months (Schafer *et al.* 1998; Shady, 1996; Shi *et al.*, 2003, 2004), and the highly frequent determiner "the" at 8 months (Shi *et al.*, 2004). The present study investigates French-learning infants' recognition of function words. As French is a syllable-timing language, the fuller syllabic status may allow infants to recognize function words earlier than English-learning infants. Syntactically and morphologically, functional elements occur more systematically in French than in English, providing reliable statistical cues to functor segmentation. Using a preferential looking procedure, we familiarized 8-month-olds with a target function word ("des," "la," "mes" or "ta"), and tested them with phrases containing the target versus a non-target.

Results showed that infants' looking time to the phrases containing the targets versus those containing the non-targets differed significantly. Thus, infants recognized the target functors in continuous speech. As the targets included both high-frequency ("des," "la") and low-frequency ("mes," "ta") function words, we suggest that infants may begin segmenting high-frequency functors at an even younger age. The implications of early processing of function words to language acquisition will be discussed.

2aSC15. Bilinguals reaction times and category goodness judgments in two language-sets: Spanish and English. Adrian Garcia-Sierra (Univ. of Texas, CMA A2-2001, Univ. Station A1100, Austin, TX 78712, gasa@austin.utexas.edu)

Two monolingual groups (Spanish and English speakers) and one bilingual group (Mexican-American) were compared in reaction times (RTs) and category goodness (CG) ratings during the identification of a synthetic continuum ranging from /ga/ to /ka/. The task consisted of two sessions for the bilingual listeners and one session for the monolingual listeners. Each session was performed in either a Spanish or English language-set. Language-sets were defined by the language used by the researcher and by filler sentences in the language of interest during the identification task (e.g., what do you hear? or Qu fue lo que escuchó?). The results show that voicing boundaries were different across all groups including bilinguals in both language-sets (voicing boundary shift). RTs were larger near the voicing boundaries in all groups. Interestingly, bilinguals showed two RT peaks, whereas monolinguals showed only one RT peak. In regard to CG, participants were asked to rate how good exemplar each token was (1 = worst; 5 = best). Bilinguals rated the synthetic continuum in both language-sets. The scores given by the bilinguals differed in each language-set at VOT values close to the voicing boundary.

2aSC16. Perceived nativeness and sensitivity to temporal adjustments in speech. Yue Wang (Dept of Linguist., Simon Fraser Univ., Burnaby, BC, Canada V5A 1S6, yuew@sfu.ca) and Dawn M. Behne (Norwegian Univ. of Sci. and Technol., NO-7491 Trondheim, Norway)

Native Mandarin Chinese speakers productions of English consonant-vowel (CV) syllables have shown syllable-internal temporal adjustments in the direction of native (English)-like CVs (Wang and Behne, 2004). The current study presents two experiments investigating whether these temporal adjustments affect perceived nativeness. For three production types (native-English, Chinese productions of English, native-Chinese), three syllable-internal timing patterns (English-like, Chinese-English-like, Chinese-like) were applied, resulting in nine stimuli types. Native English listeners judged how English-like each stimulus was on a 7-point scale. In the first experiment, production-types and timing patterns were randomized. Results show that listeners can reliably identify nativeness of the three productions, with Chinese productions of English perceived as intermediate to the native Chinese and native American English productions. Listeners also showed a tendency toward using timing within the CV to identify nativeness. In the second experiment the same materials were therefore blocked by production type. Results reveal the perceptual saliency of the temporal adjustments in nonnative productions. These findings support a view of L2 acquisition as a gradual process toward the target L2 (e.g., Caramazza *et al.*, 1973). The current study extends this view, showing evidence that listeners can perceive the inter-language system, bearing the nature of both L1 and L2.

2aSC17. Relation between perception and production ability during a speech training course. Teruaki Tsumahima and Mayumi Hamada (Ryutsu Kagaku Univ., 3-1, Gakuen-Nishi-Machi, Nishi-Ku, Kobe, 651-2188, Japan)

Previous research has indicated that perception and production ability are significantly related among L2 learners in natural learning settings. The present study focused on the relation between these two abilities

during speech training, specifically examining whether perception or production training alone led to improvements of production or perception ability, and whether the order of perception and production training influenced the improvement of the abilities. Forty-five Japanese university students received thirteen-week perception and production training on six American English contrasts (e.g., b/v, l/r). One group received perception training first, followed by production training, while the order of training was reversed for the other group. It was found that the initial perception training in the former group resulted in a significant but relatively weak transfer to improvements of production ability, while the initial production training in the latter group showed a significant and strong transfer to those of perception ability. It was also shown that the improvements of perception and production ability during the speech training were significantly related in both groups. The order of training, however, did not significantly influence the overall degree of improvements in either of the abilities. Implications for speech learning models will be discussed.

2aSC18. The effect of L1 prosodic backgrounds of Cantonese and Japanese speakers on the perception of Mandarin tones after training. Connie K. So (Dept. of Linguist., Simon Fraser Univ., Burnaby, BC, Canada V5A 1S6, kso@sfu.ca)

The present study investigated to what extent ones' L1 prosodic backgrounds affect their learning of a new tonal system. The question as to whether native speakers of a tone language perform differently from those of a pitch accent language will be addressed. Twenty native speakers of Hong Kong Cantonese (a tone language) and Japanese (a pitch accent language) were assigned to two groups. All of them had had no prior knowledge of Mandarin, and had never received any form of musical training before they participated in the study. Their performance of the identification of Mandarin tones before and after a short-term training was compared. Analysis of listeners' tonal confusions in the pretest, posttest, and generalization tests revealed that both Cantonese and Japanese listeners had more confusion for two contrastive tone pairs: Tone 1–Tone 4, and Tone 2–Tone 3. Moreover, Cantonese speakers consistently had greater difficulty than Japanese speakers in distinguishing the tones in each pair. These imply that listeners L1 prosodic backgrounds are at work during the process of learning a new tonal system. The findings will be further discussed in terms of the Perceptual Assimilation Model (Best, 1995). [Work supported by SSHRC.]

2aSC19. How auditory discontinuities and linguistic experience affect the perception of speech and non-speech in English- and Spanish-speaking listeners. Jessica F. Hay (Dept. Psych., Univ. of Texas, Austin, TX 78712, hay@psy.utexas.edu), Lori L. Holt (Carnegie Mellon Univ., Pittsburgh, PA 15213), Andrew J. Lotto (Boys Town Natl. Res. Hospital, Omaha, NE 68131), and Randy L. Diehl (Univ. of Texas, Austin, TX 78712)

The present study was designed to investigate the effects of long-term linguistic experience on the perception of non-speech sounds in English and Spanish speakers. Research using tone-onset-time (TOT) stimuli, a type of non-speech analogue of voice-onset-time (VOT) stimuli, has suggested that there is an underlying auditory basis for the perception of stop consonants based on a threshold for detecting onset asynchronies in the vicinity of +20 ms. For English listeners, stop consonant labeling boundaries are congruent with the positive auditory discontinuity, while Spanish speakers place their VOT labeling boundaries and discrimination peaks in the vicinity of 0 ms VOT. The present study addresses the question of whether long-term linguistic experience with different VOT categories affects the perception of non-speech stimuli that are analogous in their acoustic timing characteristics. A series of synthetic VOT stimuli and TOT stimuli were created for this study. Using language appropriate labeling and ABX discrimination tasks, labeling boundaries (VOT) and discrimination peaks (VOT and TOT) are assessed for 24 monolingual English speakers and 24 monolingual Spanish speakers. The interplay between language experience and auditory biases are discussed. [Work supported by NIDCD.]

2aSC20. Method for automatic measurement of second language speaking proficiency. Jared Bernstein and Jennifer Balogh (Ordnate Corp., Menlo Park, CA 94025)

Spoken language proficiency is intuitively related to effective and efficient communication in spoken interactions. However, it is difficult to derive a reliable estimate of spoken language proficiency by situated elicitation and evaluation of a person's communicative behavior. This paper describes the task structure and scoring logic of a group of fully automatic spoken language proficiency tests (for English, Spanish and Dutch) that are delivered via telephone or Internet. Test items are presented in spoken form and require a spoken response. Each test is automatically-scored and primarily based on short, decontextualized tasks that elicit integrated listening and speaking performances. The tests present several types of tasks to candidates, including sentence repetition, question answering, sentence construction, and story retelling. The spoken responses are scored according to the lexical content of the response and a set of acoustic base measures on segments, words and phrases, which are scaled with IRT methods or parametrically combined to optimize fit to human listener judgments. Most responses are isolated spoken phrases and sentences that are scored according to their linguistic content, their latency, and their fluency and pronunciation. The item development procedures and item norming are described.

2aSC21. Effects of linguistic experience on early levels of perceptual tone processing. Tsan Huang (Dept. of Linguist., SUNY Buffalo, 609 Baldy Hall, Buffalo, NY 14260) and Keith Johnson (UC Berkeley, Berkeley, CA 94720-2650)

This study investigated the phenomenon of language-specificity in Mandarin Chinese tone perception. The main question was whether linguistic experience affects the earliest levels of perceptual processing of tones. Chinese and American English listeners participated in four perception experiments, which involved short inter-stimulus intervals (300 ms or 100 ms) and an AX discrimination or AX degree-of-difference rating task. Three experiments used natural speech monosyllabic tone stimuli and one experiment used time-varying sinusoidal simulations of Mandarin tones. AE listeners showed psychoacoustic listening in all experiments, paying much attention to onset and offset pitch. Chinese listeners showed language-specific patterns in all experiments to various degrees, where tonal neutralization rules reduced perceptual distance between two otherwise contrastive tones for Chinese listeners. Since these experiments employed procedures hypothesized to tap the auditory trace mode (Pisoni, *Percept. Psychophys.* **13**, 253–260 (1973)), language-specificity found in this study seems to support the proposal of an auditory cortical map [Guenther *et al.*, *J. Acoust. Soc. Am.* **23**, 213–221 (1999)]. But the model needs refining to account for different degrees of language-specificity, which are better handled by Johnsons (2004, *TLS03:26-41*) lexical distance model, although the latter model is too rigid in assuming that linguistic experience does not affect low-level perceptual tasks such as AX discrimination with short ISIs.

2aSC22. Perceptual and production variables in explicating interlanguage speech intelligibility benefit. Ameer P. Shah and Zoi Vavva (Dept. of Speech and Hearing, Cleveland State Univ., 2121 Euclid Ave., MC 431-B, Cleveland, OH 44115, a.shah101@csuohio.edu)

This study attempts to investigate the importance of the degree of similarity or difference in the language backgrounds of the speakers and listeners, as it interacts differentially in intelligibility judgment of foreign-accented speech (Bent and Bradlow, 2003). The present study attempts to clarify the distinction in the matched and mismatched listening conditions, in context of addressing the overarching question whether auditory exposure to a language alone, without corresponding proficiency in production of that language, can provide a listening advantage. Particularly, do listeners understand accented-English speech spoken by native individuals of the language to which they are exposed to, as compared to listeners without that exposure? Greek-accented English speakers (and native monolin-

gual English speakers) were judged for their speech intelligibility by four groups of listeners ($n=10$, each): native Greek speakers (matched), Greek-Americans (matched only through auditory exposure to Greek without any corresponding spoken proficiency), native monolingual American-English speakers (unmatched), and a mixed group (mismatched). Pilot data have shown that the intelligibility judgments by Greek-American listeners are intermediate to the native Greeks, and both the American-English and the mixed group. Further data-collection is underway, and will be presented as they bear important theoretical and clinical implications.

2aSC23. Phonological systems in bilinguals: Age of learning effects on the stop consonant systems of Korean-English bilinguals. Kyoung-Ho Kang and Susan G. Guion (Dept. of Linguist., 1290 Univ. of Oregon, Eugene, OR 97403, kkang@darkwing.uoregon.edu)

The stop systems of adult Korean (L1)-English (L2) bilinguals were studied through acoustic analysis of Korean and English stop productions. The interaction of the first and second language stop systems was investigated as a function of age of exposure to English. The main goals of the investigation were to examine the extent to which early and the late bilinguals produced a given stop category in a native-like way and the extent to which the two stop systems were held independent from each other in the phonological systems of the bilinguals. Two specific questions were asked: whether early bilinguals were more native-like in the production of English stops and thus were more likely to establish L2 phonetic categories than late bilinguals, and whether the Early bilinguals maintain a greater extent of independence between the Korean and English stop systems than the late bilinguals. For this purpose, productions of Korean and English stops were analyzed in terms of three acoustic-phonetic properties, VOT, $H1-H2$, and f_0 . The results suggested that fine-grained phonetic information is crucial to investigation of bilingual phonological systems and they were discussed in terms of the role of perceived phonetic distance between L1 and L2 phonetic categories in L2 speech learning.

2aSC24. Validation of an automatic measurement of Spanish speaking proficiency. Elizabeth Rosenfeld, Jared Bernstein, and Jennifer Balogh (Ordnate Corp., Menlo Park, CA)

A 15-min computer-based test of spoken Spanish was designed to measure candidate proficiency in Spanish. The test presents seven tasks: reading, elicited imitation, word opposites, short-answer questions, sentence constructions, opinion questions, and story retellings. The tests were presented to 579 adult non-native Spanish learners and to 552 native Spanish speakers. Expert human judgments of the non-native responses showed that the spoken response material carried sufficient information for highly reliable judgments of proficiency. In the development and validation process, 57 000 responses were transcribed and 21 000 human judgments were analyzed. The paper describes the validation of the automatic scoring system with reference to concurrent oral proficiency interviews conducted by professional raters certified by the US Government or by ACTFL. The outcomes of the comparisons of the machine scored tests with interactive human interviews and with human ratings from recorded speech indicate that the test produces scores that have virtually the same information that is found in oral proficiency interviews. Almost all assessments correlate highly with the other assessments with coefficients in the range 0.86–0.96. The test correlation with the combined interview scores ($r=0.92$) is higher than the inter-rater reliability of the professional interviewers themselves.

2aSC25. An acoustic investigation of the Cantonese vowels in the speech of the adult and child speakers. Wai-Sum Lee (Dept. of Linguist., The Univ. of Hong Kong, Pokfulam Rd., Hong Kong, wsleeba@hku.hk)

The study analyzes the formant center frequencies for the seven Cantonese vowels [i, y, u, e, æ, ɔ, a] from 30 native speakers of Cantonese, 10 male and 10 female adults and 5 male and 5 female 9–10 year old children. Results show that the formant frequencies for the vowels are

largest for the female children, followed by the male children, female adults, and male adults in decreasing order. Despite the differences, the patterns of formant frequencies for any one vowel for the different groups are similar. The difference in F -values for any one vowel between the male and female children is smaller than the difference between the male and female adults. As for individual formant frequencies, the difference in $F1$ between the males and females of the same age group and between the adults and children of the same gender group is smaller for the high vowels [i, y, u] than the non-high vowels [ɛ, æ, ɔ, a]. The difference in $F2$ between the males and females of the same age group and between the adults and children of the same gender group is smaller for the high rounded vowels [y, u] than the other vowels. The paper will also present the ratios of speaker group-to-speaker group for individual formant frequencies.

2aSC26. Voice onset time (VOT) in Canadian French and English: Monolingual and bilingual adults. Andrea A. N. MacLeod and Carol Stoel-Gammon (Dept. of Speech and Hearing Sci., Univ. of Washington, 1417 N.E. 42nd St., Seattle, WA 98119)

This study focused on the contrasts produced by early bilingual speakers ($n=6$) across their two languages in comparison with monolingual speakers (Canadian English (CE), $n=5$; Canadian French (CF), $n=6$). VOT production was measured in monosyllabic CE and CF words that began with one of four stop consonants, /p, b, t, d/ followed by one of three vowels. A total of 14–18 words for each of the four stop consonants for each language was elicited with a total number 1700 acoustically analyzed productions. The participants were tested individually in quiet rooms using a single target language throughout the session. As expected, the monolingual speakers produced a two-way contrast (statistically significant: $p < 0.05$): for CE speakers, short-lag VOT versus long-lag VOT; for CF speakers, lead VOT versus short-lag VOT. Rather than producing a two-way contrast (e.g., lead VOT versus lag VOT) or a three-way contrast (e.g., lead VOT versus short-lag VOT versus long-lag VOT), the bilingual speakers produced a four-way contrast (statistically significant: $p < 0.05$): long lead VOT (CF /b, d/), short lead VOT (CE /b, d/), short-lag VOT (CF /p, t/) and long-lag VOT (CE /p, t/). These results suggest that bilinguals are maintaining phonetic contrasts both within and across their two languages.

2aSC27. The effect of speaking rate on perception of syllables in second-language speech. Keiichi Tajima (Dept. of Psych., Hosei Univ., Tokyo 102-8160, Japan; ATR Human Information Sci. Labs., Kyoto 619-0288, Japan) and Reiko Akahane-Yamada (ATR Human Information Sci. Labs., Kyoto 619-0288, Japan)

Past studies on second-language (L2) speech perception have suggested that L2 learners have difficulty exploiting contextual information when perceiving L2 utterances, and that they exhibit greater difficulty than native listeners when faced with variability in temporal context. The present study investigated the extent to which native Japanese listeners, who are known to have difficulties perceiving English syllables, are influenced by changes in speaking rate when asked to count syllables in spoken English words. The stimuli consisted of a set of English words and non-words varying in syllable structure spoken at three rates by a native English speaker. The stimuli produced at the three rates were presented to native Japanese listeners in a random order. Results indicated that listeners' identification accuracy did not vary as a function of speaking rate, although it decreased significantly as the syllable structure of the stimuli became more complex. Moreover, even though speaking rate varied from trial to trial, Japanese listeners' performance did not decline compared to a condition in which the speaking rate was fixed. Theoretical and practical implications of these findings will be discussed. [Work supported by JSPS and NICT.]

2aSC28. Learning to talk: A non-imitative account of the replication of phonetics by child learners. Piers Messum (Dept. of Phonet. and Linguist., UCL, Gower St., London WC1E 6BT, UK)

How is it that an English-speaking 5-year-old comes to: pronounce the vowel of seat to be longer than that of sit, but shorter than that of seed; say a multi-word phrase with stress-timed rhythm; aspirate the /p/s of pin, polite, and spin to different degrees? These are systematic features of English, and most people believe that a child replicates them by imitation. If so, he is paying attention to phonetic detail in adult speech that is not very significant linguistically, and then making the effort to reproduce it. With all the other communicative challenges he faces, how plausible is this? An alternative, non-imitative account of the replication of these features relies on two mechanisms: (1) emulation, and (2) the conditioning of articulatory activity by the developing characteristics of speech breathing. The phenomena above then become no more than expressions of how a child finds ways to warp his phonetic output in order to reconcile conflicting production demands. The criteria he uses to do this make the challenges both of learning to talk and then of managing the interaction of complex phonetic patterns considerably more straightforward than has been imagined.

2aSC29. Acoustics of contrastive prosody in children. Rupal Patel, Jordan Piel (Dept. of Speech Lang. Pathol. & Audiol., Northeastern Univ., 360 Huntington Ave., Boston, MA 02115, r.patel@neu.edu), and Maria Grigos (New York Univ., New York, NY 10003)

Empirical data on the acoustics of prosodic control in children is limited, particularly for linguistically contrastive tasks. Twelve children aged 4, 7, and 11 years were asked to produce two utterances "Show Bob a bot" (voiced consonants) and "Show Pop a pot" (voiceless consonants) 10 times each with emphasis placed on the second word (Bob/Pop) and 10 times with emphasis placed on the last word (bot/pot). A total of 40 utterances were analyzed per child. The following acoustic measures were obtained for each word within each utterance: average fundamental frequency (f_0), peak f_0 , average intensity, peak intensity, and duration. Preliminary results suggest that 4 year olds are unable to modulate prosodic cues to signal the linguistic contrast. The 7 year olds, however, not only signaled the appropriate stress location, but did so with the most contrastive differences in f_0 , intensity, and duration, of all age groups. Prosodic differences between stressed and unstressed words were more pronounced for the utterance with voiced consonants. These findings suggest that the acoustics of linguistic prosody begin to differentiate between age 4 and 7 and may be highly influenced by changes in physiological control and flexibility that may also affect segmental features.

2aSC30. Infant-directed speech: Final syllable lengthening and rate of speech. Robyn Church, Barbara Bernhardt (School of Audiol. and Speech Sci., Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z1), Rushen Shi (Univ. of Quebec at Montreal), and Kathleen Pichora-Fuller (Univ. of Toronto)

Speech rate has been reported to be slower in infant-directed speech (IDS) than in adult-directed speech (ADS). Studies have also found phrase-final lengthening to be more exaggerated in IDS compared with ADS. In our study we asked whether the observed overall slower rate of IDS is due to exaggerated utterance-final syllable lengthening. Two mothers of preverbal English-learning infants each participated in two recording sessions, one with her child, and another with an adult friend. The results showed an overall slower rate in IDS compared to ADS. However, when utterance-final syllables were excluded from the calculation, the speech rate in IDS and ADS did not differ significantly. The duration of utterance-final syllables differed significantly for IDS versus ADS. Thus, the overall slower rate of IDS was due to the extra-long final syllable occurring in relatively short utterances. The comparable pre-final speech rate for IDS and ADS further accentuates the final syllable lengthening in IDS. As utterances in IDS are typically phrases or clauses, the particularly

strong final-lengthening cue could potentially facilitate infants' segmentation of these syntactic units. These findings are consistent with the existing evidence that pre-boundary lengthening is important in the processing of major syntactic units in English-learning infants.

2aSC31. Neural-network simulation of tonal categorization based on F_0 velocity profiles. Bruno Gauthier, Rushen Shi (Dept. of Psych., Univ. of Quebec in Montreal, C.P. 8888, Succ. Centre-ville, Montreal, QC, Canada H3C 3P8), Yi Xu (Univ. College London, London, NW1 2HE, UK), and Robert Proulx (Univ. of Quebec in Montreal, Montreal, QC, Canada H3C 3P8)

Perception studies have shown that by the age of six months, infants show particular response patterns to tones in their native language. The present study focuses on how infants might develop lexical tones in Man-

darin. F_0 is generally considered the main cue in tone perception. However, F_0 patterns in connected speech display extensive contextual variability. Since speech input to infants consists mainly of multi-word utterances, tone learning must involve processes that can effectively resolve variability. In this study we explore the Target Approximation model (Xu and Wang, 2001) which characterizes surface F_0 as asymptotic movements toward underlying pitch targets defined as simple linear functions. The model predicts that it is possible to infer underlying pitch targets from the manners of F_0 movements. Using production data of three of the speakers from Xu (1997), we trained a self-organizing neural network with both F_0 profiles and F_0 velocity profiles as input. In the testing phase, velocity profiles yielded far superior categorization than F_0 profiles. The results confirm that velocity profiles can effectively abstract away from surface variability and directly reflect underlying articulatory goals. The finding thus points to one way through which infants can successfully derive at phonetic categories from adult speech.

2aSP1. Signal processing techniques for inverse problems in stochastic propagation and scattering channels. Leon H. Sibul, Michael J. Roan, and Christian M. Coviello (Appl. Res. Lab., Penn State Univ., P.O. Box 30, State College, PA 16804-0030, lhs2@psu.edu)

The basic signal processing techniques associated with inverse problems are signal extraction, deconvolution, signal and signal parameter estimation, channel modeling and characterization. Maximum entropy, minimum cross-entropy, Kullback-Liebler divergence and other information theoretic criteria have been widely used for regularization of underdetermined inversion. We show how maximum entropy and continuous wavelet transforms can be used for spreading function (reflection density function) estimation. If the signal source or receivers are in motion through heterogeneous medium with randomly rough boundaries, propagation and scattering channels are stochastic. Stochastic channels can be characterized by stochastic Greens functions and spreading functions. If the medium probing signals are narrow band, spreading functions are random functions that show how the received signal is spread in delay and Doppler. For wideband probing signals, spreading function spread the received echo in time and time-scale dilation. If the probing signal satisfies admissibility conditions for CWT, wideband spreading functions can be estimated by inverting CWT. Rebollo-Neira and Fernandez-Rubio have shown that the continuous wavelet transform is an optimal solution of the inverse problem, estimation of the spreading function, in a maximum entropy sense. [Work supported by Office of Naval Research Code 333 and Code 321 US.]

8:30

2aSP2. Quantifying heterogeneity: Attributes, modeling, and inversion. Matthias Georg Imhof (Dept. of Geosciences, Virginia Tech, Blacksburg, VA 24061)

Characterization of reservoir heterogeneity is a necessary step in reservoir delineation, characterization, and modeling. Reservoir heterogeneity can be described deterministically, statistically, or with reservoir-forming geologic processes. Deterministic heterogeneity models are easy to build, but may have insufficient resolution and may not provide enough insights into the reservoir and its properties. The parameterization of stochastic heterogeneity models is nontrivial. Seismic data can be used to determine geostatistical parameters or to refine the geometry parameters used for Boolean modeling. The geostatistical parameters (ranges and orientations) are obtained from seismic heterogeneity attributes measuring the second-order statistics contained in small seismic datacubes. Seismic heterogeneity relates to acquisition and processing artifacts, structure, or stratigraphy and lithology. Seismic data could also be used as additional constraints in Boolean reservoir models which allows both construction of conforming reservoir models and optimization

of the geometry parameters to reduce the misfit between model and observations. Reservoirs could also be built by reconstructing their formation and evolution based on mathematical descriptions of processes such as sediment erosion, transport and deposition, compaction, deformation, subsidence and uplift, etc. The process parameters, e.g., rates of sediment input and transport, compaction, or subsidence, could be estimated by inversion of seismic and geologic data.

8:55

2aSP3. Sparseness- and continuity-constrained seismic imaging. Felix J. Herrmann (Dept. of Earth and Ocean Sci., Univ. of British Columbia, 6339 Stores Rd., Vancouver, BC, Canada V6T 1Z4, fherrmann@eos.ubc.ca)

Non-linear solution strategies to the least-squares seismic inverse-scattering problem with sparseness and continuity constraints are proposed. Our approach is designed to (i) deal with substantial amounts of additive noise ($\text{SNR} < 0$ dB); (ii) use the sparseness and locality (both in position and angle) of directional basis functions (such as curvelets and contourlets) on the model: the reflectivity; and (iii) exploit the near invariance of these basis functions under the normal operator, i.e., the scattering-followed-by-imaging operator. Signal-to-noise ratio and the continuity along the imaged reflectors are significantly enhanced by formulating the solution of the seismic inverse problem in terms of an optimization problem. During the optimization, sparseness on the basis and continuity along the reflectors are imposed by jointly minimizing the l^1 - and anisotropic diffusion/total-variation norms on the coefficients and reflectivity, respectively. [Joint work with Peyman P. Moghaddam was carried out as part of the SINBAD project, with financial support secured through ITF (the Industry Technology Facilitator) from the following organizations: BG Group, BP, ExxonMobil, and SHELL. Additional funding came from the NSERC Discovery Grants 22R81254.]

9:20

2aSP4. Reconciling data using Markov chain Monte Carlo: An application to the Yellow Sea–Korean Peninsula region. Michael Pasyanos (Lawrence Livermore Natl. Lab., 7000 East Ave., Livermore, CA 94550)

We present a technique for developing seismic models using multiple data sets using a probabilistic inverse technique. A Markov Chain Monte Carlo (MCMC) algorithm is used to sample models from a prior distribution and test them against multiple data types to generate a posterior distribution. This approach has several advantages over deterministic models, notably the reconciliation of different data types that constrain the model, the proper handling of uncertainties, and the ability to include prior information. We also benefit from the advantage of forward modeling rather than inverting the data. We demonstrate this method by using it to determine the 3-D crust and upper mantle structure for the Yellow Sea and Korean Peninsula (YSKP) region. The model is parameterized as a series of layers in a regular lat-lon grid. We start with an *a priori* model and use surface wave dispersion measurements, body wave travel times, teleseismic receiver functions, and gravity data to drive the model. The end result is a robust model distribution for the region that is best able to fit multiple data sets, and is consistent with our understanding of the tectonics of the region.

9:45

2aSP5. Global seismic tomography: Present status and future perspectives. Barbara Romanowicz (Berkeley Seismological Lab., 215 McCone Hall, Berkeley, CA 94720)

Global seismic tomography of the Earth's mantle has traditionally focused on the inversion of travel times from a small number of seismic phases, well isolated in time domain seismograms. The resulting uneven sampling of the Earth, dictated by the available distribution of earthquake sources and receivers, greatly limits the resolution of 3-D structure that can be attained. With recent progress in the simulation of wave propagation in realistic 3-D Earth models combined with significant increases in computational power, seismologists are well positioned to start fully exploiting the wealth of information contained in the rapidly expanding database of high quality broadband seismic waveforms, accumulated globally and regionally over the last twenty five years. New opportunities presented by 3-D forward and inverse modeling of long period waveforms will be presented with illustrations from recent work on deep and shallow elastic and anelastic mantle structure, addressing, among others, such questions as: what is the fate of subducted slabs or the nature of the lower mantle "superplumes"?

10:10–10:30 Break

10:30

2aSP6. Surface wave tomography from seismic ambient noise in Southern California. Karim Sabra, Peter Gerstoft, Philippe Roux, William Kuperman (Marine Physical Lab., Scripps Inst. of Ocean., UCSD, La Jolla, CA 92093-0238, ksabra@mpl.ucsd.edu), and Michael Fehler (Los Alamos Natl. Lab., NM)

It has been demonstrated experimentally that an estimate of the Green's tensor between two seismic stations can be obtained from the long-time average of the cross-correlation of ambient noise at the two stations. This result provides a means to image Earth structure using the ambient noise field only, without the use of active seismic sources or earthquakes. Seismic noise data from 148 broadband seismic stations in Southern California were used to extract the surface wave arrival-times between all station pairs in the network in the frequency band 0.05–0.4 Hz. In this frequency band, ambient noise (originating from ocean microseisms) propagating over long distances is typically dominated by surface waves. A record section of the waveforms as a function of increasing receiver separation shows clearly that the recovered signals are propagating wavetrains. The seismic data were then used in a simple, but densely sampled tomographic procedure to estimate the surface wave velocity structure for a region in Southern California. The result compares favorably with previous estimates obtained using more conventional and elaborate inversion procedures. This demonstrates that coherent ambient noise between station pairs can be used for seismic imaging purposes.

10:55

2aSP7. An overview of geophysical investigations at archaeological sites in Helike, Greece. Alan Witten and Jamie Rich (School of Geology and Geophys., Univ. of Oklahoma, 810 Energy Ctr., Norman, OK 73019)

Helike is an area on the south-central coast of the Gulf of Corinth. This name is derived from the lost Classical Greek city of Helike that vanished during an earthquake and subsequent tsunami in 373 BC. It was originally believed that the remains of Helike were located offshore in the Gulf of Corinth; however, early searches of this area proved fruitless. More recently, boreholes developed in the coastal plain revealed marine sediments that date to the Classical Greek period suggesting that, as a result of uplift and/or sedimentation, Helike now lies onshore. This find stimulated a sequence of ongoing geophysical investigations and excavations that have revealed buried architecture and artifacts from three periods; Early Bronze Age, Classical Greek, and Roman.

11:20

2aSP8. Acoustic archeology at the lost city of Helike. Sean K. Lehman (Lawrence Livermore Natl. Lab., L-154, 7000 East Ave., Livermore, CA 94550)

In 373 BC an earthquake and tsunami destroyed and submerged the classical Greek city of Helike (HELL-E-KEY) on the north Peloponnese shore of the Gulf of Corinth. In June 2004, surface seismo-acoustic surveys were performed in the area of present Helike in order to collect non-invasive tomographic data to guide the archeological excavations. Prior to tomographic inversion and imaging, the raw data time series must be preprocessed to estimate ground acoustic velocity, and to remove the ground roll signal. We present a generalized cross-correlation technique which appears successful in solving both problems. We describe the technique as applied to the data and present tomographic inversions.

2aUW1. Direct-path rough surface scattering experiments with milled surfaces in acoustic tank facilities. Raymond J. Soukup, Robert F. Gragg, Jason E. Summers, and Edward L. Kunz (Naval Res. Lab., 4555 Overlook Ave., Washington, DC 20375, soukup@abyss.nrl.navy.mil)

To investigate specific issues relating to rough surface scattering theoretical predictions, the Naval Research Laboratory has been conducting scaled-down versions of its direct-path ocean bottom scattering experiments. These experiments utilize milled elastic rough surfaces in acoustic tank facilities. Investigations into the dependence of scattering on roughness and geoacoustic parameters lend themselves to a systematic treatment with milled surfaces that are fabricated to match specific roughness spectral parameters. The characterization and fabrication of such rough surfaces, and the methodology for creating experimental geometries that are analogous to previous measurements with elastic ocean bottoms, are described. A set of scattering strength measurements in the 100–300 kHz band with a quasi-monostatic geometry is compared with the theoretical predictions given by perturbation theory and the NRL small slope model. The results show that these experiments are a viable means of verifying the predictions of the scattering models, given a sufficiently large statistical sample. [Work supported by ONR.]

8:00

2aUW2. Observations of a geocloud feature in the straits of Sicily. Thomas C. Weber, Charles W. Holland (Appl. Res. Lab., The Pennsylvania State Univ., State College, PA 16804), and Giuseppe Etiope (Natl. Inst. of Geophys. and Volcanology, Rome, Italy)

Several persistent sonar clutter features were observed in 2002 during an experiment in the Straits of Sicily (Malta Plateau) in a region that is nominally flat and thickly sedimented. High frequency sidescan and seismic reflection data from the region indicated that mud volcanoes were present and were possibly expelling clouds of methane bubbles. In 2004 the region was revisited with oceanographic equipment including a multi-beam sonar, an acoustic Doppler current profiler (ADCP), CTD's, temperature loggers, a methane sensor, and a video camera. The visual observations at one site show carbonate mounds comprised of large heterogeneous blocks that suggest the presence of mud volcanism. A multibeam sonar survey of the area shows that the carbonate mounds are of order 5–10 m in height and 10–100 m in lateral dimension, and that they form in clusters. The multibeam backscatter data show high amplitudes in the region surrounding the carbonate mounds, possibly indicating the surficial extent of the carbonate material. High levels of methane were observed in the water column above the mounds, although conclusive evidence of the presence of methane bubble clouds was not found. However, high frequency backscatter recorded on the ADCP above multiple

carbonate mounds showed plume-like features that may be bubble clouds, suspended fine-grained sediment, and/or schools of fish.

8:15

2aUW3. Close-range acoustic scattering from mud volcanoes.

Charles W. Holland, Thomas C. Weber (Appl. Res. Lab., Penn State Univ., State College, PA, 16804), and Giuseppe Etiope (Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy)

Submarine mud volcanoes occur in many parts of the world's oceans and form an aperture for gas (mostly methane) and fluidized mud emission from the earth's interior. Their characteristics are of considerable interest to the geology, geophysics, geochemistry, and underwater acoustics communities. For the later community, mud volcanoes are important because they pose a potential source of clutter for active sonar. Close-range (single boundary interaction) scattering measurements from a mud volcano in the Straits of Sicily were conducted with a vertical source and receive array. The data show target strengths from 800–3600 Hz of 6–12 dB for a monostatic geometry with grazing angles of 3–5 degrees. The target strengths are very similar for vertically bi-static paths with incident grazing angles of 3–5 degrees and scattered angles of 33–45 degrees. The evidence suggests that the scattering mechanism is the mud volcano (carbonate) structure. [Work supported by the Office of Naval Research and NATO Undersea Research Centre.]

8:30

2aUW4. Comparison of the magnitude and phase of the reflection coefficient from a smooth water/sand interface with elastic and poroelastic models.

Marcia Isakson (Appl. Res. Labs., Univ. of Texas, Austin, TX 78713-8029), H. John Camin (The Penn State Univ., State College, PA 16804-0030), and Gaetano Canepa (NATO Undersea Res. Ctr., La Spezia, Italy)

The reflection coefficient from a sand/water interface is an important parameter in modeling the acoustics of littoral environments. Many models have been advanced to describe the influence of the sediment parameters and interface roughness parameters on the reflection coefficient. In this study, the magnitude and phase of the reflection coefficient from 30 to 160 kHz is measured in a bistatic experiment on a smoothed water/sand interface at grazing angles from 5 to 75 degrees. The measured complex reflection coefficient is compared with the fluid model, the elastic model and poro-elastic models. Effects of rough surface scattering are investigated using the Bottom Response from Inhomogeneities and Surface using Small Slope Approximation (BoRIS-SSA). Spherical wave effects are modeled using plane wave decomposition. Models are considered for their ability to predict the measured results using realistic parameters. [Work supported by ONR, Ocean Acoustics.]

8:45

2aUW5. Laboratory study of high frequency scattering from water-saturated sandy sediments.

Anatoliy Ivakin (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, ivakin@apl.washington.edu), Jean-Pierre Sessarego, and Patric Sanchez (CNRS/LMA, Marseille cedex 20, France)

Backscattering from a water-saturated well-sorted fine sand and from this sand with various inclusions was studied in a laboratory tank at frequencies from 200 kHz to 3 MHz and grazing angles from 20 to 90 degrees. Acoustic and granulometric properties of the sand are presented and discussed in a companion paper. First, the measurements of the frequency-angular dependencies of the backscattering strength were made for a thick sediment layer with a smoothed surface and without any inclusions in the volume. Then glass beads and coarse sand particles were used as additional scatterers or inclusions placed on the sediment surface or covered by sediment layers of various thickness. The data were compared with a previously reported model of scattering from discrete inclusions in the sediment [A. N. Ivakin, *J. Acoust. Soc. Am.* **116**, 2575 (2004)]. The

model inputs are material parameters of the sediment and inclusions and the size-depth distribution of inclusions. The results of model/data comparison are discussed and possibilities for inversion of various sediment parameters from backscattering data are shown.

9:00

2aUW6. Theory and experiments for surface-wave focused acoustic arrivals: A deterministic view.

Grant Deane (Mail Code 0238, Scripps Inst. of Oceanogr., UCSD, La Jolla, CA 92093-0238) and James Preisig (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

Statistical descriptions of surface wave scattering are now highly developed, and have proven very effective in relating the first and second order statistics of surface-reflected acoustic arrivals to surface conditions. Notwithstanding this success, the deterministic features of surface-scattered arrivals are of considerable importance. The limits of performance of underwater communications systems in very shallow water, for example, are determined by the frequency and properties of extreme surface focusing events. The analysis of data from the Wavefronts I, II, and V series of experiments has led to an understanding of the wave properties controlling the focusing events, as well as their impact on acoustic channel estimators. Data from the wavefronts experiments (SIO pier, 7 m deep, 40 m range) and the SPACE02 experiment (Martha's Vineyard, 15 m depth, 250–1000 m range) will be presented and discussed. [Work supported by ONR.]

9:15

2aUW7. Forward scattering from the sea surface: Observations of both subtle and profound effects of bubbles in single-interaction measurements.

Peter H. Dahl (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

For frequencies of O(10) kHz and above, field data show that near-surface bubbles impact forward scattering from the sea surface in three phases. The first occurs under mild conditions (wind speed less than 5–7 m/s); here a pulse forward scattered from the sea surface is extended in time, but only at levels ~30 dB below the peak level, which itself is not attenuated. The second occurs under more vigorous conditions (wind speed 7–12 m/s); here a significant energy loss is observed, but time and angle spreading (dominated by rough surface scattering) remain relatively unchanged. The third occurs under still more vigorous conditions (wind speed greater than ~12 m/s). Here, there is near total occlusion of the sea surface, time and angle spreading are manifestly altered, and bubble-mediated energy loss becomes bounded by scattering from bubbles. Examples from ASIAEX East China Sea and other archival data sets will be discussed along with a model for bubble-mediated energy loss in forward scattering from the sea surface. In the case of near total occlusion, an interesting example of the knock-down of horizontal coherence will be discussed along with a model that utilizes the van Cittert-Zernike Theorem. [Research supported by ONR Ocean Acoustics.]

9:30

2aUW8. On the relationship between sea state and the coherent-to-incoherent intensity ratio for high frequency, shallow water propagation.

Philippe Roux, William A. Kuperman (Marine Physical Lab., Scripps Inst. of Oceanogr., UCSD, 8820 Shellback Way, La Jolla, CA 92093-0238), R. Lee Culver, Steven D. Lutz, David L. Bradley (State College, PA 16804, rlc5@psu.edu), and Mark Stevenson (NATO Undersea Res. Ctr., La Spezia, Italy)

A 29-element source array and 32-element receiver array have been deployed in shallow water to investigate various aspects of the acoustic channel. Both arrays spanned much of the water column. Source-receiver range was 800 m, and 3.5 kHz pulses were transmitted using one source at a time and recorded on all elements. In this analysis, we compare the ratio of coherently to incoherently averaged intensities for each source-receiver pair, and averaged over all such pairs, to measure surface roughness. We find that the coherent-to-incoherent intensity ratio decreases with time after the direct path arrival, and that the slope becomes more negative as

wind speed and thus surface roughness increases. A simple model for signal phase variation induced by surface scatter shows a direct relationship between the degree of phase variation and wind speed. The relationship between the slope of the coherent-to-incoherent intensity ratio and a physics-based model of incoherent sea surface forward scatter is also considered. [Work supported by ONR Code 321US.]

2aUW9. Scintillation index of ocean surface forward scattered HF acoustic signals: Beam pattern and pulse length effects. Benjamin Cotté, David Bradley, and R. Lee Culver (Appl. Res. Lab., Penn State Univ., State College, PA 16804, bzc125@psu.edu)

The intensity fluctuations of surface bounce path measured during a field test near San Clemente Island in August 2002 have been presented previously. Signals used during this test were 20- and 40-kHz continuous wave (CW) pulses with 0.14- and 1.0-ms durations (“short” and “long” pulses, respectively). Experimental results have been compared to predictions of a model by Yang and McDaniel [Waves Random Media, **1**, 419–439 (1991); J. Acoust. Soc. Am. **91**, 1960–1966 (1992)]. Their initial model assumes CW signals and omni-directional projectors and receivers. We observed a good fit between model and experimental results for the long pulse data when the specular point was in the main lobe of both projector and receiver. The discrepancies observed in the other cases were attributed to beam pattern and pulse length effects. We have extended the model to incorporate these two effects. [Work supported by ONR Code 321US.]

10:15

2aUW10. Measurements of mid-frequency bottom backscattering strengths on the Outer Hebrides Platform and the Stanton Banks. Edward L. Kunz and Roger C. Gauss (Nav. Res. Lab, Code 7140, Washington, DC 20375-5350, edward.kunz@nrl.navy.mil)

In July 2002, direct-path, mid-frequency (2–5 kHz) bottom backscattering strength measurements were conducted at 21 sites on the Outer Hebrides Platform and the Stanton Banks (northwest of Scotland) during The Technical Cooperation Program’s T-MAST 02 sea trial. This is a complex area, with bottom grabs indicating the wide presence of stones, pebbles, gravel and rocks throughout most of the region. When stones, etc. were present, bottom backscattering strengths were generally high and flattish in angle (over 10 to 40 deg), with many sites empirically exhibiting a $\sin\theta$ or flatter angular dependence. The frequency dependence in these cases was mild. When stones, etc. were absent, bottom backscattering strengths were less high and less flat in angle, with strong frequency dependence. These results dramatically illustrate the inadequacies of using Lambert’s Law to model bottom backscattering strengths and suggest that active sonars operating in this environment will encounter strong reverberation. [Work supported by ONR.]

10:30

2aUW11. A semi-empirical model for predicting surface scattering strengths. Roger C. Gauss, Joseph M. Fialkowski, and Daniel Wurmser (Nav. Res. Lab, Code 7144, Washington, DC 20375-5350, roger.gauss@nrl.navy.mil)

Accurate monostatic and bistatic active sonar performance predictions require accurate predictions of reverberation which in turn rely on accurate estimates of surface scattering strength. This paper presents a new model that estimates the surface scattering strength due to both the rough air-sea interface (small-slope theory) and subsurface bubble clouds (a Lloyd-mirror model), given the acoustic frequency (<5 kHz), incident grazing angle, scattered grazing angle, bistatic angle, wind speed, and sound speed in the water. This semi-empirical surface scattering strength (SESS) model advances previous incarnations [Gauss and Fialkowski, J. Acoust. Soc. Am. **105**, 1254 (1999) and ECUA 2000] by: (1) incorporating a low wavenumber cut-off to the surface-wave roughness spectra; (2) adding

significant sets of low- and mid-frequency, open-ocean backscattering strength data to the database used to derive model parameters (using more comprehensive procedures); and (3) adding a new angle-dependent factor to the bubble-cloud scattering formula. All these changes have increased prediction accuracy, with variances of least-square fits to the new, full data set down from 9.7 dB² for the old model to 5.3 dB² for the new model. [Work supported by ONR and SPAWAR PMW-180.]

10:45

2aUW12. Backscattering of short acoustic pulses from 3-D rough surfaces: Statistical properties of first arrivals. Oleg A. Godin (CIRES, Univ. of Colorado and NOAA/Environ. Technol. Lab., 325 Broadway, Boulder, CO 80305), Isosif M. Fuks, and Mikhail I. Charnotskii (Zel Technologies, Broadway, Boulder, CO 80305)

Time history of a pulse backscattered by a rough surface contains information about position of the surface and properties of the scatterers. Such information is utilized successfully in a number of remote sensing techniques ranging from echo sounding of the ocean bottom to medical ultrasonics and satellite altimetry. In this paper, statistical properties of backscattered waves are considered in the geometrical acoustics approximation. The probing pulse duration is assumed to be sufficiently short so that signals backscattered in a vicinity of individual specular points on a rough surface do not overlap in time. Theoretical results previously obtained in a 2-D problem [I. M. Fuks and O. A. Godin, Waves Random Media **14**, 539–562 (2004)] are extended to sound scattering from 3-D rough surfaces by following an approach developed in stochastic geometry. Predictions of an asymptotic theory are verified against results of a numerical simulation. Travel times and intensities of the first and the second arrivals of the backscattered wave are quantified in terms of statistical moments of roughness. It is found that, as in 2-D case, the travel time and the intensity are strongly correlated; on average, the earlier a signal arrives, the smaller is its intensity.

11:00

2aUW13. Backscattering from targets residing in caustics resulting from ocean boundary interactions. Benjamin R. Dzikowicz (Naval Surface Warfare Ctr., Panama City, FL 32407) and Philip L. Marston (Washington State Univ., Pullman, WA 99164-2814)

Detection of targets by backscatter in shallow water can be enhanced by interactions with ocean boundaries. A laboratory experiment is performed where a spherical target passes through an Airy caustic formed by a curved surface. When the target resides in the insonified region of the caustic there are two sets of multi-path rays: two pairs reflecting once off the surface (either to or from the target), and three reflecting twice off the surface (to and from the target). When a target moves across the caustic the singly reflected rays merge, as do the doubly reflected. With a longer tone burst the rays in each set overlap and the backscatter is greatly enhanced as the target moves into the insonified region. For a point target the singly reflected backscatter scales as an Airy function [B. R. Dzikowicz and P. L. Marston, J. Acoust. Soc. Am. **116**, 2751–2757 (2004)], and the doubly reflected as the square of an Airy function. For a finite target the doubly reflected backscatter unfolds into a hyperbolic umbilic function. The arguments of the Airy and Hyperbolic Umbilic functions are calculated using the relative echo times of transient pulses. [Work supported by ONR.]

11:15

2aUW14. Determining flat interface reflection coefficients using forward scattering from a rippled sediment interface. Kevin L. Williams (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

For sediment interfaces that are very rough on the scale of the acoustic wavelength (i.e., kh greater than 1 where k is $2\pi/\text{wavelength}$ and h is the rms roughness of the water/sediment interface) it is possible to estimate what the reflection coefficient would be if the interface were flat. In order to do so, a large ensemble of forward scattering measurements are

needed in order to reduce the statistical uncertainty of the estimated reflection coefficient. In addition to the statistical uncertainty there can be biases in the estimate (for some grazing angles) that must be taken into account. The above conclusions will be supported through the use of monte carlo simulations of scattering from a rippled interface. The simulations are carried out in the context of discriminating between alternative acoustic models of sand sediments. [Work supported by ONR.]

11:30

2aUW15. Bayesian inversion of frequency-averaged reflection data. Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC, Canada) and Charles W. Holland (Penn State Univ., State College, PA 16801)

This paper presents a nonlinear Bayesian inversion of high-resolution seabed reflection data to estimate visco-elastic parameters of the upper sediments. The inversion is applied to data from two sites in the Strait of Sicily. One site is characterized by low-velocity, silty-clay sediments, resulting in data with a well-defined angle of intromission. The second site is characterized by high-velocity clayey sand, resulting in a critical angle. The data were frequency averaged from 500–2000 Hz and inverted for visco-elastic parameters of a half-space seabed model. The likelihood function employed in the inversion is based on the assumption of independent, Gaussian-distributed data errors, with the standard deviation included as a nuisance parameter in the inversion. Statistical tests are applied to the data residuals *a posteriori* to validate these assumptions. Good results are obtained for sediment compressional-wave velocity, compressional attenuation, and density; shear parameters are less-well determined although low shear-wave velocities are indicated. The Bayesian analysis

provides a quantitative comparison of inversion results for the two sites in terms of the resolution of specific geoacoustic parameters, and indicates that the geoacoustic information content is significantly higher for angle-of-intromission data.

11:45

2aUW16. Bayesian inversion of multi-frequency reflection data with strongly correlated errors for density gradients. Jan Dettmer, Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC, Canada), and Charles W. Holland (Penn State Univ., State College, PA 16801)

This paper develops a non-linear Bayesian inversion for multi-frequency reflection-loss data with strongly correlated data errors to resolve density and sound-velocity gradients which are often observed in the uppermost sediment layer. Although data errors are usually assumed to be independent in geoacoustic inversion, in reality measured data often show strong error correlations. The inversion developed here is designed to take error correlations into account. A full data covariance matrix is estimated from initial residuals of non-uniformly sampled data. This covariance matrix is then used in the likelihood function of a fast Gibbs sampler to sample the posterior probability density and provide parameter estimates and credibility intervals. Rigorous statistical tests are applied to the resulting data residuals to illustrate the benefits of this error treatment. The approach is applied to reflectivity data collected at a site characterized by low-velocity, water-saturated sediments in the Strait of Sicily. Density and sound-speed gradients are clearly resolved by the reflectivity data and agree with core measurements from the experiment site within the credibility bounds.

Meeting of the Standards Committee Plenary Group

to be held jointly with the

ANSI-Accredited U.S. Technical Advisory Group (TAG) Meetings for:

ISO/TC 43 Acoustics
ISO/TC 43/SC 1 Noise and
IEC/TC 29 Electroacoustics

P. D. Schomer, Chair, U.S. Technical Advisory Group (TAG) for ISO/TC 43 Acoustics and ISO/TC 43/SC 1 Noise
2117 Robert Drive, Champaign, IL 61821

V. Nedzelnitsky, U.S. Technical Advisor (TA) for IEC/TC 29, Electroacoustics
*National Institute of Standards and Technology (NIST), Sound Building, Room A147, 100 Bureau Drive, Stop 8221,
Gaithersburg, MD 20899-8221*

The meeting of the Standards Committee Plenary Group will precede the meetings of the Accredited Standards Committees S1, S2, S3, and S12, which are scheduled to take place in the following sequence:

ASC S1 Acoustics	17 May 2005	1:45 p.m. to 3:15 p.m.
ASC S12 Noise	17 May 2005	3:30 p.m. to 5:00 p.m.
ASC S2 Mechanical Vibration and Shock and TAGs to TC 108	18 May 2005	8:00 a.m. to 9:30 a.m.
ASC S3 Bioacoustics	18 May 2005	10:30 a.m. to 12:00 noon

Discussion at the Standards Committee Plenary Group meeting will consist of national items relevant to all S Committees.

The ANSI-Accredited US Technical Advisory Group (TAGs) for ISO/TC 43 Acoustics and IEC/TC 29 Electroacoustics, whose membership consists of members of S1 and S3, and other persons not necessarily members of these Committees, will meet during the Standards Plenary meeting. The ANSI-Accredited US Technical Advisory Group (TAG) for ISO/TC 43/SC 1 Noise, whose membership consists of the members of S12 and other persons not necessarily members of S12, will meet as well. The reports of the Chairs of these TAGs will not be presented at any other S Committee meeting. There will be a report on the interface of S1 and S3 activities with those of ISO/TC 43 and IEC/TC 29 including plans for future meetings of ISO/TC 43 and IEC/TC 29.

Members of S2 Mechanical Vibration and Shock (and U.S. TAG for ISO/TC 108 and its Subcommittees, (SC2, SC3, SC4, SC5, and SC6) are also encouraged to attend the Standards Committee Plenary Group meeting even though the S2 meeting will take place the next day.

The U.S. Technical Advisory Group (TAG) Chairs for the various international Technical Committees and Subcommittees under ISO and IEC, which are parallel to S1, S2, S3, and S12 are as follows:

<u>U.S. TAG Chair/Vice Chair</u>	<u>TC or SC</u>	<u>U.S. TAG</u>
ISO		
P. D. Schomer, Chair	ISO/TC 43 Acoustics	S1 and S3
P. D. Schomer, Chair	ISO/TC 43/SC1 Noise	S12
D. J. Evans, Chair	ISO/TC 108 Mechanical Vibration and Shock	S2
A. F. Kilcullen, Co-Chair R. Taddeo, Co-Chair	ISO/TC 108/SC2 Measurement and Evaluation of Mechanical Vibration and Shock as Applied to Machines, Vehicles and Structures	S2
D. J. Evans, Chair	ISO/TC 108/SC3 Use and Calibration of Vibration and Shock Measuring Instruments	S2
D. D. Reynolds, Chair	ISO/TC 108/SC4 Human Exposure to Mechanical Vibration and Shock	S3
D. J. Vendittis, Chair R. F. Taddeo, Vice Chair	ISO/TC 108/SC5 Condition Monitoring and Diagnostics of Machines	S2
G. Booth, Chair	ISO/TC 108/SC6 Vibration and Shock Generating Systems	S2
IEC		
V. Nedzelnitsky, U.S. TA	IEC/TC 29 Electroacoustics	S1 and S3

2pAAa1. Subjective evaluation of speech and noise in learning environments in the realm of classroom acoustics: Results from laboratory and field experiments. Markus Meis (Hearing Ctr. Oldenburg/Univ. of Oldenburg, Marie-Curie-Str. 2, 26129 Oldenburg, Germany, markus.meis@hoerzentrum-oldenburg.de), Christian Nocke (Akustikbuero Oldenburg), Simone Hofmann (Freudenberg Bldg. Systems), and Bernhard Becker (Deutsche Rockwool Mineralwool GmbH & CO. OHG)

The impact of different acoustical conditions in learning environments on noise annoyance and the evaluation of speech quality were tested in a series of three experiments. In Experiment 1 ($n=79$) the auralization of seven classrooms with reverberation times from 0.55 to 3.21 s [average between 250 Hz to 2 kHz] served to develop a Semantic Differential, evaluating a simulated teacher's voice. Four factors were found: acoustical comfort, roughness, sharpness, and loudness. In Experiment 2, the effects of two classroom renovations were examined from a holistic perspective. The rooms were treated acoustically with acoustic ceilings (RT=0.5 s [250 Hz–2 kHz]) and muffling floor materials as well as non-acoustically with a new lighting system and color design. The results indicate that pupils ($n=61$) in renovated classrooms judged the simulated voice more positively, were less annoyed from the noise in classrooms, and were more motivated to participate in the lessons. In Experiment 3 the sound environments from six different lecture rooms (RT=0.8 to 1.39 s [250 Hz–2 kHz]) in two Universities of Oldenburg were evaluated by 321 students during the lectures. Evidence found supports the assumption that acoustical comfort in rooms is dependent on frequency for rooms with higher reverberation times.

1:45

2pAAa2. Prevalence, nature and risks of voice problems among public school teachers. Linda Rammage (Dept. of Surgery, UBC, PVCPRP, 4th Fl. Willow Pavilion, VGH, 805 West 12th Ave, Vancouver, BC, Canada V5Z 1M9, lira@interchange.ubc.ca), Murray Hodgson (Univ. of British Columbia, Vancouver, BC V5Z 1M9), and Charlie Naylor (British Columbia Teachers Federation)

Voice problems among teachers represent a rising cause of teacher absenteeism, use of sick benefits, and stress among teachers and students. In British Columbia, the BC Teachers Federation and Workers Compensation Board are receiving increasing numbers of claims from teachers experiencing occupational voice problems and in the provincial voice clinic, the percentage of teachers in the clinic population is rising. Previous studies of teachers voice problems have typically had low return rates, which can bias the prevalence estimates, and have not incorporated standardized voice inventories, psychological inventories and acoustic measures. A survey study is in progress in B.C. to probe demographic, environmental, voice-use, health, psychological and personality issues that are thought to contribute to development of voice problems among teachers. To ensure validity of prevalence estimates by high return rates, on-site completion of questionnaires is being used in schools. Acoustical measures are also being made of representative classrooms, to determine the degree to which noise and reverberation contribute to voice problems among teachers.

2:05

2pAAa3. Benefits of teaching voice amplification as related to subjective laryngeal symptoms and perceived voice quality in teachers. Valdis Jonsdottir (Hraukbajarkot v/ Akureyri 601, Iceland)

Loud speaking due to noisy working conditions is a common cause for teachers' voice disorders. One way to diminish the vocal load of teaching is to make use of technical equipment. This Icelandic study explores: (1) if the use of amplification in classrooms would diminish the teachers' experienced symptoms of vocal fatigue; and (2) whether there is a possible change in perceptual voice quality during a teachers' working day. Thirty-three teachers, from grade school to university level, voluntarily served as subjects. They used amplifiers while teaching for one week at least. After that, they filled out a questionnaire concerning their symptoms and experiences. The results showed that the majority of teachers found amplification beneficial. They found it easier to talk and experienced less fatigue. The few disadvantages were technical. For a perceptual analysis, three females and two males (mean age 51 years) with long teaching experience and three or more dysphonic symptoms during the term, had their speech recorded while teaching, with and without amplification. In the clinical examination, no pathological changes were found in the vocal folds. In both studies, the quality of the voices was esteemed better when amplification was used.

2pAAa4. Benefits of teaching voice amplification as related to subjective laryngeal symptoms in teachers, and to the listening conditions for pupils. Valdis Jonsdottir (Hraukbjarkot v/ Akureyri 601, Iceland)

Teachers unfavorable working conditions—large classrooms with poor acoustics, background noise and the great distance between teacher and pupils often are the main reasons for teachers voice problems. For pupils, the same circumstances simultaneously create unfavorable listening conditions. One way to diminish the vocal load of teaching is by making use of technical equipment. This Icelandic study explores whether voice amplification usage: (1) diminishes the teachers subjective symptoms of vocal fatigue; (2) makes it easier for pupils to listen and follow lessons; and (3) reveals other benefits and/or disadvantages of the usage of amplification in classrooms. Thirty-three teachers with their students (total 791), from grade school to university level, volunteered as subjects. The teachers used amplification in class for at least a week. At the end of the research period, the participants answered questionnaires, except the pupils between 6–9 years of age who were asked two questions. The results showed: (1) the majority of teachers found it easier to talk and experienced less fatigue using vocal amplification; (2) the students found it easier to hear the teacher through class chatter and to follow the lessons; (3) the disadvantages mentioned were mainly technical problems.

2pAAa5. Acoustic and other factors relating to the use of sound field systems in classrooms. Anne Carey, Bridget Shield (Dept. of Eng. Systems, Faculty of Eng., Sci. and Built Environment, London South Bank Univ., London SE1 0AA, UK), Julie Dockrell, and Kate Rigby (Univ. of London, 25 Woburn Square, London WC1H 0AA, UK)

A study has been made of thirty-five primary school classrooms which have Sound Field Systems (SFS) installed. Acoustic surveys of the classrooms have been undertaken and detailed observations made of the physical characteristics of each room such as its construction and design, plus any acoustic treatment. The positioning and type, e.g., column or separate speakers, of SFS installed were also noted. Details of the procedures for purchasing, installing, and maintaining the SFS were obtained where possible, together with information concerning training of teachers in their use. Results from these surveys suggest that in many cases SFS are installed in rooms where their performance may be compromised because of inadequate acoustic conditions. Additionally problems may arise due to inappropriate installation, choice of system, poor maintenance, or lack of training. The effectiveness of acoustic treatment such as absorption applied to ceilings and walls has also been investigated in a range of classrooms and its impact on the use of SFS considered.

3:05–3:20 Break

2pAAa6. Installation and impact of sound field systems on hearing and hearing impaired children and their teachers. Julie Dockrell, Kate Rigby (School of Psych. and Human Development, Inst. of Education, Univ. of London, 25 Woburn Square, London WC1H 0AA, UK), Bridget Shield, and Anne Carey (London South Bank Univ., London SE1 0AA, UK)

An evaluation of the installation and use of sound field systems in ten schools in England has been carried out. The evaluation included noise surveys of classrooms, questionnaire surveys of pupils and teachers and experimental testing of children with and without the use of SFS. The aim of this project was to investigate the impact of SFS on teaching and learning in elementary school classrooms, in particular, to ascertain whether the SFS differentially benefited children with hearing impairments. Barriers to teachers use of SFS were found in terms of equipment placement and maintenance, appropriate training, and teacher's knowledge. Nonetheless positive reports are recorded from both teachers and pupils. Teachers' and pupils' perceptions are compared with objective data evaluating change in performance when SFS are used for language and cognitive tasks. Data from children with hearing impairments and additional learning needs are analyzed for comparative purposes. The results are discussed in terms of effective practice for the use of SFS with elementary school pupils.

2pAAa7. Acoustic and electromagnetic noise from lighting in classrooms. Charles A. Laszlo, Jonathan Lashin (UBC Dept. of Elec. and Comput. Eng., 2356 Main Mall, Vancouver, BC, Canada V6T 1Z4, claszlo@telus.net), and Murray R. Hodgson (UBC Acoust. and Noise Res. Group, Vancouver, BC, Canada V6T 1Z3)

Following complaints by hard-of-hearing students using assistive-listening devices, and their teachers, the hum-like noise generated by fluorescent lighting was investigated in classrooms and the school library in a typical school. This hum is caused by vibrations in the core of the magnetic ballasts. Measurements were made in several rooms without students present. Noise levels increased between 7 and 15 dB when fixtures using magnetic ballasts were switched on. Spectral analysis showed the presence of 30, 60, 120, and 240 Hz components. In rooms where electronic ballasts were installed, there was no increase in noise level when the lights were switched on. Since hearing aids and assistive-listening devices worn by students may also be influenced by magnetic fields, these were also surveyed in these classrooms. The magnetic fields generated by the lights were not significant, but near some wiring and electrical panels the interference was strong. In rooms with electronic ballasts some infrared assistive-listening devices picked up strong high-frequency hum. It is recommended that the effect of lighting fixtures and the electrical-distribution system be taken into account in the acoustical and communication design of classrooms.

4:00

2pAAa8. Real world issues in classroom acoustics for hearing impaired students. Klaus Kleinschmidt (Acoust. Consultant, 132 Mary Catherine Dr., Lancaster, MA 01523)

Experience is being gained from evaluating and modifying the acoustical properties and background noise levels of existing classrooms for use by hearing impaired students. Projects include more than 25 schools in public school systems that are mainstreaming handicapped children. Various practical and economic restrictions have led to recommendations for modifications that do not necessarily comply with ANSI S12.60 2002. Examples of real world conditions and practical solutions will be described.

4:15

2pAAa9. Noise problem in a primary level classroom. Sergio Beristain (IMA, ESIME, IPN. P.O. Box 12-1022, Narvarte, 03020, Mexico D. F., Mexico. sberista@hotmail.com)

Noise was assessed in a primary school in Mexico City (six to twelve year old kids), known as having significant noise inside classrooms. Several sources were identified, among them, traffic noise and noise from the sports and recreational areas, which were in the center of the school with the classrooms surrounding them. Reverberation was an issue, but not very significant. But in some cases the most annoying sound (noise), was the one made by the students within the classroom, inducing a number of reactions in the lecturers. These reactions ranged from shouting to give the lecture, through trying to control the students, to ignore them and let it go. Lecturer's voice levels were also measured, finding out a wide spread in normal speech voice level, and some of their experiences and comments were analyzed. Results are summarized in this presentation.

TUESDAY AFTERNOON, 17 MAY 2005

BALMORAL, 1:30 TO 5:00 P.M.

Session 2pAAb

Architectural Acoustics and the National Council of Acoustical Consultants: Student Design Competition

Robert C. Coffeen, Cochair

Univ. of Kansas, School of Architectural and Urban Design, Marvin Hall, Lawrence, KS 66045

Byron Harrison, Cochair

The Talaske Group Inc., 105 N Oak Park Ave., Oak Park, IL 60301

The Technical Committee on Architectural Acoustics of the Acoustical Society of America and the National Council of Acoustical Consultants are sponsoring this Student Design Competition that will be professionally judged at this meeting. The purpose of this design competition is to encourage students enrolled in architecture, architectural engineering, and other university curriculums that involve building design and/or acoustics to express their knowledge of architectural acoustics in the design of a drama theater complex located within an urban mixed-use development. This competition is open to undergraduate and graduate students from all nations.

Submissions will be poster presentations that demonstrate room acoustics, noise control, and acoustic isolation techniques in building planning and room design.

The submitted designs will be displayed in this session and they will be judged by a panel of professional architects and acoustical consultants. An award of \$1,250 US will be made to the submitters of the entry judged "First Honors." Up to four awards of \$700 US each will be made to submitters of entries judged "Commendation."

2pAB1. Effects of surveillance towed array sensor system (SURTASS) low frequency active sonar on fish. Arthur N. Popper, Michele B. Halvorsen, Diane Miller, Michael E. Smith, Jiakun Song, Lidia E. Wysocki (Dept. of Biol., Univ. of Maryland, College Park, MD 20742, apopper@umd.edu), Mardi C. Hastings (Office of Naval Res., Arlington, VA 22217), Andrew S. Kane (Univ. of Maryland, College Park, MD 20742), and Peter Stein (Sci. Solutions, Inc., Nashua, NH 03049)

We investigated the effects of exposure to Low Frequency Active (LFA) sonar on rainbow trout (a hearing non-specialist related to several endangered salmonids) and channel catfish (a hearing specialist), using an element of the standard SURTASS LFA source array. We measured hearing sensitivity using auditory brainstem response, effects on inner ear structure using scanning electron microscopy, effects on non-auditory tissues using general pathology and histopathology, and behavioral effects with video monitoring. Exposure to 193 dB re 1 microPa (rms received level) in the LFA frequency band for 324 seconds resulted in a TTS of 20 dB at 400 Hz in rainbow trout, with less TTS at 100 and 200 Hz. TTS in catfish ranged from 6 to 12 dB at frequencies from 200 to 1000 Hz. Both species recovered from hearing loss in several days. Inner ears sensory tissues appeared unaffected by acoustic exposure. Gross pathology indicated no damage to non-auditory tissues, including the swim bladder. Both species showed consistent startle responses at sound onsets and changed their position relative to the sound source during exposures. There was no fish death attributable to sound exposure even up to four days post-exposure. [Work supported by Chief of Naval Operations.]

1:45

2pAB2. The effects of stimulus parameters on the auditory brainstem response of zebrafish (*Danio rerio*). Maria Margaritis and Dennis Higgs (Dept. of Biol., Univ. of Windsor, Windsor, ON, Canada N9B 3P4, dhiggs@uwindsor.ca)

In mammals and birds it is well documented that stimulus parameters have significant effects on auditory processing. However in fish, the effect of different stimulus types remains unclear. Therefore it is difficult to directly compare piscine auditory responses obtained by different investigators, due to variability in testing methods. The current study uses zebrafish (*Danio rerio*) to evaluate the effects of stimulus type (800 Hz tone bursts versus broadband stimuli from 100–4000 Hz) and stimulus duration (1, 5, 10, or 20 ms) on the auditory brainstem response (ABR). Threshold was significantly lower ($p=0.04$) for broadband sounds than for tones, but there was no effect on either latency or amplitude. There was a direct and significant effect of duration on threshold ($p=0.001$), suggesting the response was due to the offset rather than the onset of the stimulus. Duration had no effect on either threshold or amplitude. The stimulus level had no significant effect on latency, however amplitude significantly increased as level increased ($p=0.001$). Thus, stimulus parameters can significantly affect ABRs. The current findings show the need for a consistent method of testing among investigators in order to reliably compare results. 2pAB3. Auditory evoked potential measurements in elasmobranchs. Brandon Casper and David Mann (Univ. of South Florida, College of Marine Sci., 140 Seventh Ave. South, St. Petersburg, FL 33701)

Auditory evoked potentials (AEP) were first used to examine hearing in elasmobranchs by Corwin and Bullock in the late 1970s and early 1980s, marking the first time AEPs had been measured in fishes. Results of these experiments identified the regions of the ear and brain in which sound is processed, though no actual hearing thresholds were measured. Those initial experiments provided the ground work for future AEP experiments to measure fish hearing abilities in a manner that is much faster and more convenient than classical conditioning. Data will be presented on recent experiments in which AEPs were used to measure the hearing thresholds of two species of elasmobranchs: the nurse shark, *Ginglymostoma cirratum*, and the yellow stingray, *Urobatis jamaicensis*. Audiograms were analyzed and compared to previously published audiograms obtained using classical conditioning with results indicating that hearing thresholds were similar for the two methods. These data suggest that AEP testing is a viable option when measuring hearing in elasmobranchs and can increase the speed in which future hearing measurements can be obtained.

2:15

2pAB4. Bottlenose dolphins audiogram dependence on azimuth: Evoked potential study. Vladimir Popov (Inst. of Ecology and Evolution, 33 Leninsky Prosp., 119071 Moscow, Russia)

ABR thresholds to tonal pips were measured in two bottlenose dolphins at different azimuthal positions of the sound source. The tested frequency range was from 8 to 128 kHz. Azimuth varied within a limit of 90 degree relative to the animals' longitudinal axis. This experimental paradigm allowed us to obtain ABR audiograms at different locations of the sound source. The zero-azimuth audiogram, at the sound source position in front of the animal, was of a standard appearance (minimum thresholds at frequencies of 38–90 kHz, steep threshold increase at higher frequencies, and shallower increase at lower frequencies). The audiograms at lateralized sound-source positions looked in a different manner. With the azimuth increase, high-frequency thresholds rose much higher than low-frequency ones, so at azimuths of 60–90, the threshold versus frequency function was almost monotonous: the lowest threshold was observed at the lowest frequency (8 kHz) and the highest threshold at the highest frequency (128 kHz). With monaural ABR recording, audiograms contralateral to the sound source featured higher thresholds and steeper threshold increase with frequency as compared to the ipsilateral ones. [Work supported by the Russian Foundation for Basic Research.]

2pAB5. Audiogram variability in normal bottlenose dolphins.

Mikhail B. Tarakanov, Mikhail G. Pletenko, Vladimir V. Popov, and Alexander Ya. Supin (Inst. of Ecology and Evolution, 33 Leninsky Prospect, 119071 Moscow, Russia)

Audiograms have been obtained in about a dozen of odontocete species, but mostly in one or two individuals each. However, some inter-individual difference in hearing sensitivity is inevitable. Therefore, a representative number of animals should be investigated to get a normal audiogram standard. In the present study, an attempt has been made to estimate the audiogram scatter among normal bottlenose dolphins. Measurements were made in dolphins captured in wild and kept in captivity 3 to 5 months, using auditory evoked potential technique (envelope following response) to measure hearing thresholds in far acoustic field. Seven subjects, 5 males and 2 females, provisionally from 3 to 15 years old, were investigated during the summer season of 2004. Hearing thresholds were measured at frequencies from 8 to 152 kHz with quarter-octave steps. All the subjects had qualitatively similar audiograms. The best sensitivity was from 38.9 dB re 1 uPa (at 32 kHz) to 51.9 dB (at 16 kHz), with a minimum of the averaged audiogram of 47.1 dB at 45 kHz. High-frequency cut-off was 152 kHz at a level of 40 dB above the lowest threshold. Standard deviation of threshold was from 4.1 to 10.3 dB. [Work supported by RFBR and Russian President Grants.]

2:45

2pAB6. Auditory evoked potential (AEP) measurements in stranded rough-toothed dolphins (*Steno bredanensis*).

Mandy L. H. Cook (USF College of Marine Sci., 140 Seventh Ave. South, Saint Petersburg, FL 33701-5016, mhill@marine.usf.edu), Charles A. Manire (Mote Marine Lab., Sarasota, FL 34236), and David A. Mann (USF College of Marine Sci., Saint Petersburg, FL 33701-5016)

Thirty-six rough-toothed dolphins (*Steno bredanensis*) live-stranded on Hutchinson Island, FL on August 6, 2004. Seven animals were transported to Mote Marine Laboratory for rehabilitation. Two auditory evoked potential (AEP) measurements were performed on each of five of these dolphins in air using a jawphone to present acoustic stimuli. Modulation

rate transfer functions (MRTFs) were measured to establish how well the auditory system follows the temporal envelope of acoustic stimuli. A 40 kHz stimulus carrier was amplitude modulated (AM) with varying rates ranging from 200 Hz to 1800 Hz, in 200 Hz steps. The best AM-rate from the first dolphin tested was 1500 Hz. This AM rate was used in subsequent AEP measurements to determine evoked-potential hearing thresholds between 5000 and 80 000 Hz. These findings show that rough-toothed dolphins can detect sounds between 5 and 80 kHz, and are most likely capable of detecting frequencies much higher than 80 kHz. MRTF data suggest that rough-toothed dolphins have a high temporal resolution, similar to that of other cetaceans.

3:00

2pAB7. Stimulus-response characteristics of a harbor porpoise during active echolocation and passive hearing studied with auditory brain stem recordings (ABR).

Kristian Beedholm and Lee A. Miller (Inst. of Biol., Univ. of Southern Denmark, Campusvej 55, DK-5230 Odense M, Denmark, lee@biology.sdu.dk)

We evaluated the stimulus-response characteristics of hearing by a harbor porpoise using narrow band pulses resembling the animal's own echolocation pulse (130 kHz, 100 us), but shifted in frequency (80, 100, 125, 160 kHz). Our animal was trained to accept two suction cup electrodes and to station 1 m below the water surface. Stimuli could be presented either as simulated echoes at a fixed delay (5 ms) relative to the animal's echolocation signals, or at a constant rate chosen by the experimenter. Stimulus levels were varied between 90 and 150 dB re 1uPa and the ABR responses were averaged (16 or more responses) at each level. The relationship between input level (in dB) and ABR amplitude was reasonably linear for simulated echo and constant rate experiments. Regression lines were calculated to determine the level at which the response met the noise, defining the ABR threshold. There was little difference in the ABR threshold (100 to 110 dB re 1uPa) for the four frequencies. The rate of growth of the ABR response with increasing stimulus level was steepest at 125 kHz, which could well reflect a relatively denser population of neurons tuned to this frequency area. [Work done at Fjord & Baelt, Kerteminde, Denmark, and supported by ONR.]

2pAO1. Seafloor classification using artificial neural network architecture from central western continental shelf of India.

Vasudev Mahale, Bishwajit Chakraborty, Gajanan S. Navelkar, and R. G. Prabhu Desai (Natl. Inst. of Oceanogr., Dona Paula, Goa: 403 004, India, bishwajit@darya.nio.org)

Seafloor classification studies are carried out at the central western continental shelf of India employing two frequency normal incidence single beam echo-sounder backscatter data. Echo waveform data from different seafloor sediment areas are utilized for present study. Three arti-

ficial neural network (ANN) architectures, e.g., Self-Organization Feature Maps (SOFM), Multi-Layer Perceptron (MLP), and Learning Vector Quantization (LVQ) are applied for seafloor classifications. In case of MLP, features are extracted from the received echo signal, on the basis of which, classification is carried out. In the case of the SOFM, a simple moving average echo waveform pre-processing technique is found to yield excellent classification results. Finally, LVQ, which is known as ANN of hybrid architecture is found to be the efficient seafloor classifier especially from the point of view of the real-time application. The simultaneously acquired sediment sample, multi-beam bathymetry and side scan sonar and echo waveform based seafloor classifications results are indicative of the

2pAO2. Geoacoustic parameters inversion by ambient noise in South China Sea experiment of ASIAEX. Ruey-Chang Wei, Yao-Hsien Kuo, Cheng-Hung Chen (Natl. Sun Yat-Sen Univ., No. 70, Lien-Hai Rd., Kaohsiung, Taiwan 804), and Hsiang-Chih Chan (Natl. Taiwan Univ., Taipei, 106, Taiwan)

Knowing bottom geoacoustic parameters is of great importance for using sonar systems effectively in shallow water. This study is based upon the vertical line array (VLA) in South China Sea experiment of the Asian Seas International Acoustic Experiment (ASIAEX), dated from May 3, 2001 to May 16, 2001, in which the ambient noise was also measured in shallow water. Beamforming is used to calculate the vertical directionality of ambient noise, but limited by the array element spacing, the major analysis frequency range is 100 to 400 Hz. Comparison between forward modeling (normal mode code) and experimental results show the energy ratio of up-looking and down-looking beams, which can be referred to the energy reflection coefficient of the bottom-potentially a function of angle and frequency. From the reflection coefficient, critical parameters of the sediments such as sound speed, density, and attenuation coefficient can be obtained. Finally, this result is verified by on-site chirp sonar surveys during the experiment, and also by other inversion investigation in this area using other sound source.

2:00

2pAO3. Single beam echosounding: Considerations of depth and seabed slope. Ben R. Biffard, N. Ross Chapman, Steve F. Bloomer (School of Earth and Ocean Sci., Univ. of Victoria, P.O. Box 3055, Victoria, BC, Canada V8W 3P6), and Jon M. Preston (Quester Tangent Corp., Sidney, BC, Canada V8L 5Y8)

The topic of depth compensation of single beam echo time series for seabed classification is fairly well studied. The effect of seabed slope has not been publicized. In applications for seabed classification, seabed slope is observed to be associated with classification inaccuracy and failure. In cases of higher slope, single beam bathymetry also becomes inaccurate. A survey of 2 fjords with extreme variation in slope is presented as a representative example and testing bed for investigating slope. The direct effect on seabed echoes is investigated and explained in reference to a simple model of beam-echo geometry. Survey bathymetry is compensated for slope; inaccuracies of up to 5% of depth are corrected, however bottom picking accuracy is diminished in areas of slope and cannot be improved. Surveys of a gas hydrate site and a river will also be presented as applications of these ideas. Early results from BORIS model studies of methods for compensation of slope and depth may also be presented.

2:15

2pAO4. Estimating the uncertainty of geoacoustic parameters of a range-dependent environment. Mark Fallat (Dept. of Earth and Ocean Sci., Univ. of BC, Canada), Stan Dosso (Univ. of Victoria, Canada), and Peter Nielsen (NATO Undersea Res. Ctr.)

In this study, data from a range-dependent environment are inverted to obtain estimates of the geoacoustic properties and their uncertainties. The technique consists of combining the results of a series of range-independent inversions to produce a model of the range-dependent environment. A rigorous uncertainty analysis provides a way of discerning whether variations in the inversion results are due to range-dependent features of the environment or simply due to uncertainty/variability in the results. Broadband acoustic data from a track off the island of Sicily were analyzed. Ground-truth information in the form of core measurements and a high-resolution seismic profile were also collected and used for verification of the results. The method of fast Gibbs sampling (FGS) was used to estimate the uncertainties of the geoacoustic properties. FGS is based on a Bayesian approach to inversion which samples the posterior probability

distribution to estimate marginal probability distributions and parameter correlations. Marginal probability distributions were computed at various points along the track and compared to the ground-truth information. Overall, the analysis showed that the dominant range-dependent features of the environment could be estimated.

2pAO5. A method for obtaining the geoacoustic properties of marine sediments using sound generated by aircraft. Eric M. Giddens and Michael J. Buckingham (Scripps Inst. of Oceanogr., La Jolla, CA 92093-0238)

A low-frequency geoacoustic inversion method has been developed for an isovelocity waveguide using light-aircraft as a source of sound. The high Doppler shift of the acoustic field facilitates the inversion, allowing directional information to be gathered by a single, omnidirectional receiver. The inversion method has been applied to simulations and to field experiments conducted in shallow water (14.4 m depth) off the coast of La Jolla. The inversion results will be discussed along with an error analysis using the Cramer-Rao Lower Bounds. [Work supported by ONR and the ARCS Foundation.]

2:45

2pAO6. Uncertainty bounds for geoacoustic inversions due to sound speed variations in water column. Ying-Tsong Lin and James F. Lynch (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

The uncertainty bounds for geoacoustic inversion results due to sound speed variability in the water column perturbed by internal waves are assessed. Our previous work showed that if the sound speed variations are not taken account into the water column model, they will affect the accuracy of geoacoustic inversions. In this paper, we seek to quantify how well the error bounds could be given under certain knowledge of the sound speed variations. In doing so, the equivalent transform method derived from the linear perturbation theory plays a role in error transferral from water column to bottom. The water column variability is decomposed into ocean dynamic modes or as empirical orthogonal function (EOF) modes. Obtaining the ocean dynamic modes requires having the buoyancy frequency profile, whereas obtaining the EOF modes requires having vertical time series data. In general, it is difficult to assemble full statistics of the sound speed variations, so we examine the uncertainty bounds of the inversion results in the case where only partial statistics can be observed.

3:00

2pAO7. Geoacoustic inversion of broadband data by matched beam processing. N. Ross Chapman and Yongmin Jiang (School of Earth and Ocean Sci., Univ. of Victoria, P.O. Box 3055, Victoria, BC, Canada V8W 3P6)

This paper describes results of geoacoustic inversion using broadband signals from an experiment carried out at a site near the South Florida Ocean Measurement Centre in the Florida Straits. M-sequence coded pulse trains at different center carrier frequencies from 100 to 3200 Hz were transmitted in the acoustic experiment, and received by a tri-axial array at a distance around 10 km. Geoacoustic inversion was carried out to determine the possibility of inverting the environmental parameters from this long-range propagation experiment. The received signal at 100 Hz consisted of a dominant water column signal and a secondary arrival delayed by 0.4 s. The secondary signal was spatially filtered by beamforming the array data, and the beam data were inverted by matched beam processing combined with an adaptive simplex simulated annealing algorithm. The estimated values of compressional wave speed and density were in good agreement with ground truth values from sediment cores. The inverted shear wave speed appears to be a sensitive parameter and consistent with compressional wave speed. Range and water depth were also included as inversion parameters, and the inversion results were close to the known values within small uncertainties. [Work supported by ONR.]

3:15

2pAO8. Matched-field geoaoustic inversion with correlated data errors. Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC, Canada)

Many approaches to geoaoustic inversion are based implicitly on the assumption that data errors (including measurement and theory errors) are uncorrelated. However, this assumption is often not valid, and can lead to inefficient geoaoustic parameter estimates and an under-estimation of parameter uncertainties. This paper examines the effects of data error (residual) correlations in matched-field geoaoustic inversion. Statistical tests for error correlations in both space and frequency are considered. An inversion approach is developed based on an iterative, non-parametric method of estimating the full error covariance matrix (assuming ergodic residuals), and including this covariance in the likelihood function of a Bayesian formulation. The inversion approach is illustrated for broadband, vertical-array data from the Mediterranean Sea.

2pAO9. Bounding the error on bottom estimation for multi-angle swath bathymetry sonar. Geoff K. Mullins and John S. Bird (School of Eng. Sci., Simon Fraser Univ., 8888 University Dr., Burnaby, BC, Canada V5A 1S6)

With the recent introduction of multi-angle swath bathymetry (MASB) sonar to the commercial marketplace (e.g., Benthos Inc., C3D sonar, 2004), additions must be made to the current sonar lexicon. The correct interpretation of measurements made with MASB sonar, which uses filled transducer arrays to compute angle-of-arrival information (AOA) from backscattered signal, is essential not only for mapping, but for applications such as statistical bottom classification. In this paper it is shown that aside from uncorrelated channel to channel noise, there exists a tradeoff between effects that govern the error bounds on bottom estimation for surfaces having shallow grazing angle and surfaces distributed along a radial arc centered at the transducer. In the first case, as the bottom aligns with the radial direction to the receiver, footprint shift and shallow grazing angle effects dominate the uncertainty in physical bottom position (surface aligns along a single AOA). Alternatively, if signal from a radial arc arrives, a single AOA is usually estimated (not necessarily at the average location of the surface). Through theoretical treatment, simulation, and field measurements, the aforementioned factors affecting MASB bottom mapping are examined. [Work supported by NSERC.]

4:00

2pAO10. Posterior probability distributions for Biot parameters from experimental data. Buye Xu, Traci Neilsen (Dept. of Phys. and Astron., Brigham Young Univ., N203 ESC, Provo, UT 84602, bxu@email.byu.edu), and Marcia Isakson (Univ. of Texas, Austin, TX 78712)

Reflectivity measurements can be used in inversion techniques to obtain estimates of the physical characteristics of seabed sediments. In addition, computation of posterior probability distributions (PPDs) [S. E. Dosso, *J. Acoust. Soc. Am.* **111**, 129–142 (2002)] provide an uncertainty of each parameter estimate obtained by a simulated annealing inversion. In this work, PPDs are calculated for experimental reflection loss data to evaluate the sensitivities associated with the parameters in the Biot-Stoll poro-elastic model for sediments. The data comes from a lab tank experiment in which reflection loss from a sandy sediment was measured as a function of grazing angle for frequencies between 75 kHz and 150 kHz. The sampling for the PPDs is based on the least-squares error between simulated reflection coefficient data and values modeled with the reflection module of OASES. [H. Schmidt, “OASES Version 2.1 User Guide

and Reference Manual,” Department of Ocean Engineering, Massachusetts Institute of Technology, 1997.] The PPDs resulting from the lab data are compared with those obtained for simulated data, and the effects of experimental error on the results are explored.

4:15

2pAO11. Measurement of the bulk density gradient in the transition layer of a sand/water interface using a diver deployed X-Ray Attenuation Measurement System (XRAM). Todd Hay and Marcia Isakson (Appl. Res. Labs., Univ. of Texas, Austin, TX 78713)

The reflection coefficient is an important parameter for modeling acoustic applications in littoral environments. However, a density gradient in the transition layer of the interface can change the value of the reflection coefficient by 15 dB for high frequencies. Therefore, an accurate measurement of the bulk density gradient is crucial to the interpretation of reflection coefficient data. Previously, bulk density gradients have been determined by coring which disrupts grain microstructure or by electrical methods which do not measure the density directly. For this study, a novel means of directly determining the density gradient in situ using x-ray attenuation was developed. The system is small, lightweight, and diver deployed allowing a greater flexibility in density measurements. Calibration measurements of materials with varying densities as well as measurements of the transition layer of a sand/water interface will be presented. [Work supported by ONR, Ocean Acoustics.]

4:30

2pAO12. Geoaoustic inversion for single paths of Haro Strait data. A. Tolstoy (A. Tolstoy Sci., 1350 Beverly Rd., Ste. 115 PMB 293, McLean, VA 22101)

This presentation will discuss efforts to date for the geoaoustic inversion of selected, single, Haro Strait Source-Receiver (SR) paths. The parameters emphasized will include water depth, linear sound-speed profiles, and the range between SR. The path will assume 3 segments: one segment for the region at S, one for the region at R, and one for an average region in between. The inversions will operate using the SUB-RIGS method which is based on multiple frequencies where higher frequencies are most sensitive to surficial geoaoustic properties while the lower frequencies are most sensitive to the deeper properties. Some paths have already been successfully inverted by earlier research efforts (Chapman *et al.*). This paper will demonstrate efforts on some of those paths as well as on other, more problematic SR paths.

4:45

2pAO13. Classification of acoustic signals using the statistics of the 1-D wavelet transform coefficients. Michael I. Taroudakis (Dept. of Mathematics, Univ. of Crete and FORTH/IACM, P.O. Box 1527, 711 10 Heraklion, Greece) and George Tzagkarakis (Univ. of Crete and FORTH/ICS, Heraklion, Greece)

The representation of an acoustic signal in terms of the wavelet sub-band coefficients is studied using their statistical features. This type of representation is suggested as an alternative tool for tomographic or geoaoustic inversions. Using a set of representative shallow water environments, the variation of the statistical behavior of the sub-band coefficients is associated with corresponding variations of the environmental parameters. Low frequency signals suitable for ocean acoustic tomography are simulated. It is shown that the statistics of the sub-band coefficients are best described using non-Gaussian heavy-tailed distributions such as those of the alpha-stable family. The variations of the distribution parameters are measured using special statistical similarity functions such as the Kullback-Leibler divergence which has been adopted in the present study. The distances between the statistical parameters of a given and reference signals determined by these functions, can be used for subsequent non-linear inversions aiming at the recovery of the environmental parameters.

2pBB1. Computational synthesis of ultrasound breast images from a three-dimensional anatomical model. Yi-Ting Shen and James C. Lacefield (Univ. of Western Ontario and Robarts Res. Inst., London, ON, Canada)

A three-dimensional breast anatomy model has been implemented using spline surfaces and fractal structures to represent the architecture of the lactiferous ducts, mammary fat lobules, skin, and supporting connective tissues. The model randomly varies user-specified structural parameters to provide an unlimited number of realizations of the gross anatomy. Cross-sectional views extracted by slicing through a realization of the model are input to a two-dimensional k -space (i.e., spatial frequency domain) ultrasound propagation simulator. The k -space simulator iterates pressure and particle velocity fields in 30-ns steps to compute scattering from the structures defined by the anatomical model and small random variations in compressibility that are added to generate speckle. A synthetic aperture method is employed to simulate B -mode imaging with a 5 MHz, 192-element linear array operated using multiple transmit focal zones and dynamic receive focusing. Simulated images of random-scattering phantoms possess approximately Rayleigh speckle statistics. The anatomical model is expected to yield images with speckle statistics comparable to clinical breast images. The long-term objectives of these simulations are to investigate sources of focus aberration in ultrasound breast imaging and the impact of aberration on cancer detection. [Work supported by an NSERC Discovery Grant.]

2:00

2pBB2. Tissue-type imaging (TTI) based on ultrasonic spectral and clinical parameters for detecting, evaluating, and managing prostate cancer. Ernest J. Feleppa, Jeffrey A. Ketterling, Shreedevi Dasgupta, Andrew Kalisz, Sarayu Ramachandran (Biomed. Eng. Labs., Riverside Res. Inst., 156 William St., New York, NY 10038, feleppa@rrinyc.org), and Christopher R. Porter (Virginia Mason Medical Ctr., Seattle, WA 98101)

This study seeks to develop more-sensitive and -specific ultrasonic methods of imaging cancerous prostate tissue and thereby to improve means of guiding biopsies and planning, targeting, and monitoring treatment. Ultrasonic radio-frequency, echo-signal data, and clinical variables, e.g., PSA, voiding function, etc., during biopsy examinations were acquired. Spectra of the radio-frequency signals were computed in each biopsied region, and used to train neural networks; biopsy results served as the gold standard. A lookup table gave scores for cancer likelihood on a pixel-by-pixel basis from locally computed spectral-parameter and global clinical-parameter values. ROC curves used leave-one-patient- and leave-one-biopsy-out approaches to minimize classification bias. Resulting ROC-curve areas were 0.80 ± 0.03 for neural-networks versus 0.66 ± 0.03 for conventional classification. TTIs generated from data acquired pre-surgically showed tumors that were unrecognized in conventional images

and during surgery. 3-D renderings of prostatectomy histology and TTIs showed encouraging correlations, which shows promise for improving the detection and management of prostate cancer, e.g., for biopsy guidance, planning dose-escalation and tissue-sparing options for radiation or cryotherapy, and assessing the effects of treatment. Combining MRS parameters with US spectral parameters appears capable of further improving prostate-cancer imaging. [Work supported by NIH.]

2:15

2pBB3. Bioheat Transfer Model (BHTE) based temperature estimation technique for high intensity focused ultrasound therapy monitoring. Peter J. Kaczowski and Ajay Anand (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

The spatial distribution of tissue temperature is an essential indicator of thermal therapy progress, treatment safety and efficacy. Here, it is shown through in vitro experiments that temperature rise can be accurately measured during therapy delivery and post-treatment cool down phases using RF backscatter data collected with a modified ultrasound scanner. RF data is acquired prior to, during, and after HIFU exposures, in tissue mimicking phantoms and excised animal tissue. Through two calibration experiments, initial estimates for key BHTE parameters (local thermal diffusivity, and magnitude of the HIFU heat source) and the temperature dependence of ultrasonic travel time are obtained prior to therapy. Tissue heterogeneity over a larger targeted region of interest is modeled as a change in the magnitude of the focal heat source. During therapy this magnitude is updated using an iterative optimization technique that minimizes the difference between predicted and measured travel time values. Temperature and thermal dose maps are generated throughout therapy delivery and post-treatment cooling periods. The ultrasound derived estimates are validated against independent thermocouple measurements close to but not at the HIFU focus. This model-based technique permits noninvasive temperature estimation throughout the entire therapeutic range, and is thus a departure from previously reported techniques.

2:30

2pBB4. Comparison of three models at high frequency for ultrasound tissue scattering. Michael Oelze, William O'Brien, Jr. (Dept. of Elec. and Comput. Eng., Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801), and James Zachary (Univ. of Illinois at Urbana-Champaign)

A mammary carcinoma was grown in mice and imaged with an ultrasound transducer operating with a center frequency of 65 MHz. Quantitative ultrasound (QUS) analysis was used to characterize the tumors using the bandwidth of 30 to 85 MHz. Three models (Gaussian scatterer, fluid-filled sphere, and a new cell scatterer) for scattering were examined and scatterer property estimates were compared to real tissue morphology as seen from optical microscope images of the tumors. The Gaussian scattering model did not fit the data well compared to the fluid-filled sphere and new cell scatterer models. The fluid-filled sphere model fit the measure-

ments better than any other model but did not yield scatterer property estimates that resembled underlying structure. Using the fluid-filled sphere model, the average estimated scatterer diameter was $25.5 \pm 0.14 \mu\text{m}$. A new cell scatterer model was developed, which was based on scattering from a cell by incorporating the effects of the cytoskeleton and nucleus. The new cell scatterer model yielded estimates that appeared to reflect underlying structure more accurately. Using the new cell scatterer model, the average estimated nuclear diameter was $15.6 \pm 2.2 \mu\text{m}$ compared with $13.2 \mu\text{m}$ as measured from optical microscope images.

2:45

2pBB5. Importance of local attenuation on the estimation of scatterer size from ultrasound backscattered waveforms. Timothy A. Bigelow and William D. O'Brien, Jr. (Univ. of Illinois, 405 N. Mathews Ave., Urbana, IL 61801, bigelow@uiuc.edu)

Estimating the characteristic size of the tissue microstructure from a statistical analysis of the backscattered power spectrum could improve the diagnostic capability of medical ultrasound. Previously, size estimates were obtained for focused sources after compensating for source focusing, the frequency-dependent attenuation along the propagation path (total attenuation), and the frequency-dependent attenuation in the region of interest (local attenuation) given the attenuation values. In this study, the importance of the local attenuation on the scatterer size estimate was determined using computer simulations. The simulations used Gaussian impedance distributions with an effective radius of $25 \mu\text{m}$ randomly positioned in a homogeneous half-space (attenuation from 0.05 to 1 dB/cm-MHz) sonified by a spherically focused source ($f/1$ to $f/4$). The total attenuation and focusing were assumed known. The scatterer size was estimated assuming that the local attenuation was zero, the local attenuation was the mean value of the true attenuation over the frequency range used to obtain the estimates, and the local attenuation was 0.5 dB/cm-MHz. These three size estimates were then compared to estimates obtained using the true local attenuation value as well as estimates obtained when both focusing and local attenuation were not compensated.

3:00–3:15 Break

3:15

2pBB6. Non-invasive measurement of *in situ* thermal diffusivity and local heat source using backscattered ultrasound for thermal therapy planning and monitoring. Ajay Anand and Peter Kaczkowski (Univ. of Washington, 1013 40th St NE, Seattle, WA 98105)

Bioheat transfer equation (BHTE) estimates of applied dose during HIFU therapy typically use *prior* knowledge or assume standard values for tissue properties that determine thermal diffusivity (K) and heat source (Q). We have developed a novel signal-processing based technique to *noninvasively* estimate these parameters *in situ* based on analysis of raw backscattered RF data from two localized HIFU exposures, one at sub-ablative intensities to determine K , and another at therapeutic intensities to obtain Q . Both exposures are performed prior to therapy. To estimate K , a short HIFU exposure is applied resulting in a temperature rise of less than 15°C . The Gaussian radius of the temperature induced apparent strain profile during cool down is estimated and fit to an approximate analytical heat diffusion expression to obtain K . Independent estimates of K derived using the transient hotwire technique validated the ultrasonic measurements. To estimate Q , an audio range hydrophone was acoustically coupled to the sample to detect the onset of boiling. The time required to bring the sample to boiling was used to estimate Q by iteration of a numerical BHTE model. These results are validated against *in situ* measured values using thermocouples and linear acoustic calculations.

2pBB7. Validation of high-frequency ultrasound measurements of tissue layer thickness. Qiang Qiu, Joy Dunmore-Buyze, Derek R. Boughner, and James C. Lacefield (Univ. of Western Ontario, Robarts Res. Inst., and London Health Sci. Ctr., London, ON, Canada)

High-frequency ultrasound imaging enables nondestructive measurement of layer thickness in tissue specimens. These measurements are valuable for mechanical testing of soft biomaterials. This paper demonstrates a method for assessing the accuracy of high-resolution ultrasonic thickness estimates. Three-dimensional images of six porcine aortic valve cusps were acquired *in vitro* using a 40 MHz ultrasound system with $40 \times 80 \times 80 \mu\text{m}^3$ spatial resolution. The cusps were then frozen in liquid nitrogen, sectioned into $10\text{-}\mu\text{m}$ slices, and micrographs of one slice from each specimen were acquired at $4\times$ magnification. The two-dimensional micrographs were registered to the three-dimensional ultrasound images using a cross-correlation method. The boundaries of the fibrosa, spongiosa, and ventricularis layers were segmented in both sets of images using an active contour model. The average thicknesses of the tissue layers in the registered images were estimated and the absolute differences of the optical and ultrasonic estimates were computed. The absolute differences were $55.8 \pm 22.6 \mu\text{m}$ (mean \pm standard deviation), $23.5 \pm 14.3 \mu\text{m}$, and $22.7 \pm 17.2 \mu\text{m}$ for the fibrosa, spongiosa, and ventricularis, respectively. The measurement differences are comparable to the axial resolution of the ultrasound system and are not significant as determined by *t*-tests ($p > 0.30$ for each layer).

3:45

2pBB8. Automatic 3D acoustic tissue models from histologic tissue sections and application to *ex vivo* tissue characterization. Jonathan Mamou, Michael L. Oelze, William D. O'Brien, Jr. (Dept. of Elec. and Comput. Eng., Univ. of Illinois at Urbana-Champaign, 1406 W. Green St., Urbana, IL 61801, mamou@uiuc.edu), and James F. Zachary (Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801)

Three-dimensional acoustic tissue models (3DATMs) can be used as computational tools for ultrasonic imaging algorithm development and analysis. 3DATMs are automatically constructed from digitized light microscope images of consecutive H&E-stained histologic tissue sections. Construction necessitated contrast equalization, registration, and interpolation of missing sections. The registered (with interpolated) sections yield a 3D histologic volume (3DHV). Acoustic properties are then assigned to each tissue constituent of the 3DHV to obtain the 3DATM. A tissue characterization technique was developed to obtain scatterer parameter estimates (size and acoustic concentration) from a 3D impedance map (3DZM) deduced from a 3DHV by assigning acoustic impedance values. 3DZMs were constructed for a rat fibroadenoma (FA), a mouse mammary tumor (MMT) and a mouse sarcoma (EHS). From these 3 3DZMs estimates, effective scatterer diameters of $91 \mu\text{m}$, $31.5 \mu\text{m}$, and $34.5 \mu\text{m}$, respectively, were determined. Independent ultrasonic measurements yielded average scatterer diameters of $105 \mu\text{m}$, $30 \mu\text{m}$, and $33 \mu\text{m}$, respectively. The 3DZM estimation scheme showed results similar to those obtained by the ultrasonic measurements. 3DATMs may therefore be a useful tool for quantifying ultrasonic tissue properties. 2pBB9. Automated set of test simulations for non-ideal medical ultrasound transducers using Monte-Carlo method. Hotaik Lee, Nadine B. Smith (Grad. Program in Acoust., The Penn State Univ., University Park, PA 16802), and Terry A. Kling (Sound Technol. Inc., State College, PA 16803)

Using Field II program and Monte-Carlo method, we developed new design tools for medical ultrasound transducers with the automated set of imaging simulations. This simulation environment is used to create and assess the parametric specification of design factors affecting the quality of medical ultrasound imaging. In order to obtain accurate and realistic results, non-ideal transducers whose transfer functions vary either across the transducer or within the transducer are considered. These variations

include, but are not limited to: center frequency, bandwidth, sensitivity, ringdown, angular response, time-of-flight, and lateral focus. By applying random numbers within the tolerance range to the variations in input parameters, the automated set of simulations is performed. First, critical input parameters for components of the transfer function are identified by sensitivity analysis. Next, the statistical range of parameter values that

yield a transducer model with a certain performance level is determined and the limit of variations in each factor for acceptable degradation of images is set. Finally, the creation of many “what if” cases to predict yield and statistical performance of a transducer and the imaging simulation are performed based on Monte-Carlo method. 2pEA1. Injection-molded 1-3 piezocomposite sensor development: The last ten years. Kim C. Benjamin (Naval Sea Systems Command Div. Newport, 1176 Howell St., Newport, RI 02841)

The past ten years have seen several interesting demonstrations of 1-3 piezocomposite when used as the active component in sonar sensors. Initially considered receive only by most in the field, piezocomposite has evolved into a proven broadband transducer material with both receive and transmit capability. From large aperture single element calibration transducers, to parametric mode projectors, the material has surprised many experts with its power handling capability. Its polymer constituent provides an amazing degree of versatility by allowing the thermoforming and shaping of transducer substrates for packaging into today's undersea vehicles. This talk will review the last ten years of piezocomposite transducer and array development focusing on both the materials transmit behavior and fabrication benefits for future sonar applications. [Work supported by the U.S. Navy.]

1:30

2pEA2. Engineering applications of limited diffraction beams. Jian-yu Lu (Ultrasound Lab, Dept. of Bioengineering, The Univ. of Toledo, Toledo, OH 43606, jilu@eng.utoledo.edu)

Limited diffraction beams (LDBs) are non-divergence and non-dispersive solutions to isotropic-homogeneous wave equations. These beams have a common characteristic of X-shaped branches and thus are also called X waves. Because of their highly directional propagation property, they have potential applications in medicine, underwater acoustics, and nonlinear optics (Charles Day, *Phys. Today*, October, 2004, pp. 25–26). In this talk, an overview of the development of LDBs will be given. This includes the conversion of any existing solutions to homogeneous or non-homogeneous wave equations to LDB solutions using Lorentz-related transformation, and a discussion of the orthogonal properties of the X wave transformation pair in representing any physically realizable waves. Experiments on applications of LDBs using our newly developed general-purpose ultrasound system will also be reported. (The system is capable of 128-channel simultaneous ultrasound data acquisitions at 12-bit/40 MHz rate and can hold real-time radio-frequency (RF) data up to 64 GB in one acquisition operation. Arbitrary ultrasound waveforms can be simultaneously produced by 128 12-bit/40 MHz D/A converters and then be linearly amplified to drive 75-Ohm loads or an array transducer at about ± 150 V.)

1:55

2pEA3. Fiber optic acoustic sensor technology. James Cole, Clay Kirkendall, and Anthony Dandridge (Naval Res. Lab, 4555 Overlook Ave., SW, Washington, DC 20375)

Fiber optic sensor technology has been under development for over 25 years, recently a major milestone has been reached- the introduction of the Fiber Optic Wide Aperture Array on the first Virginia class submarine. This paper will review the development of this technology, outlining the principles of operation and the technological developments that led to fiber optic interferometric sensors becoming viable for production in an advanced sonar system. The Fiber Optic Wide Aperture array is a large channel count planar array mounted on the side of the submarine, but fiber sensor technology is also being developed for both towed arrays (as a replacement for the Navy's thin-line towed arrays) and for bottom mounted acoustic arrays for a number of Navy applications. This

paper will describe the development of the fiber optic hydrophones for these applications as well as the optical interrogation techniques. One of the key features of fiber optic sensor technology is the ability to passively multiplex many hydrophone channels per fiber, several multiplexing techniques will also be described. Some of the issues and challenges of this technology, such as coherent noise for large channel count systems will also be briefly discussed.

2pEA4. Twenty years of barrel-stave flextensional transducer technology in Canada. Dennis F. Jones (Defence R&D Canada—Atlantic, P.O. Box 1012, Dartmouth, NS, Canada B2Y 3Z7, dennis.jones@drdc-rddc.gc.ca)

The barrel-stave flextensional transducer, a compact underwater sound source, was conceived at DRDC Atlantic in 1986 [G. W. McMahon and D. F. Jones, U.S. Patent No. 4,922,470 (1 May 1990); Canadian Patent No. 1,285,646 (2 July 1991)]. Over the years, five barrel-stave designs belonging to three flextensional classes were built and tested at DRDC Atlantic. Three Class I transducers with operating frequencies ranging from 800 to 1600 Hz were integrated into submarine communications buoys, low frequency active horizontal projector arrays, and a broadband sonar towbody. A high-power Class II and broadband (1–7 kHz) Class III transducer were deployed under the ice in the Lincoln Sea for research related to rapidly deployable surveillance systems. These barrel-stave flextensional transducers have also supported a variety of marine mammal studies including vocal mimicry in long-finned pilot whales, coda dialects in sperm whales, and the R&D of acoustic detection and tracking systems for endangered northern right whales. In August 2004 a barrel-stave transducer was used to lure a trapped juvenile humpback whale to the sluice gates of a tidal generating station on the Annapolis River in Nova Scotia by transmitting humpback whale calls underwater. The acoustic performance parameters for all 5 transducers will be presented.

2:35–2:50 Break

2:50

2pEA5. Single crystal cylinder transducers for sonar applications. Harold Robinson, Gerald Stevens, Martin Buffman (NUWC Div. Newport, 1176 Howell St., Newport, RI 02841), and James Powers (EDO Corp., Salt Lake City, UT 84115)

A segmented cylinder transducer constructed of single crystal lead magnesium niobate-lead titanate (PMN-PT) has been under development at NUWC and EDO Corporation for several years. The purpose of this development was to provide an extremely compact, high power broadband source. By virtue of their extraordinary material properties, ferroelectric single crystals are the ideal transduction material for developing such compact broadband systems. This presentation shall review the evolution of the transducer design as well as present the results of a successful in-water test conducted at NUWC in October of 2003. It shall be shown that design changes intended to eliminate spurious modes limiting the transducer bandwidth first observed in 2002 were successful, resulting in a transducer with a clean frequency response and an effective coupling factor of 0.85. The measured transducer admittance was in nearly exact agreement with theoretical predictions. The NUWC in-water tests demonstrated that the single crystal cylinder achieved an admittance bandwidth (based on the Stansfield criterion) of over 100%, while the tuned power factor was 0.8 or more over 2.5 octaves of frequency. Additionally, the transducer produced 12 dB higher source levels than a similarly sized PZT transducer. [Work sponsored by DARPA.]

3:05

2pEA6. Dipole projectors for conformal sonar system applications. Michael D. Gray (Acoust. and Mech. Systems Div., Georgia Tech Res. Inst., Atlanta, GA 30332-0810), Peter H. Rogers, and Gregg D. Larson (Georgia Inst. of Technol., Atlanta, GA 30332-0405)

Dipole projectors are being investigated for use in active sonar arrays on compliantly coated, low input impedance hulls. When the projector standoff d is acoustically small ($k_0 d < 1$), the direct and hull-reflected signals add in phase in the far field, leading to an increase in signal

strength on the order of 2 relative to a free field dipole. By contrast, the direct and reflected signals for monopole transducer will have nearly opposite phase, and the monopole will have a reduction in total signal strength on the order of $2k_0 d$. Ideally, both transducer types have cosine directivities in-situ, although the monopole transducer response can be more strongly influenced by hull elastic contributions. Designs for two simple realizations of a dipole projector will be presented, along with beam pattern measurements made with prototype transducers at the Georgia Tech water tank facility.

3:20

2pEA7. A novel underwater acoustic transmitter. Chung Chang and Richard Coates (Schlumberger-Doll Res., 36 Old Quarry Rd., Ridgefield, CT 06877)

A strong wide bandwidth low-frequency acoustic transmitter was designed and built to operate in the high-pressure environment of 20 000 psi and temperature over 200 °C inside an oil well. The same design idea can be easily adapted to the naval application in order to use it in the deep ocean environment. This transmitter is pressure balanced and does not use conventional piezoelectric material. Therefore, there is no performance degradation with changing pressure and temperature. This new transmitter uses impact force onto an acoustic resonator to generate sound. The impact force is generated by an electrical hammer. The design is simple, robust and the radiated acoustic wave fields are as repeatable as the piezoelectric source. In addition this new transmitter does not require an expensive amplifier to operate. A video clip will be shown to demonstrate the strength of the source. Further research was done to understand the impact physics and its controlling parameters. Using signal deconvolution technique one can measure the impact force function. A peak impact force of a few thousand pounds by the hammer was measured.

3:35

2pEA8. 3D spatial sampling with a cylindrical multibeam sonar array. Daniel S. Brogan and Christian P. de Moustier (Ctr. for Coastal and Ocean Mapping, Univ. of New Hampshire, 24 Colovos Rd., Durham, NH 03824-3525, daniel.brogan@unh.edu)

Various beam pair combinations can be formed with cylindrical multibeam sonar arrays to obtain a 3D spatial sampling of a patch of seafloor for each ping. This capability is explored with a 286 deg sector cylindrical array transmitting a stepped FM pulse over a 243 deg vertical fan beam centered on nadir and receiving with twenty-seven beam pairs, symmetrically steered about nadir in the fore-aft direction and spaced at 7.16 deg intervals across track. Conventional conjugate product techniques yield two across-track profiles of 26 soundings each (52 phasors total) per ping. However, by combining one or two phasors along-track and one, two or three phasors across-track, soundings can be obtained at the spatial bisectors of the angles between the 52 phasors. This yields three profiles consisting of 51 soundings each, for a total of 153 soundings. This effectively creates a 3D patch of detected seafloor for each ping, which may overlap with the patches from adjacent pings depending on the sonars attitude changes and altitude above the seafloor. [Work supported by NRL-SSC grant N00173-00-1-G912 and NOAA grant NA170G228.]

2pEA9. Techniques in piezoelectric transducer health monitoring. Eli M. Hughes I, Karl M. Reichard, and Tom B. Gabrielson (Penn State Appl. Res. Lab., 3075 Research Dr., CATO Park State College, PA 16801)

For many high intensity underwater applications, the piezoelectric elements within a transducer can be placed under high thermal, electrical and mechanical stress. One particular area of piezoelectric transducer research that has received little attention is *in-situ* health monitoring and failure prediction of the piezoelectric elements. While some studies have been performed in the theoretical mechanics of fractures due to device stress, there is a lack of practical information about piezoelectric health

monitoring and failure prediction. This study was directed at providing practical information about a transducer's electrical characteristics as it is stressed such that failure predictions can be made. The two major failure modes examined in this study were electro-mechanical stress and thermal depolarization. A large part of this research was devoted to the development of novel low-cost electronics that permit measurement of the broad band electrical impedance of the device from 0 to 50 kHz in a small time aperture. The new measurement techniques allow for a large amount of visibility in how a transducer's electrical impedance changes before and during failure. This added visibility provides information that can be used to accurately predict if a transducer is failing and what mechanism is causing the failure.

2pNS1. Blast noise impacts on sleep. Edward T. Nykaza and Larry L. Pater (Eng. Res. and Development Ctr., Construction Eng. Res. Lab., 2902 Farber Dr., Champaign, IL 61822)

Firing large guns during the hours of darkness is essential to combat readiness for the military. At the same time most people are particularly sensitive to noise when sleeping or trying to fall asleep. Laboratory studies done by Griefahn [J. Sound and Vib. **128**, 109–119 (1989)] and Luz [see Luz *et al.*, ERDC/CERL, TR-04-26 (2004)] suggest that a time period at night may exist where people are more tolerant to large weapon impulse noise (blast noise) and therefore, are less likely to be awakened from noise events. In the fall of 2004, a field study was conducted around a military installation to determine if such a time period(s) exists. Noise monitors were set up inside and outside of residents homes to record noise levels from live military training activities and actimeters were worn by participants sleeping their natural environment to measure sleep disturbance and awakening. The method and results of this study will be presented. [Work supported by US Army Engineer Research and Development Center CERL.]

1:15

2pNS2. Development of metrics to identify military impulse noise. Jeffrey S. Viperman (Dept. of Mech. Eng., Univ. of Pittsburgh, 648 Benedum Hall, Pittsburgh, PA 15261)

Urban encroachment of military bases continues to be a serious problem, affecting training exercises and overall military readiness. The military currently performs noise monitoring around bases to ensure that environmental conditions are favorable for tests or exercises. Despite refinements, current monitoring systems still suffer from occasional false positives and rely heavily on human interpretation. The long range goal of this work is to create a more accurate and autonomous noise classifier. The specific aims of the work are to create a library of recorded military impulse noise sources and to develop, test, and refine the noise classifier algorithms. Representative, high quality field measurements of various noise sources (25 mm and larger) will be conducted at a few military bases under varying environmental conditions. Measurements of wind noise and thunder will also be recorded. The software will be developed in MATLAB and will employ several common impulse noise metrics used for hearing conservation, including rise, peak, and fall times, crest factor, A-

and B-durations, L_{pk} and kurtosis, among others. A neural network will be trained to discern between the recorded military noise sources and naturally occurring noise based on these metrics. Preliminary results from the measurements and analysis will be presented. [Work supported by SERDP.]

1:30

2pNS3. Highway noise levels in a suburban environment under inversion conditions. James Chambers (Dept. of Mech. Eng., Univ. of Mississippi, University, MS 38677), Hugh Saurenman (ATS Consultants Inc., Los Angeles, CA 90017), Robert Bronsdon, Louis Sutherland (Simi Valley, CA 93063), Ken Gilbert, Roger Waxler, and Carrick Talmadge (The Univ. of Mississippi, University, MS 38677)

Noise levels were measured in Scottsdale, AZ during a two week period in March, 2004 to identify the reasons for increased noise levels near a major highway during early morning hours. The noise levels were accompanied by meteorological measurements as well as traffic counts to fully describe the problem. The noise levels were measured in one-third octave bands and ranged 100 ft to 2620 ft (30–800 m) from the highway and included data on both sides of the highway. The meteorological data indicated inversion conditions or downward refraction during the times of interest and model results from a Parabolic Equation (PE) calculation indicated good results with the data. The data and model indicated an approximately 10–15 dB increase in levels during inversion conditions which rapidly transitioned to neutral and lapsed conditions shortly after sunrise. The results of the modeling effort as well as the data will be presented. [Work supported by Arizona Dept. of Transportation.]

1:45

2pNS4. Determination of noise descriptors and criteria for pyrotechnic noise sources. Weixiong Wu (AKRF, 117 East 29th St., New York, NY 10016)

A noise study was conducted to determine appropriate noise descriptors and criteria for assessing pyrotechnic noise sources. The study was carried out to support an environmental impact statement (EIS) that defined sensitive land uses adjacent to reservoirs in New York City area, where potential noise impacts from avian dispersion measures would occur. The pyrotechnic techniques defined as impulsive noise sources are

among the avian dispersion measures that would be used at the reservoirs. Determining appropriate noise descriptors and criteria was critical to the EIS because of the distinctive sound characteristics of pyrotechnic impulse noise sources, the lack of published literature on assessing them, and the absence of corresponding noise regulations. Noise descriptors and criteria used for EIS in the United States were investigated, and noise measurements for pyrotechnic noise sources and some impulsive noise sources were also performed. The study results demonstrate that *C*-weighted DNL is an appropriate descriptor for assessing noise impacts from the pyrotechnics based on the U.S. Army Environmental Noise Management Program criteria, and peak hour *A*-weighted $Leq(1)$ is a suitable noise descriptor for determining noise impacts for avian dispersion measures, including the pyrotechnics, based on the New York City Environmental Quality Review criteria.

2:00

2pNS5. A study of automobile exhaust noise preferences. Jay B. Haire, Melinda J. Carney, and Dominique J. Cheenne (Dept. of Audio Arts & Acoust., Columbia College Chicago, Chicago, IL 60605)

A study was conducted to investigate the relationship between preferences in automobile exhaust noise and the demographic factors of a listening jury. Noise samples of four different vehicles were recorded at idle as well as at 3000 RPM, and 1/3 octave sound spectra were acquired simultaneously. The recordings were presented to the jury using headphones and a preference survey was administered. Zwicker loudness was computed for all samples. Demographic factors such as gender, age, current and future vehicle ownership, were correlated to listening preferences, and unforeseen results were found, especially in regards to sport utility vehicles (SUV).

2:15

2pNS6. Sound-quality analysis of sewing machines. James Chatterley, Andrew Boone, Jonathan Blotter (Dept. of Mech. Eng., Brigham Young Univ., 435 CTB, Provo, UT 84602), and Scott Sommerfeldt (Brigham Young Univ., Provo, UT 84602)

Sound quality analysis procedure and results for six sewing machines ranging from entry level to professional grade will be presented. The procedure consisted of jury-based listening tests and quantification of sound quality using standard metrics. The procedures and analysis of the jury testing will be presented and discussed. The correlation between the quantitative metrics and the qualitative jury results will be presented. Sound localization scans, using near field acoustic holography techniques with accompanying results, performed in order to determine machine sound hot spots and possible sources for undesired sounds, will also be presented. Proposed modifications to machine structure in order to alter machine sound signature into a more sensory pleasant sound will also be presented.

2:30

2pNS7. Criteria for multiple noises in residential buildings using combined rating system. Jin Yong Jeon, Jong Kwan Ryu, and Young Jeong (School of Architectural Eng., Hanyang Univ., Seoul 133-791, Korea)

Multiple residential noises such as floor impact, air-borne, bathroom, drainage, and traffic noises were classified using a combined rating system developed from a social noise survey and auditory experiments. The effect of individual noise perception on the evaluation of the overall noise environment was investigated through a questionnaire survey on annoyance, disturbance, and noise sensitivity. In addition, auditory experiments were undertaken to determine the allowable sound pressure level for each residential noise source and the percent satisfaction for individual noise levels. From the results of the survey and the auditory experiments, a combined rating system was developed and annoyance criteria for multiple residential noises were suggested.

2pNS8. Noise impact on community: A case study for power generation facility. Yong Ma, Jonathan Chui, and Salem Hertil (ATCO Noise Management, 1243 McKnight Blvd. NE, Calgary, AB, Canada)

Power generation plant will make noise impact on the surrounding communities and cause noise complaints from the residences. Noise mitigation treatment for plant is required to achieve the specified noise regulations. In this paper, a case study of the noise control design for a power generation facility is presented. Major noise sources included five engines and generators, five gas conditioning skids, five radiator coolers, and other accessory equipment. The acoustic modeling software Cadna/A was used to predict the noise contributions from sources and assess the noise impact on the nearby communities. During the acoustic modeling, alternative noise mitigation measures underwent two specific investigations before they were chosen as a noise solution recommendation. The first was to determine the technical feasibility of attenuating the source equipment. The second was to perform a cost benefit analysis, necessary to find the most cost-effective solution. For example, several acoustic wall and roof assemblies were entered into the acoustic model and the acoustic performance of the ventilation system was varied until we were able to achieve the most economical acoustic solution.

3:00

2pNS9. Multi-channel active noise control on an axial fan using variable loads. Connor Duke and Scott Sommerfeldt (Brigham Young Univ., N283 ESC Provo, UT 84602)

A multi-channel active noise control system using a mock computer enclosure has been shown to produce significant reduction in tonal noise produced by an axial fan. The mock computer enclosure creates an impedance which influences the fan operation. For this system to be used commercially, it should be versatile enough to be used in a variety of enclosures and environments. Various enclosures and environments can be simulated using a fan plenum to create different back pressures on the system. The effects of different loads seen by the system on the performance of the system will be discussed. The performance of the system can be characterized in either a reverberant or anechoic environment, and the results so obtained will be presented.

3:15

2pNS10. Low-frequency noise and air vibration generated by a simple cycle gas turbine installation. Chris Giesbrecht and Salem Hertil (ATCO Noise Management, 1243 McKnight Blvd NE, Calgary, AB, Canada T2E 5T1, Chris.Giesbrecht@atconoise.com)

Standard noise regulations, measurement techniques, and acoustic treatments can fail to address energy emitted by certain problem gas turbine installations in the form of low-frequency noise and air vibrations. Survey and treatment of the entire acoustic environment is necessary to diagnose and solve these annoyance problems. The presence of ground-borne vibrations, infrasound, and noise in the lower octave bands complicates environmental noise assessment and limits mitigation options. Variability in the perception, effects, and annoyance level of low-frequency noise and air vibrations prevents this relatively common problem from being well understood by industry. Particular attention must be paid to propagation paths when the dynamic range of air-borne and ground-borne vibrations overlaps. This paper is the case study of a 2002 analysis, by ATCO Noise Management, of an installation consisting of 3–120 MW combustion generator turbines causing such low-frequency noise and air vibrations.

2pNS11. Global active control of broadband noise from small axial cooling fans. Matthew J. Green and Scott D. Sommerfeldt (Dept. of Phys. and Astron., Brigham Young Univ., N-281 ESC, Provo, UT 84602, green.mattgreen@gmail.com)

The filtered-x LMS algorithm has previously been used for feed-forward control of the tonal noise of a small axial cooling fan. This system consists of four actuator-sensor pairs surrounding the small fan. The ideal placement of these elements has been previously determined by Gee and Sommerfeldt [Gee and Sommerfeldt, *J. Acoust. Soc. Am.* **115**, 228–236 (2004)]. With success in reducing tonal noise to about the same level as broadband noise it now becomes desirable to control the broadband noise of the small axial cooling fan. This is accomplished with active feedback control. The performance of the broadband control system will be reviewed, and the results of a hybrid (feed-forward and feedback) system for overall reduction of cooling fan noise will be discussed. Ideal methods and configurations for feedback control will also be discussed.

2pNS12. A predictive noise study regarding the proposed Cincinnati Municipal Airport expansion. Grant E. Limberg, Melinda J. Carney, and Dominique J. Cheenne (Dept. of Audio Arts & Acoust., Columbia College Chicago.)

A noise study was performed on the landing path of runway 21L of Cincinnati Municipal Airport to determine the effect of the runway expansion project set to begin in 2005. Sound pressure levels were acquired along the landing path branches to evaluate the eight-hour Leq and the test data were compared to those predicted by the Integrated Noise Model (INM) software. The test data line up to the modeled results within 3.5 dB, an amount that can be explained by weather patterns and other environmental noise variables. The model shows that the 65 dB Day/Night Level (DNL) contour area could negatively affect 46 residents near the airport. Suggestions for the expansion plans include a detailed review of all relevant noise issues using an appropriate computer model.

2pNS13. An outdoor noise propagation study to predict the effect of a power plant expansion. Philip J. Brasovan, Melinda J. Carney, and Dominique J. Cheenne (Dept. of Audio Arts & Acoust., Columbia College Chicago, 600 S. Michigan Ave., Chicago, IL 60605)

The results of an outdoor noise propagation model using CadnaA were compared to test data obtained on-site. The subject property is the central utility plant of a hospital located in Milwaukee, scheduled to be expanded with the addition of cooling towers. The modeled area was 400 m squared with a resolution grid of 2 m squared. The model was used to validate the observed test data as well as to predict the anticipated noise levels at completion of the expansion. A total of 11 points were investigated and the predicted data were found to match the test values within 2 dB at many locations. The data from the model show that the anticipated noise levels at the East property line will exceed those mandated by local ordinances by 3 dB. The model also predicts that the addition of a three meter absorbing barrier and the use of reduced noise fans for the six cell cooling system will bring the overall noise level from the system into compliance.

2pNS14. Is Lighthill's acoustic analogy still relevant? Werner Richarz (Aercoustics Eng. Ltd., 50 Ronson Dr., Ste. 165, Toronto, ON, Canada M9W 1B3)

More than fifty years after Lighthill's seminal paper, the acoustic analogy appears to be out of favor, even though the theory has been able to cope with all aspects of jet noise. This review examines the principal features of Lighthill's acoustic analogy through the lens of the self-and shear noise theory (one of several possible formulations), introduced by Proudman and extended by Ribner and others. One to infer a great deal about the sound field of a jet with a minimum of information about the details of the flow. For example, the well-known U8 scaling law is readily extended to predict the variation of the far-field power spectra of jet noise. The validity has been demonstrated by applying the prediction algorithm to measured jet noise data. Correlations of the source terms and the far-field sound have been measured and shown to exhibit closure. Subtle features such as two-point correlations of far-field sound pressures are accurately described. Recently, Ribner has proposed a means by which the elusive refraction due to flow and temperature gradients can be dealt with in a consistent manner. Predictions based thereon agree quite well with measurement, even for small angle from the jet axis.

2pPA1. Assessment of atmospheric models for tele-infrasonic propagation. Mihan McKenna (Dept. of Geological Sci., Southern Methodist Univ., P.O. Box 750395, Dallas, TX 75275-0395, smckenna@smu.edu) and Sylvia Hayek (Natural Resources, Canada)

Iron mines in Minnesota are ideally located to assess the accuracy of available atmospheric profiles used in infrasound modeling. These mines are located approximately 400 km away to the southeast (142) of the Lac-Du-Bonnet infrasound station, IS-10. Infrasound data from June 1999 to March 2004 was analyzed to assess the effects of explosion size and atmospheric conditions on observations. IS-10 recorded a suite of events from this time period resulting in well constrained ground truth. This ground truth allows for the comparison of ray trace and PE (Parabolic Equation) modeling to the observed arrivals. The tele-infrasonic distance (greater than 250 km) produces ray paths that turn in the upper atmosphere, the thermosphere, at approximately 120 km to 140 km. Modeling based upon MSIS/HWM (Mass Spectrometer Incoherent Scatter/Horizontal Wind Model) and the NOGAPS (Navy Operational Global Atmospheric Prediction System) and NRL-GS2 (Naval Research Laboratory Ground to Space) augmented profiles are used to interpret the observed arrivals.

1:45

2pPA2. Infrasound radiation of cyclones. Konstantin A. Naugolnykh (NOAA/ETL/Zeltech, 325 Broadway, Boulder, CO 80305)

Tropical cyclones produce strong perturbations of atmosphere and the ocean surface accompanied by acoustical radiation. Infrasonic signals in the 0.1–0.5 frequency band can be observed at distances of thousands of miles from the cyclone. The effect of infrasound radiation is connected apparently to the interaction of the counter-propagating sea-surface waves that produces a sound radiation of the doubled frequency of the surface wave oscillation. This radiation has narrow-angle vertical directivity pattern. The essential refraction of radiated infrasound in the atmosphere perturbed by the cyclone leads to trapping of the infrasound by the horizontal atmospheric wave-guide providing its long distance propagation.

2:00

2pPA3. Characteristics of infrasound signals from earthquakes. Paul Mutschlechner and Rodney Whitaker (Los Alamos Natl. Lab., EES-2 MS J577, LANL, Los Alamos, NM 87545)

Analysis of infrasound signals is presented for a set of 31 earthquakes located mostly in the western United States and recorded at infrasound arrays operated by the Los Alamos National Laboratory. By normalizing measured amplitudes for the effects of propagation and distance, a pressure-amplitude versus earthquake magnitude relation is derived. Further analysis showed that the observed variance in this relation is likely due to the variation in source ground motion and variation in upper atmospheric winds. Signal durations can be tens of minutes and azimuth devia-

tions have a mean of three degrees (measured from array data compared to great circle azimuths). Other characteristics of the infrasound data will be discussed. Our analysis of the observed data combined with surface ground motion accelerations, led to estimates of the minimum surface accelerations needed to generated infrasound signals measured at distant arrays.

2:15

2pPA4. An analysis of seismic and acoustic signals from the June 3, 2004 Washington state bolide. Stephen Arrowsmith, Michael Hedlin (IGPP, Scripps, Univ. of California, San Diego, La Jolla, CA 92093-0225), Lars Ceranna (BGR, Hannover 30625, Germany), and Wayne Edwards (Univ. of Western Ontario, Canada, N6A 3K7)

On June 3rd, 2004 a spectacular bolide was reported over British Columbia, Washington, Oregon and Idaho. In addition to eyewitness accounts and video recordings, the event was recorded on a number of seismometers in the Pacific Northwest Seismograph network and at infrasound arrays in Washington State and California. Using the NRL-G2S atmospheric model for the time of the event, source locations have been determined with seismic and acoustic signals separately. Estimates of the yield and acoustic efficiency of the explosion have also been determined. By simulating the propagation of infrasound through the atmosphere, the arrival of discrete acoustic phases at the infrasound arrays has been modeled.

2:30

2pPA5. Acoustic observations of large earthquakes and associated phenomena. Catherine de Groot-Hedlin (Scripps Inst. of Oceanogr., UCSD, 9500 Gilman Dr., La Jolla, CA 92093-0225, chedlin@ucsd.edu) and David McCormack (Geological Survey of Canada, Ottawa, ON, Canada K1A 0Y3)

Recent global events have renewed interest in acoustic observations of large earthquakes and associated phenomena such as landslides and tsunamis. In addition, the proliferation of global networks of atmospheric acoustic (infrasound) and hydroacoustic observing systems mean that signals from such events are captured in close to real-time more frequently and with better resolution than ever before. Such data provide a useful complement to more traditional seismological observations of such events. In this paper, recent acoustic and hydroacoustic observations from large earthquake events are presented. As well as the scientific insights provided by use of such monitoring systems, operational applications useful for hazard mitigation or hazard alerting are considered. Current plans to develop observing systems to perform systematic studies of areas susceptible to earthquake and tsunami hazard offshore western Canada, and the use of such proposed systems to make systematic studies of hydroacoustic signals from seismic events, underwater slumping and landslides are described.

2:45

2pPA6. High trace-velocity events associated with auroral activity in Alaska. Charles R. Wilson and John V. Olson (Geophysical Inst., Univ. of Alaska, Fairbanks, AK 99775)

Data from the CTBT/IMS station 153US at Fairbanks, AK covering 2003 and 2004 have been surveyed for high-correlation, high trace-velocity events. Although such events have been detected at all times of the day the distribution shows a strong maximum in the morning hours (near 15UT) and a weaker maximum in the evening hours (near 5UT). Twenty intervals containing high trace-velocity events from 2003 and 37 intervals from 2004 have been studied in detail. The intervals containing high trace-velocity events can last from a few hours up to 10 hours. All-sky video records show that the high trace-velocity events are associated with stable, pulsating auroral patches that occur during the recovery phase of substorms. This talk will review the characteristics of the high trace-velocity events and the associated auroral video where available.

2pPA7. Source localization of non-stationary acoustic data using time-frequency analysis. Jack Stoughton (NASA-Langley Res. Ctr., MS 488, Hampton, VA) and William Edmonson (Hampton Univ., Hampton, VA 23668)

An improvement in temporal locality of the generalized cross-correlation (GCC) for angle of arrival (AOA) estimation can be achieved by employing 2-D cross-correlation of infrasonic sensor data transformed to its time-frequency (TF) representation. Intermediate to the AOA evaluation is the time delay between pairs of sensors. The signal class of interest includes far field sources which are partially coherent across the array, nonstationary, and wideband. In addition, signals can occur as multiple short bursts, for which TF representations may be more appropriate for time delay estimation. The GCC tends to smooth out such temporal energy bursts. Simulation and experimental results will demonstrate the improvement in using a TF-based GCC, using the Cohen class, over the classic GCC method. Comparative demonstration of the methods will be performed on data captured on an infrasonic sensor array located at NASA Langley Research Center (LaRC). The infrasonic data sources include Delta IV and Space Shuttle launches from Kennedy Space Center which belong to the stated signal class. Of interest is to apply this method to the AOA estimation of atmospheric turbulence. [Work supported by NASA LaRC Creativity and Innovation project: Infrasonic Detection of Clear Air Turbulence and Severe Storms.]

3:45

2pPA8. Multiparameter studies of surf infrasound. Milton Garces, David Fee, Pierre Caron, Claus Hetzer (Infrasound Lab., Univ. of Hawaii, Manoa, 73-4460 Queen Kaahumanu Hwy., #119, Kailua-Kona, HI 96740-2638), Jerome Aucan, Mark Merrifield (Univ. of Hawaii, Manoa, Honolulu, HI 96822), Robert Gibson, and Joydeep Bhattacharyya (BBN Technologies, Arlington, VA 22209)

Infrasound stations on islands or near coastlines routinely detect signals associated with breaking ocean waves. Although the source mechanisms of these infrasonic surf signals are not well understood, they might provide useful insight into coastal processes and permit an assessment of

wave energy distribution in the littoral zone. Near-shore infrasonic arrays, ocean bottom sensors, an infrared imager, and a video camera were deployed on rocky and sandy coastlines in Hawaii during the 2004–2005 Winter swell season, with the aim of establishing a relationship between the directional ocean swell height and the infrasonic source distribution, intensity, and spectral content. The cameras targeted acoustically active regions for selected time periods to associate the timing of the infrasonic signal arrivals with the breaking and dissipation of ocean wave sets. A wide range of sea states and weather conditions were captured during two separate deployments. The results of our multiparameter analyses and preliminary comparisons of our observations with mesoscale ocean wave model predictions will be presented. [Work supported by the Defense Advanced Research Projects Agency. Support of the State of Hawaii is acknowledged.]

2pPA9. Multiple array infrasound observations in the Netherlands. Láslo Evers and Hein Haak (Royal Netherlands Meteorological Inst. (KNMI), P.O. Box 201, 3730 AE De Bilt, The Netherlands, evers@knmi.nl)

Infrasound in the Netherlands is observed with multiple arrays. The current architecture consists of 4 arrays. These arrays vary in aperture from 30 to 1500 m while the number of microbarometers ranges from 6 to 16 per array. Continuous observation of infrasound implies a huge number of automatic detections per year. In other words, thousands of coherent waves cross the arrays each year. Although a lot of sources can be identified, there are still unknown sources having a coherent infrasonic signature. Among the identified sources are: supersonic airplanes, bolides, severe weather, oceanic waves, volcano explosions, and military activity. Current efforts in source identification concentrate on the integration of infrasonic and seismic data. Furthermore, atmospheric characteristics are included such as the state of the boundary layer and propagation conditions in the higher atmospheric, i.e., stratospheric winds and temperatures. In this presentation the influence of the atmosphere on the detection capability will be shown. Furthermore, the detailed analysis of specific sources shows the enormous potential of infrasound as atmospheric probe and monitoring technique.

4:15

2pPA10. Status report on the establishment of the CTBTO IMS infrasound network. Thomas L. Hoffmann (CTBTO IMS, Vienna Intl. Ctr., P.O. Box 1200, A-1400 Vienna, Austria)

Steady progress has been made in the establishment of the CTBTO IMS infrasound monitoring network. To date 86% of the site surveys for 60 infrasound stations in the network have been completed, 50% of the stations are transmitting continuous data to Vienna, and 40% of the stations have been certified. While the global distribution pattern of infrasound stations transmitting data to Vienna is still disperse, regional networks begin to form in North and South America as well as in the Australian and South African regions. This presentation will focus on an overview of recent progress made in the establishment of the global infrasound network, and also present some of the challenges and difficulties encountered in this program.

2pPP1. Søren Buus. Thirty years of psychoacoustic inspiration. Torben Poulsen (Oersted-DTU, Acoust. Technol., Tech. Univ. of Denmark, DK 2800 Lyngby, Denmark, tp@oersted.dtu.dk)

Søren Buus did his MSc at the Acoustics Laboratory, Technical University of Denmark (DTU), in 1975 on the topic headphone calibration. He showed the importance of reliable reference values for psychoacoustic research and Søren was a great inspiration for my work [Scand. Audiol. **20**, 205–207 (1991); **27**, 105–112 (1998)]. Already from the seventies, temporal integration of loudness has been a major topic in the collaboration with Søren [Buus *et al.*, *J. Acoust. Soc. Am.* **105**, 3464–3480 (1999)] and the measurements of temporal integration over a wide range of presentation levels led to the important finding about the shape of the loudness function [Buus *et al.*, *J. Acoust. Soc. Am.* **100**, 669–680 (1997)]. Søren talked about the importance of the psychophysical procedure and the influence from the procedure on the results [Buus, *Proceedings 19th Danavox Symposium* (2001), pp. 183–226]. The goal was to obtain reliable, unbiased, and precise results. An overview of some of the above investigations will be presented together with recent results from a MSc project on headphone calibration of short duration sounds for ABR measurements.

1:30

2pPP2. Søren Buus' contribution to speech intelligibility prediction. Hannes Müsch (Sound ID, Palo Alto, CA 94303, hmuesch@soundid.com) and Mary Florentine (Northeastern Univ., Boston, MA 02115)

In addition to his work in psychoacoustics, Søren Buus also contributed to the field of speech intelligibility prediction by developing a model that predicts the results of speech recognition tests [H. Müsch and S. Buus, *J. Acoust. Soc. Am.* **109**, 2896–2909 (2001)]. The model was successful in test conditions that are outside the scope of the Articulation Index. It builds on Green and Birdsall's concept of describing a speech recognition task as selecting one of several response alternatives [in D. Green and J. Swets, *Signal Detection Theory* (1966), pp. 609–619], and on Durlach *et al.*'s model for discriminating broadband sounds [*J. Acoust. Soc. Am.* **80**, 63–72 (1986)]. Experimental evidence suggests that listeners can extract redundant, independent, or synergistic information from spectrally distinct speech bands. One of the main accomplishments of the model is to reflect this ability. The model also provides for a measure of linguistic entropy to enter the intelligibility prediction. Recent model development has focused on investigating whether this measure, the cognitive noise, can account for the effects of semantic and syntactic context. This presentation will review the model and present new model predictions. [Work supported by NIH grant R01DC00187.]

1:55

2pPP3. Borrowing a trick from Søren Buus: Application of a simple quantitative model to data obtained from an impaired population. Robert P. Carlyon (MRC Cognition and Brain Sci. Unit, 15 Chaucer Rd., Cambridge, CB2 2EF, England)

One of the many things that Søren taught me was to apply a simple quantitative model to psychophysical data, even when studying impaired populations, renowned for inter-listener variability. Here I present a recent application of this approach, applied to cochlear implant patients' detection thresholds for electrical stimulation. Most implants stimulate the nerve with trains of biphasic pulses, in which a rectangular pulse of one polarity is followed, with a short inter-phase gap (IPG), by an equal pulse of opposite polarity. Together with van Wieringen and colleagues in Leuven, Belgium, we have shown that psychophysical thresholds in humans drop as IPG increases to at least 2900 microseconds implying a much longer time constant than predicted from physiological studies on animals. By applying a simple model, we showed that this long time constant is quantitatively consistent with the threshold drop observed for electrical sinusoids as frequency is lowered to about 100 Hz. The model involves passing the electrical waveform through a low-pass filter and calculating the RMS output. Despite its simplicity, the model successfully predicts the results of several novel manipulations, and helps constrain explanations of the physiological basis of the observed time constants.

2pPP4. Sequential grouping constraints on across-channel auditory processing. Andrew J. Oxenham (Res. Lab. of Electron., MIT, Cambridge, MA 02139, oxenham@mit.edu) and Torsten Dau (Tech. Univ. of Denmark, DK-2800 Lyngby, Denmark)

Søren Buus was one of the pioneers in the study of across-channel auditory processing. His influential 1985 paper showed that introducing slow fluctuations to a low-frequency masker could reduce the detection thresholds of a high-frequency signal by as much as 25 dB [S. Buus, *J. Acoust. Soc. Am.* **78**, 1958–1965 (1985)]. Søren explained this surprising result in terms of the spread of masker excitation and across-channel processing of envelope fluctuations. A later study [S. Buus and C. Pan, *J. Acoust. Soc. Am.* **96**, 1445–1457 (1994)] pioneered the use of the same stimuli in tasks where across-channel processing could either help or hinder performance. In the present set of studies we also use paradigms in which across-channel processing can lead to either improvement or deterioration in performance. We show that sequential grouping constraints can affect both types of paradigm. In particular, the perceptual segregation of off-frequency from on-frequency components, using sound sequences preceding or following the target, leads to results similar to those found in the absence of the off-frequency components. This suggests a high-level locus for some across-channel effects, and may help provide a functional distinction between within- and across-channel mechanisms. [Work supported by NIH R01DC03909 and Danish Research Council.]

3:00

2pPP5. Tone-burst otoacoustic emissions and loudness. Michael Epstein (Inst. of Hearing, Speech and Lang., Comm. Res. Lab, and Comm. and DSP Ctr., ECE Dept. (440 DA), Northeastern Univ., Boston, MA 02115, mepstein@ece.neu.edu) and Mary Florentine (Northeastern Univ., Boston, MA 02115)

Several models of cochlear mechanics lead to the conclusion that the amplitude of tone-burst otoacoustic emissions (TBOAEs) is proportional to basilar-membrane (BM) motion. Buus and Florentine [Fechner Day 2001 (Pabst, Berlin), 236 (2001)] showed that the square of loudness, derived from measurements of spectral and temporal integration, closely matched basilar-membrane velocity at the best frequency. Buus *et al.* [Physiological and Psychophysical Bases of Auditory Function, 373 (2001)] examined the relationship between distortion-product otoacoustic emissions (DPOAEs) and BM motion. Follow-up work by Epstein *et al.* [*J. Acoust. Soc. Am.* **117**, 263 (2005)] showed in a direct comparison that TBOAEs and psychoacoustical measures, of loudness and of pulsation threshold, on six subjects with normal hearing led to very similar estimations of basilar-membrane motion. These outcomes suggest that otoacoustic emissions could serve as an excellent tool—one that is objective, non-invasive, and rapid—for estimating in subjects with normal hearing both relative basilar-membrane motion and relative loudness. [Work supported by NIH/NIDCD Grant R01DC02241.]

3:25

2pPP6. Induced loudness reduction: A review. Bertram Scharf (Psychol. Dept., Northeastern Univ., Boston, MA 02115), Eva Wagner, and Bärbel Nieder (Northeastern Univ., Boston, MA 02115, scharf@neu.edu)

Under appropriate stimulus conditions, a tone may decline in loudness the equivalent of 10 dB and more when preceded by a stronger tone. This induced loudness reduction or ILR was uncovered, indirectly, in a large number of studies by L. E. Marks and his associates [e.g. Marks, *J. Exp Psychol HPP* **20**, 382–396 (1994)]. Those studies seemed to suggest that ILR required that tones be presented at two widely separated frequencies over a relatively large range of SPLs. Although part of the measured loudness changes seemed to stem from response biases, recent studies show unequivocally that the reduction in loudness is mostly sensory and that tones need be presented at only a single frequency and at two levels some 10 to 20 dB apart. The present paper puts together what is known about the dependence of ILR on signal frequency, level, duration, temporal relations, and hearing loss. The role of ILR in various other psychoacoustical phenomena such as induced loudness adaptation and loudness enhancement is reviewed. Much of this knowledge was obtained in direct and indirect collaboration with Søren Buus. [Work supported by NIH/NIDCD Grant No. R01 DC 02241.]

Contributed Paper

3:50

2pPP7. Extension of Søren Buus's modeling to loudness growth at high frequencies. Rhona P. Hellman (Dept. of Speech-Lang. Path. and Audiol. and Inst. for Hearing, Speech, & Lang. (106A FR), Northeastern Univ., Boston, MA 02115, hellman@neu.edu)

Loudness matching between tones at different frequencies leads to results that imply that loudness functions, which relate loudness to sound pressure level (SPL) are parallel at frequencies from 1 to 10 kHz but not at higher frequencies [Hellman *et al.*, *J. Acoust. Soc. Am.* **109**, 2349 (2001)]. Within the 12.5 to 16 kHz frequency range, the loudness-matching func-

tions are curvilinear in shape being steeper below 60 phons than at higher loudness levels. The higher the frequency, the greater is the decrease in slope above 60 phons. The slope reduction above 60 phons for frequencies from 12.5 to 16 kHz is ascribed to the tone's restricted excitation pattern. A computer model by Søren Buus described in part in Florentine *et al.* [*Modeling Sensorineural Hearing Loss* (Erlbaum, 1997), pp. 187–198] provides a good account of the decrease in the mid-to-high level slope of loudness functions derived at high frequencies from the matching data. The agreement between the model predictions and the empirical results further supports the notion that the rate of loudness growth at moderate-to-high SPLs depends on the upward spread of excitation.

Structural Acoustics and Vibration: General Vibration; Excitation, Radiation, and Dampening

Kenneth D. Frampton, Chair

*Dept. of Mechanical Engineering, Vanderbilt Univ., Nashville, TN 37235-1592***Contributed Papers**

2:30

2pSA1. Non-contact mode excitation of small structures in air using ultrasound radiation force. Thomas M. Huber, John C. Purdham (Dept. of Phys., Gustavus Adolphus College, 800 College Ave., St. Peter, MN 56082, huber@gustavus.edu), Mostafa Fatemi, Randall R. Kinnick, and James F. Greenleaf (Mayo Clinic College of Medicine, Rochester, MN 55905)

With the advent of MEMS, modal analysis of small structures is increasingly important. However, conventional excitation techniques normally require contact, which may not be feasible for small objects. We present a non-contact method that uses interference of ultrasound frequencies in air to produce low-frequency excitation of structures. Objects studied included hard-drive HGA suspensions and MEMS devices. The vibration induced by the ultrasound radiation force was varied in a wide range from 0 Hz to 50 kHz. Object motion was detected using a laser vibrometer; measured frequencies agreed with expected values. Also demonstrated was the unique capability to selectively enhance or suppress modes independently. For example, the ratio of the vibrational amplitudes of the 175 Hz first-bending and 1.33 kHz torsional modes of a small cantilever could be changed from in excess of 10:1 to less than 1:10 by shifting the ultrasound modulation phase 90 degrees. Similar changes were obtained for a 3 mm square MEMS mirror in the ratios of vibration amplitude around its two separate axes. Torsional modes of a hard-drive suspension could be selectively enhanced by over a factor of two by moving the ultrasound focus point from near the center to near the edge of the suspension.

2:45

2pSA2. Direction selective structural-acoustic coupled radiator. Hee-Seon Seo and Yang-Hann Kim (NOVIC, KAIST, 373-1 Sci. Town Daejeon-si, Korea)

This paper presents a method of designing a structural-acoustic coupled radiator that can emit sound in the desired direction. The structural-acoustic coupled system is consisted of acoustic spaces and wall. The wall composes two plates and an opening, and the wall separates one space that is highly reverberant and the other that is unbounded without any reflection. An equation is developed that predicts energy distribution and energy flow in the two spaces separated by the wall, and its computational examples are presented including near field acoustic characteristics. To design the directional coupled radiator, Pareto optimization method is adapted. An objective is selected to maximize radiation power on a main axis and minimize a side lobe level and a subjective is selected direction of the main axis and dimensions of the walls geometry. Pressure and intensity distribution of the designed radiator is also presented.

3:00

2pSA3. Development of a directivity controlled piezoelectric transducer for sound reproduction. Magella Bédard and Alain Berry (G.A.U.S., Dept. of Mech. Eng., Université de Sherbrooke, 2500, boul. de l'Université, Sherbrooke, Québec, Canada, J1K 2R1, magella.bedard@usherbrooke.ca)

One of the inherent limitations of loudspeaker systems in audio reproduction is their inability to reproduce the possibly complex acoustic directivity patterns of real sound sources. For music reproduction for example,

it may be desirable to separate diffuse field and direct sound components and project them with different directivity patterns. Because of their properties, poly (vinylidene fluoride) (PVDF) films offer lot of advantages for the development of electroacoustic transducers. A system of piezoelectric transducers made with PVDF that show a controllable directivity was developed. A cylindrical omnidirectional piezoelectric transducer is used to produce an ambient field, and a piezoelectric transducers system, consisting of a series of curved sources placed around a cylinder frame, is used to produce a sound field with a given directivity. To develop the system, a numerical model was generated with ANSYS Multiphysics TM8.1 and used to calculate the mechanical response of the piezoelectric transducer. The acoustic radiation of the driver was then computed using the Kirchoff-Helmoltz theorem. Numerical and experimental results of the mechanical and acoustical response of the system will be shown.

3:15

2pSA4. Progress towards an electro-acoustic resonance technique for determining quantitative material and geometrical properties in high contrast multi-layer elastic structures.. Karl Fisher (7000 E. Ave, Livermore, CA 94551)

High contrast multilayered elastic structures continue to be problematic for ultrasonic inspection. Large acoustic material impedance mismatches, refraction, reverberation, multiple echoes, and high elastic attenuations are just some of the issues one is faced with standard high frequency (1–20 MHz) pulse echo detection and imaging methods. In this presentation, we will present progress towards developing a low frequency resonance technique that operates in the 20 to 70 kHz regime. The technique is based on a direct correlation between the electrical impedance of a standard electro-acoustic transducer and the mechanical loading it experiences when placed in contact with a layered elastic structure. Preliminary experimental and theoretical results are in good agreement.

3:30

2pSA5. A simple model for coupled acoustic-structure resonance in Stratospheric Observatory for Infrared Astronomy. Jerry H. Ginsberg (G. W. Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0405)

The Stratospheric Observatory For Infrared Astronomy (SOFIA) is a joint project of NASA and the Deutsches Zentrum für Luft- und Raumfahrt that has mounted a 2.5 m, 20 000 kg infrared telescope on a bulkhead of a specially modified Boeing 747-SP. A large sliding door will expose the observation bay to the exterior flow field at Mach 0.85 and 13 km altitude. In the open configuration the interaction of turbulence vortices generated at the leading and trailing edges of the opening has the possibility of inducing a strong acoustic signal. A concern has been raised that the peak frequencies of such a signal might coincide with the cavity resonances. The present work examines the transfer function for a known source in order to identify the cavity resonances. Simplistic reasoning argues that the worst case would occur if the cavity resonant frequencies are close to structural resonances. However, the structure's impedance is very low at its resonances, which means that the cavity resonant frequencies are shifted from their nominal values. The present work uses a simple one-dimensional waveguide model, in which one end is terminated by a damped single-degree-of-freedom oscillator, to explain the coupled-fluid

structure resonance. The characteristic equation and formulas for the pressure and displacement transfer functions are derived. Analysis of these results leads to some surprising insights regarding the role of a structure's stiffness and mass. [Work supported by the NASA.]

4:00

2pSA6. Non-intrusive ground-contacting vibrometer for acoustic/seismic landmine detection. James S. Martin, Gregg D. Larson (Georgia Inst. of Tech., Atlanta, GA 30332-0405), and Waymond R. Scott, Jr. (Georgia Inst. of Tech., Atlanta, GA 30332-0250)

The detection of buried landmines using seismic waves and full wave-field measurements has been demonstrated. The technique requires a sensor that is non-intrusive with sufficient fidelity, reproducibility, and noise immunity for imaging processes. This has been accomplished in the past with non-contact techniques. For reasons of cost and scalability in large arrays, ground-contacting sensors are currently of interest as an alternative to these. A ground-contacting sensor configuration was studied in which an accelerometer was coupled to the ground through a viscoelastic layer with a bias force provided by a soft coil spring. This sensor was found to meet the noise, fidelity, and reproducibility requirements of a seismic landmine detection system operating in a laboratory experimental model. The fidelity of this sensor was found to vary with the bias force because of the nonlinear stiffness of the soil surrogate in the model. This dependence was sufficiently weak that no feedback of the bias force was necessary to reproducibly couple the sensor over a flat surface. The sensor offers the potential benefit of information that was not available from non-contact measurements regarding the in-plane motion of the soil surface. This data may provide additional cues for the detection of buried mines. [Work supported by ONR.]

4:15

2pSA7. Vibro-acoustic response of convected fluid loaded plates. Kenneth Frampton (Dept. of Mech. Eng., Vanderbilt Univ., Nashville, TN 37235)

This work demonstrates the effects that fluid convection has on the vibro-acoustic response of rectangular plates. The effects of fluid flow on the vibration and stability of plates is reasonably well understood. These effects include dramatic structural modal coupling along with static and dynamic instabilities. However, the resulting effect on sound radiation is not so well understood. The presentation will include a description of the fundamental physics associated with a simply supported, vibrating, rectangular plate in an infinite baffle and radiating into a semi-infinite, convected fluid. Then, simulation results will demonstrate the effects of flow-induced modal coupling and acoustic radiation. It will be demonstrated that convection can significantly increase the radiated sound power and dramatically affect the vibro-acoustic response.

4:30

2pSA8. Behavior of the intermediate and exterior layers of a close fitting enclosure surrounding a cylindrical fluid-loaded acoustic source. Joseph Cuschieri (Lockheed Martin MS2, Perry Technologies, 100 East 17th street, Riviera Beach, FL 33404)

Previously, results for the Insertion Loss (IL) of a close fitting enclosure surrounding a submerged (in water) cylindrical acoustic source [Cuschieri, J. Acoust. Soc. Am. **115**, 2537 (2004); **116**, 2521 (2004)] were presented for different intermediate layer materials, different characteristics of the exterior cladding layer material and different source sizes. The IL results were presented as a function of frequency and layer/cladding characteristics. In this presentation, details on the behavior of the intermediate and outside layers enclosing the cylindrical source are presented which demonstrate the coupling between the cylindrical source the exter-

nal acoustic (water) medium. These results help to explain the IL results previously obtained and presented. Furthermore, the scattering characteristics of the cylindrical source with and without the close fitting enclosure are considered. [Work supported by ONR.]

4:45

2pSA9. A focused multi-layered spherical shell with guided wave enhancements. John D. Smith (Dstl. Porton Down, Salisbury, SP4 0JQ, UK) and Duncan P. Williams (Dstl. Winfrith, Dorchester DT2 8WX, UK)

There is a continued need for underwater reflective targets to be used as relocation and navigational aids. Traditionally, fluid-filled thin spherical shells have been used as passive reflectors, similar to cat's eyes, and would usually be filled with liquid chlorofluorocarbons (CFC's). Other options are needed now that the production of CFC's has been restricted. This paper looks at the relationship between a system of multi-layered concentric elastic shells and their target strength in water. The problem is formulated using the global matrix method and is applicable to any system with an arbitrary number of layers. Results show that, by using certain combinations of low loss elastic layers together, the target strength is higher than it would be for any one of the materials used in isolation. This result is explained by geometric focussing on the back surface of the sphere and guided elastic waves that circumnavigate the outer layer or shell and enhance the focussing. The results are compared with calculations and existing experiments for a stainless steel shell filled with CFC.

2pSA10. Sound radiation of a plate excited by an impact. Physical and perceptual comparisons between numerical and experimental results. Dominique Habault, Florence Demirdjian, Sabine Meunier, and Georges Canevet (CNRS-LMA, 13402 Marseille Cedex 20, France)

The study is concerned with the response of a thin elastic baffled plate, immersed in a fluid, and excited by an impact force. An experiment was run, in which a plate was struck by an impact hammer which provides excitations of very short duration. Various shapes of excitation functions were obtained by using different kinds of hammer heads (rubber, plastic, metal). The resulting acceleration on the plate and sound pressure radiated in the fluid were measured, with an emphasis on the very first portion of the signals (initial 30 ms). The recorded signals were then compared, in the time domain, with theoretical predictions based on expansions in resonance modes of the fluid-loaded plate. These predictions provide a quite accurate description of the experimental data. Auditory tests were also run, to compare the signals obtained from the calculations and the recorded sounds. Subjects were asked to evaluate the dissimilarity between test sounds, using an analog scale graduated from 0 (very similar) to 6 (very dissimilar). The tests allowed to identify the perceptual criteria used by the subjects. The aim of the study is to use these criteria to improve the numerical method of prediction of the sound radiation.

2pSA11. A variational approach to modeling the vibration of timber joist floors. Colin Fox and Hyuck Chung (Mathematics Dept., Univ. of Auckland, PB 92019, Auckland, New Zealand, fox@math.auckland.ac.nz)

We present a comprehensive variational model for the vibration of timber joist floors and a simple computer algorithm for finite, particularly rectangular, floors. We allow for floor constructions that are typical in the New Zealand context, consisting of edge-supported timber joists with flooring material above, often a suspended ceiling below with absorptive material in the cavity, and a range of joint types such as gluing or nailing. The model and algorithm are structured in such a way that a component can easily be either added to, or removed from, the structure. Hence the configuration may be made progressively more complex from the simplest floor-joists type to floor-joists-ceiling with cavity air and damper-spring connectors.

Session 2pSC

Speech Communication: Cross-Linguistic and Dialectal Studies (Poster Session)

Richard A. Wright, Chair

Dept. of Linguistics, Univ. of Washington, Seattle, WA 98195-4340

Contributed Papers

All posters will be on display from 1:00 p.m. to 4:30 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 2:15 p.m. and contributors of even-numbered papers will be at their posters from 2:15 p.m. to 4:30 p.m.

2pSC1. Free choice task effects in cross-linguistic stop perception.

Alexei Kochetov (Dept. of Linguist., Simon Fraser Univ., 8888 Univ. Dr., Burnaby, BC, Canada V5A 1S6, alexei_kochetov@sfu.ca)

This paper examines the identification of stop place and secondary articulation using a free choice task. Russian syllable-initial and syllable-final stops /p pj t tj/ in nonsense utterances were presented to Russian and Japanese listeners ($N=30$). Correct identification rates for place and secondary articulation of the target consonants were determined based on written responses (in Cyrillic or Katakana). Both groups of listeners showed better identification of syllable-initial stops compared to syllable-final stops. Among the consonants, /p/ was identified better, and /pj/ was identified worse than the other stops. Native listeners performed better than non-native listeners. The overall correct identification rates were lower than (yet strongly correlated with) the rates previously obtained with the same stimuli using a forced choice phoneme identification task. The lower identification rates in the current study can be explained in part by the errors involving the segmentation and syllabification of palatalized stops. Thus, the palatal articulation of the syllable-final palatalized /pj/ was often interpreted as independent of the stop (e.g., /tapj api/ rendered as /taj papi/ or /tjap api/). It is concluded that the free choice task can successfully complement the forced choice task, providing additional information about the perception of secondary palatalization. [Supported by SSHRC.]

2pSC2. The preliminary study about neutral tone: Dialect effect between North Official Mandarin speakers in China and Taiwan Mandarin speakers.

Jennifer Li (Dept. of English Lit., Natl. Chiao Tung Univ., 1001 Ta Hsueh Rd., Hsinchu, Taiwan 300, Republic of China, wahaha_jennifer@yahoo.com.tw)

According to general theories, neutral tone is not regarded as an independent tone in Mandarin. Previous research shows that the most important characteristic of the neutral tone is that it does not have a certain target and pitch contour. (Lin and Yang, 1980) Namely, its pitch contour is uncertain, and it is weak in perception level. However, those studies ignore the variant between different dialects. Our study examined the features of the neutral tone between two dialects of Mandarin speakers and aimed at figuring out the dialect difference effect on the pronunciation of the neutral tone. Our subjects were chosen from two groups of Mandarin speakers. One group is from the North Mainland China, and the other is from Taiwan. The experiment was designed with a speak-it-out process. All subjects read a randomized script written in Mandarin, and the whole process was recorded spontaneously. The preliminary result shows that the dialect difference effect actually matters. It shows a tendency that the neutral tone has a certain target in Taiwan Mandarin speakers.

2pSC3. The phonetic rhythm/syntax headedness connection: Evidence from Tagalog.

Sonya Bird, Laurel Fais, and Janet Werker (Univ. of Victoria and Univ. of British Columbia, Canada, sbird@uvic.ca)

Ramus, Nespor, and Mehler [Cognition (1999)] show that the rhythm of a language (broadly: stress- versus syllable- versus mora-timing) results from the proportion of vocalic material in an utterance (%V) and the standard deviation of consonantal intervals (delta-C). Based on 14 languages, Shukla, Nespor, and Mehler [submitted] further argue that rhythm is correlated with syntactic headedness: low %V is correlated with head-first languages (e.g., English); high %V is correlated with head-final languages (e.g., Japanese). Together, these proposals have important implications for language acquisition: infants can discriminate across rhythm classes [Nazzi, Bertoncini, and Mehler, J. Exp. Psych: Human Perception and Performance (1998)]. If rhythm, as defined by %V and delta-C, can predict headedness, then infants can potentially use rhythm information to bootstrap into their languages syntactic structure. This paper reports on a study analyzing rhythm in a language not yet considered: Tagalog. Results support the Shukla *et al.* proposal in an interesting way: based on its %V and delta-C, Tagalog falls between head-first and head-last languages, slightly closer to the head-first group. This placement correlates well with the fact that, although Tagalog is said to be primarily head-first syntactically, head-last phrases are permitted and common in the language.

2pSC4. A comparison of the acoustic characteristics of American English and Cantonese vowels.

Eric Zee (Dept. of CTL, City Univ. of Hong Kong, 83 Tat Chee Ave., Hong Kong, ctlee@cityu.edu.hk)

The study compares the formant frequencies of the American English vowels [i, ε, a, o, u, ɪ, ʊ] (Peterson and Barney, 1952) and [i, ε, a, o, u, ɪ, ʊ] in Cantonese (Zee, 2004). Results of the comparison show that the differences in formant values for the vowels between the two languages vary according to vowel type and gender. Between male speakers of the two languages, the differences in F -values are minimal for [i] and [ɔ]. For [ε, u], the difference between the two groups is mainly in $F2$, with [ε] having a larger $F2$ and [u] a smaller $F2$ for Cantonese speakers. [a] in American English has smaller $F1$ and $F2$ than [a] in Cantonese. [ɪ, ʊ] occupy the position in between the level of [i, u] and level of [ε, ɔ] in the $F1/F2$ plane for American English speakers, and there is a noticeable difference in $F2$ between [ɪ] and [ε] and between [ʊ] and [ɔ]. For Cantonese speakers, [ɪ, ʊ] are on the same level of [ε, ɔ], and the difference in $F2$ is minimal between [ɪ] and [ε] and between [ʊ] and [ɔ]. The differences between female speakers of the two languages will also be presented.

2pSC5. Acoustic characteristics of Korean stops in Korean child-directed speech. Minjung Kim and Carol Stoel-Gammon (Dept. of Speech & Hearing Sci., Univ. of Washington, 1417 NE 42nd St., Seattle, WA 98105-6246)

A variety of cross-linguistic studies have documented that the acoustic properties of speech addressed to young children include exaggeration of pitch contours and acoustically salient features of phonetic units. It has been suggested that phonetic modifications of child-directed speech facilitate young children's speech perception by providing detailed phonetic information about the target word. While there are several studies reporting vowel modifications in speech to infants (i.e., hyper-articulated vowels), there has been relatively little research about consonant modifications in speech to young children (except for VOT). The present study examines acoustic properties of Korean stops in Korean mothers' speech to their children aged 29 to 38 months ($N=6$). Korean tense, lax, and aspirated stops are all voiceless in word-initial position, and are perceptually differentiated by several acoustic parameters including VOT, f_0 of the following vowel, and the amplitude difference of the first and second harmonics at the voice onset of the following vowel. This study compares values of these parameters in Korean motherese to those in speech to adult Koreans from same speakers. Results focus on the acoustic properties of Korean stops in child-directed speech and how they are modified to help Korean young children learn the three-way phonetic contrast.

2pSC6. Relationship between perceived politeness and spectral characteristics of voice. Mika Ito (Dept. of Linguist., Univ. of Edinburgh, 40 George Square, Edinburgh EH8 9LL, UK, itomika@ucla.edu)

This study investigates the role of voice quality in perceiving politeness under conditions of varying relative social status among Japanese male speakers. The work focuses on four important methodological issues: experimental control of sociolinguistic aspects, eliciting natural spontaneous speech, obtaining recording quality suitable for voice quality analysis, and assessment of glottal characteristics through the use of non-invasive direct measurements of the speech spectrum. To obtain natural, unscripted utterances, the speech data were collected with a Map Task. This methodology allowed us to study the effect of manipulating relative social status among participants in the same community. We then computed the relative amplitudes of harmonics and formant peaks in spectra obtained from the Map Task recordings. Finally, an experiment was conducted to observe the alignment between acoustic measures and the perceived politeness of the voice samples. The results suggest that listeners' perceptions of politeness are determined by spectral characteristics of speakers, in particular, spectral tilts obtained by computing the difference in amplitude between the first harmonic and the third formant.

2pSC7. Size-constraints on intonation groups in speech: Evidence of an independent syllable-count principle. Annie C. Gilbert and Victor J. Boucher (Univ. of Montreal, C.P. 6128 succ. Centre-ville, Montreal, QC, Canada H3C 3J7)

This poster examines size-limits on intonation (F_0) contours in spontaneous speech and presents the results of an experiment on a syllable-count principle, which is seen to constitute, irrespective of syntax, a factor restricting the length of F_0 groups. Studies of various languages indicate a general tendency to restrict stress-groups in speech to four syllables or less. In languages where stress is not lexically coded (e.g., French), syntax is not a sufficient predictor of stress. The object was to determine whether these aspects of stress patterning also apply to tonal groups. Statistics are lacking with respect to the extent of F_0 contours in speech. Pitch-extracting software was used to analyze the speech of 15 native speakers of French (20 minutes each). Initial results suggest an eight-syllable limit on tonal groups. Based on these statistics an experiment was conducted where 40 Ss read and repeated visually presented sentences containing major syntactic divisions (phrase boundaries) at different locations. There are two central findings: (1) phrase boundaries placed at different points in

the sentence did not serve to predict tonal grouping; (2) even when the sentence structure offered the possibility of creating large tonal groups, Ss did not create contours exceeding an eight-syllable limit.

2pSC8. Sociological effects on vocal aging: Age related F_0 effects in two languages. Kyoko Nagao (Indiana Univ., Memorial Hall 406, 1021 3rd St., Bloomington, IN 47405-7005)

Listeners can estimate the age of a speaker fairly accurately from their speech (Ptacek and Sander, 1966). It is generally considered that this perception is based on physiologically determined aspects of the speech. However, the degree to which it is due to conventional sociolinguistic aspects of speech is unknown. The current study examines the degree to which fundamental frequency (F_0) changes due to advanced aging across two language groups of speakers. It also examines the degree to which the speakers associate these changes with aging in a voice disguising task. Thirty native speakers each of English and Japanese, taken from three age groups, read a target phrase embedded in a carrier sentence in their native language. Each speaker also read the sentence pretending to be 20-years younger or 20-years older than their own age. Preliminary analysis of eighteen Japanese speakers indicates that the mean and maximum F_0 values increase when the speakers pretended to be younger than when they pretended to be older. Some previous studies on age perception, however, suggested that F_0 has minor effects on listeners' age estimation. The acoustic results will also be discussed in conjunction with the results of the listeners' age estimation of the speakers.

2pSC9. Cues used for distinguishing African American and European American voices. Erik R. Thomas (Dept. of English, Box 8105, North Carolina State Univ., Raleigh, NC 27695-8105, ethomas@social.chass.ncsu.edu) and Norman J. Lass (West Virginia Univ., Morgantown, WV 26506-6122)

Past studies have shown that listeners can distinguish most African American and European American voices, but how they do so is poorly understood. Three experiments were designed to investigate this problem. Recordings of African American and European American college students performing various reading tasks were used as the basis for stimuli in all three. In the first experiment, stimuli were subjected to monotonization, lowpass filtering at 660 Hz, and no modification. In the second, stimuli featuring certain ethnically diagnostic vowels and control stimuli were subjected to monotonization, conversion of vowels to schwa, or no modification. In the third, stimuli featuring diagnostic vowels and control stimuli were modified so that the intonation of paired African American and European American speakers was swapped. In all three experiments, African American and European American listeners in North Carolina and European American listeners in West Virginia identified the ethnicity of the speaker of each stimulus. Vowel quality emerged as the most consistent cue for identifications. However, listeners accessed other cues differently for male and female speakers. Breathiness was correlated with identifications of male speakers but not of female speakers. F_0 -related factors proved more important for female speakers than for male speakers. [Work supported by NSF.]

2pSC10. Effects of aspiration on fundamental frequency in Taiwanese syllables. Yuwen Lai and Allard Jongman (Linguist. Dept., Blake Hall, Univ. of Kansas, Lawrence, KS 66044)

The perturbation effect on vowel fundamental frequency (F_0) by voiceless aspirated and unaspirated prevocalic obstruents is investigated in Taiwanese. It is well known that F_0 is significantly higher after voiceless than voiced stops. However, the perturbation effect caused by aspiration has received much less attention. Twenty-eight minimal pairs contrasting in prevocalic aspiration across three different places of articulation from seven tonal categories in Taiwanese were recorded from two male and two female speakers. An acoustic study was conducted on a total of 1120

syllables. Onset, offset, and mean F_0 as well as contours of the tones after the aspirated and unaspirated obstruents were compared. Results indicate that the onset and mean F_0 are significantly higher when following aspirated obstruents but no difference was found in offset F_0 . Tonal contour comparison shows that the F_0 raising effect triggered by aspirated obstruents disappears at 50–60% of the tone. Higher larynx and faster airflow rate are posited as the major factors for the higher F_0 after voiceless aspirated obstruents. The present results warrant a reconsideration of the traditional theory of aspiration-induced tonal split according to which a tonal split resulted from the lowering of F_0 due to aspiration.

2pSC11. Coarticulatory nasalization in modern Greek: Evidence for a link between coarticulation and syllable structure. Evanthia Diakoumakou (Oakland Univ., Linguist. Dept., Rochester, MI 48309)

An acoustic analysis of the temporal extent of vowel nasalization in the productions of six native speakers of (Standard) Modern Greek showed that the temporal extent of anticipatory vowel nasalization is limited in all contexts, although it is more extensive before tautosyllabic than heterosyllabic nasals. (On average, in stressed syllables, heterosyllabic anticipatory nasalization was 27 ms long, tautosyllabic anticipatory was 48 ms long, and carryover was 70 ms.) Modern Greek patterns in this aspect with languages like Spanish, Italian, Ikalanga, which also show a tendency toward open syllables, and obstruents are, in general, dispreferred as codas. It is hypothesized that there may be a link between a tendency for open syllables in a language and limited extent of anticipatory nasalization and it is suggested that investigation of the prosodic organization of languages may prove fruitful in determining the factors that lead to cross-language coarticulatory differences regarding vowel nasalization.

2pSC12. Examination of voicing onset time during Mandarin tone productions. Yang Chen (Dept. of Speech-Lang. Pathol., Duquesne Univ., 600 Forbes Ave., Pittsburgh, PA 15282) and Manwa Ng (Long Island Univ., Brookville, NY 11548-1300)

The voice onset time (VOT) of stop consonant is defined as the time interval between the release of a stop and the onset of the following vowel (Lisker and Abramson, 1964, 1970). Previous studies indicated that VOT could be used as a perceptual cue for identification of both voicing and place of articulation of stops (Kewley-Port, 1983; Ladefoged, 2001). Abramson (1977) suggested VOT could be interpreted as interrelated acoustic consequences of variation in the relative timing of glottal and oral gestures. This study will attempt to extend the probe on this suggestion by comparing the VOT values among different tones. Mandarin, which is a tone language, where a change in the tone of a syllable leads to a change in meaning, will be used in the study. There are four contrastive tones in Mandarin, each of which is realized by changing the vocal pitch during the course of the syllable production. The proposed study will determine if VOT values for each of the six stop sounds (/p,b,t,d,k,g/) will vary with the variation of different tones at which each of the following vowel sounds is produced. The interrelationship between VOT and tone production will be discussed.

2pSC13. A perceptual account of dissimilation. Anthony Brasher (Dept. of Linguist., Univ. of Michigan, 4080 Frieze Bldg., 105 S. State St., Ann Arbor, MI 48109-1285)

Ohala [J. J. Ohala, CLS Parasession on Language and Behavior, 178, 203 (1981)] argues that long-distance dissimilation results from hypercorrection; when confronted with words with multiple similar segments, listeners may be confused as to the origin of coarticulated features and attribute cues to one, but not all, segments. The present study evaluates this theory for a sound change involving dissimilation of breathy stops: in sequences of two or more breathy stops, all but the last become modal. If this pattern were reproduced in the laboratory then, when hearing a word with multiple breathy stops, listeners would have trouble assigning the

source of the breathy voicing. In this study, Hindi speakers heard two continua of disyllables, where the first syllable varied systematically in the temporal extent of breathy voicing. The continua differed in that the second syllable had a breathy stop in one continuum (dadhak>dhadhak) but a non-breathy stop in the other (dadak>dhadak) (dh=breathy stop). Initial results for Hindi speakers responding in a four-choice identification task support Ohala's hypothesis. Listeners identified the first syllable reliably when the second syllable is modal, but identified the first syllable inconsistently when the second syllable is breathy.

2pSC14. Pacific northwest vowels: A Seattle neighborhood dialect study. Jennifer K. Ingle, Richard Wright, and Alicia Wassink (Dept. of Linguist., Univ. of Washington, Box 354340, Seattle, WA 98195-4340, merywen@u.washington.edu)

According to current literature a large region encompassing nearly the entire west half of the U.S. belongs to one dialect region referred to as Western, which furthermore, according to Labov *et al.*, "... has developed a characteristic but not unique phonology." [http://www.ling.upenn.edu/phono_atlas/NationalMap/NationalMap.html] This paper will describe the vowel space of a set of Pacific Northwest American English speakers native to the Ballard neighborhood of Seattle, Wash. based on the acoustical analysis of high-quality Marantz CDR 300 recordings. Characteristics, such as low back merger and [u] fronting will be compared to findings by other studies. It is hoped that these recordings will contribute to a growing number of corpora of North American English dialects. All participants were born in Seattle and began their residence in Ballard between ages 0–8. They were recorded in two styles of speech: individually reading repetitions of a word list containing one token each of 10 vowels within carrier phrases, and in casual conversation for 40 min with a partner matched in age, gender, and social mobility. The goal was to create a compatible data set for comparison with current acoustic studies. F_1 and F_2 and vowel duration from LPC spectral analysis will be presented.

2pSC15. Breathiness in Indic languages. Christina Esposito, Sameeruddin Khan, and Alex Hurst (Dept. of Linguist., UCLA, 3125 Campbell Hall Box 951543, LA, CA 90095-1543, esposito@humnet.ucla.edu)

Previous work on breathiness in Indic languages has focused on the acoustic properties of breathy oral stops in languages like Hindi ([bal] hair versus [bhal] forehead) or Bengali ([baSa] house versus [bhaSa] language). However, breathiness in Indic languages often extends to nasals (e.g., Marathi ([maar] beat versus [mhaar] a caste). It is unclear if languages such as Hindi and Bengali have breathy nasals in addition to breathy oral stops. This study addresses the following questions: (1) Are breathy nasals (Nh) acoustically different from N+h sequences, both in languages where they are phonemic and ones where they are not? (2) In sequences of a breathy stop and a modal nasal (e.g., Hindi [udhmi] naughty) where is the breathiness realized, if at all? To answer these questions, audio, aerodynamic, and electroglottographic recordings will be made of Hindi, Bengali, and Marathi speakers. It is hypothesized that acoustically breathy nasals in Hindi and Bengali will not be distinct from sequences of N+ h. We believe that this will also be true for the oral stops. In addition, it is believed that in sequences of breathy oral stop followed by a modal nasal (e.g., ChN), the breathiness will be produced on the nasal.

2pSC16. Low vowels and transparency in Kinande vowel harmony. Bryan Gick, Douglas Pulleyblank (Dept. of Linguist., Univ. of British Columbia, E270-1866 Main Mall, Vancouver, BC, Canada V6T 1Z1, gick@interchange.ubc.ca), Nguessimo Mutaka (Univ. of Yaounde 1, Cameroon), and Fiona Campbell (Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z1)

Transparency—in which a harmony effect passes over a segment without affecting it phonetically or phonologically—has been a controversial concept in previous literature on harmony systems. A typical case of so-called transparency involves cross-height vowel harmony in Kinande, a Bantu language (J.40). Previous accounts have analyzed low vowels in this system as being transparent to harmony [Schlindwein, *NELS* 17, 551–567 (1987)]. Further, some analysts have considered low vowels theoretically incapable of undergoing tongue root harmony. These claims were tested in a single-subject field study using ultrasound imaging to measure tongue root position in low vowels. Results indicate that (a) advanced versus retracted tongue root position (ATR) is a viable feature for describing the phonological distinction in the vowel system; (b) there is a phonetic difference between low vowels when adjacent to ATR triggering vowels; (c) this distinction in low vowels does not decrease with distance from trigger vowels, suggesting that these vowels are undergoing phonological harmony rather than phonetic assimilation; and finally, (d) the ATR distinction is phonetically categorical in high vowels, but shows crossover in mid and low vowels. Implications for phonological theory and phonetics-phonology interface will be discussed. [Work supported by NSERC and SSHRC.]

2pSC17. The role of psychophysical difference in the discrimination of non-native contrasts. James Harnsberger, Rahul Shrivastav (Dept. Comm. Sci. and Disord., Univ. of Florida, Gainesville, FL 32611), and Mark Skowronski (Univ. of Florida, Gainesville, FL 32611)

Models of cross-language speech perception have shown only limited success in predicting the discriminability of non-native contrasts. These failures may be attributed partly to an inability to quantify the phonetic similarities between non-native speech sounds and between non-native speech sounds and native speech categories. This study represents an attempt to quantify gross psychophysical differences between consonants (e.g., the absolute difference between two consonants as represented in the peripheral auditory system). Two metrics were evaluated with a set of nasal consonant place contrasts from Malayalam. The first focused only on formant transitions at nasal-vowel boundaries (critical cue measure) while the second compared the spectrum of temporal windows spanning the entire length of both syllables that constituted a contrast (whole stimulus measure). The critical cue measure was presumed to have the advantage of incorporating only perceptually relevant information, while the whole stimulus measure was thought to be preferable if the relevant cues were poorly understood and/or were distributed throughout the syllable. The results showed a significant correlation ($r=0.63$) between the critical cue measure and discrimination scores. The whole stimulus measure showed only a weak correlation ($r=0.35$) unless a set of outliers (bilabial contrasts) was excluded ($r=0.80$).

2pSC18. Comparing listener preferences for text-level prosody in English and French. Caroline Smith (Dept. of Linguist., Univ. of New Mexico, MSC 03-2130, Albuquerque, NM 87131-1196)

Cross-language prosodic differences are well-known at the phrasal level and below, and a few studies have shown language-dependent differences in speakers' prosody over a discourse or text [Fon (2002), Smith and Hogan (2003)]. For comparison with the patterns found in production, this study examines listeners' preferences in text-level prosody. Previously-analyzed recordings of one speaker of American English reading aloud an English text, and one speaker of Parisian French reading a comparable French text, were used as a basis. The discourse organization of each text was analyzed by several native speakers who categorized each sentence-to-sentence transition as a Topic Shift, Continuation or Elaboration.

The original recordings were manipulated in several ways to alter rate, sentence-final lengthening and pause duration, and the manipulated versions were presented to listeners. English listeners liked best those versions where values for rate and lengthening matched the speakers' means for each separate type of topic transition. French listeners preferred the version where each prosodic variable kept the same mean value throughout. These results are supported by acoustic measurements which also point to a more salient role for rhythmic effects at the discourse level in English than in French. [Work supported by NSF grant BCS-9983106.]

2pSC19. Identifying native Cantonese stops: Implication for native speakers perception. Man Gao (Dept. of Linguist., Yale Univ., New Haven, CT 06511)

A series of perception tasks were conducted to probe Cantonese speakers' ability to perceive their languages syllable-final unreleased stops. Stimuli consisted of minimal sets of monosyllabic words with contrasting codas produced by a speaker of Hong Kong Cantonese. Twelve Guangzhou Cantonese speakers and five Hong Kong Cantonese speakers performed the perceptual tasks which included: matching stimuli with the corresponding orthographic character; AXB discrimination; and identifying word-final [p], [t], [k] and vowel explicitly. Five native speakers of Mandarin (where final stops are not allowed) also took the AXB and identification tasks. Both Guangzhou and Hong Kong speakers scored high in matching task: 93 and 96 percent correct respectively; for AXB task, subjects from Hong Kong (93%) did slightly better than those from Guangzhou (85%), and Mandarin speakers scored the lowest (78%). The most interesting findings were in the identification tasks, although subjects from Hong Kong scored the highest (82%), the accuracy of Guangzhou Cantonese speakers was surprisingly low (49%)—even worse than Mandarin speakers (69%). Explanation for the observed discrepancy between Guangzhou and Hong Kong subjects will be discussed with respect to their different language education as well as their distinct language experience. Implications for phonological awareness will also be discussed.

2pSC20. Processing voiceless vowels in Japanese: Effects of language-specific phonological knowledge. Naomi Ogasawara (Dept. of Linguist., Univ. of Arizona, Douglass 200E, P.O. Box 210028, Tucson, AZ 85721)

There has been little research on processing allophonic variation in the field of psycholinguistics. This study focuses on processing the voiced/voiceless allophonic alternation of high vowels in Japanese. Three perception experiments were conducted to explore how listeners parse out vowels with the voicing alternation from other segments in the speech stream and how the different voicing statuses of the vowel affect listeners' word recognition process. The results from the three experiments show that listeners use phonological knowledge of their native language for phoneme processing and for word recognition. However, interactions of the phonological and acoustic effects are observed to be different in each process. The facilitatory phonological effect and the inhibitory acoustic effect cancel out one another in phoneme processing; while in word recognition, the facilitatory phonological effect overrides the inhibitory acoustic effect.

2pSC21. The influence of stress on some acoustic correlates to the stop voicing distinction in French. Nassima Abdelli-Beruh (Dept. of Speech-Lang. Pathol. and Audiol., New York Univ., 719 Broadway Ste. 200, New York, NY 10003 and Dept. of Speech and Hearing Sci., City Univ. of New York, 365 Fifth Ave., New York, NY 10016) and Radhika Aravamudhan (Post-Doc Res. Fellow at Boys Town Natl. Res. Hospital, Omaha, NE)

This study examined how monolingual French speakers produced the stop voicing distinction in stressed and unstressed syllable-initial stops. Syllables were embedded in sentences. Voicing-related differences in du-

rations of VOT, closure and vowel were calculated and analyzed as a function of stress (stressed on the target syllable, stress on the syllable preceding the target syllable). Percentages of closures with voicing were tallied as function of the voicing category of the stops and the stressed condition. Results from ANOVA showed that the absolute durations were smaller in the unstressed than in the stressed condition. The magnitude of the voicing-conditioned related duration differences in VOT, closure and vowel were also influenced by stress.

2pSC22. The effects of implosives and prenasalized stops on pitch in Shona. Mario E. Chavez-Peon (Dept. of Linguist., Univ. of British Columbia, E-270, 1866 Main Mall, Vancouver, BC, Canada V6T 1Z1)

It is well known that F_0 at vowel onset can be influenced by a preceding consonant. That influence varies significantly across languages and consonant types, and may function as a perceptual signal to consonant manner. It has further been suggested that tone languages may behave differently from non-tone languages in this respect, with a shorter duration of consonantal perturbation [Hombert, *Studies in African Linguistics*, 1977]. Previous studies include a limited range of consonant types, and too few tone languages to test Hombert's proposal. This study presents the results of an acoustical investigation of the effects of implosives and prenasalized stops on the F_0 of a following vowel in Shona, a tone language. It is found that implosives have a similar raising effect on F_0 at vowel onset than that of voiceless (aspirated) stops, contrary to expectations based on previous studies [Wright and Shryock, *Journal of the Phonetic Association*, 1993]. It is also found that prenasalized consonants behave as nasals, having no effect on the F_0 of the following vowel, again contrary to expectation [cf. Trithart, *Studies in Bantu Tonology*, 1976; and Hombert, *Studies in Bantu Tonology*, 1976]. Finally, duration results do not support Hombert's position regarding tone languages.

2pSC23. Revisiting the Canadian English vowel space. Robert Hagiwara (Linguist. Dept., Univ. of Manitoba, Winnipeg, MB, Canada R3T 5V5)

In order to fill a need for experimental-acoustic baseline measurements of Canadian English vowels, a database is currently being constructed in Winnipeg, Manitoba. The database derives from multiple repetitions of fifteen English vowels (eleven standard monophthongs, syllabic /r/ and

three standard diphthongs) in /hVd/ and /hVt/ contexts, as spoken by multiple speakers. Frequencies of the first four formants are taken from three timepoints in every vowel token (25, 50, and 75% of vowel duration). Preliminary results (from five men and five women) confirm some features characteristic of Canadian English, but call others into question. For instance the merger of low back vowels appears to be complete for these speakers, but the result is a lower-mid and probably rounded vowel rather than the low back unrounded vowel often described. With these data Canadian Raising can be quantified as an average 200 Hz or 1.5 Bark downward shift in the frequency of F_1 before voiceless /t/. Analysis of the database will lead to a more accurate picture of the Canadian English vowel system, as well as provide a practical and up-to-date point of reference for further phonetic and sociophonetic comparisons.

2pSC24. Concurrent recognition of focus and question in Mandarin. Fang Liu (Univ. of Chicago, Dept. of Linguist., 1010 E. 59th St., Chicago, IL 60637)

F_0 has been shown to vary not only with lexical tones but also with focus and sentence type (statement versus question) in Mandarin. This study further investigates whether listeners can detect concurrent focus and sentence type information in speech. 320 statements and unmarked questions with initial, medial, final, or neutral focus produced by two speakers were tested on 11 listeners. Results show that listeners can identify both sentence type and focus in most cases (89.1% and 88.7%, respectively), suggesting that F_0 variations related to the two functions can be simultaneously perceived. Meanwhile, the lowest rates were found for identifying neutral focus in questions (71%) and for identifying statement in sentences with final focus (78%). In both cases the confusions seem to arise from the conflicting F_0 adjustments by sentence type and focus in the sentence-final position (final F_0 being raised for both question and final focus, but not for statement). Overall, the findings not only indicate that F_0 can concurrently encode both focus and sentence type in addition to tonal information, but also demonstrate how delicate a balance is maintained between these communicative functions when they have to share the same articulatory/acoustic parameter for their respective manifestations.

1:30

2pUW1. Uncertainty propagation in ocean acoustic waveguides. Steven Finette (Acoust. Div., Naval Res. Lab., Washington, DC 20375)

This presentation discusses a general method for representing uncertainty in numerical models that describe acoustic field propagation within partially specified ocean waveguide environments. The approach treats uncertainty within a probabilistic framework, representing both the sound speed distribution and acoustic field as stochastic processes. In this talk, environmental uncertainty is linked to incomplete knowledge of the vol-

ume sound speed field and is directly incorporated into the mathematical formulation for acoustic propagation in a stochastic ocean waveguide. As an example, equations describing the propagation of uncertainty [Finette, *J. Acoust. Soc. Am* (in press)] are solved analytically for the special case of a point source in a random, but spatially uniform sound speed field bounded by a pressure release surface and a rigid bottom. Results for the first two moments of the acoustic field are calculated using this approach and compared with an independent estimate of the same moments obtained from Monte Carlo based realizations that are computed from a deterministic parabolic wave equation. [Work supported by ONR.]

2pUW2. Converting sound speed uncertainty to an effective correlated noise term in array processing. Jit Sarkar, Bruce Cornuelle, Philippe Roux, W. S. Hodgkiss, W. A. Kuperman (Scripps Inst. of Oceanogr., UCSD, 9500 Gilman Dr., Mail Code 0238, La Jolla, CA 92093-0238, jit@mpl.ucsd.edu), and Mark Stevenson (NATO SACLANT Undersea Res. Ctr., La Spezia 19138, Italy)

The sensitivity of the received acoustic field at an array from a specific source to perturbations of the sound speed field about a mean value can be computed using a Born approximation formulation involving forward model calculations. When this sensitivity map is appropriately combined with a covariance of the uncertainty of the sound speed perturbations, one obtains the resultant perturbation to the cross spectral density matrix (CSDM) of the acoustic field. This additional term to the mean CSDM can be thought of as a noise term resulting from the uncertainty in the sound speed field. Computations indicate that this additional term is a form of correlated noise that suggests the possibility of mitigating environmental uncertainty with a robust array processing procedure.

2:00

2pUW3. Rapid acoustic field computations within environmental uncertainty bounds. Kevin D. Heaney (OASIS, Inc., Falls Church, VA 22044)

Oceanographic and geo-acoustic variability in the shallow water can dominate acoustic propagation. Often the environment is critically under-sampled, compared to the sensitivity of the full-field propagation model used [such as the Parabolic Equation (PE) model]. For regions with environmental uncertainty (which is known from measurements or models), there will be a Minimum Achievable Uncertainty (MAU) in acoustic propagation modeling (Transmission Loss). Given this MAU, it is proposed that field interpolation techniques be applied to speed up the acoustic propagation computation, consistent with keeping the interpolation errors below the MAU. Techniques for estimating the uncertainty in TL and speeding up the broadband range-dependent computation using the Navy Standard PE model will be presented. For fully 3-D field computations in a range-dependent environment, the speed up is expected to be several orders of magnitude.

2:15

2pUW4. In-situ estimates of environmental uncertainty on sonar performance prediction. Kevin D. Heaney (OASIS, Inc., Falls Church, VA 22044)

Oceanographic and geo-acoustic variability in the shallow water can dominate acoustic propagation. Sonar performance predictions using archival sound speed and geo-acoustic information do not contain any information about variability or uncertainty in the environment and its likely impact on sonar performance prediction. Using measurements from the NATO Undersea Research Centres BOUNDARY 2003 sea test, an approach is presented that estimates the uncertainty and transfers it through the acoustic propagation and the sonar equation to sonar performance. The sound speed field is characterized by an Empirical Orthogonal Function decomposition of the measured profiles. The geo-acoustic uncertainty is considered to be a normal distribution around the inverted geo-acoustic parameters (from 4 separate inversions). Dynamic ambient noise variability is measured from the array beamformer output. Uncertainty in propagation is quantified in terms of sound speed, geo-acoustic, and ambient noise uncertainty. The uncertainty in sonar performance, due to environmental uncertainty, is then displayed to the operator. [Work supported by the ONR Capturing Uncertainty DRI.]

2pUW5. Performance of mode-based processing in the presence of environmental uncertainty. Lisa Zurk (Elec. & Comput. Eng., Portland State Univ., P.O. 751, Portland, OR 97207)

A critical limiting factor to the performance of many underwater sonar detection and localization techniques is the typically high degree of uncertainty regarding the ocean environment. Several researchers have proposed mode-based processing methods for Matched Field Processing, depth-dependent pre-filtering, and sub-array processing. Provided that an appropriate modal decomposition can be applied, these methods are believed to provide processing that is less sensitive to environmental mismatch, with the added potential advantage of computational efficiency. In this paper, we attempt to quantify the performance of mode-based processing in uncertain environments, and compare this performance to more classic processing approaches. Results are presented from Monte Carlo simulations of range-dependent environments in which the uncertainty is varied parametrically. An analytical framework for describing the uncertainty is presented and discussed.

2:45

2pUW6. A high frequency time reversal array deployment in a very shallow water environment. Thomas Folegot (NATO Undersea Res. Ctr., MILOC, Viale San Bartolomeo 400, 19138 La Spezia, Italy), Dominique Clorennec, Jean-Gabriel Minonzio, Julien de Rosny, Claire Prada (Laboratoire Ondes et Acoustique, ESPCI, 75005 Paris, France), Mathias Fink (Laboratoire Ondes et Acoustique, ESPCI, 75005 Paris, France), Sidonie Hibrat, and Lothar Berniere (Atlantide, Technopole Brest Iroise, 29238 Brest Cedex 3, France)

A new rigid 24-element acoustic source receiver array in the 10 to 15 kHz frequency band has recently been developed [Folegot *et al.*, submitted to OCEANS2005-Europe]. Despite of a height of 10 m, it has been specified to be easily deployed from a pier and to allow low cost at-sea experiments with water depth up to 12 m. The array has been deployed in a pool of 50 m length and 10 m depth, where calibrated surface plane waves have been generated. The objective of the trial was to undertake a first deployment of the system, to calibrate the instrument and provide some scientific results based on time reversal in a very controlled experimental setup. The Time Reversal Operator has been measured in several configurations. Subsequently, its eigenvectors associated with target reflections have been emitted by the mirror in order to focus separately on each target. The sensitivity of the method against target depth, target type, emission basis, and surface roughness has been investigated. The collected data will help to improve the understanding of environmental factors affecting acoustic propagation in the 10–15 kHz range and will make an important contribution to the development of advanced acoustic communications methods and tomographic capabilities.

3:00–3:15 Break

3:15

2pUW7. Improvement of time reversal communications in underwater acoustic channels using adaptive equalizers. Heechun Song, William S. Hodgkiss, William A. Kuperman, Philippe Roux (MPL/SIO, UCSD, La Jolla, CA 92093), Tuncay Akal (MPL/SIO, UCSD, La Jolla, CA 92093), and Mark Stevenson (NATO Undersea Res. Ctr., La Spezia, Italy)

The spatial and temporal focusing properties of time reversal methods can be exploited for undersea acoustic communications. Spatial focusing mitigates channel fading and produces a high signal-to-noise ratio at the intended receivers along with a low probability of interception elsewhere. While the temporal focusing (compression) reduces significantly intersymbol interference (ISI), there always is some residual ISI depending upon the number of transmitters and the complexity of the channel. Moreover, a slight change in the environment over the two-way propagation interval introduces additional ISI. Using shallow water experimental data, we dem-

onstrate that the performance of multiple-input/multiple-output time reversal communications can be improved significantly by cascading the received time series with adaptive equalizers to remove the residual ISI.

3:30

2pUW8. Broadband source localization using matched correlation processing. Gordon R. Ebbeson, Marie-Noël R. Matthews, Garry J. Heard, Francine Desharnais (DRDC Atlantic, P.O. Box 1012, 9 Grove St., Dartmouth, NS, Canada B2Y 3Z7), and David J. Thomson (Victoria, BC, Canada V9C 4A4)

For many years, model-based signal processing algorithms using Matched Field Processing (MFP) techniques have been analyzed with the goal of improving the capability of passive sonar systems for localizing quiet underwater sources. Recently, researchers at DRDC Atlantic have been investigating Matched Correlation Processing (MCP) as a faster alternative to MFP. In this method, the cross-correlations for a source as measured with a pair of hydrophones in a horizontal array are matched with those generated with a correlation model for many candidate ranges and depths along a candidate bearing. These matches are carried out with a number of hydrophone pairs to form many ambiguity surfaces. The maximum on the average of these surfaces is assumed to yield the best estimate of the source position. By carrying out this procedure over a number of candidate bearings, a full 3-D search for the source location is achieved. Since 2002, a number of localization trials have been carried out east of Nova Scotia, Canada. During those trials, an array was deployed on the sea floor and used to collect acoustic signals from various broadband sources. In this paper, we describe the broadband MCP localization technique and show some localization results from those trials.

3:45

2pUW9. Broadband continuous wave source localization via pair-wise, cochleagram processing. Eva-Marie Nosal and L. Neil Frazer (Univ. of Hawaii at Manoa, 1680 East-West Rd., Post 813, Honolulu, HI 96822)

A pair-wise processor has been developed for the passive localization of broadband continuous-wave underwater sources. The algorithm uses sparse hydrophone arrays and does not require previous knowledge of the source signature. It is applicable in multiple source situations. A spectrogram/cochleagram version of the algorithm has been developed in order to utilize higher frequencies at longer ranges where signal incoherence, and limited computational resources, preclude the use of full waveforms. Simulations demonstrating the robustness of the algorithm with respect to noise and environmental mismatch will be presented, together with initial results from the analysis of humpback whale song recorded at the Pacific Missile Range Facility off Kauai. [Work supported by MHPCC and ONR.]

4:00

2pUW10. Modeling of forward sector adaptive matched field processing. Jeffrey Dunne (Johns Hopkins Univ. Appl. Phys. Lab., 11100 Johns Hopkins Rd., Laurel, MD 20723, Jeffrey.Dunne@jhuapl.edu)

A modeling study was undertaken to examine the potential benefit of adaptive matched field processing (AMFP) to the forward sector capability of single-line, twin-line, and volumetric arrays. Comparisons are made with conventional MFP (CMFP) and plane-wave beamforming (PWB) in order to assess the degree of ownship noise reduction obtainable and any corresponding improvement to the signal-to-noise ratio (SNR). A minimum variance distortionless response beamformer using dominant mode rejection was implemented, applied to both uniform and distorted array shapes. Significant improvement over CMFP and PWB in tracking and SNR was seen for modeled data in both cases, with the distorted array showing, not surprisingly, better left-right rejection capability. A brief investigation of the effects of environmental mismatch was undertaken in order to assess its potential impact on the value-added of AMFP. [Work was supported by the Defense Advanced Research Projects Agency, Advanced Technology Office.]

2pUW11. An iso-deviant approach for acoustic computations using efficient adaptive gridded for littoral environments. Erik R. Rike and Donald R. DelBalzo (Neptune Sci. Div. of Planning Systems, Inc., 40201 Hwy 190 E, Slidell, LA 70461, delbalzo@neptunesci.com)

Transmission Loss (TL) computations in littoral areas require a dense spatial and azimuthal grid to achieve acceptable accuracy and detail. The computational cost of accurate predictions led to a new concept, OGRES (Objective Grid/Radials using Environmentally-sensitive Selection), which produces sparse, irregular acoustic grids, with controlled accuracy. Recent work to further increase accuracy and efficiency with better metrics and interpolation led to EAGLE (Efficient Adaptive Gridded for Littoral Environments). On each iteration, EAGLE produces grids with approximately constant spatial uncertainty (hence, iso-deviance), yielding predictions with ever-increasing resolution and accuracy. The EAGLE point-selection mechanism is tested using the predictive error metric and 1-D synthetic data-sets created from combinations of simple signal functions (e.g., polynomials, sines, cosines, exponentials), along with white and chromatic noise. The speed, efficiency, fidelity, and iso-deviance of EAGLE are determined for each combination of signal, noise, and interpolator. The results show significant efficiency enhancements compared to uniform grids of the same accuracy. [Work sponsored by ONR under the LADC project.]

4:30

2pUW12. Adapting a truly nonlinear filter to the ocean acoustic inverse problem. Andrew A. Ganse and Robert I. Odom (Appl. Phys. Lab. (APL-UW), 1013 NE 40th St., Seattle, WA 98105, aganse@apl.washington.edu)

Nonlinear inverse problems including the ocean acoustic problem have been solved by Monte Carlo, locally-linear, and filter based techniques such as the Extended Kalman Filter (EKF). While these techniques do provide statistical information about the solution (e.g., mean and variance), each suffers from inherent limitations in their approach to nonlinear problems. Monte Carlo techniques are expensive to compute and do not contribute to intuitive interpretation of a problem, and locally-linear techniques (including the EKF) are limited by the multimodal objective landscape of nonlinear problems. A truly nonlinear filter, based on recent work in nonlinear tracking, estimates state information for a nonlinear problem in continual measurement updates and is adapted to solving nonlinear inverse problems. Additional terms derived from the system's state PDF are added to the mean and covariance of the solution to address the nonlinearities of the problem, and overall the technique offers improved performance in nonlinear inversion. [Work supported by ONR.]

4:45

2pUW13. A neural network for mode space source depth estimation. William Lee and Yung Lee (Sci. Applications Intl. Corp., 1710 SAIC Dr., McLean, VA 22102)

A great deal of research in mode space source localization processing exists. One technique proposed by Shang performs mode filtering of the observed pressure field on a vertical line array, using the calculated mode amplitude distributions and phase differences to estimate source location. Ozard *et al.* proposed a feed forward neural network using input vectors of mode energy distribution for source localization, a dedicated neuron for each possible source location was employed in their study. Instead of employing a dedicated neuron for each possible search location, the interest of this study is to determine an efficient setup of neurons to properly sample the search space. In MATLAB neural network toolbox, the self-organizing-map function learns to classify input vectors according to how they are grouped in the input space, specifically their distribution and topology. We used this function to examine how input vectors of mode energy distribution for signals at different depths are grouped to determine the sampling grids of the search space in depth. We also compared the neural network performance using input vectors of mode amplitude distribution with those using input vectors of mode energy distribution.

Meeting of Accredited Standards Committee (ASC) S1 Acoustics

J. P. Seiler, Chair S1

*U.S. Department of Labor, Mine Safety and Health Admin., P.O. Box 18233, Bldg. 38,
Cochrans Mill Road, Pittsburgh, PA 15236*

G. S. K. Wong, Vice Chair S1

*Institute for National Measurement Standards, National Research Council, Montreal Road, Bldg. M36,
Ottawa, Ontario K1A 0R6, Canada*

Accredited Standards Committee S1 on Acoustics. Working group chairs will report on the status of standards currently under development in the areas of physical acoustics, electroacoustics, sonics, ultrasonics, and underwater sound, etc. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAGs for ISO/TC 43 Acoustics and IEC/TC 29 Electroacoustics, take note - those meetings will be held in conjunction with the Standards Plenary meeting at 10:30 a.m. on Tuesday, 17 May 2005.

Scope of S1: Standards, specifications, methods of measurement and test, and terminology in the field of physical acoustics, including architectural acoustics, electroacoustics, sonics and ultrasonics, and underwater sound, but excluding those aspects which pertain to biological safety, tolerance and comfort.

Meeting of Accredited Standards Committee (ASC) S12 Noise

R. D. Hellweg, Chair S12

Hewlett Packard Co., Acoustics Lab, MR01-1/P18, 200 Forest Street, Marlborough, MA 01752

R. D. Godfrey, Vice Chair S12

Owens Corning Science & Technology Center, 2790 Columbus Road, Route 16, Granville, OH 43023-1200

Accredited Standards Committee S12 on Noise. Working group chairs will report on the status of noise standards currently under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAG for ISO/TC 43/SC 1 Noise, take note - that meeting will be held in conjunction with the Standards Plenary meeting at 10:30 a.m. on Tuesday, 17 May 2005.

Scope of S12: Standards, specifications, and terminology in the field of acoustical noise pertaining to methods of measurement, evaluation and control, including biological safety, tolerance and comfort and physical acoustics as related to environmental and occupational noise.

Session 3aAA

**Architectural Acoustics, Speech Communication and Psychological and Physiological Acoustics:
Possibilities and Problems with Auralizations of Classroom Acoustics**

Robert C. Coffeen, Chair

*Univ. of Kansas, School of Architectural and Urban Design, Lawrence, KS 66045***Chair's Introduction—8:30***Invited Papers***8:35****3aAA1. Predicting and auralizing acoustics in classrooms.** Claus Lyng Christensen (Odeon A/S c/o Acoust. Technol., Oersted DTU, Bldg. 352, DK-2800 Lyngby, Denmark)

Although classrooms have fairly simple geometries, this type of room is known to cause problems when trying to predict their acoustics using room acoustics computer modeling. Some typical features from a room acoustics point of view are: Parallel walls, low ceilings (the rooms are flat), uneven distribution of absorption, and most of the floor being covered with furniture which at long distances act as scattering elements, and at short distance provide strong specular components. The importance of diffraction and scattering is illustrated in numbers and by means of auralization, using ODEON 8 Beta.

8:55**3aAA2. Subjective evaluation of auralizations created from multi-channel anechoic recordings of a talker in motion.** Michelle C. Vigeant and Lily M. Wang (Architectural Engr. Prog., Univ. of Nebraska–Lincoln, Peter Kiewit Inst., 1110 S. 67th St., Omaha, NE 68182-0681, mvigeant@unlnotes.unl.edu)

A high degree of speech intelligibility is very important in educational environments. When designing such spaces, like classrooms, auralizations can be used to subjectively assess the degree of speech intelligibility and clarity. Auralizations are most commonly made by convolving the impulse response (IR) of an omni-directional source with a single channel anechoic speech recording. This paper explores the idea of using multi-channel recordings to create the auralizations, using a female talker in motion. An omni-directional source is split into quadrants and the IR is calculated for each section. These IR's are convolved with the appropriate channel of the anechoic recording and then the four auralizations are mixed to create one final auralization. The auralizations were made using four-channel anechoic recordings of a person walking on a platform while talking. Subjective tests were conducted to determine the ease with which subjects could identify the direction of the movement of the source in rooms with varying amounts of absorption. This method can be used to create more realistic classroom auralizations, as teachers typically move around the room as they teach. [Work supported by the National Science Foundation.]

9:15**3aAA3. ClassTalk system for predicting and auralizing speech in noise with reverberation in classrooms.** Murray Hodgson and Daniel Graves (UBC Acoust. & Noise Res. Group, SOEH, 3rd Fl., 2206 East Mall, Vancouver, BC, Canada V6T 1Z3)

This paper discusses and demonstrates the ClassTalk system for predicting, visualizing and auralizing speech in noise with reverberation in classrooms. The classroom can contain a speech-reinforcement system (SRS). Male or female speech sources, SRS loudspeakers and overhead, slide or digital projectors, or ventilation-noise sources, can have four output levels. Empirical models are used to predict speech and noise levels, and Early Decay Times, from which Speech Transmission Index (STI) and Speech Intelligibility (SI) are calculated. ClassTalk visualizes the floor-plan, speech- and noise-source positions, and the receiver position. The user can walk through the room at will. In real time five quantities, background-noise level, speech level, signal-to-noise difference, STI and SI, are displayed along with occupied and unoccupied reverberation times. The sound module auralizes male or female speech mixed with the relevant noise signals, with predicted, frequency-varying reverberation superimposed using MaxxVerb. Technical issues related to the development of the sound module are discussed. The potential of the systems auralization module for demonstrating the effects of the acoustical environment and its control on speech is discussed and demonstrated.

9:35**3aAA4. Comparison of speech intelligibility scores for direct listening and headphone playback.** John S. Bradley, Hiroshi Sato, Bradford N. Gover, and Natalie York (Inst. for Res. in Construction, Natl. Res. Council, Montreal Rd., Ottawa, Canada K1A 0R6)

Speech recognition test scores from direct listening and headphone playback were compared to validate the use of headphone playback for investigating the effects of varied room acoustics conditions. Varied acoustical conditions for direct listening, that were representative of classrooms, were achieved using simulated sound fields in an anechoic room with an 8-channel electro-acoustic simulation system. Eight conditions consisting of the combinations of 2 reverberation times and 4 signal-to-noise ratios were used. By recording these conditions with an acoustical mannequin, headphone playback of the same conditions could be achieved and the corresponding speech recognition scores compared. Two different approaches for correcting for the microphone and headphone

responses were compared. Subjects also responded to a short questionnaire to describe the audible differences between direct playback and headphone listening. Because spatial characteristics were frequently found to differ between the two listening modes, further comparisons were carried out using sound fields with systematic differences in the locations of the speech and noise sources. Although there were always some audible differences between the two playback modes, it was possible to obtain the same speech recognition scores using headphone playback as with direct listening. [Work supported by CLLRnet.]

9:55

3aAA5. Auralizations and other computer model studies to predict qualitative and quantitative measures of speech intelligibility in classrooms. Gary Siebein, Hyeong-seok Kim (Univ. of Florida School of Architecture, P.O. Box 115702, Gainesville, FL 32607), and Hyun Paek (Siebein Assoc., Inc., Consultants in Architectural Acoust., Gainesville, FL 32607)

Auralizations and other computer model studies were used to predict qualitative and quantitative measures of speech intelligibility in classrooms under realistic conditions of background noise and reverberation. Speech intelligibility tests were given to college students in two classrooms and one racquetball court at 5 signal-to-noise ratios. Auralizations of the speech intelligibility tests were made from computer. Speech intelligibility tests were then administered in a sound booth using the auralized material. Fifteen different acoustical measurements related to speech intelligibility were also made at multiple locations in the actual classrooms and in the computer models of the classrooms. The scores on the speech intelligibility tests given in the actual rooms in the five noise conditions were closely duplicated in the equivalent tests conducted in a sound booth using the simulated speech signals obtained in the computer models. Both quantitative and qualitative measures of speech intelligibility in the actual rooms were accurately predicted in the computer models. Correlations (R2) between acoustical measures made in the full size classrooms and the computer models of the classrooms of 0.92 to 0.99 were found.

10:15–10:30 Break

10:30

3aAA6. Classroom auralizations using both speech and intruding noise. Robert C. Coffeen (School of Architecture and Urban Design, Marvin Hall, The Univ. of Kansas, Lawrence, KS 66045)

Continuing work with computer auralizations for education spaces—Can realistic speech auralizations be obtained for classrooms and similar spaces with disturbing ambient noise as produced by HVAC systems, noise from adjacent spaces, aircraft flyovers, and other common noise sources? Several auralizations will be presented relating to these situations.

10:50

3aAA7. Classroom sound quality—a comparison of recordings to virtual auralization. Kenneth P. Roy and Sean D. Browne (Armstrong Innovation Ctr., 2500 Columbia Ave., Lancaster, PA 17604)

Sound quality in classrooms is an important consequence of the architectural and mechanical systems design. And it is the primary factor in determining the potential for speech intelligibility, which of course is also dependent on individual listening characteristic and capabilities. So the question is “how do we assess the potential for good sound quality within the design phase of school construction?” An obvious solution is to use architectural modeling and auralization . . . but the question here is “how good are these virtual techniques?” as with the use of EASE software. We will present 1st a sample of the modeling and auralization process showing the capabilities via the generated sound files. Next we will listen to recordings made in an occupied classroom both before and after architectural interventions. Then we will listen to a series of auralized classroom settings. And finally, we will compare recordings to auralizations for the same classroom. One important aspect of “real room” sound quality is occupant generated noise (non-speech), which is not an easy aspect to include in virtual models.

11:10

3aAA8. Rapid Speech Transmission Index predictions and auralizations of unusual instructional spaces at MIT’s new Stata Center. David A. Conant (McKay Conant Brook Inc., 5655 Lindero Canyon Rd., Westlake Village, CA 91326)

The Stata Center for Computer, Information and Intelligence Sciences, recently opened at the Massachusetts Institute of Technology, includes a variety of oddly-shaped seminar rooms in addition to lecture spaces of somewhat more conventional form. The architects design approach prohibited following conventional, well understood room-acoustical behavior yet MIT and the design team were keenly interested in ensuring that these spaces functioned exceptionally well, acoustically. CATT-Acoustic room modeling was employed to assess RASTI through multiple design iterations for all these spaces. Presented here are computational and descriptive results achieved for these rooms which are highly-regarded by faculty. They all sound peculiarly good, given their unusual form. In addition, binaural auralizations for selected spaces are provided.

3aABa1. Hearing and the round goby: Understanding the auditory system of the round goby (*Neogobius melanostomus*). Andrea J. Belanger and Dennis M. Higgs (Dept. of Biological Sci., Univ. of Windsor ON, 401 Sunset Ave., Windsor, ON, N9B 3P4, Canada)

The round goby (*Neogobius melanostomus*), is an invasive species in the Great Lakes watershed. Adult round gobies show behavioral responses to conspecific vocalizations but physiological investigations have not yet been conducted to quantify their hearing abilities. We have been examining the physiological and morphological development of the auditory system in the round goby. Various frequencies (100 Hz to 800 Hz and conspecific sounds), at various intensities (120 dB to 170 dB re 1 Pa) were presented to juveniles and adults and their auditory brain-stem responses (ABR) were recorded. Round gobies only respond physiologically to tones from 100–600 Hz, with threshold varying between 145 to 155 dB re 1 Pa. The response threshold to conspecific sounds was 140 dB re 1 Pa. There was no significant difference in auditory threshold between sizes of fish for either tones or conspecific sounds. Sacculus epithelia were stained using phalloidin and there was a trend towards an increase in both hair cell number and density with an increase in fish size. These results represent a first attempt to quantify auditory abilities in this invasive species. This is an important step in understanding their reproductive physiology, which could potentially aid in their population control. [Funded by NSERC.]

8:15

3aABa2. Sound localization and auditory response capabilities in round goby (*Neogobius melanostomus*). Audrey K. Rollo and Dennis M. Higgs (Dept. of Biol., Univ. of Windsor, Windsor, ON, Canada N9B 3P4, audrey-rollo@hotmail.com)

A fundamental role in vertebrate auditory systems is determining the direction of a sound source. While fish show directional responses to sound, sound localization remains in dispute. The species used in the current study, *Neogobius melanostomus* (round goby) uses sound in reproductive contexts, with both male and female gobies showing directed movement towards a calling male. The two-choice laboratory experiment was used (active versus quiet speaker) to analyze behavior of gobies in response to sound stimuli. When conspecific male spawning sounds were played, gobies moved in a direct path to the active speaker, suggesting true localization to sound. Of the animals that responded to conspecific sounds, 85% of the females and 66% of the males moved directly to the sound source. Auditory playback of natural and synthetic sounds showed differential behavioral specificity. Of gobies that responded, 89% were attracted to the speaker playing *Padogobius martensii* sounds, 87% to 100 Hz tone, 62% to white noise, and 56% to *Gobius niger* sounds. Swimming speed, as well as mean path angle to the speaker, will be presented during the presentation. Results suggest a strong localization of the round goby to a sound source, with some differential sound specificity.

8:30

3aABa3. Do laboratory rearing conditions affect auditory and mechanosensory development of zebrafish (*Danio rerio*)? Kirsten R. Poling, Eva Jaworski, Kristen R. Fantetti, and Dennis M. Higgs (Dept. of Biol., Univ. of Windsor, Windsor, ON, Canada N9B 3P4, kpoling@uwindsor.ca)

The effect of anthropogenic noise on the fish auditory system has become of increasing concern due to possible detrimental effects of intense sounds on auditory function and structures. This is especially problematic when raising fish in laboratory and aquaculture settings using filtration and aeration, which increase sound levels. To assess the effects of laboratory rearing conditions, one group of zebrafish (*Danio rerio*) embryos (“controls”) were placed into aerated aquaria in a normal laboratory rearing environment. A second set of embryos (“quiet”) were reared in aquaria with no aeration or filtration in a sound-resistant room. The intensity difference between the two sets of tanks was over 30 dB. Preliminary data show that there was no affect of differential rearing environments on saccular hair cell numbers or on hearing ability in fish up to 25 mm total length. However, rearing environment did affect neuromast number. “Quiet” fish had higher numbers of both cephalic and trunk superficial neuromasts, relative to controls. This difference was maintained up to 11 mm total length (the size at which canal formation begins). This suggests that acoustic environments normally found in the laboratory do not affect development of hearing in zebrafish, although laboratory acoustics may affect mechanosensory development.

8:45

3aABa4. The effect of sweep direction on avian auditory brainstem responses. Elizabeth Brittan-Powell, Amanda Lauer, Julia Callahan, Robert Dooling (Dept of Psych., Univ. of Maryland, College Park, MD 20742), Marjorie Leek (Army Medical Ctr., Washington, DC 20307), and Otto Gleich (Univ. of Regensburg, 93042 Regensburg, Germany)

In mammals, brief rising frequency sweeps result in increased amplitudes for both auditory brainstem response (ABR) and compound action potential (CAP) recordings (Dau, 2000; Shore and Nuttall, 1985). The rising sweep is thought to result in increased synchronous activity. Changing the direction of the sweep exaggerated the delay of processing along the basilar membrane and decreased synchrony of neural responses. Here we recorded ABRs from budgerigars, canaries, and zebra finches to a variety of stimulus parameters, including rising and falling sweeps with different sweep rates, determined by changing duration and frequency range. Both linear and nonlinear sweeps in frequency over time were tested. Results show that rising sweeps produce larger peak amplitudes, shorter latencies and changes in wave morphology such as a narrower wave 1 width than falling sweeps, suggesting greater synchrony of response to sweeps moving from low to high frequency. These data are consistent with mammalian results, but with a different time scale related to temporal characteristics of cochlear stimulation on the short basilar papilla in birds. 3aABa5. Novel technique for rapid screening of tinnitus in rats.

Jeremy G. Turner, Thomas J. Brozoski, Jennifer L. Parrish, Carol A. Bauer, Larry F. Hughes, and Donald M. Caspary (Southern Illinois Univ. School of Medicine, P.O. Box 19620, Springfield, IL 62794-9620, jturner@siu.edu)

Measuring tinnitus in laboratory animals is difficult, involving weeks or months of operant training. Preliminary data suggest that rapid screening for tinnitus in rats can be accomplished using an unconditioned acoustic startle reflex. In control animals, a gap in an otherwise constant acoustic background inhibits a subsequent startle response to a sound impulse. If, however, the background signal is qualitatively similar to the animal's tinnitus, poorer detection of the gap and less inhibition of the startle might be expected. Fourteen animals with putative tinnitus at 10 kHz and 13 control animals were tested for gap detection using three different background signals: broadband noise, and filtered bandpass noise centered either at 16 kHz (15.5–16.5 kHz) or at their suspected tinnitus locus of 10 kHz (9.5–10.5 kHz). As predicted, animals with evidence of tinnitus exhibited significantly worse gap detection at 10 kHz, and were not significantly different than control animals at 16 kHz and broadband noise. These results suggest a new methodology for rapidly detecting tinnitus in individual animals. Equipment donated by Hamilton-Kinder Inc Behavioral Testing Systems in the memory of SIU graduate Dorothy Jean Kinder (Walker). [Work supported by NIH grants AG023910-01 (JT), DC4830 (TB & CB), and DC00151 (DC).]

9:15

3aABa6. Emotional learning modulates the rats sensitivity to transient changes in correlation between sounds.

Juan Huang, Liang Li, Zhigang Yang, Junli Ping (Dept. of Psych., Natl. Key Lab. on Machine Percept. Speech and Hearing Res. Ctr., Peking Univ., Beijing 100871, China), Xian Liu, Yixin Chen, and Xihong Wu (Peking Univ., Beijing 100871, China)

Humans are sensitive to small discrepancies between two sounds, and can detect a transient change in sound correlation. Here, prepulse inhibition of the startle reflex was used to examine rats sensitivity to transient changes in correlation between two correlated broadband noises, which were delivered by two spatially separated loudspeakers. The results show that either an uncorrelated noise fragment (UCNF, a drop of inter-sound correlation from 1.00 to 0 and then return to 1.00) or an anti-phase noise fragment (APNF, a drop of inter-sound correlation from 1.00 to -1.00 and then return to 1.00) could be detected by rats, since each of the changes in correlation could act as a prepulse stimulus to inhibit the startle reflex. The duration threshold for detecting the APNF was much lower than that for the UCNF. The detection of each of the changes in correlation was improved either by prolonged testing or by temporally pairing the UCNF or APNF with footshock. Thus similar to humans, rats also have the sensitivity to a sudden change in inter-sound correlation. Moreover, an increase of the sensitivity can be induced in rats either by repeated exposure to the change in correlation or by emotional learning.

3aABa7. The role of tragus on echolocating bat, *Eptesicus fuscus*.

Chen Chiu (Neurosci. and Cognit. Sci. Program, Univ. of Maryland, College Park, MD 20742) and Cynthia Moss (Univ. of Maryland, College Park, MD 20742)

Echolocating bats produce ultrasonic vocal signals and utilize the returning echoes to detect, localize and track prey, and also to avoid obstacles. The pinna and tragus, two major components of the bats external ears, play important roles in filtering returning echoes. The tragus is generally believed to play a role in vertical sound localization. The purpose of this study is to further examine how manipulation of the tragus affects a free-flying bat's prey capture and obstacle avoidance behavior. The first part of this study involved a prey capture experiment, and the bat was trained to catch the tethered mealworms in a large room. The second experiment involved obstacle avoidance, and the bat's task was to fly through the largest opening from a horizontal wire array without touching the wires. In both experiments, the bat performed the tasks under three different conditions: with intact tragus, tragus-deflection and recovery from tragus-deflection. Significantly lower performance was observed in both experiments when tragi were glued down. However, the bat adjusted quickly and returned to baseline performance a few days after the manipulation. The results suggest that tragus-deflection does have effects on both the prey capture and obstacle avoidance behavior. [Work supported by NSF.]

3aABa8. Minimum audible angles for aerial pure tones in a northern elephant seal (*Mirounga angustirostris*).

Marla M. Holt, Ronald J. Schusterman (UC Santa Cruz Long Marine Lab., 100 Shaffer Rd, Santa Cruz, CA 95060), Brandon L. Southall (UCSC Long Marine Lab. and NOAA Fisheries Acoust. Program, Silver Spring, MD 20910), and David Kastak (UC Santa Cruz Long Marine Lab., Santa Cruz, CA 95060)

Recent work has shown that several pinniped species localize aerial broadband signals as accurately as some terrestrial carnivores. Additionally, both harbor seals and California sea lions can better localize both the lower and higher frequencies of their hearing range compared to performance at intermediate frequencies. These results are congruent with the duplex theory of sound localization which states that low frequencies are localized by interaural time differences while high frequencies are localized by interaural intensity differences. Northern elephant seals are land breeding pinnipeds whose range of best hearing sensitivity is shifted toward lower frequencies compared to other pinnipeds tested thus far. In this study, we tested a female northern elephant seal in a hemi-anechoic chamber at six frequencies ranging between 0.8 and 16 kHz that were presented at levels approximately 25 dB above threshold. A left/right behavioral procedure was used to measure minimum audible angles (MAAs) at 75 percent correct discrimination. MAAs ranged from approximately three to fifteen degrees. Best performance occurred at the lower frequencies while worse performance occurred at the two highest test frequencies. Unlike sea lions and harbor seals, this subject showed a decreased ability to utilize interaural intensity differences above 4 kHz.

3aABb1. Variation in acoustic activity of North Atlantic right whales in three critical habitat areas in 2004. Susan E. Parks and Christopher W. Clark (Bioacoustics Res. Program, Cornell Univ., 159 Sapsucker Woods Rd., Ithaca, NY 14850)

The North Atlantic right whale is a critically endangered species. Five major habitat areas have been defined based on the presence of groups of right whales during different seasons of the year. Autonomous seafloor acoustic recorders, "pop-ups," have been used over the past five years to identify the presence/absence of right whales in Cape Cod Bay, Massachusetts by detection of right whale contact calls. These recordings have shown the effectiveness of using acoustics to monitor right whale behavior. In 2004, multi-unit arrays of pop-ups were deployed in three critical habitat areas; Cape Cod Bay (January–April), Great South Channel (May), and the Bay of Fundy (August). The presence/absence of right whale calls within range of the array, estimates of the minimum number of individuals calling, the types of calls recorded, and the diurnal patterns of sound production were measured to compare the acoustic repertoire use of right whales in these three habitats. These data were compared to visual survey data in the Bay of Fundy. These results can be used to compare diurnal and nocturnal behavioral patterns of the whales and provide information on behavioral differences between these three critical habitat areas.

10:30

3aABb2. Variation in acoustic behavior of delphinids in the Pacific Ocean based on school size and species composition. Shannon Rankin and Jay Barlow (SWFSC/NOAA, 8604 La Jolla Shores Dr., La Jolla, CA 92037, shannon.rankin@noaa.gov)

Variation in acoustic behavior based on school size and species composition was examined for surveys in the eastern tropical Pacific (2000), along the U.S. West Coast (2001), and in the U.S. EEZ surrounding Hawaii (2002). Sounds were monitored using a towed hydrophone array, and vocal schools were defined as those producing any combination of whistles, burst pulses, and/or echolocation clicks. Delphinid schools containing mixed species were consistently more vocal than single species schools. Vocal schools of *Stenella attenuata*, *S. longirostris*, *Delphinus delphis*, and *Lissodelphis borealis* were significantly larger than non-vocal schools. Vocal schools of *Tursiops truncatus* and *Grampus griseus* were somewhat larger than non-vocal schools, although this relationship was not significant. There was no relationship between group size and vocal activity for *S. coeruleoalba*, *Steno bredanensis*, and *Globicephala* spp. For species without a strong group size effect, all but *T. truncatus* were more vocal in the Hawaiian waters. The ability to use acoustic techniques in dolphin population estimation depends on their effectiveness in consistently detecting dolphin schools. This study suggests that small single-species schools of *S. attenuata*, *S. longirostris*, *D. delphis*, and *L. borealis* are more likely to be missed during acoustic monitoring in these regions.

10:45

3aABb3. Long term stability and individual distinctiveness in captive orca vocalizations. Michael Noonan and Malini Suchak (Canisius College, Buffalo, NY 14208, noonan@canisius.edu)

With focus on the question of signature calling in killer whales, recordings from five captive orcas (of Icelandic origin) held at Marineland of Canada were compared. For the present analysis, samples of three different call syllables were selected from recordings made five years apart and from instances in which the identity of the calling whale was unambiguous due to temporary isolation, concomitant bubbling, and/or head nodding. The Raven software package was used to ascertain the frequency range, frequency (max), duration, and timing of maximum and minimum power within each sample. For two of the three call syllables, statistically significant differences were found among the five whales for call length and for the timing of maximums and minimums ($p < 0.01 - 0.001$). This similarly proved true for nearly all pairwise comparisons between whales, including mother-offspring dyads. By contrast, for three of four whales for which we had sufficient samples, no significant differences were found on any measure between samples taken from the same whales five years apart. These findings therefore support the notion that the voices of individual orcas are distinct from one another in ways that are stable over the course of multiple years.

11:00

3aABb4. The acoustic repertoire of bottlenose dolphins (*Tursiops truncatus*) from the southern Gulf of Mexico. Carmen Bazua-Duran (Lab. Acustica, Facultad de Ciencias, UNAM, Cd. Universitaria, 04510 Mexico DF, Mexico)

Bottlenose dolphins live in a variety of habitats of the world's oceans using their acoustic repertoire to communicate and inspect their environment. This work investigates the acoustic repertoire of bottlenose dolphins that inhabit a coastal lagoon of the southern Gulf of Mexico, the Laguna de Terminos and how it may relate to the dolphins' general behavioral state and herd size, and to the general characteristics of the habitat, such as visibility, depth, and sea state. Preliminary results show that bottlenose dolphins produce by far more clicks than whistles in all behavioral states (feeding, resting, social, and travel) and herd sizes, which may correlate with the decreased visibility and shallow depth of the Laguna de Terminos. Additionally, silence was found during all behavioral states, but very seldom in herds of large size. These preliminary results suggest that bottlenose dolphins are choosing when and where to produce their phonations. Therefore, more detailed studies are needed to understand how these animals are using their acoustic sense to communicate and inspect their environment. [Work supported by CONACyT-Gobierno Edo. de Campeche and PAPIIT, UNAM.]

11:15

3aABb5. Automated categorization of bioacoustic signals: Avoiding perceptual pitfalls. Volker B. Deecke (Marine Mammal Res. Unit, Univ. of British Columbia, 6248 Biosciences Rd., Vancouver, BC, Canada V6T 1Z4) and Vincent M. Janik (Univ. of St. Andrews, St. Andrews, Fife KY16 8LB, Scotland, UK)

Dividing a species acoustic repertoire into biologically relevant categories presents a widespread problem in the study of animal sound communication. Such categorization is fundamental to any attempt to compare repertoires between contexts, individuals, populations or species. Automated procedures allow rapid, repeatable and objective categorization, however, in the past they have often performed poorly at detecting biologically meaningful sound classes. Arguably this is because automated methods have often failed to address the nonlinearities of animal sound perception and a method that incorporates dynamic time warping and an adaptive resonance theory (ART) neural network to avoid some of the problems is presented here. The method was tested on 104 randomly chosen whistles recorded from four captive bottlenose dolphins (*Tursiops truncatus*). This data set includes known biologically meaningful categories in the form of 42 distinctive stereotyped whistles produced when each individual was kept in isolation. The automated procedure correctly grouped all but two of the stereotyped whistles into their respective categories, and thus performed as good as human observers. However, compared to humans, the automated system provided finer categorization of the remaining non-stereotyped whistles. These results suggest that this methodology provides a repeatable and objective means of splitting bioacoustic signals into biologically meaningful categories.

11:30

3aABb6. Unsupervised classification of beluga whale vocalizations. Patrick J. Clemins and Michael T. Johnson (Marquette Univ., P.O. Box 1881, Milwaukee, WI 53201, patrick@clemins.name)

Unsupervised classification techniques are designed to discover natural groupings in a collection of data. For instance, unsupervised classification methods can be used to help define a repertoire for a species by grouping similar vocalizations together. The vocalizations grouped together are then defined as a single call type in the repertoire. There are a number of

difficulties in applying these algorithms to vocalizations including quantifying the vocalization into a set of features and accounting for temporal variations in the vocalizations. Using generalized perceptual linear prediction coefficients and a set of hidden Markov models to overcome these difficulties, beluga whale vocalizations are classified using *K*-means unsupervised classification. These classifications are then compared to labels assigned by human experts in order to determine the reliability of the classification system. The underlying goal of this research is to establish a generalized framework that can be used to analyze and classify the vocalizations of a number of species. [Work supported by the National Science Foundation under the Dr. Dolittle Project.]

11:45

3aABb7. Whale song analyses using bioinformatics sequence analysis approaches. Yian A. Chen, Jonas S. Almeida (Dept. of Biostatistics, Bioinformatics, and Epidemiology, 135 Cannon St., Medical Univ. of South Carolina, Charleston, SC 29425), and Lien-siang Chou (Inst. of Ecology & Evolutionary Biol., NTU, Taipei, Taiwan)

Animal songs are frequently analyzed using discrete hierarchical units, such as units, themes and songs. Because animal songs and bio-sequences may be understood as analogous, bioinformatics analysis tools DNA/protein sequence alignment and alignment-free methods are proposed to quantify the theme similarities of the songs of false killer whales recorded off northeast Taiwan. The eighteen themes with discrete units that were identified in an earlier study [Y. A. Chen, masters thesis, University of Charleston, 2001] were compared quantitatively using several distance metrics. These metrics included the scores calculated using the Smith-Waterman algorithm with the repeated procedure; the standardized Euclidean distance and the angle metrics based on word frequencies. The theme classifications based on different metrics were summarized and compared in dendrograms using cluster analyses. The results agree with earlier classifications derived by human observation qualitatively. These methods further quantify the similarities among themes. These methods could be applied to the analyses of other animal songs on a larger scale. For instance, these techniques could be used to investigate song evolution and cultural transmission quantifying the dissimilarities of humpback whale songs across different seasons, years, populations, and geographic regions. [Work supported by SC Sea Grant, and Ilan County Government, Taiwan.]

9:00

3aAO1. Long-term variability in hydrothermal vent flow and temperature fluctuations by acoustic scintillation. Daniela Di Iorio (Dept. of Marine Sci., Univ. of Georgia, Athens, GA 30605)

An acoustical scintillation instrument is described that has been used to measure flow and temperature fluctuations at a hydrothermal vent plume. The vertical buoyancy driven flow together with the root-mean-square temperature fluctuations are obtained for vent structure 8F of the Main Endeavour vent field on the Endeavour segment of the Juan de Fuca Ridge. Long term (71 days) measurements are obtained and an estimate of the heat flux density which is of the order 0.06 MW m^{-2} is calculated. Measurements also show oscillations in the log-amplitude variance that result from either plume advection or increased entrainment of ambient fluids by the ambient tidal currents, thus demonstrating the need for a long time series measurement of simultaneous horizontal and vertical

flow. Future measurements in the Main Endeavour vent field, with possible integration into the NEPTUNE seafloor observatory, will be over extended periods of time so that comparisons of these processes can be made with independent seismic data collected by NOAA/PMEL SOSUS array.

9:20

3aAO2. Real-time observations and predictions of scour burial at the Martha's Vineyard Coastal Observatory. Michael D. Richardson (Marine Geosciences Div., Naval Res. Lab., Stennis Space Center, MS 39520, mrichardson@nrlssc.navy.mil), Peter Traykovski, Arthur C. Trembanis (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543), and Carl T. Friedrichs (Virginia Inst. of Marine Sci., Gloucester Point, VA 23062)

Mine burial by scour was measured in real-time using cylindrical instrumented mines and rotary and two-axis pencil beam sonar. Two mines and the sonar were connected to a shore-based facility at the Martha's Vineyard Coastal Observatory. Data on mine movement (heading, pitch, and roll), scour pit geometry, percent burial, and environmental processes responsible for scour burial including significant wave height, period, and tidal height were analyzed daily and presented on a mine burial web site. Sonar images show scour pits developing around the mines in response to storm generated significant wave heights greater than 2.0 m. Mines pitch, change heading as they roll into scour pits. A comparison of the observed mine burial and real-time predictions using a modified version of the Whitehouse equations for wave-induced scour model exhibited good agreement suggesting mine burial by scour in similar sandy environments is predictable from bathymetry, sediment type, and measured or predicted surface wave conditions. The Coastal Observatory at Martha's Vineyard provided a unique opportunity for real-time data collection and analysis of both sediment transport events and seafloor-object interactions during storms. [Work supported by ONR.]

9:40

3aAO3. Autonomous and ship-cabled, bottom mounted sonar systems—Development, uses and issues associated with transitioning to ocean observatories. Kevin L. Williams, Russell D. Light, and Vernon W. Miller (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, williams@apl.washington.edu)

Three bottom mounted sonar systems will be described that were built over a span of fifteen years. The complexity of deployment and sophistication of the tasks performed increased with each system. The first system is an autonomous tower with rotating sonar designed to examine backscattering from an area within 50 m radius of the tower. The second is a ship-cabled system that includes a diver movable tower and separate buried array for examining both backscattering and acoustic penetration into sediments. The last is a ship-cabled rail/tower system designed to carry out forward scattering and synthetic aperture backscattering measurements. All three systems are designed to remain deployed for time periods up to a couple of months. After describing the systems, their deployment and some example results, recent efforts will be described that are aimed at transitioning these types of systems to cabled ocean observatories. The overall goal of the talk is to indicate both the level of complexity that can be envisioned for bottom mounted systems as well as the new issues that must be addressed in moving to cabled ocean observatories. [Work supported by ONR.]

3aAO4. Development of interactive digital scientific acoustic systems for monitoring and assessment of physical and biological variables from ocean observatory platforms. Robert McClure, Tim Acker, James Dawson, and Assad E. K. Ebrahim (BioSonics, Inc., 4027 Leary Way NW, Seattle, WA 98107)

Scientific echosounders are in regular use for measurement of fish and plankton distribution and abundance, fish behavior, submersed aquatic vegetation, bottom sediment classification and water mass interface characteristics. Both fixed-aspect and mobile acoustic data are commonly collected from surface-deployed echosounders. Advancements in digital scientific echosounder technology and integration of other technologies has moved the capabilities of advanced echosounder systems into the realm of new applications and deployment possibilities. These advancements make possible the deployment of a new generation of integrated and interactive sensors which can provide high resolution, continuous, extended duration, recording, intelligent processing, and reliable monitoring and assessment of both biological and physical parameters of the ocean environment. Deployments from cabled observatories, moored and drifting buoys, manned and unmanned mobile platforms, and fully autonomous installations are all now reality. The deployment of these quality scientific instrument suites hold unlimited potential for research, resource management, and education. Existing and planned implementation of advanced digital scientific

echosounder applications on observatories as well as considerations in design, deployment, and integration with other observatory and oceanic acoustic activities are discussed.

10:30

3aAO5. Passive acoustic detection of fish sound production: The promise of ocean observatories. David Mann (USF College of Marine Sci., 140 7th Ave. S., St. Petersburg, FL 33701, dmann@marine.usf.edu)

Many fishes make species-specific sounds during courtship and spawning. These sounds can be recorded and quantified to study the temporal and spatial dynamics of spawning. Fish sounds typically range in frequency from 20–1500 Hz, and are usually inversely related to fish size. Time series of fish sound production recorded with autonomous recorders from Tampa Bay, Florida, and the mid-Atlantic bight, New Jersey illustrate how passive acoustics can be used to determine diel and seasonal timing of spawning. The great promise of ocean observatories is that they will not only provide unprecedented data on fish sound production, but that these data will be coupled with physical data on the same time and space scales. Ocean observatories will be powerful tools in studying the role of physical factors in driving variability in spawning and recruitment of fishes.

10:45

3aAO6. Basin Acoustic Seamount Scattering Experiment (BASSEX '04) III. Array performance. Kyle M. Becker (Penn. State Univ., Appl. Res. Lab., State College, PA 16804), Arthur B. Baggeroer (MIT, Cambridge, MA 02090), Kevin D. Heaney (Ocean Acoust. Services and Instrumentation Systems, Inc., Lexington, MA), Edward K. Scheer, and Keith von der Heydt (Woods Hole Oceanogr. Inst., Woods Hole, MA)

The ONR Five-Octave Research Array (FORA) was employed as the acoustic receiving system during the Basin Acoustic Seamount Scattering Experiment (BASSEX04). The array was primarily used in a towed configuration with receptions recorded for source/receiver separation distances ranging from 500–3200 km. Measurements made in proximity to the 75 Hz source moored near Kauai used a vertical array configuration. This paper presents array capabilities and performance during this first deep-water application of the FORA. Both acoustic and non-acoustic array performance during the BASSEX will be examined. In particular, array attitude and stability will be reviewed for different tow conditions, and for the array vertically deployed. Flow noise over the array will be examined for different tow speeds. Own-ship noise contamination will be presented for the array deployed vertically. Acoustic data will be presented as both individual channel measurements and beamformed output for a variety of source/receiver geometries and propagation conditions. Data quality will be assessed as it pertains to the stated objectives of a particular measure-

ment. Based on both acoustic and non-acoustic performance characteristics the advantages and/or deficiencies of the FORA will be discussed for its use in future low-frequency long-range acoustic propagation research. [Work supported by ONR Ocean Acoustics Program.]

11:00

3aAO7. Remote acoustic observations from a real-time observing system of the response of a shallow coastal embayment to hurricane forcing. Douglas J. Schillinger and Alex E. Hay (Dept. of Oceanogr., Dalhousie Univ., Halifax, NS, Canada B3H 4J1)

Results are presented from the acoustic remote sensing component of Dalhousie University's interdisciplinary Coastal Ocean Observatory in Lunenburg Bay, Nova Scotia, operational since June 2002 (www.cmep.ca/bay). Remote acoustic measurements of water column velocity and backscatter are made from bottom-mounted instruments hard-wired to surface buoys. The data are telemetered in near real-time to a shore station via wireless Ethernet, and to Dalhousie over the Internet. The fixed-point measurements from the bottom pods are augmented by a vessel-mounted profiling system, and by opportunistic deployments of internally-recording instruments. Highlights from the first three years of the observing system operation will be presented, including sediment suspension from the seabed and bubble penetration from the surface during Hurricane Juan.

3aBBa1. Augmented and selective delivery of liquid perfluorocarbon nanoparticles to melanoma cells with ultrasound. Michael S. Hughes, Kathryn C. Crowder, Gregory M. Lanza, and Samuel A. Wickline (322 Yalem, 216 S. Kings Hwy., Washington Univ. Med. School, St. Louis, MO 63110, msh@cvu.wustl.edu)

Previous work has demonstrated the ability of liquid perfluorocarbon (PFC) nanoparticles to deliver therapeutic agents to cells selectively by binding to specific cellular epitopes, and confirmed the ability to simultaneously image these targeted nanoparticles with ultrasound. In this study, enhanced delivery of targeted PFC nanoparticles to cells expressing the integrin avb3 using clinical levels of ultrasound energy were studied. Nanoparticles complexed with ligands targeted to avb3 were incubated with cells (C32 melanoma) that expressed avb3 in culture. Control nanoparticles were produced that carried no ligand targeted to avb3. A custom specimen holder permitted simultaneous microscopic visualization of cell interactions during exposure to calibrated levels of ultrasound energy. After nanoparticle binding to cells and application of ultrasound, a roughly 2-fold increase in PFC content of the cells was observed. For control (nonbinding) nanoparticles, ultrasound exposure also increased PFC deposition, but the overall level was substantially less. Videodensitometric data show that nanoparticles were not destroyed by ultrasound exposure. Moreover, the alignment of nanoparticles relative to incident acoustic field demonstrate conclusively that acoustic radiation forces influence the nanoparticles and implicate these forces as participates in the enhanced delivery.

8:25

3aBBa2. The application of acoustic radiation force for molecular imaging and drug delivery. Paul A. Dayton and Katherine W. Ferrara (UC Davis Biomed. Eng., 1 Shields Ave., Davis, CA 95616)

Acoustic radiation force is exerted on objects in an acoustic field. By optimizing acoustic parameters to maximize this force, ultrasound contrast agents can be manipulated and concentrated with an acoustic field. This technique can be used to enhance molecular imaging and drug delivery. Ultrasonic molecular imaging employs contrast agents such as microbubbles, nanoparticles, or liposomes coated with ligands specific for receptors expressed on cells at sites of angiogenesis, inflammation, or thrombus. Concentration of these highly echogenic contrast agents at a target site enhances the ultrasound signal received from that site, promoting

ultrasonic detection and analysis of disease states. It is demonstrated that acoustic radiation force can be used to displace targeted contrast agents to a vessel wall, greatly increasing the number of agents binding to available surface receptors. Radiation force can also be used for microparticle-carrier based drug delivery. Acoustically active drug-carrier vehicles can be concentrated with radiation force, and then disrupted with high-intensity ultrasound bursts, resulting in local delivery of the therapeutic agent. This talk will discuss simulations and experimental results demonstrating these applications.

Contributed Papers

8:45

3aBBa3. A new targeted drug delivery method using ultrasound and acoustically active lipospheres. Michaelann Shortencarier, Susannah Bloch, Paul Dayton, Kathy Ferrara (Dept. of Biomed. Eng., UC Davis, 451 East Health Sci. Dr., Davis, CA 95616), Terry Matsunaga, Rachel Labell, and Patricia Schumann (ImaRx Therapeutics, Inc., Tucson, AZ 85719)

The goal is to create a strategy for localized drug delivery using engineered delivery vehicles and ultrasound energy. These drug delivery vehicles, referred to as acoustically active lipospheres (AALs), consist of small gas bubbles surrounded by thick oil shells (where drugs can be carried) and are enclosed by an outermost lipid layer. Ultrasound radiation force can be used to displace these vehicles near the blood vessel wall, after which a higher intensity pulse can fragment the vehicle and transfer its contents to the endothelium. Blood velocity ranges from 1 to 10 mm/s in the microvasculature. Therefore, agents in capillaries insonified by a transducer with a 1 mm focal beam width for 0.1 to 1 seconds can be displaced of 1 to 2 mm. Delivery vehicles containing various fluorescent dyes within the oil layer are exposed to ultrasound in cell chambers or flowing vessels. Fluorescence intensity increases more than 10-fold with application of radiation force and fragmentation, both over no exposure and over fragmentation pulses alone (both $P < 0.001$). This implies radiation force is necessary to bring AALs into proximity of the cell monolayer before their destruction in order for drug delivery to occur.

9:00

3aBBa4. Delivery of anticancer drugs and antibodies into cells using ultrasound. Junru Wu, Jason Pepe (Dept. of Phys., Univ. of Vermont, Burlington, VT 05405), and Mercedes Rincon (Univ. of Vermont, Burlington, VT 05405)

It has been shown experimentally in cell suspensions that pulsed ultrasound (2.0 MHz) could be used to deliver an anti-cancer drug (Adriamycin hydrochloride) into Jurkat lymphocytes and antibodies (goat anti rabbit IgG and anti mouse IgD) into human peripheral blood mononuclear (PBMC) cells and Jurkat lymphocytes assisted by encapsulated microbubbles (Optison). When Adriamycin hydrochloride (ADR) was delivered, the delivery efficiency reached 4.80% and control baseline (no ultrasound and no ADR) was 0.17%. When anti-rabbit IgD was delivered, the efficiencies were 34.90% (control baseline was 1.33%) and 32.50% (control baseline was 1.66%) respectively for Jurkat cells and PBMC. When goat anti rabbit IgG was delivered, the efficiencies were 78.60% (control baseline was 1.60%) and 57.50% (control baseline was 11.30%) respectively for Jurkat cells and PBMC.

9:15

3aBBa5. 1 kHz vibration increases proteoglycan production in ATDC5 chondrocytes. Heather M. Argadine, Randall R. Kinnick, James F. Greenleaf (Dept. of Physio. and Biomed. Eng., Mayo Clinic College of Medicine, 200 First St. SW, Rochester, MN 55905, argadine.heather@mayo.edu), and Mark E. Bolander (Mayo Clinic College of Medicine, Rochester, MN 55905)

In vitro studies have shown that treatment with 1.5 MHz ultrasound signal (160 mW/cm²) at a 200 μ s tone burst repeating at 1 kHz increases proteoglycan synthesis in chondrocytes [J. Parvisi *et al.*, J. Orthop. Res. **17**, 488–494 (1999)]. It was hypothesized that a continuous 1 kHz signal would be similar to the pulsed 1.5 MHz signal in stimulating chondrocytes to produce proteoglycan, which may cause accelerated fracture healing. *In vitro* experiments were performed with ATDC5 cells, a chondrogenic clonal cell line, plated in 6-well plates for 3 to 7 days before receiving ultrasound treatments. Cells were treated with either 1.5 MHz pulsed signal or 1 kHz signal for 20 minutes per day for 9 to 11 days. The signals were calibrated so that the bottom of the 6-well plate moved 10 nm for each condition. After the final treatment, cell layers were stained with Alcian blue, which stains cartilage nodules providing a measure of chondrogenesis. Both 1.5 MHz and 1 kHz led to a highly significant increase in chondrogenesis compared to control. Quantitative image analysis of stained wells showed that treatments with either signal increased number of nodules 2.3-fold ($p < 0.02$) and total area of nodules 3-fold ($p < 0.02$) compared to controls.

9:30

3aBBa6. A theoretical study of the feasibility of acoustical tweezer: Ray acoustics approach. Jungwoo Lee and Kirk Shung (Dept. of Biomed. Eng., Univ. of Southern California, DRB132, Los Angeles, CA 90089, jungwool@usc.edu)

Optical tweezer has been found to have many biomedical applications in trapping macromolecules and cells. For the trapping mechanism, there has to be a sharp spatial change in axial optical intensity and the particle size must be much greater than the wavelength. Similar phenomenon may exist in acoustics. This work was undertaken to demonstrate theoretically that it is possible to acoustically trap particles near the focal point if certain conditions are met. Acoustic force exerted on fat tissue in ultrasonic fields is analyzed in ray acoustics regime where the wavelength of acoustic beam is much smaller than the size of the particle. In this paper, the analysis is therefore based on the field pattern produced by a strongly focused 100 MHz ultrasonic transducer with Gaussian intensity distribution. The magnitude of force and Fresnel coefficients at various positions are calculated. According to the simulation results, acoustical tweezer works particularly when the beam width at focus is one wavelength and the tolerance of acoustic impedance mismatch between two media lies within 6.7%. Biomedical Ultrasound/Bioresponse to Vibration: Contrast Agents and Cavitation

Paul A. Dayton, Chair

Univ. of California, Biomedical Engineering, 1 Shields Ave., Davis, CA 95616

Contributed Papers

10:15

3aBBb1. Cavitation effects of therapeutic ultrasound. Kenneth Bader and Karen Gipson (Grand Valley State Univ., Allendale, MI 49401-9403)

In order to model possible effects of cavitation on bone structure, the formation of cavitation along an acoustically reflective PVC surface was studied. The bubbles were generated by a commercial therapeutic transducer (1 MHz), for both water and agar gel mediums. Bubble formation and activity were monitored using light scattering techniques: a HeNe laser was directed through the medium, and the transmitted light was detected using an optical power meter. The data show a decline in cavitation activity further from the surface and offer suggestive evidence of a boundary layer. Temporal saturation is also evident in both mediums, though an anomalous increase in transmitted light for the agar medium suggests the possibility of pressure variations due to microstreaming. Analysis of the microstreaming pattern was subsequently performed at lower frequencies in order to allow visualization with a standard laboratory microscope.

10:30

3aBBb2. Interacting bubble dynamics in Hamiltonian mechanics. Yurii A. Ilinskii, Mark F. Hamilton, and Evgenia A. Zabolotskaya (ARL, Univ. of Texas, 10000 Burnet Rd., Austin, TX 78758-4423)

A Hamiltonian formulation of the equations of motion is presented for the oscillation and 3D translation of N interacting spherical bubbles. Existing alternative formulations contain second derivatives of both the bubble radius and the three coordinates of the position vector. For two or three bubbles the systems may be reduced analytically to explicit first-order equations that can be solved with standard numerical algorithms. For large N , the equations cannot realistically be recast in explicit first-order form, and the leading derivatives must be evaluated by matrix inversion at each time step. The inversions introduce substantial errors for large N . We avoid the inversions by using Hamiltonian mechanics to derive a system of explicit first-order equations for all N , and which includes the influence of an applied sound field. For large N , the approach based on Hamiltonian mechanics results in both increased numerical accuracy and reduced computation time. The Hamiltonian system is validated by comparison with solutions obtained by alternate means. Examples are presented demonstrating various effects of bubble interaction. Although developed for modeling cavitation in shock-wave lithotripsy, the model is also applicable to bubble clouds in the ocean. [Work supported by NIH Grant EB004047 and ARL IR&D funds.]

10:45

3aBBb3. Modeling of initial bubble growth rates during high-intensity focused ultrasound. Wayne Kreider, Michael R. Bailey, and Lawrence A. Crum (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, wkreider@u.washington.edu)

In therapeutic applications of biomedical ultrasound, it is important to understand the behavior of cavitation bubbles. For applications that use high-intensity focused ultrasound (HIFU), both large negative acoustic pressures and heating can independently lead to bubble formation. Although neglected previously, heating during HIFU is expected to affect the growth and dissolution of bubbles by both raising the vapor pressure and

promoting outgassing from gas-saturated tissues. Herein, the dynamics of a single, spherical bubble in water have been modeled using the Gilmore equation closed with an energy balance on bubble contents for calculation of pressures inside the bubble. Moreover, heat and mass transfer at the bubble wall are incorporated using the Eller-Flynn zeroth-order approximation for gas diffusion, an estimation of non-equilibrium phase change based on the kinetic theory of gases, and assumed shapes for the spatial temperature distribution in the surrounding liquid [Yasui, J. Phys. Soc. Jpn. **65**, 2830–2840 (1996)]. This model allows explicit coupling of the ambient heating during HIFU to the thermodynamic state of an oscillating bubble and is currently being used to explore the growth rates of initially small, undetectable bubbles exposed to various HIFU treatment protocols. [Work supported by NIH T32-EB-001650, NIH DK43881, and NSBRI SMS00203.]

11:00

3aBBb4. Microbubble dynamics in contrast agent shell rupture. Azzdine Y. Ammi, S. Lori Bridal (CNRS UMR 7623, Université Pierre et Marie Curie, 15 rue de l'école de médecine, 75006 Paris, France, ammi@lip.bhdc.jussieu.fr), Robin O. Cleveland (Boston Univ., Boston, MA 02215), Jonathan Mamou, Grace I. Wang, and William D. O'Brien, Jr. (Univ. of Illinois, Urbana, IL 61801)

A passive cavitation detector (PCD) was used to study the features of insonified contrast agent microbubble rupture. When Optison microbubbles ruptured, the PCD signal received from single microbubbles showed the presence of post-excitation echoes identified as inertial cavitation and rebounds. Using these signals, the collapse threshold was evaluated as a function of insonation frequency, pulse duration, and pressure amplitude. For each excitation signal, 128 received time traces were recorded (200 MHz sampling, 12-bit), and frequency-domain analysis of the received signals was performed to characterize microbubble collapse. The peak rarefactional pressure threshold for detection of these emissions increased with frequency (e.g., 0.53, 0.87, and 0.99 MPa for 0.9, 2.8, and 4.6 MHz, respectively; 5-cycle pulse duration) and decreased with pulse duration. The modified Herring equation was used to model the bubble response at experimentally determined threshold conditions. These predicted microbubble dynamics were used to determine microbubble rupture indices based on: radial strain, peak velocity, and peak acceleration. This work provides a clearer understanding of the role of contrast agent dynamics in bubble destruction. [Work supported by the cooperative project for biomedical engineering between the University of Illinois at Urbana-Champaign, USA and the Centre National de la Recherche Scientifique, France.]

11:15

3aBBb5. The effect of size on the acoustic response of polymer-shelled ultrasound microbubble contrast agents. Susannah H. Bloch, Katherine W. Ferrara (Dept. of Biomed. Eng., Univ. of California Davis, Davis, CA 95616, kwferrara@ucdavis.edu), and Erik R. Wisner (Univ. of California Davis, Davis, CA 95616)

Hard-shelled microbubble contrast agents differ from lipid-shelled agents in that the extra stability provided by their shell prevents dissolution of small gas bubbles: consequently, stable agents can be manufactured with diameters below 1 μm . Near-micron and submicron-sized contrast

agents may enable new biomedical applications because they can traverse narrow barriers such as the lymphatic endothelium and the permeable vascular endothelium found in actively growing solid tumors. However, several studies have suggested fundamental differences in the mechanisms of acoustic response of “soft” lipid-shelled ultrasound microbubble contrast agents and “hard” albumin- or polymer-shelled agents. In particular, hard-shelled contrast agents exhibit strong echoes only after the shell is damaged and the enclosed gas is allowed to oscillate freely. Here three polymer-shelled agents with mean diameters of 0.74 μm , 0.91 μm , and 1.33 μm (POINT Biomedical Corp.) are investigated. Significant differences among the agents exist in the probability of response to acoustic interrogation, but not the amplitude or frequency of their acoustic response. These results are explained by a hypothesis of a pressure-dependent threshold diameter above which single hard-shelled agents respond to acoustic interrogation. The implications of this hypothesis for the design of imaging methods and clinical protocols using these agents will be presented.

11:30

3aBBb6. Contrast-enhanced detection of arterial bleeding. Wenbo Luo, Vesna Zderic, Frank Starr, Marla Paun (Appl. Phys. Lab., Univ. of Washington, Box 355640, 1013 NE 40th St., Seattle, WA 98105, wenbo@u.washington.edu), and Shahram Vaezy (Univ. of Washington, Seattle, WA 98105)

The purpose of this study was to determine the feasibility and usefulness of contrast agent to detect internal bleeding. In a model of acute femoral artery injury, bleeding sites were produced percutaneously in 9 rabbits, using an 18 G needle guided by Doppler and B-mode ultrasound. Imaging was performed pre- and post-injury and after i.v. injection of contrast agent (Optison) using B-mode, Color Doppler (CD), and Pulse Inversion. Gross and histological examination (light microscopy) of the injured blood vessel and the surrounding tissue were performed. Experiments with similar procedure were achieved in a pulsatile phantom with carotid arteries as targeted blood vessels in vitro. Bleeding sites could not be located in non-contrast B-mode sonography. After administration of contrast agent, injuries could be detected by the increased echogenicity of

the extravasated blood flow. The resulted hematoma appeared as inhomogeneous hyper-echo region. Color mosaic patterns were observed in the surrounding tissue with CD. Cluster of cavities were found within hematoma upon microscopy, which may be due to aggregated microbubbles. Bleeding sites were recognized in all contrast studies by CD; compared with only 11% in non-contrast control. Contrast-enhanced sonography is a promising tool in detection and evaluation of internal bleeding.

11:45

3aBBb7. Ultrasound contrast agents for bleeding detection and acoustic hemostasis. Vesna Zderic, Wenbo Luo, Andrew Brayman, Lawrence Crum (Appl. Phys. Lab. and Bioengineering, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, vesna@u.washington.edu), and Shahram Vaezy (Univ. of Washington, Seattle, WA 98105)

Objective: To investigate the application of ultrasound contrast agents (UCA) in improving both therapeutic and diagnostic aspects of ultrasound-guided High Intensity Focused Ultrasound (HIFU) therapy. Methods: Incisions (3 cm long, 0.5 cm deep) were made in rabbit livers (in anterior surface for HIFU treatment, or posterior surface for bleeding detection). UCA Optison (~0.1 ml/kg) was injected into mesenteric vein or ear vein. A HIFU applicator (5.5 MHz, 6400 W/cm²) was scanned manually over the incision until hemostasis was achieved. Occult bleeding was monitored with Doppler ultrasound. Results: The presence of Optison produced 37% reduction in hemostasis times normalized to initial bleeding rates. Gross and histological observations showed similar appearance of HIFU lesions produced in the presence of Optison and control HIFU lesions. The temperature reached 100°C in both HIFU only and HIFU +UCA treatments. Tension strength of hemostatic liver incisions was 0.9±0.5 N. Almost no bleeding could be detected before Optison injection. First appearance of contrast enhancement localized at the bleeding site was 15 s after Optison injection, and lasted for ~50 s. Conclusion: The presence of UCA during HIFU treatment of liver incisions resulted in shortening of HIFU application times and better visualization of bleeding sites.

3aMU1. Phase preservation in musical signals. V. Vijayakumar and C. Eswaran (Multimedia Univ., Jalan Air Keroh Lama, 75450 Melaka, Malaysia)

The intensity variations of the harmonics of musical instruments in the frequency domain can be interpreted to store phase information. The motivation for this arises by considering the similarity of the timbre of in-

struments to that obtained through a diffraction model proposed here. The intensity modifications of an input spectrum of discrete frequencies of unit intensity into the known spectra of different musical instruments have been found to match that of known instruments. According to diffraction theory, the modifying envelope encodes phase information. By considering the similarity, it is proposed that musical instrument timbre store phase information. It is suggested that timbre itself could have diffraction origins. Specific examples of musical instruments are considered to illustrate this interpretation.

3aMU2. Practical system for recording spatially lifelike 5.1 surround sound and 3D fully periphonic reproduction. Robert E. (Robin) Miller III (FilmmakerTechnol., 606 W. Broad St., Bethlehem, PA 18018)

In acoustic spaces that are played as extensions of musical instruments, tonality is a major contributor to the experience of reality. Tonality is described as a process of integration in our consciousness over the reverberation time of the room of many sonic arrivals in three dimensions, each directionally coded in a learned response by the listeners unique head-related transfer function (HRTF). Preserving this complex 3D directionality is key to lifelike reproduction of a recording. Conventional techniques such as stereo or 5.1-channel surround sound position the listener at the apex of a triangle or the center of a circle, not the center of the sphere of lifelike hearing. A periphonic reproduction system for music and movie entertainment, Virtual Reality, and Training Simulation termed PerAmbio 3D/2D (Pat. pending) is described in theory and subjective tests that capture the 3D sound field with a microphone array and transform the periphonic signals into ordinary 6-channel media for either decoderless 2D replay on 5.1 systems, or lossless 3D replay with decoder and five additional speakers. PerAmbio 3D/2D is described as a practical approach to preserving the spatial perception of reality, where the listening room and speakers disappear, leaving the acoustical impression of the original venue.

8:30

3aMU3. The glissando illusion: A spatial illusory contour in hearing. Diana Deutsch, Kamil Hamaoui (Dept. of Psych., Univ. of California, San Diego, La Jolla, CA 92093, ddeutsch@ucsd.edu), and Trevor Henthorn (Univ. of California, San Diego, La Jolla, CA 92093)

In the glissando illusion (originally demonstrated by Deutsch, 1995) a synthesized oboe tone of constant pitch is played together with a sine wave whose pitch repeatedly glides up and down. These are presented through two loudspeakers, placed to the listeners left and right, and are repeatedly switched between loudspeakers, such that when the oboe tone emanates from one, a segment of the sine wave emanates from the other. The oboe tone is perceived correctly as switching between loudspeakers; however the segments of the sine wave appear to be joined together seamlessly, such that a single, continuous tone is heard, which appears to emanate from a source that moves slowly around in space in accordance with its pitch motion. In the present experiment, righthanders ($n=22$) tended strongly to hear the glissando move between left and right, and also between low and high in space, as its pitch moved between low and high. It was therefore frequently heard as tracing an elliptical path aligned diagonally between a position low and to the left when its pitch was lowest, and high and to the right when its pitch was highest. Nonrighthanders ($n=42$) perceived the illusion in statistically different ways.

8:45

3aMU4. Effect of critical-band smoothing of musical instrument spectral data. James W. Beauchamp (School of Music and Dept. of Elec. and Computer Eng., Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801, jwbeauch@uiuc.edu) and Andrew B. Horner (Hong Kong Univ. of Sci. and Technol., Clear Water Bay, Kowloon, Hong Kong)

It has been found that second-order harmonic smoothing of musical instrument spectral data can have a significant effect on timbral perception, depending on the instrument tested [McAdams *et al.*, *J. Acoust. Soc. Am.* **102**, 882–897 (1999)]. With critical-band smoothing, the lower harmonics, since they are in different critical bands, retain their individual amplitudes and temporal envelopes. Thus, it is hypothesized that critical-band smoothing has a lesser perceptual effect on most instrument tones than harmonic smoothing. On the other hand, upper critical bands consist of groups of harmonics. It is hypothesized that it is difficult to hear out individual harmonics within critical bands. Thus, for each band the independent harmonic temporal envelopes can be replaced by a composite rms-amplitude envelope. Spectra within bands can be replaced by time-averaged spectra. Alternatively, time-dependent amplitude versus Bark-

frequency spectral envelopes can be smoothed for each individual analysis frame. Further, amplitudes can be averaged in dB or linear units. Results for various processing combinations and various musical instrument sounds will be given and demonstrated.

9:00

3aMU5. An improvisation on the Middle-Eastern mijwiz; auditory roughness profiles and tension/release patterns. Pantelis N. Vassilakis (DePaul Univ., School of Music, 804 W. Belden Ave., Chicago, IL 60614-3250, pantelis@acousticslab.com)

Within western musical tradition, auditory roughness constitutes one of the principle perceptual correlates of dissonance. A previous study [P. N. Vassilakis, *Selected Reports in Ethnomusicology*, Vol. 12 (in press)] addressed the musical significance of auditory roughness within western as well as three non-western musical traditions. It introduced a new roughness estimation model that predicts successfully roughness ratings of synthesized complex diatonic dyads. For the present study, an application was created that uses the aforementioned model to estimate the roughness of natural signals with arbitrary spectra, as well as roughness profiles of short musical pieces. The application was used to examine if and how the pattern of tension and release within a stylized improvisation on the Middle Eastern mijwiz (double clarinet) relates to roughness changes. Tension/release patterns were indicated by the Lebanese improviser and expert mijwiz player (Dr. A. J. Racy) and were also obtained by both musicians and non-musicians (American-raised) in a perceptual experiment. The results suggest that auditory roughness is a good predictor of the tension/release pattern indicated by the improviser. The patterns obtained by the subjects, although not very consistent, appear to be different overall, suggesting that musical tension and release may be culture-specific concepts.

9:15

3aMU6. Visual feedback for retuning to just intonation intervals. R. Dean Ayers (Phys. Dept., Southern Oregon Univ., 1250 Siskiyou Blvd., Ashland, OR 97520), Peter R. Nordquist, and Justin S. Corn (Southern Oregon Univ., Ashland, OR 97520)

Musicians become used to equal temperament pitch intervals due to their widespread use in tuning pianos and other fixed-pitch instruments. For unaccompanied singing and some other performance situations, a more harmonious blending of sounds can be achieved by shifting to just intonation intervals. Lissajous figures provide immediate and striking visual feedback that emphasizes the frequency ratios and pitch intervals found among the first few members of a single harmonic series. Spirograph patterns (hypotrochoids) are also especially simple for ratios of small whole numbers, and their use for providing feedback to singers has been suggested previously [G. W. Barton, Jr., *Am. J. Phys.* **44**(6), 593–594 (1976)]. A hybrid mixture of these methods for comparing two frequencies generates what appears to be a three dimensional Lissajous figure—a cylindrical wire mesh that rotates about its tilted vertical axis, with zero tilt yielding the familiar Lissajous figure. Sine wave inputs work best, but the sounds of flute, recorder, whistling, and a sung “oo” are good enough approximations to work well. This initial study compares the three modes of presentation in terms of the ease with which a singer can obtain a desired pattern and recognize its shape.

9:30

3aMU7. Directivity measurements of the violin during performance. Jean-François Hardy and Jean-Gabriel Migneron (Laboratoire d'acoustique de l'Université Laval, 1 Côte de la Fabrique, Québec, PQ, Canada G1K 7P4, jean-francois.hardy.1@ulaval.ca)

Many studies have shown that directivity of musical instruments is significant for the perceived sound within the hall and for performer's ease of hearing each other. The directivity patterns explain in part the differences between many common or special orchestral stage plots. Measure-

ments of the violin's directivity have been performed using an acoustical intensimetry procedure. The precise directivity characteristics of isolated tones have been compared with the mean directivity resulting from performance of four extracts chosen among the orchestral repertoire. Results, which were measured in both horizontal and vertical planes, show interesting differences between the average directivity of each test. They lead to links with few important distinctions in the traditional violin's positions inside the orchestra.

9:45

3aMU8. Application of cochlear analysis techniques to percussion in electro-acoustic music. John Mills III (ECE Dept, The Univ. of Texas, 1 Univ. Station 0803, Austin, TX 78712, nodog@mail.utexas.edu)

This presentation is focused upon the audio analysis involved in the creation of a "pseudo-score" for electro-acoustic music. This research was undertaken because the lack of an objective visual representation prevents music theorists from being able to easily discuss electro-acoustic music in written form. The "holy grail" of automatic computer music analysis has most often been the translation of a continuous pressure variation into traditional Western musical notation. Since electro-acoustic music is rarely able to be transcribed into this type of notation, the automatic analysis of electro-acoustic music confounds many previous algorithms. A top-down approach is suggested in order to extract acoustic and musical information from recordings of electro-acoustic music. Because humans are the best known system for translating a continuous pressure variation into useful acoustic information, a cochlear model, Patterson's Auditory Image Model (AIM), is used as a front end. The audio property of self-similarity of percussion has been chosen for initial study. This self-similarity property requires first that the audio property of percussion is quantified. The nuances of using AIM to determine percussion will be discussed. Models of self-similarity of percussion for varying time-scales will then be discussed.

10:45–10:50 Break

All posters will be on display and authors will be at their posters from 10:50 a.m. to 12:00 noon.

3aMU11. Microrhythmic characteristics of musical instrument initial transients. Rolf Bader (Inst. of Musicology, Univ. of Hamburg, Neue Rabenstr. 13, 20354 Hamburg, Germany)

A microrhythmic analysis of initial transients of the violin, the guitar, the saxophone, the clarinet, and percussion instruments has been performed. They show characteristic patterns between instrument families, concerning the derivation of microrhythmic intervals within the tonal frequency range compared to psychoacoustic discrimination tasks by listeners. Microrhythm here is defined as the temporal distance between two amplitude peaks. As initial transients are a crucial part of the sound in terms of identification of instruments and the initial is just in the range of the second integration time of the ear, where frequency components can just be identified, these microrhythmic patterns could be a possibility for listeners to identify the instrument families. This is because microrhythmic intervals are instantaneously present and do not need an integration time span.

10:00–10:15 Break

10:15

3aMU9. Fractal dimension analysis of complexity in Ligeti piano pieces. Rolf Bader (Inst. of Musicology, Univ. of Hamburg, Neue Rabenstr. 13, 20354 Hamburg, Germany)

Fractal correlation dimensional analysis has been performed with whole solo piano pieces by Gyrgy Ligeti at every 50ms interval of the pieces. The resulting curves of development of complexity represented by the fractal dimension showed up a very reasonable correlation with the perceptual density of events during these pieces. The seventh piece of Ligeti's "Musica ricercata" was used as a test case. Here, each new part of the piece was followed by an increase of the fractal dimension because of the increase of information at the part changes. The second piece "Galamb borong," number seven of the piano Etudes was used, because Ligeti wrote these Etudes after studying fractal geometry. Although the piece is not fractal in the strict mathematical sense, the overall structure of the psychoacoustic event-density as well as the detailed event development is represented by the fractal dimension plot.

10:30

3aMU10. Attack transients on lip reed instruments. Murray Campbell, Seona Bromage (School of Phys., Univ. of Edinburgh, Edinburgh EH9 3JZ, UK, d.m.campbell@ed.ac.uk), and John Chick (Univ. of Edinburgh, Edinburgh EH9 3JL, UK)

The generation of sound in a lip reed (brass) instrument relies on a non-linear coupling between two vibrating systems: the lips of the player, and the air column contained by the walls of the instrument. The nature of this coupling has been studied by filming the motion of the lips of a number of players using a specially constructed transparent mouthpiece, while simultaneously recording the pressure in the mouthpiece and at the bell of the instrument. Attention has been focused on the attack transient, and the way in which its duration and evolution depend on the extent to which the air column modes are harmonically related. For this reason the instrument chosen was the serpent; on this instrument certain fingerings give air column modes whose relationship is close to harmonic, while other fingerings give strikingly inharmonic air column modes. The relationship between measurements of transient character and judgements of the playability or responsiveness of the instrument will be discussed.

3aMU12. Signal-to-background-ratio preferences of normal-hearing listeners as a function of music. Jillian G. Barrett (Dept. of Communicative Sci. and Dis., California State Univ. Hayward, 25800 Carlos Bee Blvd., Hayward, CA 94542)

The primary purpose of speech is to convey a message. Many factors affect the listener's overall reception, several of which have little to do with the linguistic content itself, but rather with the delivery (e.g., prosody, intonation patterns, pragmatics, paralinguistic cues). Music, however, may convey a message either with or without linguistic content. In instances in which music has lyrics, one cannot assume verbal content will take precedence over sonic properties. Lyric emphasis over other aspects of music cannot be assumed. Singing introduces distortion of the vowel-consonant temporal ratio of speech, emphasizing vowels and de-emphasizing consonants. The phonemic production alterations of singing make it difficult for even those with normal hearing to understand the singer. This investigation was designed to identify singer-to-background-ratio (SBR) prefer-

ences for normal hearing adult listeners (as opposed to SBR levels maximizing speech discrimination ability). Stimuli were derived from three different original songs, each produced in two different genres and sung by six different singers. Singer and genre were the two primary contributors to significant differences in SBR preferences, though results clearly indicate genre, style and singer interact in different combinations for each song, each singer, and for each subject in an unpredictable manner.

3aMU13. Normal-hearing listener preferences of music as a function of signal-to-noise-ratio. Jillian G. Barrett (Dept. of Communicative Sci. and Dis., California State Univ. Hayward, 25800 Carlos Bee Blvd., Hayward, CA 94542)

Optimal signal-to-noise ratios (SNR) for speech discrimination are well-known, well-documented phenomena. Discrimination preferences and functions have been studied for both normal-hearing and hard-of-hearing populations, and information from these studies has provided clearer indices on additional factors affecting speech discrimination ability and SNR preferences. This knowledge lends itself to improvements in hearing aids and amplification devices, telephones, television and radio transmissions, and a wide arena of recorded media such as movies and music. This investigation was designed to identify the preferred signal-to-background ratio (SBR) of normal-hearing listeners in a musical setting. The signal was the singer's voice, and music was considered the background. Subjects listened to an unfamiliar ballad with a female singer, and rated seven different SBR treatments. When listening to melodic motifs with linguistic content, results indicated subjects preferred SBRs similar to those in conventional speech discrimination applications. However, unlike traditional speech discrimination studies, subjects did not prefer increased levels of SBR. Additionally, subjects had a much larger acceptable range of SBR in melodic motifs where the singer's voice was not intended to communicate via linguistic means, but by the pseudo-paralinguistic means of vocal timbre and harmonic arrangements. Results indicate further studies investigating perception of singing are warranted.

3aMU14. Soprano and source: A laryngographic analysis. Laura Anne Bateman (Canadian College of Performing Arts, 1701 Elgin Rd., Victoria, BC, Canada)

Popular music in the 21st century uses a particular singing quality for female voice that is quite different from the trained classical singing quality. Classical quality has been the subject of a vast body of research, whereas research that deals with non-classical qualities is limited. In order to learn more about these issues, the author chose to do research on singing qualities using a variety of standard voice quality tests. This paper looks at voice qualities found in various different styles of singing: Classical, Belt, Legit, R&B, Jazz, Country, and Pop. The data was elicited from a professional soprano and the voice qualities reflect industry stan-

dards. The data set for this paper is limited to samples using the vowel [i]. Laryngographic (LGG) data was generated simultaneously with the audio samples. This paper will focus on the results of the LGG analysis; however, an audio analysis was also performed using Spectrogram, LPC, and FFT. Data from the LGG is used to calculate the contact quotient, speed quotient, and ascending slope. The LGG waveform is also visually assessed. The LGG analysis gives insights into the source vibration for the different singing styles.

3aMU15. Optimized interpolations and nonlinearity in numerical studies of woodwind instruments. Apostolos Skouroupathis (Dept. of Phys., Univ. of Cyprus, P.O. Box 20537, Nicosia CY-1678, Cyprus, php4as01@ucy.ac.cy)

The impedance spectra of woodwind instruments with arbitrary axisymmetric geometry are studied. Piecewise interpolations of the instruments' profile are performed, using interpolating functions amenable to analytic solutions of the Webster equation. Our algorithm optimizes on the choice of such functions, while ensuring compatibility of wave-fronts at the joining points. Employing a standard mathematical model of a single-reed mouthpiece, as well as the time-domain reflection function which is derived from our impedance results, the Schumacher equation is solved for the pressure evolution in time. Analytic checks are made to verify that, despite the nonlinearity in the reed model and in the evolution equation, solutions are unique and singularity-free.

3aMU16. An alternative solution for positioning sound sources in loudspeaker-based virtual environments. Jonas Braasch (CIRMMT, McGill Univ., Montreal, QC, Canada H3A 1E3, jb@music.mcgill.ca)

In auditory virtual environments it is often required to position an anechoic point source in three-dimensional space. When sources in such applications are to be displayed using multichannel loudspeaker reproduction systems, the processing is typically based upon simple amplitude-panning laws. This paper describes an alternative approach based on an array of virtual microphones. The aim of the system architecture design was to comply with the expectations of audio engineers and to create sound imagery similar to those associated with standard sound recording practice. In the newly designed environment, the microphones, with adjustable directivity patterns and axis orientations, can be spatially placed as desired. This way, time-delay panning can be included by simulating a non-coincident microphone array. By the use of omnidirectional microphones the panning is almost solely based on time-delay panning and thus performance can take advantage of the precedence effect. Also, the proposed architecture is flexible enough to include classic amplitude panning laws by translating the requested panning law into physically non-existing microphone directivity patterns. Moreover, the virtual directivity patterns do not have to be rotationally symmetrical. [Work supported by VRQ.]

Session 3aNS**Noise: Progress in Managing Occupational Noise**

3aNS1. Hearing conservation practices in eight noisy industries. William E. Daniell, Susan S. Swan, Janice Camp, Martin Cohen (Dept. of Environ. and Occupational Health Sci., Univ. of Washington, Box 357234, Seattle, WA 98195), Mary M. McDaniel (Pacific Hearing Conservation, Seattle, WA 98117), John Stebbins (Dept of Labor & Industries, Olympia, WA 98504), and Robert Leo (Dept of Labor & Industries, Seattle, WA 98104)

This study evaluated noise exposures and hearing conservation practices at 76 companies in eight industries with high rates of workers' compensation claims for hearing loss. Nearly all companies had exposures that required a hearing conservation program, and more than half had exposures that required consideration of noise controls. The use of noise measurements and consideration of controls was low in all industries. The completeness of hearing conservation programs was strongly associated with the extent of exposure in an industry, although practices varied widely within industries. Most companies had substantial deficiencies. More than one-third did not conduct annual training, and training had shortcomings at many others. One-third had not conducted audiometry. Hearing protection was commonly underused. Reported use was highest at companies with relatively complete programs, and in industries where exposure was most prevalent and least intermittent. Many employees had difficulty estimating how often, and presumably when, their exposure was excessive. There is a need for new strategies to promote and maintain hearing conservation efforts in noisy industries. The industries with greatest margin for improvement are not the noisiest industries but those where exposure is moderate or intermittent. [Work supported by the National Institute for Occupational Safety and Health.]

8:25

3aNS2. Effectiveness of the hearing conservation program: Change in hearing threshold shift incidence among industrial workers, 1978 to 2003. Hugh Davies (UBC School of Occupational and Environ. Hygiene, 2206 East Mall, Vancouver, BC, Canada V6T 1Z3, hugh.davies@ubc.ca)

Hearing conservation programs (HCP) are widely employed in preventing noise-induced hearing loss, but studies of their effectiveness have been rare. The impact of the implementation of hearing conservation programs was assessed in a large group of highly noise-exposed blue-collar workers by investigating time-trends in hearing-threshold shift incidence. Serial annual audiograms for employees of 14 British Columbia lumber mills for the period 1978 to 2003 were obtained from local regulatory-agency archives. Audiograms and concomitant otological medical histories were linked to subjects' work histories and noise exposure data. Multivariable Cox proportional hazard models were used to model the incidence of hearing threshold shift while controlling for age, baseline level of hearing loss, and other potential confounders. A total of 109 257 audiograms were associated with 10 590 subjects. Mean noise exposure in this group was 91.4 dBA(A). Mean interval between hearing tests was 566 days and mean age at first threshold shift was 44. Forty-six percent of subjects had at least one OSHA significant threshold shift during follow up. Preliminary analyses indicated a trend toward lower incidence of threshold shifts over the study period, with incidence in 5 approximately equal 5-year periods from 1978 to 2003 being 3.2%, 6.6%, 4.9%, 4.3% and 2.4%, respectively.

8:45

3aNS3. Use and effectiveness of hearing protection in construction. Richard Neitzel and Noah Seixas (Dept. of Env. and Occup. Health Sci., Univ. of Washington, 4225 Roosevelt Way NE #100, Seattle, WA 98105, rneitzel@u.washington.edu)

This paper presents an analysis of data on noise exposure and hearing protection device (HPD) use among construction workers drawn from several large datasets covering nine construction trades. A unique combination of one-minute dosimetry noise exposure level and simultaneous self-reported HPD use data were evaluated, as were occupational and non-occupational HPD use data collected by questionnaire as part of a longitudinal noise and hearing loss study among apprentices. Direct HPD attenuation measurements were also made on workers at their worksite. Workers reported using HPDs less than one-quarter of the time they were exposed above 85 dBA, the NIOSH Recommended Exposure Limit. Workers who reported always using HPDs in high noise were found to wear them only one-third of the time their exposures exceeded 85 dBA. Direct attenuation measurements indicated that workers achieved more

than 50% of the rated attenuation of their HPD on average, but that the variability in achieved attenuation was large. Lastly, when the measured HPD attenuation level and use time data were combined, the effective protection afforded by HPDs was less than 3 dB on average, though there was substantial variation among the different trades. These results demonstrate the need for better hearing conservation programs in construction.

9:05

3aNS4. Alternative noise exposure metrics among construction workers. Noah Seixas, Rick Neitzel, Lianne Sheppard, and Bryan Goldman (DEOHS, Univ. of Washington, Box 357234, Seattle, WA 98195-7234)

There continues to be some uncertainty in the choice of noise exposure metrics for assessing the risk of hearing damage. In particular, the Leq, based on a 3 dB exchange rate (ER) and the Lavg, which uses a 5 dB ER are both in use, as are various metrics representing exposure peaks. This paper presents an analysis of a large database of noise exposures among construction workers, comparing several noise metrics, and their application to a cohort of construction workers, followed audiometrically over a three year period. Metrics examined were the Lavg, Leq, and Lmax, expressing average levels. Two novel metrics were derived from these monitored metrics, Leq/Lavg, and Lmax/Leq, as measures of exposure variability and peakiness. A total of 730 workshifts, including data on 361 492 min of exposure to workers in 9 trades were examined. Correlations between average metrics (Leq, Lavg, Lmax) are generally very high, while the variability metrics are poorly correlated with average levels and with each other, indicating that they characterize different aspects of exposure. The task-specific estimates of individual exposure, using the various metrics, were applied to the cohorts work history and their effects on changes in hearing were assessed.

3aNS5. Special issues in hearing loss prevention in the Canadian military environment. Christian Giguère and Chantal Laroche (Univ. of Ottawa, 451 Smyth Rd., Ottawa, ON, Canada K1H 8M5)

Noise can be particularly noxious to hearing in the military. The personnel regularly face a wide range of noise-hazardous situations, many of which are seldom encountered in other work environments. High noise levels are associated with the operation of small arms and large caliber weapons, combat vehicles, aircrafts, ships and vessels, and industrial equipment. This can induce permanent and temporary hearing loss, compromise speech communication, interfere with the detection and localization of sound sources and warning sounds and thus, can jeopardize life or safety of the personnel. This paper will review the essential elements of a hearing loss prevention program proposed for the Canadian Armed Forces. The ultimate goal is to preserve hearing health as well as all hearing abilities necessary for effective operations. The program has been designed to meet the noise measurement and hazard investigation procedures, limits on noise exposure, use of hearing protection and other regulatory measures contained in the Canadian Occupational Health and Safety (COHS) Regulations (Part VII: Levels of Sound), while addressing the particular nature of the military environment. The paper will focus on issues that are not typically found in other occupational environments (variable work schedules, excessive impulse noise, extended exposures, communication devices).

9:45

3aNS6. In-situ personal assessment of hearing protector performance—recommendations for an updated standard. Jérémie Voix, Frédéric Laville (École de technologie supérieure, Université du Québec, Montreal (PQ), Canada H3C 1K3), and Jean Zeidan (Sonomax Hearing Healthcare Inc., Montreal (PQ), Canada H4P 2E2)

Standardized method currently used to assess Hearing Protection Devices (HPD) performance have little correspondence with protection achieved by users in practice. To overcome this problem new measurement method are being proposed. They no longer rely on statistically-based, population-based estimate, such as the Noise Reduction Rating (NRR), but on an individual assessment of the performance of the HPD. These new methods are highly beneficial for effective Hearing Conservation Programs as they provide individual attenuation values for noise-exposed workers in lieu of the statistically-based laboratory performance estimate, but their implementation will necessitate complete revision of existing standards. Among the issues to be addressed, are the aspect of the accuracy of the measurements performed by those methods and associated devices and also the replacement of any single number rating of HPD (such as the NRR) in existing standards. Solutions to address these issues and some general guidelines for an updated standard will be presented.

10:20

3aNS7. Active hearing protectors: Prospects for improving speech intelligibility while maintaining noise reduction and audibility of warning alarms. Anthony J. Brammer, Donald R. Peterson, Martin G. Chorniack, and Subhash Gullapalli (Ergonomic Technol. Ctr., Univ. of Connecticut Health Ctr., 263 Farmington Ave., Farmington, CT 06030, anthonybrammer@hotmail.com)

Users of hearing protection devices (HPDs), including the communication headsets and helmets commonly worn by aircraft air and ground crews, emergency responders, military personnel, and persons in industry working in hostile environments, have long complained that HPDs interfere with their ability to communicate and to hear warning alarms. There thus appears to be a need for additional specialized HPDs designed specifically for these situations. The technology of active noise control together with signal processing applied to the communication channel of the HPD may provide a potential solution. The combination could improve noise reduction at low frequencies and enhance the intelligibility of speech reproduced by the communication channel, while maintaining the overall noise reduction within occupational exposure requirements, and assisting the perception of external warning alarms. A

strategy for achieving these goals using an active circumaural earmuff equipped with sub-band processing will be described, in which parallel controllers optimize the speech signal-to-noise ratio in bands that contribute most to intelligibility. The perception of a tonal alarm is assisted by binaural feed through to the earphones, within the constraints imposed by occupational exposure limits, and by sub-band processing to reduce the upward spread of masking.

3aNS8. The combined effect of noise and carbon monoxide on hearing thresholds of exposed workers. Adriana Lacerda, Tony Leroux, and Jean-Pierre Gagn (Univ. of Montreal, C.P.2168, succursale centre-ville, H3C 3J7, Montreal, Canada, Adriana.lacerda@umontreal.ca)

Animal models have been used to demonstrate the potentiation of noise-induced hearing loss (NIHL) by carbon monoxide. It has been shown that the addition of carbon monoxide to otherwise safe noise exposure levels produces significant NIHL in rats. However, the effects of chronic exposure to low level of carbon monoxide in a noisy work environment are still unknown. The aim of this study was to compare the hearing thresholds of a group of workers exposed to noise and carbon monoxide (Group 1) to another group of workers where carbon monoxide exposure is absent or negligible (Group 2). The analysis was based on 9396 audiograms collected by the Quebec National Public Health Institute between 1983 and 1996. The results show significantly poorer hearing thresholds at high frequencies (3, 4, and 6 kHz) for the carbon monoxide exposed group ($p < 0.001$). The potentiation effect also varied according to years of exposure in work place; a larger effect is observed for workers with between 15 to 20 years of exposure ($p < 0.001$). This study provides the first demonstration of a potentiation effect of NIHL by carbon monoxide in humans.

10:55

3aNS9. Derivation of an analytic expression for the error associated with the noise reduction rating. William J. Murphy (Hearing Loss Prevention Team, NIOSH 4676 Columbia Pkwy., MS C-27, Cincinnati, OH 45226-1998)

Hearing protection devices are assessed using the Real Ear Attenuation at Threshold (REAT) measurement procedure for the purpose of estimating the amount of noise reduction provided when worn by a subject. The rating number provided on the protector label is a function of the mean and standard deviation of the REAT results achieved by the test subjects. If a group of subjects have a large variance, then it follows that the certainty of the rating should be correspondingly lower. No estimate of the error of a protector's rating is given by existing standards or regulations. Propagation of errors was applied to the Noise Reduction Rating to develop an analytic expression for the hearing protector rating error term. Comparison of the analytic expression for the error to the standard deviation estimated from Monte Carlo simulation of subject attenuations yielded a linear relationship across several protector types and assumptions for the variance of the attenuations.

3aPA1. Intermediate scale measurement system for underwater acoustic measurements. Jan M. Niemiec, Paul C. Shang (NSWCCD, 9500 MacArthur Blvd., West Bethesda, MD 20817, niemiecjm@nswccd.navy.mil), and Stephan Schreppler (ONR, Code 334, Arlington, VA 22217)

The Intermediate Scale Measurement System (ISMS) provides high quality acoustic measurements on large-scale submarine models and other underwater structures in a controlled environment. Development and implementation of advanced marine technology designs require a thorough understanding of structural acoustic response mechanisms. The only practical and cost effective approach to developing this understanding is through the use of a combination of numerical models and large-scale physical models. The ISMS provides an affordable, unique capability of making precision acoustic measurements on models large enough to contain the structural detail and the instrumentation required to understand structural acoustic mechanisms and to confirm and guide the use of numerical models. This is a key element for prediction of full-scale performance and integration of advanced submarine technologies into operational systems.

3aPA2. Scattering by truncated targets with and without boundary interactions. Philip L. Marston, Kyungmin Baik, Aubrey Espana, Curtis F. Osterhoudt (Phys. Dept., Washington State Univ., Pullman, WA 99164-2814, marston@wsu.edu), Scot F. Morse (Western Oregon Univ., Monmouth, OR 97361), Brian T. Hefner (Univ. of Washington, Seattle, WA 98105), and Florian J. Blonigen (Northeastern Univ., Boston, MA 02115)

Ray methods have been applied to the scattering of various truncated targets having wavenumber-radius products as small as 10 [F. J. Blonigen and P. L. Marston, *J. Acoust. Soc. Am.* **107**, 689–698 (2000); S. F. Morse and P. L. Marston, *ibid.* **112**, 1318–1326 (2002); B. T. Hefner and P. L. Marston, *ARLO* **2**, 55–60 (2001)]. Recent work emphasizes the exploration of scattering enhancements for other situations including plastic cylinders having curved ends, truncated plastic cones, partially exposed cylinders, and objects in simulated conditions for burial in a seabed. Enhanced scattering is often associated with a locally flat outgoing wavefront. For plastic targets it has been helpful to examine the time dependence of the backscattered envelope as a function of target tilt for targets illuminated by short tone bursts. For partially exposed objects it is helpful to examine the backscattering as a function of the target exposure. For simulated buried targets, it has been helpful to excite target resonances. [Work supported by the Office of Naval Research.]

9:20

3aPA3. Finite-element modeling of acoustic scattering from realistic elastic structures. David S. Burnett (Naval Surface Warfare Ctr., Code R21, 110 Vernon Ave., Panama City, FL 32407, david.s.burnett@navy.mil)

Over the last twenty years the author has developed several finite-element codes for modeling acoustic scattering from complicated elastic structures. All the codes have employed 3-D continuum mechanics throughout the computational domain. Thin structural components, such as plates and shells, are modeled with 3-D elasticity rather than plate or shell theories. The codes are therefore fully 3-D, i.e., in both physics and geometry. The talk will first explain the rationale for this approach and touch briefly on essential aspects of previous codes. It will then focus in more detail on the current code under development, which employs relatively inexpensive commercial software well-suited for this fully 3-D approach.

3aPA4. Acoustic scattering from an obstacle in a homogeneous non-uniform moving medium via the ray method. Tatiana Semenova (Natl. Res. Council Postdoctoral Res. Associate, NASA Langley Res. Ctr., Hampton, VA 23666)

For an accurate noise prediction for aircraft in forward flight, scattering of engine noise from airframe must be included into the description of the sound field. A realistic model of acoustic scattering by airframe in flight must account for the effects of the background flow. We consider acoustic scattering from an obstacle in the presence of a time-independent background flow at low Mach number and we neglect all other effects of the variation of the medium on sound propagation. The model is based on a convected Helmholtz equation with coefficients dependent on the background flow, which can be given either analytically or by CFD. A high-frequency solution is sought by the ray acoustics with a simple method based on the Fresnel volumes of the rays employed to determine the caustic zones and the field on the caustics. The weaker effects of a tip or smooth-body diffraction are neglected and only the reflection and edge diffraction are taken into account. The source of noise is modeled as a point source. The upstream shielding effect of a boundary layer is investigated as an example and uniform versus non-uniform flow effects are illustrated. Other numerical examples will be considered. [Work supported by NRC.]

10:00–10:30 Break

10:30

3aPA5. Scattering by tilted plastic cylinders having curved ends and truncated plastic cones. Aubrey Espana, Kyungmin Baik, and Philip L. Marston (Phys. Dept., Washington State Univ., Pullman, WA 99164-2814, marston@wsu.edu)

In prior research an acoustic backscattering enhancement was demonstrated for a bluntly truncated plastic cylinder caused by a merged caustic [F. J. Blonigen and P. L. Marston, *J. Acoust. Soc. Am.* **107**, 689–698 (2000)]. This was confirmed with analogous light scattering experiments [P. L. Marston, Y. B. Zhang, and D. B. Thiessen, *Appl. Opt.* **42**, 412–417 (2003)]. In recent work a different backscattering enhancement associated with a caustic was identified for tilted plastic cylinders having curved

ends. When the cylinder is tilted so as to focus a shear wave at the point of internal specular reflection, the curvature of the outgoing acoustic wavefront vanishes orthogonal to the meridional plane. This was verified with analogous light scattering experiments. The flatness of the outgoing wavefront enhances the scattering. Backscattering by truncated plastic cones as a function of tilt also shows enhancements associated with the composition of the target. The time dependence of the backscattering envelope as a function of tilt reveals different features depending on whether the top or bottom of the cone is illuminated by tone bursts. [Work supported by the Office of Naval Research.]

10:45

3aPA6. Effect of changes of complex surface impedance for acoustic scattering from a wedge. Ron G. Hughes, Jan M. Njemić (NSWC Carderock Div., W. Bethesda, MD 20817), and Herbert Überall (NSWC Carderock Div., W. Bethesda, MD 20817)

A code written earlier for the calculation of acoustic scattering from a submerged wedge has been employed in order to study the dependence of the scattering amplitude on various assumed surface impedances of the wedge. Typical wedge opening angles are 10° . Plane waves are assumed incident with source and observation points coinciding in the far field along the bisector of the wedge. The target strength for an impedance-coated wedge is found to lie in between those of a rigid and a pressure release wedge. A frequency region up to 20 kHz was considered. Various numerical impedances and angles of incidence are assumed.

11:00

3aPA7. Analysis of scattering by spheres having a negative acoustical refractive index. Philip L. Marston (Phys. Dept., Washington State Univ., Pullman, WA 99164-2814, marston@wsu.edu)

Electromagnetic waves having oppositely directed phase and group velocities propagate in metamaterials having a negative permeability and negative permittivity [J. B. Pendry and D. R. Smith, *Phys. Today* **57**(6), 37–44 (2004)]. Such materials are predicted to have unusual electromagnetic scattering properties [R. Ruppin, *Solid State Commun.* **116**, 411–415 (2000)]. If it is possible to fabricate acoustical materials having a simultaneously negative effective elastic modulus and density (in a dynamical sense), the mechanical energy flux will have the opposite direction as the

wave-vector associated with phase evolution. Rays descriptive of the energy flux refracted by such hypothetical materials at interfaces with ordinary fluids would be characterized by a negative acoustical refractive index. Partial-wave-series calculations of high frequency scattering by fluid spheres having an acoustical refractive index at (or close to) 1 reveal backscattering enhancements associated with glory rays which, unlike ordinary spheres [P. L. Marston and D. S. Langley, *J. Acoust. Soc. Am.* **73**, 1464–1475 (1983)], require only a single internal chord. Generalized Lamb waves on elastic shells having opposite phase and group velocities also cause enhanced backscattering associated with unusual rays [G. Kaduchak, D. H. Hughes, and P. L. Marston, *J. Acoust. Soc. Am.* **96**, 3704–3714 (1994)].

11:15

3aPA8. Production of evanescent acoustic waves and their scattering by resonant targets. Curtis F. Osterhoudt, Christopher Dudley, David B. Thiessen, Philip L. Marston (Dept. of Phys. and Astron., Washington State Univ., Pullman, WA 99164-2814, gardyloo@mail.wsu.edu), and Scot F. Morse (Western Oregon Univ., Monmouth, OR 97361)

An environmentally-friendly liquid mixture, denser than water and immiscible with it, and with a sound speed slower than water's, has been produced and incorporated into a scattering facility. This liquid mixture is submerged in a volume of water. In this way, the water above the denser fluid simulates a sandy ocean bottom, with the dense fluid simulating the ocean water column. When insonified by an acoustic beam from within the denser liquid, evanescent wave fields are produced in the water volume. Various targets and detectors are scanned in the water (the simulated sandy bottom) or in the mixture (the simulated ocean water column), and coupling of the evanescent waves to low-frequency resonances of cylindrical targets has been observed. Such coupling may reveal important structural characteristics of scatterers. Additionally, the complicated soundfield structure in the simulated bottom has been mapped. The structure is associated with the production of evanescent acoustic waves by a beam of sound. A model for this structure was developed using numerical wave-number integration. [Work supported by the Office of Naval Research.]

11:30

3aPA9. Sound scattering by clusters of rigid cylinders in air. Miguel Figueres, Francisco Cervera, Andreas Håkansson, José Sánchez-Dehesa, and Jaime Llinares (Univ. Politécnic de Valencia, E-46022 Valencia, Spain, jsdehesa@upvnet.upv.es)

The scattering of sound by a cluster of rigid cylinders in air has been investigated both theoretically and experimentally. The cluster was made by a lattice of cylinders with hexagonal symmetry. The sound scattered in all directions around the cluster is measured and compared with a calculation based on multiple scattering theory. The behavior as a function of the external geometry of the cluster will also be presented. The refraction and reflection of the sound by the boundaries of the cluster is analyzed by a theoretical model that takes into account its inner crystal symmetry. [Work supported by MEC of Spain.]

11:45

3aPA10. Complete regularization of boundary integral equations in wave field diffraction problems on curved surfaces. German A. Maximov and Dmitry N. Lesonen (Dpt. 39, Moscow Eng. Phys. Inst., Kashirskoe sh. 31, Moscow, 115409, Russia, maximov@dpt39.mephi.ru)

The method of regularization of exact integral Fredholm equations of the second kind for field or its normal derivative on the scattering surface was suggested in the previous work. It allows to obtain the stable solutions, including ones for the resonant domains, when the direct numerical solution of exact initial integral equations results to unstable solutions. Mathematically the regularization concludes in the splitting of exact integral Fredholm equations on the equivalent system of two equations, one of them possesses the restricted by geometrically illuminated area integral operator, and other one corresponds by form to an initial one, but with diffracted source. The solution of the first equation is considered as regularized one, which coincides with exact solution in the short wavelength limit. From the physical point of view the regularization of initial integral equations concludes in their replacement on the restricted analogs, where the contributions of geometrically shadowed areas are eliminated. In the given work the regularization of the rested after splitting integral equation is represented and it is shown that the process of such regularization is auto-similar one, so that it is possible to carry out the complete regularization of the problem.

3aPP1. High resolution auditory perception system. Iftekhar Alam (1013-Clover Heights, Opp Salunke Vihar, Salunke Vihar Rd., Wanowrie, Pune-411040, India [iftekharamk@yahoo.com]) and Ashok Ghatol (Pune Inst. of Engg. and Technol. Shivajinagar, Pune, Maharashtra, India)

Blindness is a sensory disability which is difficult to treat but can to some extent be helped by artificial aids. The paper describes the design aspects of a high resolution auditory perception system, which is designed on the principle of air sonar with binaural perception. This system is a

vision substitution aid for enabling blind persons. The blind person wears ultrasonic eyeglasses which has ultrasonic sensor array embedded on it. The system has been designed to operate in multiresolution modes. The ultrasonic sound from the transmitter array is reflected back by the objects, falling in the beam of the array and is received. The received signal is converted to a sound signal, which is presented stereophonically for auditory perception. A detailed study has been done as the background work required for the system implementation; the appropriate range analysis procedure, analysis of space-time signals, the acoustic sensors study, amplification methods and study of the removal of noise using filters. Finally the system implementation including both the hardware and the software

part of it has been described. Experimental results on actual blind subjects and inferences obtained during the study have also been included.

8:50

3aPP2. Sex differences present in auditory looming perception, absent in auditory recession. John G. Neuhoff (Dept. of Psych., The College of Wooster, Wooster, OH 44691) and Erich Seifritz (Univ. of Bern Switzerland)

When predicting the arrival time of an approaching sound source, listeners typically exhibit an anticipatory bias that affords a margin of safety in dealing with looming objects. The looming bias has been demonstrated behaviorally in the laboratory and in the field (Neuhoff 1998, 2001), neurally in fMRI studies (Seifritz *et al.*, 2002), and comparatively in non-human primates (Ghazanfar, Neuhoff, and Logothetis, 2002). In the current work, male and female listeners were presented with three-dimensional looming sound sources and asked to press a button when the source was at the point of closest approach. Females exhibited a significantly greater anticipatory bias than males. Next, listeners were presented with sounds that either approached or receded and then stopped at three different terminal distances. Consistent with the time-to-arrival judgments, female terminal distance judgments for looming sources were significantly closer than male judgments. However, there was no difference between male and female terminal distance judgments for receding sounds. Taken together with the converging behavioral, neural, and comparative evidence, the current results illustrate the environmental salience of looming sounds and suggest that the anticipatory bias for auditory looming may have been shaped by evolution to provide a selective advantage in dealing with looming objects.

9:05

3aPP3. Lateralization of high-frequency transposed stimuli under conditions of binaural interference. Leslie R. Bernstein and Constantine Trahiotis (Dept. of Neurosci. and Dept. of Surgery (Otolaryngol.), Univ. of Connecticut Health Ctr., Farmington, CT 06030, Les@neuron.uconn.edu)

The purpose of this study was to determine whether binaural interference would occur if ITD-based extents of laterality were measured using high-frequency transposed stimuli as targets. The results of an earlier study [L. R. Bernstein and C. Trahiotis, *J. Acoust. Soc. Am.* **116**, 3062–3069 (2004)], which focused on threshold-ITDs rather than extents of laterality, suggested that high-frequency transposed stimuli might be immune to binaural interference effects resulting from the addition of a spectrally-remote, low-frequency interferer. In contrast to the earlier findings, the data from this study indicate that high-frequency transposed targets can, indeed, be susceptible to binaural interference. High-frequency transposed targets, even when presented along with an interferer, yielded greater extents of ITD-based laterality than did Gaussian noise targets presented in isolation. That is, the enhanced potency of ITDs conveyed by transposed stimuli persisted even in the presence of a low-frequency interferer. Predictions made using an extension of the model of Heller and Trahiotis [L. M. Heller and C. Trahiotis, *J. Acoust. Soc. Am.* **99**, 3632–3637 (1996)] accounted well for binaural interference obtained with conventional Gaussian noise targets but generally over-predicted the amounts of interference found with the transposed targets.

9:20

3aPP4. Binaural models for the detection of interaural incoherence. Matthew J. Goupell (Dept. of Phys. and Astron., Michigan State Univ., 4230 BPS Bldg., East Lansing, MI 48824) and William M. Hartmann (Michigan State Univ., East Lansing, MI 48824)

Human listeners have a remarkable ability to detect small amounts of interaural incoherence in bands of noise. Experiments using frozen noise, all with the same value of interaural coherence (0.9922), show that when the bandwidth is large the ability to detect incoherence is essentially determined by the value of coherence itself. However, when the bandwidth is narrow, e.g. 20 Hz, detection depends on some function of the moment-

to-moment fluctuations in interaural phase differences and interaural level differences. Experiments using hundreds of different frozen noises and two bandwidths were performed to find the best binaural model for predicting detection performance for such narrow bands. Successful models incorporated known elements of binaural hearing—temporal averaging and compression. Models with independent processing of interaural phase fluctuations and interaural level fluctuations were marginally more successful than models based on fluctuations in lateral position. The most successful models correlated well with average human responses, $r = 0.89$. It seems likely that such individual fluctuations remain dominant in masking level difference experiments in the narrow band limit. [Work supported by the NIDCD grant DC 00181.]

9:35

3aPP5. A binary masking technique for isolating energetic masking in speech perception. Douglas S. Brungart, Brian D. Simpson (AFRL/HECB, 2610 Seventh St., WPAFB, OH 45433, douglas.brungart@wpafb.af.mil), Peter S. Chang, and DeLiang Wang (Ohio State Univ., Columbus, OH 43210)

When a target speech signal is obscured by interfering speech, two distinct types of masking contribute to the resulting degradation in the intelligibility of the target talker: energetic masking caused by overlap in the time-frequency distribution of energy in the two voices, and informational masking caused by the listener's inability to correctly segregate the acoustic elements of the two voices into distinct streams. This study attempted to isolate the effects of energetic masking on multitalker speech perception with ideal time-frequency binary masks that retained those spectro-temporal regions of the acoustic mixture that were dominated by the target speech but eliminated those regions that were dominated by the interfering speech. This procedure removed the same phonetic information from the target speech that would ordinarily be lost due to energetic masking, but eliminated the possibility for the kinds of target-masker confusions that are thought to produce informational masking. The results suggest that energetic masking may play a surprisingly small role in the overall masking that occurs in certain types of multitalker speech signals. They also indicate that the number of competing talkers has a much greater influence than target-masker similarity on the amount of energetic masking that occurs in a multitalker stimulus.

9:50

3aPP6. Binaural effects in simultaneous room reflection masking. Joerg M. Buchholz (MARCS Auditory Labs., Univ. of Western Sydney, Locked Bag 1797, Penrith South DC NSW 1797, Australia)

Masked thresholds (MT) for a single test reflection masked by a direct sound (200 ms long broadband noise) were measured dependent on the time delay of the reflection for diotic as well as dichotic stimulus presentation. In the diotic case, the direct sound and the test reflection were presented equally to both ears via headphones. In the dichotic case, an ITD of 0.5 ms was added to the test reflection. In order to focus on simultaneous masking effects, the reflection was truncated in such a way that it formed a common offset with the direct sound. For the diotic case, the resulting data showed a MT increase with increasing reflection delay and for the dichotic case a MT decrease with increasing reflection delay, producing an intercept between both curves at a reflection delay of 6–8 ms. Hence, negative BMLDs (up to –8 dB) were found for very early reflections and positive BMLDs (up to +8 dB) for later reflections, suggesting a binaural mechanism that suppresses very early reflections and enhances later reflections. The measurement results are discussed in the background of different auditory models.

10:20

3aPP7. The influence of target-masker similarity in a three-talker diotic listening task. Nandini Iyer and Douglas Brungart (Air Force Res. Labs, 2610 Seventh St., Wright–Patterson AFB, OH 45433)

In diotic cocktail-party listening tasks, performance decreases dramatically when the number of talkers increases from two (one target and one masker) to three (one target and two maskers). In this experiment, listeners were asked to extract information from a Coordinate Response Measure (CRM) target phrase that was masked by one or two interfering utterances. The maskers were either semantically similar to the target (i.e., CRM phrases with different call signs than the target phrase) or semantically different from the target (time-reversed, contextually dissimilar, or in a different language than the target phrase). The two-talker results showed that performance was much worse when the interfering phrase was semantically similar to the target than when it was semantically different. However, given that one interfering talker was similar to the target, the contextual similarity of the second interfering talker had very little effect on performance; in other words, target intelligibility in the presence of two CRM maskers was no worse than with one CRM masker and one time-reversed or foreign-language masker. These results suggest that the disruption of speech segregation caused by the addition of a second interfering talker cannot be explained solely by contextual similarity between the target and masking speech.

10:35

3aPP8. Onsets, autocorrelation functions and spikes for direction-based sound source separation. Leslie S. Smith and Dagmar S. Fraser (Dept. of Computing Sci. and Mathematics, Univ. of Stirling, Stirling FK9 4LA, Scotland, lss@cs.stir.ac.uk)

The aim of this work is separation of foreground speech from background sound sources using selective remixing of bandpass filtered channels. Clearly, the remixing parameters must be dynamic since the speech and noise spectra are highly non-stationary. Remixing parameters are re-computed at onsets, detected using biologically motivated techniques [L. S. Smith and D. S. Fraser, *IEEE TNS* **15**, 1125–1134 (2004)]. However, onsets may originate from the foreground or the background. To select appropriate onsets from the foreground source (whose direction is known) a two microphone system is used, selecting onsets for which the estimated direction in that channel corresponds to the foreground direction. Two different techniques for direction estimation are used: a channel by channel short-term autocorrelation technique, and a channel by channel spike based phase synchronous system (SBPSS), computing ITDs [L. S. Smith, in *Artificial Neural Networks*, Proc ICANN 2001, LNCS 2130, pp. 1103–1108 (Springer, 2001)] and IIDs [L. S. Smith, in *From Animals to Animats*, Vol. 7, pp. 60–61 (MIT Press, 2002)]. Results comparing the performance of autocorrelation and SBPSS on single source and source plus noise signals in an office environment are presented. [Work supported by UK EPSRC.]

10:50

3aPP9. How does the mammalian brain code for binaural information? Torsten Marquardt and David McAlpine (Dept. Physiol., UCL, Gower St., London WC1E 6BT, UK)

We will summarize new physiological results which contradict established models of binaural hearing, namely (1) the A-limited range of encoded interaural time difference, ITD, (2) a correlation between ipsilateral inhibition and best ITD, and (3) a frequency dependent non-linear mapping of ITD which reflects distribution of naturally occurring ITDs. Furthermore, we will outline a new concept for binaural models which incorporates these new results, and will propose a new illustrative format in which to present the triplet of binaural parameters: interaural phase difference, interaural intensity difference, and interaural coherence (redefined).

3aPP10. Adjustment of interaural time difference in head related transfer functions based on listeners' anthropometry and its effect on sound localization. Yōiti Suzuki, Kanji Watanabe, Yukio Iwaya (R.I.E.C./G.S.I.S., Tohoku Univ., 2-1-1 Katahira, Aoba-ku, Sendai, 980-8577, Japan), Jiro Gyoba (Tohoku Univ., Aoba-ku, Sendai, 980-8576, Japan), and Shouchi Takane (Akita Pref. Univ., Tsuchiya, Honjo, Akita, 015-0055, Japan)

Because the transfer functions governing subjective sound localization (HRTFs) show strong individuality, sound localization systems based on synthesis of HRTFs require suitable HRTFs for individual listeners. However, it is impractical to obtain HRTFs for all listeners based on measurements. Improving sound localization by adjusting non-individualized HRTFs to a specific listener based on that listener's anthropometry might be a practical method. This study first developed a new method to estimate interaural time differences (ITDs) using HRTFs. Then correlations between ITDs and anthropometric parameters were analyzed using the canonical correlation method. Results indicated that parameters relating to head size, and shoulder and ear positions are significant. Consequently, it was attempted to express ITDs based on listener's anthropometric data. In this process, the change of ITDs as a function of azimuth angle was parameterized as a sum of sine functions. Then the parameters were analyzed using multiple regression analysis, in which the anthropometric parameters were used as explanatory variables. The predicted or individualized ITDs were installed in the nonindividualized HRTFs to evaluate sound localization performance. Results showed that individualization of ITDs improved horizontal sound localization.

11:20

3aPP11. Spatial perception of motion-tracked binaural sound. Joshua B. Melick, V. Ralph Algazi, and Richard O. Duda (CIPIC Interface Lab., UC Davis, Davis, CA 95616)

Motion-tracked binaural sound reproduction extends conventional headphone-based binaural techniques by providing the dynamic cues to sound localization produced by voluntary head motion [V. R. Algazi, R. O. Duda, and D. M. Thompson, *J. Aud. Eng. Soc.* **52**, 1142–1156 (2004)]. It does this by using several microphones to sample the acoustic field around a dummy head, interpolating between the microphone signals in accordance with the dynamically measured orientation of the listener's head. Although the provision of dynamic cues reduces the sensitivity of the method to characteristics of the individual listener, differences between the scattered field produced by the dummy head and the scattered field that would be produced by a particular listener distorts the spatial perception. A common observation is that sound sources appear to rise in elevation when the listener turns to face them. We investigate this effect by comparing the perceived rise in elevation under three different conditions: recordings in which recordings are made using (a) the listener's own head, (b) a KE-MAR mannequin, and (c) a cylindrical head with no torso. Quantitative results are presented showing the degree to which perceptual distortions are least for (a) and greatest for (c). [Work supported by NSF.]

11:35

3aPP12. Transaural virtual reality applied to front-back localization. Peter Xinya Zhang (Dept. of Phys. and Astron., Michigan State Univ., 4230 BPS Bldg., East Lansing, MI 48824) and William M. Hartmann (Michigan State Univ.)

Human sound localization can be studied by measuring head-related transfer functions for different source locations and subsequently using the data to simulate different spatial locations using headphone presentation. This technique fails to adequately simulate the difference between front and back locations because the frequencies relevant to pinna cues are so high. A transaural (cross-talk cancellation) technique has been developed that is accurate up to 16 kHz. By controlling the levels and phases of spectral components, as measured by probe microphones in the ear canals, the technique eliminates significant differences between the baseline simulation and reality. The technique has been used, with modifications to the baseline simulation, to study the front-back information content in differ-

ent frequency bands by eliminating the information while maintaining the energy. It has also been used to test for orthogonality between front-back localization and azimuthal localization based on simple interaural differences. The technique has verified that front-back discrimination cannot be

mediated by interaural differences alone. By flattening the level spectrum in one ear while leaving the other ear unchanged it has been possible to demonstrate an ear advantage for front-back discrimination. [Work supported by the NIDCD, grant DC 00181.]

Structural Acoustics and Vibration: Approximation Techniques for Fluid Loading Effects I

David Feit, Cochair

Applied Physical Sciences, Inc., 2 State St., New London, CT 06320

Joel M. Garrelick, Cochair

Cambridge Acoustical Associates/ETC, 84 Sherman St., Cambridge, MA 02140

Invited Papers

8:30

3aSA1. The rational function approximation for fluid loaded vibrating structures. David Feit (Appl. Physical Sci. Corp., Ste. 300, 2 State St., New London, CT 06320)

A complicating feature of fluid-structure interaction problems is the non-local or long-range effect of the fluid loading acting on a structure vibrating in response to time-harmonic loading while submerged in an acoustic medium. DiPerna and Feit [J. Acoust. Soc. Am. **114**, 194–199 (2003)] recently introduced an approximation for this effect using a rational function approximation (RFA) to the spectral impedance. The latter relates the transform of the surface pressure to that of the surface velocity, and transforming back to the physical domain gives rise to a high-order differential pressure-velocity relationship. The coefficients of the n th order differentials are inversely proportional to the n th order of frequency so that the approximation gets better with increasing frequency. The approximation originally developed for a planar vibrating surface, has now been extended to a cylindrical surface, and this development and several applications of the RFA technique are presented. [Work supported by the Carderock Division Naval Surface Warfare Center Intra-laboratory Independent Research (ILIR) program and the Office of Naval Research.]

9:00

3aSA2. Transmission line analysis of cylindrical shells with exterior fluid loading. Ann Stokes, Charles Corrado, and Joel Garrelick (Appl. Physical Sci., Inc., 2 State St., Ste. 300, New London, CT 06320)

The Wave Transmission Line (WTL) numerical modeling formulation has been developed to understand and efficiently compute the transmission of acoustic energy through fluid-filled elastic shells. The structural systems are represented as a sequence of components and discontinuities connected with straight duct sections. The motion of straight segments is described in terms of amplitudes of freely traveling, left-and-right propagating waves. Recent work in Rational Function Approximation (RFA) of exterior fluid loading permits this approach to be extended to cylindrical structures with interior and exterior fluid loading. The resulting approach is more computationally efficient than conventional finite element approaches. This paper describes development of systems of transmission line equations for segmented cylindrical shells with exterior and interior fluid loading.

9:30

3aSA3. The Fresnel-Product Approximation, and comments on extending rational function approximation to include flow. Rudolph Martinez and Carina Ting (Anteon Corp., 84 Sherman St., Cambridge, MA 02140)

The first half of this presentation reviews the existing development of the Fresnel-Product Approximation as a replacement of the exact fluid impedance on a two-sided blade-like object. Excellent performance versus exact calculations is demonstrated for vibration patterns above, below, and at coincidence, viz., for flexural wavelengths that are longer, shorter, or equal to that of characteristic sound. The approximate solution is global and thus of the WKB type: (1) It captures the correct edge behavior of diffraction loads on the vibrating blade; (2) Collapses to the Kirchhoff solution away from both edges at high frequencies; and (3) Differs by only a small factor when applied at low frequencies to predict the blades globally entrained fluid mass. The second half of the talk addresses the Rational Function Approximation (RFA) pioneered by Feit and DiPerna. It shows how their spectral technique could be readily generalized to add flow effects, including the influence of shed vorticity as it co-exists with sound. Flowless acoustics will be derived from fully unsteady aerodynamics/aeroacoustics through a delicate limiting process and an integration by parts. The talk ends with a discussion of how current applications of the RFA could be stripped of some of their structural-acoustic artifacts.

10:15

3aSA4. Rational approximations of surface impedance operators on curved surfaces with application to high-frequency scattering by thin shells. David C. Calvo (Acoust. Div. Naval Res. Lab., Washington, DC 20375-5320)

In the analytical solution of scattering and radiation problems on curved surfaces using Fourier transforms, surface impedance functions featuring ratios of Hankel functions arise. Recently, an approach of approximating the impedance by a rational function was introduced in which the squared transform variable is replaced by a differential operator. By taking into account the impedance function poles in the rational approximation, an accurate and efficient numerical scheme is obtained applicable to wide-frequency ranges and wide-scattering angles where creeping waves are important. The rational approximation and operator introduction in effect creates an inverse Fourier transform operator so explicit residue calculus inversion is not needed if numerical results are desired. For general convex surfaces, the approximate impedance operator is a wide-angle on-surface radiation condition operator with more accuracy than the narrow-angle one of Kriegsmann *et al.* The use of rational approximations resembles that of Collins *et al.* for the square-root function in ocean acoustics and DiPerna & Feit for the flat plate, the important difference being the curvature. Results of using this approach for two and three-dimensional scattering problems will be presented along with recent application to scattering by thin cylindrical and spherical shells at high frequencies. 10:45

3aSA5. Well- and ill-considered numerical solution constructions. John J. McCoy (The Catholic Univ. of America, Washington, DC 20064)

One requirement for a prediction problem to be well posed is that its solution must not be unduly sensitive to small changes in the problem specification. A similar requirement can be demanded for the numerical construction of the solution of a well-posed problem to be well considered; the achieved solution must not be unduly sensitive to small numerical errors that are unavoidable in the construction's implementation. Ill-considered constructions typically result on reformulating a well-posed problem, now as a series of sub problems, one of which is ill posed. Three classes of potentially ill-considered constructions of the steady state vibration field in a bounded continuous structure and of the narrow band acoustic field in an extended propagation environment appear prominently in the literature. One class is solution constructions based on "marching." A second class is solution constructions based on "substructuring" the computational domain. A third class is solution constructions that are based on a Born-series representation. Examples of well- and ill-constructions for each of the classes are briefly described, with well- and ill-considered marching solutions discussed in some detail.

11:00

3aSA6. Elastoacoustic response of laminated plates. Ramesh Kolar (Naval Postgrad. School, Mech. & Astro Eng., Code ME/Ko, Monterey, CA 93943)

The application of composite materials in the aerospace and naval structures has increased enormously due to high specific strength and specific stiffness afforded by these materials. In this paper a formulation is developed based on Hamilton's Principle and laminated composite plate theory to study the elasto-acoustical response of composite plates under heavy fluid loadings. The formulation starts by using Hamilton's principle in conjunction with shear deformable theory of laminated composite plates. The acoustic pressure described by wave equation is computed similar to Sandman and Nelisse. Using the Rayleigh Ritz method and symbolic mathematics for evaluation of integrals, the formulation provides efficient approach for the problem defined. Typical results include radiation impedance as a function of driving frequency, vibroacoustic indicators such as radiated sound power and mean square velocity for a model problem. Such results are very important in studying constrained layer damping when viscoelastic dampers are used in structural components.

11:15

3aSA7. Prediction of radiation from finite-length fluid-loaded periodic structures subject to broadband excitation using local-global homogenization. Pavel V. Danilov and Donald B. Bliss (Mech. Eng. and Mater. Sci., Duke University, Durham, NC 27708, dbb@duke.edu)

Local-Global Homogenization (LGH) is a method to predict directly the smooth global response of periodic fluid-loaded structures in a self-contained manner. Many fluid-loaded structures, such as fuselages and hulls, have periodically spaced braces, ribs, or attachments. Structural motion, acoustic radiation, and the interior sound field are of interest. Calculating the motion of such fluid-loaded structures is difficult because of their complexity and the disparity of length scales. Periodic discontinuities cause the structural response to occur in a broad spectrum of spatial wavenumbers, and to exhibit stop-band and pass-band behavior. The broad spatial wavenumber spectrum contains both radiating and non-radiating components. The global low-wavenumber part of the response is most efficiently coupled to the acoustic field, since low wavenumbers correspond to supersonic phase speeds. In the LGH reformulation, an infinite order operator that embodies both the structural modes and the evanescent component of the fluid loading governs the equivalent smooth global problem. Numerical implementation is demonstrated for the structural response and acoustic radiation from a finite-length fluid-loaded plate with periodic impedance discontinuities subject to broadband excitation. Calculations show good agreement with the exact solution and substantially improved computational efficiency. Radiation characteristics are discussed for single frequency and broadband structural motions.

11:30

3aSA8. Vibroacoustic optimization of skin damped structures for noise reduction. Lionel Zoghaib (Lab. de Mécanique et d'Acoustique CNRS, Marseille, France, zoghaib@lma.cnrs.mrs.fr)

Most of the time the widely used passive treatments are designed to obtain the highest achievable damping. Although this might be satisfactory from a vibrational point of view the approach is not optimal for noise reduction. The idea is illustrated in the case study of a plate on which polymer/aluminum thin patches have been bonded. The system acoustic pressure and structure displacement equations are transformed into a single integro differential one governing the plate displacement. The solution is then expanded into a series of resonance modes. These modes are estimated using a perturbation expansion with respect to the fluid/solid density ratio. Numerically, in vacuo resonance modes are firstly computed using a viscoelastic incompressible 3D FE program together with a Newton-type iterative method and a sparse complex matrix solver implementing ARPACK. Radiation modal impedances are then computed to ponderate the in vacuo solution. The numerical model has been experimentally validated. Its specificity lies in the separate computation of three damping components: thermoelastic, skin and acoustic damping, this last

one being caused by the fluid/structure coupling. Finally an optimization process determines an optimal system configuration to achieve the lowest acoustic damping while obtaining the highest viscoelastic damping.

11:45

3aSA9. An impedance modeling technique of a fluid-loaded structure. Chih-Chun Cheng and Pi-Wen Wang (Dept. of Mech. Eng., Natl. Chung Cheng Univ., 160, San-Hsing, Ming-Hsiung, Chia-Yi 621, Taiwan)

A methodology of modeling the fluid-loaded structures using the impedance technique is proposed. The structural response and the fluid loading effect are expressed in terms of structural impedance and the acoustic wave impedance. Then a formulation that assembles the acoustic imped-

ance and the structural impedance is derived and can be used to determine the response of a fluid-loaded structure. The advantage is simply that the impedance can be obtained either experimentally or analytically and then the response of the fluid-loaded structure can be found using the proposed impedance coupling formula without deriving the equation of motion which usually encounters difficulties when the structure is in an irregular shape or the associated boundary conditions are complicated. Two numerical examples are presented. The first is to validate that the fluid loading calculated using the proposed methodology is the same as that from the traditional Fourier Transformation method. The second is to demonstrate the potential of this proposed method applied in analyzing an active material system which is commonly used in the vibro-acoustic control. [Work supported by NSC of Taiwan.]

Session 3aSC

Speech Communication: Indigenous Languages of North America (Lecture/Poster Session)

Sonya F. Bird, Chair

Dept. of Linguistics, Univ. of Victoria, Victoria, BC V8W 3P4, Canada

Chair's Introduction—8:00

Invited Papers

8:05

3aSC1. Phonetic study of North American languages history and results. Ian Maddieson (Dept of Linguist., Univ. of California, Berkeley, CA 94720)

Serious phonetic study of North America languages started at the beginning of the 20th century. Within limits of available technology, aspects of speech articulation, aerodynamics and acoustics were investigated. One clear motivation was to understand how classes of sounds unfamiliar from study of better-known European and Asian languages were produced. Glottalized consonants and stops then referred to as "intermediate" (voiceless unaspirated) received particular attention. Nasal airflow, lip position in vowels, and tone and pitch accent were also investigated. Significant insights on relative timing were obtained, inter alia foreshadowing VOT measurement as a useful discriminator of laryngeal activity and revealing part of the mechanism by which ejective consonants are made. After the 1920's, the idea of "psychologically real" phonemes which ignored phonetic differences became the ruling paradigm in American linguistics, contributing to a decline of interest in phonetic studies that basically lasted until around the 1980's. When interest renewed, a new vision that phonetic patterns show regularities independent of phonemic structure guided research, and considerable attention was also paid to how indigenous American languages fit into overall phonetic typologies. Recent work is also often informed by concern for documentation of endangered languages and community interest in language revival.

8:30

3aSC2. Pitch accent timing in Chickasaw. Matthew K. Gordon (Dept. of Linguist., Univ. of California, Santa Barbara, Santa Barbara, CA 93106)

This paper examines the temporal realization of pitch accents in Chickasaw, a Muskogean language of Oklahoma. Questions in Chickasaw have a Lat their right edge preceded by a H* pitch accent that docks on one of the final three syllables of the last word in the Intonational Phrase: on a final CVV, otherwise on a heavy (CVV or CVC) penult, otherwise on the antepenult. Three speakers of Chickasaw were recorded uttering a list of words varying in the location of the pitch accent and the type of syllable carrying the pitch accent. Results indicate a tendency to realize the pitch accent relatively late in non-final pitch accented syllables (during the last 25 and during the coda consonant following a short vowel). However, final accented syllables realize the pitch accent early (within the first 20 vowel) and also display substantial vowel lengthening (by over 50 vowels in the penult or antepenult). These results suggest that pressure to avoid tonal crowding between the pitch accent and boundary tone overrides the late realization of pitch accents characteristic of positions in which crowding is less of an issue.

8:55

3aSC3. How the pharyngeal resonator is controlled articulatorily. John H. Esling (Dept of Linguist., Univ. of Victoria, Victoria, BC, Canada V8W 3P4, esling@uvic.ca)

Indigenous languages of North America, especially west coast Vancouver Island Nuuchahnulth and Interior BC Salish, illustrate an extensive range of use of the pharyngeal resonator. The pharynx is classified as part of the laryngeal articulator (rather than lingual) because the laryngeal constrictor mechanism (controlling changes from the glottis to the aryepiglottic folds) is the principal articulator whose movements determine the shape of the pharynx. The Nuuchahnulth (Nootka) dialects (e.g., Ahousaht) and Thompson, Moses-Columbia, and Spokane/Kalispel Salish varieties all close the larynx completely for the speech sound epiglottal stop. With the airway optimally shut, the pharynx is small; the aryepiglottic folds are pressed against the epiglottic tubercle, the tongue is retracted, and the larynx is raised. There are good indications that the thyroarytenoid, aryepiglottic, thyroepiglottic, hyoglossus and hyothyroid muscles participate in this buckling manoeuvre. These languages also contain either a pharyngeal fricative or approximant (at the same place of articulation but with less stricture) and, in Thompson, also pharyngealized uvulars (with even less stricture). Pharyngeal resonance in all of these cases is dependent initially on the shortening of the supraglottic tube and subsequently on the combined effect of tongue retraction and larynx raising reducing the volume immediately above the supraglottic tube.

9:20

3aSC4. One hundred years of instrumental phonetic fieldwork on North America Indian languages. Joyce McDonough (Dept. of Linguist., Univ. of Rochester, Rochester, NY 14627)

A resurgence of interest in phonetic fieldwork on generally morphologically complex North American Indian languages over the last 15 years is a continuation of a tradition started a century ago with the Earle Pliny Goddard, who collected kymographic and palatographic field-data between 1906–1927 on several Athabaskan languages: Coastal Athabaskan (Hupa and Kato), Apachean (Mescalero, Jicarilla, White Mountain, San Juan Carlos Apache), and several Athabaskan languages in Northern Canada (Cold Lake and Beaver); data that remains important for its record of segmental timing profiles and rare articulatory documentation in then largely monolingual communities. This data in combination with new work has resulted in the emergence of a body of knowledge of these typologically distinct families that often challenge notions of phonetic universality and typology. Using the Athabaskan languages as benchmark example and starting with Goddard's work, two types of emergent typological patterns will be discussed; the persistence of fine-grained timing and duration details across the widely dispersed family, and the broad variation in prosodic types that exists, both of which are unaccounted for by phonetic or phonological theories.

9:45

3aSC5. Coronal ejectives in Ahtna Athabaskan. Siri Tuttle (Univ. of Alaska, Fairbanks, AK 99775)

Ahtna, a non-tonal Alaskan language, is one of few Athabaskan languages that has retained word-final ejectives. The loss of stem-final glottal stops and ejectives in the other languages is correlated with tonogenesis. Hargus (2004) finds voice quality distinctions (creakiness, variability, and increased energy in higher harmonics) preceding stem-final glottal consonants in Witsuwiten, another nontonal Northern language. The present study considers the acoustics of stem-initial and stem-final [t'] and [ts'] in Central and Lower Ahtna. Stem-initial ejectives are canonically shaped, with defined silent period following oral release. In stem-final position, as predicted by Kari (1990), variable non-ejective realizations are found in both word-final and intervocalic (suffixed) position. These realizations are accompanied by variable voice quality effects in preceding vowels, more frequent and pronounced than those found variably in vowels following stem-initial ejectives. Stem-final [t'] is frequently pronounced as glottal stop, and final [ts'] as [s] where <, > stands for glottal stop. Strikingly, non-ejective realizations of stem-finals are found in suffixed and non-suffixed pairs with the same stem, suggesting that stem-final effects generalize to all tokens of stems. These findings support Leers (1979) picture of spirantization and suprasegmentalization in Athabaskan tonogenesis, as glottal effects gravitate to nucleus position.

10:10–10:25 Break

10:25

3aSC6. Tone and prosodic organization in Cherokee nouns. Keith Johnson (Dept. of Linguist., 1203 Dwinelle Hall, UC-Berkeley, Berkeley, CA 94720-2650) and Marcia Haag (Norman, OK 73019-2032)

Preliminary observations in the speech of one speaker of Cherokee led us to postulate three factors affecting tone in Cherokee. (1) Tone may be lexically specified with distinctive low, low fall, low rise, and high tones. (2) There is a metrically determined high fall pattern which may be distributed over not more than 2 syllables from the right edge of a prosodic domain. (3) Intonational domains may be associated with discourse functions, marked by high fall, or by pitch range upstep. This paper tests these observations in recordings of word lists and sentences produced by five additional speakers. The analysis we give, positing both lexical tone and metrical prosodic accent, is not unique in descriptions of language, but is different from the usual description of Cherokee. [Work supported by NSF.]

3a WED. AM

All posters will be on display and all authors will be at their posters from 10:50 a.m. to 12:00 noon.

3aSC7. Harmony in Gitksan. Noriko Yamane-Tanaka and Atsushi Fujimori (Dept. of Linguist., Univ. of University, E270-1866 Main Mall, Vancouver, BC, Canada V6T 1Z1)

What types of consonants are transparent in vowel harmony in Gitksan has been little understood. Previous studies suggest that it is translaryngeal harmony, where the qualities of unstressed suffixal vowels are harmonized with the ones of last stem vowels, apparently skipping the stem-final laryngeal stop and laryngeal fricative [Rigsby, unpublished manuscript, University of Queensland, Australia, 1986; Rigsby and Ingram, *International Journal of American Linguistics* 56, 251–263 (1990)]. However, our original data show that harmony takes place when the stem-final consonant is uvular as well. It suggests that it cannot simply be analyzed as laryngeal transparency, but it could be reanalyzed as [+low] transparency. The present study examines cross-consonantal vowel harmony through acoustic experiment. It is predicted that there is a significant difference in formant values between the vowels across uvular or laryngeal consonants versus the ones across the other consonants. New data from an Eastern Gitksan speaker (female, 72) and its analysis will be presented. Implications for locality of vowel harmony as well as for the phonological treatment of consonantal transparency will be discussed. [Work supported by SSHRC.]

3aSC8. The effect of [h] on tonal development in Nahuatl. Susan G. Guion (Linguist. Dept., 1290 U. of Oregon, Eugene, OR 97403, guion@uoregon.edu) and Jonathan D. Amith (Gettysburg College, Gettysburg, PA 17325)

In both its classical and modern forms, Nahuatl is usually described as having penultimate accent (with little discussion as to whether this is a phrase- or word-level phenomena). However, some varieties of Mexican Guerrero Nahuatl have recently been described as having word accent in locations related to the position of a historical non-word-final coda *h. Here, the hypothesis is investigated that coda *h lowered the fundamental frequency (F0) of the tautosyllabic vowel and that a H–L pitch contour was subsequently incorporated into the lexical representation of the word as *h was weakened and lost. Recordings were made of four dialects at varying stages of *h loss and tonal innovation. Six speakers from each dialect were recorded producing words in phrase medial and phrase final positions, some with historical coda *h and some without, and the F0 of each syllable in these words measured. The results indicated that the new accentual patterns found in some dialects have their origin in the phonetic lowering of F0 in syllables containing coda *h. It also seems that once a new accentual pattern is developed and the *h lost, the resulting phonologized pattern may not correspond to the phonetic locus of the sound change.

3aSC9. Glottalization cues of Nuu-chah-nulth glottalized resonants. Marion G. Caldecott (Dept. of Linguist, Univ. of British Columbia, Canada V6T 11, mariongc@interchange.ubc.ca)

Theories of positional neutralization (Steriade, 1997) predict that pre-glottalized resonants should not occur word-initially because the cues to glottalization are not salient. Contrary to this, Nuu-chah-nulth, a Wakashan language, has pre-glottalized that do occur in word-initial position. This paper will show that a severely truncated resonant portion is the cue to glottalization in resonants in Nuu-chah-nulth. Previous research [Carlson *et al.*, *J. Jpn. Int. Prop. Assoc.* 31, 275–279 (2001)] shows that Nuu-chah-nulth glottalized resonants consist of a stop closure that is phonetically identical to phonemic glottal stop followed by a (mostly) plain resonant. That study also found that glottalized resonants are twice as long in initial position as plain resonants. Following up on this, a pilot study [Caldecott and Kim, presented at the 1st annual Wakashan Linguistics Conference,

2004] indicated that the length of the resonant portion in glottalized resonants was in fact half that of a normal resonant. This paper expands on the previous study, incorporating new acoustic data on resonants in all word positions. Data are elicited from a fluent native speaker and measured using Praat. [Work supported by SSHRC.]

3aSC10. Glottalized resonants in NLe kepmxcin (Thompson River Salish). Patricia A. Shaw, Fiona M. Campbell (Dept. of Linguist., Univ. of British Columbia, E270–1866 Main Mall, Vancouver, BC, Canada V6T 1Z1), and Flora Ehrhardt (Lytton Indian Band, BC)

This study examines properties of glottalized resonants (/m', n', l', y', w'/) in NLe?kepmxcin, a Northern Interior Salish language, both comparing them with their plain counterparts (m, n, l, y, w) and considering contextual factors as defined by word, syllable, and prominence positions. Despite the relative cross-linguistic rarity of glottalized resonants, they are of considerable theoretical interest given that several recent studies [e.g., Bird and Caldecott, *Proceedings of the 10th AICSST* (in press)] indicate that their articulatory and acoustic realization may vary significantly across languages and contexts. Of particular relevance to the present study is Carlson, Esling, and Harris' [UMOPL 17, 58–71 (2004)] claim that in NLe?kepmxcin “glottalized resonants are a sequential combination of the resonant plus [glottal stop]” [pg. 64]. Based on the analysis of glottalized resonants in this study, it appears that the picture is more complex than consistent post-glottalization. Of special interest are glottalized resonants in word-initial position, both because this class is seriously under-represented in the previous literature, and because its characteristics challenge Carlson, Esling, and Harris' sequencing generalization. Understanding the organization of glottalized resonants will help clarify both sequential and markedness issues in NLe?kepmxcin phonology. [Work supported by SSHRC.]

3aSC11. Phonetic structures of Washo. Patrick J. Midtlyng and Alan C. L. Yu (Dept. of Linguist., Univ. of Chicago, 1010 E 59 St., Chicago, IL 60637, aclyu@uchicago.edu)

Washo is a severely moribund language spoken in several townships near the California-Nevada border southeast of Lake Tahoe. The Washo language is now used only by approximately 13–20 elderly speakers with very few fluent speakers under 60. Recordings were collected in Dressler-ville, Nevada from two native speakers. Recordings collected by William Jacobsen Jr. in the 1960s provided additional data for comparison. Analysis showed that all the stops were either voiceless unaspirated, voiceless aspirated, or ejectives. Vowel analyses showed the nature of the six long and short vowels. Special attention was paid to the nature of vowels and consonants in and around the stressed syllable. Post-tonic sibilants and sonorants are lengthened intervocalically even though consonantal length is not contrastive in Washo. Vowel length contrasts only in the stressed syllable. Stressed vowels are always long before an intervocalic voiceless unaspirated stop, but vocalic length contrast remains before aspirated stops and ejectives.

3aSC12. An ultrasonic investigation of retracted consonants in St'at'imcets (Lillooet Salish). Nahal Namdaran (Dept. of Linguist., Univ. of British Columbia, 1866 Main Mall, Buchanan E270, Vancouver, BC, Canada V6T 1Z1)

Tongue retraction is rare in native languages of North America. Previous literature on St'at'imcets (also known as Lillooet) has left unanswered the question of how retracted consonants (uvulars, a pharyngeal, and a subset of retracted coronals) are articulated, and whether they in fact involve tongue retraction. Based on perceptual and acoustic data, previous descriptions differ with respect to the involvement of the tongue dorsum

and tongue root in the articulation of St'at'imcets retracted consonants, particularly with the orthographic “g,” disputed to be either a uvular or pharyngeal approximant [Shahin, 1997; van Eijk, 1997]. Articulatory data of retracted and nonretracted consonants were collected from 4 St'at'imcets speakers via a portable ultrasound machine. Results indicate a significant difference in tongue root, dorsum, and body position for retracted versus nonretracted consonants, with the former possessing more tongue root and dorsum backing and tongue body lowering than the latter. Furthermore, results show “g” to be articulated similarly to the uvular consonant, with the tongue dorsum moving towards the posterior uvula/upper pharyngeal region of the vocal tract. These results provide direct evidence for the articulatory makeup of St'at'imcets retracted consonants and shed light on St'at'imcets retraction effects and phonological harmony processes. [Work supported by SSHRC.]

3aSC13. An acoustic study of Deg Xinag fricatives. Richard Wright, Sharon Hargus, and Julia Miller (Dept. of Linguist., Univ. of Washington, Box 354340, Seattle, WA 98195-4340)

Few studies have looked at the acoustic properties of fricatives in Native American languages. Notable exceptions are McDonough (2003) on Navajo, and Gordon, Barthmaier, and Sands (2002), which examined a variety of languages, including several Native American ones. In Deg Xinag, an endangered Athabaskan language spoken in Alaska, there are eight places of articulation for voiceless fricatives [a relatively large phonetic inventory, according to Maddieson (1984)], including some rarely studied place contrasts (e.g. alveolar versus retroflex). In this study, pre- and post-vocalic fricatives were digitally recorded in the field from eight speakers (two males, six females) using a head-mounted mic to control for distance from the source. The segmental context was also controlled for, the neighboring vowel being [a] in all cases. Each speaker produced four repetitions of each word. The first four spectral moments, lowest spectral peak, and the three loudest spectral peaks were measured at the midpoint of each fricative, and each speaker's average for each of the measures was calculated. In this poster, qualitative results in the form of spectrographic analysis will be presented. Repeated measures ANOVA for each of the quantitative measures will also be presented. [Work supported by NSF.]

3aSC14. Glottalized consonants in Oaxaca Chontal. Heriberto Avelino and Ian Maddieson (Dept. of Linguist., Univ. of California, Berkeley, CA 94720)

Lowland Oaxaca Chontal, a language generally classified as Hokan and hence related to Yuman and Pomo languages, is now spoken by only a small percentage of the Chontal people who live on the Pacific coast of Oaxaca state, Mexico. Recordings were made of seven speakers in their 60's to 80's in December 2003. The language has a series of glottalized obstruents some of which vary in production between fricative and affricate realizations. Our data show the labio-dental and lateral are the most likely to have fricative realizations, the coronals are regularly affricates and the velar is regularly a stop. These segments are contrastive but morphologically related to the voiceless fricatives of the language. This is demonstrated by one common plural formation process which adds glottalization to a final consonant (e.g. /apix/ “stone,” /apik'/ “stones”). After a vowel the same morpheme is realized as a glottal stop (e.g. /u/ “eye,” /u/ “eyes”). However, not all sequences of voiceless fricative + glottal stop are realized as glottalized obstruents (e.g. /ase/ “atole”). Chontal also has glottalized nasals and approximants. As in other languages the accompanying glottal constriction is variable in degree and timing.

3aSC15. Consonantal perturbations of pitch in Halkomelem Salish. Jason Brown and James J. Thompson (Dept. of Linguist., Univ. of British Columbia, 1866 Main Mall, Buchanan E270, Vancouver, BC, Canada V6T 1Z1, jcb@interchange.ubc.ca)

It has long been noted that consonants have an effect on the pitch of a following vowel: voiceless stops tend to raise F_0 , while voiced stops lower it. It has also been suggested that the duration of such perturbations is shorter in tone languages than in non-tone languages [Hombert, *Studies in African Linguistics* (1977)]. This study compares the effects that consonants have on F_0 in two closely related Salish languages: Island Halkomelem, a non-tone language, and Upriver Halkomelem, a language that has reportedly undergone some limited tonogenesis but offers no clear prosodic clues regarding tonality. The effects of the voiceless and ejective stop series were observed, and measurements of F_0 were taken at the onset of voicing for the vowel, then at 20 msec. intervals up to 100 msec. Preliminary results indicate that i) Island Halkomelem shows a greater magnitude of difference in F_0 at vowel onset between the voiceless and ejective stops than Upriver Halkomelem, and ii) Island Halkomelem shows greater durations of consonantal perturbations of F_0 than does Upriver Halkomelem. This suggests that Upriver Halkomelem may have become more sensitive to pitch than the Island dialect, supporting the interpretation of this language as tonal. [Work supported by Phillips Fund.]

3aSC16. Acoustic cues to Nehiyawewin constituency. Clare Cook and Jeff Muehlbauer (Univ. of British Columbia, Dept. of Linguist., 1866 Main Mall, Buchanan E270, Vancouver, BC, Canada V6T 1Z1, clarec@interchange.ubc.ca)

This study examines how speakers use acoustic cues, e.g., pitch and pausing, to establish syntactic and semantic constituents in Nehiyawewin, an Algonquian language. Two Nehiyawewin speakers autobiographies, which have been recorded, transcribed, and translated by H. C. Wolfart in collaboration with a native speaker of Nehiyawewin, provide natural-speech data for the study. Since it is difficult for a non-native-speaker to reliably distinguish Nehiyawewin constituents, an intermediary is needed. The transcription provides this intermediary through punctuation marks (commas, semi-colons, em-dashes, periods), which have been shown to consistently mark constituency structure [Nunberg, CSLI 1990]. The acoustic cues are thus mapped onto the punctuated constituents, and then similar constituents are compared to see what acoustic cues they share. Preliminarily, the clearest acoustic signal to a constituent boundary is a pitch drop preceding the boundary and/or a pitch reset on the syllable following the boundary. Further, constituent boundaries marked by a period consistently end on a low pitch, are followed by a pitch reset of 30–90 Hz and have an average pause of 1.9 seconds. I also discuss cross-speaker cues, and prosodic cues that do not correlate to punctuation, with implications for the transcriptional view of orthography [Marckwardt, Oxford 1942].

3aSC17. Discourse-level contours in Nehiyawewin. Jeff Muehlbauer and Clare Cook (Univ. of British Columbia, Dept. of Linguist., 1866 Main Mall, Buchanan E270, Vancouver, BC, Canada V6T 1Z1, jefmuehl@interchange.ubc.ca)

This study describes declination and discourse-sized intonation contours in Nehiyawewin, an Algonquian language whose pitch and intonation systems have not been previously studied. The study draws on 270 min of recordings of two female Nehiyawewin elders telling their life stories to another Nehiyawewin native speaker. Data is analyzed by using Praat's default algorithm to generate f_0 curves for each breath group. Preliminary results indicate: (1) When breath-group internal pitch peaks are considered, an obvious downward trend of f_0 occurred in fewer than half the breath groups analyzed (about 40% or 37/90). This raises questions about the role of classical declination in natural discourse [Umeda, *Journal of*

Phonetics **10** (1982)]. (2) When we abstract away from declination within a breath group by computing mean f_0 and mean pitch peak for each breath group and tracking trends for these means, larger patterns seem to emerge; breath groups can be grouped into larger units based on raising

and lowering trends. These units have a mean peak range of 150 Hz with a 30 Hz change from one breath group to the next and correspond to a domain of around five clauses (about 3–4 breath groups, about 45 syllables).

3aSP1. Wavelet based detection of manatee vocalizations. Berke M. Gur and Christopher Niezrecki (Dept. of Mech. Eng., Univ. of Massachusetts Lowell, One University Ave., Lowell, MA 01854-2881, Chris_Niezrecki@uml.edu)

The West Indian manatee (*Trichechus manatus latirostris*) has become endangered partly because of watercraft collisions in Florida's coastal waterways. Several boater warning systems, based upon manatee vocalizations, have been proposed to reduce the number of collisions. Three detection methods based on the Fourier transform (threshold, harmonic content and autocorrelation methods) were previously suggested and tested. In the last decade, the wavelet transform has emerged as an alternative to the Fourier transform and has been successfully applied in various fields of science and engineering including the acoustic detection of dolphin vocalizations. As of yet, no prior research has been conducted in analyzing manatee vocalizations using the wavelet transform. Within this study, the wavelet transform is used as an alternative to the Fourier transform in detecting manatee vocalizations. The wavelet coefficients are analyzed and tested against a specified criterion to determine the existence of a manatee call. The performance of the method presented is tested on the same data previously used in the prior studies, and the results are compared. Preliminary results indicate that using the wavelet transform as a signal processing technique to detect manatee vocalizations shows great promise.

9:15

3aSP2. Background noise cancellation for improved acoustic detection of manatee vocalizations. Zheng Yan (Dept. of Mech. and Aersp. Eng., Univ. of Florida, Gainesville, FL 32611-6250), Christopher Niezrecki (Univ. of Massachusetts Lowell, Lowell, MA 01854-2881, Chris_Niezrecki@uml.edu), and Diedrich O. Beusse (Univ. of Florida, Gainesville, FL 32610-0126)

The West Indian manatee (*Trichechus manatus latirostris*) has become endangered partly because of an increase in the number of collisions with boats. A device to alert boaters of the presence of manatees, so that a collision can be avoided, is desired. Practical implementation of the technology is dependent on the hydrophone spacing and range of detection. These parameters are primarily dependent on the manatee vocalization strength, the decay of the signal strength with distance, and the background noise levels. An efficient method to extend the detection range by using background noise cancellation is proposed in this paper. An adaptive line enhancer (ALE) that can detect and track narrowband signals buried in broadband noise is implemented to cancel the background noise. The results indicate that the ALE algorithm can efficiently extract the manatee calls from the background noise. The improved signal-to-noise ratio of the

signal can be used to extend the range of detection of manatee vocalizations and reduce the false alarm and missing detection rate in their natural habitat.

9:30

3aSP3. Electronic noise suppression in the wavelet, frequency, and time domains. Juan Arvelo, Jr. (Appl. Phys. Lab., Johns Hopkins Univ., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099)

Automatic machine gun recordings were severely contaminated with electronic noise. A detailed examination of the character of the electronic noise revealed that it consists of periodic pulses at an interval of about 4.2 ms and that its frequency content is rich in narrow-band lines with a colored broadband background. Given the impulsive nature of the electronic noise in the time domain, wavelet decomposition was applied in an attempt to harness the noise and to null it out. An alternative approach was also implemented where a bank of stop band Butterworth filters were applied in the frequency domain to suppress the narrow-band components of the electronic noise. Other approaches include the use of adaptive cancellation in the time and frequency domains. We will demonstrate and compare the performance of these approaches emphasizing the need to minimize their influence in distorting the signal of interest.

3aSP4. Maximum entropy method for constructing environmental parameter probability density functions. Leon H. Sibul, R. Lee Culver, David L. Bradley, and H. John Camin (Appl. Res. Lab. and Grad. Program in Acoust., P.O. Box 30, State College, PA 16804, rlc5@psu.edu)

At-sea experience has shown that target detection ranges are often less than predicted using current sonar system performance prediction methods. One possible reason for this disparity is that classical, sonar equation-based performance prediction models do not take into account the random and uncertain nature of signal propagation and scattering in a real ocean environment. Our goal is to develop a probabilistic sonar performance prediction methodology that can make use of limited knowledge of random or uncertain environment, target and sonar system parameters, but does not make unwarranted assumptions or rely upon unknown information. Beginning with models that describe how the ocean environment effects the received signal, the Maximum Entropy method (MEM) can be used to construct probability density functions (PDFs) for the parameters of those models. The benefit of the MEM is that it allows one to incorporate available knowledge about the parameters, but is maximally non-committal about what is not known about the parameters. The methodology is presented and illustrated using a model for particular environmental effects on the structure of low-frequency signals propagating over long distances in the ocean. [Work supported by ONR Code 321US.]

10:15

3aSP5. Stochastic filtering. David I. Havelock (Natl. Res. Council, 1200 Montreal Rd., Ottawa, ON, Canada K1A 0R6, david.havelock@nrc.ca)

Digital filters convolve a signal with an impulse response. This is equivalent to computing a weighted sum of delayed versions of the signal, with the signal versions indexed by their sample-delay and the weights given by the filter impulse response. This talk explores a different approach to filtering. Rather than computing a weighted sum of data values, the *stochastic filter* uses a sequence of random indices to select output data values from delayed versions of the signal. No summation is done. The probability distribution of the random indices is made identical to the normalized modulus of the impulse response of the corresponding conventional filter. For indices with negative weights, data values are negated. For a random index sequence $s(n)$ the stochastic filter output is simply $y(n) = \pm x(n - s(n))$. The output of such a stochastic filter is noisy but it is *equal in the mean* to the output of the corresponding conventional filter. If the sequence of random indices is identically and independently distributed then the noise is spectrally white. Such a filter can be useful for estimating spectral parameters with minimal computation. The principle is illustrated by an application to double-talk detection for telephones.

10:30

3aSP6. Autonomous signal separation microphone system based on the spatio-temporal gradient analysis. Kenbu Teramoto and Kosuke Tsuruta (Dept. of Mech. Eng., SAGA Univ., SAGA, 8408502, Japan)

This paper presents a novel autonomous directivity microphone system based on the newly proposed spatio-temporal blind source separation. Recently, the methods of blind source separation and multi-deconvolution of source signals have been proposed in various fields, especially, acoustic applications including the cocktail-party problem. The blind source separation principally uses no *a priori* knowledge about parameters of convolution, filtering and mixing. In the simplest case of the blind source separation problems, observed mixed signals are linear combinations of unknown mutually statistically independent, zero-mean source signals. The spatio-temporal blind signal separation algorithm utilizes the linearity among the four signals: (1) temporal gradient, (2) x ; (3) y ; and (4) z -directional spatial gradients of the sound-pressure, all of which are governed by the equation of advection. The proposed method, therefore, has an ability to simplify the convolution blind source separation problems into the instantaneous blind source separation over the spatio-temporal gradient space. The acoustical experiments are performed with the particle velocity microphone (Microflown) successfully instead of sound pressure microphones. Because, x ; y ; and z -directional gradients of the sound pressure are equivalent the temporal derivatives of the corresponding directional particle velocities theoretically.

10:45

3aSP7. Bayesian sampling with applications to energy decay analysis in acoustically coupled spaces. Tomislav Jaska and Ning Xiang (School of Architecture and Dept. of Electrical, Computer, and Systems Eng., Rensselaer Polytechnic Inst., Troy, NY 12180)

Bayesian inference comprises of parameter estimation and model selection/comparison. A common approach to solving both of these problems has been to use statistical sampling techniques that are inherently non-Bayesian. This paper presents new Bayesian sampling method that solves both problems by changing the focus of Bayesian inference to the model selection problem first. In the papers [N. Xiang and P. M. Goggins, *J. Acoust. Soc. Am.* **110**, 1415–1424 (2001); **113**, 2685–2697 (2003)], the authors developed a model for the decay times and decay modes of acoustically coupled rooms in terms of measured Schroeder's decay functions. This paper shows how the Bayesian sampling method can be used to evaluate the "Bayesian evidence" term used in model selection as well as determining the decay times along with error estimates.

3aSP8. Adaptive Schur algorithm dedicated to underwater transient signal processing. Maciej Lopatka (Lab. d'Informatique Industrielle et Automatique, Univ. Paris XII, 61 av Gaille, 94010 Créteil, France), Olivier Adam, Christophe Laplanche (Univ. Paris XII, France), Jan Zarzycki (Tech. Univ. of Wroclaw, Poland), and Jean-François Motsch (Univ. Paris XII, France)

The algorithm proposed by Lee and Morf [*IEEE Transactions on Circuits and Systems* **28**(6) (1981)] which stems from the method defined by Schur [*Operator Theory: Advances & Application*, Vol. 18 (Birk-Verlag, 1986)] has acquired a new significance [Zarzycki, *Journal of Multidimensional Systems & Signal Processing* (Kluwer Academic, 2004)], due to its performances and particularly due to its applications in real time, made possible by the speed of processors available nowadays. Based on the innovations filter principle, Schur's proposal models the signal by calculating reflection coefficients, describing entirely the second-order signal. The reflection coefficients can be simply transformed to the AR coefficients, from which one derives the time-frequency representation. We compare performances of this approach with other time-frequency representations commonly used in the signal processing (spectrogram, AR, wavelet transform); we subsequently present the results obtained for transitory underwater acoustic signals, which our laboratory is investigating. The Lee and Morf algorithm offers an excellent tracking of the signal's characteristics and allows us to systematically detect transitory signals. This is particularly pertinent to segmentation problems relating to the application of underwater acoustics. The robustness of the Schur detector and a resolution of the Schur time-frequency representation support the resurgence of the Schur algorithm.

11:15

3aSP9. Laser Doppler signal for high amplitude sound wave. Jean-Christophe Valiere, Solenn Moreau, Helene Bailliet (LEA-CNRS UMR 6609, Université de Poitiers, France), Philippe Herzog (LMA-CNRS, Marseille, France), and Laurent Simon (LAUM-CNRS 6613, Université du Maine, France)

Laser Doppler velocimetry (LDV) is now recognized as a very useful technique for estimating acoustic velocity with a good time resolution in many applications. Previous research showed that the most important parameter in LDV for acoustics is the particle displacement and particularly its magnitude compared with the size of the probe volume formed by the crossing of the laser beams. Specific techniques were developed to estimate the acoustic wave when the displacement is of the same order of magnitude as the probe diameter and when it is much smaller. In this study, we investigate situations where the displacement is much higher than the probe volume. The measuring process has been simulated numerically and it appears that the process leads to an under-estimation of the velocity around zero. This under-estimation is due to the processing of the laser Doppler signal in the case of high displacements. The associated signal is a non poissonnian randomly sampled signal to which classical processing methods are not adapted. It is compared to experimental signals obtained in the context of a study of non linear effects in an acoustic wave guide. To this end, different processing of both simulated and experimental signals are presented and compared.

11:30

3aSP10. Cross-frequency Doppler sensitive signal processing. Ronald A. Wagstaff (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, Univ., MS 38677, rwagstaf@olemiss.edu)

When there is relative motion between an acoustic source and a receiver, a signal can be Doppler shifted in frequency and enter or leave the processing bins of the conventional signal processor. The amount of the shift is determined by the frequency and the rate of change in the distance between the source and the receiver. This frequency Doppler shifting can cause severe reductions in the processors performance. Special cross-frequency signal processing algorithms have recently been developed to mitigate the effects of Doppler. They do this by using calculation paths that cut across frequency bins in order to follow signals during frequency

shifting. Cross-frequency spectral grams of a fast-flying sound source were compared to conventional grams, to evaluate the performance of this new signal processing method. The Doppler shifts in the data ranged up to 70 contiguous frequency bins. The resulting cross-frequency grams showed that three paths provided small to no improvement. Four paths showed improvements for either up-frequency or down-frequency shifting, but not for both. Two paths showed substantial improvement for both up-frequency and down-frequency shifting. The cross-frequency paths will be defined, and comparisons between conventional and cross-frequency grams will be presented. [Work supported by Miltec Corporation.]

11:45

3aSP11. Eliminating clutter by coordinate zeroing. Harry DeFerrari (RSMAS—Univ. of Miami, 4900 Rickenbacker Cswy, Miami, FL 33149) and Andrew Rodgers (Woods Hole Group, East Falmouth, MA 02536)

Shallow water doppler sonar is limited by clutter that masks the presence of slow targets. Clutter arises from scattering from irregularities in

the bottom or from fish schools. If the source and receiver are fixed in a bi-static sonar configuration, then the bottom scatterers (and sometimes the fish) have only a zero doppler component. Clutter arises from the doppler leakage resulting from sonar signals that are inherently short in time and therefore cannot resolve bottom reverberation in frequency. Here long continuous pulse compressions signals are considered (m-sequences). Ambiguity diagrams are compared with simple CW pulse and PCM pulses. The unique correlation properties of M-sequences lead to a signal sampling method that resolves sonar returns in complete ortho-normal (CON) data sets. Zero doppler returns are identified as either direct arrivals or reverberation returns and then their particular coordinate can be set zero (coordinate zeroing) without affecting other data points. In this way, the zero-doppler bottom reverberation and all doppler leakage is eliminated. As an example, the return from a slow doppler target is imbedded in a very large number of reverberation returns that have higher signal level. As the zero doppler contributions are removed by coordinate zeroing the target becomes detectable.

3aUW1. Nonlinear frequency dependence of the effective seabottom acoustic attenuation from low-frequency field measurements in shallow water. Ji-Xun Zhou and Xue-Zhen Zhang (Georgia Inst. of Technol., Atlanta, GA 30332-0405 and Inst. of Acoust., Chinese Acad. of Sci., Beijing 100080, PROC)

Hamilton's seabed geo-acoustic model, which is widely accepted, predicts that the attenuation of sound in marine sediments increases linearly with frequency over the full frequency range of interest in ocean acoustics (a few hertz to megahertz). However, Biot-Stoll's physics-based seabed geo-acoustic model predicts that the bottom attenuation should exhibit non-linear frequency dependence, particularly in sandy bottoms. Since the publication of previous papers [Zhou, *J. Acoust. Soc. Am.* **78**, 1003–1009 (1985); Kibblewhite, *ibid.* **86**, 716–738 (1989)], more low-frequency field data, collected from different coastal zones around the world, have shown inconsistencies with the often-used linear frequency dependence. This paper attempts to support the non-linear frequency dependence of sea bottom attenuation through a review of shallow-water acoustic field measurements, with a special emphasis on the 50–1000 Hz frequency range. The relevant measurements include bottom reflection loss, sound transmission loss, dispersion analysis, vertical coherence of both propagation and reverberation, normal-mode spatial filtering, and optimum frequency and transition range of sound propagation. A non-linear frequency dependence of equivalent bottom acoustic attenuation, derived from these measurements, will be introduced. [Work supported by ONR and NNSF of China.]

3aUW2. Overview of SAX99 and SAX04 measurements of sediment sound speed and attenuation. Eric I. Thorsos, Kevin L. Williams, Darrell R. Jackson, and Dajun Tang (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, eit@apl.washington.edu)

During SAX99 (for sediment acoustics experiment—1999) the sediment sound speed (125 Hz to 400 kHz) and attenuation (2.5 to 400 kHz) in sandy sediments were measured by a variety of techniques. The SAX99 site was 2 km from shore on the Florida Panhandle near Fort Walton Beach in water of 18–19 m depth. SAX04 was held in the fall of 2004 at a site close to the SAX99 site, about 1 km from shore in water of 17 m depth. The sediment sound speed and attenuation were again measured over a broad

frequency range by multiple techniques, with even more attention paid to the low frequency band from 1–10 kHz. The results and corresponding uncertainties from SAX99 will be reviewed, and the consistency with Biot model predictions and alternative models (e.g., Buckingham's model) will be discussed. An overview will then be presented of the recently completed SAX04 measurement program on sediment sound speed and attenuation. [Work supported by ONR.]

3aUW3. Models for attenuation in marine sediments that incorporate structural relaxation processes. Allan D. Pierce, William M. Carey (Boston Univ., Boston, MA 02215, adp@bu.edu), and James F. Lynch (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

Biot's model leads to an attenuation coefficient at low frequencies that is proportional to ω^2 , and such is consistent with physical models of viscous attenuation of fluid flows through narrow constrictions driven by pressure differences between larger fluid pockets within the granular configuration. Much data suggests, however, that the attenuation coefficient is linear in ω for some sediments and over a wide range of frequencies. A common model that predicts such a dependence stems from theoretical work by Stoll and Bryan [J. Acoust. Soc. Am. **47**, 1440 (1970)], in which the elastic constants of the solid frame are taken to be complex numbers, with small constant imaginary parts. Such invariably leads to a linear ω dependence at sufficiently low frequencies and this conflicts with common intuitive notions. The present paper incorporates structural relaxation, with a generalization of the formulations of Hall [Phys. Rev. **73**, 775 (1948)] and Nachman, Smith, and Waag [J. Acoust. Soc. Am. **88**, 1584 (1990)]. The mathematical form and plausibility of such is established, and it is shown that the dependence is as ω^2 at low frequencies, and that a likely realization is one where the dependence is linear in ω at intermediate frequency ranges.

9:20

3aUW4. Propagation and reverberation implications of seabed dispersion. Henrik Schmidt (MIT, 77 Massachusetts Ave., Cambridge, MA 02139)

The significance of the seabed geoacoustic properties to shallow water acoustic propagation is well established, and consequently the dispersion, or frequency dependence of the sound speed and the attenuation may be significant to the performance of broadband acoustic systems, whether for acoustic sensing or for communication. On the other hand, it is equally well established that the seabed significance is highly dependent on the system configuration, e.g., source and receiver depths, and the same will therefore obviously be the case for the dispersion. This paper will review the propagation effects of frequency dependent seabed geoacoustics, under characteristic seasonal environmental conditions, and typical system configurations. The associated implications to the acoustic system performance will be discussed in the context of theoretical performance bounds, such as the Cramer-Rao lower bounds, using established wave theory propagation models for range-independent and -dependent environments. Among the specific examples will be the effect of strong sediment dispersion in sandy sediments on buried target detection by low-frequency SAS systems operating in the 1–10 kHz regime, and broadband acoustic communication systems, including the effect of dispersion on seabed reverberation. [Work supported by ONR.]

3aUW5. Attenuation in the sediment layers in East China Sea. Gopu R. Potty and James H. Miller (Dept. of Ocean Eng., Univ. of Rhode Island, Narragansett, RI 02882, potty@oce.uri.edu)

Compressional wave attenuation in the frequency range 50 to 350 Hz is estimated using broadband data collected in the East China Sea. A time-frequency analysis provides amplitudes of individual modes which are used to estimate the modal attenuation coefficients. Different modes are sensitive to sediment properties at different depths and this mode-depth sensitivity is explored in a sensitivity study. Based on this sensitivity study attenuation in different layers of the sediments will be estimated using different modes which are sensitive at these depths. This is a variation of previous studies where different frequencies have been used to invert for different sediment parameters using sub-space approaches. This approach focuses the inversion to various layers (provided by the geophysical surveys at the site) of the sediment and hence presents a tool to describe the depth variations in the sediment. The attenuation versus frequency behavior of the different sediment layers will be discussed. [Work supported by ONR.]

3aUW6. Measuring dispersion and attenuation in sediment at low frequency. Steven A. Stotts, Robert A. Koch, and David P. Knobles (Appl. Res. Labs., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029, stotts@arlut.utexas.edu)

Much work has been done at frequencies above 1 kHz to measure sediment dispersion and attenuation and these results have been analyzed within the context of various models such as Biot-Stoll, Buckingham, and BICSQS. Some effort has been made to establish the frequency dependence of sediment attenuation below 1 kHz, but few results are available concerning dispersion in that frequency band. The present work examines a technique for measuring low frequency sediment dispersion and attenuation with a real dataset. Recently, data were collected off the coast of Florida using implosive broadband sources to perform geo-acoustic inversions. Previous inversion studies with this data ignored any dispersion effects. [Stotts *et al.*, J. Acoust. Soc. Am. **115**, 1078–1102 (2004).] The environment was shown to consist of thin, hard, porous material less than 1 m thick overlying sand sediment. A ray trace plus plane-wave reflection coefficient model was used for the analysis. Here, dispersion is repre-

sented phenomenologically over a finite frequency band in the model by allowing both the sound speed and attenuation to be frequency dependent in both layers of a two-layer sediment plus substrate model.

10:30

3aUW7. Frequency dependence of posterior probability distributions for Biot parameters. Tracianne B. Neilsen, Marcia Isakson (Appl. Res. Labs., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029, neilsen@arlut.utexas.edu), and Buye Xu (Brigham Young Univ., Provo, UT 84602)

The Biot-Stoll poro-elastic model for sediments is parameterized by 13 properties. Initial investigations indicate that the individual Biot parameters influence reflection loss differently depending on the frequency range of interest. A more extensive study of the frequency dependence of the parameter sensitivities is performed by computing posterior probability distributions (PPDs) [S. E. Dosso, *J. Acoust. Soc. Am.* **111**, 129–142 (2002)] to determine which parameters most influence reflection loss for each frequency decade from 100 Hz to 1 MHz. The sampling for the PPDs is based on the least-squares error between simulated reflection coefficient data and values modeled with the reflection module of OASES. [H. Schmidt, "OASES Version 2.1 User Guide and Reference Manual," Department of Ocean Engineering, Massachusetts Institute of Technology, 1997.] The PPDs provide a quantitative value of the uncertainty in the optimum parameter estimates obtained by sampling or inversion techniques. A good value of the uncertainty is critical if one wants to use parameter estimates obtained with data from one frequency range to predict acoustic response for a different frequency range. [Work supported by the ONR.]

10:45

3aUW8. A hybrid model of sound propagation in unconsolidated sediments. Brian T. Hefner and Kevin L. Williams (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

Efforts to model sound speed and attenuation in sandy sediments have centered on the use of theories for which either the relative motion of the pore fluid is the dominant attenuation mechanism, such as Biot theory, or the dominant loss mechanism is grain-to-grain friction. A recent model which attempts to incorporate grain-to-grain loss mechanisms into a model of sandy sediments was proposed by Buckingham. This model can fit the frequency dependence of the attenuation measured in ocean sediments and laboratory glass bead sediments, but it does not capture the sound speed dispersion as effectively as Biot theory. The relative success of each model suggests that both attenuation mechanisms may play important roles in sediment acoustics. In order to explore this possibility, a hybrid model has been developed which incorporates Buckingham's grain-to-grain shearing mechanisms into the frame moduli used in Biot theory. In the hybrid model, the grain-to-grain losses dominate at high and very low frequencies while pore fluid attenuation dominates at mid-frequencies where the sound speed dispersion is the most pronounced. As a consequence, the hybrid model is able to describe both the measured sound speed and attenuation in ocean and laboratory sediments. [Work supported by ONR.]

3aUW9. Attenuation in sand sediments due to scattering from force chains. Brian T. Hefner and Darrell R. Jackson (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

The stresses in a granular media, such as an ocean sediment, are known to be heterogeneous and tend to form chains along which the stresses are particularly high. Because the elastic properties of a granular medium depend nonlinearly on the static forces between the grains, these force chains should induce inhomogeneities in the frame moduli. The correlation lengths of these inhomogeneities have been observed to be on the order of only a few grain diameters and as a consequence have not been thought to produce any significant scattering of acoustic energy. However, for high frequency sound in a saturated granular medium, these inhomogeneities should be on the order of the slow compressional wave. As a

consequence, as the fast wave propagates through the sediment, it may scatter energy into the slow wave which is then rapidly attenuated. This scattering process may account for the deviation of the measured attenuation from the predictions of Biot theory that have been observed in ocean and laboratory sediments at high frequencies. We present a model of sound propagation through sand sediments that incorporates this loss mechanism and compare the results of this model to recent measurements. [Work supported by ONR.]

11:15

3aUW10. Sediment layer perturbation influences on the frequency dependence of effective bottom attenuation. James D. Nickila (Adv. Sonar Technol. Div. Naval Undersea Warfare Ctr., Newport, RI 02841), Kevin B. Smith (Naval Postgrad. School, Monterey, CA 93943), and Gopu Potty (Univ. of Rhode Island, Narragansett, RI 02882)

Over the past several years, concern has grown over the appropriateness of bottom attenuation models that assume a linear frequency dependence. Empirical analyses of experimental data have suggested power law dependence with frequency exponents as high as 1.7 and above, but with large variability between geographic regions. [Zhou *et al.*, *J. Acoust. Soc. Am.* **82**, 287–292 (1987).] The fundamental cause of this dependence is unknown. In this study, we investigate the effect of perturbations (both random and deterministic) in the sediment layer on the effective attenuation factor for a range of frequencies. A parabolic equation (PE) model is used to generate the acoustic field for a given environmental realization. The pressure field is decomposed using a normal mode expansion and an effective attenuation factor is calculated. Regression is performed on the resulting attenuation vs. frequency curve, with particular emphasis placed on testing for non-linearity.

11:30

3aUW11. Dependence of modal attenuation coefficient frequency variation on upper sediment attenuation. Wendy Saintval, William L. Siegmann (Dept. of Mathematical Sci., Rensselaer Polytech. Inst., 110 15th St., Troy, NY 12180), William M. Carey, Allan D. Pierce (Boston Univ., Boston, MA 02115), and James F. Lynch (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

The range-averaged transmission loss increase in shallow water propagation depends critically on the intrinsic attenuation of the upper sediment. The attenuation coefficients of low-frequency (<1 kHz) propagating modes determine the frequency dependence. Ingenito [*J. Acoust. Soc. Am.* **53**, 858–863 (1973)] showed with measurements and theory that while individual mode attenuation coefficients decrease with frequency f , the sediment attenuation coefficient increases proportional to $f^{1.75}$. When results from many other shallow-water transmission experiments (broadband and narrowband) over sandy-silty sediments are compared to numerical calculations, it is found that a nonlinear-frequency dependent attenuation is required with an exponent between 1.5 and 2. The question considered here is how the intrinsic upper-sediment attenuation produces such behavior. A recent simplification of the Biot model [A. D. Pierce *et al.*, *J. Acoust. Soc. Am.* **114**, 2345 (2003)] has a power-law exponent of two. With this frequency-dependent bottom attenuation, a two-layer Pekeris waveguide yields modal attenuation coefficients that decrease with frequency as observed by Ingenito. However, a depth-dependent attenuation profile or a third near-surface layer with requisite properties can reverse this behavior. This suggests why higher-frequency numerical computations may require nonlinear frequency-dependent sediment profiles to calculate sound transmission accurately. [Work partially supported by ONR.]

11:45

3aUW12. Frequency dependence of the frame bulk moduli of granular marine sediments. Masao Kimura (Dept. of Geo-Environ. Technol., Tokai Univ., 3-20-1 Shimizu-Orido, Shizuoka, Shizuoka 424-8610, Japan, mkimura@scc.u-tokai.ac.jp)

The frame bulk modulus is important in analyzing the acoustic wave propagation in porous granular marine sediments. As the value of the frame bulk modulus, notable researchers in the community used about $10^8 P_a$ (constant value). However, the measured frequency characteristics

of the longitudinal wave velocity are not consistent with the calculated characteristics using the constant frame bulk modulus using the Biot-Stoll model. It was reported that the frame bulk moduli in water-saturated glass beads and beach sands are about $10^9 P_a$ at the frequency of 500 kHz, and are about ten times greater than that of air-saturated samples. It is also seen that the frame bulk moduli have dependence on the grain size. Moreover, these phenomena can be explained using the gap stiffness model [M.

Kimura, J. Acoust. Soc. Am. **116**, 2529 (2004)]. The grain size dependence of the frame bulk modulus suggests that there is the frequency dependence of the modulus. In this study, the measured results of the frequency characteristics of the longitudinal wave velocity in water-saturated glass beads and beach sand are compared with the calculated results using the Biot-Stoll model with the frequency dependent frame bulk modulus, derived using the gap stiffness model.

STANLEY ROOM, 8:00 TO 9:30 A.M.

Meeting of Accredited Standards Committee (ASC) S2 Mechanical Vibration and Shock

to be held jointly with the

ANSI-Accredited U.S. Technical Advisory Group (TAG) Meetings for:
ISO/TC 108 Mechanical Vibration and Shock
ISO/TC 108/SC 2 Measurement and evaluation of mechanical vibration and shock as applied to machines, vehicles and structures
ISO/TC 108/SC 3 Use and calibration of vibration and shock measuring instruments
ISO/TC 108/SC 4 Human exposure to mechanical vibration and shock
ISO/TC 108/SC 5 Condition monitoring and diagnostics of machines and
ISO/TC 108/SC 6 Vibration and shock generating systems

R. J. Peppin, Chair S2
5012 Macon Road, Rockville, MD 20852

D. J. Evans, Vice Chair S2 and Chair of the U.S. Technical Advisory Group (TAG) for ISO/TC 108 Mechanical Vibration and Shock
and Chair of the U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 3
Use and calibration of vibration and shock measuring devices
National Institute of Standards and Technology (NIST), 100 Bureau Drive, Stop 8221, Gaithersburg, MD 20899-8221

A. F. Kilcullen, Co-Chair of the U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 2
Measurement and evaluation of mechanical vibration and shock as applied to machines, vehicles and structures
5012 Woods Road, Hedgesville, WV 25427

R. Taddeo, Co-Chair of the U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 2
Measurement and evaluation of mechanical vibration and shock
as applied to machines, vehicles and structures
Naval Sea Systems Command 05T, 1339 Patterson Ave. SE, Stop 8800, Washington Navy Yard, Washington DC 20376-8800

D. D. Reynolds, Chair, U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 4
Human exposure to mechanical vibration and shock
3939 Briar Crest Court, Las Vegas, NV 89120

D. J. Vendittis, Chair of the U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 5
Condition monitoring and diagnostics of machines
701 Northeast Harbour Terrace, Boca Raton, FL 33431

G. Booth, Chair of the U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 6
Vibration and shock generating systems
44 Bristol Street, Branford, CT 06405-4842

Accredited Standards Committee S2 on Mechanical Vibration and Shock. Working group chairs will report on the status of various shock and vibration standards currently under development. Consideration will be given to new standards that might be needed over the next few years. There will be a report on the interface of S2 activities with those of ISO/TC 108 and its subcommittees including plans for future meetings of ISO/TC 108 and/or its Subcommittees. The Technical Advisory Groups for ISO/TC 108 and its Subcommittees consists of members of S2 and other persons not necessarily members of those Committees. Open discussion of committee reports is encouraged.

Scope of S2: Standards, specifications, methods of measurement and test, and terminology in the field of mechanical vibration and shock, and condition monitoring and diagnostics of machines, including the affects of exposure to mechanical vibration and shock on humans, including those aspects which pertain to biological safety, tolerance and comfort.

WEDNESDAY MORNING, 18 MAY 2005

STANLEY ROOM, 10:30 A.M. TO 12:00 NOON

Meeting of Accredited Standards Committee (ASC) S3 Bioacoustics

R. F. Burkard, Chair S3

Hearing Research Laboratory, State University of New York at Buffalo, 215 Parker Hall, Buffalo, NY 14214

C. A. Champlin, Vice Chair S3

Department of Communication Sciences & Disorders, University of Texas, CMA 2-200, Austin, TX 78712

Accredited Standards Committee S3 on Bioacoustics. Working group chairs will report on the status of standards under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAGs for ISO/TC 43 Acoustics and IEC/TC 29 Electroacoustics, take note - those meetings will be held in conjunction with the Standards Plenary meeting at 10:30 a.m. on Tuesday, 17 May 2005.

Scope of S3: Standards, specifications, methods of measurement and test, and terminology in the fields of psychological and physiological acoustics, including aspects of general acoustics, which pertain to biological safety, tolerance, and comfort.

Architectural Acoustics: Scattering in Architectural Acoustics

Kerrie G. Standlee, Chair

4900 SW Griffith Dr., Suite 216, Beaverton, OR 97005

Contributed Papers

1:00

3pAA1. Here and there, near and far: How proximity and separation affect scattering in concert halls. James B. Lee (6016 S. E. Mitchell, Portland, OR 97206)

Classical theory of scattering deals with plane waves, waves which are so far from their source that they form straight fronts of sound, with pressure amplitude and particle velocity exactly in phase. If such waves are much larger than objects they encounter inverse fourth power (Rayleigh) scattering obtains; if the waves are about the same size as the objects resonant (Mie) scattering occurs; if waves are much shorter than the objects specular (Ufimtsev) scattering is the rule. These all affect sound in the far field. But if sources are closer than a wavelength to objects their waves encounter the plane approximation is not valid; pressure amplitude and particle velocity are not in phase, so resonance-like phenomena occur. These occur on stages of concert halls: bass instruments producing waves 2 m or longer always are close to the floor; some, like tympani and violas, can be close to vertical surfaces too. This sort of scattering enhances fundamentals of notes with respect to the overtones, strongly affecting the timbre of such instruments.

1:15

3pAA2. Diagnosing scattering with the Wigner distribution. James B. Lee (6016 S. E. Mitchell, Portland, OR 97206)

The Wigner distribution resolves the power of a signal in both the time domain and the frequency domain. It also is a complete representation because it displays the relative phases of a signal's components as cross-products between them. This means that if one records the time-series of an impulse response in a room and computes a Wigner distribution from it, the kind of scattering, predominantly resonant or predominantly specular, is readily apparent, because the phase response of each is radically different. Specular scattering preserves the relative phases among components comprising the initial impulse and so preserves the impulse itself; resonant scattering randomizes the phases among components and so converts an impulse into a wide band of frequencies spread smoothly in time. Thus specular scattering tends to promote echoes and resonant scattering tends to promote diffusion. Graphic examples of each are given in the literature.

3pAA3. The influence of surface diffusivity on reverberation time prediction. Yan Zhang and Godfried Augenbroe (College of Architecture, Georgia Inst. of Technol., Atlanta, GA 30332)

It has been reported in the literature that the reverberation time tends to be overestimated if the ray-tracing simulation does not consider surface scattering effects. However no simple, quantitative method is available to estimate the effect of surface diffusivity on reverberation time. This article provides such a model to establish the relation between reverberation time and a surface diffusivity factor. It has also been observed that the influence of scattering reflections increases when the material is less uniformly distributed. Therefore the authors studied the current prediction method with non-uniformly distributed material and observed the following: Kuttruff equation based on the diffusive surface assumptions yields shorter reverberation times than Eyrings formula, while another equation containing reflective assumptions yields longer RT than Eyrings formula. It is demonstrated that the difference can reach up to 50%. Therefore the authors propose a linear combination of these two equations, with the proportion to each end determined by the surface diffusivity, assessed against Hann and Fricks method. A comparison between Boston Symphony Hall and New York Avery Fisher Hall is performed to demonstrate the significance of the surface diffusivity, and a Monte-Carlo simulation is included to support the result even under parameter uncertainties.

1:45

3pAA4. Aurally-adequate time-frequency analysis for scattered sound in auditoria. Molly K. Norris, Ning Xiang, and Mendel Kleiner (Dept. of Architectural Acoust., Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180)

The goal of this work was to apply an aurally-adequate time-frequency analysis technique to the analysis of sound scattering effects in auditoria. Time-frequency representations were developed as a motivated effort that takes into account binaural hearing, with a specific implementation of interaural cross-correlation process. A model of the human auditory system was implemented in the MATLAB platform based on two previous models [A. Härmä and K. Palomäki, HUTear, Espoo, Finland; and M. A. Akeroyd, A. Binaural Cross-correlogram Toolbox for MATLAB (2001), University of Sussex, Brighton]. These stages include proper frequency selectivity, the conversion of the mechanical motion of the basilar membrane to neural impulses, and binaural hearing effects. The model was then used in the analysis of room impulse responses with varying scattering characteristics. This paper discusses the analysis results using simulated and measured room impulse responses. [Work supported by the Frank H. and Eva B. Buck Foundation.]

2:00

3pAA5. Characteristics of scattered sound from overhead reflector arrays: Measurements at 1:8 and full scale. Timothy Gulsrud (Kirkegaard Assoc., 954 Pearl St., Boulder, CO 80302, tgulsrud@kirkegaard.com)

Measurements of sound scattering from reflector arrays have been carried out both at 1:8 scale in a controlled environment and at full scale in a concert hall. The results indicate wave interference between reflections from adjacent panels, resulting in an audible comb filter-like effect. Implications for the appropriate degree of overlap in coverage of adjacent panels will be discussed.

3pAA6. Effect of incidence angle and panel size on the phase of scattered energy from panel arrays. Jonathan Rathsam, Lily M. Wang (Architectural Eng. Program, Univ. of Nebraska Lincoln, 247 PKI, 1110 S. 67th St., Omaha, NE 68182-0681, jrathsam@mail.unomaha.edu), and Rendell R. Torres (Rensselaer Polytechnic Inst., Troy, NY 12180-3590)

This investigation focuses on factors that influence scattering from different ceiling panel arrays (e.g., incidence angle, and array size and density) by examining the scattered phase. A previous study by the third author [Torres and Vorländer, *Acta Acust.* (in press)] measured impulse responses using the maximum length sequence method at various receiver positions from scale model panel arrays of different sizes and densities. One interesting conclusion was that for multi-element arrays with panel dimensions and separation on the order of a wavelength, the reflected amplitude decreased, apparently due to destructive interference from inter-panel scattering. Analysis focused on the magnitude of the frequency response but the author noted that the phase curves could also contain information about scattered energy and the hypothesized inter-panel scattering. What the phase curves reveal is the subject of this study. It is expected that noticeable deviations from smoothness observed in the phase curves indicate non-specular scattering from the panels. The frequencies at which these deviations occur are examined to give insight into how the geometrical conditions of the panel array affect scattering.

2:30

3pAA7. A comparison of partially specular radiosity and ray tracing for room acoustics modeling. C. Walter BeamerIV (Dept. of Civil, Env., and Arch. Eng., Univ. of Colorado, Boulder, CO 80309) and Ralph T. Muehleisen (Illinois Inst. of Technol., Chicago, IL 60616)

Partially specular (PS) radiosity is an extended form of the general radiosity method. Acoustic radiosity is a form of bulk transfer of radiant acoustic energy. This bulk transfer is accomplished through a system of energy balance equations that relate the bulk energy transfer of each surface in the system to all other surfaces in the system. Until now acoustic radiosity has been limited to modeling only diffuse surface reflection. The new PS acoustic radiosity method can model all real surface types, diffuse, specular and everything in between. PS acoustic radiosity also models all real source types and distributions, not just point sources. The results of the PS acoustic radiosity method are compared to those of well known ray tracing programs. [Work supported by NSF.]

2:45

3pAA8. A new scattering method that combines roughness and diffraction effects. Claus Lyng Christensen (Odeon A/S c/o Acoust. Technol., rsted-DTU, Bldg. 352, DK-2800 Lyngby, Denmark)

Most of today's room acoustics programs make use of scattering coefficients which are used in order to describe surface scattering (roughness of material) and scattering of reflected sound caused by limited surface size (diffraction). A method which combines scattering caused by diffraction due to typical surface dimension, angle of incidence, and incident path length with surface scattering is presented. Each of the two scattering effects is modeled as frequency dependent functions. The benefits are two-fold: (a) Separating the user specified surface scattering coefficient from the room geometry, makes it easier for the user to make good guesses of the coefficients which will be in better agreement with the ones which can be measured. In many cases a scattering coefficient of say 1% for all surfaces may be sufficient. (b) Scattering due to diffraction is distance and angle dependent and as such it is not known before the actual raytracing or image source detection takes place. An example of this is that a desktop will provide a strong specular component to its user whereas it will provide scattered sound at far distances.

Session 3pAO**Acoustical Oceanography: Acoustical Oceanography Prize Lecture**

N. Ross Chapman, Chair

*Univ. of Victoria, School of Earth and Ocean Sciences, Victoria, BC V8W 3P6, Canada***Chair's Introduction—1:30*****Invited Paper*****1:35****3pAO1. Acoustic explorations of the upper ocean boundary layer.** Svein Vagle (OSAP, Inst. of Ocean Sci., P.O. Box 6000, Sidney, BC, Canada V8L 4B2, vagues@pac.dfo-mpo.gc.ca)

The upper ocean boundary layer is an important but difficult to probe part of the ocean. A better understanding of small scale processes at the air-sea interface, including the vertical transfer of gases, heat, mass and momentum, are crucial to improving our understanding of the coupling between atmosphere and ocean. Also, this part of the ocean contains a significant part of the total biomass at all trophic levels and is therefore of great interest to researchers in a range of different fields. Innovative measurement plays a critical role in developing our understanding of the processes involved in the boundary layer, and the availability of low-cost, compact, digital signal processors and sonar technology in self-contained and cabled configurations has led to a number of exciting developments. This talk summarizes some recent explorations of this dynamic boundary layer using both active and passive acoustics. The resonant behavior of upper ocean bubbles combined with single and multi-frequency broad band active and passive devices are now giving us invaluable information on air-sea gas transfer, estimation of biological production, marine mammal behavior, wind speed and precipitation, surface and internal waves, turbulence, and acoustic communication in the surf zone.

Session 3pID**Interdisciplinary: Hot Topics in Acoustics**

Beverly A. Wright, Chair

*Dept. of Communication Science and Disorders, Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208***Chair's Introduction—1:30*****Invited Papers*****1:35****3pID1. The Student Council.** David T. Bradley (Univ. of Nebraska—Lincoln, 1110 S. 67th St., PKI 245 Omaha, NE 68182-0681, dbradley@mail.unomaha.edu)

Throughout its history, the Society has been a strong advocate for students exploring the world of acoustics. However, only recently was that support institutionalized and the responsibility placed in the hands of the students themselves. In the spring of 2000, a nascent body was formed to address the needs and concerns of Student Members of the ASA. The Vancouver meeting marks the 5th anniversary of this group, now formally known as the Student Council. The Council has evolved markedly in the past several years. The Council is currently composed of one student representative from each of the 13 technical committees and one Student Chapter Liaison. Recent student focused activities include the creation of a state-of-the-art website, the production of the first in a series of fellowship/grant workshops, and the presentation of a new award honoring the efforts of mentors in the Society. The Council's main focus is disseminating information of concern to students, advocating participation of students in Society activities and meetings, and promoting Society membership benefits to potential student members. Current and future programming and opportunities available to students, and those who work with students, will be presented and discussed.

3pID2. The ASA Regional Chapters program. Elizabeth McLaughlin (Chair of Committee on Regional Chapters) and Juan Arvelo (Co-Chair of Committee on Regional Chapters, Johns Hopkins Univ., Appl. Phys. Lab., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099)

Are you involved in a Regional Chapter? The Regional Chapters Program certainly embraces the intent of our Society. "The ASA was founded . . . to increase and diffuse the knowledge of acoustics and promote its practical applications. Any person . . . interested in acoustics is eligible for membership." The history and the activities of each Chapter are unique. There are currently twenty active chapters uniquely positioned to promote acoustics through outreach and involvement with the public. There have been several new developments in the Regional Chapters Program, the most exciting being the incorporation of Student Chapters! Our first, the Nebraska Student Chapter, was approved at the 75th Meeting of the ASA in NYC. Several more are on their way! Existing Chapters are revitalizing! The Washington DC Chapter has recently found new enthusiasm, re-establishing a robust program. A new student scholarship has been organized thanks to the generosity of Larry and Julia Royster. Another recent enhancement is the expansion of the Regional Chapters Website. There one can find useful materials including an updated Chapter Start-up Kit. Involvement in a chapter is a great way to give back to the ASA, to learn, promote acoustics, to socialize, and to involve new persons in our exciting field!

3pID3. Imaging for understanding speech communication: Advances and challenges. Shrikanth Narayanan (Signal and Image Processing Inst., Univ. of Southern California, Viterbi School of Eng., Los Angeles, CA 90089-2564)

Research in speech communication has relied on a variety of instrumentation methods to illuminate details of speech production and perception. One longstanding challenge has been the ability to examine real-time changes in the shaping of the vocal tract; a goal that has been furthered by imaging techniques such as ultrasound, movement tracking, and magnetic resonance imaging. The spatial and temporal resolution afforded by these techniques, however, has limited the scope of the investigations that could be carried out. In this talk, we focus on some recent advances in magnetic resonance imaging that allow us to perform near real-time investigations on the dynamics of vocal tract shaping during speech. Examples include Demolin *et al.* (2000) (4–5 images/second, ultra-fast turbo spin echo) and Mady *et al.* (2001,2002) (8 images/second, T1 fast gradient echo). A recent study by Narayanan *et al.* (2004) that used a spiral readout scheme to accelerate image acquisition has allowed for image reconstruction rates of 24 images/second. While these developments offer exciting prospects, a number of challenges lie ahead, including: (1) improving image acquisition protocols, hardware for enhancing signal-to-noise ratio, and optimizing spatial sampling; (2) acquiring quality synchronized audio; and (3) analyzing and modeling image data including cross-modality registration. [Work supported by NIH and NSF.]

2:35

3pID4. Some recent condensed-matter applications of physical acoustics. Albert Migliori (Los Alamos Natl. Lab., MS E536, Los Alamos, NM 87545)

A non-inclusive sampling of recent advances in the application of physical acoustics to condensed matter physics is presented. Work by Ogi *et al.* on resonant ultrasound microscopy to map nano-scale variations in elastic moduli provides a new twist to the use of resonances. Laser-ultrasound studies by Wright and Matsuda on photoacoustic effects in ultra-thin metallic and semiconductor films leads to new meso-scale ultrasound studies, while Isaak and Ohno push the symmetry limits and temperature range of resonant ultrasound modulus studies. Migliori and Ledbetter extract the final pieces of an unusually-well-characterized charge-density-wave phase transition and examine very odd elastic behavior in materials with negative thermal expansion, while Pantea demonstrates an all-digital pulse echo system for high pressure work. Souslov probes hidden order with pulse-echo studies in pulsed magnetic fields. [Work supported by the National Science Foundation, the Department of Energy and the State of Florida.]

2:55

3pID5. Speech perception in the presence of other sounds. C. J. Darwin (Dept. of Psychol., Univ. of Sussex, Brighton BN1 9QG, UK)

The human listener's remarkable ability to recognize speech when it is mixed with other sounds presents a challenge both to models of speech perception and to approaches to speech recognition. This talk will review some of the work on how human listeners can perceive speech in sound mixtures and will try to indicate areas that might be particularly fruitful for future research.

3pSA1. Doubly asymptotic approximations for transient and time-harmonic acoustics. Thomas L. Geers (Dept. of Mech. Eng., Univ. of Colorado, Boulder, CO 80309-0427)

The development and application of doubly asymptotic approximations (DAAs) in computational structural acoustics are reviewed. Transient radiation/scattering is emphasized, but application to time-harmonic radiation/scattering is also addressed. DAAs formulated for elastodynamic, poroelastic, and electromagnetic scattering are described that illustrate the breadth of application. The advantages and limitations of DAAs are described, and their relation to retarded-potential, similarity-based, and infinite-element methods are discussed.

1:45

3pSA2. Extension of infinite elements to explicit dynamic and eigenanalysis of submerged structures. Jeffrey Cipolla (ABAQUS, Inc., 166 Valley St., Providence, RI 02909-2499)

Infinite elements are distinct from alternative methods for exterior problems in that, like a finite element, they describe a small sub-region of the problem domain, and use locally supported shape functions to derive a method of weighted residuals statement thereon. Until recently, transient analyses using explicit time-integration methods, and eigenanalysis, were not possible using infinite elements. A formulation of acoustic infinite element compatible with implicit dynamics, time-harmonic acoustics, far-field extrapolation, explicit dynamics, and eigenanalysis is described. First steps in the development are the adoption of a basis corresponding to spherical radiating harmonics, the Bettess geometric map, and the Astley-Leis weighted residual formulation. A modified means to compute the element integrals, and a modification of the spherical harmonic basis, improve numerical conditioning of the element and stability of the formulation. The trivial frequency dependence of the Astley-Leis formulation, critical for its application to transient problems, also enables a formulation for eigenanalysis, which will be discussed. Finally, a splitting of the element operator into tangential mass- and stiffness-like terms enables a partial lumping of the element, and compatibility with explicit time integration schemes. Importantly, this splitting preserves the essential radiation mode accuracy of the formulation. Some computational examples are shown.

2:15

3pSA3. Numerical study of fluid loading approximations for submerged spherical shells using finite, infinite and boundary element methods. Rui M. Botelho (Electric Boat Corp., Dept. 462-M.S. J129-2, 75 Eastern Point Rd., Groton, CT 06340-4989, rbotelho@ebmail.gdeb.com), Michael J. Butler (Electric Boat Corp., Groton, CT 06340-4989), and John F. Waters (Electric Boat Corp., Groton, CT 06340-4989)

Numerical studies were conducted to compare acoustic fluid loading approximations for submerged spherical shells. Rigid and empty elastic shells submerged in a heavy acoustic fluid and subjected to harmonic excitation were considered. Solutions using boundary elements, infinite elements, and analytical approximations were compared, with special attention to modeling the near-field fluid beneath the infinite elements. In this case, the near-field fluid is typically modeled using fluid finite elements with frequency dependent mesh refinement and radial extent. The spherical shell is modeled in the same manner using shell finite elements for both boundary and infinite element solutions in order to provide a direct comparison of the fluid loading approximations. Convergence studies involving the near-field fluid were performed with emphasis on the effects of meshing parameters, including refinement, mesh grading, and polynomial order of the radial basis functions for p -version fluid finite elements. Results of interest include comparisons of the submerged structural response, focusing on the reactive and resistance parts of the fluid impedance.

3pUW1. Frequency dependence of elliptical particle motion of acoustic waves transmitted into the seabed from a point source in water. David M. F. Chapman, Paul C. Hines, and John C. Osler (Defence Res. and Development Canada Atlantic, P.O. Box 1012, Dartmouth, NS, Canada B2Y 3Z7, dave.chapman@drdc-rddc.gc.ca)

When perpendicular components of the particle velocity of a continuous acoustic wave have unequal amplitude and phase, the displacement traces an elliptical path. This is caused by inhomogeneous waves and/or losses in the medium. For spherical waves radiating from a point source in water and transmitted into the seabed, the orientation of the elliptical orbit varies with receiver location and frequency, and the ellipse major axis is not always parallel to the direction of propagation suggested by Snell's law. If not accounted for, this could bias estimates of sediment sound speed derived from particle velocity measurements. This presentation describes a simple orbit model based on numerical evaluation of integrals for the transmitted field over the entire wavenumber range. The model provides rapid simulation of results for different experimental geometries and source frequencies. The model is validated using an established full-field model and compared with experimental data. [Work supported in part by ONR Code 32.]

3pUW2. Acoustic velocity measurements in seafloor sands at frequencies from 1 to 400 kHz. Michael A. Zimmer, L. Dale Bibee, and Michael D. Richardson (Naval Res. Lab., 1005 Balch Blvd., Stennis Space Center, MS 39529-5004)

We measured the acoustic velocity and attenuation at frequencies from 1 kHz to 400 kHz in shallow seafloor sands off Fort Walton Beach, FL, USA. We used three separate systems with overlapping frequency ranges in order to cover this entire frequency range. For frequencies from 1 to 20 kHz, we implanted a seafloor array of 35 hydrophones and 5 three-component accelerometers at depths from 0 to 1 m over a 4 m by 4 m area, and recorded signals from two acoustic sources positioned at offsets from 1 m to 20 m. Measurements from 15 to 120 kHz were made at 30-cm sediment depths with the *In Situ* Sediment Acoustic Measurement System (ISSAMS), which consists of a linear array of 4 piezoelectric probes; the outer probes transmit a single-frequency burst while the inner probes act as receivers. Additionally, velocity measurements were made on diver-collected cores (5–20 cm sediment depths) at frequencies from 50 to 400 kHz. We present comparisons of the measured frequency dependence of the acoustic velocity and attenuation to theoretical predictions from various constitutive and wave propagation models, parameterized with inputs from detailed characterizations of diver-collected cores.

2:00

3pUW3. Inverting for sandy sediment sound speed in very shallow water using boat noise. Dajun Tang (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

Small boat propeller noise was recorded on a single hydrophone in very shallow water for the purpose of estimating sediment sound speed. The experiment was conducted near shore in water depth between 2 and 10 m. The sediment consisted of uniform sand. The lone hydrophone was moored 2 m above the bottom at 6 m depth. A small boat traveling at constant speed was used as the sound source, and ran both parallel and perpendicular to shore. Thus, both the range independent waveguide case and wedge shaped waveguide case could be investigated. The source tracks were recorded by using a GPS recorder on the boat. Water depth in the entire area was measured, as was the sound speed profile at the receiver. The processed data sets resulted in interference patterns in range-frequency plots. Aided by numerical simulations, sediment sound speed can be estimated over the frequency range of 500–4500 Hz. [Work supported by the U.S. Office of Naval Research.]

3pUW4. Effect of frequency dependence of complex sound speed on impulse response in littoral seas. David Knobles (Appl. Res. Labs., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029)

For certain classes of sediments common to littoral ocean environments, there exists theoretical reasons and experimental evidence that the real part of the sound speed is frequency dependent. Further it has been observed for more than 30 years that to model transmission loss data below 1 kHz for such sediments, it is often required that the attenuation possess a non-linear frequency dependence. However, analyses of broadband propagation below 2 kHz in littoral waveguides commonly assume that sound speeds in marine sediments are frequency independent and that the attenuation depends linearly on frequency. It is natural to explore how the neglect of the frequency dependence of the complex sound speed affects the predictability of broadband propagation and under what conditions can inversion methods estimate the functional form of the frequency dependence. In this study simulated impulse responses for typical littoral waveguides over the 10–2000 Hz band are generated assuming a Biot-Stoll formulation. The effects of the frequency dependence of the complex sound speed on the impulse response are examined within the context of how does one form a valid inverse problem that would allow for the frequency dependence of the complex sound speed to be uniquely determined. [Work supported by ONR.]

3pUW5. Longitudinal wave dispersion and attenuation in a two phase granular material. Hasson Tavossi (Dept. of Physical and Environ. Sci., Mesa State College, 1100 North Ave., Grand Junction, CO 81501)

Longitudinal elastic wave-velocity and attenuation in a two phase granular material are investigated, in the cases of a random arrangement of grains in contact with each other, surrounded by water or air. The velocity dispersion and attenuation of a longitudinal wave are measured experimentally, at low and high frequencies and are analyzed in light of a modified

Biot theory. The results of these analyses on wave velocity and attenuation are expressed as a function of frequency, grain size, porosity, viscosity of the fluid phase, as well as elastic moduli and densities of the solid and fluid phases. It is shown that longitudinal wave velocity in such a material decreases with grain size and frequency at high frequencies. Results obtained by increasing the grain size resemble those measured by increasing the frequency. Wave attenuation is expressed as a function of frequency, porosity, grain size and fluid viscosity. Theoretical results are compared with the experimental findings on the wave velocity and attenuation.

*Elementary School Teacher, Vancouver, BC, Canada***Chair's Introduction—6:30****6:35****3eAA1. The need for good acoustic design of schools.** Bridget Shield (Dept. of Eng. Systems, Faculty of Eng. Sci. and Built Environment, London South Bank Univ., London SE1 0AA, UK)

This paper gives an overview of research into classroom acoustics, highlighting the importance of a good acoustic environment in schools to enhance teaching and learning. The paper is aimed at a general audience of people interested in education and school design. In the past 30 years there has been a great deal of research into the effects of noise and poor acoustics in schools on children and teachers. It has been shown in many studies that children have difficulty hearing and understanding their teachers in noise, and both external environmental noise and noise within a school affect children's academic performance. Furthermore many teachers suffer from voice and throat problems which may be attributable to a poor acoustic environment in the classroom. The acoustic design of a classroom has a direct influence upon noise levels and the intelligibility of speech. Poor sound insulation and excessive reverberation have the potential to increase noise levels and reduce speech intelligibility. However, despite the introduction in many countries of legislation or guidelines for acoustic design of schools, in general acoustics still has a low priority in school design and many schools, old and new, fail to meet the current standards.

7:35–9:35**Panel Discussion**

ACOUSTICAL SOCIETY OF AMERICA
Silver Medal in
Psychological and Physiological Acoustics

H. Steven Colburn

2004

The Silver Medal is presented to individuals, without age limitation, for contributions to the advancement of science, engineering, or human welfare through the application of acoustic principles, or through research accomplishment in acoustics.

ENCOMIUM FOR H. STEVEN COLBURN

... for contributions to psychological and physiological aspects of binaural hearing

VANCOUVER, CANADA • 18 MAY 2005

Steve Colburn was born in Portsmouth, Ohio on June 23rd, 1941. He attended Clay Township Rural High School in a farming community where his main interest was playing trumpet in the high school band and in a "dance band". He moved to Boston in 1959 to attend the Massachusetts Institute of Technology (MIT), being only the second person from his high school to attend college outside Ohio. He has lived and worked in Boston ever since.

At MIT Steve received S.B., S.M., and Ph.D. degrees during the 1960's and served as a faculty member in the Electrical Engineering Department for a number of years thereafter. From the early 1980's to the present, he has been a faculty member in the Biomedical Engineering Department at Boston University (BU), serving as Chair of the Department for about a decade. Steve's extended family includes, in addition to his wife Theo, three sons, a daughter-in-law, and two grandchildren.

Steve's scientific contributions in the area of binaural hearing, his main area of interest, are unique in their overall breadth; the extent to which they integrate perceptual data, physiological data, and sophisticated mathematical modeling; and, more generally, their profound influence on the criteria employed to define what it means to be a serious auditory scientist.

The breadth of his research is evident in his work published in *The Journal of the Acoustical Society of America* (JASA) over the past 40 years on the relation of binaural detection to lateralization, the effects of envelope and carrier interaural time delays, the implications of frozen-noise detection experiments for models of binaural detection, the roles played by peripheral versus central limitations on perceptual performance, the challenges faced by the binaural system in complex acoustic environments, and a large variety of issues associated with hearing impairments and hearing aids (including cochlear implants). Also noteworthy are the two review chapters in *The Handbook of Perception* on binaural hearing that he coauthored in 1979 and that still serve as major sources of information on both empirical and theoretical results underlying our understanding of binaural hearing. Finally, and perhaps most importantly, Steve's elaboration of Jeffress' model of binaural interaction, which appears in various forms in many of his JASA articles, has not only contributed greatly to binaural hearing theory, but also constitutes a wonderful tribute to perhaps the most highly revered figure in this field (and the first Silver Medal recipient in Psychological and Physiological Acoustics).

Steve's remarkable ability to exploit both experimental data and mathematical-modeling tools to gain deep understanding of the auditory system is clearly evidenced by his research on the performance that would be achieved by an ideal processor operating on the noisy outputs of the peripheral processing observed in the auditory system. In general, this approach provides a "synthetic surgical knife" to the problem of determining where in the auditory system the loss of information about an acoustic stimulus is most severe. To the extent that performance of this model matches the perceptual performance observed in humans, the major loss is in the periphery. To the extent that the performance of the model exceeds that of the human, the major loss is central. Steve's exploitation of this approach in the area of binaural hearing began while he was working with William Siebert at MIT in the 60's and has continued to this day. As time passes and quantitative physiological knowledge of neural activity includes increasingly central activity, the points at which this "synthetic surgical knife" can be applied include increasingly central locations in the auditory system.

In addition to Steve's outstanding direct contributions to auditory science, he has made enormous indirect contributions via his teaching and administrative/organizational work. His devotion to students and his excellence as a teacher are evidenced by his superior work as housemaster while at MIT, the many teaching awards he has received at BU, the great warmth shown to him by all of his students, and the substantial contributions these students have themselves made to auditory science. His great skills as an administrator/organizer have been clearly revealed by his work as Department Chair at BU; his creation and leadership of the Hearing Research Center at BU (which is recognized internationally as a leading center in auditory science); his contributions as an Associate Editor of *The Journal of the Acoustical Society of America*; and his service as a member of various review committees of the National Institutes of Health. Most remarkable,

perhaps, is his creation and leadership of the “Binaural Bash” at BU, an annual meeting dedicated to informal exchange of ideas, problems, and results, which is attended by a wide variety of scientists from all over the world.

As evidenced early on by his exploits as a mountain climber and cold-weather camper (who used to enjoy sleeping in a tent on Mt. Washington at -30° with 40 mph winds), Steve has a long history of addressing and solving challenging problems of many kinds.

CITATION FOR LILY M. WANG

... for contributions to room and musical acoustics

VANCOUVER, CANADA • 18 MAY 2005

Lily Wang has a contagious enthusiasm for life and acoustics, reinforced with responsibility, determination and resilience. Both of her parents were born in China and were raised in Taiwan. After her father received his degrees, her family moved to Chattanooga, Tennessee where he worked for the Tennessee Valley Authority. At the age of 11, Lily was involved in an automobile accident that took her mother's life. She continues to motivate herself with her mother's image in the back of her mind. While in high school she read about careers in architectural acoustics. This led her to a Bachelor of Science degree in Civil Engineering (with a Certificate in Architecture) from Princeton University, a Ph.D. in Acoustics from Penn State, an ASA Hunt Fellowship and a faculty position in architectural acoustics at the University of Nebraska.

She graduated from an all-female high school as class Valedictorian and was selected to be a United States Presidential Scholar, a program established to recognize and honor the nation's most distinguished graduating high school students. On her way to graduating from Princeton Magna Cum Laude, Lily began her foray into acoustics with summer internships at Georgia Tech and Jaffe Holden Associates, studying the integration of acoustics, aesthetics and technical design of fabric tension membrane structures.

Lily won National Science Foundation (NSF) and American Association of University Women (AAUW) fellowships to support her graduate studies in acoustics at Penn State. At Penn State, her interest in music, acquired at the age of four, led to her study of the acoustic radiation from violins. She recognized that there are three elements in the sound production from violins; excitation by the bow/string interaction, vibration of the violin body and acoustic radiation from the body, and that the last element had received far less attention than the first two elements. However, the analysis of the acoustic radiation from violins: required visualization of the acoustic field with a spatial resolution smaller than an acoustic wavelength. This required the application of nearfield acoustical holography to a violin played continuously over long periods of time. Lily applied ingenuity and tenacity in designing and building a bowing machine to excite violins and a nearfield acoustical holography system that surrounded the bowed violin, within the budgetary constraints typical of research on the acoustics of musical instruments. Her dissertation results were received with great interest by the musical acoustics community. She was invited three times to present papers at ASA meetings on her research. Her Ph.D. thesis led to several publications, one in *The Journal of the Acoustical Society of America*. Carleen Hutchins (and people passing by during a demonstration in Carleen's driveway) were impressed with the bowing machine. Carleen was also impressed with Lily, turning to me to tell me that she thought Lily knew more than I did. She got no argument there. The bowing machine now hangs from the rafters of my garage. Lily now says that she loved her time at Penn State, but only after the pain of sewing hundreds of horse hairs into the belt used in the bowing machine has diminished with time.

In the midst of her Ph.D. studies, Lily worked one summer at Bell Laboratories with Gary Elko on the application of boundary layer models to the turbulent field of a talker's mouth during speech plosives, and to methods of attenuation of the effects of the turbulent field. She demonstrated her ability to mix theory and measurements in developing a simple model that produced predictions that agreed with measured results.

Upon completion of her Ph.D., Lily was awarded the ASA F.V. Hunt Postdoctoral Research Fellowship in Acoustics. She then returned to her first interest, architectural acoustics, to study the subjective responses to acoustic fields in rooms, including auralization, at the Technical University of Denmark with Anders Christian Gade and Jens Holger Rindel. Her work was valuable and she has been invited back to the Technical University of Denmark to continue working on collecting data that relate subjective responses and objective measures of acoustic fields in large spaces, one of the most challenging problems in architectural acoustics. When Lily arrived at the University of Nebraska, the Architectural Engineering Department Program in the Peter Kiewit Institute had no acoustics program. In less than five years, she has developed one of the best programs in architectural acoustics in the country. She has transferred her enthusiasm to her students, many of whom are now active in the Society. Her work on spatial impression of musical acoustical fields in auditoria, objective measures in concert halls, effects of sound directivity and scattering on auralization, computer modeling of acoustic fields in rooms, classroom acoustics, reverberation and acoustic fields in coupled spaces, correlation of subjective and objective measures of speech

intelligibility, and the combined effects of temperature and noise on human performance are well known and favorably received as indicated by the seven invited ASA papers on these research projects. Lily is now one of the 'stars' in architectural acoustics and her impact on building a strong program at the University of Nebraska has been exemplary.

She is an active and popular contributor to the Society. In addition to being invited ten times to present papers at ASA meetings, she was one of the nine young presenters selected to speak on the future of acoustics at the Society's 75th anniversary meeting in May 2004. Lily is now the chair of the Architectural Acoustics technical committee, one of the largest and most active (and sometimes unwieldy) of the ASA technical committees. She is a member of the Newman Student Award Fund Advisory Committee and the Committee on Women in Acoustics, and has worked hard to develop the flourishing Architectural Acoustics Student Design competition.

In addition to her outstanding technical and educational contributions, Lily is a pleasure to be with. She is always surrounded by people at ASA meetings. I am sure we will see a lot of Lily in the future as she continues to serve the Society, the academic community and the world of acoustics with distinction.

Lily lives with Oliver, who I am sure, is one spoiled cat.

Gilles A. Daigle
2005

The Silver Medal is presented to individuals, without age limitation, for contributions to the advancement of science, engineering, or human welfare through the application of acoustic principles, or through research accomplishment in acoustics.

CITATION FOR GILLES A. DAIGLE

... for contributions to understanding the effects of micrometeorology, topography, and ground properties on outdoor sound propagation

VANCOUVER, CANADA • 18 MAY 2005

Gilles Daigle received a B.Sc. in physics from the Université de Moncton, New Brunswick, in 1975. He intended to do graduate work in nuclear physics, but that summer he worked as a student in the Acoustics Section at the National Research Council (NRC) in Ottawa and Gilles' career path underwent an abrupt change. He decided he would prefer to pursue a life in acoustics instead. NRC is not a degree-granting institution and so special arrangements were made with Carleton University in Ottawa. Gilles did the required coursework at the university and the acoustical work, both theoretical and experimental at NRC under the supervision of Tony Embleton and Joe Piercy.

Between 1975 and 1981 Gilles' work was devoted mainly to measuring the meteorological parameters of wind and temperature gradients, and the spectrum of sizes and intensity of turbulence. He related these parameters theoretically and by measurement, under many different weather conditions, to the resulting fluctuations of sound pressures. In this period, the titles of his M.Sc. and Ph.D. theses were "Effects of atmospheric turbulence on the interference of acoustic waves due to the presence of a boundary" and "Interference, diffraction and scattering of acoustic waves in a turbulent atmosphere." Apart from new theory, this work developed new measuring techniques using very short-time-constant electrical thermoanemometers originally developed for the air-conditioning and heating industry.

Since 1981 Gilles and his colleagues both at the National Research Council and elsewhere have systematically measured, and compared with the new theories, each of the many mechanisms that are relevant to sound propagation outdoors. These mechanisms include interference between direct waves and those reflected at the ground surface (often at near-grazing incidence where ground waves and surface waves can play a dominant role), the acoustical properties of many types of ground, diffraction over barriers, penetration into shadow zones, scattering by atmospheric turbulence, and refraction by vertical gradients of wind and temperature. Also included in Gilles' range of studies are more complicated, but realistic, ground surfaces such as layers of snow over harder ground surfaces and propagation across an asphalt-to-grass interface. Gilles' contributions to theoretical understanding, to experimental work indoors, and to field measurements outdoors have been substantial and sometimes unique. He has provided a theoretical structure that unifies several previously-incompatible databases and explains their deviations from traditional predictions. These databases were derived either from drive-by tests of motor vehicles at ranges up to 50 feet, from community noise measurements (50 to 1000 feet from the sources), or from measured aircraft or airport noise levels at ranges greater than a thousand feet. Often acousticians elsewhere have studied parts of this technical area in greater depth but less breadth than Gilles'; but he has worked in all the areas and so has a broad overview of the subject.

Gilles has shown that meteorological and topographical effects are noticeable and usually dominant for all distances of propagation greater than a few feet. This work is laying the foundation for community noise prediction schemes that can accurately predict sound levels for specific rather than average situations. These include different daytime and nighttime atmospheric profiles, and whether the listener is on the ground, in a highrise building, up a hillside or behind a hill. The economic benefits of this more accurate knowledge are immense—consider the economic consequences of decisions about the siting of airports and major highways, and the social benefits of locating highway noise barriers where they will provide the expected acoustical performance.

The peer recognition accorded Gilles' technical work is worldwide. The recognition started early when he received the Governor General's Gold Medal in 1975 from the Université de Moncton (awarded annually to the top undergraduate student, one in each Canadian university). He received the R. B. Lindsay Award of the Acoustical Society in 1988 and was a Plenary Session speaker at the 15th International Congress of Acoustics in Norway in 1995. He was a Guest Researcher at the Agency of Industrial Science and Technology in Japan in 1996, was awarded the Médaille Etrangère by the Société Française d'Acoustique in 2002, and has co-supervised over a dozen M.Sc. and Ph.D. students in both Canadian and French universities.

Gilles serves the Acoustical Society with great energy and enthusiasm. He has been chair of the Technical Committee on Physical Acoustics (1987-1990), chair of the Committee on Meetings (1996-1999), Associate Editor of *The Journal of the Acoustical Society of America* for Noise and its Effects and Control (1993-1997), chair of the Ottawa meeting in 1993, member of the Medals

and Awards Committee (1991-1994) and of the Nominating Committee for the 1993 election. Gilles was elected as a member of the Executive Council (1992-1995), as Vice-President Elect and Vice President he served as an Officer of the Society from 1999 to 2001, and while Past Vice President for one more year as a member of the Executive Council. Service to other acoustical organizations includes serving as Secretary General of the International Commission on Acoustics (1998-2001) and as its President (2001-2004). For the International Institute of Noise Control Engineering, he chaired an international study group on the effectiveness of roadside noise barriers, was Vice President for Technical Initiatives (1996-2002) and is currently its President Elect. Gilles has served different levels of government in a variety of ways, from training courses for local police forces to being a technical expert on a federal government environmental panel on military flying activities in Labrador and Quebec.

Gilles Daigle is a leader in the field of outdoor sound propagation with knowledge that spreads beyond acoustics to encompass the related factors of topography and micrometeorology. He serves as a leader of the international acoustical community through several of its societies and organizations. It is fitting that today the Acoustical Society of America recognizes Gilles Daigle by its most appropriate award, the Helmholtz-Rayleigh Interdisciplinary Silver Medal in Noise and Physical Acoustics.

TONY F.W. EMBLETON
MICHAEL R. STINSON

GOLD MEDAL of the Acoustical Society of America

Allan D. Pierce

2005

The Gold Medal is presented in the spring to a member of the Society, without age limitation, for contributions to acoustics. The first Gold Medal was presented in 1954 on the occasion of the Society's Twenty-Fifth Anniversary Celebration and biennially until 1981. It is now an annual award.

CITATION FOR ALLAN D. PIERCE

. . . for contributions to physical, environmental, and structural acoustics, acoustics education, and leadership as Editor-in-Chief of the Society.

VANCOUVER, CANADA • 18 MAY 2005

Iowa has made important contributions to acoustics; one of them is Allan Pierce, who was born December 18, 1936 in Clarinda. Allan's family lived in Wichita, Kansas during World War Two, then moved to Las Cruces, New Mexico, where he attended New Mexico State University. Two and a half years were sufficient for him to earn a B.S. with highest honors in Physics in 1957. From there, he pursued his graduate studies in the Physics Department of the Massachusetts Institute of Technology, which marks the beginning of his well-known affinity for the Boston area. In 1962 he was awarded the Ph.D. in physics for his thesis on electron lattice interactions in the Born-Oppenheimer approximation. With the encouragement of Philip Morse, who was on his Ph.D. committee, Allan went to work for the Rand Corporation in Santa Monica. We are thankful that Allan was new to the company. Otherwise Albert Latter probably would not have turned to Allan when the senior researchers working in quantum physics turned down a project in atmospheric propagation, thereby diverting Allan from the area of his doctoral work to acoustics.

Allan's second stay in the Boston area came when he transferred to the Avco Corporation in Wilmington from 1963 to 1966. He then returned to MIT as an Assistant Professor, where he was promoted to Associate Professor in 1968. Allan departed for the warmer climate of Atlanta in 1973 when he moved to the Georgia Institute of Technology as a Professor of Mechanical Engineering. He was awarded a Regents' Professorship there in 1976. During his tenure at Georgia Tech he had visiting positions at the Max Planck Institut für Strömungsforschung from 1976 to 1977, and the Transportation Systems Center of the U.S. Department of Transportation, which was his third stay in Boston. He departed Georgia Tech in 1988 for Pennsylvania State University, where he was a Professor and the Leonhard Chair Holder, with joint appointments in the Department of Mechanical Engineering and the Graduate Program in Acoustics. His most recent return to the Boston area was in 1993, when he became the Chair of the Department of Aerospace and Mechanical Engineering at Boston University. He stepped down from that position in 1999, but continues there as a Professor. Throughout his career, his wife Penelope Claffey, who he married in 1961, has been by his side. She and their children, Jennifer and Bradford, are justifiably proud of his accomplishments. He has successfully managed the difficult task of being a devoted husband and father, while simultaneously being fully committed to his profession.

Allan is an intellectual in the truest sense. If you cannot find Allan during a professional meeting, look for him in an antique bookstore. His interests are universal, and his research in a diverse range of topics always blends physical insight and mathematical rigor. Allan's early work addressed propagation of sound in the atmosphere. In a Letter to the Editor in *Nature*, he described how the magnitude of an explosion could be determined from its measured waveform, which was used to verify the ban on atmospheric testing of nuclear weapons, and subsequently to estimate the magnitude of the Mt. Saint Helen's eruption. His analysis explaining the effects of turbulence on sonic boom rise time remains one of the best available theories. It was a logical transition for him when he turned to problems in propagation in natural waveguides. The theory he developed to predict propagation in natural waveguides whose properties vary slowly with horizontal distance is still quoted today. Interestingly, this work was guided by analogies he drew with his thesis work. In fact, Allan's ability to recognize analogies between apparently different areas is an important attribute of his approach.

A complete survey of Allan's work would need to describe his contribution to development of the surface variational principle for radiation and scattering, and his application of geometrical acoustics concepts to describe wave propagation of plates and shells, which led to new insights into the interpretation of experimental data. A hot topic several years ago was "fuzzy structures," about which he provided mathematical insight to a much debated subject. One should also recognize his efforts in laser generation of sound, and diffraction around thick barriers. In each area, Allan's papers are at the core, and often the first to be cited by others.

Research is only one aspect of Allan Pierce. He was the chief architect of two outstanding programs in acoustics. At Georgia Tech, the prospect of working with him enticed several individuals, including me, to join the School of Mechanical Engineering. As department chair at Boston University he convinced the administration to expand the faculty, with many of the subsequently recruited faculty having research interests in acoustics. At Penn State, where the acous-

tics program was highly respected prior to his arrival, Allan provided an intellectual focus as a faculty colleague, as well as the Technical Director of the Center for Acoustics and Vibrations. In every academic position Allan has held, he has had a profound impact on a generation of young acousticians who he nurtured and mentored, and now are highly accomplished members of our Society. An important aspect of Allan's educational activities is his textbook, *Acoustics: An Introduction to Its Physical Principles and Applications*, which is one of the best-sellers in the ASA Books program. What a wonderful treatise it is, filled with theory, data, explanations, and references. I begin each acoustics course by telling the students that they will hate using his book in class, because it is more intense than most books they will encounter, but they will recognize upon completion of their studies that it has made them an acoustics expert.

Perhaps education will be his greatest legacy, and yet there is much more that is important. Allan is tireless in his professional activities, especially within our Society. Is there an area where he has not participated? Is there an activity where he has not taken a leadership role? Technical committees, Executive Council, Education, Membership, Chair of the American Society of Mechanical Engineers (ASME) Noise Control and Acoustics Committee, US National Committee for Theoretical and Applied Mechanics, and countless other activities that do not show up on a resumé. He was an area editor for our *Journal*, founding co-editor of the *Journal of Computational Acoustics* and co-editor of the Physical Acoustics series published by Academic Press. Presently he is a member of the Editorial Board of the *Journal of Sound and Vibration*. All this while serving as Editor-in-Chief for our *Journal*. He has taken over in a perilous time, with technology threatening our old ways. He has launched major initiatives to ensure that our *Journal* continues to be the premiere vessel for disseminating knowledge of acoustics. He has converted a part-time job into a full-time avocation. There are no better hands than his to guide the *Journal* into the future.

If Allen has an idol, it is Lord Rayleigh, which is a demonstration of the standards that he sets for himself and others. Allan delivered the Rayleigh Lecture at the ASME annual meeting in 1992. In November of last year at our meeting in San Diego, he was the first recipient of the Rossing Prize in Acoustics Education, for which he gave an enthralling talk on the life of Rayleigh. An incident when he was on the faculty of Georgia Tech vividly illustrates Allan's esteem for Rayleigh. We were conducting the oral part of the Ph.D. qualifying exam in acoustics. One student had done quite well, but we had some time left, so Allan asked him "Who was the greatest acoustician?" The student had studied everything, but not in a historical context, and clearly was flustered. After thinking for approximately a minute, he said to Allan "You!" Allan corrected him by simply saying "Rayleigh", then thanked him for the compliment. The student passed despite this serious gap in his knowledge!

Other recognitions Allan Pierce has received include the Senior U.S. Scientist Award from the Alexander von Humboldt Foundation in 1976, the Silver Medal in Physical Acoustics from ASA in 1991, and the Per Bruel Gold Medal for Noise Control and Acoustics from ASME in 1995. He was named the Outstanding Thesis Advisor by the Georgia Tech Chapter of Sigma Xi in 1988. I do not think that any one now alive has done as much as he to advance acoustics, not just as an area in which to work, but as a place in which to make a home. It is most appropriate that the prior recognitions of Allan Pierce's contributions be capped by our Gold Medal.

JERRY H. GINSBERG

Session 4aAA**Architectural Acoustics and Noise: Preserving Acoustical Integrity in the Course of Renovation**

Daniel R. Raichel, Chair
 2727 Moore Ln., Fort Collins, CO 80526

Chair's Introduction—8:30*Invited Papers***8:35**

4aAA1. Renovating Teatro alla Scala Milano for the 21st century, Part I. Higiní Arau (Travesera de Dalt, 118, 08024 Barcelona, Spain, h.arau@arauacustica.com)

Teatro alla Scala of Milan, known simply as La Scala throughout the world, is an old but venerable opera house that achieved legendary status in the world of music. A great number of singers of Olympian status have sung there; and major operas, among them Verdi's Falstaff and Otello and Puccini's Turandot, premiered there. The 227-year-old theater is beloved with a passion by the Milanese and the Italians, but it has suffered the ravages of time. It needed to be renovated in order to reverse material decay, meet current fire codes and security requirements, incorporate a new HVAC system, and to accommodate badly needed modern stage machinery. This renovation project took 3 years during which the theater was closed, and it included the construction of an elliptical 17-floor fly tower, designed by architect Mario Botta, for housing rehearsal rooms and serving as a scenery changing facility. The renovation proposal originally aroused a strong sense of melodrama among the extremely excitable Italian opera buffs who feared the desecration of their beloved edifice, but the acoustics and the beauty (carried out by Elisabetta Fabbri Architect) of the auditorium were preserved (and even enhanced). In this paper we explain how this project was achieved.

8:55

4aAA2. Renovating Teatro alla Scala Milano for the 21st century, Part II. Higiní Arau (Travesera de Dalt, 118, 08024 Barcelona, Spain, h.arau@arauacustica.com)

The acoustic phase of La Scala renovation began in September 2002, after the main stalls and other sections of the theater were demolished. This assignment was twofold: (a) design of the auxiliary building with architect Mario Botta, and more importantly, (b) collaboration with architect Elisabetta Fabbri in restoration of the auditorium through acoustic analyses of proposed solutions. Only one set of acoustical measurements was known to be taken before demolition; and reliance had to be placed on hearsay from audience members. The author used his own computer program that included some of the salient features of other programs such as Odeon, Epidaure, Raynoise, etc. but avoided their pitfalls. This program was the only one that correctly predicted the known RT of the auditorium through the use of H. Arau Purchades formula [Arau, H., 1988. *Acustica*. Hirzel Verlag **65**(4), 163–180] and the authors dimension theory [Arau, H. 1997. Variation of the reverberation time of places of public assembly. *Building Acoustics* **4**(2)]. A new floor was designed to provide sufficient vibration transmission to the audience, actuating as a radiation box installed to direct sound vertically. Music Director Ricardo Muti pronounced the acoustical results as being excellent.

9:15

4aAA3. Maintaining the acoustics of Boston Symphony Hall. Robert Berens, Benjamin Markham, and Carl Rosenberg (Acentech Inc., 33 Moulton St., Cambridge, MA 02138, rberens@acentech.com)

Boston Symphony Hall celebrated its centennial in 2000; one of its biggest birthday presents was a new organ. More correctly, the partially new and partially refurbished organ made its debut in October 2004, for James Levine's inaugural concert as Music Director of the Boston Symphony Orchestra. Symphony Hall's original organ was replaced in 1949, but its replacement was never regarded as a great concert instrument. While some wanted the new organ work to include turning the Hall into an organ showcase, the BSO management was adamant that the acoustics of the Hall not be affected. Acentech was asked to provide technical oversight to help minimize any such changes. Tests were conducted to assess the potential impacts that removal and renovation of the organ pipes could have on Symphony Hall's acoustics. Reverberation times were measured in the organ chamber, on-stage, and in the Hall. Remedial measures were devised for use, if necessary, to counteract the expected changes in the organ chamber acoustics as the pipes were removed. However, such changes showed little effect on the acoustics of the stage or the hall. This paper describes the work done during the organ renovation process to protect the hallowed acoustics of Symphony Hall.

9:35

4aAA4. Historical preservation of acoustics at Spelman College, Atlanta. Carl Rosenberg, Benjamin Markham (Acentech Inc., 33 Moulton St., Cambridge, MA 02138, crosenberg@acentech.com), and Barbara Kovacs Black (Surber Barber Choate & Hertlein Architects, Inc., Atlanta, GA 30309)

In 1926, Spelman College in Atlanta dedicated its new Sisters Chapel, named after Laura Spelman Rockefeller and Lucy Maria Spelman, mother and aunt of John D. Rockefeller, Jr., the major donor. The Chapel has around 1000 seats and serves as a major venue for a myriad of programs, ceremonies, concerts, and student activities. In 2003, architects Surber Barber Choate and Hertlein were commissioned to renovate and rehabilitate the chapel with air-conditioning, new toilet facilities, new roof, enlarged balcony, and new sound system. The neo-classic pseudo Georgian basilica has a barrel vault running the length of the room. Sometime in the past, probably around 1950, the chapel ceiling was covered with a sound absorbing acoustic tile, presumably to rectify a focusing problem from the curved ceiling. With computer modeling, Acentech reconstructed the apparent acoustical problems and used this information to guide a renovation. The goal was to recapture the visual aspects of the original design, enhance the reverberation for the renovated Holtkamp organ and singing, and at the same time avoid any focusing problems for which the acoustic tile was presumably added. The project included mechanical system noise and vibration control and a new highly directional sound system.

9:55

4aAA5. Barnum Hall—The continuing renovation of a Streamline Moderne theater. Neil A. Shaw (Menlo Sci. Acoust., Inc. P.O. Box 1610, Topanga, CA 90290-1610, menlo@ieee.org), Kenneth Koslow (Santa Monica Malibu Unified School District, Santa Monica, CA 90404), Jean Sedillos (Restore Barnum Hall, Santa Monica, CA 90403), and Jim Mobley (Renkus-Heinz, Foothill Ranch, CA 92610)

Barnum Hall, built by the WPA in 1937 and located on the campus of Santa Monica High School, was the first Santa Monica Civic Auditorium. After 60 years it was closed for renovations. The building has historic significance, which placed some limitation on the renovation design as to what could be done. Balancing the interests of the various stakeholders—the Santa Monica-Malibu Unified School District, the City of Santa Monica Landmarks Commission, fund raisers, high school faculty, and community members, among others—impacted the design and construction process. The first phase included expanding and modernizing the stage house and surrounding support areas. Phase II of the work was concerned with mitigating the orchestra level rear wall reflections, modifying the balcony nose profile, adding an orchestra pit lift, the purchase of a custom acoustical orchestra shell, and improving creature comfort (air conditioning) and amenities (improving restrooms, creating a backstage area, and refurbishing 75% of the theater seats). A study of several sidewall shaping schemes were then analyzed to determine if the improvement in the level of envelopmental sound warranted the cost. Phase III will see the installation of a modern sound reinforcement system and refurbishing the last section seats.

10:15–10:30 Break

10:30

4aAA6. Renovating cultural icons. Gregory Miller (Talaske, 105 N Oak Park Ave., Oak Park, IL 60301, greg@talaske.com)

Three case studies of historic renovations are presented where acoustics were a key component of the renovation process. Each hall is an icon of the cultural life in the surrounding community. The first case study is Troy Savings Bank Music Hall, a late nineteenth century musical gem where recent renovations (adding variable acoustic features) required that the unamplified acoustics be unaltered. The second example, the Coronado Theatre in Rockford, Illinois, illustrates the sensitive modification of the acoustics in a historic vaudeville house adapted to modern multi-use requirements. Finally, The Great Hall at The Cooper Union in New York City, where Abraham Lincoln delivered his great “Right Makes Might” speech in 1860, is presented as an example of a renovation that utterly destroyed a historic acoustic environment, and discusses how this can be avoided.

Contributed Papers

10:50

4aAA7. Returning an acoustic legend to its original glory (and then some). Scott Pfeiffer (Kirkegaard Assoc., 801 W. Adams St., 8th Fl., Chicago, IL 60607)

Hill Auditorium at the University of Michigan broke all of the rules of modern day acoustic design, while still providing a tremendously rewarding experience for large audiences. The combination of diverse and intriguing programming by the University Music Society and the University Music Department, including the use of the Frieze Memorial Organ, provides tremendous opportunities for the community of Ann Arbor, MI to access great performances. The restoration project included air conditioning, elevators, and new sound systems. Additionally, improvements were made with respect to seating; specifically, sightlines, accessible seating, and under balcony seating were improved upon. This restoration project provided opportunities to revitalize the already famous acoustics without sacrificing unique and characteristic qualities of the hall. By drawing on

the original architects, Albert Kahn Associates, utilizing the expertise of Quinn Evans Architects, as well as through the help of Gary Steffy Lighting, Fisher Dachs Associates, and many others in design and construction, (most notably a great client in the University of Michigan), the project secured the 2004 AIA National Honor Award.

11:05

4aAA8. Preserving the acoustics of the Mahaiwe Theater. Ronald Eligator (Acoust. Dimensions, 145 Huguenot St., New Rochelle, NY 10801, religator@acousticdimensions.com)

The Mahaiwe Theater, Great Barrington, Massachusetts, opened in 1905. It has been home to vaudeville, traveling Broadway shows, opera, concerts, and movies. In 2003, the theater began a multi-phase renovation project. The renovation project includes restoration of historic finishes,

4a THU. AM

new seating, installation of air conditioning and heating systems, and installation of sound and projection systems. A stage shell for music performances will also be installed. A key aspect of the renovation is the preservation of what has been widely regarded as excellent acoustics. Some aspects of the original structure contributed to this reputation (e.g., room shaping, finishes), while others undoubtedly were less helpful (e.g., the 1905-era ventilation system). The renovation provides an opportunity to preserve the positive attributes of the room, while correcting the deficiencies. Among the key issues discussed are the design of historically-sensitive finishes that respect the acoustic requirements of the multi-use space, acoustical design of a new quiet air conditioning system, and design of an enclosure for music ensembles.

11:20

4aAA9. Preservation of the acoustics of the Salt Lake Tabernacle, Lessons learned from acoustical characterization of the hall. Sarah Rollins and Timothy Leishman (Acoust. Res. Group, N283 ESC, Brigham Young Univ., Provo, UT 84606, sr223@email.byu.edu)

Current and historical properties of the Salt Lake Tabernacle have been investigated to characterize its unique acoustics. This characterization will be used to help maintain the current acoustical conditions after a seismic renovation. This paper discusses computer models developed for this purpose and impulse response measurements taken to quantify the acoustics in their current state. It also explores spatial variation of room acoustic parameters derived from the models and measurements.

Animal Bioacoustics: Tools for Animal Bioacoustics: New Designs and Directions I

William C. Burgess, Chair
Greeneridge Sciences, 6060 Graham Hill Rd., Felton, CA 95018

Chair's Introduction—8:15

Invited Papers

8:20

4aAB1. A binaural acoustic recording tag reveals details of deep foraging in beaked whales. Mark Johnson, Peter Madsen, Peter Tyack (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543, majohnson@whoi.edu), and Natacha Aguilar de Soto (Univ. La Laguna, Tenerife, Spain)

A new acoustic and orientation recording tag (DTAG) for marine mammals contains two hydrophones, 25 mm apart, sampled at 192 kHz. Data are stored with loss-less compression in 6.6 GB of memory giving a 9.5 h recording capacity. Stereo DTAGs have been attached with suction cups to Cuvier's and Blainville's beaked whales in Liguria and the Canary Islands. Both species make regular clicks centered at 40 kHz during foraging dives. The DTAGs recorded clicks from the tagged whale and other whales nearby as well as echoes from targets in the water. The angle-of-arrival (AoA) of these sounds was determined both by cross-correlation and time-delay fitting of signals from the two hydrophones on the tag. The AoAs of clicks from tagged whales reveal that they turn their heads from side-to-side while foraging while the AoAs of echoes are consistent with a beam-width of about 20°. By scanning a narrow acoustic beam, the whales may be able to search a large water volume while reducing clutter from multiple echoes. Frequent clicks from untagged whales with distinct AoAs indicate that several whales forage together during deep dives and such group cohesion may be a contributing factor to strandings of these species related to use of naval sonar.

8:40

4aAB2. Miniature self-contained acoustic recorders applied in a survey of beluga-whale populations in Knik Arm, Alaska. William C. Burgess (Greeneridge Sci., 6060 Graham Hill Rd Ste F, Felton, CA 95018), Michael T. Williams (LGL Alaska Res. Assoc., Anchorage, AK 99518), and Susanna B. Blackwell (Greeneridge Sci., Aptos, CA 95003)

Since 1995, acoustic recording tags attached to marine wildlife have increased our understanding of how animals use and respond to sound. Tagging studies require these instruments to be designed for minimum size and maximum recording capability; however, by designing for ease of use as well, a variety of other acoustic studies become feasible that could not otherwise be attempted for lack of time, staff, or support. As a result, designing for ease of use multiplies the scientific power of acoustic recording tag technology. In late 2004 four acoustic recording tags, known as Bioacoustic Probes and developed by Greeneridge with ONR support, were used as fixed recorders in a primarily visual survey of beluga whales in the Knik Arm of Cook Inlet, Alaska. The study took place with a compressed schedule and was staffed by field biologists with little time available for technical training on the use and maintenance of the instruments. Designing the instruments for ease-of-use enabled the study to include an independent acoustic component for assessing the presence or absence of beluga whales in areas that were being surveyed visually during daylight hours. [Work supported by Knik Arm Bridge and Toll Authority.]

9:00

4aAB3. Modular autonomous array deployments using passive acoustic time synchronization. Aaron Thode (Marine Physical Lab., Scripps Inst. of Oceanogr., 9500 Gilman Dr., MC 0238, La Jolla, CA 92093-0238, thode@mpl.ucsd.edu) and William Burgess (Greeneridge Sci., Felton, CA 95018)

Multi-element acoustic arrays generally use wired cable to transmit signals to a central recording location. While convenient, hardwiring hydrophones together increases array fragility and field costs while decreasing deployment flexibility. It is thus difficult to integrate acoustic array operations with field activities involving marine mammals in remote environments. Economic trends in the cell-phone and consumer electronics industries, combined with recent trends in tagging technology development, have led to the existence of compact low-power autonomous acoustic recorders that store data to either flash memory or small hard drives. In this presentation it is shown how two or more autonomous recorders can be time-synchronized using passive acoustic measurements of the background ambient noise field, effectively creating coherent array processing systems of varying aperture, spacing, and deployment geometry. Configurations tested to date include short and large-aperture vertical arrays off the coasts of Australia and Alaska, bottom-mounted horizontal arrays in San Ignacio Lagoon, Baja California, and instruments installed inside a glider. [Work sponsored by ONR Acoustic Entry Level Faculty Award.]

9:20

4aAB4. High-frequency Acoustic Recording Package (HARP) for long-term monitoring of marine mammals. Sean Wiggins, Chris Garsha, Kevin Hardy, and John Hildebrand (Scripps Inst. of Oceanogr., 9500 Gilman Dr. MPL-0205, La Jolla, CA 92093-0205)

Advancements in low-power and high-data-capacity computer technology during the past decade have been adapted to autonomously record sounds from whales over long time periods. Acoustic monitoring of whales has advantages over traditional visual surveys including greater detection ranges, continuous long-term monitoring in remote locations under various weather conditions, and lower cost. One currently used tool for providing long-term acoustic monitoring of marine mammals is an autonomous acoustic recording package (ARP) which uses a tethered hydrophone above a seafloor-mounted instrument frame. Since 2000, ARPs have been deployed to record baleen whale sounds in the Bering Sea, in the Beaufort Sea, in the Gulf of Alaska, off the coast of southern California, around Antarctica and near Hawaii. ARP data have provided new information on the seasonal presence, abundance, call character and patterns of calling whales. The need for a broader-band, higher-data capacity system capable of recording odontocete whales, dolphins and porpoises for long time periods has prompted the development of a High-frequency Acoustic Recording Package (HARP). The HARP design is described and data analysis strategies are discussed using examples of HARP broad-band (sample rates up to 200 kHz) recorded data.

9:40

4aAB5. A near-real-time acoustic detection and reporting system for endangered species in critical habitats. Christopher W. Clark, Thomas Calupca (Bioacoustics Res. Program, Cornell Lab. of Ornithology, 159 Sapsucker Woods Rd., Ithaca, NY 14850), Douglas Gillespie (Intl. Fund for Animal Welfare, Yarmouth Port, MA 02675), Keith Von der Heydt, and John Kemp (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Passive acoustics is an effective mechanism for detection and recognition of species-specific sounds and can be a more cost-effective approach than visual techniques for monitoring populations of rare or endangered species. A network of moored buoys has been strategically deployed in and around Cape Cod Bay to report detections of northern right whales in critical habitat. Each buoy continuously and automatically monitors for right whale contact calls and transmits detection and ambient noise data by cell or satellite phone to Cornell University on a regular basis. Each day, validated data are automatically unloaded into a Website database to provide on-line graphical and numerical data summaries. The array of three buoys deployed in the Bay will eventually be synchronized to allow localization and tracking of individual animals. [Work supported by funds from the NOAA Right Whale Grants Program and augmented by funds from the Commonwealth of Massachusetts Division of Marine Fisheries.]

10:00–10:10 Break

10:10

4aAB6. Extensible bioacoustical analysis software: Two examples. Harold G. Mills and Harold K. Figueroa (Bioacoustics Res. Program, Cornell Lab. of Ornithology, 159 Sapsucker Woods Rd., Ithaca, NY 14850, hgm1@cornell.edu)

Two extensible software tools for bioacoustical analysis have been developed by the Bioacoustics Research Program at the Cornell Laboratory of Ornithology. Each tool provides a framework for sound visualization and analysis, supporting both manual selection and automatic detection of acoustic events in arbitrarily long recordings, manual annotation and automatic measurement of properties of these events, and management of the created acoustic metadata. The acoustic events of interest might include animal vocalizations and/or anthropogenic sounds. Simple examples of measurable event properties include duration, total energy, and spectrum. More advanced measurements might classify sounds according to the species or individuals that produced them, or estimate the location of a vocalizing animal. Both software tools can be extended in various ways, including the addition of new detectors and measurements. It has been found that this extensibility adds great value to the tools by allowing them to be readily adapted for new applications by bioacousticians or others with programming ability. It has also been found that such tools greatly facilitate the development of new detection and measurement algorithms by allowing prototype algorithms to be rapidly evaluated. Several case studies are presented that illustrate these principles. [Work supported in part by NSF.]

4aAB7. Measurement of biosonar signals of echolocating bat during flight by a telemetry system. Hiroshi Riquimaroux (Dept. of Knowledge Eng. and Comput. Sci., Doshisha Univ., Kyotanabe, Kyoto 610-0321, Japan)

A telemetry microphone system (Telemike) has been developed, which can be mounted on the bat's head, to measure acoustic characteristics of emitted pulses and returning echoes. The system allows us to monitor what the bat listens to during its flight. A high-speed video camera system has been also adopted together with the Telemike to trace positions in space of the flying bat for analyzing temporal pulse emission patterns. With those devices, how the CF-FM bats execute parallel time-sharing real-time processing during their flight can be investigated. Doppler-shift compensation, echo amplitude compensation and processing for multiple target detections were observed. Some of the evidence found by the Telemike will be introduced and discussed. [Work partly supported by the Innovative Cluster Creation Project promoted by MEXT and by a grant to RCAST at Doshisha University from MEXT.]

4aAB8. 3D modeling and animation techniques to elucidate mechanisms of echolocation-based acoustic perception. Seth Horowitz (Univ. at Stony Brook, Dept Psychiatry, HSC T-10 Rm. 086, Stony Brook, NY 11794, shorowitz@neuropop.com) and James Simmons (Brown Univ., Providence, RI 02912)

Current models of echolocation focus on the presence of specular acoustic surface reflections or "glints" as the perceptual cues that provide information about object distance and geometry. Using current material and motion 3D modeling techniques for visual animation, we have developed models of common real-world elements that can be detected by bat biosonar. By mapping acoustic reflectivity data from natural and artificial targets onto luminosity, specularity and reflection coefficients for materials and accurate spatial models of these objects, we have generated visual glint-like reflections from object surfaces that are similar to echolocation data. This allows us to create 3D visual animations of echolocation auditory scenes. Using these animations, human observers can integrate object shapes, sizes and movements based on gestalt grouping, particularly when the target moves or the echolocation source is in moving in relation to the target. These types of modeling tools may help elucidate the perceptual phenomena arising from integration of the individual acoustic glint structures that allow bats and other echolocating animals to create complex umwelts from auditory data.

4aAB9. The acoustic environment of the southern resident killer whales in Haro Strait: Propagation modeling and analysis of field measurements. Christopher Jones and Michael Wolfson (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

We will discuss the complicated shallow water acoustic environments of the southern resident killer whales in the Haro Strait of the Puget Sound through combined analysis of field measurements and acoustic propagation modeling in the frequency range of 1 to 20 kHz. Haro Strait is a highly variable acoustic environment with active commercial shipping, whale watching, and Naval activity. Southern resident killer whales are of unique public concern in this area because of potentially high impact by anthropogenic sound sources, either by auditory masking that may interfere with foraging strategies or annoyance and disorientation due to complicated reverberation. Predictive acoustic modeling in combination with field measurements can aid in understanding the mechanisms of impact and better inform assessment of the risk, providing a critical step towards the quantitative evaluation of impact in the context of complicated environments, changing background sound levels, and emerging management issues. Preliminary results of modeling and analysis of data collected in the summer of 2004 will be presented.

11:20

4aAB10. Ship strike acoustics. Edmund Gerstein, Joseph Blue (Leviathan Legacy Inc., 1318 SW 14th St., Boca Raton, FL 33486), and Steve Forsythe (Naval Undersea Warfare Ctr., Newport, RI)

The confluence of Lloyds mirror effect together with acoustical shadowing and spherical spreading pose significant detection challenges for whales and manatees. Direct measurements of approaching vessels using horizontal and vertical hydrophone arrays demonstrate how the noise from vessels can become indistinguishable from ambient noise. Geometric scattering is also estimated for various hull dimensions as the acoustical shadows cast ahead of ships provide no warning to animals near the surface within the shadow zone. Animals at sufficient depths, or outside the shadow boundaries that hear approaching vessels, may seek refuge near the surface or directly in the path of vessels where it is relatively quiet. Speed reductions proposed to reduce collisions do not address the underlying acoustical challenges marine mammals face. Field measurements support predictions that noise intensity is proportional with vessel speed to the 5th power. In multiple ship environments the acoustical masking challenges are greatest and noise from slow vessels operating in marine mammal corridors can mask the sounds of distant faster moving vessels. A low intensity bow-mounted projection system has been designed to selectively fill-in acoustical shadows with modulated ship noise to mitigate masking and near surface effects, and neutralize the dangerous ambiguity posed by acoustical shadows.

4aAB11. Detection ranges for acoustic based manatee avoidance technology. Richard Phillips (Dept. of Mech. and Aerosp. Eng., Univ. of Florida, Gainesville, FL 32611-6250), Christopher Nierecki (Univ. of Massachusetts Lowell, Lowell, MA 01854-2881, Chris_Nierecki@uml.edu), and Diedrich O. Beusse (Univ. of Florida, Gainesville, FL 32610-0126)

The West Indian manatee (*Trichechus manatus latirostris*) has become endangered partly because of watercraft collisions in Florida's coastal waterways. Several boater warning systems, based upon manatee vocalizations, have been proposed to reduce the number of collisions. One aspect of the feasibility of an acoustically based system relies upon the distance at which a manatee vocalization is detectable. The magnitude of environmental noise and manatee vocalizations, as well as the acoustic spreading properties of the habitat will help to estimate the detection range of a vocalizing manatee. This study combines measured source levels of manatee vocalizations with the modeled acoustic properties of manatee habitats to develop a method for determining hydrophone spacing requirements for acoustically reliant manatee avoidance technologies. In quiet environments (background noise 70 dB) it was estimated that manatee vocalizations are detectable at approximately 250 m, with a 6 dB detection threshold. In louder environments (background noise 100 dB) the detection range drops to 2.5 m. Noise generated by boating traffic is also investigated. In a habitat with 90 dB of background noise, a passing boat with a maximum noise floor of 120 dB would be the limiting factor when it was within approximately 100 m of the hydrophone.

Session 4aNS**Noise, ASA Committee on Standards and Engineering Acoustics: Noise Control Feasibility: Technical, Legal and Economic Issues**

John P. Seiler, Cochair

Mine Safety and Health Administration, Cochran Mill Rd., Pittsburgh, PA 15236

Angelo J. Campanella, Cochair

*Campanella Associates, 3201 Ridgewood Dr., Hilliard, OH 43026-2453***Chair's Introduction—9:00*****Invited Paper*****9:05****4aNS1. Industrial noise control—Technical and economic feasibility.** Stephen I. Roth (Roth Acoust. Assoc., 2352 Norton Rd., Pittsburgh, PA 15241, sroth@rothacoustics.com)

Industrial noise control is too often considered technically not possible or economically infeasible. The use of ear protection devices becomes the fallback approach to attempt to reduce the risk of worker hearing loss. In reality there are noise control opportunities in industrial settings than are low cost and provide significant noise reduction without affecting production and maintenance practices. This paper will present mechanical and pneumatic noise controls that can be successfully applied to industrial environments. This paper will also present information on OSHAs approach to determine whether engineering noise controls are considered economically feasible.

Contributed Papers**9:25****4aNS2. The feasibility of noise and reverberation control for good acoustics in classrooms.** Bennett M. Brooks (Brooks Acoust. Corp., 27 Hartford Turnpike, Vernon, CT 06066, bbrooks@brooksaoustics.com)

The acoustics of classrooms has been the subject of increasing scrutiny, as good speech intelligibility is recognized as an essential feature of an effective educational environment. There is consensus on the need for low levels of background noise and reverberation. Acceptable values for these parameters have been published as a standard [ANSI S12.60-2002]. The technical feasibility of achieving these goals is well established. In the US, few jurisdictions require that classrooms meet acoustical standards. The limits to constructing acoustically adequate classrooms are primarily economic. Perception and understanding of the issue are also important, as those who specify and pay for classrooms, school boards and taxpayers, are not those directly served in them, students. As the direct customers and their immediate providers, teachers, have little power, feasibility depends on competing priorities set by interested non-users. Therefore, advocates must sell the cost/benefits to the decision makers. Widely scattered data are available on costs as a percentage of the total school building project. However, detailed cost data for individual mechanical system components that meet noise standards are scarce. Also, long-term economic paybacks

must be quantified. Available cost data and areas needing better definition are summarized here.

9:40**4aNS3. Low impact renovations with high performance sound insulation.** Kenneth P. Roy and Sean D. Browne (Armstrong Innovation Ctr., 2500 Columbia Ave., Lancaster, PA 17604)

Architectural renovations, although often driven by visual objectives, are a good opportunity to pursue acoustical interventions involving both sound intrusions into a space, and sound quality of the acoustic environment within the space. A high priority is to keep the construction impact low as it affects both project cost and schedule. Obviously, if the architectural intervention can be accomplished using external measures such as the addition of added elements to the existing structure, then that would be a definite advantage. Test data will be presented for the application of sound insulating/absorbing panels to existing drywall structures. It will be shown that such an overlay panel can add sufficient damping to result in essentially "mass law" performance of the system. This will not only result in STC improvement, but more importantly will result in even higher voice insulation between spaces. This effect will be auralized for comparison listening purposes. If the added panel is also of a sound absorbing nature, such as those used in the tested cases, then they will also have the effect of adding to the receiving room sound performance.

9:55

4aNS4. Structural vibration isolation design for a magnetic resonance imaging (MRI) system. Chad Himmel (JEAcoust., 1705 W Koenig Ln, Austin, TX 78756, info@jeacoustics.com)

This structural vibration control case study presents problems, constraints and design solutions for existing magnetic resonance imaging system (MRI) installation in a medical office facility. Objective: Reduce MRI noise received in adjacent, unrelated spaces. Manufacturer's data indicated that airborne MRI sound emissions could exceed permissible noise criteria for nearby occupied rooms. Experience with MRI systems indicated possibility of structure borne vibration that could result in radiated noise in other spaces. Structure borne vibration paths needed attenuation or isolation, to prevent excessive or annoying and distracting noise to adjacent office spaces. In addition, containment design was required for loud noises in the magnet room. Measurements revealed transient vibration of building floors, walls, and ceilings coincident with MRI operation. Measurements also revealed transient airborne noise levels consistent with radiated sound produced by vibration acceleration of large surfaces. Spectral analyses of noise and vibration led to design of a retrofit vibration isolation mounting scheme for the MRI on existing building floor. Design parameters included structural resonance of slab, manufacturer's allowable vibration for MRI, and receiver room permissible criteria. Noise and vibration measurements will show building conditions before and after implementation of retrofit vibration isolation mounts. Plan and section drawings will illustrate design solutions.

4aNS5. MRI system vibration and noise considerations in hospital design. Eric E. Ungar and Jeffrey A. Zapfe (Acentech, Inc., 33 Moulton St., Cambridge, MA 02138, eungar@acentech.com)

Magnetic Resonance Imaging (MRI) systems are increasingly being located on above-grade floors of hospital buildings. The floor structures that support these systems need to provide vibration environments that satisfy the system's criteria, and airborne and structure-borne transmission of noise to neighboring areas needs to be taken into account in order to provide acceptable acoustical environments in these spaces. The fundamental operating principles of MRI systems are reviewed in relation to the systems' susceptibility to vibration and to their sound producing mechanisms. Vibration criteria for some widely used systems are discussed and spectra of airborne and structure-borne noise are illustrated. Means for vibration control and for the attenuation of structurally transmitted sound are delineated, together with architectural considerations for limiting noise transmission to spaces adjacent to MRI suites.

10:45

4aNS6. Psychoacoustical comparison of active versus passive noise control techniques. Gerard Mangiante and Georges Canevet (Laboratoire de Mécanique et d'Acoustique, CNRS, 31 Chemin Joseph-Aiguier, 13402 Marseille Cedex 20, France)

Comparisons of active versus passive noise control techniques can be found in various papers. However, this comparison mainly concerns economic, operational, or technical considerations. The present contribution aims at describing the psychoacoustical effects produced by some of the classical solutions used in passive and active noise control. The models introduced by Zwicker and his coworkers, and by Moore and Glasberg are used to evaluate the auditory efficiency of passive and active noise control techniques. Several types of signals were examined: (i) test signals obtained with a band of noise embedded in a white noise or a pink noise; (ii) actual environmental noises: noise produced by the turbine of an aircraft or by a car engine, and several interior noises (locomotive, helicopter and car). It is shown that the modifications in the spectrum of a signal that can be produced by active control are sometimes disappointing, because they

induce a subjective enhancement of the high-frequency portion of the spectrum. What the listener then commonly reports is that overall the signal has become slightly softer, but also more unpleasant. The use of a hybrid noise control technique, combining active and passive control, can greatly reduce this effect.

11:00

4aNS7. Adaptive multi-modal active noise control. Adam K. Smith, Jeffrey S. Vipperman, and Daniel D. Budny (Univ. of Pittsburgh, Dept. of Mech. Eng., 648 Benedum Hall, Pittsburgh, PA 15261)

Low frequency Active Noise Control (ANC) has been found to work well for sound suppression in acoustic ducts. Feedforward and feedback are the two distinct methods in which to implement (ANC) schemes. A feedforward implementation is realized by utilizing a known disturbance measurement (e.g. with a microphone), and using the measurement to compute the actuator (loudspeaker) signal. Feedback control modifies dynamics of an enclosed sound field to add damping. For example, one can use a resonant filter in the feedback path that is tuned to a selected mode in the enclosed sound field to be controlled. The resonant filter model is similar to those used for positive position feedback (PPF) in structures. A method of compensating the strong speaker dynamics (phase angle) was recently investigated by Bisnette and Vipperman (2004). The method was found to improve the performance and stability of the controller. Here, the above mentioned procedure is expounded upon to provide improved multi-modal performance, using higher order band-pass filters. Methods for adapting the controller parameters (e.g., gain, frequency, bandwidth) are also presented.

11:15

4aNS8. Acoustic power and intensity control by absorptive materials arrangement in an enclosure. Sung-Ho Cho and Yang-Hann Kim (Dept. of Mech. Eng. KAIST, 373-1 Sci. Town, Daejeon-shi, Korea)

This paper studies how the sound distribution of room or cavity is affected by the absorptive materials arrangement on the wall. In other words, we want to know, very specifically, how the change of boundary condition affects rooms sound distribution. The boundary condition can be modified by changing not only absorbers position but also its acoustic impedance. The effect of changing boundary condition is expressed in terms of modal admittance on the enclosures surface. What we have gotten from this study is that the absorptive materials placement is closely related to wave length, cavity size and geometry. The authors pay attention to the intensity field, especially reactive intensity divergence in space. The divergence of reactive component of intensity is directly related to acoustic energy distribution which is composed of potential and kinetic energy. Using acoustic energy balance equation, the relation between global noise control performance and absorptive material arrangement is explained. In this point of view, the possibility of global noise reduction will be discussed in terms of acoustic potential energy reduction.

11:30

4aNS9. Sound attenuation by lattices of rigid elliptic cylinders. Daniel Torrent, Andreas Håkansson, and José Sánchez-Dehesa (Nanophotonics Technol. Ctr., Tech. Univ. of Valencia, E-46022 Valencia, Spain, jsdehesa@upvnet.upv.es)

The attenuation properties of acoustic barriers consisting of a few layers of rods with elliptical cross section has been studied by multiple scattering theory. Their performance as a function of number of layers and orientation of the ellipses will be reported and compared with similar structures based on cylinders of circular section. A comparison with available experiments will also be presented. Finally, a genetic algorithm is applied to optimize the attenuation in a wide range of frequencies. [Work supported by MEC of Spain.]

Session 4aPAa**Physical Acoustics, Biomedical Ultrasound/Bioresponse to Vibration and ASA Committee on Standards: Cavitation and Other Mechanical Effects in Biomedical Ultrasound: A Special Session to Honor the Work of Wesley Nyborg I**

Lawrence A. Crum, Cochair

Applied Physics Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698

Junru Wu, Cochair

*Dept. of Physics, Univ. of Vermont, Burlington, VT 05405***Chair's Introduction—7:55*****Invited Papers*****8:00****4aPAa1. Wes Nyborg: Scientist, role model, and friend.** Marvin C. Ziskin (Ctr. for Biomed. Phys., Temple Univ. Med. School, 3420 N. Broad St., Philadelphia, PA 19140)

Wesley L. Nyborg obtained his Ph.D. degree in physics at Pennsylvania State College in 1947. He has held faculty positions at Penn State, Brown University, and since 1960 has been at the University of Vermont where he is presently Emeritus Professor. Dr. Nyborg's entire career has been devoted to biophysical acoustics: low frequencies at first, but since the early 50s ultrasonic frequencies of biomedical interest. He has made significant contributions in many areas of ultrasound biophysics, especially in cavitation and other non-thermal mechanisms relevant to biological effects. He has also derived a number of important relationships that are widely used today in determining temperature elevation in clinical ultrasound examinations. He has been the role model and friend to many colleagues, and has received many awards.

8:20**4aPAa2. Sound sources and propagation.** Mahlon Burkhard (157 Stephen Ln., Charles Town, WV 25414)

From July 1945 through May 1950, the Acoustics Laboratory of the Department of Physics at Pennsylvania State [College] University conducted "investigations concerning the production and propagation of sound, both sonic and ultrasonic, in the lower atmosphere, through the ground, and in other media." Wesley L. Nyborg was a key member of the group of 53 researchers employed in the program at some-time during the period. A sound source used extensively in the study of ultrasonic propagation in the atmosphere was a small whistle. "Edge tones" generated by a jet of air impinging on a narrow object are phenomena critical to the operation of these whistles as well as organ pipes and many sounds associated with fluid flow. Because the sound can be controlled and levels can be quite high, one proposed application was as a source for radiating small quantities of liquids with ultrasound. In addition to developing a physical understanding of this sound generation mechanism, Nyborg participated in studies and analysis of the influence of micrometeorology on propagation of high frequency sound in the atmosphere.

8:40**4aPAa3. Infrasonic tonal resonances of tropical hurricanes.** Samuel A. Elder (Phys. Dept., U.S. Naval Acad., Annapolis, MD 21402)

In news pictures saturating the media last summer there is contained subtle but compelling evidence that tropical hurricanes emit intense and extremely low-frequency tones, originating in the eye. The excellent symmetry of a well-formed eye predisposes the central cavity of a hurricane to resonate in the normal modes of a low- Q nearly cylindrical chamber, due to the slight mismatch in sound speed at the eye wall. Second order perturbation analysis of interaction between eye-modes and steady wind corkscrewing up through the eye has confirmed that positive feedback is generated, the condition for self-excited oscillation. Dimensions and speed of typical hurricanes require that the tones have frequencies on the order of $1/100$ of 1 Hz, which is doubtless the reason why they have escaped previous detection. Visual evidence appears in multiple alternating rain and dry bands that originate around the inner circumference of the eye wall, observable in aerial photos by NOAA. These are most easily explained as due to intense acoustically-driven temperature oscillations about the dew point, inside the eye. For a given hurricane, the actual tonal frequencies can be deduced from the spacing of these startups.

9:00

4aPAa4. Some medical applications of acoustic streaming. Lawrence A. Crum (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

Classical acoustic streaming results when an acoustic field is absorbed in a liquid, and the resulting momentum transfer causes the liquid to be translated. Acoustic microstreaming results when a bubble or other compressible entity is caused to oscillate by an acoustic field and hydrodynamic flow is induced in the vicinity of the oscillating surface. Much of the pioneering work on this general topic was performed by Wesley Nyborg and his students at the University of Vermont. There are a number of conditions for which acoustic streaming can be useful in medical ultrasound; e.g., one can enhance diffusion rates of drugs by inducing streaming at a specific site in tissue; together with Doppler imaging, one can determine the consistency of a particular sample of fluid, such as a blood clot. These and other examples of the use of streaming in medical ultrasound will be presented. [Work supported in part by the NIH and NSBRI.]

9:20

4aPAa5. The mechanical index and cavitation in tissue. Charles C. Church and Xinmai Yang (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

The mechanical index (MI) quantifies the likelihood that exposure to diagnostic ultrasound will produce an adverse biological effect by a nonthermal mechanism. The current formulation of the MI is based on inertial cavitation thresholds in two liquids, water and blood, as calculated by Apfel and Holland [Ultrasound Med. Biol. **17**, 179–185 (1991)]. Although tissue contains a high proportion of water, it is not a liquid but a viscoelastic solid. The importance of this difference was studied by deriving a Keller-Miksis-like equation assuming a gas bubble in a linear Voigt solid and performing numerical computations similar to the analytical work underlying the MI. Thresholds for inertial cavitation were determined for pulse lengths of 1–14 acoustic periods, equilibrium bubble radii (R_o) of 0.1–10.0 mm, a frequency range of 0.5–15.0 MHz, 2 threshold (P_t) criteria: $R_{max} = 2R_o$, and $T_{max} = 5000$ K, and tissue elasticities and viscosities of $G = 0, 0.5, 1.0$ or 1.5 MPa and $\mu = 0.005$ or 0.015 Pa·s; which span the range of values for soft tissue. It is found that thresholds in tissue are up to 10 times those in liquid, and that P_t increases nearly linearly with frequency. The relevance of these results to ultrasound safety will be discussed.

9:40

4aPAa6. Wesley Nyborg and bioacoustics at the University of Vermont. Junru Wu (Dept of Phys., Univ. of Vermont, Burlington, VT 05405)

Wes Nyborg came to UVM in 1960. Burlington, Vermont has become his home. He did his most pioneering research in microstreaming, acoustic radiation pressure and bioeffects of ultrasound at UVM. His research was continuously supported over 20 years by NIH. In 1987, after receiving Ph.D. in Physics and working with Isadore Rudnick for two years as a postdoc in the field of nonlinear physics, I joined the faculty of the University of Vermont as an assistant professor. Dr. Nyborg just retired from teaching in 1986. He was the person who convinced me to start research in the field of biomedical ultrasound. This presentation will review the development and achievement of bioacoustics at UVM and will also introduce him as a mentor, friend, colleague and collaborator.

4aPAa7. A technique for monitoring and controlling cavitation activity during high intensity focused ultrasound application. Charles R. Thomas, Caleb H. Farny, Ronald A. Roy, and R. Glynn Holt (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington Street, Boston, MA 02215)

It has been reported that cavitation can lead to enhanced heating in the focal region of a HIFU source. In order to exploit this heating for *in vivo* use, it is essential that the cavitation only occur in the focal region. Thus, the onset and evolution of inertial cavitation activity must be monitored and controlled during HIFU therapy. One candidate sensor is a confocally-aligned passive cavitation detector; however this would add complexity to a clinical HIFU applicator. Instead we propose that the HIFU source itself can serve as a monitoring device. The combination of broadband acoustic emissions (inertial cavitation) and backscatter (stable cavities) emanating from the HIFU focus manifests itself as fluctuations of the otherwise constant driving voltage amplitude, providing a convenient means for sensing cavitation activity. We will present results of experiments assessing the feasibility of using the variance in the amplitude of the HIFU drive voltage as a feedback control signal. Success is determined by the shape of the lesion created using supplemental control compared to the shape obtained otherwise. Two independent control parameters were used: the amplitude and the duty cycle of the HIFU. [Work supported by the Department of the Army award DAMD17-02-2-0014.]

10:45

4aPAa8. Spherical bubble pulsation between parallel plates. Jianying Cui, Mark F. Hamilton (Dept. of Mech. Eng., Univ. of Texas, 1 University Station C2200, Austin, TX 78712-0292), Preston S. Wilson, and Evgenia A. Zabolotskaya (Univ. of Texas, Austin, TX 78713-8029)

A simple model is proposed for investigating bubble pulsation in a constrained medium. In free space, compressibility of the surrounding medium introduces primarily radiation losses that can often be neglected. In a constrained medium, compressibility plays an essential role. The example we investigate here is linear pulsation of an acoustically driven spherical bubble between two parallel rigid plates. The method of images is used to obtain a bubble dynamic equation that accounts for time delays associated with reflections of pressure waves radiated by the bubble. When the bubble is midway between the plates, the series of terms for the reflections can be expressed in closed form. For narrow plate separations, less than about ten bubble diameters, the bubble resonance frequency is reduced from its value in a free field due to increased effective inertia of the liquid, and radiation damping is increased. For larger plate separations, but less than the acoustic wavelength, the quality factor associated with radiation damping is proportional to plate separation. If effects of compressibility are ignored, the effective inertia becomes infinite, and bubble pulsation is prohibited by the equations of fluid mechanics. [Work supported by NIH Grant EB004047 and ARL IR&D funds.]

11:00

4aPAa9. Evaluation of backscattered intensity to quantify the destruction rate of echogenic liposomes. Tyrone M. Porter, Sampada S. Vaidya, Christy K. Holland (Dept. of Biomed. Eng., Univ. of Cincinnati, Cincinnati, OH 45267), Shao-Ling Huang, Robert C. MacDonald (Northwestern Univ., Evanston, IL), and David D. McPherson (Northwestern Univ., Chicago, IL)

Echogenic liposomes (ELIP) are vesicles with a phospholipid bilayer shell that can serve as ultrasound contrast agents (UCA) for diagnostic purposes and for targeted drug delivery. The efficacy of ELIP as an UCA depends upon its stability in an acoustic field, whereas the use of ELIP for drug delivery will require releasing the encapsulated drug rapidly at the desired treatment site. The objective of this study was to evaluate the rate of destruction of ELIP as a function of pressure and pulse repetition frequency (PRF). Assuming ELIP destruction is directly related to its echogenicity, transducers with center frequencies of 3.5, 7.5, and 10 MHz were used to acquire pulse-echo data from ELIP suspensions ([lipid] = 0.2 mg/ml). The rate of ELIP destruction was defined by fitting an exponential decay function Ae^{-kt} to the backscattered intensity data. The relationship between ELIP destruction and acoustic pressure and PRF was determined by comparing the decay time constant k across samples. Based on this analysis, the rate of ELIP destruction was found to be directly proportional to pressure and PRF for all frequencies tested.

11:15

4aPAa10. Microbubble oscillations and stability for drug delivery. John S. AllenIII (Dept. of Mech. Eng., Univ. of Hawaii-Manoa, 2540 Dole St., Honolulu, HI 96822)

Ultrasound contrast agents have been developed from micron size bubbles whose gas core is enclosed by a polymer, lipid or protein shell. Furthermore, specific designs have been developed for drug delivery in which the ultrasound contrast agent acts as drug delivery vehicle. A drug may be suspended in the shell of these agents which is released at a

particular site as the microbubble undergoes destruction. Localized delivery depends on the destruction of a sufficient number of bubbles within a confined geometry typically a capillary or small vessel. Experimental evidence suggests the composition and thickness of the shell play important role in the break-up. Break-up scenarios of buckling have been suggested for elastic shell agents and shape stability for fluid shell agents. However, these have not been rigorously examined theoretically. The formulations of contrast agent designed for drug delivery are highlighted including a description of a double polymeric layer design. Shape stability equations for fluid shell agents are derived and analyzed in limiting cases. Furthermore, biological issues related to potential endothelial cell transport and interactions are briefly discussed.

11:30

4aPAa11. Cavitation inception on micro-particles: Possible drug carriers? Manish Arora, Bram Borkent, and Claus-Dieter Ohl (Phys. of Fluids, U. Twente, Postbus 217, 7500 AE Enschede, The Netherlands)

Hydrophobic particles are known to act as cavitation nuclei when they are exposed to a sufficient tensile wave. Yet, the dynamics of cavitation inception from particles, the growth of the bubble and the separation from the particle has only recently been observed. [M. Arora, C. D. Ohl, and K. A. Moerch, Phys. Rev. Lett. **92**, 174501 (2004)] In this presentation, high-speed photography of the remarkable dynamics is presented together with a modeling effort using a force balance approach. One of the results is that particles are accelerated to velocities up to 10 m/s and detach from the bubble. It was proposed, that micro-particles might act as drug carriers which can be activated by a tensile wave and accelerate into tissue or cells. In an effort to explore this possibility experiments on the cavitation inception ability on various types of micro-particles have been conducted in a reproducible way. Cavitation inception is initiated with a single cycle tensile wave and recorded with a camera. The number of cavitation bubbles decreases from shot-to-shot, which can be explained with one-time trigger-able nucleation sites on the particles.

Physical Acoustics: Wind Noise and Atmospheric Sound Propagation

Richard Raspet, Chair
Univ. of Mississipi, NCPA, Coliseum Dr., University, MS 38677

Contributed Papers

8:00

4aPAb1. Framework for windnoise studies. Richard Raspet, Jeremy Webster, and Kevin Dillion (Dept. of Phys. and Astron., Univ. of Mississippi, P.O. Box 1848, University, MS 38677)

Research in wind noise reduction in outdoor measurement microphones has been limited largely to comparisons between bare and screened microphones. Morgan and Raspet [J. Acoust. Soc. Am. **92**, 1180–1183 (1992)] used simultaneous wind velocity and noise measurements to show that the source of wind noise is incident wind fluctuations. In this paper, two methods for predicting the upper limits of wind noise pressure spectra

from velocity spectra in the inertial range are developed. A lower limit on wind noise is estimated from two theories of the intrinsic turbulent pressure fluctuations. Empirical results for the self-noise windscreens in substantially non-turbulent flows are also presented. Measurements of the wind velocity spectra and wind noise spectra from a variety of windscreens are described and compared to the theoretical predictions. All of the wind noise data lies between the upper and lower limits. The theoretical framework allows windscreens to be evaluated in terms of the best and worst-case scenarios and establishes practical lower limits on wind noise reduction for varying wind conditions. 4aPAb2. Nighttime traffic noise in an urban environment. Kenneth E. Gilbert, Roger Waxler, Carrick L. Talmadge, and James P. Chambers (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677, kgilbert@olemiss.edu)

Traffic noise ducted near the ground at night and in the early morning can be represented simply in terms of normal modes. The effects of surface loss and atmospheric absorption, as well as meteorology, are contained in the mode attenuation coefficients. For a long (5–10 km) road section, the average noise levels are a function of the product of the mode attenuation coefficients and the perpendicular distance from the roadway. This paper considers a two-dimensional model for computing the effective mode attenuation coefficients in an urban environment. Modal attenuation is estimated by propagating modes over an irregular surface that approximates typical urban structures. The mode attenuation due to scattering from the urban structures is compared to the attenuation from atmospheric absorption and from a finite ground impedance. Predicted noise levels are compared to available data and the implications for nighttime urban traffic noise are discussed.

4aPAb3. The stability of the nocturnal quiet height. Roger Waxler, Kenneth E. Gilbert, (NCPA, U. of Mississippi, University, MS 38677, rwax@olemiss.edu), and Carrick Talmadge (NCPA, University, MS 38677)

It has recently been demonstrated that for narrow band signals propagating in the nocturnal boundary layer there is a height, a few meters off the ground, at which the sound pressure is significantly reduced. In this presentation the stability of the quiet height against fluctuations of the sound speed will be discussed. It is demonstrated theoretically, and verified by experiment, that, in the first few meters of the atmosphere, the dependence of the sound pressure level on altitude, relative to the sound pressure level at any fixed altitude, is insensitive to sound speed fluctuations.

8:45

4aPAb4. Wind noise at a flush microphone in a flat plate. Kevin Dillion, Richard Raspet, and Jeremy Webster (Dept. of Phys. and Astro., Univ. of Mississippi, P.O. Box 1848, University, MS 38677)

Elliot [Boundary Layer Meteorology 2, 476–495 (1972)] states that a flush-mounted microphone can measure the turbulent pressure fluctuations in outdoor flows without self-noise problems. This suggests that flush mounted microphones can be used to minimize wind noise. Wind velocity spectra from a hot wire anemometer and wind noise spectra from a flush-mounted microphone in a flat plate at ground level have been measured outdoors. The velocity power spectral densities and average velocities as a function of height are determined from the data. The measured pressure power spectral densities are compared to theoretical values calculated from fluid dynamic and meteorological turbulence theory. In particular we investigate the contributions of predicted turbulence-turbulence and turbulence-mean shear contributions to the pressure spectrum measured at the surface of the plate. [Prepared in part through collaborative participation in the Collaborative Technology Alliance for Advanced Sensors sponsored by the US Army research Laboratory under Cooperative Agreement DAAD19-01-0008.]

4aPAb5. Spatial correlations in fluctuations induced by long-range propagation of sound in the atmosphere. Carrick L. Talmadge, Shantharam Dravida, Kenneth E. Gilbert, and Roger Waxler (Univ. of Mississippi, NCPA, Oxford, MS 38677, clt@olemiss.edu)

Amplitude and phase fluctuations associated with sound propagating over long distances are well known to increase rapidly with distance [e.g., Wilson, Noble, and Coleman, J. Atmos. Sci. 60, 2473 (2003)]. This increase in the fluctuation level is usually given as an argument that the

sound source becomes temporally incoherent after propagating large distances, making signal processing techniques that rely on the temporal coherence of the signal impracticable for single microphone measurements. Results are presented from a series of experiments designed to measure the spatial coherence of sound in both day- and nighttime conditions. In these experiments, 24-element horizontal and 8-element vertical arrays were used to measure the coherence of sound sources over the frequency range 30–200 Hz (horizontal array) and 100–500 Hz (vertical array). In many of these experiments, surprisingly large spatial coherences in the source strength were observed. These results suggest that array measurements may allow us to compensate for the poor temporal coherence of the signals for long-range propagated sound. We will also discuss the different sources of the observed fluctuations in the sound level and phases for daytime versus nighttime conditions. These sources include atmospheric turbulence, changes in the nocturnal boundary layer height and nocturnal gravity waves.

9:15

4aPAb6. Numerical simulation of acoustic tomography of the atmosphere. Vladimir E. Ostashev, Sergey N. Vecherin, George H. Goedecke (Phys. Dept., New Mexico State Univ., Las Cruces, NM 88003, vostashe@nmsu.edu), D. Keith Wilson (U.S. Army Engineer Res. and Development Ctr., Hanover, NH 03755), Alexander G. Voronovich (NOAA/ETL, Boulder, CO 80305), and Edward G. Patton (Natl. Ctr. for Atmospheric Res., Boulder, CO 80307)

A state-of-the-art array for acoustic travel time tomography of the atmosphere is under construction by several organizations in the U.S. The array will allow the estimation of the temperature and wind velocity fields within a tomographic volume located a few meters above the ground with a horizontal size of about 80 m. This paper is devoted to numerical simulation of acoustic travel time tomography of the atmosphere. The temperature and velocity fields within the tomographic volume are modeled with the use of quasi-wavelets and Large Eddy Simulation. Then, the travel times of sound propagation between different pairs of sources and receivers of the tomography array are calculated. Given these travel times, three algorithms for reconstruction of the temperature and velocity fields are employed: the cell approach, basis function approach, and stochastic approach. It is shown that the first of these approaches allows us to reliably estimate the mean temperature and velocity vector within the tomographic volume, while the other two give a good reconstruction of fluctuations in the temperature and velocity with respect to their mean values. [Work supported by ARO, Grants DAAD19-03-1-0104 and DAAD19-03-1-0341.]

9:30

4aPAb7. Modeling pulse propagation in the nocturnal boundary layer. Roger Waxler, Kenneth E. Gilbert (NCPA, Univ. of Mississippi, University, MS 38677, rwax@olemiss.edu), Sergey Kulichkov (Russian Academy of Sciences), and Carrick Talmadge (NCPA, University, MS 38677)

The propagation of broad band (0 to 1000 Hz) pulses in downward refracting atmospheres over lossy ground is modeled in the time domain by Fourier synthesis using a modal model for sound propagation in the frequency domain. Of particular interest is the dispersion of the pulse as it propagates. A conjecture of Chunchuzov, Bush, and Kulichkov [J. Acoust. Soc. Am. 88, 455–461 (1990)] that at long ranges such pulses have a universal form, is shown to be true. In general, at long ranges from the source, the pulse develops a narrow band tail, centered around 20 or 30 Hz. This tail is formed by the superposition of surface modes.

9:45

4aPA8. Prediction of aerodynamically generated sound via 3D particle velocity measurements. Sean Wu, Aditya Kumar, Zhi Ni (Dept. of Mech. Eng., Wayne State Univ., 5050 Anthony Wayne Dr., Detroit, MI 48202), and Hans-Elias de Bree (Microflow Technologies, AH Zevenaar, The Netherlands)

It has been shown [Wu and Hu, *J. Acoust. Soc. Am.* **103**, 1763–1774 (1998)] that acoustic radiation from a vibrating object can be calculated directly by an Alternate Integral-formulation Method (AIM), once the particle velocity distribution over a hypothetical surface enclosing this object is specified. This concept is extended here to prediction of aerodynamically generated sound. The particle velocity distribution on a hypothetical enclosure is measured by a fully integrated sound pressure-velocity ($p-u$) probe. This novel $p-u$ sensor combines a MEMS particle velocity sensor and miniature pressure transducer, which allows for measurements of the acoustic pressure and particle velocity at a single point simultaneously. It is simple and easy to use and is suitable for both narrow and broadband sound measurements. This $p-u$ probe is employed to measure the particle velocity field generated by a typical hairdryer. Measurements thus obtained are taken as input to AIM to predict the radiated acoustic pressure field. Experiments are conducted inside an anechoic chamber at the Acoustics, Vibration, and Noise Control Laboratory at Wayne State Uni-

versity. The predicted acoustic pressures are then compared with those measured at the same locations by microphones. Satisfactory agreements are obtained at all frequencies.

10:00

4aPA9. A comparison of conventional and metal foam windscreens. Gunnar R. Becker, Guenther H. Hermstruewer, and Rainer Knoetsch (Rheinmetall Defence Electron. GmbH, Brueggeweg 54, 28309 Bremen, Germany)

In outdoor applications wind induced noise reduces the signal quality significantly. Conventional windscreens made of polyurethane (PU) foam are widely used to reduce this noise. However under harsh environmental conditions such as high temperatures, exposure to UV radiation, etc., PU may suffer. An alternative may be the usage of metal foams instead of PU foams. Spherical windscreens made of open-pored metal foam with dimensions close to commercial ones and different pore distributions have been manufactured by m-pore and were tested under different wind conditions. Comparative measurements between both conventional PU- and metal foam windscreens indicated that the reduction of wind induced noise is almost the same. A reduction of the receiver level due to the windscreens was not observed. Measurements and test results will be presented. [Work supported by m-pore.]

Physical Acoustics: Thermoacoustics and Particle Agglomeration

Matthew E. Poese, Chair

Applied Research Lab., Pennsylvania State Univ., State College, PA 16804

Contributed Papers

10:45

4aPac1. Specific acoustic impedance measurements of a thermoacoustic stack. Heui-Seol Roh, Richard Raspet, and Henry E. Bass (Dept. of Phys. and Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

Simmons [Ph.D. dissertation, University of Mississippi, 2003] attempted to use a two-microphone specific acoustic impedance (SAI) measurement of a thermoacoustic stack to determine the thermoviscous functions and the coefficient of the thermal gradient in the acoustic pressure differential equation for arbitrary geometry stacks. The proposed method was tested in part by comparing the measured and predicted SAI of a well-characterized parallel pore stack. Significant disagreement between theory and measurement occurred. In this paper the results of an improved four microphone SAI measurement on the well-characterized stack are reported. This measurement will reduce uncertainties in the transfer matrix method used by Simmons and determine if the discrepancies in Simmons work were experimental or if the thermoacoustic theory is incomplete.

11:00

4aPac2. High frequency operation of thermoacoustic coolers and prime movers. Husam El-Gendy, Young Sang Kwon, and Orest G. Symko (Dept. of Phys., Univ. of Utah, 115 S. 1400 E., Rm. 201, Salt Lake City, UT 84112-0830)

By operating thermoacoustic engines at high frequencies, 4 kHz and higher, the devices have characteristics which are important for many applications. Since they are resonant systems, the power density increases with frequency. Reduction of device size provides quick thermal response time in both the cooler and the prime mover. Moreover, small device size

makes it practical to incorporate them into arrays, which can handle large powers. Most important is the fact that small devices make it simple for operation at high pressures in working gas without exceeding strength of materials limitations. This leads to high power densities. Results will be presented to illustrate how the above features affect device performance for the frequency range of 4 kHz to 21 kHz. Measurements using Particle Image Velocimetry of streaming, instabilities, and resonator mode interactions will be discussed for this high frequency range. Ultimately as the operating frequency is raised, device efficiency is limited by heat conduction along the stack and working fluid. [Work supported by the Office of Naval Research and the State of Utah.]

11:15

4aPac3. Initial investigations into thermoacoustic coal agglomerators. Gordon Smith (Dept. of Phys. and Astronomy, Western Kentucky Univ., 1 Big Red Way, Bowling Green, KY 42101)

Each year, Kentucky coalmines produce about 160 million tons of coal, mainly used to generate electricity at power plants in Kentucky and throughout the midwestern and southeastern United States. Coal processing generates an excessive amount of pollution in the form of heavy exhaust, which creates an environmental concern. In response to this growing concern for a balance between environmental impact and energy production, many processing plants utilize electrostatic precipitation (ESP) systems to agglomerate and filter out particulate matter (PM) from exhaust streams before they enter the general environment. However, ESP efficiency is limited by the size of the particulate exhaust. Particle agglomeration also results via time-averaged forces inherent in an acoustic standing wave. Thermoacoustic technology, which utilizes waste heat sources for operation, embodies an ideal source for providing the requisite acous-

4a THU. AM

tic conditions. This technology could also be installed to supplement existing technology as a preconditioner (increasing the particle size to one more suitable for current ESP systems), and increase the overall PM removal efficiency. This talk will present initial investigations into applying thermoacoustic technology to this problem.

11:30

4aPac4. Experimental study of aerosol concentration in flow-through, low-frequency resonators. Douglas Meegan, Justin Smith, and Wayne Wright (Appl. Res. Labs., Univ. of Texas, Austin, TX 78713-8029)

An experimental method to study the concentration of micron-sized aerosols in a low-frequency sound field was developed. The physical mechanism for acoustic aerosol concentration in a low-frequency sound field is the asymmetric Stokes drag which has been predicted to exceed the effects of radiation pressure for typical aerosol sizes [Meegan and Ilinski, *J. Acoust. Soc. Am.* **114**, 2387 (2003)]. Related experiments were conducted in which 5 micron aerosol was drawn through a small duct that was driven in a transverse resonant mode with peak sound pressure levels of greater than 150 dB re 20 microPascals and frequencies in the range 1 to 10 kHz. The aerosol stream was illuminated by a laser sheet through the transparent walls of the duct in order to visualize (by video) the effects of the sound field. The experiments confirm the basic feature of the asymmetric Stokes drag model—specifically, the aerosol is observed to concen-

trate along acoustic velocity nodes. Ongoing experiments to quantify the level of concentration will be described. [Work supported by RDECOM.]

11:45

4aPac5. The effects of orthokinetic collision and the acoustic wake effect on acoustic agglomeration of polydisperse aerosols. Shaozeng Dong (Dept. of Mech. Eng., Virginia Commonwealth Univ., 601 West Main St., Richmond, VA 23284), Bart Lipkens (Western New England College, Springfield, MA 01119), and Timothy Cameron (Kettering Univ., Flint, MI 48504)

A new concept of effective agglomeration length, which measures the maximum particle separation distance for effective collisions, is proposed for acoustic agglomeration of polydisperse aerosols with respect to the separate and combined effects of orthokinetic collision and acoustic wake in a horizontal acoustic wave. Particle gravity is found to be significant for the acoustic wake effect while the particle collision efficiency is important for the orthokinetic collision. Results indicate that orthokinetic collision dominates at low frequencies for intermediate size ratios while the acoustic wake effect is more significant at higher frequencies for all particles. The optimum frequency for orthokinetic collision is confirmed but shifts downward with the increase of sound power. For the acoustic wake effect, the agglomeration increases monotonically with sound frequency. Results also show that the orthokinetic collision is not effective for agglomeration of sub-micron particles because of low particle collision efficiency.

Session 4aPP

Psychological and Physiological Acoustics: Temporal Factors, Masking and Pitch (Poster Session)

Magdalena Wojtczak, Chair

Dept. of Psychology, Univ. of Minnesota, 75 East River Rd., Minneapolis, MN 55455

Contributed Papers

All posters will be on display from 8:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:00 a.m. to 10:00 a.m. and contributors of even-numbered papers will be at their posters from 10:00 a.m. to 12:00 noon.

4aPP1. The temporal effect for signal frequencies around a notched cochlear hearing loss. Elizabeth Strickland and Lata Krishnan (SLHS Dept., Purdue Univ., W. Lafayette, IN 47907)

The temporal effect (or overshoot) refers to the change in signal-to-masker ratio at threshold for a short-duration tone as it is delayed from the onset of a longer-duration masker. This study is one in a continuing series of studies on the relationship between the temporal effect and the cochlear active process. In a previous study, the temporal effect was measured as a function of signal level in a broadband masker, for listeners with cochlear hearing loss. Results showed that the pattern of the temporal effect with level depended not only on the degree of hearing loss at the signal frequency, but also on the degree of hearing loss above the signal frequency. In the present study, this was examined further by measuring the temporal effect as a function of signal level in listeners with notched cochlear hearing loss, when the signal frequency was below, at or above the frequency of the greatest hearing loss (the notch). Results will be analyzed in terms of changes in the amplification due to the cochlear active process at and above the signal frequency. [Work supported by the Kinley Trust.]

4aPP2. Effect of frequency on the relationship between intensity discrimination and the detection of amplitude modulation. Rebecca E. Millman and Sid P. Bacon (Dept. of Speech and Hearing Sci. Arizona State Univ., P.O. Box 870102, Tempe, AZ 85287-0102, rebecca.millman@asu.edu)

Wojtczak and Viemeister [*J. Acoust. Soc. Am.* **106**, 1917–1924 (1999)] found a clear relationship between the detection of intensity increments and the detection of amplitude modulation (AM) for continuous 1-kHz sinusoids. In the present study AM detection thresholds and intensity difference limens (DLs) were measured for 1-s gated sinusoids with a frequency of 125 Hz or 1 kHz. The sinusoids were presented at levels between 10 dB SL and 90 dB SPL. Modulation detection thresholds [$20 \log(m)$] improved as the carrier level was increased; for a comparable range of levels (45 dB), the improvement was similar at the two frequencies. Intensity DLs [$10 \log(\Delta I/I)$] generally improved as the level of the reference sinusoid was increased, although the improvement (“near miss” to Weber’s Law) was smaller at 125 Hz than at 1 kHz over the same 45-dB range of levels. For the 1-kHz sinusoids, the relationship between intensity DLs and modulation detection thresholds was consistent with that shown by Wojtczak and Viemeister (1999). This same relationship apparently does not hold at 125 Hz. Because the relationship between intensity dis-

crimination and modulation detection depends upon frequency, the mechanisms underlying the two tasks may be somewhat different. [Work supported by NIDCD.]

4aPP3. Level effects in amplitude modulation tuning. Magdalena Wojtczak and Neal F. Viemeister (Univ. of Minnesota, 75 East River Rd., Minneapolis, MN 55455, wojtc001@umn.edu)

Psychophysical experiments on amplitude-modulation (AM) masking suggest the existence of channels selectively sensitive to different ranges of modulation rates. This study investigates whether tuning depends on carrier level. Masking of a 40-Hz signal AM was measured as a function of the masker-AM rate selected from the range between 4 and 256 Hz, for Gaussian-noise and 5.5-kHz carriers. For the noise carrier, similar patterns were observed at two different spectrum levels (25 and 40 dB SPL), leading to similar estimates of the modulation-filter bandwidths. For the tonal carrier, however, tuning in AM masking varied considerably across levels. At the lowest level tested (40 dB SPL), the patterns were very broad and highly asymmetric. The patterns became more similar across carrier levels when a highpass noise was presented with the carrier. The noise limited the use of spread of excitation and thus, raised thresholds for the unmasked signal detection. The data suggest that the AM selectivity is strongly affected by the detection threshold for the unmasked AM. [Work supported by NIH grants DC00683 and DC006804.]

4aPP4. Comparison of intensity discrimination, increment detection, and comodulation masking release in the envelope and audio-frequency domains. Paul C. Nelson (Dept. of Biomed. & Chemical Eng. and Inst. for Sensory Res., Syracuse Univ., 621 Skytop Rd., Syracuse, NY 13210, pcnelson@syr.edu), Stephan D. Ewert (Tech. Univ. of Denmark, 2800 Kgs. Lyngby, Denmark), Laurel H. Carney (Syracuse Univ., Syracuse, NY 13210), and Torsten Dau (Tech. Univ. of Denmark, 2800 Kgs. Lyngby, Denmark)

In the audio-frequency domain, the envelope apparently plays an important role in detection of intensity increments and in comodulation masking release (CMR). The current study addressed the question whether the second-order envelope (“venelope”) contributes similarly for comparable experiments in the envelope-frequency domain. One set of experiments examined the relationship between gated intensity discrimination and continuous-carrier increment detection. In contrast to the asymmetry observed in the audio-frequency domain (listeners are more sensitive to increments), AM-depth discrimination thresholds were found to be the same in conditions with a continuous (modulated) carrier and with traditional gated stimuli for AM frequencies ranging from 4–64 Hz. The second set of experiments compared the amount of CMR in a tone-in-noise detection task when slow, regular fluctuations were imposed on the masking waveform in both domains. A significant release from masking of a 32-Hz signal in the modulation frequency domain was obtained only when the venelope fluctuations were slower than 1–2 Hz. Both experiments suggest a relatively weak contribution of venelope cues in the AM domain when compared to those provided by envelope cues in the spectral domain. [Work supported by NIH-NIDCD R01001641 (PCN, LHC) and the Danish Research Council (SDE, TD).]

4aPP5. Temporal integration functions of amplitude modulation detection and amplitude modulation depth discrimination. Jungmee Lee and Glenis Long (Speech and Hearing Sci., The Grad. School and Univ. Ctr., The City Univ. of New York, 365 5th Ave., New York, NY 10016)

Previous studies (Lee and Green, 1994; Lee and Bacon, 1997) suggested that both AM rate and AM depth discrimination were influenced by the number of AM cycles, instead of the duration of stimuli. AM detection and AM depth discrimination (standard depth=0.1) were measured as a function of the number of AM cycles for modulation rates of 10, 20, 40,

80, 125, 160, and 320 Hz. Different numbers of modulation cycles were used for each modulation rate: 2, 4, or 8 for 10 Hz; 2, 4, 8, or 16 for 20 Hz; 2, 4, 8, 16, or 32 for 40 Hz; 2, 4, 8, 16, 32, or 64 for 80, 125, 160, and 320 Hz. The carrier was a broadband-noise (10 kHz lowpass), and the carrier was either gated with the modulator or presented 250 ms earlier and 250 ms later than the modulator. The overall level of each presentation was randomized within 6-dB range from 65 dB SPL. The results suggest that there might be different temporal integration processes for AM detection and AM depth discrimination. The pattern is different for lower and higher modulation rates. [Work was supported by NIDCD Grant No. R03 DC06605-01.]

4aPP6. Coherent modulation enhancement: Improving performance in noise for hearing aids and cochlear implants. Pamela Souza (Dept. of Speech and Hearing Sci., Univ. of Washington, 1417 NE 42nd St., Seattle, WA 98105), Les Atlas, Steven Schimmel (Univ. of Washington, Seattle, WA 98105), Jay Rubinstein, Ward Drennan, and Jong Ho Won (Univ. of Washington, Seattle, WA 98105)

Difficulty hearing in noise is a pervasive problem for hearing-impaired listeners. One approach is to digitally reduce noise using a modulation filter, which can selectively modify the time envelope of selected spectral bands. Previous approaches to modulation filtering, such as those based upon a Hilbert transform magnitude, increased signal distortion. A new coherent approach was used to determine a fixed and an optimal adaptive modulation filter. The optimal adaptive filter used information from the target speech to design the modulation filter. Threshold signal-to-noise ratio was measured adaptively using a spondee-in-noise task [Turner *et al.*, *J. Acoust. Soc. Am.* **115**, 1729 (2004)]. Subjects selected the spondee heard in a forced-choice task with a two-talker babble background. The spondee level was fixed at the listeners most comfortable level and noise level adjusted adaptively using a 2 dB step size, with threshold based on 10 reversals. Sensorineural hearing-impaired listeners completed three conditions: unprocessed speech; fixed modulation filter; and optimal adaptive modulation filter. Normal-hearing subjects heard a parallel set of conditions processed to simulate a 6-channel cochlear implant. There was significant improvement in threshold signal-to-noise ratio with the optimal adaptive filter for both groups. There was no improvement for the fixed modulation filter relative to unprocessed speech.

4aPP7. Factors affecting gap duration discrimination performance. John H. Grose, Joseph W. HallIII, and Emily Buss (Dept. Otolaryngol.-HNS, Univ. of North Carolina at Chapel Hill, 1115 Bioinformatics CB#7070, Chapel Hill, NC 27599-7070, jhg@med.unc.edu)

This investigation tests the hypothesis that reduced acuity in temporal tasks is evident relatively early on in the aging process for tasks involving brief stimuli or intervals, across-frequency processing, and/or significant processing loads. In an earlier study of gap duration discrimination (GDD) using fixed 20-ms markers, it was found that young listeners performed significantly better than middle-aged listeners for both within-channel and across-channel configurations. However, this age effect did not emerge in a subsequent study that employed random-duration markers. The purpose of the present study was to clarify stimulus conditions under which early aging effects are evident in GDD tasks. Normal-hearing young (20–25 years) and middle-aged (40–55 years) listeners were tested using both fixed- (20-ms) and random- (40 ms ± 50%) duration markers in configurations that were either within-channel or across-channel. In addition, task complexity was manipulated by incorporating a rhythm discrimination feature into the GDD task. Results to date indicate that performance declines when marker duration varies randomly, both for within- and across-channel conditions, as well as when task complexity is increased. These findings will be discussed in the context of identifying early aging effects in temporal processing. [Work supported by NIDCD DC001507.]

4aPP8. Fundamental frequency discrimination and harmonic resolvability in sensorineural hearing impairment. Joshua G. W. Bernstein and Andrew J. Oxenham (MIT Res. Lab. of Electron. and Harvard-MIT Speech & Hearing Bioscience & Technol. Prog., 77 Massachusetts Ave., Cambridge, MA 02139, jgbern@mit.edu)

Sensorineural hearing loss (SNHL) often results in impaired fundamental frequency (F_0) processing. Three experiments tested the hypothesis that this deficit is related to a loss of frequency selectivity, which may result in fewer peripherally resolved harmonics. F_0 difference limens (F_0 DLs) were measured as a function of F_0 for bandpass filtered sine- and random-phase harmonic complexes in listeners with mild-to-moderate SNHL. All listeners showed a transition between small (good) F_0 DLs at high F_0 s and large (poor) F_0 DLs at low F_0 s, although the transition point varied across subjects. Two measures that are thought to reflect frequency selectivity generally corresponded to the F_0 DL transition point: the maximum F_0 for which F_0 DLs were phase-dependent, and the minimum modulation frequency required to discriminate amplitude modulation from quasi-frequency modulation. These results provide some support for the idea that the F_0 -processing deficit associated with SNHL is related to poor frequency selectivity. However, contrary to our hypothesis, poor correspondence was observed between the F_0 DL transition point and auditory filter bandwidths estimated using the notched-noise method in the same subjects. This suggests a possible discrepancy between traditional spectral-masking estimates of frequency selectivity and estimates based on temporal interactions between unresolved components. [Work supported by NIH grants R01DC05216 and 5T32DC00038.]

4aPP9. Modeling comodulation masking release using an equalization cancellation mechanism. Tobias Piechowiak, Stephan D. Ewert, and Torsten Dau (Ctr. for Appl. Hearing Res., Oersted-DTU, Tech. Univ. of Denmark, Bldg. 352, 2800 Kgs. Lyngby, Denmark, tda@oersted.dtu.dk)

Across-filter comparisons of temporal envelopes are a general feature of auditory pattern analysis which plays an important role in extracting signals from noise backgrounds. One example where a comparison of the temporal envelope in different frequency regions can lead to a substantial facilitation of detecting a signal in noise is comodulation masking release (CMR). It has been suggested that in (monaural) across-channel processing, like in (binaural) across-ear processing, an equalization-cancellation (EC) based circuit might be an effective strategy of noise reduction. The first part of the study investigates the relation between CMR and envelope-based binaural masking level differences (BMLD), using narrowband noise maskers and classical across-channel configurations (like N0Spi, N0Sm). In the second part, a model is presented that explicitly simulates CMR whereby the EC mechanism is assumed to take place at the output of a modulation filterbank. In the case of several flanker bands, the equalization is realized effectively by averaging the flanker bands, and cancellation by subtracting the averaged representation from the signal band. A generalized version of the model is presented that considers both across-channel and within-channel contributions to signal detection in CMR. [Work supported by the Danish Research Council.]

4aPP10. A unified view of the temporal-window and the adaptation-loop model in conditions of forward- and simultaneous masking. Ole Hau, Stephan D. Ewert, and Torsten Dau (Ctr. for Appl. Hearing Res., Oersted DTU, Tech. Univ. of Denmark, Bldg. 352, 2400 Kgs. Lyngby, Denmark, se@oersted.dtu.dk)

Two different mechanisms have been discussed in the literature as a possible explanation for forward masking: persistence (or temporal integration) and adaptation. In this study, two well established models of temporal processing in the auditory system are compared in a unified modeling framework. The temporal-window model representing a temporal-integration mechanism and the adaptation-loop model as the representative for the adaptation mechanism. The unified modeling framework shared a compressive, non-linear auditory filter stage and a template-based (optimal detector) decision stage. Predictions from both models

were obtained in conditions of forward masking at 1 and 4 kHz for masker-to-signal gaps of 0 to 160 ms, and in conditions of simultaneous masking, where the signal was temporally overlapping with the masker. The signal was a 10- or 12-ms raised-cosine ramped pure tone and the masker a 200-ms broadband noise. It was found that when both models are adjusted to behave similarly, the two mechanisms can be considered as being essentially equivalent. In fact, the combination of integration and the signal-to-noise-ratio based detection criterion in the temporal-window model can be interpreted as adaptation. Suggestions for a unified model of auditory processing are presented. [Work supported by the Danish Research Council.]

4aPP11. An examination of temporal signal uncertainty for sequences of noise or random-frequency maskers. Lori Leibold, Donna Neff, and Walt Jesteadt (Boys Town Natl. Res. Hospital, 555 North 30th St., Omaha, NE 68131, leiboldl@boystown.org)

The effect of temporal uncertainty was examined on detection of a 1000-Hz tone presented simultaneously with one of a sequence of five masker bursts, using a 2-AFC, adaptive procedure. The signal and each masker burst were 100-ms (10-ms rise/fall), with no temporal overlap between masker bursts. Each masker burst was 60 dB SPL. Across conditions, maskers were broadband-noise (300–3000 Hz) or random-frequency multi-tonal maskers with 1, 2, or 10 components. Components for the random-frequency maskers were drawn from 300 to 3000 Hz, excluding a 160-Hz band around the signal. Thresholds for conditions with no temporal uncertainty (signal presented with the first, third, or fifth masker burst on all trials) were compared to performance with maximal temporal uncertainty (signal position varied on every trial). There was no effect of temporal uncertainty for the noise masker. For random-frequency maskers, performance was uniformly poor for both fixed- and random-position signals, except for some release from masking for signals presented with the last masker burst. For three of four listeners, even 1-component maskers showed large amounts of masking in all conditions. These results suggest that the effects of temporal uncertainty are minimal for these stimuli. [Work supported by NIDCD.]

4aPP12. Spectral integration and multiple looks. Robert Lutfi (Dept. of Communicative Disord. and Waisman Ctr., Univ. of Wisconsin, Madison, WI 53706)

A fundamental property of hearing is that signals become more detectable as their bandwidth is increased. The rate at which detection improves is reasonably well predicted by models that assume integration of energy at the output of a single auditory filter roughly matched in bandwidth to the signal. This paper tests an alternative account in which detection is mediated by not one but several independent auditory filters whose outputs are combined (multiple-looks model). Listeners detected an increment in the level of a multitone complex whose bandwidth was increased by adding tones at successively higher and lower frequencies. In different conditions the frequencies were fixed (F) or were perturbed at random from trial to trial with the perturbation being the same (PS) or different (PD) for each frequency. The multiple-looks model predicts performance should improve with bandwidth at a faster rate for PD and at a slower rate for PS compared to F; this due to differences in the shared variance in the output of separate auditory filters. The single filter model predicts little effect of frequency perturbation in either case. Individual differences in the results provided partial support for both models. [Work supported by NIDCD.]

4aPP13. Response growth with and without a low-frequency suppressor. Jeffrey J. DiGiovanni (School of Hearing, Speech and Lang. Sci., Ohio Univ., Athens, OH 45701) and Magdalena Wojtczak (Univ. of Minnesota, Minneapolis, MN 55455)

In a psychophysical study, Wojtczak and Viemeister (2005) demonstrated that the response to a tone suppressed by a fixed-level, higher-frequency suppressor grows faster than the response to the same but un-

suppressed tone. This finding is consistent with a linearization of the response under suppression. This study extends their experiment to suppressors with frequencies below that of the suppressee. Detection of a 10-ms, 4-kHz probe was measured under two forward-masking conditions: one with a 200-ms, 4-kHz masker presented alone, and the other with the same masker/probe paired with a 2.4-kHz fixed-level suppressor. A range of probe levels was used to measure growth of masking with and without the suppressor. The 4-kHz masker level was varied adaptively to find the masked threshold. Suppression was revealed by the difference between the masker levels needed for the masked threshold in the presence and absence of the suppressor. Initial comparison of the rates of masking growth between the two conditions suggests a linearization of the response to the 4-kHz masker in the presence of a lower-frequency suppressor. A few levels of the suppressor were used to determine the rate of suppression growth and its effect on the growth of response at the suppressee-frequency place.

4aPP14. Stochastic resonance in Gaussian and uniform noise. Dennis Ries (School of Hearing, Speech, and Lang. Sci., Ohio Univ., Grover Ctr. W221, Athens, OH 45701, ries@ohio.edu)

The improvement in threshold of a 2.0 kHz tone in the presence of low levels of uniform and Gaussian noise is compared to tonal threshold measured in quiet. Uniform noise was created using a rectangular amplitude distribution. The noises were low-pass filtered at 12.0 kHz and were presented continuously throughout a run at spectrum levels ranging from 0 to -30 dB/Hz. Pure-tone signals were 400 ms in duration including 10 ms raised cosine onset and offset ramps. Thresholds were obtained using a 3-interval, forced-choice procedure with correct answer feedback in conjunction with a two down, one up adaptive tracking paradigm that targets 70.7% correct on the psychometric function. Subjects were instructed to select the interval that was different from the others. Preliminary results for the Gaussian noise conditions are similar to earlier results [Zeng *et al.*, Brain Res. **869**, 251–255 (2000)]. Initial results for the uniform noise indicate that it produced equivalent or slightly lower thresholds than those measured in the presence of Gaussian noise.

4aPP15. Spatial release from informational masking along the front-back dimension. Neil L. Aaronson (Dept. of Phys. and Astron., Michigan State Univ., 4230 BPS Bldg., East Lansing, MI 48824), Brad Rakerd (Michigan State Univ., East Lansing, MI 48824), and William M. Hartmann (Michigan State Univ., East Lansing, MI 48824)

When two independent speech samples are presented together from a single location in front of the listener, one will mask the other. The amount of masking can be reduced by presenting a repeated masker from a different location off to the side and shifting it slightly forward (+) or backward (-) in time compared to the masker in front. New experiments, using the coordinate response measure technique with a two-female-talker masker and a female target, show that masking release can also be obtained when the target and masker are in front and the repeated masker is directly in back. Release is seen for both forward and backward time shifts, ranging from -32 to 32 ms. The amount of release is somewhat more than half that obtained when the repeated masker is off to the side. Release from masking can also be seen when the repeated masker comes from a location directly above the target and masker in front, but only for a single value of time shift, namely ± 2 ms. It is concluded that both

spatial and spectral cues mediate release from informational masking in the front-back dimension. [Work supported by the NIDCD grant DC 00181.]

4aPP16. The advantage of knowing where to listen. Gerald Kidd, Jr., Tanya L. Arbogast, Christine R. Mason, and Frederick J. Gallun (Commun. Disord. and Hearing Res. Ctr., Boston Univ., 635 Commonwealth Ave., Boston, MA 02215)

This study examined the importance of *a priori* knowledge about the location of a target in a multitalker environment. On each trial, three equal-level sentences from the Coordinate Response Measure test were presented from different loudspeakers separated by 60° azimuth. The sentences—target and 2 maskers—had the structure “Ready [callsign] go to [color] [number] now.” The task was to repeat the color and number associated with a specific callsign. The target location was chosen among the 3 loudspeakers on every trial. The main experimental variables were the probability of occurrence of the target at each speaker location and whether the listener was provided with the callsign of the target before or after stimulus presentation. Performance ranged from near perfect when the target location was completely certain to about 33% correct when the location was random and the callsign was not known in advance. When target location was random, performance improved from about 33% to 70% correct when the callsign was known in advance. Overall, these results support the view that knowing where to focus attention provides a great advantage in speech recognition in complex and uncertain environments. [Supported by NIH/NIDCD.]

4aPP17. Effect of signal frequency uncertainty for random multi-burst maskers. Rong Huang and Virginia M. Richards (Dept. of Psych., Univ. of Pennsylvania, 3401 Walnut St., Ste. 302C, Philadelphia, PA 19104)

The detectability of a sequence of equal-frequency tone pips masked by random multi-burst complexes may depend on the perceptual segregation of the signal stream from the random masker. If so, detection thresholds may be independent of whether the signal frequency is known versus uncertain. In this experiment observers detected a signal stream of 8 sequential equal-frequency 30 ms tone pips embedded in a random masker composed of 8 sequential bursts. A yes/no procedure was used, and the independent variable p (probability a tone was played at a particular time-by-frequency location) governed the number of masker tones in each burst. The dependent variable was d . Threshold values of p were obtained for signal streams at 5 different frequencies. Sensitivity was superior for the mid-frequency signal, and decreased as the signal frequencies approached the edge of the frequencies the masker tones occupied (200–5000 Hz). When the frequency of the signal stream was randomly varied from trial to trial, sensitivity was poorer than for any of the fixed-frequency signals. Thus, the detectability of a sequence of tone pips is reduced when the signal frequency is uncertain compared to certain. Additionally, sensitivity increased when the signal stream was delayed relative to the masker bursts.

4aPP18. Training listeners or preserving phase information improves the effect of perceived spatial separation on releasing spectrally degraded Chinese speech from information masking. Jing Chen, Chenfei Ma, Chun Wang, Hongwei Qu (Natl. Key Lab. on Machine Percept. Speech and Hearing Res. Ctr., Dept. of Psych., Peking Univ., Beijing 100871, China), Xihong Wu, Liang Li (Peking Univ., Beijing 100871, China), and Bruce Schneider (Univ. of Toronto at Mississauga, Canada L5L 1C6)

Physical or perceived spatial signal/masker separation unmasks speech more when maskers are informational than when energetic. However, it is unclear how beneficial the separations are to cochlear-implant listeners, because signal transductions applied in cochlear implant degrade signals

spectrally, and spectrally degraded speech is more vulnerable to maskers. Here, spectrums of both target speech (nonsense sentence) and masker (steady speech-spectrum noise, speech modulated speech C -spectrum noise, or speech) were filtered into 15 frequency bands. For both target and masking speech, the center-frequency pure tone of each band was modulated by the extracted envelope from the band. The target speech was composed by the sum of the 8 odd-band tones, and the masker was either same-band (with the 8 odd-band tones) or different-band (with the 7 even-band tones). The results show that physical but not perceived spatial separation unmasked target speech in naive normal-hearing listeners. However, following pre-presentations of both degraded and normal correspondent speech to listeners for a period of time or the introduction of phase information into modulated tones, perceived spatial separation reduced the influence of different-band speech masking but not that of same-band speech masking. These results are useful for improving cochlear-implant programs at both behavioral and technical levels.

4aPP19. Development of backward masking in elementary school children. Cynthia M. Zettler, Marsha G. Clarkson, Rose A. Sevcik, and Robin D. Morris (Dept. of Psych., Georgia State Univ., Atlanta, GA 30303)

Previous research on backward masking (BM) suggests that the ability develops slowly across childhood. When a spectral notch is placed in a noise masker, thresholds improve due to a decrease in masker energy at the frequency of the signal. To further clarify the developmental course of BM thresholds for BM and backward notched-noise (BM-N), conditions were measured in 81 children ranging in age from seven to ten years. BM stimuli consisted of a 20-ms, 1000-Hz tone presented 20 ms prior to a 300-ms, 600–1400 Hz bandpass noise. BM-N stimuli consisted of a 1000-Hz tone presented 20 ms prior to the onset of a 300-ms, 400–1600 Hz bandpass noise with a spectral notch between 800 and 1200 Hz. Multivariate analysis of variance indicated a significant difference among age groups for the BM condition ($F(3,77)=3.63, p<.05$), but not for the BM-N condition. Thresholds generally decreased with increasing age in the BM condition (age seven 87.86 dB; eight 81.36 dB; nine 75.31 dB, and ten 77.26 dB). Increased BM thresholds in younger children may indicate poorer processing efficiency, whereas the notched results suggest that frequency selectivity is relatively mature by age seven.

4aPP20. Tone-in-noise detection using narrowband reproducible maskers with restricted energy and envelope cues. Sean A. Davidson (Dept. of Biomed. and Chem. Eng., Inst. for Sensory Res., 621 Skytop Rd., Syracuse Univ., Syracuse, NY 13244, sadavids@syr.edu), Robert H. Gilkey (Wright State Univ., Dayton, OH), and Laurel H. Carney (Syracuse Univ., Syracuse, NY 13244)

Both energy- and envelope-based models have been successfully used to predict narrowband tone-in-noise detection thresholds. To distinguish between these models, hit and false-alarm rates for 25 reproducible maskers were measured in the N_0S_0 and N_0S_π interaural configurations and 4 cue conditions: (1) normal energy and envelope cues, (2) restricted envelope cues, (3) restricted energy cues, or (4) restricted energy and envelope cues. Preliminary results show that hit and false-alarm rates were strongly correlated between the conditions with and without restricted energy cues, indicating that the reduction of energy cues *did not* substantially affect the detection process. However, hit and false-alarm rates were more weakly correlated between the conditions with and without restricted envelope cues, suggesting that the reduction of envelope cues *did* affect the detection process. Restricting envelope cues also had a larger (but still modest) effect on d' under the N_0S_π configuration, but restricting energy cues had a larger effect for the N_0S_0 configuration. Overall, these results are more consistent with envelope-based models, but indicate that additional cues must play a role. [Work supported by NIDCD R01-DC-001641 (LHC, SAD) and the Ohio Board of Regents (RHG).]

4aPP21. The spiral model of pitch: Interrelations with musical and psychoacoustic scales and with cochlear parameters. James D. Miller (Dept. of Speech and Hearing Sci., Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405, jamdmill@Indiana.edu)

A spiral model of pitch can represent pitch chroma and pitch height. Its arclength provides the frequency-position map of the cochlea, and, when scaled by the number of auditory-ganglion cells, provides the Mel scale. Pitch-like scales fall into three groups. Group I is typified by the Cent scale, which can be expressed as a pitch spiral. Other Group-I scales are musical notation, logarithmic scales of frequency, Fechners Law for complex tones, and the pitch helix. Group II is typified by Greenwoods cochlear map, which is simply related to the arclength of the pitch spiral. Other Group-II scales are the sums of the number of (a) equivalent-rectangular bandwidths (NERBs); (b) difference limens for frequency (NDFs); and (c) inner-hair cells (NIHCs) and are consistent with critical ratios. Group III is typified by the Mel Scale, which can be derived from the pitch spiral and the distribution of auditory-ganglion cells. Other Group-III scales are the sums of the number of (a) auditory ganglion cells (NSGCs), (b) frequency-modulation-difference limens (NFMDLs), and (c) Barks (NBARKs). The pitch spiral seems a basic concept from which other pitch-like scales can be derived.

4aPP22. Repetition “pitch” in chinchillas. William P. Shofner and William M. Whitmer (Parmlly Hearing Inst., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626, wshofne@luc.edu)

Repetition pitches are evoked in human listeners by rippled noises. Infinitely iterated rippled noise (IIRN) is generated when wideband noise is delayed, attenuated, and added to the original wideband noise through positive (+) or negative (–) feedback. In human listeners, the pitch of IIRN(+) is matched to the reciprocal of the delay, whereas the pitch of IIRN(–) is an octave lower. A stimulus generalization paradigm was used to characterize IIRN repetition pitch in chinchillas. Chinchillas were trained to discriminate IIRN(+) with a 4-ms delay from IIRN(+) with a 2-ms delay. In the generalization task, chinchillas were tested with IIRN(+) having delays between 2–4 ms. The pitches evoked by these IIRNs ranged from 500–250 Hz. The delayed noise attenuation for all IIRNs was fixed at –1 dB. A systematic gradient in behavioral response occurred along the dimension of delay for each animal tested, suggesting that a perceptual dimension of pitch exists. Responses to IIRN(–) evoking pitches between 500–250 Hz (delays of 1–2 ms) were also measured. Responses to IIRN(–) were more variable among animals, suggesting that other perceptual cues such as timbre differences may be stronger than the pitch cues. [Work supported by NIDCD R01 DC005596.]

4aPP23. Influence of beats on mistuning detection in consonant and dissonant musical intervals. Craig E. Lewiston and Andrew J. Oxenham (MIT Res. Lab. of Electron. and Harvard-MIT Speech & Hearing Bioscience & Technol. Prog., 77 Massachusetts Ave., Cambridge, MA 02139, lewiston@mit.edu)

This study investigated the mechanisms underlying the detection of mistuning in musical intervals. Musical consonance is thought to be defined in part by an absence of cochlea-generated beats. Dissonant intervals, and mistuned consonant intervals, produce a percept of beats. Thus, mistuning of consonant intervals might be detected through the presence of beats, whereas mistuning of dissonant intervals might be detected by a change in the pattern of beats. Alternatively, mistuning might be detected by a direct comparison of the two pitches in each interval. In our experiment the presence of beats was controlled by presenting the two tones to both ears or to separate ears, by using either pure tones or complex tones, and by presenting the tones sequentially or concurrently. Results using highly trained musicians showed large threshold elevations (poorer performance) in the absence of cochlea-generated beats, suggesting that the mistuning of concurrent sounds in normal circumstances is mediated by beat detection. However, even in the absence of beats, mistuning detection

thresholds for dissonant intervals, such as the tritone or minor second, were poorer than for consonant intervals, such as the octave or fifth. [Work supported by NIH grants T32DC00038 and R01DC05216.]

4aPP24. Further explorations of the contribution of a nonsimultaneous mistuned harmonic to residue pitch. Hedwig E. Gockel, Robert P. Carlyon (MRC Cognition and Brain Sci. Unit, 15 Chaucer Rd., Cambridge CB2 2EF, UK, hedwig.gockel@mrc-cbu.cam.ac.uk), and Christopher J. Plack (Univ. of Essex, Wivenhoe Park, Colchester CO4 3SQ, UK)

Ciocca and Darwin [V. Ciocca and C.J. Darwin, *J. Acoust. Soc. Am.* **105**, 2421–2430 (1999)] reported a surprising finding: The shift in residue pitch caused by mistuning a harmonic was the same when the mistuned harmonic was presented after the remainder of the complex as when it was

simultaneous. The present study tried to replicate this result, and investigated the role of the presence of the nominally mistuned harmonic in the matching sound. Subjects adjusted a matching sound so that its pitch equaled that of a subsequent 90-ms complex tone (12 harmonics of a 155-Hz F_0), whose mistuned ($\pm 3\%$) 3rd harmonic was presented either simultaneously with or after the remainder. In experiment 1, the matching sound was a harmonic complex whose 3rd harmonic was either present or absent. In experiment 2, it was a sinusoid. In experiment 3, the target and matching sound contained non-overlapping harmonics. In all experiments, a non-simultaneous mistuned component produced significantly smaller pitch shifts than a simultaneous one. In the absence of the nominally mistuned harmonic in the matching sound, the pitch shift with simultaneous presentation was about five times larger than that with non-simultaneous presentation of the mistuned component. [Work supported by EPSRC Grant GR/R65794/01.]

9:00

4aSA1. The banjo in the time-domain. Joseph Dickey (The Whiting School of Eng., Johns Hopkins Univ., 810 Wyman Park Dr. Ste. G010, Baltimore, MD 21211)

The banjo is under-represented in the musical acoustics literature. This is the case even though it is basically a vibrating and radiating membrane driven by a plucked string, and thereby lends itself naturally to modeling and analysis. A recent frequency domain model, [Dickey, *J. Acoust. Soc. Am.* **114**, 2958–2966 (2003)] will be reviewed. The work reported here is a time domain analysis. First, the response of an isolated, plucked, lossy and dispersive string is presented. The string is then connected through a bridge to the center of a circular membrane. The string and head are treated as two fully connected dynamic systems and the response of the head is calculated. The isolated head is then driven off-center with an harmonic drive and the temporal response is determined by ray-tracing and summing amplitudes over a grid. Resonance frequencies and modal patterns agree well with experiment thereby validating the technique. Finally, the resonant string is considered as an external, transient, off-center and spatially distributed drive and the temporal response of the head is derived using the ray tracing technique. These modal patterns evolve in time and eventually stabilize to patterns that are in qualitative agreement with experiment.

9:30

4aSA2. Structural vibrations and sound radiation fields of classical guitars. Bernard E. Richardson (School of Phys. and Astron., Cardiff Univ., 5 The Parade, Cardiff CF24 3YB, UK, RichardsonBE@cardiff.ac.uk)

In its few lines, Federico Garcia Lorca's poem "Las Seis Cuerdas" (the six strings) invokes a beautiful image of sound production on the guitar. It is the player's interaction with the six strings which makes the music, but were it not for the body of the guitar, the instrument would have no voice. Most studies of the acoustical function of guitars have concentrated on measuring the structural vibrations or the sound radiation fields in isolation of the strings. These studies fail to encapsulate the important aspects of string-body coupling, which has a marked influence on the decay rates of string vibrations, and the radiativity of individual body modes. By measuring both input admittance at the bridge and sound-field topology for individual modes of the guitar, it is possible, through psychoacoustical experiments, to investigate the relative importance of the various acoustical parameters which define the response of the instrument. This paper will discuss experimental techniques and present data on ten classical guitars which go some way to identifying key components in the low- to mid-frequency mechanical and acoustical actions of the guitar. [Work originally supported by the Leverhulme Trust.]

10:15

4aSA3. Development of a composite material concert harp soundboard to match the structural acoustic performance of a wooden soundboard. Thomas J. Royston, Melinda J. Carney, Curt Preissner, and John Roxworthy (Acoust. & Vib. Lab., Univ. of Illinois at Chicago, 842 W. Taylor St., MC 251, Chicago, IL 60607, troyston@uic.edu)

The replacement of a Sitka spruce grand concert harp soundboard with a carbon fiber-reinforced plastic soundboard could provide improved durability and long-term stability, helping to mitigate stresses relating to fluctuating temperature and humidity that are inherent in wooden instruments. This presentation outlines the development of a composite soundboard by a combined experimental and computational approach. Experimental modal analysis data was compared with the results from a computational finite-element model to find the effective material properties of the multi-layered laminate wooden soundboard, treating the veneer, soundboard and varnish as one material. With the effective wood material properties determined, a composite test section was designed and fabricated based on specific matching criteria, duplicating the behavior of the wood with the composite laminate. The experimental natural frequencies and mode order of the composite test section closely matched the experimental results of the wood section within a 10% difference. Given these results, the method was then applied to design and manufacture a full composite soundboard. Various finite element models were created to develop the most practical design while sufficiently matching the wood soundboard properties. Issues regarding the implementation of the composite soundboard were also investigated.

10:45

4aSA4. Modes of vibration and sound radiation from percussion instruments. Thomas D. Rossing (Phys. Dept., Northern Illinois Univ., DeKalb, IL 60115, rossing@physics.niu.edu)

When a membrane or bar or plate is struck, it vibrates in a complex manner, which can be described in terms of normal modes of vibration. We describe the modes of vibration of percussion instruments, such as drums and bells, some ways in which the normal modes are observed, and the way in which they determine sound radiation from the instruments.

11:15

4aSA5. Interferometric studies of a piano soundboard. Thomas R. Moore (Dept. of Phys., Rollins College, Winter Park, FL 32789, tmoore@rollins.edu)

Ongoing efforts to understand and model the dynamics of the modern piano are hampered by a lack of understanding of the deflection shapes of the soundboard, which are extremely complicated due to the complex construction. Often deflection shapes of harmonically vibrating objects can be determined using holographic or speckle pattern interferometry, but in practice the stability necessary to implement these methods is difficult to achieve for a large wooden structure such as a piano. We show theoretically and experimentally that the deflection shapes of large objects that are typically too unstable for interferometry can be determined by modifying the common form of the electronic speckle pattern interferometer. Furthermore, using this modified interferometer the decorrelation of the speckle due to ambient vibrations actually enhances the precision of the interferogram. We discuss some interesting observations of the deflection shapes of the soundboard of a fully assembled piano, compare the deflection shapes of the lowest resonances with simple models, and demonstrate how the interferograms can be used to determine the driving point impedance.

Session 4aSC

Speech Communication: Advanced Methods in Speech Research and Speech Technology (Poster Session)

Terrance M. Nearey, Chair

*Dept. of Linguistics, Univ. of Alberta, 4-32 Assiniboia Hall, Edmonton, AB T6G 2E7, Canada**Contributed Papers*

All posters will be on display from 8:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:00 a.m. to 10:00 a.m. and contributors of even-numbered papers will be at their posters from 10:00 a.m. to 12:00 noon.

4aSC1. Development of an anthropomorphic talking robot and the mimicking speech control. Kotaro Fukui, Kazufumi Nishikawa, Toshiharu Kuwae, Atsuo Takanishi (Dept. of Mech. Eng., Waseda Univ, 3-4-1 Ookubo, Shinjuku-ku, Tokyo, Japan), Hideaki Takanobu (Kogakuin Univ., Tokyo, Japan), Takemi Mochida (Commun. Sci. Labs., NTT, Kanagawa, Japan), and Masaaki Honda (Waseda Univ., Saitama, Japan)

We developed an anthropomorphic talking robot WT-4 (Waseda Talker No. 4) to produce human speech. WT-4 consists of 1-DOF lungs, 4-DOF vocal cords and articulators (the 7-DOF tongue, 5-DOF lips, 1-DOF teeth, nasal cavity and 1-DOF soft palate); the total DOF is 19. The lips and the tongue are made of elastic material to allow large deformation and to prevent from the air and sound leaks, and are controlled by a looped wire mechanism to form their various configurations. The talking robot enables to produce vowel and consonant sounds by mimicking the vocal cords vibration and the fricative and plosive source generation by the air flow as well as dynamically controlled vocal tract acoustic resonance in human speech production. Articulatory control of the talking robot is designed to track the acoustic goals (pitch, sound power, two formant frequencies, and voice-unvoiced timing) of the speech. The robot parameters are determined by minimizing the weighted mean squared error of these acoustic parameters between the human and robot speech sounds. It is shown that this mimicking speech control is effective in producing fluent continuous speech by the talking robot.

4aSC2. The tube resonance model speech synthesizer. Leonard C. Manzara (Dept. of Comput. Sci., Univ. of Calgary, 2500 Univ. Dr. NW, Calgary, AB, Canada T2N 1N4, manzara@cpsc.ucalgary.ca)

The Tube Resonance Model (TRM) synthesizer is an articulatory speech synthesizer implemented in software. It directly emulates the resonant behavior of the oropharyngeal and nasal tracts using digital waveguides. The oropharyngeal cavity is subdivided into 8 regions of unequal length, where particular regions correspond to the human articulators of tongue, teeth, and mouth. The radius (cross-sectional area) of each region can be varied independently over time. The differences in radii between regions gives rise to differences in acoustic impedance, which is modeled using two-way scattering junctions. The nasal cavity is composed of 5 equal-length sections, and is connected to the vocal tract via another section (the velum) using a three-way scattering junction. The total length of the tube can be varied over a continuous range, allowing one to synthesize male, female, and juvenile voices.

4aSC3. Study of effect of speaker variability and driving conditions on the performance of an automatic speech recognition engine inside a vehicle. Shubha Kadambe (HRL Labs., LLC, 3011 Malibu Canyon Rd., Malibu, CA 90265)

Spoken dialogue based information retrieval systems are being used inside vehicles. The user satisfaction of using such a system depends on how an ASR engine performs. However, the performance of an ASR is affected by speaker variability, driving conditions, etc. Here, we report the study that we performed to analyze these effects of speaker variability, different driving conditions and the effect of driving task on the ASR performance. This study consists of experimental design, data collection and systematically testing an ASR engine using this data. From the obtained results, it can be observed that (I) the ASR performance exhibits (a) significant speaker variability since the stress of driving task varies from speaker to speaker, (b) significant performance degradation across driving conditions since the noise type and level varies and (c) significant effect of driving task on recognition performance, and (II) the effect of live noise on recognition performance is not same as adding car noise to the pre-recorded speech data. The former observation is important since by just training an ASR engine on lots of speech data will not help and it is essential to include stress factors and cognition load in ASR engines to improve its performance.

4aSC4. A noise-reduction strategy for speech based on phase-opponency detectors. Om Deshmukh (Dept. of Elec. and Comp. Engr. and Inst. for Systems Res., Univ. of Maryland, College Park, MD 20742), Michael C. Anzalone (Syracuse Univ., Syracuse, NY 13224), Carol Y. Espy-Wilson (Univ. of Maryland, College Park, MD 20742), and Laurel H. Carney (Syracuse Univ., Syracuse, NY 13224)

A noise-reduction algorithm was developed based on a neural model for detection that is robust in fluctuating noise. The phase-opponency (PO) neural model correlates the outputs of two different auditory filters that differ in phase by 180 degrees at the target frequency. The PO detector used here consists of a pair of overlapping bandpass filters with phase responses that differ by 180 degrees near the center frequency (CF). The correlation between the filter responses is reduced when a narrowband signal near CF is present in a noisy background. A bank of PO detectors was used to process speech corrupted by additive Gaussian noise. The time-varying outputs of the detectors can be post-processed to retain information-rich regions, such as formants and frication onsets, while greatly reducing noise between formants. The final detector output controlled the gains in a separate analysis/synthesis filterbank. Spectrograms of speech sounds before and after noise reduction illustrate the ability of the system to detect major features in speech down to low signal-to-noise ratios. The quality of the processed signal will be demonstrated. This system is intended as a front-end for speech recognition systems or in

4aSC5. A new method of extracting the filter characteristics of the nasal cavity using homorganic nasal-stop sequences. Hansang Park (Dept. of English Education, Hongik Univ., 72-1 Sangsu-dong, Mapo-gu, Seoul, Korea)

This study attempts to derive the filter characteristics of the nasal cavity of individual speakers. Since the only difference between a nasal and a homorganic voiced stop, such as [mb] and [nd], is whether the passage to the nasal cavity is open or not, the subtraction of the LPC spectrum of the voiced stop from that of the preceding nasal leads to the filter characteristics of the nasal cavity of an individual speaker regardless of place of articulation. The results showed that the spectral differences between samples of 20 ms taken from the steady states of the nasal and the following voiced stop were close to constant regardless of place of articulation, representing characteristic poles and zeroes, and that the spectral differences varied with speakers. This study is significant in that it provides a new method of extracting the filter characteristics of the nasal cavity, and that the spectral difference between a nasal and a homorganic voiced stop can be used as a parameter of the filter characteristics of the nasal cavity of individual speakers.

4aSC6. Synthesizing speech acoustics from head and face motion. Adriano V. Barbosa, Hani C. Yehia (CEFALA/PPGEE, Universidade Federal de Minas Gerais, Av. Antonio Carlos, 6627, Belo Horizonte, MG, 31270-010, Brazil, adriano.vilela@gmx.net), Andreas Daffertshofer (Vrije Universiteit, Amsterdam, The Netherlands), and Eric Vatikiotis-Bateson (Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z1)

This work outlines a quantitative analysis of the relation between speech acoustics and the face and head motions that occur simultaneously [A. V. Barbosa, Ph.D. thesis, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil, 2004]. 2-D motion data is obtained by means of a video camera. An algorithm has been developed for tracking markers on the speaker's face from the acquired video sequence [A. V. Barbosa, E. Vatikiotis-Bateson, and A. Daffertshofer, in Proceedings of the 8th ICSLP Interspeech 2004, Korea, 2004]. The motion domain is represented by the 2-D marker trajectories, whereas line spectrum pairs (LSP) coefficients and the fundamental frequency F_0 are used to represent the speech acoustics domain. Mathematical models are trained to estimate the acoustic parameters (LSPs + F_0) from the motion parameters (2-D marker positions). The estimated acoustic parameters are then used to synthesize the acoustic speech signal. Cross-domain analysis for undecomposed (i.e., full head + face) and decomposed (i.e., separated head and face) normalized 2-D motions is performed. Syntheses from each method using intelligibility tests and qualitative comparison of the original and synthesized utterances are being evaluated.

4aSC7. ArtiSynth designing a modular 3D articulatory speech synthesizer. Florian Vogt, Oliver Guenther, Allan Hannam, Kees van den Doel (Univ. of British Columbia, 2356 Main Mall, Vancouver, BC, Canada V6T 1Z4, fvogt@ece.ubc.ca), John Lloyd, Leah Vilhan, Rahul Chander, Justin Lam, Charles Wilson, Kalev Tait, Donald Derrick, Ian Wilson, Carol Jaeger, Bryan Gick, Eric Vatikiotis-Bateson, and Sidney Fels (Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z4)

ArtiSynth is a modular, component-based system for performing dynamic 3D simulations of the human vocal tract and face. It provides a test bed for research in areas such as speech synthesis, linguistics, medicine, and dentistry. ArtiSynth's framework enables researchers to construct, refine, and exchange models of all parts of the vocal tract and surrounding structures. ArtiSynth introduces a probe concept to unify input and output data flow, which allows control of and access to models with time varying data series. ArtiSynth supports interconnected heterogeneous models, such

as rigid body, mass-spring, and parametric, using a point-set connection method, called markers, for constraint satisfaction. Using ArtiSynth, we created a muscle-driven rigid body jaw model, a parametric principle component tongue model from MRI images, a parametric lip model, and mass-spring face tissue model. We combined them in various ways. Data from medical imaging (MRI, CT, and ultrasound) and other technologies such as optical tracking can be used to drive ArtiSynth models. We are currently developing an acoustical rendering framework supporting source-filter models and other advanced methods. The system incorporates a powerful scripting interface as well as an easy-to-use graphical interface. [Work supported by NSERC Canada and ATR Japan.]

4aSC8. Design of a 6 degree of freedom anthropomorphic robotic jaw. Edgar Flores and Sidney Fels (Dept. of Elec. & Comput. Eng., UBC, 2356 Main Mall, Vancouver, BC, Canada V6T 1Z4)

We have created a 6 DOF robotic jaw capable of producing, in real-time, the complex set of motions described by the human jaw during speech or mastication. The jaw is designed to fit within a larger robotic human figure such as the head, neck and torso of the 25 DOF Infanoid. [Kozima, Hideki: Infanoid: A Babybot that Explores the Social Environment, K. Dautenhahn *et al.* (eds.), Socially Intelligent Agents: Creating Relationships with Computers and Robots, Kluwer Academic Publishers, pp. 157–164, 2002]. The produced mechanical prototype has been designed to accommodate a prosthesis mandible with dentures. The mechanism could fit within the skull of the average man; where it would occupy less than 1/3 of the skull cavity. Two TMJs (temporomandibular joints) support the prosthesis, where each is driven by a 3 DOF parallel manipulator. In order to combine the motion of both manipulators each TMJ is capable of 3 DOF. The system is controlled via a USB port using software that models the human skull including collision detection mechanisms. The jaw allows for linear control, zero-backlash, and up to three times exaggerated mobility ranges making it also suitable for speech research, facial gesture affect research and dentistry applications.

4aSC9. Effects of subglottal acoustics on phonation onset. Juergen Neubauer, Zhaoyan Zhang, and David Berry (UCLA School of Medicine, 31-24 Rehabilitation Ctr., 1000 Veteran Ave., Los Angeles, CA 90095, zyzhang@ucla.edu)

The effect of subglottal acoustic loading on the vocal fold vibration was investigated using a self-oscillating mechanical model of the folds. Although the influence of the supraglottal tract on vocal fold vibration has received more attention than the subglottal system, the influence of the subglottal system on vocal fold vibration is also potentially significant, and merits investigation. In this study, the subglottal system consisted of a uniform tube connected to an expansion chamber on the flow supply end (e.g., a pseudo-lung). The length of the subglottal tube was varied systematically over a relatively large range in order to investigate the influence of subglottal acoustics on vocal fold vibration. Phonation onset and offset pressures were measured in the subglottal tube as a function of tube length. Over the range of investigation, the fundamental frequency of phonation was found to be negatively correlated with the subglottal tube length. However, both phonation onset and offset pressure were positively correlated with subglottal tube length, with the onset pressure increasing faster than the offset pressure. This hysteresis effect vanished and the two pressures merged at a small value of the subglottal tube length, indicating a change in the onset behavior from a subcritical Hopf bifurcation to a supercritical Hopf bifurcation (a codimension-2 bifurcation point). In addition, phonation did not exist below a critical subglottal tube length.

4aSC10. Classification of initial segments of sounds using onset data structures. Dagmar S. Fraser and Leslie S. Smith (Dept. of Computing Sci. and Mathematics, Univ. of Stirling, Stirling FK9 4LA, Scotland, dsf@cs.stir.ac.uk)

Biologically motivated techniques are used to record onset data structures [L. S. Smith and D. S. Fraser, IEEE TNNS **15**, 1125–1134 (2004)]. These structures record sets of events detailing both the spectral and intensity structure of sound onsets. They are inspired by the output spikes from onset cells in the cochlear nucleus. We suggest that the spectro-temporal characteristic of these structures provides useful information for classifying initial segments of sounds. The original onset data structure is of high dimensionality, and is difficult to interpret directly. A self-organizing feature map (SOFM or Kohonen network) is therefore used to provide a lower dimensional coding. The SOFM requires fixed-length data vectors, preferably not of too high a dimensionality. A number of different reformatting techniques are used to provide this. For the SOFM, identified activated map areas are associated with particular sounds. Using the TIMIT database these areas can be labelled, providing a testable classification scheme. This is compared with other work classifying TIMIT phonemes. We believe that the SOFM can be extended to classify the onsets of other (non-speech) sounds. [Work supported by UK EPSRC.]

4aSC11. Computational fluid dynamics simulation of a sibilant. Kazunori Nozaki, Toyokazu Akiyama, Shinji Shimojo (Cybermedia Ctr., Osaka Univ., 5-1 Mihogaoka, Ibaraki, Osaka 567-0047, Japan, nozaki@cmc.osaka-u.ac.jp), Shingo Maeda, Takeshi Kaishima (Osaka Univ.), Hiroo Tamagawa, and Yoshinobu Maeda (Osaka Univ.)

It is well known that a sibilant is generated around the anterior teeth and the frontal part of palate. However, there is no study that the sibilant sound source is detected and visualized. Dentists often need to fabricate the prostheses including the anterior teeth and the palate. It would be useful if the critical part of the prostheses on the generation of sibilant could be detected before the fabrication and treatment. In this present study, Computational Fluid Dynamics simulation was performed in order to examine the oral air flow on pronouncing sibilant. Moreover, Powell sound source around the anterior teeth was detected and visualized by combining Computational Fluid Dynamics simulation and Computational Acoustical Analysis. As a result of this study, dentists can obtain the clinical criteria of the prosthetic treatment with considering sibilant.

4aSC12. Deriving speaking rate effects on tonal realization without varying the speech rate. Alan C. L. Yu (Univ. of Chicago, 1010 E 59th St., Chicago, IL 60637, aclyu@uchicago.edu)

Previous research investigates the effect of durational variation on tonal realization by artificially inducing a change in speaking rate. Through an investigation of the f_0 pattern of Cantonese mid-rising tone, this paper introduces a novel, indirect, method of investigating durational effect on tonal realization by looking at the variation in tonal realization in different syllable types. Cantonese has three syllable types: CV, CV(V)O, CV(V)N. CV(V)N syllables are found to be significantly longer than CV syllables, which in turn are significantly longer than CV(V)O syllables. In this study, five native Cantonese speakers were asked to recite a list of Cantonese words with a mid-rising tone in a carrier phrase. The f_0 of the Turning Point (the lowest point of a rise), the f_0 peak of the rise, the durations of the Turning Point and the f_0 peak relative to the onset of voicing, and the duration of the syllable rime were measured. The results show that the f_0 peak frequency remains constant regardless of the duration of the syllable. The f_0 of the Turning Point gets higher when the duration of the syllable becomes shorter. Finally, the slope of the f_0 rise remains constant regardless of the duration of the syllable.

4aSC13. Mechanical vocal cord model mimicking human biological structure. Eiji Shintaku, Kotaro Fukui, Kazufumi Nishikawa, Shunsuke Ikeo (Dept. of Mech. Eng., Waseda Univ., 3-4-1 Ookubo, Shinjuku-ku, Tokyo 169-8555, Japan), Kentaro Takada, Atsuo Takanishi (Waseda Univ., Saitama, Japan), Hideaki Takanobu (Kogakuin Univ., Tokyo, Japan), and Masaaki Honda (Waseda Univ., Saitama, Japan)

We present a mechanical vocal cord model aiming for a talking robot, WT-5 (Waseda Talker No. 5). Unlike a musical reed which has been used in conventional mechanical speech synthesizer, the vocal cord model is formed to mimic the human's vocal cord in the shape and the biological structure. It is made of a thermoplastic rubber, Septonh (Kuraray Co. Ltd.) of which the elasticity like a human's, and has 3-DOF mechanisms which is similar to the human structure. 1-DOF link mechanism could change the pitch by stretching the length of the vocal cords. The 2-DOF arm mechanism is used to mimic the abduction and adduction of a human arytenoid cartilage. The vocal cord model was excited by air flow exhausted from a mechanical lung model. The vibration pattern was observed by a high-speed camera, and the glottal volume velocity and the sound pressure were recorded by a mask-type wire screen pneumotachograph and a microphone. It was shown that the lower and upper edges of the vocal cords could vibrate in a different phase and the sound spectrum was similar to the source spectrum of human speech.

4aSC14. An educational articulatory synthesizer, EASY. Richard S. McGowan (CReSS LLC, 1 Seaborn Pl., Lexington, MA 02420) and Reiner Wilhelms-Tricarico (CReSS LLC and Haskins Labs., New Haven, CT 06511)

An articulatory synthesizer has been written for general educational and research use. It has been named Educational Articulatory Synthesizer, EASY, and written in the MATLAB programming language. In its current instantiation, the synthesizer performs calculations in the frequency domain and includes the effects of wall-vibration, viscous and thermal boundary layer loss, and radiation loss. Sources anywhere from the glottis to the mouth can be specified. Further, the code allows for side branches other than the nasal tract so that sounds such as laterals can be specified. A low-frequency aerodynamic module has also been included. Midsagittal shape is controlled by a hierarchy of flesh points. Points high in the hierarchy specify the overall shape by determining reference positions for points lower in the hierarchy, which, in turn, determine the shape locally. [Work supported by grant NIDCD-001247 to CReSS LLC.]

4aSC15. The relation between learning Mandarin Pinyin or Zhuyin and L2 (English) production. Yan Helen Yu and Fredericka Bell-Berti (Dept. of Speech, Commun. Sci., & Theatre, St. John's Univ., 8000 Utopia Pkwy, Jamaica, NY 11439)

This study investigates the relation between early written first language learning experience and the perception and production of speech in a person's second language (L_2). It compares the English pronunciation of native Mandarin speakers who have had different sound-annotating learning experiences (Pinyin versus Zhuyin). We predict that native Mandarin speakers who used the Pinyin system will produce some English sounds as their Pinyin counterparts if the same Roman letter is used as a pronunciation symbol both in English and in Pinyin system. However, because Pinyin and Zhuyin are not the primary written form for Mandarin, and are extensively used only in the first years of school, and because L_2 learning involves exposure to speech as well as reading, we expect only moderate differences between the two groups' perception and production abilities. We will examine the interaction for Pinyin and Zhuyin learners between (Mandarin) L_1 learning experience, age effects, L_2 experiences, and the establishment of English phonetic categories for the English monophthongal vowels and consonants /r/, /z/, and /l/.

4aSC16. Characterization of voice pathologies from acoustic signals using wavelet analysis. Sarah A. Bentil and Yuling Yan (Dept. of Mech. Eng., 302 Holmes Hall 302, Univ. of Hawaii-Manoa, Honolulu, HI 96822, bentil@hawaii.edu)

We present a method to quantitatively characterize voice abnormalities using wavelet analysis. The proposed method uses wavelets to decompose acoustic signals, acquired clinically from patients with normal and pathological voices, into their designated frequency/time components. These components contain valuable information on the unique dynamic properties of the vocal system and correlate with specific voice conditions. A comparative analysis of these vocal signals using spectrogram is also presented. These combined analyses provide comprehensive representation and quantitative characteristics of the vocal dynamics, which may provide key indication of vocal abnormalities. Further wavelet analysis of acoustic data evaluates variations in the characteristics of the vocal signal from one glottal cycle to the next. This is valuable since vocal signals representing most pathological voice productions exhibit inter-cycle variations in intensity or/and frequency. Our results of analysis show that the wavelet analysis can be used to characterize voice pathologies and provide information regarding the type and severity of the disorder. [Work supported by NSF awarded to Yan.]

4aSC17. Synthesizer software for modeling voice quality. Norma Antonanzas-Barroso, Bruce R. Gerratt, and Jody Kreiman (Div. of Head/Neck Surgery, UCLA School of Medicine, 31-24 Rehab Ctr., Los Angeles, CA 90095-1794, jkreiman@ucla.edu)

This poster presents a formant synthesizer that is designed especially for detailed modeling of voice quality. Users may interactively manipulate source pulse shapes and/or spectral characteristics of the voice source, the noise spectrum and noise-to-signal ratio, jitter and shimmer, vocal tremor rate and extent, and the vocal tract transfer function (formants and bandwidths), all in near-real time. Pitch contours can be modeled directly or imported. The synthesizer may be utilized in method-of-adjustment tasks, or sequences of stimuli may be created for use in other experimental paradigms. An interactive audio-visual display makes this a useful tool for teaching voice acoustics as well. Both an executable version of the program and the underlying code will be available during the conference. Copies of software that supports the voice modeling effort, including an interactive inverse filter, will also be distributed. [Work supported by NIDCD grant DC01797.]

4aSC18. Simulation and analysis of tremor in speech production. Kimberly A. Farinella and Brad H. Story (Dept. of Speech, Lang., and Hearing Sci., Univ. of Arizona, P.O. Box 210071, Tucson, AZ 85721-0071)

Tremor of the muscles used for voice and speech production creates frequency and amplitude modulations in the acoustic speech signal. Frequency modulation results primarily from changes in muscle activations that alter the mass and stiffness of the vocal folds, consequently altering the fundamental frequency (F_0). The primary source of amplitude modulation comes from time-varying activation of the respiratory muscles (which alter alveolar pressure), from laryngeal muscles that modify the maximum glottal area, or from interaction of voice source harmonics with the vocal tract filter. The purpose of this preliminary investigation was to analyze acoustic signals generated with an articulatory speech synthesizer in which tremor was imposed separately at each of the three anatomical sites: the respiratory system, larynx, and upper airway (pharynx). The synthesizer consisted of a voice source model of the time-varying glottal area coupled to a wave propagation model of the airways upstream and downstream of the vocal folds. This allowed for complete control of F_0 , alveolar pressure, glottal area, vocal tract shape, and modulation frequencies of each. Frequency and amplitude contours of the resulting acoustic

signals were extracted from the waveform and analyzed and compared using customized Matlab routines. Submitted For (Speech Communication) Young Presenter Award and (Speech Communication) Best Student Paper Award.

4aSC19. Temporal features in TV news and weather forecasts. Tatiana I. Shevchenko and Natalia Uglova (Moscow State Linguistic Univ., 38 Ostozhenka, Moscow 119992, Russia)

The paper is aimed at investigating the specific features of temporal component as manifested in authentic TV speech, news and weather forecasts of the three channels: NBC, Texas News, Philadelphia Fox. In our 10 min corpus (9 speakers, 5 men and 4 women) durational patterns and pauses between them as well as their ratio were measured. The data showed that on average a durational pattern lasts 2655 ms, while an average pause duration is 193 ms. Thus pausing does not take a major amount of time, while phonation is 14 times as long. Furthermore, the analysis reveals the abundance of short and extra short pauses which also stands for a rapid tempo. The temporal characteristics were correlated with regional affiliation, genre and gender distinctions. The speakers demonstrated uniformity in the basic temporal features determined by time limit constraints. The results of our investigation basically agree with previous research based on mass media interviews, reading and spontaneous monologues. However, our findings show that a salient feature of newsreaders speech is their ability to deliver an enormous volume of information at a very quick tempo, which is a real challenge to viewers.

4aSC20. Stabilization techniques for ultrasound imaging of speech articulations. Lisa Davidson and Paul De Decker (Dept. of Linguist., New York Univ., 719 Broadway 4th Fl, New York, NY 10003)

One challenge for the ultrasound imaging of the tongue during connected speech is stabilization of both speakers heads and the ultrasound transducer. To accurately analyze tongue shapes, researchers must ensure that differences among images result from changes in tongue shape, not head or transducer movement. In this validation study, we present an inexpensive, space-saving technique for stabilizing the head and transducer during the collection of ultrasound images in the laboratory. Four speakers were video-recorded producing 5 blocks of 19 sentences each. The speakers' heads were immobilized with a moldable head stabilizer (Comfort Company, model #HSM) affixed to a wall while the transducer was held by a microphone stand. Markers were attached to points on the speakers' faces and the transducer. Custom-written MATLAB software was used to find the center of the markers for every 10th frame of the recordings. Results indicate that the transducer does not move, and head movement beyond the measurement error of 1 mm is confined to the first block, while speakers are adjusting to the equipment. As compared to other stabilization techniques [Stone and Davis, J. Acoust. Soc. Am. **98**, 3107–3112 (1995)], this method provides equivalent immobilization that is significantly less expensive and portable for fieldwork.

4aSC21. Acoustic eigenmodes and formant-cavity affiliations for the time-varying vocal tract. Gordon Ramsay (Haskins Labs., 270 Crown St., New Haven, CT 06511-6204, ramsay@haskins.yale.edu), Philip Rubin (Haskins Labs., New Haven, CT 06511-6204), and Catherine Best (Haskins Labs., New Haven, CT 06511-6204)

Acoustic analyses of speech production are often based on assumptions about formant-cavity affiliations. Typically, these are derived from approximations based on coupled resonators, or from small-perturbation analyses for open vowel configurations. Few studies have accurately calculated formant-cavity affiliations for tightly-constricted vocal tract shapes, or for vocal tract shapes that change in time. In this paper, we show how to determine the acoustic eigenmodes of the vocal tract from a physical simulation, and apply this to examine time-varying formant-cavity affiliations during sequences of consonants and vowels. A state-

space model of quasi-one-dimensional acoustic wave propagation in a time-varying elastic tube is derived, using the finite volume method. The eigenvalues and eigenvectors of the resulting implicit matrix recursion are shown to determine the formant frequencies and bandwidths, and the spatial distribution of potential and kinetic energy for each formant, at each

point in time. Illustrations are given for examples of VCV sequences constructed using an articulatory model, including stops, fricatives, and approximants in different vocalic contexts. Formant-cavity affiliations, as defined by the localization of acoustic energy along the vocal tract, do not necessarily correspond to actual cavities. [Work supported by NIH.]

4aSP1. Broadband nearfield beamformer with compact size by using Nash genetic algorithm. Soonkwon Paik (Elect. & Comput. Eng., Univ. of Texas, 1 Univ. Station Stop C0803, Austin, TX 78712, soonkwon@mail.utexas.edu) and Elmer L. Hixson (Univ. of Texas, Austin, TX 78712)

Though the acoustical array is effective in the reverberant field, its usage has been limited at low frequencies since the array with the length of more than 1 meter is difficult to install inside a vehicle. Furthermore, it is impractical to use circular coordinates especially inside vehicle since the sound source, a human mouth, stays at a fixed distance from and moves along the parallel line to the surface of the headliner. For the delay-and-sum beamformer in near-field, it is difficult to get the complex coefficients, amplitude weight and time delay, by analytical methods. In this paper, one numerical optimization method for a fixed microphone array is investigated which uses the Nash Genetic Algorithm (Nash GA) which was originally used in electromagnetism problems. By using Nash GA, first the optimal geometry of array element alignment inside a vehicle is found, then the complex coefficients are obtained. The results measured in an anechoic chamber correspond to that of computer simulation and satisfy the requirement of hands-free mobile telephony where the microphone array is installed in a vehicle's headliner and the data is also measured in a reverberant field to investigate the signal to noise ratio.

4aSP2. Capacity of the oceanic waveguide. W. J. Higley, Philippe Roux, and W. A. Kuperman (Marine Physical Lab., Scripps Inst. of Oceanogr., 9500 Gilman Dr., La Jolla, CA 92093-0238)

Capacity between two multiple-input/multiple-output (MIMO) arrays can be computed by decomposing the Green's function matrix into orthogonal functions, which can be thought of as independent subchannels. In a waveguide with sufficient array sampling, the modes are the independent subchannels, and capacity can easily be calculated for given waveguide parameters. Capacity is calculated using the optimal power allocation strategy of "water-filling." Water-filling is simultaneously done across modes and frequency. Theoretically computed capacities for an oceanic waveguide between two vertical arrays for various waveguide parameters, along with physical explanation, will be presented.

4aSP3. Detection enhancement using multiple time-reversed guide sources in shallow water: Analysis of TREX04 data. David C. Calvo, Charles F. Gaumont, and David M. Fromm (Acoust. Div. Naval Res. Lab., Washington, DC 20375-5320)

Detection in a monostatic, broadband, active sonar system in shallow water is degraded by propagation-induced spreading. In the TREX04 experiment, performed south of the Hudson Canyon off the coast of New Jersey, 0.25 sec LFMs were transmitted with 500 Hz bandwidths chosen over a 0.5–3.5 kHz range using the NRL 64 element source-receiver array. The transmissions were then echo-repeated by a distant ship at a range varying between 1–5 km. The echo-repeating ship also transmitted one-way, 1 s, LFMs which were used as guide-source signals. These guide-source signals, which contain environmental information, form the basis of a technique for improving detection without having explicit environmental knowledge. Using an empirical-orthogonal-function representation of the set of monostatic guide-source signals, echoes were convolved with the time-reversed orthogonal functions as part of a filter bank. The result is improved probability of detection of noisy echoes using multiple guide-source signals in comparison with a baseline probability of detection using matched-filtering. In this talk, ROC curve improvement is analyzed as a function of the many parameters, e.g., target depth, source aperture, bandwidth, number of guide sources and their spatial and temporal separation. Comparison with numerical simulations is also made. [Work supported by ONR.]

4aSP4. Backpropagation image analysis of broadband decomposition of the time reversal operator (DORT) data from TREX-04. David M. Fromm, Charles F. Gaumont, Richard Menis, David C. Calvo (Naval Res. Lab., 4555 Overlook Ave. SW, Washington, DC 20375-5320), Joseph F. Lingeitch, Geoff F. Edelmann, and Elisabeth Kim (Naval Res. Lab., Washington, DC 20375-5320)

Single-frequency DORT is a method of isolating scatterers with a multiple-source/multiple-receiver system [C. Prada *et al.*, J. Acoust. Soc. Am. **99**, 2067–2076 (1996)]. Broadband DORT overcomes problems of frequency fading and dispersion by exploiting the response of singular values across the entire signal bandwidth. In spring 2004, the Time Reversal Experiment, TREX-04, collected data for the evaluation of the broadband DORT technique. An 80 m vertical source/receiver array with 64 hydrophones was deployed in 100 m deep water in an area south of Hudson Canyon off the New Jersey coast. Sets of four, five, or six beams were transmitted at small angles from horizontal and the response from an echo repeater was recorded on 64 channels. Data was collected in 500 Hz bands between 500 and 3500 Hz with the echo repeater at ranges from 0.5 to 5.0 km and at mid-water column and near-bottom depths. Applying the

broadband DORT algorithm, the isolation of the echo repeater signal in the singular vectors and the robustness of broadband backpropagation images will be presented as a function of frequency band, signal coherence, echo repeater range and depth, noise levels, and receiver aperture. [Work supported by the ONR.]

4aSP5. Ultrasonic tomography for density gradient determination and defect analysis. Xiang Zhao and Joseph L. Rose (Dept. of Eng. Sci. and Mech., Penn State Univ., University Park, PA 16802)

Ultrasonic tomography is used to study density gradients and structural defects. In practice, it is not possible to measure an almost infinite number of projections, necessary for the transform-based techniques to produce highly accurate results. To overcome this difficulty, interpolations with respect to sample angle and projection angle based on fewer measurements are used to generate the required projection data. The number of sampled grid values necessary for displaying a well-balanced reconstructed image to reduce the aliasing distortions caused by insufficiency of the input data is then possible. For slowness reconstruction, as an example, one should constrain the time of flight at a source point to zero when using interpolation, other than using extrapolation to generate projection data to guarantee that the interpolated data around the source converges to zero. Hence no time is taken when a source and a detector overlap. Algebraic reconstruction algorithms, however, lack the accuracy when using a smaller number of measurements, and computational efficiency when using an abundant data set generated by interpolating. Results show that this approach can improve the overall accuracy and cost more effectively, thus making it a potentially, powerful tool for studying in-situ process and health monitoring. [Work supported by NSF.]

4aSP6. Implementation of a nearfield acoustic holography system based on pressure and velocity measurements. Michael C. Harris, Jonathan D. Blotter (Dept. of Mech. Eng., Brigham Young Univ., 435 CTB, Provo, UT 84602), and Scott D. Sommerfeldt (Brigham Young Univ., Provo, UT 84602)

Analytical models have indicated that a pressure and velocity-based nearfield acoustic holography (NAH) method will provide the same reconstruction resolution of current NAH methods with significantly fewer measurement locations. This would lead to a considerable savings in data acquisition time for scanning array systems and reduce the inefficiency of NAH for high spatial frequencies. The pressure and velocity-based NAH method will be introduced. Experimental results for a simply supported plate and cylinder will be presented. These results will be compared to results obtained using conventional NAH methods.

4aSP7. Energetically optimal regularization in nearfield acoustical holography. Xiang Zhao (Dept. of Eng. Sci. and Mech., Penn State Univ., University Park, PA 16802)

Regularization techniques, such as singular value discarding or Tikhonov regularization, are commonly used to improve estimate of source field to be reconstructed from measured acoustic pressures at many points in nearfield acoustical holography. Theoretically, however, the regularized solution always underestimates the sound power of the real source. This paper presents an energetically optimal regularization method to solve this problem in nearfield acoustical holography by introducing a compensation factor in the generalized cross-validation function used to determine the optimal regularization parameter based on the Tikhonov regularization technique. Numerical examples show that the resulting regularization parameter will not only ensure a good fit of the predicted acoustic pressures to all measured data, but also ensure that the sound power of the equivalent source is always in agreement with the measured

sound power, thus making this regularization method more ideal and much better than others in finding a compromise between the fidelity to input data and the fidelity to source field, and yielding a robust solution to the source field. [Work supported by NSF.]

10:30

4aSP8. Multi-variate error analysis of beam-forming acoustic measurements in a wind-tunnel. Ramani Ramakrishnan, Greg Kawall, Pushpinder Bhullar (Ryerson Univ., 350 Victoria St., Toronto, ON, Canada M5B 2K3, rramakri@ryerson.ca), and Norman Ball (Inst. for Aerospace Res., NRCC, Ottawa, Canada K1A 0R6)

Source localization has been in the forefront in acoustics, since quantification of the source power and its exact location is de rigeur for successful noise control. Starting from single microphone measurements, many different methods, progressively more successful and complex, have been attempted for source localization. Recently, beam-forming methods, due to their success in underwater acoustics and architectural acoustics, have been used in wind tunnel tests. These tests have been quite extensively utilized both in automotive and aircraft tests. Beamforming techniques use an array of microphones, arranged in different patterns, to detect the source location and source power. In beamforming, the array in effect beams, not in the physical sense, towards the source to determine its position. Various parameters determine the success of the beamforming techniques. Some of these parameters are: number of microphones, microphone spacing, array pattern, source frequency and signal analysis procedures. A series of microphone array tests were conducted at the national Research Council of Canada's wind tunnel, with and without flow. The source location was known *a priori*. A multi-variate error analysis was performed to determine the importance of the different parameters. The results of the analysis will be presented in this paper.

4aSP9. Acoustical spectral analysis of a wake vortex cross-section using microphone-arrays. Hadi S. Wassaf (John A. Volpe Natl. Transportation Systems Ctr., Cambridge, MA 02142), Oliver C. Ibe (Univ. of Massachusetts, Lowell, MA 01854), and Robert P. Dougherty (OptiNav Inc., Bellevue, WA 98004)

The ability to unambiguously identify the acoustic energy generated by airplane wake vortices using phased microphone-array intensity distribution maps is hampered by the lack of knowledge of the associated non-stationary spectrum throughout the wake's duration. This ambiguity is especially pronounced when the low broadband signal to noise ratio renders the wake signal difficult to isolate from contaminating background noise. In this paper, a technique to isolate the acoustic spectral content of a cross sectional wake track (CSWT) is presented. First, image processing is used to generate a CSWT from vertical intensity distribution maps. In a second beamforming stage, the array's main-lobe traces the track to amplify the acoustic signal along the CSWT and estimate its time-varying power spectral density $P_{CSWT}(f)$ using Short Time Fourier Transform. Simultaneously, the background noise frequency-dependent upper confidence limit $CL(f)$ is estimated at each time increment by steering the array away from the wake source. The time varying $CL(f)$ is then used as an adaptive threshold function on $P_{CSWT}(f)$ in order to dynamically segment out the wake frequency bands from those of the contaminating noise sources.

11:00

4aSP10. Performance analysis of ambiguity function based broadband chirp direction of arrival estimation. Ning Ma and Joo Thiam Goh (DSO Natl. Labs., Singapore)

When estimating the direction of arrival (DOA) estimation of broadband sources with an array, the source is usually modeled as white noise. However, when the source signal has certain time-frequency structure, studies have shown that the DOA estimation performance can be improved

by using the information about its structure. In our previous work [Ning Ma and Joo Thiam Goh, "DOA Estimation for Broadband Chirp Signals," Proc. of ICASSP 2004, Vol. II, pp. 261–264], we have proposed two new methods for broadband chirp signal DOA estimation based on the ambiguity functions, namely Incoherent Broadband Chirp DOA estimation (CBD-I) and Coherent Broadband Chirp DOA estimation (BCD-C). Besides improving the accuracy of the DOA estimates, these algorithms work with signal frequencies that are higher than the array design frequency. The number of sources are also not constrained by the number of sensors. The performance of the proposed DOA estimation methods is analyzed theoretically and numerically in this work. The analysis results show that these methods can improve the output SNR and therefore the DOA estimation performance when input SNR is higher than certain level.

11:15

4aSP11. Experimental reproduction of random pressure fields in laboratory conditions. Teresa M. Bravo and Cedric Maury (Dept. de Genie Mecanique Acoustique, UTC, Ctr. de Recherche Royallieu, BP20529, 60205 Compiègne France, teresa.bravo-maria@utc.fr)

The design and the physical implementation of an experimental set-up are discussed for the off-line reproduction of random wall-pressure fluctuations with given spatial correlation characteristics. This approach could provide a cost-effective laboratory method of both reducing the variability of low frequency sound transmission measurements as well as measuring the boundary layer noise transmitted through aircraft fuselage structures. Three different types of random excitations are considered, namely an acoustic diffuse field, a turbulent boundary layer excitation and an acoustic progressive wave at grazing incidence angle. The corresponding excitations are generated in a semi-anechoic chamber using a near-field array of 4×4 loudspeakers optimally driven and located above a set of 13×16 microphones. The microphones are positioned a short distance apart from

an aluminum test panel. The optimal driving signals are determined from acoustic transfer functions measurements between the grid of microphones and the array of loudspeakers. Given this number of loudspeakers, a reasonable reproduction of the boundary-layer excitation is achieved up to about 200 Hz and a good approximation of both the acoustic diffuse field and the progressive wave is obtained over the frequency range of interest, i.e. up to about 700 Hz. [Work supported by ANVAR.]

11:30

4aSP12. Acoustic to seismic ground excitation using time reversal. Brad Libbey and Douglas J. Fenneman (Night Vision and Electron. Sensors Directorate, 10221 Burbeck Rd., Fort Belvoir, VA 22060)

Time reversal is a promising method of controlling the arrival of acoustic signals at receiver locations underwater and in biomedical tissues. This work applies the techniques in soil for landmine detection. The measurement of seismic vibrations between 50 and 300 Hz is problematic due to difficulties in transmitting energy into and through the soil from loudspeakers. The experimental setup consists of an array of loudspeakers capable of playing independent signals and a soil vibration sensor. The system response between the loudspeakers and the sensor are approximated, time reversed, and rebroadcast such that arrivals at the sensor are coincident. If the airborne and seismic paths are sufficiently complex, time reversal may help to control the energy distribution of a signal reaching the target region. However, the focusing ability is limited by an auto-correlation of the system impulse response that is inherent with time reversal processing. Simulations and experiments will be presented that demonstrate the advantages and limitations of using time reversal for controlling energy at a receiver. Results will compare vibration amplitude with and without the time reversal processing for target soil locations.

4aUW1. Spectral features of sound field fluctuations in shallow water with internal solitons. Mohsen Badiey (Univ. of Delaware, College of Marine Studies, Newark, DE 19716), Valery Grigorev (Voronezh State Univ., Voronezh 394006, Russia), Boris Katsnelson (Voronezh State Univ., Voronezh 394006, Russia), and James Lynch (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

Mode coupling of acoustic wave propagation in shallow water, in the presence of internal soliton is considered. It is shown that quasiperiodical behavior of temporal variability of the received signal (arising from the motion of soliton packets) provides some peaks in frequency spectrum. Positions of these peaks in spectrum are determined both by the space scales of interference beating (ray cycles) and velocity of solitons. Results of theoretical and numerical modeling as well as related experimental setup is discussed. [Work supported by ONR, RFBR and CRDF.]

8:45

4aUW2. Influence of random nonlinear internal wave parameters on resonant acoustic mode coupling. Scott D. Frank (Dept. of Mathematics, Marist College, Poughkeepsie, NY 12601) and William L. Siegmann (Rensselaer Polytechnic Inst., Troy, NY 12180)

Shallow water transmissions sometimes suffer anomalous amplification or loss caused by mode coupling due to the presence of nonlinear internal wave packets. The possibility of coupling between two acoustic modes is specified by an internal wave-acoustic resonance condition, which relates acoustic wavenumber differences to peak locations of the packet spectrum. This mechanism is critical in a recent analysis [S. D. Frank *et al.*, J. Acoust. Soc. Am. **116**, 3404–3422 (2004)] of some broadband intensity variations from the SWARM 95 experiment. That investigation used regularly spaced, evenly-sized nonlinear internal wave packets and it is important to determine how random variations in the wave widths and inter-wave spacings affect propagation results. An analytic expression

for the wavenumber spectrum of an idealized packet is obtained in terms of these parameters. This expression predicts spectral peak locations for parameters from the SWARM 95 model that correspond with observed data. Estimates of peak location statistics arising from random packet parameter variations are analyzed computationally and analytically. Variability of internal wave spectral peak locations is correlated with broadband intensity fluctuations obtained from parabolic equation computations. [Work partially supported by ONR.]

9:00

4aUW3. Influence of internal wave fluctuations on acoustic underwater propagation. Tatiana A. Andreeva, William W. Durgin, and Stefanie E. Wojcik (Mech. Eng. Dept., Worcester Polytechnic Inst., 100 Institute Rd., Worcester, MA 01609)

The work presents a ray acoustic based analysis of the effect of ocean internal waves and its fluctuations on acoustic wave propagation. In the present work, it is shown that consideration of only perfect internal waves simplifies the real problem, disregarding the fluctuations of internal waves. The focus of the paper is to study numerically the influence of internal wave fluctuations and the role of an initial ray angle onto underwater acoustic propagation. In the present formulation the eikonal equation is considered in the form of a second order, nonlinear ordinary differential equation with harmonic excitation due to internal wave. The harmonic excitation is taken imperfect, i.e., with a random phase modulation due to Gaussian white noise. The amplitude and wavelength of the acoustic waves are used as the principle signal characteristics in bifurcation analysis. The regions of instability are identified using the bifurcation and phase diagrams. The effect of internal waves phase modulation is demonstrated by means of comparison of the numerical data obtained in the present work with data, obtained perfect internal wave. The preliminary analysis shows very strong dependence of acoustic propagation on intensity of fluctuations.

9:15

4aUW4. Influence of internal waves on vertical coherence of sound propagation in the East China Sea. Jie Yang and Peter H. Rogers (School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0405)

Literature of the last two decades has shown that internal waves are a major factor determining sound field fluctuations [Zhou *et al.*, J. Acoust. Soc. Am. **90**, 2042–2054 (1991); Lynch *et al.*, *ibid.* **99**, 803–821 (1996)]. Due to its time-dependent and anisotropic nature, internal waves can cause both temporal and spatial variations in the sound speed profile and hence, the acoustic field. In this paper, a model is built to study the range and azimuthal dependence of wave propagation in the presence of internal wave activity. The results are based on an *in situ* experiment ASIAEX in the East China Sea where intense tidal driven internal waves were recorded. The model explains the observed decorrelation after long range propagation (20 km) and in certain directions relative to the internal wave wavefront.

9:30

4aUW5. Intensity and time-angle fluctuations of high frequency signal propagation in shallow water. Mohsen Badiy, Jing Luo, and Aijun Song (Univ. of Delaware, College of Marine Studies, Newark, DE 19716)

Several high frequency experiments in recent years have been directed towards assessing signal variability as a function of channel environmental parameters. In this paper, results from one of these experiments in a shallow water region are shown. Acoustic communication coded signals were transmitted between a source and two receiver arrays separated 1 and 2 km respectively while detailed measurement of the channel environmental parameters were recorded. Channel impulse response function and the correlation time of the channel are obtained. Ray theory is used to analyze and interpret the experimental data. Arrival time-angle fluctuations were found to be directly correlated with the environmental variability due to ocean dynamics in the experiment region.

4aUW6. Mean and variance of the 3-D field forward propagated through random internal waves in continuously stratified deep and shallow water ocean waveguides. Tianrun Chen, Purnima Ratilal, and Nicholas C. Makris (MIT, 77 Massachusetts Ave., Cambridge, MA 02139)

A general modal solution for the mean and covariance of an acoustic field propagating through 3-D random inhomogeneities in an ocean waveguide [Ratilal and Makris, J. Acoust. Soc. Am. **114**, 2428 (2003)] is applied to propagation through a general 3-D internal wave field. Our previous two-layer internal wave parameterization is extended to continuous stratification and applied in both continental shelf and deep ocean waveguides. Physical and statistical properties of the internal waves are modeled with the Garret-Munk and other theoretical and empirical formulations. The mean and variance of the forward field propagating through internal waves is expressed in terms of the stochastic moments of the medium's scatter function density. This is formulated with the Rayleigh-Born approximation to Green's theorem in terms of the medium's compressibility and density fluctuations. In this way, the effect of both internal-wave sound speed and density variations on the forward propagated field are quantified. Density variations are shown to greatly affect high order modal propagation in some cases. Two-dimensional models of propagation through random internal wave fields are shown to become inaccurate after exceeding threshold ranges where 3-D scattering becomes important.

10:00

4aUW7. A mean field transport theory for long-range ocean acoustics. Michael Wolfson and Frank Henyey (Univ. of Washington, APL, 1013 NE 40th St, Seattle, WA 98105-6698)

Voronovich has found from an ocean model that the mean acoustic wavefield at low frequency persists after multi-megameter propagation in the deep ocean. The common belief has been that only the incoherent field survives long propagation distances. His results, if true in the real ocean, have important consequences to extracting signals from long-range propagation. The results of an alternative ocean model, for which the mean field is evaluated using transport theory, are presented, and compared to his results. Our model consists of a single background sound speed field superposed with sound speed fluctuations due to internal waves. We present results for sources used in recent experiments such as LOAPEX (75 Hz with about 30 Hz bandwidth).

10:15–10:30 Break

10:30

4aUW8. Calculation of amplitudes of acoustic normal modes from the reciprocity principle. Oleg A. Godin (CIRES, Univ. of Colorado and NOAA/Environ. Technol. Lab., Mail Code R/ET-0, 325 Broadway, Boulder, CO 80305)

Recently, J. D. Achenbach [J. Acoust. Soc. Am. **116**, 1481–1487 (2004)] put forward, on heuristic grounds, an elegant technique to calculate amplitudes of guided waves generated by mechanical loading in a range-independent elastic medium. The technique is based on application of the reciprocity principle and allows one to solve the problem without use of integral transforms. In this paper, the technique is applied to acoustic waveguides in a layered fluid. By taking into account continuous spectrum of the field, which was disregarded by Achenbach, a mathematical justification of the technique is obtained. The technique is shown to be exact. It is further extended to enable calculation of excitation coefficients of modes of both discrete and continuous spectra by a given sound source. The results are shown to be identical to those derived with the traditional, more cumbersome methods that rely on integral transforms. [Work supported by ONR.]

10:45

4aUW9. Moving ship tomography a first look at BASSEX 04. Kevin D. Heaney (OASIS Inc., Falls Church, VA 22044) and Arthur B. Baggeroer (MIT)

During the Basin Acoustic Seamount Scattering Experiment (BASSEX04) a line array was towed between two source moorings in the North Pacific separated by 500 km. The moorings were part of the SPICE04 test led by Scripps Institution of Oceanography. Each mooring had two broadband sources (center frequency 250 Hz) at depths of nominally 800 m and 3000 m. Thirty transmissions were recorded as the ship passed south along the line bisecting the two source moorings. The sources transmitted simultaneously (for each source). In order to break the conical ambiguity of the arrivals from each source, the array was turned 20 degrees for each reception. One set of sources used coded m-sequences with different laws, permitting separation of the signals by signal processing. Comparisons of the received signals will be compared with initial propagation model results using the measured sound speed field from the ship. An approach to $N \times 2-D$ tomography (where $N=30$) will be investigated. [Work supported by ONR Ocean Acoustics.]

11:00

4aUW10. Basin Acoustic Seamount Scattering Experiment (BASSEX 04) II. Downslope propagation. Kevin D. Heaney (OASIS Inc., Falls Church, VA 22044), Arthur B. Baggeroer (MIT), Kyle M. Becker (ARL-Penn State Univ.), Eddie Scheer, and Keith Vonderheydt (Woods Hole Oceanogr. Inst.)

During the Basin Acoustic Seamount Scattering Experiment (BASSEX04), the Five-Octave Research Array (FORA) was deployed near the North Pacific Acoustics Laboratory (NPAL) bottom mounted tomography source just off the coast of Kauai. Receptions from the Kauai source were taken at ranges from 2 km out to 500 km. The data was taken to examine the affects of seafloor interaction on downslope propagation (propagation down both steep and shallow slopes), shallow water range-dependent 3-D propagation and conversion from shallow water propagation to deep water propagation. Conventional and adaptive beamforming results will be presented as well as comparisons between measured responses and PE modeled responses. Geo-acoustic inversions will be performed with the broadband source in end-fire and broadside orientations of the array. [Work supported by ONR Ocean Acoustics.]

11:15

4aUW11. Forward scattering from the Kermit-Roosevelt Seamount complex during the SPICEX-LOAPEX-BASSEX experiments. Arthur B. Baggeroer, Joseph Sikora III (Massachusetts Inst. of Technol., Rm. 5-206, Cambridge, MA 02139), Kevin Heaney (Oasis Corp., Lexington, MA 02173), Edward K. Scheer, Keith von der Heydt (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543), and Kyle Becker (Pennsylvania State Univ., State College, PA)

The SPICEX-LOAPEX-BASSEX experiments were executed in the Northeast Pacific to examine several long range, low frequency propagation phenomena. Low frequency sources centered at 68 and 75 Hz with nominal bandwidth of 30 Hz and a source at 250 Hz with 100 Hz bandwidth were deployed transmitting orthogonal M sequences and FM chirps. A 64 element towed array cut for 250 Hz from Penn State Univ. was the

primary multichannel receiving system. This presentation concerns the BASSEX study of low frequency scattering around the Kermit-Roosevelt Seamount complex which shoals to 900 m near 39 N and 145 W. We examine (i) the forward scattering shadow, (ii) any patterns of horizontal refraction as a function of source and receiver range from the seamounts, (iii) any backscattering from the seamounts, and (iv) the modal content of the signals by travel time methods. In addition, directional spectra of ambient noise were measured.

11:30

4aUW12. Three different directions of sound propagation in the China South Sea. Ma Li (Inst. of Acoust., Chinese Acad. of Sci., Beijing 100080, China)

In June 2004 three directions of sound propagation experiments were done in the China South Sea. One direction is equally sea depth. The second direction is slope. The third direction is largest gradient in sea depth direction. In the mean time three temperature chains have been applied for measuring the internal wave. During each temperature chain their distances are about 1000 m. The experiment results show that the packet of solitary waves has been found and each direction of sound propagation has different transmission loss. In the equally sea depth direction the sound propagation has the smallest transmission loss. And in the largest sea depth direction the sound propagation has the largest transmission loss. By three temperature chains data the packet of solitary waves propagation velocity and direction may be measured. And through the packet of solitary waves propagation direction the packet of solitary waves may be induced by the West Sand Island. In the end the couple normal mode program has been used to simulate the sound propagation which is affected by the packet of solitary waves. The simulating results are compared to experimental data.

11:45

4aUW13. Long-range acoustic transmission in a deterministic range-dependent ocean: Contribution from interference of near-axial waves. Natalie S. Grigorieva and Gregory M. Fridman (Dept. of Appl. Mathem. and Mathem. Modeling, St. Petersburg State Marine Tech. Univ., 3 Lotsmanskaya Str., St. Petersburg, 190008, Russia, nsgrig@natalie.spb.su)

The propagation of energy along the waveguide axis cannot be described in terms of geometrical acoustics because of the presence of cusped caustics repeatedly along the axis. In neighborhoods of these cusped caustics a very complicated interference pattern is observed. Neighborhoods of interference grow with range and at long ranges they overlap. For an arbitrary range-independent ocean, it was shown in [N. S. Grigorieva and G. M. Fridman, *J. Comp. Acoust.* **12**, 127-147 (2004)] that the interference of wave fields corresponding to near-axial rays results in a diffractive (as opposed to geometrical acoustics) component of the field which can be viewed as distinct, "axial" wave and effectively calculated using its integral representation. In this paper the integral representations of the axial wave in the frequency and time domains are obtained for a range-dependent ocean. In the frequency domain this representation has the form of a linear superposition of the solutions of the Helmholtz equation that are concentrated in a neighborhood of the sound-channel axis. The weight function is selected in such a way that the localization principle holds. The axial wave is simulated for a deterministic model of a range-dependent ocean corresponding to AET experiment. [Work supported by ONR Global.]

Session 4pAA**Architectural Acoustics and Noise: Soundscapes from an Architectural Viewpoint**

Brigitte Schulte-Fortkamp, Chair

*Technical Univ. Berlin, Inst. of Technical Acoustics, Secr TA 7, Einsteinufer 25, Berlin 10587, Germany***Chair's Introduction—2:15*****Invited Papers*****2:20****4pAA1. The soundscape as a tool for urban planners and town designers.** Catherine Semidor (GRECO, EAPBx, Domaine de Raba F-33400 Talence, France, catherine.semidor@bordeaux.archi.fr)

Urban planners and other town designers need information to improve the environmental quality of cities, for instance the components of the urban soundscape. To use the latter as a decision-making tool in a planning process it is necessary first to link objective and subjective acoustic criteria with architectural parameters and then to transmit the observed characteristic relations in a way which designers will understand. One of these ways is to make use of spatial references (streets' shape, facades' material, etc.) to explain the impact of the urban morphology, for example, on the sound environment. That is why, for many years, surveys were conducted in a lot of different areas. This paper deals with some comparative results obtained in different European towns.

2:45**4pAA2. Phase characterization of soundscapes.** Vincent Gibiat, Abril Padilla (PHASE, Univ. Paul Sabatier, 118 route de Narbonne, 31062 Toulouse, France, gibiat@cict.fr), Valentin Emiya (ENST, 75014, Paris, France), and Lionel Cros (ENSIETA, 29806 Brest Cedex 09, France)

Signal processing of soundscapes remains far from the auditive perception. It is particularly true when sounds recorded inside railway stations, are compared with the most accurate spectrographic representations. Such architectural realizations provide a soundscape between closed and opened spaces. As microphones used to discriminate sound sources as well as low level sounds use diffractions properties of radiation, as time discrimination between near sounds is efficient through time domain perception, as filtering often introduces phase distortions, it has been decided to explore a new kind of signal representation based on the phase of the Short Time Fourier Transform. After a basic presentation of the numerical tool named SAFIR for Spectrography in Amplitude and Frequency, Instantaneous and Reallocated, examples will be given that first show the differences between closed and opened spaces, then the differences between the soundscape inside a train and inside a station. As this work has been realized with sounds recorded for a later musical realization that deals to reconstruct both a new realistic or imaginary coherent soundscape, it has been essential to extract the pertinent, coherent, details as magnification of time or space opposed with the incoherent urban noise. Finally SAFIR will be compared with the composer work.

3:10**4pAA3. How does hearing get into architectural design?** Juergen Bauer (Architect, Mierendorffstr. 11, 10589 Berlin, Germany, jbauer.berlin@tiscali.de) and Brigitte Schulte-Fortkamp (Tech. Univ. Berlin, D-10587 Berlin, Germany)

Serious soundscape research needs an interdisciplinary approach to architecture. The design and the perception of architecture are dominated by the visual senses. Architects developing a complex building may be advised by a specified acoustic engineer. However the support provided by the acoustic engineer focuses less on creating acoustic qualities than on minimizing acoustic problems and noise effects. How about the sense of hearing of the architect? Designing architects have learned to shape 3-D. They have a precise vision of space and proportion. They know about light and shadow, about fabric and color. This profound world of vision is the basis of their inspiration, and they would be grateful to get more consciously in touch with the world of hearing not in terms of creating extraordinary sound-effects but in terms of imaginative listening. The visual phenomena architects are dealing with offer an approach to the world of hearing or rather analogies from watching towards listening. Light, shadow, fabric and color are no more matters only of sight but subject to audiovisual awareness. What acoustic processes might be most relevant to designing architects? What acoustic events and impacts should be specified in the education of design?

3:35**4pAA4. Soundscape perception of an urban park under flight paths of Naples airport.** Giovanni Brambilla (CNR-Inst. of Acoust., via del Fosso del Cavaliere 100, 00133 Rome, Italy, giovanni.brambilla@idac.rm.cnr.it), Leda De Gregorio, and Luigi Maffei (Second Univ. of Naples, 81031 Aversa, Italy)

The Capodimonte historical urban park is the largest green area in Naples, located in the North and under the flight-paths of the city airport. Noise measurements, taken in the morning on two weekdays and one week-end in different sites inside the park, have shown LAeq levels, excluding aircraft noise, lower than 50 dB(A) and up to 55 dB(A) on Sunday morning near the museum. During the noise measurements one aircraft flyover occurred approximately every five minutes, producing an increase of LAeq in the range

5-15 dB(A) and LAmax levels up to 90 dB(A). Interviews have been carried out on a sample of subjects present in the park while the noise measurements were taken. By means of a questionnaire, they were asked to rate different factors describing the environment and influencing their experience to enjoy the park. The analysis of the subjective data collected is in progress and the preliminary outcomes show that the reported annoyance due to aircraft noise is much lower than expected by the noise levels, most likely due to synergetic effects of the other environmental factors.

4:00

4pAA5. Community design with soundscape in mind. Bennett M. Brooks (Brooks Acoust. Corp., 27 Hartford Turnpike, Vernon, CT 06066, bbrooks@brooksaoustics.com)

Community standards for sound are usually defined by limits on noise emitters. These limits may be absolute in level, or relative to a background level. Most often a limit is given as an overall A-weighted level. Occasionally, limits are placed on octave band spectrum levels or on tonal content. The time function of noise is generally addressed only broadly, defined by terms such as impulse, intermittent, or continuous. The character of sound in the community is addressed in policy or law by vague definitions which prohibit sounds which are obnoxious or that cause a nuisance. The positive aspects of sound in communities are usually left to chance. Recently, one summer resort community initiated a policy which promotes outdoor entertainment in one district, while requiring quiet in another. This unique policy balances lifestyle and economic interests, and was developed through an inclusive community-based public process. The question of how the community-based policy development process may be used to enhance the soundscape of a targeted area is explored. The implications of such a policy process for the designers of buildings and public spaces are discussed.

4pAA6. Aesthetic transformations of soundscapes as a basis for architectural design. Gary Siebein (Univ. of Florida School of Architecture, P.O. Box 115702, Gainesville, FL 32607)

A graduate design studio in acoustics examines sound and silence as manifest in urban and rural exterior soundscapes as well as interior soundscapes within performance venues as potential theoretical and formal bases for architectural form. The soundscape analyses were composed of a series of quantitative and qualitative studies of real and virtual environments such as the actual project site in downtown Orlando and the interior soundscape of the Stats Opera in Vienna in the 19th century. Transformations of the soundscape analysis served as generative ideas for the basis of architectural interventions in complex sites and programs for a multi-venue performing arts center.

4:40

4pAA7. Bow bells—creating a sound community. Brenda Kiser and David Lubman (David Lubman & Assoc., 14301 Middletown Ln., Westminster, CA 92683)

For centuries, the sound of ringing church bells has given communities a sense of identity. Church bells have long been used to announce significant events to the community, such as births and deaths, to warn of impending danger, to call the faithful to church and to announce the curfew. This paper focuses on one prominent example of a sound community—the church of St. Mary-le-Bow in the City of London, the location of the famous Bow bells. These bells have featured in London's folklore and history since the 14th century and, to this day, identify those born within the sound of Bow bells as Cockney. This sound neighborhood was extended far beyond its natural borders when a recording of the bells was played by the BBC's World Service during World War II in broadcasts to occupied Europe. Sound examples are given. A short history of European church bells is presented. A cognitive scale is proposed, ranging from belonging to alienated, delineating psychological reactions of those within a sound neighborhood.

4pAB1. Autonomous remote humpback whale acoustic monitoring devices. Whitlow Au, Alison Stimpert, Marc Lammers (Marine Mammal Res. Program, Hawaii Inst. of Marine Biol., P.O. Box 1106, Kailua, HI 96734), and Niklas Johnson (Lund Univ., Lund, Sweden)

Four acoustic monitoring devices controlled by a CF-1 Persistor Instrument Inc. microcontroller board were developed to monitor the chorusing sounds of humpback whales in their wintering grounds off the

island of Maui. The units were programmed to turn on at the same time and sample chorusing sounds at a sampling rate of 3.33 kHz for 3 minutes every hour. The CF-1 was chosen because of its low power requirement of 40 ma while collecting data during the 3-min collection period, 3 ma while sleeping and 96 ma while storing the data onto a 2 Gbyte compact flash card. At this sampling rate, sampling period duration, and interval between sampling period, each unit has sufficient power to last 30 days when powered from a 12 Ahr lead acid battery. The 2 GB memory allows for 34 days of data collection. Four of these units were deployed along the west

shore of Maui at locations separated by 15 to 20 miles. The amplitude of chorusing by singing humpback whales and the temporal characteristics at the different locations were obtained with these sensors during the 2005 humpback whale season.

4pAB2. Monitoring ecologically important fish sounds: The characteristics and diel trends of sounds produced by three species of Pomacentrids. T. Aran Mooney, Marc O. Lammers (Hawaii Inst. of Marine Biol., Univ. of Hawaii, Kaneohe, HI 96744), Pedro A. Santos (Univ. of the Azores), and Paul E. Nachtigall (Univ. of Hawaii)

Many fish species make sounds. These sounds can be recorded, characterized, identified to species, correlated with behavior, and then monitored for temporal and behavioral trends. We developed a two-part approach to accomplish these tasks. The first is a Portable Underwater Acoustic (PUA) device, composed of a two-hydrophone, handheld, digital recorder. This system is used to identify fish sounds that can then be correlated with specific behaviors. The second is a single-hydrophone, autonomous recording system that is placed on the seafloor to record the ambient sound field at set temporal intervals. This presentation describes both systems and how they are being applied in the field to study three species of fish: *Abudefduf luridus*, in the Azores, Portugal, and *Dascyllus albisella*, and *Abudefduf sordidus*, in Hawaii, USA. *A. luridus* sounds were usually produced in a doublet, 100 ms in duration, a peak frequency of 400–450 Hz, and associated with aggressive displays. Sounds produced by *D. albisella* were typically 2–4 s, with a peak frequency of 300–400 Hz and a bandwidth of up to 6 kHz. *A. sordidus* produced 100 ms broadband clicks, up to 5 kHz bandwidth, in aggressive chases. After identification, sounds were associated with behaviors and ecologically important events, and monitored for diel trends in their production.

2:00

4pAB3. Application of a diver-operated 4-channel acoustic/video recording device to study wild dolphin echolocation and communication. Michiel Schotten, Marc O. Lammers (Marine Mammal Res. Program, Hawaii Inst. of Marine Biol., 46-007 Lilipuna Rd., Kaneohe, HI 96744, micschotten@hotmail.com), Ken Sexton (The Sexton Co. LLC, Salem, OR 97301), and Whitlow W. L. Au (Hawaii Inst. of Marine Biol., Kaneohe, HI 96744)

Despite decades of research on captive dolphins, there still is much to learn about dolphin echolocation and communication in the wild. This is mainly due to the difficulties associated with recording dolphin signals accurately in the wild, such as their broadband (with frequencies over 200 kHz) and directional nature, the difficulty of identifying vocalizing dolphins, and being confined to equipment aboard a vessel. To resolve these difficulties, an underwater portable battery-operated digital recording device was developed that is capable of simultaneously capturing acoustic signals up to 220 kHz on 4 channels as well as video. It consists of a custom-made underwater housing, containing two batteries, a digital camcorder, and an acoustic recording unit with signal conditioning board, 4-channel data acquisition card, PC/104-plus single board computer and power supply, and a notebook hard disk. Attached to the housing is a 4-hydrophone star array. Post-recording, acoustic signals recorded within 15 m are accurately localized in 3-D and attributed to individual dolphins on the video. Thus, acoustic signal features are correlated with different echolocation behaviors and communicative signal exchanges among dolphins are assessed. The system has been successfully field tested with spinner dolphins (*Stenella longirostris*) along the leeward coast of Oahu, Hawaii.

2:15

4pAB4. A new acoustic bat detector. Matthew Heavner (Univ. of Alaska, Southeast, 11120 Glacier Hwy., Juneau, AK 99801, matt.heavner@uas.alaska.edu)

A new small, low-power, long-duration, field-deployable computer for the acoustic monitoring of bats in Southeast Alaska is being developed. The most recent study of bats in the region, reported by Parker *et al.*, (1997), found the geographic range of four bat species to have northern distribution limits in Southeast Alaska. (A fifth species, *E. fuscus*, goes much farther north.) The relationship of the bats to forest management practices, the habitat usage of the bats, and population size and trends are all very poorly known for bats in Southeast Alaska. Long duration monitoring of several different types of area (such as old-growth versus recently logged forest) will provide knowledge to improve management practices in regards to bat ecology in Southeast Alaska. With the motivations just described, the hardware, development methods, and analysis software designed to develop an improved detector are presented. [Work supported by Alaska Department of Fish & Game.]

2:30

4pAB5. Automatic detection of microchiroptera echolocation calls from field recordings using machine learning algorithms. Mark D. Skowronski and John G. Harris (Computational Neuro-Eng. Lab, Univ. of Florida, Gainesville, FL 32611, markskow@cnel.ufl.edu)

The authors have recently presented experimental results of applying machine learning algorithms, used extensively in human automatic speech recognition research (ASR), to automatic species identification of echolocating bats [Skowronski and Harris, *J. Acoust. Soc. Am.* **116**, 2639 (2004)]. The results of those experiments demonstrated that *frame-based* classification, preferred in ASR, out-performs *holistic* classification typically employed in automatic echolocating species identification. The authors have extended the paradigm of machine learning algorithms to the related problem of bat call detection. A robust automatic bat call detection algorithm, to replace hand labeling, is required for two reasons: (1) for real-time species identification in the field, and (2) because hand labeling is subjective, tedious, slow, and error-prone. The current experiments compare various frame-based features (log energy, pitch estimates, pitch slopes) with several models of detection (matched filters, Gaussian mixtures, decision trees). Detector sensitivity and specificity are quantified for comparison using hand-labeled calls, with considerations of classification requirements for detected calls. That is, a detector is not penalized for including a short segment of background signal before and after a hand-labeled call. The results demonstrate the superior performance of the frame-based features and machine learning detection algorithms compared to conventional features and detection algorithms.

2:45

4pAB6. Detection of FM signals in the presence of non-Gaussian noise. Ildar Urazghildiiev, Kathryn Cortopassi, and Christopher Clark (Bioacoustics Res. Program, Cornell Lab. of Ornithology, 159 Sapsucker Woods Rd., Ithaca, NY 14850)

In bioacoustics, the problem of detecting frequency-modulated signals in the presence of non-Gaussian noise is of great interest. Matched filters (MF) are often chosen over frequency-specific energy (FSE) detectors because of their improvement in both signal gain and target specificity. Under non-Gaussian conditions however, MF detectors do not ensure acceptable trade-off between false alarm and missed detection rate. To decrease false alarm rate, we propose a two-stage detection technique. First, a MF is applied, with threshold prescribed by the acceptable false alarm rate, to generate candidate detections. Second, a signal recognition (SR) algorithm is applied to the candidates. The SR algorithm estimates modulation parameters from the signal spectrogram, and a detection decision is made based on how well parameters match a criterion set for the signal of interest. We applied this technique to right whale contact calls recorded in Cape Cod Bay. Results demonstrate that the MF-SR technique decreases false alarm rate by 3–5 times, while not increasing missed detection rate

from that of a MF only. These results were compared to those of a FSE detector followed by the same signal recognition and decision stage (FSE-SR), to determine if comparable performance could be achieved without the MF first stage.

3:00–3:10 Break

3:10

4pAB7. A computational model of echolocation: Restoration of an acoustic image from a single-emission echo. Ikuo Matsuo and Masafumi Yano (Res. Inst. of Elec. Commun., Tohoku Univ., Katahira 2-1-1, Aoba-ku, Sendai 980-8577, Japan, matsuo@riec.tohoku.ac.jp)

Bats can form a fine acoustic image of an object using frequency-modulated echolocation sound. The acoustic image is an impulse response, known as a reflected-intensity distribution, which is composed of amplitude and phase spectra over a range of frequencies. However, bats detect only the amplitude spectrum due to the low-time resolution of their peripheral auditory system, and the frequency range of emission is restricted. The amplitude spectrum varies with the changes in the configuration of the reflected-intensity distribution, while the phase spectrum varies with the changes in its configuration and location. Here, by introducing some reasonable constraints, we propose a method for restoring an acoustic image from the echo produced by a single emission. The configuration is extrapolated from the amplitude spectrum of the restricted frequency range by using the continuity condition of the amplitude spectrum at the minimum frequency of the emission and the minimum phase condition. The determination of the location requires extracting the temporal changes of amplitude spectra. For this purpose, the Gaussian chirplets with a carrier frequency compatible with bat emission sweep rates was used. The location is estimated from the temporal changes of the amplitude spectra. This method can determine the acoustic images of objects.

3:25

4pAB8. Broken line 3-dimensional sperm whale diving trajectory reconstruction using passive acoustics on a single hydrophone. Christophe Laplanche, Olivier Adam, Maciej Lopatka, and Jean-François Motsch (Université Paris XII, 61 av. du Gal de Gaulle, 94010 Créteil, France)

Sperm whales make deep dives to hunt. A dive, lasting 45 minutes on average, is composed of a vertical descent to the prey layer depth, the properly so called hunt (at a quasi constant depth) inside the prey layer, and a vertical ascent back to the sea surface. Sperm whales make series of echolocation signals (*clicks*) during the two first stages. The sea surface/bottom click echo detection and delay measurements then make possible the sperm whale range/depth estimation during these stages, by passively using a single hydrophone. The vertical, rectilinear sperm whale trajectory during the first stage is unambiguously estimated from the echo delays. The sperm whale trajectory can also be reconstructed during the second stage, from the sperm whale range variations only, even when not detecting sea bottom click echoes. These range variations strongly suggest the sperm whale trajectory to be a broken line (e.g., a 2-piece line, 600 m straight ahead, 85 degree bend, 1000 m straight ahead). Assuming a vertical silent reascent, the rough hydrophone-relative 3-dimensional sperm whale trajectory can then be reconstructed for the complete dive, by using a single hydrophone.

3:40

4pAB9. Transmitting beam patterns of an echolocating bottlenose dolphin. Thomas G. Muir, Tobias J. Lemerande, Steven R. Baker (Phys. Dept., U.S. Naval Postgrad. School, Monterey, CA 93943, tmuir@olemiss.edu), and Samuel H. Ridgway (U.S. Navy Marine Mammal Program, SPAWARESCEN San Diego, CA 92152)

Measurements on a free-swimming subject, echolocating under a simple go paradigm, were conducted at SSC San Diego, with a linear array of seven simultaneously and individually processed wideband hydrophones (response to 400 kHz), arranged either vertically or horizontally, and cen-

tered on a small underwater video camera, with the video output synchronized with the recording of acoustic data. The measurement apparatus itself served as the test target. Lowering it into the water provided the cue for the blindfolded subject to locate its position in the test pen, swim to the apparatus, and touch it with the tip of its rostrum; whereupon the trainer provided a bridge signal, indicating reward due. During this process, acoustic beampattern measurements were made on echolocation clicks, as a function of frequency, which support previous, non-simultaneous, statistical beampattern measurements. Early in the experiment, the subject emitted echolocation clicks that peaked at 78 kHz, with -3 dB beamwidths of 8 to 10 degrees; but also containing high frequency components (above 135 kHz), with beamwidths that narrowed with increasing frequency, ranging to only a few degrees around 300 kHz, far beyond the subjects hearing range. After several days, the task appeared to become easier and there was much less high frequency content, but the click repetition frequency increased. Wideband noise was then introduced into the test pen, at frequencies below 135 kHz; and as the task became more difficult, the subject resumed transmitting clicks with high frequency components, although the peak frequency remained at 78 kHz, and click rates again increased, to much higher values.

3:55

4pAB10. A juvenile salmon acoustic tracking system (JSATS) for the Columbia River estuary. Lynn McComas (Natl. Marine Fisheries Service, 3305 E. Commerce St., Pasco, WA 99301) and Alex Easton (SAIC, Lynnwood, WA 98037)

The Juvenile Salmon Acoustic Tracking System (JSATS) was developed as a means to estimate the downriver survivability of sub-yearling salmon in the Columbia River. The system consists of a bottom-mounted sonar array which detects signals from acoustic projectors that are surgically implanted in juvenile salmon. JSATS is the result of a development program which began in 2001 when Northwest Fisheries Science Center National Marine Fisheries Service (NMFS) and Science Applications International Corp. (SAIC) developed the top level, biology driven, requirements for the system. SAIC then conducted environmental surveys to characterize the physical and acoustic environments in which JSATS would operate. Battelle PNNL developed the acoustic projector used in JSATS. The signaling characteristics of this projector are driven by the requirement that it not affect the behavior of the 90 mm salmon in which it is implanted, and that it operate continuously for 30 days. SAIC developed the detection array portion of JSATS. The design was driven by the requirements that it be bottom mounted, cabled to shore, and successfully withstand high current and moving sand waves. NMFS and SAIC jointly developed the shore stations and the installation/recovery procedures. Installation of an array spanning the Estuary is planned for April 2005.

4:10

4pAB11. Testing acoustic fish deterrents for use under-ice in arctic lakes. Roberto G. Racca (JASCO Res. Ltd, 2101-4464 Markham St., Victoria, BC, V8Z 7X8 Canada, rob@jasco.com)

Acoustic deterrent technologies can be used in aquatic settings in lieu of physical barriers to keep fish away from potentially harmful industrial operations. The goal of this study was to determine the efficacy of portable, temporary acoustic deterrents as a means of excluding fish from the neighborhood of sub-bottom detonation activities associated with seismic exploration under ice in arctic lakes. In October 2003 trials were conducted in Dolomite Lake near Inuvik, Northwest Territories, Canada on indigenous fish species. Groups of fish were equipped with orally inserted ultrasonic tags, placed in a large experimental net pen and monitored using an acoustic tracking system that produced a detailed three-dimensional swimming pattern for each subject, thereby revealing any behavioral responses. A flex-tensional broadband sound projector driven by digitally synthesized signals was tested as deterrent, and real-time monitoring at two hydrophone sites was used to estimate the local level of insonification throughout the pen volume. Although the study did not identify an overall effective deterrent, sufficient indications of response were observed to

support the future testing of a louder projector capable of emitting a tonally modulated sound pattern at frequencies from about 100 Hz to a few kHz. [Work supported by ESRF (esrfunds.org).]

4:25

4pAB12. Design of an oscillating flow test chamber for modeling the fish ear. Charlotte Kotas, Peter Rogers, and Minami Yoda (Mech. Eng. Dept., Georgia Inst. of Technol., Atlanta, GA 30332-0405, gtg227d@mail.gatech.edu)

The acoustically induced oscillating flow fields inside the fish ear, specifically near the otoliths, may provide clues about how fish directionalize underwater sound sources. A new experimental test apparatus has been constructed to study oscillatory and steady streaming flows around model otoliths. The flows are driven by a shaker-piston assembly attached to a 250 mm diameter, 450 mm tall cylindrical test chamber filled with liquid to a depth of 400 mm. This apparatus is capable of generating flow oscillating at frequencies of 1 to 30 Hz with displacements up to a few millimeters within the test chamber. Theoretical predictions of the fluid-borne vibrations in a fluid-filled tube in a vacuum suggest that the flow will have a uniform sinusoidally oscillating velocity field over the central portion of the test section. The flow is visualized in the optically accessible test chamber using small tracer particles; flow velocity fields are measured using particle image velocimetry (PIV). The apparatus is compatible with various working fluids of different viscosities such as water, glycerin and

silicon oils to extend the range of attainable Reynolds numbers. Initial results for oscillating flows around basic "otolith" geometries such as spheres and spheroids will be shown. [Work supported by ONR.]

4:40

4pAB13. Biomass assessment in commercial catfish ponds. James Chambers (Natl. Ctr. for Physical Acoust., The Univ. of Mississippi, University, MS 38677), C. Douglas Minchew (Mississippi State Univ., Stoneville, MS 38776), and Rachel Beecham (Mississippi Valley State Univ., Itta Bena, MS 38941)

With increasing seafood demand aquaculture is poised to become a major growth industry in the United States in the 21st century. In particular channel catfish represent an approximately \$260 million industry in Mississippi with strong growth potential. A major portion of the costs associated with raising channel catfish are related to the cost of feed and aeration which are directly related to the total number of fish being raised in each pond. Crop insurance and bank loans are also contingent upon accurate population estimates. A high frequency, horizontally scanning, active pulse echo sonar system, the Aquascanner, has been developed to estimate pond populations. Commercial catfish ponds are typically 2 to 10 acres and, unlike many offshore fisheries, have fairly shallow depths of 1 to 2 m. The system components and its use will be presented along with results from field tests. [Work supported by US Dept. of Agriculture.]

Noise, Architectural Acoustics and Engineering Acoustics: Characterization of Acoustical Materials

Brandon D. Tinianov, Chair

Quiet Solution Inc., 522 Almanor Ave., Sunnyvale, CA 94085

Invited Papers

1:30

4pNS1. On the measurement of the mechanical properties of acoustic porous materials. Nouredine Atalla (Dept. of Mech. Eng., Universit de Sherbrooke, Sherbrooke (QC), Canada J1K 2R1), Franck Sgard, and Luc Jaouen (Ecole Nationale des Travaux Publics de l'Etat, 69518 Vaulx-en-Velin Cedex, France)

This paper discusses the measurements and use of the mechanical properties of porous materials. It starts with a review of the classical methods currently used and concentrates in explaining the assumptions, difficulties and limitations of these methods. Next, it concentrates on two methods: a quasi-static approach accounting for the effect of shape factors on the measured properties and a hybrid inverse method similar to the vibrating beam method used for viscoelastic materials. Through full 3-D numerical simulations, both methods are simulated and their main features, assumptions, and limitations are investigated. In particular, the model uses full poro-elastic modeling and boundary element in order to investigate the effect of acoustic radiation damping and viscous damping. Using various types of materials, comparisons between these two methods and experimental data are also discussed.

1:50

4pNS2. Measurements of the acoustic properties of reticulated vitreous carbon. Ralph T. Muehleisen (Civil and Architectural Eng., Illinois Inst. of Technol., Chicago, IL 60616, muehleisen@iit.edu), C. Walter BeamerIV (Univ. of Colorado, Boulder, CO 80309), and Brandon D. Tinianov (Quiet Solution, Sunnyvale, CA 94085)

Reticulated vitreous carbon (RVC) is an open-cell foam structure composed of amorphous carbon that has a high porosity, strength and rigidity, low bulk thermal conductivity, a high melting point and chemical inertness. These properties make RVC an excellent candidate for use as a material for stacks and regenerators in thermoacoustic devices as well as an acoustic absorber in harsh environments. The four-microphone transfer matrix method was used to measure the characteristic impedance and wave number of 60 to 300 pore-per-inch RVC. From the measurements, a new empirical power law model and acoustic absorption charts were developed. The data are shown to be poorly predicted by the empirical models of Delany and Bazley and only fairly predicted by the Johnson-Allard microstructural model.

4pNS3. Prediction of the thermal conductivity of fiberglass insulation using propagation constant: A technique overview. Brandon Tinianov (Quiet Solution, Inc., 522 Almanor Ave., Sunnyvale, CA 94085), Masami Nakagawa, and David Muñoz (Colorado School of Mines, Golden, CO 80401)

This paper describes a novel technique for the prediction of the thermal performance of low density fiber glass insulation and other related fibrous insulation materials using a non-invasive acoustic apparatus. The project motivation is to create an enabling technology for in situ quality control testing of such fiber glass batts during production. Experimental results obtained in the laboratory show excellent correlation between the thermal conductivity and both the real and imaginary components of the propagation constant. Correlation of calculated propagation constant magnitude versus measured thermal conductivity gave an R^2 of 0.94 for the range of typically manufactured fiber glass batt materials. Given the promise of such highly correlated measurements, the acoustic technique could be used to continuously predict the thermal conductivity of the material during its production, replacing current off-line methods. The mechanisms for energy transfer through the materials are distinctly different for the acoustical propagation versus the heat transfer. The nature and behavior of the mechanisms will be reviewed and compared.

4pNS4. Estimation of the accuracy of measured acoustical parameters of porous materials with an acoustical method. Xavier Olny (ENTPE-DGCB URA, CNRS 1652, rue Maurice Audin 69518, Vaulx en Velin, France) and Raymond Panneton (Université de Sherbrooke, PQ, Canada J1K 2R1)

Acoustical parameters such as tortuosity, viscous and thermal characteristic lengths, or even static thermal permeability are often required to describe the dynamic behavior of porous materials. Using a middle frequency method, based on the use of a standing waves tube, the direct measurements of the resistivity and porosity, and the accurate measurement of the dynamic density and bulk modulus, these intrinsic parameters can be obtained from analytical inversion of Johnsons and Lafarges models. The interests of the method lie in the simplicity of the apparatus and on the clear separation of viscous and thermal dissipative contributions. This last point specially helps to understand the physics of the medium and check the validity of the assumptions made: the material should not have a strong elastic behavior, and it must fit the models used in the inversion process. In this presentation, the robustness of the method is discussed and estimations of the measurement uncertainties are given. The occurrence of systematic errors coming from the use of semi-phenomenological models for determining intrinsic parameters is tackled. The measurement procedure, and the experimental set-up are detailed, and results obtained on materials with very different properties are presented.

Contributed Papers

4pNS5. Model to simulate the acoustical absorption of laminated fiberglass insulation. Juan Arvelo, Jr. (Appl. Phys. Lab., Johns Hopkins Univ., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099), Ilene Busch-Vishniac, James West, and Robert Ng (Johns Hopkins Univ., Baltimore, MD 21218-2681)

While fiberglass insulation is known to be a very good acoustical absorber in the audible frequency range, it is not often used for this purpose in rooms because of its appearance and its delicate structural rigidity. Additionally, in some situations, notably medical facilities, the material is inappropriate because of its potential to trap and retain bacteria and dirt. In this work, we report on a study of laminate-coated fiberglass. Although the addition of a laminate coating degrades the acoustical absorption, previous experimental work demonstrated that the composite structure retains a high absorption coefficient. A model of the wall with the installed fiberglass/laminate composite was developed and a wavenumber integration approach was applied to this model to assess the impact of the laminate on the performance of the system. The estimated reflection and transmission losses are computed as functions of auditory frequency and incidence angles with and without the laminate layer to compare the distributions of acoustical energy. This work is performed under a Hafstad fellowship sabbatical appointment.

4pNS6. Impact of acoustic leakage on the absorption of mono-layer and two-layers porous material. Franck Castel, Franck Sgard (Laboratoire des sciences de l'Habitat, DGCB URA CNRS 1652, Ecole Nationale des Travaux Publics de l'Etat, 69518 Vaulx-En-Velin Cedex, France), and Nouredine Atalla (Universite de Sherbrooke, Sherbrooke, QC, Canada J1K 2R1)

This paper discusses the effects of small lateral air gaps on the normal incidence absorption coefficient of mono layer and two layers porous materials. Such mounting conditions are responsible for changes in the absorption, leading to dramatic errors in the determination of the acoustics parameter with inverse characterization methods. As this type of mounting conditions is hard to control experimentally, a hybrid finite element-modal method is used to investigate the problem of the porous material inserted in a rectangular wave-guide. At the interface of the material and the wave-guide, coupling between the different domains is accounted for accurately using a modal decomposition. An automatic meshing approach is employed to speed up and guarantee convergence of the method. A large set of materials spanning a wide range of flow resistivities is used for the simulations. The results are presented under the form of charts which makes them an easy to use tool suitable for both inspection and design. Firstly, these charts allow one to identify materials whose normal inci-

dence absorption coefficient is sensitive to lateral air leaks. Secondly, these charts are a helpful tool for designing highly absorptive solutions based on the combination of porous materials and air gaps.

3:30

4pNS7. Sound absorbers with micro-perforated stretched foils and porous materials. Christian Nocke, Catja Hilge (Akustikbuero Oldenburg, Alte Raad 20a, D-26127 Oldenburg, Germany, info@akustikbuero.info), and Jean-Marc Scherrer (Barrisol Normalu SA, F-68680 Kembs, France)

At the spring meeting 2004 in New York first results for the sound absorption of micro-perforated stretched foils have been presented. The classical set-up of a micro-perforated sound absorber consists of a micro-perforated panel in front of an air cavity. The sound absorption coefficient of these set-ups can easily be calculated with a high accuracy according to the well-known approximation of D.-Y. Maa if all defining geometrical parameters (diameter of microperforation, distance between orifices, panel thickness and air cavity depth) are known. In this contribution measured sound absorption coefficients of other set-ups with micro-perforated foils as well as combinations with different porous materials will be presented. For these assemblies no closed calculation model exists so far. Comparisons between computer-based calculations of layered absorber set-ups show promising results for some assemblies. Finally different applications in various rooms will be presented. As expected the comparison between theoretical design and the final result show a very high degree of agreement.

3:45

4pNS8. Measured characteristic impedance and propagation constant of some common materials using the two cavity method. Richard Godfrey (Owens Corning, Sci. & Technol., 2790 Columbus Rd., Granville, OH 43023)

The acoustics of porous rigid frame materials is characterized by their characteristic impedance and propagation constant. These properties can be measured using the two cavity method. A sample is placed in an impedance tube with an air space behind the sample and ahead of the rigid termination. Measurements are made in accordance with ASTM E 1050. This procedure is repeated with the same sample, but a different air space. These data are analyzed as outlined by Seybert *et al.* [J. Acoust. Soc. Am. 86, 637 (1989)] to yield the characteristic impedance and propagation constant. This method was used to characterize fiber glass boards with a range of flow resistivities from 2600 to 56000 mks rays/m. Repeat measurements were made, and these measurements were compared with the Delaney and Bazley model, [Applied Acoustics (3), 1970]. Measurements were also made for cotton shoddy and cellulose, and power law models were developed. The method produced repeatable results comparable to the Delaney and Bazley model with little effort, and it is a useful method of obtaining property data for modeling tools such as Mechels Acoustics Program System (MAPS).

4:00

4pNS9. Estimation of the absorption coefficients of classroom surfaces by multiple regression. Katrina Scherebnyj and Murray Hodgson (UBC Acoust. & Noise Res. Group, SOEH, 3rd Fl., 2206 East Mall, Vancouver, BC, Canada V6T 1Z3)

The absorption coefficients of room surfaces are important parameters for predicting room sound fields. Of particular interest are classrooms, for which characteristics such as speech intelligibility are essential. Values

obtained in laboratory settings may differ significantly from those measured in real-world situations. This study determined surface absorption coefficients in university classrooms and compared them with values given by manufacturers and published literature. Various surface categories were established, and the total area of each was measured in 104 UBC classrooms, along with the early decay times (EDT) in octave bands from 125 to 8000 Hz when the rooms were unoccupied. Average octave-band absorption coefficients for these surfaces were determined from the measured EDTs, using diffuse-field theory. Multiple-regression analysis was then applied, and the data was fit to estimate the average absorption coefficients of each surface category in each octave band. Absorption coefficients were established for seven types of surfaces commonly found in university classrooms; in general they tended to be significantly lower than commonly accepted values.

4:15

4pNS10. Effects of damping materials on heavy-weight impact noise in reinforced concrete floor. Jin Yong Jeon, Young Jeong, and Seung Yup Yoo (School of Architectural Eng., Hanyang Univ., Seoul 133-791, Korea)

Damping materials for reducing heavy-weight floor impact noise in reinforced concrete structures were tested in apartment buildings. The effect of damping materials and an impact isolator were compared in an on-site experiment conducted in a high-rise apartment building. The results showed that the resonance frequency increased and vibration acceleration level decreased when the damping materials were used. Heavy-weight impact sound levels of the structure decreased substantially at 63 Hz, whereas the sound levels of the structure with the impact isolator increased. Subjective evaluation of the perceptual effects of the damping material and the impact isolator were also conducted in the laboratory.

4:30

4pNS11. In situ measurement of absorption of acoustic material with a parametric source in air. Volker Mellert and Roland Kruse (Oldenburg Univ., Inst. Phys., 26111 Oldenburg, Germany)

Measurement of properties of acoustic material in situ is quite desirable in numerous applications. But pulse-echo methods often lack from spurious reflections in a closed-space environment. It is therefore necessary to irradiate the sample material with a highly focussed acoustic beam of defined width. The principle of parametric transducers, which is well known in underwater acoustics, can be used in air as well, if the sound pressure of the ultrasound carrier is high enough. This was recently demonstrated by Hibrál and Zakharia (Proc. of the Joint Congr. of CFA/DAGA 04, Strasbourg 2004, p. 541). The new measurement set-up is in principle best suited for in-situ measurements due to the narrow beam-width. But ultrasound intensity, efficiency of generation of audio sound etc. give rise to several limitations. Applications of in-door measurements, in particular at grazing-angle, are presented.

Session 4pPAa**Physical Acoustics, Biomedical Ultrasound/Bioresponse to Vibration and ASA Committee on Standards: Cavitation and Other Mechanical Effects in Biomedical Ultrasound: A Special Session to Honor the Work of Wesley Nyborg II**

Lawrence A. Crum, Cochair

Applied Physics Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698

Junru Wu, Cochair

*Dept. of Physics, Univ. of Vermont, Burlington, VT 05405***Invited Papers****2:00****4pPAa1. How does ultrasound induce strain related responses in cells?** James Greenleaf and Mark Bolander (Mayo Clinic College of Medicine, 200 First St., Rochester MN 55905)

The fact that modulated ultrasound at a pulse intensity of 160 mW/cm^2 can induce fracture healing implies that cells that are sensitive to strain can feel and respond to this signal. A hypothesis that uses Nyborg inspired methods to investigate this effect will be presented along with data from a wide variety of simulations and experimental data. It appears that the response is mediated through the cytoskeleton and may be associated with interaction of the sound with focal adhesion complexes at one end of the skeletal fibers for high frequency responses and with the nuclear membrane at the other end of the fibers for low frequency responses. Although this hypothesis is nascent it is supported with experimental data from the literature.

2:20**4pPAa2. The influence of agent delivery mode on cardiomyocyte injury induced by myocardial contrast echocardiography in rats.** Douglas Miller, Chunyan Dou, and William Armstrong (Univ. of Michigan, Ann Arbor, MI 48109)

Bioeffects induced in rat hearts by the interaction of ultrasound with contrast agent gas bodies depends on user controlled parameters. This study examined the influence of contrast agent delivery mode on cardiomyocyte injury. Hairless rats were anesthetized and mounted vertically in a water bath. Evans blue dye was injected as stain for cardiomyocyte injury. The contrast agent (Definity, Amersham Health Inc., Princeton NJ) was diluted in saline and injected IV at 20 or 80 $\mu\text{L/kg}$ either as bolus or continuous infusion. Echocardiography was performed with a GE Vingmed System V in a short axis view with 1:4 or 1:16 ECG triggering at 1.5 MHz for 5 or 20 min. The peak rarefactional pressure amplitude (PRPA) was 2.0 MPa. Fluorescent stained cells were scored on frozen sections of heart samples obtained 24 hr after scanning. Five min infusion led to 3.4 times ($P < 0.01$) more cardiomyocyte injury than bolus injection for the same 20 $\mu\text{L/kg}$ dose. Contrast agent dose appeared to be a more important parameter than infusion rate and number of triggers. Contrast agent delivery mode, as well as dose and PRPA, has a significant influence on the bioeffects potential of myocardial contrast echocardiography. [Work supported by NIH grant EB00338.]

2:40**4pPAa3. Nonlinear model for detection of bubble activity from pulse-echo ultrasound.** Emad S. Ebbini (200 Union St. SE, Rm. 4-174, Minneapolis, MN 55455)

Cavitation and transient cavitation plays an important role in modern application of biomedical ultrasound, both in therapeutics and diagnostics. Special imaging and signal processing methods have been recently introduced for the detection and localization of cavitation and other nonlinear phenomena for improving image quality and/or characterization of therapeutic outcome of the ultrasound-based treatments. We have recently developed a model-based approach for separating the linear and nonlinear components of the pulse-echo data. In its simplest form, the approach separates the linear and quadratic signal components from the echo data. The latter is related to the sum and difference frequency interactions in the nonlinear medium. When used in conjunction with elongated coded transmit waveforms (e.g., chirp signals), the approach provides significant separation of bubble activity from tissue nonlinear components. Application to ultrasound contrast-agent imaging and detection of HIFU-induced lesions will be discussed.

3:00**4pPAa4. Effect of clinical diagnostic ultrasound pressure amplitude and pulse repetition frequency on echogenic liposome destruction.** Denise A. B. Smith, Tyrone M. Porter, Christy K. Holland (Dept. of Biomed. Eng., Univ. of Cincinnati, Medical Sci. Bldg, Rm. 6152, 231 Albert Sabin Way, Cincinnati, OH 45267-0586, smitdn@ email.uc.edu), Shao-Ling Huang, Robert C. MacDonald (Northwestern Univ., Evanston, IL 60208), and David D. McPherson (Northwestern Univ., Chicago, IL 60611)

Liposomes are submicron-sized phospholipid vehicles that contain both gas and fluid. Entrapped microbubbles within the liposome cause them to be echogenic. With antibody conjugation and thrombolytic drug incorporation, such as rt-PA, these liposomes can be used as novel targeted diagnostic ultrasound echo contrast agents to deliver a drug locally. In this study, the echogenicity of

unconjugated liposomes suspended in distilled water was assessed by measuring the decay rate of backscattered intensity using a Philips HDI5000 diagnostic ultrasound scanner with a 12-5 MHz linear array. Pulses of ultrasound with a 7-MHz center frequency and derated peak rarefaction pressure amplitudes of 0.16, 0.35, and 0.61 MPa were used to expose the liposomes. Pulse repetition frequencies in the range of 6.7 kHz to 13.3 kHz were employed at frame rates between 16 and 35 Hz, respectively. The average backscatter intensity was determined from a 20 mm² region-of-interest in each image frame. An exponential decay was fit to each data set. Ultrasound pulses with higher acoustic pressures and higher pulse repetition frequencies destroyed the liposomes at a faster rate.

3:20

4pPAa5. Cavitation detection during ultrasound-assisted thrombolysis in porcine blood clots. Saurabh Datta (Dept. of Biomed. Eng., Univ. of Cincinnati, Cincinnati, OH 45267), Louis E. McAdory (Univ. of Cincinnati), Jun Tan, and Christy K. Holland (Univ. of Cincinnati, Cincinnati, OH 45267-0586, Christy.Holland@uc.edu)

Substantial enhancement of recombinant tissue plasminogen activator (rt-PA) mediated thrombolysis can be achieved with exposure of a thrombus to pulsed ultrasound. However, the mechanism of this interaction has not yet been elucidated. In this work cavitation is investigated as a possible mechanism for enhancement in 120-kHz pulsed ultrasound-assisted thrombolysis. Porcine blood clots were immersed in plasma as control and exposed to rt-PA, ultrasound (0.35 MPa, 80% duty cycle, 1667 Hz pulse repetition frequency), or a combination of rt-PA and ultrasound. A confocally aligned active and passive cavitation detection system was employed to detect subharmonic emissions from stable cavitation and broadband superharmonic emissions from inertial cavitation. After exposure, clot mass loss was determined, and clots were subjected to immunohistochemical analysis of fibrin degradation. Spatial investigation of cavitation thresholds inside the clot, on the clot surface, and in the fluid surrounding the clot showed the threshold to be lowest on the clot surface. Stable cavitation was detected in clots exposed to ultrasound alone and a combination of rt-PA and ultrasound. Curiously, inertial cavitation was detected only in samples containing rt-PA. The presence of both stable and inertial cavitation correlated with increased clot mass loss and a distinct pattern of fibrin degradation on histologic evaluation.

4pPAa6. Occlusive thrombosis in the rabbit auricular vein *in vivo* targeted by induction of intraluminal cavitation using HIFU and ultrasound contrast agent. Andrew A. Brayman, Juan Tu, Thomas Matula, Lawrence A. Crum (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698), Joo Ha Hwang, and Michael B. Kimmey (Univ. of Washington, Seattle, WA 98195)

Hypotheses tested: (1) inertial cavitation [IC] could be induced in the venous lumen *in vivo* by combined use of intravascular microbubble contrast agent and transcutaneous application of 1-MHz high intensity focused ultrasound [HIFU] of very low duty factor, and that IC activity could be detected and quantified *in vivo* as in earlier *in vitro* studies via passive cavitation detection methods; (2) robust IC activity would damage the venous endothelium in treated regions; (3) endothelial damage would be proportional to the IC dose developed in the region; (4) severe local endothelial damage alone may be sufficient to induce occlusive thrombosis, or may sensitize the region to low systemic doses of prothrombotic agents, and (5) biologically significant temperature rises and attendant thermal bioeffects in the vessel and perivascular tissues would not occur, even under the highest amplitude acoustic conditions applied. Each hypothesis was supported by the data. The principal result was that under treatment conditions involving very high peak negative acoustic pressures and contrast agent, treated areas thrombosed acutely but non-occlusively. When fibrinogen was administered locally after such treatment, occlusive thrombi formed acutely and only in the treated region, a response observed with none of the other treatments.

4:20

4pPAa7. Controlled nucleation of microcavitation with laser-illuminated nano-particles. Ronald A. Roy, Caleb H. Farny, Tianming Wu, Todd W. Murray (Dept. of Aerosp. and Mech. Eng., Boston Univ., Boston, MA 02215), and R. Glynn Holt (Boston Univ., Boston, MA 02215)

The safe utilization of controlled cavitation in HIFU therapy requires the presence of nucleation sites for bubble formation. Effective cavitation nuclei do not exist in most tissues; nucleation threshold pressures in excess of 4–5 MPa have been reported. We investigate the efficacy of transient vapor cavity generation from laser-illuminated gold nano-particles as a means for nucleating cavitation with high-intensity focused ultrasound. An acrylamide tissue phantom seeded with 82-nm diameter gold particle was exposed to 20 ns pulses from a 532 nm Nd:Yag laser. Laser firing was precisely synchronized with a pulsed 1.1 MHz HIFU pressure field. Acoustic emissions from inertial cavitation were detected by a 15 MHz focused transducer at a laser energy of 0.10 mJ/pulse and a HIFU peak-negative focal pressure as low as 0.92 MPa. In comparison, a peak-negative focal pressure of 4.50 MPa was required to nucleate detectable cavitation without laser illumination; nano-particles were present in both cases. Since the particles are durable, one can re-activate them as needed, essentially yielding cavitation nuclei on demand. 4:40

4pPAa8. Sonochemical synthesis and modification of protein microspheres. Kenneth S. Suslick, Farah J.-J. Toublan, and Elizabeth M. Dibbern (School of Chemical Sci., Univ. of Illinois at Urbana-Champaign, 600 S. Mathews Av., Urbana, IL 61801, ksuslick@uiuc.edu)

The need for organ-targeted delivery of drugs and imaging agents creates an interest in biocompatible, biodegradable vesicles. We make protein microspheres using high-intensity ultrasound; these microspheres have a protein shell and a hydrophobic interior making them ideal for delivering hydrophobic materials. We have previously shown that various proteins, e.g., bovine serum albumin (BSA), form a microsphere shell stabilized by inter-protein cross-linking of cysteine residues. In this study, we explore methods to modify the surface of these microspheres by (1) nanoparticle incorporation and (2) layer by layer electrostatic adhesion of macromolecules. We have explored applications of these microspheres for organ targeted imaging using both MRI and optical coherence tomography (OCT).

4:55

4pPAa9. Nonlinear dynamics of gas bubbles in soft tissue. Xinmai Yang and Charles Church (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

Understanding the behavior of cavitation bubbles driven by ultrasonic fields is an important problem in biomedical acoustics. The previous studies are largely limited by availability of experimental data on soft tissue. To approach this problem, we combine the Keller-Miksis equation for nonlinear bubble dynamics with the linear Voigt model for viscoelastic media. Using experimentally determined values of viscoelastic properties of soft tissue as a guide, the effects of elasticity on bubble oscillations are studied. The inertial cavitation thresholds are determined using a criterion of $R_{\max}/R_0=2$, and subharmonic emissions from an oscillating bubble are calculated. The results show that the presence of the elasticity increases the threshold pressure for inertial cavitation, and subharmonic signals only can be detected in a certain region of radii and driving pressures at a given frequency. These results should be useful in cavitation detection and bubble-enhanced imaging work. The model also could be used to determine values for the viscoelastic properties of soft tissue.

Contributed Papers

2:00

4pPAb1. Acoustic Casimir pressure for arbitrary media. Raul Esquivel-Sirvent, Luis Reyes, and Jeffrey Barcenas (Instituto de Fisica, UNAM Apdo. Postal 20-364, Mexico DF 01000, Mexico, raul@fisica.unam.mx)

We derive a general expression for the acoustic Casimir pressure between two parallel slabs made of arbitrary materials and whose acoustic reflection coefficients are not equal. The formalism is based on the calculation of the local density of modes using a Green's function approach. The results for the Casimir acoustic pressure are generalized to a sphere/plate configuration using the proximity theorem.

2:15

4pPAb2. Use of complex source points to simplify numerical Gaussian beam synthesis. Stephen Forsythe (Naval Undersea Warfare Ctr., 641 Middle Rd., Portsmouth, RI 02871, stephen.forsythe@verizon.net)

It is often desirable to generate the acoustic field due to a so-called Gaussian beam. One way to do this is to use the free-space Greens function for the acoustic field and to sum small area sources over a circular plate with the appropriate shading for the desired Gaussian beam. For very high frequencies and narrow beams, the computation time to give an accurate sum can be large when calculating the sum for many points in the acoustic field. An alternate approach comes from the use of a single point source with complex coordinates $R=[Xr+iXi, Yr+iYi, Zr+iZi]$. When this complex source point is used in the free-space Greens function, the formal expressions for pressure and particle velocity can be used if careful attention is paid to the interpretation of the complex distance, r , that arises in the $\exp(ikr)/r$ term. The singularity is no longer a single point in the

case of a complex source, but a circular disk. The far field of a complex source point is a good approximation to a Gaussian beam. Several computational uses of the technique will be demonstrated. Extension to the shear wave Greens function will be explored.

4pPAb3. Causality and acoustic group velocity in dispersive media. Joel Mobley (U.S. Army Res. Lab., 2800 Powder Mill Rd., Adelphi, MD 20783, jmobley@arl.army.mil)

This talk examines two specific issues related to causality and the group velocity of acoustic pulses in dispersive media. First, the causal prediction of group velocity from attenuation with finite-bandwidth Kramers-Kronig ($K-K$) relations is discussed. Without extrapolating beyond the measurement bandwidth, the causal linkages of resonant-type data are established using expressions derived from the acoustic $K-K$ relations to predict group velocity and slope of attenuation (frequency derivative of attenuation). These predictions provide a stricter test of causal consistency than the determination of the phase velocity and attenuation coefficient due to their shape-invariance with respect to subtraction constants. Secondly, conditions under which the group velocity is the velocity of the peak in the envelope of a acoustic pulse are described. The spatial and temporal signatures of acoustic pulses with arbitrarily large (e.g., superluminal) and negative group velocities are also demonstrated. These signatures are shown to be consistent with both simple and relativistic causality.

4pPAb4. Ultrasonic backscatter in two-dimensional domains. Goutam Ghoshal and Joseph A Turner (Dept. of Eng. Mech., W317.4 Nebraska Hall, Univ. of Nebraska–Lincoln, Lincoln, NE 68588-0526)

The scattering of elastic waves in polycrystalline materials is relevant for ultrasonic materials characterization and nondestructive evaluation (NDE). Ultrasonic backscatter measurements are used widely to extract the microstructural parameters such as grain size and also to detect flaws in materials. Accurate interpretation of experimental data requires robust scattering models. Line transducers are often used for ultrasonic experiments such that an appropriate model for these two-dimensional problems is needed. Here, a theoretical expression for the temporal backscatter is derived for such domains under a single-scattering assumption. The result is given in terms of transducer and microstructural parameters. In addition, the problem is examined in terms of numerical simulations using Voronoi polycrystals that are discretized using finite elements in a plane-strain formulation. The material properties of the individual Voronoi cells are chosen according to appropriate material distributions. Such numerical models also allow scattering theories, including the one discussed here, to be examined for well-controlled microstructures. Example numerical results for materials with varying degrees of scattering that are of common interest are presented. The numerical results are compared with the theory developed with good agreement. These results are anticipated to impact ultrasonic NDE of polycrystalline media. [Work supported by US DOE.]

4pPAb5. Local dynamical effects in inhomogeneous elastic waveguides. Victor T. Grinchenko (Inst. of Hydromechanics of NAS of Ukraine, 8/4 Zhelyabov Str., 03680 Kiev, Ukraine)

The properties of normal waves in elastic waveguides are essentially different than properties of normal waves in acoustical waveguides. As the physical reason of the differences one can indicate the specific phenomena of reflection of elastic waves from a free surface. When an elastic wave reflects from the surface, the energy of longitudinal waves transforms to shear waves and vice versa. It is shown that the conversion of the wave motion types sets condition for generation of local disturbances in wave fields when normal waves are reflected from geometrical and physical inhomogeneities. The paper presents quantitative and qualitative analysis of the local effects for different cases. It was shown that such effects occur in a simple elastic waveguide. The specific features and physical meaning of the edge resonance effect in semi-infinite waveguides is presented. It was shown that for the waveguides with geometrical and physical inhomogeneous interesting phenomena of anomalous transparency of discontinuity can occur for any frequency bands. For other frequency bands the same discontinuity can be as an effective reflector of incident normal wave.

3:15

4pPAb6. Simplified series expansions for radiation from a baffled circular piston. T. Douglas Mast (Dept. of Biomed. Eng., Univ. of Cincinnati, Cincinnati, OH 45267-0586, doug.mast@uc.edu) and Feng Yu (Univ. of Cincinnati, Cincinnati, OH 45221-0070)

Computation of acoustic radiation from a baffled circular piston continues to be an active area of investigation, both as a canonical problem and because of numerous practical applications. For time-harmonic radiation, exact series expansions are an attractive approach because they do not require numerical integration or limiting approximations. Here, series expansions due to Hasegawa, Inoue, and Matsuzawa [J. Acoust. Soc. Am. **74**, 1044–1047 (1983); **75**, 1048–1051 (1984)] are shown to reduce to simpler expressions suitable for numerical computations. For the region $r \geq a$, where a is the piston radius and r is the distance from the piston center, an exact solution is given by a series of spherical Hankel functions and Legendre polynomials with explicit, closed-form, position-independent coefficients. For the paraxial region $w \leq a$, where w is the distance from the piston axis, a second exact series expansion is valid for all axial distances z and reduces to the known analytic solution for w

$= 0$. These two expansions allow the radiated field to be computed at any point, with rapid convergence except for points near the circle bounding the piston. Example numerical results illustrate application of this method to ultrasonic sources.

3:30

4pPAb7. Fast calculations of time-harmonic near field pressure distributions produced by triangular sources. Duo Chen and Robert McGough (Michigan State Univ., 2120 Eng. Bldg., East Lansing, MI 48824, mcgough@egr.msu.edu)

An analytical expression is derived for the near field pressure response to a sinusoidal excitation for a triangular piston. The analytical expression eliminates a numerical singularity from the impulse response and therefore achieves much more rapid convergence than the impulse response. This results in shorter computation times relative to the impulse response for a given peak error value. These fast-converging expressions are represented by three integrals, where each integral expression corresponds to an edge of the triangle. Pressure fields are evaluated within a grid that includes the face of the triangular source, and computation times are compared with the impulse response for given values of the peak error. For a specified peak error of 1%, the rapidly converging expressions are at least 50% faster than the impulse response for equilateral triangles with sides ranging from one-half wavelength to 8 wavelengths. For a specified peak error of 10%, the rapidly converging expressions are at least 120% faster than the impulse response when applied to the same group of equilateral triangles. Different reductions in computation time are achieved by other piston and grid geometries.

3:45

4pPAb8. Tangible interactive interface using acoustic time reversal process. Ros K. Ing, Nicolas Quieffin (Sensitive Object, Res. and Development Dept., 10 rue Vauquelin 75005 Paris, France), Stefan Catheline, and Mathias Fink (Univ. Paris VII, 75231 Paris cedex 05, France)

Time reversal in acoustic is a very efficient solution to focus sound back to its source in a wide range of material including reverberating media. It expresses the following physical properties: a wave still have the memory of its source location. The concept presented in this paper consists in detecting the acoustic waves in solid objects generated by a simple human touch. In a second step, the information related to the source location are extracted from a virtual time reversal experiment in the computer. Then, an action (turn on the light or a CD player) is associated to each location. Thus, the whole system transforms solid objects into interactive interfaces. Compared to the existing acoustic techniques, it presents the great advantage to be simple and easily applicable on inhomogeneous objects with any shape. The number of possible touch locations at the surface of objects is shown to be directly related to the mean wavelength of the detected acoustic wave.

4:00

4pPAb9. Telecommunication in a disordered environment with iterative time reversal. Gabriel Montaldo, Geoffroy Lerosey, Arnaud Derode, Arnaud Tourin (LOA, ESPCI, CNRS, 10 rue Vauquelin, 75005 Paris, France), Julien de Rosny, and Mathias Fink (CNRS, 75005 Paris, France)

Recent researches in the area of wave propagation in random media applied to telecommunications showed that, contrary to intuition, reverberation or scattering of waves in a disordered medium can actually help to increase the information transfer rate. The key element therein is the ability of a communication system to exploit independent channels of propagation. We present a method to transmit digital information through a highly scattering medium. It is based on iterations of a time-reversal process, and permits to focus short pulses, both spatially and temporally, from a base antenna to different users. This iterative technique is shown to be more efficient (lower inter-symbol interference and lower error rate)

than classical time-reversal communication, while being computationally light and stable. Experiments are presented: digital information is conveyed from 15 transmitters to 15 receivers by ultrasonic waves propagating through a highly scattering slab. From a theoretical point of view, the

iterative technique achieves the inverse filter of propagation in the subspace of non null singular values of the time reversal operator. We also investigate the influence of external additive noise, and show that the number of iterations can be optimized to give the lowest error rate.

THURSDAY AFTERNOON, 19 MAY 2005

REGENCY C, 1:00 TO 5:00 P.M.

Session 4pPP

Psychological and Physiological Acoustics: Localization, Binaural Hearing and Physiology (Poster Session)

Beverly A. Wright, Chair

Northwestern Univ., Dept. Communication Science and Disorders, Evanston, IL 60208

Contributed Papers

All posters will be on display from 1:00 p.m. to 5:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 5:00 p.m.

4pPP1. Auditory and visual performance in an open sound field. Kim F. Fluitt, Tomasz Letowski, and Timothy Mermagen (U.S. Army Res. Lab., HRED-VAP, Bldg 520, Aberdeen Proving Ground, MD 21005)

The ability to estimate a distance to a sound source in an open field is an important element of situational awareness on the battlefield, and is affected by many technical and environmental conditions. A limited body of knowledge regarding auditory perception of sources located over long distances makes it difficult to develop models predicting auditory behavior on the battlefield. Results of previous studies have shown that people greatly underestimate distances. However, it is not known if there is a connection between a visual estimation, verbally reporting an estimate, and auditory estimation. The purpose of the present study was to compare listeners' visual, verbal reporting, and auditory estimates to sound sources 25 to 200 m from the listening position. Data were collected for auditory as well as visual estimations of distance expressed verbally. Twenty-two subjects (men and women, ages 18–25) participated in the study. Six types of sounds were presented from five loud speakers in random order. Test results indicate that auditory and visual estimation errors increased with distance and that at some distances the visual estimation errors exceeded auditory estimations errors, but the differences were not statistically significant. Specific results will be presented.

4pPP2. Effects of different amounts of brief training and rest on the generalization of learning from interaural-level-difference to interaural-time-difference discrimination. Jeanette A. Ortiz and Beverly A. Wright (Dept. of Commun. Sci. and Disord. and Inst. for Neurosci., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208-3550)

Training-induced improvements on perceptual skills can be enhanced by increasing the amount of training and by resting between training and testing. However, how these two factors affect the generalization of learning from a briefly trained condition to an untrained one is unknown. Here, listeners were trained on an interaural-level-difference (ILD) discrimination condition (4-kHz tones), then were tested for generalization to an interaural-time-difference (ITD) discrimination condition (0.5-kHz tones). The amount of training and the time between training and testing differed across four groups. Listeners tested 10 hours after training had significantly lower ITD discrimination thresholds than naive listeners ($n=94$), regardless of whether training lasted for 20 min ($n=14$) or 2 h (n

$=11$). Thus, when there was a long time between training and testing, learning generalized from ILD to ITD discrimination regardless of the amount of training. In contrast, listeners tested immediately after training on ILD discrimination showed generalization to ITD discrimination with 20 min ($n=14$), but not 2 h ($n=14$), of training, suggesting that without rest between training and testing, longer training disrupted generalization. Hence, increased training interfered with generalization from ILD to ITD discrimination for short, but not long, delays between training and testing. [Work supported by NIH.]

4pPP3. The impact of helmet design on sound detection and localization. Angelique Scharine (U.S. Army Res. Lab.–HRED)

The shape and absorptiveness of a ballistic helmet changes the sound signal reaching the soldier's ear. Although the attenuation of current helmets is minimal, soldiers have reported removing their Personnel Armor System for Ground Troops (PASGT) helmet when it was necessary to determine sound source direction. The Advanced Combat Helmet (ACH) has reduced ear coverage and absorptive internal padding that decreases localization errors. In an effort to provide more integrated headgear, the U.S. Army is testing a new, Scorpion (R4) helmet that has rings that allow the insertion of earmuffs and a modified version without the rings (R4-R). Two studies were conducted to measure the effect of these four designs on sound detection and localization. None of the helmets differed significantly in the degree of attenuation nor did attenuation correlate with localization. However, localization performance varied greatly. The current ACH and the R4-R had the least impact on localization. The older, unpadded PASGT, caused high error rates despite having the lowest attenuation. Despite being otherwise similar to the R4-R, the R4 impaired localization just as much as the PASGT and its rings increased the attenuation by more than a decibel.

4pPP4. Principal components analysis interpolation of head related transfer functions using locally-chosen basis functions. Jacob W. Scarpaci and H. Steven Colburn (Hearing Res. Ctr. and Dept. of Biomed Eng., Boston Univ., 44 Cummington St., Boston, MA 02215)

Spatial interpolation between measured head related transfer functions (HRTFs) may be accomplished by using principal components analysis (Kistler and Wightman, 1992). The data set can be reduced by using only

the most important basis functions (BFs) when reconstructing the magnitude spectrum of the HRTFs. Relatively good performance can be achieved by using a small fraction of the BFs required for an error free representation. In this study a comparison is made between two methods for choosing which basis functions are included in the HRTF reconstruction for a given position. The usual approach is to choose the subset of BFs which have the largest impact (common variance) on the global set of measured HRTFs. This will be compared to a method in which the subset of BFs are chosen to have the largest impact on the measured HRTFs in the area local to the position being reconstructed. Advantages and disadvantages to the two methods are discussed. [Work supported by NIH DC00100.]

4pPP5. Hearing space: Identifying rooms by reflected sound. Lawrence D. Rosenblum and Ryan L. Robart (Univ. of California, Riverside, Riverside, CA 92521)

The acoustic engineering literature has shown that listeners are sensitive to the sound reflecting properties of spaces so as to judge the general dimensions and acoustic quality of the space [e.g., J. S. Bradley, R. D. Reich, and S. G. Norcross, *J. Acoust. Soc. Am.* **108**, 651–661 (2000)]. There is also speculation on the perceptual processes listeners use to apprehend properties of spaces [e.g., R. K. Clifton, R. L. Freyman, and J. Meo, *Percept. Psychophys.* **64**, 180–188 (2003)]. Still, there has been little research testing whether listeners can simply recognize different types of rooms based on reflected structure. To examine this issue, five different sound sources were binaurally recorded in four different acoustic spaces. The sources ranged from human speech to white noise bursts. The acoustic spaces included a large indoor gymnasium, a moderately-sized classroom, a public restroom, and a small laboratory room. Untrained listeners heard each sound over headphones as they looked at photographs of the four rooms. They were asked to choose the room in which each sound was recorded. Overall, listeners were quite good at the task, with accuracy dependent on sound source. The results indicate a sensitivity to complex ambient structure not often addressed in the psychoacoustics literature.

4pPP6. Effects of various reverberant conditions on speech intelligibility. Suzanne P. Carr and H. Steven Colburn (Hearing Res. Ctr. and Dept. of Biomed. Eng., Boston Univ., 44 Cummington St., Boston, MA 02215)

Understanding speech in complex environments is a problem for many hearing impaired listeners, yet the specific characteristics of the listening environment which contribute most to listening difficulties are not well understood. Using virtual stimuli, a large range of conditions are tested on a small group of listeners, both normal and hearing impaired, and speech intelligibility thresholds are obtained. Systematic comparisons of the different conditions are made. The conditions that are varied are the amount of reverberation in the virtual room (ranging from pseudo-anechoic to moderately reverberant), the presence or absence of strong, early reflections such as from a wall and/or tabletop, the direction of the target speech relative to the listener, the distance of the target speech from the listener, and the number and location of competing speech maskers. Care is taken to ensure that the conditions are within the bounds of realistic listening. The validity of the use of virtual stimuli is also explored. [Work supported by NIH DC00100.]

4pPP7. The effect of spatial configuration in a divided attention task. Virginia Best, Antje Ihlefeld, and Barbara Shinn-Cunningham (Hearing Res. Ctr., Boston Univ., 677 Beacon St., Boston, MA 02215, ginbest@cns.bu.edu)

The effect of spatial separation on the ability of listeners to report keywords from two simultaneous talkers was examined. The talkers were presented with equal intensity at a clearly audible level, but were processed to minimize their spectral overlap and reduce energetic interfer-

ence. The two talkers were presented with various angular separations around references of -45° , 0° , or 45° azimuth. Overall, performance did not vary dramatically with spatial configuration, but depended on spatial separation and reference direction. With the talkers in front or to the left, performance tended to first increase and then decrease with increasing separation. With both talkers to the right, performance tended to improve monotonically with increasing separation. The relative levels of the two talkers at each ear in each configuration partially accounted for results. For each talker a different ear contained a signal-to-noise ratio advantage, and performance was positively correlated with the mean signal-to-noise ratio across the two “better ears.” Thus, when tracking two sources simultaneously, listeners may make use of the information at the two ears independently. Furthermore, the drop in performance for some large talker separations may reflect increased difficulty in following sources that do not fall within a single “spotlight” of spatial attention.

4pPP8. Localization of amplitude and frequency modulated sounds. Mark Ericson (Air Force Res. Lab., AFRL/HECB Bldg. 441, 2610 Seventh St., Wright-Patterson AFB, OH 45433, mark.ericson@wpafb.af.mil)

Everyday sounds, such as speech, music, and environmental noises, vary in level and frequency. The dynamic cues of natural sounds help to identify and segregate multiple sources. Amplitude and frequency modulation of simple pure tone complexes were manipulated in several experiments to measure their effects on auditory localization. The tonal complexes had 500 Hz fundamental frequencies and 26 components, providing 13 kHz in bandwidth. The complexes were either amplitude modulated, frequency modulated, co-modulated in frequency and amplitude, or not modulated. In addition, phase of the carrier and modulation frequencies were randomized to aid in sound source segregation. Three normal hearing subjects participated in the task of localizing and identifying up to four simultaneous sounds. Amplitude modulated sounds provided the best localization acuity and identification data. Comodulated, frequency modulated and no modulation were found to provide lower amounts of acuity performance in decreasing order.

4pPP9. Different interaural level difference processing with complex sounds and pure tones. Yuxuan Zhang and Beverly A. Wright (Dept. of Commun. Sci. and Disord. and Inst. for Neurosci., 2240 Campus Dr., Northwestern Univ., Evanston, IL 60208-3550)

Interaural level differences (ILDs) are one of the primary cues to sound source position on the horizontal plane. Most studies on human performance with ILDs use simple sounds such as pure tones. However, naturally occurring acoustic stimuli usually have complex waveforms. Here human learning of ILD discrimination was examined with complex waveforms. Sixteen listeners were trained 1 hr/day for 9 days on ILD discrimination with a 4-kHz tone sinusoidally amplitude modulated at 0.3 kHz conveyed through headphones. Before and after training, they were tested, together with sixteen untrained controls, on the trained condition and five related untrained conditions (three with amplitude modulated tones, two with pure tones). The trained listeners improved significantly more than controls on all conditions with amplitude-modulated tones, but not on those with pure tones. The lack of generalization of ILD learning from modulated to pure tones suggests that practice modified ILD processing in a region that encodes complex sounds with a variety of carrier frequencies and modulation rates, but not pure tones. Thus, these findings suggest that waveform complexity is an important factor in ILD processing, and must be considered when evaluating human ILD performance. [Work supported by NIH.]

4pPP10. Sources of variation in masking by competing speech.

Richard L. Freyman, Karen S. Helfer, and Uma Balakrishnan (Dept. of Commun. Disord., Univ. of Massachusetts, Rm. 3 Arnold House, Amherst, MA 01003, rlf@comdis.umass.edu)

The literature on speech recognition within a competing speech environment shows great variation with respect to the amount of masking produced, as well as variation in the improvement realized from spatial separation of the target and masking speech. Presumably, the sources of variation include differences in methodology and stimuli used by different researchers. In the current study the target speech stimuli were nonsense sentences spoken by a female talker. The competing speech was created from similar nonsense sentences recorded by 10 other female speakers. Five different maskers were created, each a combination of two of the 10 talkers who had similar fundamental frequencies. The results showed that the variation in masking produced by the different two-talker combinations was substantial only when target and masker were presented from the same loudspeaker. As a consequence, the observed benefit from spatial separation varied widely among the different maskers, and was ordered according to fundamental frequency in an unexpected way. The results are interpreted as showing greater variation in informational masking than in energetic masking. Also tested was the influence of different ways of blocking the trials, which effectively manipulated the uncertainty of the masking stimulus from trial to trial. [Work supported by NIH DC01625.]

4pPP11. Binaural informational masking release in children and adults.

Joseph W. HallIII, Emily Buss, and John H. Grose (Univ. of North Carolina at Chapel Hill, Chapel Hill, NC 27599, jwh@med.unc.edu)

Informational masking associated with masker spectral uncertainty can sometimes be reduced by providing cues that promote perceptual segregation of the signal from the masker. Our previous research using the multi-burst-same (MBS) paradigm of Kidd *et al.* [J. Acoust. Soc. Am. **95**, 3475–3480 (1994)] indicated that all adults and most children (5–9 YO) showed reduced informational masking when monaural segregation cues related to gating asynchrony or spectro-temporal coherence were available. The present study examined developmental effects in children aged 6–10 years for release from informational masking in a condition where perceptual segregation was manipulated using a spatial hearing cue. In the informational masking condition, the pure-tone signal and the MBS masker components were presented to the left ear. In the masking release condition, the masker components were also presented to the right ear synchronously (at a level 10-dB higher than in the left ear) so that the signal would be lateralized to the left ear and the masker would be lateralized to the right ear. Results indicated that most adults achieved masking release in this condition, but that none of the children did. These results are consistent with previous findings indicating protracted development for informational masking release related to spatial hearing cues.

4pPP12. Measuring the binaural temporal window.

Andrew J. Kolarik and John F. Culling (School of Psych., Cardiff Univ., Tower Bldg., Park Pl. Cardiff, CF10 3AT, UK)

Sensitivity to small ITDs in detection and discrimination tasks was measured. In experiment 1, four listeners performed 3 tasks. The first 2 were 4I- and 2I-2AFC adaptive detection tasks. The third was a 2I-2AFC adaptive discrimination task. All stimuli were 100 ms noise bursts. Reference stimuli were diotic, and target stimuli contained a probe duration of 64, 32, 16, 8, 4, or 2 ms, which carried an interaural time delay. These probes were temporally fringed with diotic noise. Thresholds for the discrimination task were significantly higher than for the detection tasks. In experiment 2, psychometric functions were obtained from 4 participants for the six probe durations using the same 2I-2AFC detection and discrimination tasks. Binaural temporal windows were fitted to the data using a variety of fitting functions. Fits to the detection task data demonstrated narrow tips but unmeasurably long skirts. In the discrimination task neither parameter could be accurately measured, suggesting that the overall stimulus duration was too short to encompass the window. A stimulus

length of 500 ms and probe durations of 256, 128, 64, 32 and 16 ms allowed both parameters to be measured. The resulting equivalent rectangular duration was approximately 50 ms.

4pPP13. Individual differences in the masking level difference (MLD) with a narrowband masker at 500 or 2000 Hz.

Emily Buss, Joseph W. HallIII, and John H. Grose (Univ. of North Carolina at Chapel Hill, 130 Mason Farm Rd., 1115 Binformatics Bldg., CB7070, Chapel Hill, NC 27599, ebuss@med.unc.edu)

The MLD for a narrowband masker is associated with marked individual differences. This study examines factors that might account for these individual differences, including binaural temporal resolution and sensitivity to interaural cues based on time or level. MLD data were collected for 50-Hz wide maskers at 500 and 2000 Hz, gated on for 400-ms. The signal was a pure tone at the center frequency of the masker, of either brief (15-ms) or long (200-ms) duration. Brief signals were coincident with either a local minimum or maximum in the pattern of inherent amplitude modulation. Sensitivity to interaural time and level cues was assessed using similar stimuli, with the exception that the long-duration signal was a 50-Hz band of noise, generated to provide just interaural time cues, just interaural level cues, or both types of cues. Binaural temporal windows were estimated based on pure tone detection thresholds for a brief 500-Hz tone presented at different points in time relative to an abrupt interaural phase transition in a masking noise, bandpass filtered between 100 and 2000 Hz. Relationships between MLD results and those of binaural temporal windows and interaural cues of time and level will be discussed.

4pPP14. The discrimination of interaurally correlated noise bands.

Barrie Edmonds and John Culling (School of Psych., Tower Bldg., Cardiff Univ., Cardiff, CF10 3AT, UK)

Models of binaural unmasking suggest that the auditory system detects deviations from unity in the interaural coherence of the waveforms at the two ears. Since anticorrelated noise has high coherence within a frequency channel, such a coherence-detection mechanism should be unable to distinguish a correlation of -1.0 from a high positive correlation. A 3I-2AFC paradigm was used to test whether such a limitation can be observed behaviorally. Stimuli consisted of a 1-ERB-wide sub-band of interaurally correlated noise centered at 500 Hz (i.e. 462–538 Hz) flanked by two spectrally remote bands of noise (0–329 Hz and 717–3000 Hz) with an interaural correlation of 1.0. The flanking bands were intended to reduce cues from the perceived laterality of the stimuli. Participants were presented with three stimuli (reference, target, and distracter) and asked to choose the odd-one-out: the reference and distracter intervals contained sub-bands of anticorrelated noise while the target interval contained a sub-band of noise with interaural correlation between 0.7 and 1.0. Preliminary results indicate that different participants find different values of interaural correlation to be more distinguishable than others.

4pPP15. A biologically inspired binaural approach to monaural modeling.

Daniel E. Shub and H. Steven Colburn (Boston Univ. Hearing Res. Ctr., 44 Cummington St., Boston, MA 02215)

The auditory system is often discussed as having monaural and binaural neurological pathways; similarly models are classified as either monaural or binaural. Psychophysical evidence of contra-aural interference (when performance with one ear is better than performance with two ears) suggests that the information used on monaural tasks (e.g., N_0S_0 and N_mS_m detection) may be carried by a binaural pathway. Binaural models often require monaural channels to predict the results of monaural tasks, but these monaural channels prevent the models from predicting contra-aural interference. This modeling work investigates the monaural information carried by a processor which is inherently binaural. The processor design makes the inclusion of monaural channels unnecessary and contra-

aural interference is predicted under certain conditions. The performance of the model matches results from a variety of traditional psychophysical tasks (including discrimination of differences in overall intensity; discrimination of differences in interaural level, time and coherence; as well as detection under monaural and binaural masking conditions). Results suggest that binaural neurons contain sufficient information to explain performance on both binaural and monaural tasks. [Work supported by NIH grants R01 DC 00100 and 1 F31 DC006769-01.]

4pPP16. Auditory nerve response to broadband noise with high-frequency spectral notches. Ana Alves-Pinto, Enrique A. Lopez-Poveda (Instituto de Neurociencias de Castilla y Leon, Univ. of Salamanca, Avda. Alfonso X El Sabio s/n, 37007 Salamanca, Spain), and Alan R. Palmer (MRC Inst. of Hearing Res., Nottingham NG7 2RD, UK)

The threshold notch depth for discriminating between a flat-spectrum broadband noise and a similar noise with a rectangular spectral notch centered at 8 kHz varies nonmonotonically with stimulus level (Alves-Pinto and Lopez-Poveda, submitted to J. Acoust. Soc. Am.). A possible explanation for this result is that the notch may be encoded in the rate profile of auditory nerve (AN) fibers with high spontaneous rate (HSR) at low levels and in that of low spontaneous rate (LSR) fibers at high levels. To test this hypothesis, the rate profile of guinea pig AN fibers was measured in response to broadband notched noise for different notch depths and widths and for overall levels ranging from 40 to 100 dB SPL. Preliminary results support the hypothesis that HSR fibers can encode the spectral notch only for levels up to around 70 dB SPL. However, they also suggest that, as in the psychophysics, the negative effect of level is less pronounced the wider the notch. Additional data are required to confirm the role of LSR fibers to encode for the notch at higher levels. [Work supported by Spanish FIS PI020343 and G03/203.]

4pPP17. The spatial distribution of sound pressure within the human ear canal. Michael R. Stinson and Gilles A. Daigle (Inst. for Microstructural Sci., Natl. Res. Council, Ottawa, ON, Canada K1A 0R6, mike.stinson@nrc-cnrc.gc.ca)

The sound field inside a human ear canal has been computed using 2 approaches. A simple model, a modified Webster horn equation approach, can accommodate the curvature and varying cross section of the ear canal. Calculations using the horn equation demonstrate the formation of standing waves within the canal. The pressure may be interpreted as either the pressure along the center axis of the canal or the average pressure within a cross-sectional slab. To investigate possible spatial variation through a cross section, the sound field has also been computed using the boundary element method (BEM). Over 2000 triangular mesh elements, 1 mm or less in size, were used to represent the canal geometry. For a plane piston source at the canal entrance and both a rigid and a resistive impedance condition at the eardrum position, the computed sound pressures along the center axis of the ear canal are in good agreement with the horn equation calculations, up to 15 kHz. The BEM approach, though, reveals spatial variations of sound pressure through each canal cross section, increasingly significant as frequency increases. Further, for source configurations that are more realistic than a simple piston, large transverse variations in sound pressure are anticipated.

4pPP18. Distortion product otoacoustic emissions generated by mistuned harmonic stimuli. Glenis R. Long and Jungmee Lee (Speech and Hearing Program, Grad. Ctr. CUNY, 365 Fifth Ave, New York, NY 10016)

Psychoacoustic research in humans [Lee and Green, J. Acoust. Soc. Am. **95**, 718–725 (1994)] suggests that the detection of the mistuning of an harmonic when the harmonic complex and a mistuned component were presented simultaneously to the same ear stems, at least in part, from the resulting envelope interactions on the basilar membrane. Neurophysiologi-

cal research in chinchillas [Sinex *et al.*, Hear. Res. **168**, 150–162 (2002)], provides evidence that such envelope interactions can be detected at the level of the inferior colliculus. The potential role of cochlear nonlinearities in determining the nature of the signal on the basilar membrane is explored by evaluating the DPOAE generated by multicomponent harmonic and inharmonic complexes. When harmonic complexes are used, the DPOAE all fall at harmonic frequencies. When inharmonic complexes are used, many nonharmonic DPOAE are detected.

4pPP19. The reflectivity function of the cochlear transmission line. Renata Sisto (ISPESL–DIL, Via di Fontana Candida, 1, 00040 Monteporzio Catone (RM), Italy) and Arturo Moleti (Univ. of Roma Tor Vergata, 1, 00133 Roma, Italy)

The generation of evoked otoacoustic emissions is related, for each frequency, to the reflectivity function of the cochlear membrane near the correspondent resonant place. A formal analogy exists between the transmission line equation that is often used to model the propagation of sound along the cochlea and the Schrodinger equation describing the motion of an elementary particle in a one-dimensional potential. In this analogy, the cochlear region near the tonotopic place is equivalent to a negative potential well. Analytical solutions are available in quantum mechanics textbooks, which predict partial reflection of the incoming wave from such a potential well. The reflectivity is expected to be a slow quasi-periodic function of the well width and depth, e.g., of the quality factor of the cochlear resonance. This observation could be useful to predict the large-scale spectral structure of evoked otoacoustic emissions as a function of the cochlear tuning curve.

4pPP20. Multiple auditory steady-state response thresholds to bone-conduction stimuli using three oscillator placements in premature infants. Jennifer Hatton, Susan A. Small, and David R. Stapells (School of Audiol. & Speech Sci., Univ. of British Columbia, 5804 Fairview Ave, Vancouver, BC, Canada V6T 1Z3, stapells@audiospeech.ubc.ca)

Auditory Steady State Responses (ASSRs) are a promising technique for estimating the behavioral audiogram in infants. The current study investigates the effects of bone-oscillator placement on ASSR thresholds in premature infants ($N=15$, mean age: 35 weeks PCA). Using the MASTER research system, ASSR thresholds to multiple bone-conduction tones (0–50 dBHL re:mastoid; 77–101 Hz) presented to the (i) superior-posterior temporal bone, (ii) mastoid, and (iii) forehead were obtained. Results with no response at 50 dBHL were arbitrarily assigned a threshold of 60 dBHL. No differences in threshold were found between the temporal and mastoid placements. Thresholds averaged across these placements were 17, 15, 34, and 30 dBHL for 500, 1000, 2000, and 4000 Hz, respectively. However, on average, thresholds for the forehead placement were significantly higher by at least 14, 11, 18, and 14 dB at 500, 1000, 2000, and 4000 Hz, respectively, compared to the temporal and mastoid placements. These differences may be even greater because absent responses at the maximum intensity were seen more often with forehead placement compared to other placements. In conclusion, one may use either the temporal bone or mastoid for bone-oscillator placement, but the forehead should be avoided. [Work supported by CIHR and NSERC-Canada.]

4pPP21. Multiple auditory steady-state response (ASSR) thresholds to bone-conduction stimuli in young infants with normal hearing. Susan A. Small, Jennifer Hatton, and David R. Stapells (School of Audiol. & Speech Sci., Univ. of BC, 5804 Fairview Ave., Vancouver, BC, Canada V6T 1Z3)

Bone-conduction ASSR thresholds (carrier frequencies: 500–4000 Hz; 77–101-Hz modulation rates; amplitude/frequency modulated; single-polarity stimulus) were obtained in two infant groups ($N=29$ pre-term, tested in NICU; $N=14$ 0-to-8 months of age, tested in soundbooth). Mean (1SD) ASSR thresholds were 16 (11), 16 (10), 37 (10), and 33 (13) dBHL

in pre-term infants and 14 (13), 2 (7), 26 (6), and 22 (8) dBHL in older infants at 500, 1000, 2000, and 4000 Hz, respectively. Both infant groups had significantly better thresholds for 500 and 1000 Hz compared to 2000 and 4000 Hz, in contrast to adults who have similar thresholds across frequency (22, 26, 18, and 18 dBHL) [Small and Stapells, *J. Am. Acad. Audiol.* (in press)]. When 500- and 1000-Hz thresholds were pooled, NICU infants and 0–8-month-old infants tended to have better low-frequency thresholds than adults. When 2000- and 4000-Hz thresholds were pooled, NICU and 0–8 month-old infants tended to have poorer thresholds than adults. Overall, these results suggest that low-frequency bone-conduction thresholds worsen and high-frequency bone-conduction thresholds improve with maturation. [Work supported by CIHR and NSERC Canada.]

4pPP22. Human electrophysiological examination of the buildup of the precedence effect (Clifton effect). Andrew Dimitrijevic and David R. Stapells (School of Audiol. & Speech Sci., Univ. of British Columbia, 5804 Fairview Ave., Vancouver, BC, Canada V6T 1Z3, andrew@audiospeech.ubc.ca)

The relationship between behavioral measures of buildup of precedence effect [or Clifton effect (CE)] and electrophysiological responses using an event-related potential (ERP) paradigm was examined in 14 young adults with normal hearing. The CE was elicited using a binaural paired-click (left and right speaker delay) in sound field. This study aimed to determine whether ERP measures were related to the perception of buildup. Subjects participated in two sessions: (i) Session #1 psychoacoustic measures of the degree of buildup as function of click delay (left and right side). (ii) Session #2 recorded cortical ERPs using click delays (varying from 6 to 8 ms) that would maximize the degree of buildup in each subject. Stimuli consisted of repeated trains containing 5 paired-clicks (left speaker leading) with a noise burst separating consecutive trains. Results: Significant *N1* amplitude hemispheric asymmetries were observed related to click position. *N1* responses decreased (43%) as a function click position in the train at electrode sites contralateral to the leading stimulus and, conversely, increased (30%) at electrode sites ipsilateral to the lead. These results suggest that differential refractoriness of the *N1* response may lead to the lateralized perception of buildup to the precedence effect. [Work supported by NSERC-Canada.]

4pPP23. The event-related brain potentials to uncorrelated fragment of noise. Juan Huang, Xihong Wu, Liang Li (Dept. of Psych., Peking Univ., Beijing 100871, China, jacee@pku.edu.cn), James Qi, Bruce Scheneider (Univ. of Toronto at Mississauga, Mississauga, ON, Canada), Yu He, and Claude Alain (Baycrest Ctr. for Geriatric Care, Toronto, ON, Canada)

Two correlated waveforms of broadband noise presented to the left and right ear simultaneously or with a short delay are often perceptually fused into one sound image. However, when an uncorrelated noise fragment (UCNF) is inserted in a long duration sound, listeners report hearing a transient burst of noise. The detection of the UCNF is dependent on the duration of the UCNF and the binaural delays. Here, we recorded event-related brain potentials (ERPs) to 100-ms UCNF and varied the binaural delay (0, 3, 10, and 20 ms) from trial to trial. The likelihood of detecting the UCNF decreased with increasing binaural delay. At 0 delay, the UCNF elicited negative and positive waves peaking at about 100 and 200 ms after UCNF onset (N1-P2 complex), which was present even when the stimuli were ignored. The conscious detection of the UCNF elicited an additional positive wave between 250 and 450 ms at parietal and occipital sites (P3b). The P3b latency was longer and its amplitude larger for binaural delay of 3 than 0 ms. Our results show that the detection of UCF involved both automatic and attention-dependent processes especially when a binaural delay is introduced between two source of correlated noises.

4pPP24. Tinnitus neural map; A positron emission tomography study. Martin L. Lenhardt (Dept. of Biomed. Eng., Otolaryngol., Emergency Medicine, Virginia Commonwealth Univ., Richmond, VA 23298), Abraham Shulman, and Barbara Goldstein (SUNY, Brooklyn, NY)

The neural map of tinnitus involves more than the classical auditory pathways and the limbic system. PET findings in six patients, with severe problem tinnitus, revealed the involvement of the cerebellum, insula and frontal cortices when these patients were imaged before and after high frequency bone conduction therapy. The frontal cortex and cerebellum demonstrated the highest ratios of metabolic change but changes were also noted in the thalamus and the medial temporal lobe system. The PET data supports the view that the frequency specific map of auditory cortex is dynamic and can change with high frequency therapy, presumably due to neural reorganization. The PET data further reflect alterations in multiple areas of brain in all patients to tinnitus and/or high frequency therapy. Encouraging was the observation that patients with the most dramatic change in their global pre/post PETs were also the ones who exhibited the greatest behavioral improvement in regards to tinnitus relief measured by informal report and standard questionnaires. In those patients, post therapy minimal masking levels dropped indicating less acoustic energy was need to mask their problem tinnitus, interpreted as reflecting central changes. Taken as a whole, these data support the value of frequency specific tinnitus therapy.

4pPP25. Real-time implementation of a model auditory-nerve fiber. Satish G. Iyengar (Inst. for Sensory Res. and Dept. of Elec. Eng. and Comput. Sci., Syracuse Univ., Syracuse, NY 13244), Jayant Datta (Syracuse Univ. and Discrete Labs., Inc., Syracuse, NY 13220), and Laurel H. Carney (Syracuse Univ., Syracuse, NY 13244)

A time-varying model auditory-nerve (AN) fiber based on Tan and Carney (2003) was developed on a digital signal processor (DSP) platform to simulate AN responses in real-time, using the Motorola DSP56367, a 150 MIPS audio processor. To understand the schemes employed by the brain for decoding different sound stimulus parameters, it is first essential to get an accurate representation of peripheral (external, middle, and inner ear) responses that in turn excite the higher levels along the auditory pathway. Though present computational models predict essential AN response properties, their use in testing mechanisms hypothesized to occur at higher levels of the auditory pathway is limited due to the large processing times that they require. This is because such nonlinear models require computational implementation in the time domain, with time-step-by-time-step changes in model parameters as the bandwidth and gain of the inner ear change with stimulus fluctuations. The DSP-based model presented here aims to speed up inquiries related to auditory signal processing strategies at higher levels by providing a real-time solution to AN fiber simulations. Details of the implementation and some prospective auditory-research utilities will be discussed. [Work supported by NIDCD R43-DC006591 (JD, SGI) and R01-DC001641 (LHC, SGI).]

4pPP26. Modeling inner hair cell compression. Almudena Eustaquio-Martin and Enrique A. Lopez-Poveda (Instituto de Neurociencias de Castilla y Leon, Universidad de Salamanca, Avda. Alfonso X El Sabio s/n, 37007 Salamanca, Spain)

The voltage-dependent activation of inner hair cell (IHC) basolateral potassium (K^+) currents results in a compression of voltage responses to injections of large depolarizing currents with values well within the range of IHC transducer currents (Kros and Crawford, *J. Physiol.* **421**, 263–291 (1990)). *In vivo*, this compression must add to the compressive nonlinearity produced by the gating of transducer channels. The purpose of this work is to present a biophysical model of the IHC that simulates the nonlinear compressive effects of IHC basolateral potassium currents both *in vivo* and *in vitro*. The model incorporates two components for the po-

tassium currents, one fast and one slow, as described by Kros and Crawford. Membrane parameters are provided for the model to reproduce the time course of the receptor potential in response to constant current pulses across the membrane. The model is then used to investigate the degree of

compression that the K⁺ currents contribute to the receptor potential *in vivo*. Also investigated are the effects on IHC compression of a partial blocking of the K⁺ channels, as occurs in some common forms genetic hearing loss. [Work supported by Spanish FIS PI020343 and G03/203.]

4pSA1. Piano soundboards: Experimental and modeling studies. Nicholas Giordano (Dept. of Phys., Purdue Univ., West Lafayette, IN 47907, giordano@purdue.edu)

The piano has attracted the attention of many researchers, and most of that work has focused on piano hammers and string vibrations. The vibrational and radiative properties of the soundboard have drawn much less attention, but are essential for an understanding of the sound produced by the instrument. We review experimental studies of the soundboard's vibrational modes and their radiative efficiency. We also describe modeling studies of soundboard vibrations and radiation, which aid in understanding the measurements. Prospects for future work and for applications to other instruments are suggested. [Work supported by NSF grant PHY-9988562.]

2:30

4pSA2. Phase mapping and sound radiation from Caribbean steelpan. Andrew Morrison (Dept. of Phys., Northern Illinois Univ., DeKalb, IL 60115)

The Caribbean steelpan is one of the most interesting acoustic musical instruments invented in the last century. Although simple in design, the acoustic properties of the steelpan are surprisingly complicated. Holographic interferometry was used to determine the resonances of a low tenor steelpan. Placement of a vibrating mirror in the optical path of the reference beam expands the capabilities of the holography system to include phase measurements. Phase maps of several low resonances of notes on a Caribbean steelpan will be shown. Sound intensity measurements were taken to explore the relationship between the resonances and the radiated sound field. The pan was placed in an anechoic chamber, and selected notes were excited electromagnetically with a swept sinusoid signal. A two-microphone probe was used to gather sound intensity measurements. Sound intensity maps of the first three harmonics will be shown for several notes.

3:00

4pSA3. Acoustics of Baltic psaltery; a new outstanding Latvian Kokle. Andres Peekna (Innovative Mech., Inc., 5908 N River Bay Rd., Waterford, WI 53185) and Thomas D. Rossing (Northern Illinois Univ., DeKalb, IL 60115)

We have studied the acoustics of a Latvian Baltic Psaltery (kokle) which was judged by performing and recording musicians to be outstanding. Previous work by the authors pointed out the importance of a high population of body-resonances within the tuning range of the instrument, with good string-to-resonance coupling also playing an important role. This particular kokle shows outstanding coupling of strings to body-resonances, with all strings evidencing some degree of coupling. In some cases, the strings couple to a superposition of more than one body-resonance.

3:30–3:45 Break

4pSA4. Modal analysis and computer aided design studies of acoustic guitar structural designs. Craig M. Rashkow, Robert D. Collier (Thayer School of Eng., Dartmouth College, Hanover, NH 03755), and Alan Carruth (Luthier, Newport, NH 03773)

This study seeks to systematically identify modern Computer Aided Design (CAD) techniques to optimize acoustic guitar design. The study uses traditional design as a starting point for analysis of variations in materials and bracing structures of the front sound plate. CAD techniques are used to model the guitar and provide a broadband input that allows analysis of its modal response. Design optimization occurs in creating the most favorable modal response of the instrument while still maintaining structural integrity through effective support of the forces created by the strings' tension in the bridge and neck. The measures chosen to help identify the most favorable response are modal density, magnitude of the response at each mode, and the locations of the largest magnitudes. Increased modal density provides a richer timbre while the amplitude of the response determines the relative intensity of the sound projected. Increased modal response in the upper bout of the instrument can improve the timbre of pitches in the upper frequency range of the instrument. After analyzing these measures for multiple variations and iterations of a selected set of structural parameters, an optimal design is suggested. The results show good agreement between experimental modal measurements and computer-aided design modeling.

4pSA5. Applying vibration and acoustical radiation from musical instruments in a recording studio setting. Pamela J. Harght (Berklee College of Music, 1140 Boylston St., Boston, MA 02115)

Radiation patterns affect the musical characteristics of any instrument. Applying the radiation characteristics of instruments to microphone technique will enable musicians, audio engineers and students to capture the most-desirable sound, and understand how to position microphones efficiently and appropriately. This paper will use the research done on several instruments' acoustical characteristics and apply it to microphone techniques in a professional-level recording studio at Berklee College of Mu-

sic. Audio examples will be used to demonstrate microphone placement according to the acoustical radiation of musical instruments. [Thank-you to K. Anthony Hoover for his support and encouragement with this paper.]

4:15

4pSA6. Achieving pseudo-degeneracy in handbell modes. John R. Buschert, Sungdo Cha, Daniel A. King, and Daniel B. Horst (Goshen College, 1700 S. Main, Goshen, IN 46526)

Degenerate modes in handbells are split by nonuniformity in the bell. By adding small masses to the bell, the modes can be shifted in position and frequency. Interesting things happen when one attempts to recreate a degeneracy that has been split. Holographic photos of the modes will be shown which can be used to follow the effects of the added mass on individual modes. By moving and varying the mass, one can bring the modes back to a pseudo-degeneracy. Holographic interferometry photos and graphs of the position and frequency of the modes show the stages of this transition.

4:30

4pSA7. Vibration study of Indian Gong hung at one point near the edge. Paresh Shrivage, S. Parmeswaran, and Keith deSa (Acoust. Res. Lab, Dept of Phys., N. Wadia College, Pune, India)

Indian Gong is made up of brass and circular in nature. It is Percussion Instrument. It is used in some religious processions and music concerts in India. It is hung by a metal wire through a hole near the edge of circumference. It is vibrated by a metal (iron) hammer after repeated intervals to get sound of same pitch. This paper relates to vibrational analysis of Indian Gong. A study has been done to check the vibrational properties and the modes of vibration of the Gong. The study is done by spectrum analysis (FFT) and Time-average holography as a vibration analysis tool. The study will help to analyze certain vibrational features of brass. The tonal quality of brass is also compared to other metals, so that it will be useful in making musical instruments. The analysis of hologram may yield some interesting properties of the plate. In conclusion the paper is going to deal with modes of vibration of Indian Gong. The vibrational properties will depend on the point of actuations. The paper describes the mode of vibration and its mathematical equation.

Session 4pSC

Speech Communication: Speech Production and Perception I (Poster Session)

Abeer Alwan, Chair

Dept. of Electrical Engineering, UCLA, 405 Hilgard, Los Angeles, CA 90095

Contributed Papers

All posters will be on display from 1:30 p.m. to 5:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:30 p.m. to 3:15 p.m. and contributors of even-numbered papers will be at their posters from 3:15 p.m. to 5:00 p.m.

4pSC1. Tuning phenomena of melodies and resonance frequencies (formants) in infants pre-speech utterances. Kathleen Wermke (Univ. Wuerzburg, Pre-speech Ctr., Dept. of Orthodontics, Pleicherwall 2, 97070 Wuerzburg, Germany, wermke_k@klinik.uni-wuerzburg.de), Werner Mende (Berlin-Brandenburg Acad. of Sci., Berlin, Germany), Claudia Manfredi, Pierro Bruscoloni (Univ. of Firenze, Italy), and Angelika Stellzig-Eisenhauer (Julius-Maximilians-Univ., Wuerzburg, Germany)

In a former study [Wermke *et al.*, *Med. Eng. Phys.* **24**, 501–514 (2002)], an increasing tuning between laryngeal (melody) and pharyngeal (resonance frequencies) activity was demonstrated during pre-speech development. This tuning was observed unexpectedly early during development in mitigated cries and earliest non-cry utterances and prepares probably articulation in speech-like vocalizations of older infants. A new retrospective study supported this assumption by comparing tuning processes in cries and early non-cry utterances ($N=2500$) in two groups (low versus high word production performance at 18 months) of term-born healthy infants ($N=20$). Additionally, age-matched comparisons were made in 4 cleft-lip-palate-infants treated with a palatal plate. In order to demonstrate the interaction between melody and resonance control we designed a special graphical representation. The tracking function of the resonance frequencies is displayed synchronously to the melody and its harmonics. Resonance frequencies in pre-speech utterances are not yet identical to formant bands associated with speech sounds. The results support the existence of an early active tuning and its relation to later speech. This behavior seems to prepare formant tuning in later speech. Medical applications are seen for infants with disturbances of the vocal tract transfer function, e.g., infants with cleft-lip-palate. [Work supported by DFG.]

4pSC2. The gradient influence of talker sex and perceived sexual orientation on fricative perception. Benjamin Munson, Sarah V. Jefferson, and Elizabeth C. McDonald (Dept. Speech-Lang.-Hearing Sci., Univ. of Minnesota, 115 Shevlin Hall, 164 Pillsbury Dr., SE, Minneapolis, MN 55455, Munso005@umn.edu)

Listeners are more likely to hear a synthetic fricative ambiguous between /s/ and /ʃ/ as /ʃ/ if it is appended to a woman's voice than a man's voice [Strand, *J. Lang. Soc. Psych.* **18**, 86–99 (1999)], suggesting that speech perception is sensitive to social-indexical information. This study examined the influence of two variables on listeners' fricative perception: (a) talker sex, and (b) talkers' perceived sexual orientation (PSO, i.e., the probability that a talker is identified as gay, lesbian, or bisexual (GLB) based on speech alone). Stimuli were created by pairing a synthetic nine-step /s/-to-/ʃ/ series with tokens of /æ/ and /ɪ/ taken from natural productions of *shack* and *ship* by 44 talkers (22 women, 22 men), for a total of 88 different continua. Forty listeners rated the 44 talkers' PSO. A different group of 10 listeners participated in a series of two-alternative *sack-shack* and *sip-ship* identification experiments. As expected, listeners identified more /ʃ/ tokens for women's voices than for men's. GLB-sounding

women elicited significantly fewer /ʃ/ percepts than heterosexual-sounding women. No consistent influence of PSO on fricative identification was noted for men's voices. Regression analyses showed strong relationships between fricative identification and ratings of PSO for women talkers only.

4pSC3. Recognition of English phonemes in noise. José R. Benki (Kresge Hearing Res. Inst., Dept. of Otolaryngol., Univ. of Michigan Med. School, Ann Arbor, MI 48109-1346, benki@umich.edu) and Robert Felty (Univ. of Michigan, Ann Arbor, MI 48109-1285)

Native speakers of American English identified the consonants and vowels of American English CV and VC syllables and the vowels of hVd syllables. The CV and VC syllables, consisting of all of the English consonant phonemes, were selected from recordings described by Shannon *et al.* [*J. Acoust. Soc. Am.* **106**, L71–L74 (1999)], and the hVd syllables were selected from recordings described by Hillenbrand *et al.* [*J. Acoust. Soc. Am.* **97**, 3623–3641 (1995)]. All syllables were presented binaurally in signal-correlated noise. The resulting confusion matrices and feature analyses will be presented along with a position (initial versus final) analysis for the consonant results. The consonant and vowel results will be used to derive empirical measures of similarity of English words. [Work supported by NIH/NIDCD.]

4pSC4. Perturbed palatal shape and North American English /r/ production. Mark K. Tiede (Haskins Labs, 270 Crown St., New Haven, CT 06511, tiede@haskins.yale.edu and M.I.T.-R.L.E., Cambridge, MA), Vincent L. Gracco, Douglas M. Shiller (McGill U., Montreal, QC, Canada), Carol Espy-Wilson (U. of Maryland, College Park, MD), and Suzanne E. Boyce (U. of Cincinnati, Cincinnati, OH)

It is well established that the lowered $F3$ associated with the acoustic percept of American English /r/ can be achieved with different tongue shapes in production. Broadly speaking these shapes may be grouped into "bunched" and "retroflex" varieties. In this work the effects of somatosensory perturbation on /r/ production are examined. Subjects were fitted with a custom palatal prosthesis incorporating a 0.5 cm protrusion along the alveolar ridge, and tongue position during production of /r/ in vocalic contexts was observed using EMA under four conditions: before prosthesis placement; while wearing the prosthesis immediately following placement; still wearing the prosthesis following an unrecorded 20 min adaptation period; and immediately after prosthesis removal. Acoustic effects of the perturbation were minimal, especially after adaptation; production effects were most pronounced in the low vowel context. One subject showed an unperturbed preference for a retroflex configuration, but increased the degree of retroflexion with the palatal prosthesis in place. The remaining subjects preferred unperturbed bunched shapes, but under the

perturbed conditions produced primarily retroflex configurations, which for one subject persisted after prosthesis removal. These results suggest that speaker preference for one shape over another may be determined by palatal morphology. [Work supported by NIH.]

4pSC5. Relational acoustic invariance in the single/geminate stop distinction in Japanese. Yukari Hirata and Jacob Whiton (Dept. of EALL, Colgate Univ., 13 Oak Dr., Hamilton, NY 13346)

This study addressed an issue in the theory of relational acoustic invariance [Pickett *et al.*, *Phonetica* **56**, 135–157 (1999)]. The question was whether an invariant acoustic property exists for distinguishing Japanese single and geminate voiceless stops across different speaking rates. Four native Japanese speakers produced disyllabic words with single and geminate voiceless stops spoken in a carrier sentence at three speaking rates. Durations of sentences, words, stop closures, and vowels preceding the contrasting stops were measured. Ratios of geminate to single stop closures, geminate words to single words, closures to preceding vowels, and closures to words were calculated. The stop closure duration significantly overlapped between the single and geminate categories across rates. However, the ratio of geminate to single closure duration was unaffected by rate. Among the measures examined, the ratio of closure to word duration (0.35 as an optimal boundary) best classified all single and geminate tokens with 95.7–98% accuracy. These results suggest that, in spite of overlap in absolute closure duration between single and geminate stops, there is a relationally invariant measure that divides the two phonemic categories across rates and speakers, supporting the theory of relational acoustic invariance.

4pSC6. Articulatory influences on the categorization of speech sounds. H. Henny Yeung (Dept. of Psych., Univ. of British Columbia, 2136 West Mall, Vancouver, BC, Canada V6T 1Z4, hhyeung@psych.ubc.ca), Bryan W. Gick (Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z4), and Janet F. Werker (Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z4)

This cross-modal study investigates whether production of speech gestures can influence auditory speech perception. Participants made categorization judgments on a continuum between /ba/ and /da/, while making concurrent motor gestures. Ten participants categorized synthesized sounds from a /ba/-/da/ continuum while (a) simply listening, (b) concurrently making a /ba/, /da/, or /ga/ gesture without vocal fold vibration, or (c) making a nonspeech gesture (i.e., tongue protrusion). Preliminary data indicate that making /ba/ and /ga/ gestures, or tongue protrusions, will shift the perceptual boundary away from the /da/ end of the continuum (i.e., towards the /ba/ end of the continuum), compared to a passive listening condition. Making /da/ gestures did not shift the perceptual boundary, compared to this same listening condition. These data offer support for the idea that auditory categorization of speech tokens on a continuum can be influenced by conflicting information in other modalities—specifically articulatory gestures. Further studies will be conducted to examine the influence of (a) other speech gestures on these synthesized sounds, and (b) speech gestures on the perception of naturally-produced speech tokens.

4pSC7. Does intonation have primitive units? Amebu K. Seddoh (Dept. of Commun. Sci. & Disord., Univ. of North Dakota, P.O. Box 8040, Grand Forks, ND 58202)

This study investigated whether listeners can interpret intonation based on partial rather than global fundamental frequency (F_0) or pitch information. Matched Statements and echo questions were recorded digitally at 22 kHz sampling rate using a Computerized Speech Lab (CSL). Each production was stored on the CSL and edited by slicing the wave form into two parts that corresponded to terminal (last 150–200 ms span of the F_0 contour) and preterminal (section of contour preceding the terminal re-

gion) F_0 contour regions. A total of 92 stimuli was thus generated and recorded on a DAT tape. The tape was played to 96 young (20–28 years) and old (42–79 years) adults to determine if each stimulus was part of a statement or a question. For preterminal (PTL) stimuli, both groups successfully identified statements 91% and 88% of the time, respectively, compared to 72% each for questions. The respective scores for the terminal (TL) stimuli were 94% and 91% (statements) versus 91% and 87% (questions). Across groups, statements were easier to identify with both TL ($p=0.002$) and PTL ($p=0.001$) cues compared to questions. These findings suggest that intonation decoding might involve units smaller than global F_0 contour. [Work supported by NIH (NIDCD) grant 5R03DC04955-02.]

4pSC8. Differential effects of speaking rate and phonemic vowel length on formant frequencies of Japanese vowels. Kimiko Tsukada (MARCS Auditory Labs., Univ. of Western Sydney, Penrith South DC NSW 1797 Australia) and Yukari Hirata (Colgate Univ., Hamilton, NY 13346)

This study examined the extent to which variation in speaking rate and phonemic vowel length affect the first two formant frequencies of Japanese vowels. If vowel duration is a factor that determines the degree of formant undershoot [Moon and Lindblom, *J. Acoust. Soc. Am.* **96**, 40–55 (1994)], formants of phonemic long vowels or vowels spoken at slower rates would occupy more peripheral areas in the F_1/F_2 vowel space than the short counterparts. Four male native speakers produced Japanese disyllabic non-words, /mVmV/, /mVVmV/, and /mVmVV/ (V=/i e a o u/, VV=/i: e: a: o: u:/) spoken in a carrier sentence at slow, normal, and fast rates. Effects of vowel length were clear for all five vowels: the long vowels occupied more peripheral areas of the vowel space than the short vowels. However, such a systematic effect was not found with speaking rate changes. ANOVAs performed on each vowel type indicated that, for non-high vowels /e(:) a(:) o(:)/, effects of vowel length and speaking rate interacted. The F_2 of /e:/, for example, did not differ across rates, but the F_2 of /e/ was significantly lower for faster rates. Implications are discussed in terms of Moon & Lindbloms formant undershoot model.

4pSC9. Enhancement of visual perception of speech via tactile input. Diana Gibrael, Bryan Gick, Yoko Ikegami, Kristin Johannsdottir (UBC, Dept. of Linguist., E-270, 1866 Main Mall, Vancouver, BC, Canada V6T 1Z1, gibrael@interchange.ubc.ca), and Jeff Muehlbauer (UBC, Vancouver, BC, Canada V6T 1Z1)

Motor theories of speech perception predict that perceptual information from modalities other than sound enhance speech perception directly by informing the perceiver of the speaker's gestures [A. Lieberman and I. Mattingly, *Cognition* **21**, 1–36 (1985)]. Acoustic theories predict that perceptual information from modalities other than sound will only enhance speech perception if there is a learned mapping between the acoustic speech signal speech and that modality [R. Diehl and K. Kluender, *Ecol. Psych.* **1**, 121–144 (1989)]. As normal subjects are unlikely to have learned a mapping between visual and tactile speech information, this study tests whether and how tactile input enhances visual speech perception. In the control condition, perceivers in noise repeat syllables pronounced by a speaker who they can see clearly. Accuracy is judged on the basis of the repeated syllables. In the experimental condition, subjects additionally have their hand on the speaker's face in the Tadoma position. Results show that subjects are significantly more accurate at perceiving speech when they have both visual and tactile input than when they have visual input alone. In particular, tactile input enhances perceptual accuracy of voice and manner features. [Work supported by NSERC.]

4pSC10. A model of invariant patterns of articulatory movements.

Patrizia Bonaventura (Dept. of Linguist., Univ. of British Columbia, 1866 Main Mall, Buchanan E270, Vancouver, BC, Canada V6T 1Z1, bonaventura.8@osu.edu)

The goal of the present study is to model the “iceberg” portions of the demisyllables, previously extracted from the microbeam articulatory data (Bonaventura, 2003), by curve fitting. The polynomial analysis was designed to include an appropriate weighting window centering around the threshold crossing point, and aimed to provide an estimate of how, in the vicinity of the crossing point, the curve deviates from a straight line: this deviation would be represented by the higher order coefficients of the polynomial. The model was obtained preliminarily on the basis of 100 curves for the lower lip movement for /f/ and /v/ (in initial and final demisyllable for “five”), and from 100 curves for the tongue tip displacement (for /n/ in “nine”). In order to fit the data to the model, a robust least square method (Least Absolute Residuals) has been used, in order to minimize the influence of the outliers, that are present in the read speech data, and cannot be accounted for by “phrase final lengthening effects.” The fit results for the cubic polynomials satisfactorily approximated the “iceberg” curves. The 95% confidence bounds on the fitted coefficients indicated that they were acceptably accurate.

4pSC11. The effects of auditory-visual vowel and consonant training on speechreading performance. Carolyn Richie and Diane Kewley-Port (Speech and Hearing Sci., Indiana Univ., Bloomington, IN 47405, crichie@butler.edu)

Recent work examined the effects of a novel approach to speechreading training using vowels, for normal-hearing listeners tested in masking noise [C. Richie and D. Kewley-Port, *J. Acoust. Soc. Am.* **114**, 2337 (2003)]. That study showed significant improvements in sentence-level speechreading for listeners trained on vowels compared to untrained listeners. The present study examined the effects of combining vowel and consonant training on speechreading abilities. Normal-hearing adults were tested in auditory-visual conditions in noise designed to simulate a hearing loss. Using a monosyllable context, one group of listeners received training on consonants, and another group received training on consonants and vowels combined. A control group did not receive training. All listeners performed speechreading pre- and post-tests, on words and sentences. Comparison with the earlier study showed posttest sentence-level speechreading increased by 10 percentage points for participants in the vowel training program, 8 percentage points for participants in the consonant training program, and, unexpectedly, only 2 percentage points for participants in the combined training program. Results from these relatively short training programs suggest that vowels, previously unused in speechreading training, may provide gains in speechreading abilities and play an important role in rehabilitation of hearing-impaired persons. [Work supported by NIHDC02229.]

4pSC12. Turning speech into music in a two-dimensional space by varying the bandwidth and rate of tone pulses placed along formant tracks. C. J. Darwin (Dept. of Psych., Univ. of Sussex, Brighton, BN1 9QG, UK)

A two-dimensional space is introduced which changes sounds from speech-like to music-like by varying the rate and the bandwidth (decay-time) of individual tones placed along formant contours. At one extreme of a very fast pulse rate and a long decay time, the sounds are equivalent to sine-wave speech. With a more moderate tone rate and a short decay time, the sounds become monotone (at the tone-rate) speech. For tone rates around 10/s with long decay times, individual musical tones are heard at the formant frequencies. Intelligibility is poor for such sounds because of the low sampling rate of the formant contours. Increasing the tone rate and decreasing tone decay time increases intelligibility and makes the sounds less music like. Intelligibility data together with speech-like and music-like ratings of sounds from this space will be presented.

4pSC13. Variability of oronasal coupling in children and adults.

Lakshmi Venkatesh and Christopher A. Moore (Dept. of Speech & Hearing Sci., Univ. of Washington, 1417 NE, 42nd St., Seattle, WA 98105)

Oronasal coupling in young children remains poorly understood primarily because of experimental challenges associated with non-invasive techniques for transducing velopharyngeal movement. Productions of the word [bama] were studied in children with normal speech acquisition (NSA) and children with speech delay (SD; 3-to-5 years of age) with respect to adults. Nasal vibration was transduced using a small, light-weight accelerometer affixed to the lateral alar cartilage of the participant's nose. The variability in the nasal acceleration signals obtained for multiple productions of the stimuli for each participant was described using the spatiotemporal index (STI) and functional data analysis (FDA). The spatiotemporal index served as a composite method of variability following linear time normalization of the signals. The FDA technique involving nonlinear time normalization allowed for independent evaluation of amplitude and phase variability. The two groups of children with NSA and SD were more variable than the adults on both measures of STI and amplitude variability, while the amount of phase variability was similar between children and adults. These methods have complementary merits and potential in revealing the properties of development and disruption of oronasal coupling in children and adults. [Work supported by NIH-NIDCD.]

4pSC14. Final devoicing in Russian: Acoustic evidence of incomplete neutralization. Olga Dmitrieva (Dept. of Linguist., Univ. of Kansas, 1541 Lilac Ln., Blake Hall, Rm. 427, Lawrence, KS 66044-3177, olga@ku.edu)

A number of acoustic and perceptual studies conducted on German, Polish, Catalan, and Dutch found evidence of incomplete neutralization of the voicing contrast of obstruents in word-final position. The present study investigates the acoustic correlates of word-final stops and fricatives in Russian. 34 minimal pairs differing in the underlying voicing characteristics of the final segment were incorporated into the body of filler items organized as a stream of associations. This word list was presented to 14 native speakers of Russian. Measurements were obtained for the duration of the vowel preceding the final obstruent, the closure/frication portion of the final obstruent, the burst for the final stops, and duration of the voicing into closure/frication of the final obstruent. Statistical analysis revealed that the effect of underlying voicing, as well as manner of articulation, was significant for all parameters measured. The results strongly suggest that final devoicing in Russian represents a case of incomplete neutralization, at least in the experimental conditions employed.

4pSC15. Haptic-auditory interference from air flow in speech perception. Yoko Ikegami, Diana Gibrael, Bryan Gick, and Kristin Johannsdottir (Dept. of Linguist., The Univ. of British Columbia, E270-1866 Main Mall, Vancouver, BC, Canada V6T 1Z1)

Previous work on haptic interference in auditory perception has shown McGurk-like effects from manual-tactile contact with the face [Fowler and Dekle, *JEP:HPP* **17**, 816–828 (1991)]. The present study investigates whether indirect haptic input affects auditory perception. A novel method was developed in which one experimenter blew puffs of air onto a subject's neck while another produced English plosives, creating possible mismatches between the sensation of aspiration and its acoustic presence. Subjects were blindfolded and wore headphones playing white noise. For 50% of the trial, one experimenter, whose presence was hidden from the subjects, blew puffs of air on subjects' necks lightly enough to be perceived but not noticeable as unnatural. Simultaneously, a second experimenter produced syllables with bilabial plosive onsets (aspirated /p/ or unaspirated /b/) and subjects were asked to repeat what was heard. Sessions were videotaped and three observers rated successful simultaneity of stimuli. Results indicate cross-modal interference. Subjects showed higher accuracy of speech perception when appropriate haptic stimuli accompanied the auditory stimuli. Moreover, when presented with mismatched

tactile and auditory stimuli, subjects demonstrated the fusion of the two modes. Subjects perceived /pa/ when auditory stimulus /ba/ was presented with emulating aspiration. [Work supported by NSERC.]

4pSC16. The (non) categorical perception of place assimilated coronal stops. David W. Gow, Jr. (Cognit./Behavioral Neurology Group, Massachusetts General Hospital, Ste. 340, 175 Cambridge St., Boston, MA 02114, gow@helix.mgh.harvard.edu)

English coronal place assimilation generally produces gradient modification of stop place cues. Acoustic analyses are presented that show that labial assimilation of coronal stops often produces a distinctive pattern of formant movement, hereafter referred to as the coronal step. The coronal step is characterized by an initial pattern of $F1$, $F2$, and $F3$ movement consistent with coronal closure, followed by a second wave of movement producing formant values at offset that are intermediate between those associated with coronal and labial stops. The perceptual consequences of this pattern were examined in categorization and 4I2AFC discrimination tasks using a linear /t/-p/ synthetic VC continuum, as well as a continuum displaying a coronal step but produced by manipulating the same acoustic parameters. The linear continuum produced data consistent with strong categorical perception, while the stepped continuum showed no evidence of categorical perception. These results are discussed in the context of a model of the perception of assimilated speech that relies on the simultaneous activation of competing phonetic categories by assimilated segments. [Work supported by the NIH.]

4pSC17. Position and place effects in Russian word-initial and word-medial stop clusters. Alexei Kochetov (Dept. of Linguist., Simon Fraser Univ., 8888 Univ. Dr., Burnaby, BC, Canada V5A 1S6, alexei_kochetov@sfu.ca) and Louis Goldstein (Haskins Labs./Yale Univ., New Haven, CT 06511-6695)

Studies of inter-gestural timing have shown that (i) word-initial obstruent clusters tend to exhibit less gestural overlap than word-medial or word-boundary clusters, and (ii) the degree of overlap is further affected by the place of articulation of the obstruents (Byrd, 1996; Chitoran, Goldstein, and Byrd, 2002). Both findings have been attributed to perceptual recoverability considerations. This paper presents results of a magnetic articulometer (EMMA) study of Russian word-initial and word-medial stop clusters (e.g., [pt]ashka little bird versus la[pt]a bat). Data collected from 3 native speakers of Russian show that clusters with coronals and dorsals as C1 ([tk], [kt], [kp], [tjm]/[djb]) exhibit less overlap word-initially than word-medially, while the cluster with the labial as C1 ([pt]) does not exhibit the same timing pattern. The findings are interpreted as providing additional support for the role of perceptual recoverability in intergestural timing. First, less overlap in word-initial clusters, compared to word-medial clusters, ensures better place recoverability of C1 (cf. Chitoran *et al.*, 2002). Second, unreleased labials are more perceptually robust than unreleased coronals (Byrd, 1992; Surprenant and Goldstein 1998) and dorsals (Wright, 2001; Kochetov and So, 2005), and thus do not require the same degree of overlap. [Work supported by SSHRC.]

4pSC18. Self-organizing maps for measuring similarity of audio-visual speech percepts. Hans-Heinrich Bothe (Tech. Univ. of Denmark, Ctr. for Appl. Hearing Res., Oerstedts Plads b.352, DK-2800 Lyngby, Denmark, hhb@oersted.dtu.dk)

The goal of this work is to find a way to measure similarity of audio-visual speech percepts. Phoneme-related self-organizing maps (SOM) with a rectangular basis are trained with data material from a (labeled) video film. For the training, a combination of auditory speech features and corresponding visual lip features is used. Phoneme-related receptive fields result on the SOM basis; they are speaker dependent and show individual locations and strain. Overlapping main slopes indicate a high similarity of respective units; distortion or extra peaks originate from the influence of

other units. Dependent on the training data, these other units may also be contextually immediate neighboring units. The poster demonstrates the idea with text material spoken by one individual subject using a set of simple audio-visual features. The data material for the training process consists of 44 labeled sentences in German with a balanced phoneme repertoire. As a result it can be stated that (i) the SOM can be trained to map auditory and visual features in a topology-preserving way and (ii) they show strain due to the influence of other audio-visual units. The SOM can be used to measure similarity amongst audio-visual speech percepts and to measure coarticulatory effects.

4pSC19. Perception of “asymmetrical” German vowels by humans, monkeys and gerbils. Joan M. Sinnott, Leigh Ann Long, and Allen C. Ernst (Psych. Dept., Univ. of South Alabama, Mobile, AL 36688)

Polka and Bohn [J. Acoust. Soc. Am. **100**, 557–592 (1996)] report that human infants perceive certain vowels asymmetrically when tested with a repeating-background category-change operant headturn procedure. Specifically, discrimination is easier when the background is a more central vowel (e.g. /y/) and the target is a more peripheral vowel (e.g. /u/), compared to the opposite condition. We are testing human (adult native English listeners) and monkey discrimination of the German vowel pair /dut-dyt/, using both synthetic and natural stimuli (obtained from Polka and Bohn), and a within-subject design. So far, no significant asymmetries have emerged in the data using a percent correct measure. We will also report preliminary data from gerbils being trained in a between-subject design more comparable to that used with human infants. Plans are to continue testing all species until they reach asymptotic performance levels in order to determine if an RT measure will indicate vowel asymmetries. A video will be shown of humans, monkeys and gerbils working on the experiments.

4pSC20. Effects of reduced orosensory feedback on spectral characteristics of medioalveolar /s/. Juha-Pertti Laaksonen, Stina Ojala, Olli Aaltonen (Dept. of Phonet., Univ. of Turku, FIN-20014 Turku, Finland, juhlaa@utu.fi), Matti Niemi, and Risto-Pekka Happonen (Univ. of Turku, FIN-20520 Turku, Finland)

Effects of reduced orosensory feedback on the production of fricative sounds were studied by measuring spectral characteristics of medioalveolar /s/. Five Finnish male speakers produced sibilant /s/ embedded in 8 different word contexts under normal condition and under reduced condition, in which the tactile information from the tongue was reduced by blocking the lingual nerve on the right side by local anesthesia. Parameters of Long Time Average (LTA) spectrum (i.e., center of gravity, standard deviation, skewness, and kurtosis) were measured by Praat software for every speaker. In comparison between the two conditions, center of gravity, standard deviation, skewness, and kurtosis changed for every speaker. However, the changes were variable and individual. The results of acoustic analysis show that reduced tactile sensation have effects on tongue function producing spectral alterations for sibilant /s/. The inter-individual variation between different talkers suggests that there are no general compensatory mechanisms of speech production, but the mechanisms are highly speaker-dependent.

4pSC21. BMSA, a new Bayesian model selection criterion for assessing audiovisual models of speech perception. J. L. Schwartz (Institut de la Commun. Parle, UMR 5009 CNRS, INPG, Université Stendhal, 46 Av. Flix Viallet, 38031 Grenoble Cedex 1, France)

Audiovisual speech perception has provided matter for many model comparison and assessment studies. Most involved “Root Mean Square Error” (RMSE), a criterion based on the differences between predicted and observed probabilities of response in auditory, visual and audiovisual categorization experiments. RMSE is related to the best fit of a model considering data. However, some models are known for their ability to

adapt to almost any data set. This is always associated to a large fit instability: very small variations of the model parameters lead to dramatic modifications of the predicted data. A new criterion is derived from the Bayesian Theory of model selection. Considering that best fit estimation is not error-free, model comparison in this theory involves the total likelihood of the model knowing the data, integrating on the whole parameter space. This results in penalizing a too flexible model, for which local likelihood is high, but global likelihood is low. An approximation of this criterion, called BMSA, is presented. This criterion, easy to compute, results in combining fit and stability. An application of the BMSA criterion in an audiovisual speech perception experiment is proposed, enabling to show for the first time that the fusion process is subject-dependent.

4pSC22. Age differences in detecting gaps in speech and non-speech.

M. Kathleen Pichora-Fuller, Bruce A. Schneider (Dept. of Psych., Univ. of Toronto, 3359 Mississauga Rd., Mississauga, ON, Canada L5L 1C6, kpfuller@utm.utoronto.ca), Nancy Benson (The Hospital for Sick Children, Toronto, ON, Canada M5G 1X8), Stanley Hamstra (Univ. of Toronto, Toronto, ON, Canada M5G 1L5), and Edward Storzer (McNeill Audiol., Victoria, BC, Canada V8R 1G1)

Ability to detect gaps in speech and non-speech stimuli was measured in children, young adults, and older adults with good audiograms. The markers varied in duration (40 vs 250 msec) and in spectral symmetry. In spectrally symmetrical conditions, the leading and lagging markers were the same: the vowel [u] in speech conditions and a 500-Hz tone in non-speech conditions. In asymmetrical speech conditions, the lagging marker was the same as in the symmetrical conditions, but the leading marker was the consonant [s] in the speech conditions and a broadband noise (1 to 6 kHz) in the non-speech conditions. For all groups, gap detection thresholds in spectrally symmetrical markers were far smaller than in spectrally asymmetrical markers. Thresholds were significantly smaller in young adults than in either children or older adults. Gaps between spectrally asymmetrical speech markers were detected better than gaps between analogous non-speech stimuli. It is argued that phonological knowledge compensates for auditory processing difficulties. [Research funded by the International Dyslexia Association, the Natural Sciences and Engineering Research Council of Canada, and the Canadian Institutes of Health Research.]

4pSC23. Voice onset time in Mandarin esophageal speech.

Manwa Ng (Long Island Univ., 720 Northern Blvd., Brookville, NY 11548-1300, manwa.ng@liu.edu) and Hanjun Liu (Xi'an Jiaotong Univ., Xi'an, 710049, P. R. China)

As an important perceptual cue for voicing and aspiration of stops, voice onset time (VOT) is mainly determined by the aerodynamic interaction between the intraoral and subglottal regions. However, since the PE segment serves as a new vibratory source in esophageal phonation, aerodynamic events are very different from laryngeal phonation. VOT associated with esophageal speech of English has been reported previously. However, few studies have reported VOT characteristics of esophageal speech of tone languages. The present study will investigate the possible VOT difference between esophageal and normal laryngeal speakers of Mandarin Chinese. Seven superior esophageal speakers and 7 normal laryngeal speakers will participate in the present investigation. They will be native male speakers of Mandarin Chinese. The participants will produce the syllable /ta/ embedded in a carrier phrase at a comfortable loudness level for three times. VOT values will be measured from a time domain waveform. With reference to a wide-band (300 Hz) spectrogram, VOT will be defined as the release of stop and the first identifiable period of the

vocalic portion. An independent sample t-test will be used to determine if VOT values of esophageal and normal laryngeal speakers were significantly different.

4pSC24. A role for tracheal resonances in speech perception.

Asaf Bachrach (Dept. of Linguist. and Philosophy, MIT, Cambridge, MA 02139), Steven Lulich (MIT, Cambridge, MA 02139, lulich@mit.edu), and Nicolas Malyska (MIT, Cambridge, MA 02139)

Acoustic coupling between the vocal tract and the trachea results in the introduction of pole-zero pairs corresponding to resonances of the uncoupled trachea. If the second formant (F_2) passes through the second tracheal resonance (T_2) a discontinuity in amplitude occurs. This work explores the hypothesis that the F_2-T_2 discontinuity affects how listeners perceive the distinctive feature [back] in transitions from a front vowel (high F_2) to a labial stop (low F_2). We synthesized two versions of an utterance ("apter") with an F_2-T_2 discontinuity at different locations in the initial VC transition. Subjects heard portions of the utterance with and without the discontinuity, and were asked to identify the utterance. Results show that the presence of the F_2-T_2 discontinuity facilitated the perception of frontness in the vowel. Discontinuities of the F_2-T_2 sort are proposed to play a role in shaping vowel inventories in the world's languages [K. N. Stevens, J. Phonetics 17, 3-46 (1989)]. Our results support a model of lexical access in which acoustic discontinuities subserve phonological feature identification.

4pSC25. Targetless schwa revisited.

Edward Flemming (Dept. of Linguist. and Philosophy, M.I.T., 77 Massachusetts Ave., 32-D808, Cambridge, MA 02139, flemming@mit.edu)

It has been suggested that schwa vowels in English lack vowel quality targets, that is, they are realized as interpolations between the preceding and following segmental contexts or are the result of separating two consonantal constriction gestures, without an inherent vocalic gesture. Tests of this hypothesis have produced mixed results. The present study revisits the question of schwa targets based on acoustic analysis of schwa vowels in a wider range of segmental and morphological contexts. The main conclusions are: (i) It is important to distinguish stem-final reduced vowels (as in "pandA") from other schwa vowels (e.g., "About," "bEgin"). The former clearly have vowel quality targets they are generally mid central vowels whereas the latter are much more contextually variable. (ii) The variable schwa vowels have a target, but this target is not a particular vowel quality, it is to indicate the presence of a vowel. This is achieved through a variety of means, including duration and realization of a local amplitude peak, but is consistent with substantial variation in vowel quality, particularly F_2 .

4pSC26. The role of attention in infant phonetic perception.

Monika Molnar, Linda Polka, and Susan Rvachew (McGill Univ., 1266 Pine Ave. W., Montreal, QC, H3G 1A8 Canada monika.molnar@mcgill.ca)

Attention is an important factor underlying phonetic perception that is not well understood. In this study we examined the role of auditory attention in infant phonetic perception using a distraction masker paradigm. We tested infant discrimination of /bu/ vs /gu/ with a habituation procedure and three natural productions of each syllable. For the quiet condition each token was copied into a separate sound file. For the distractor condition, a high frequency noise was added to each sound file so that it gated on and off with the onset and offset of the syllable. The distractor noise was a recording of bird and cricket songs whose frequencies did NOT overlap with the test syllables. Thus, the noise did not change the audibility of the syllable, but it could distract infants if they do not focus their attention well. Infants (6- to 8-month-olds) were tested in each condition. Infants tested in quiet performed significantly better than infants tested in the distractor condition; discrimination scores showed little overlap between

the two groups. These findings indicate that in young infants, attention to subtle phonetic differences is easily disrupted. The implications for developmental models of speech perception will be discussed.

4pSC27. The development of laryngeal coarticulation: Comparison of women, 5-year-olds, and 10-year-olds. Laura L. Koenig (Haskins Labs & Long Island Univ., Brooklyn)

Past work has indicated that adult speakers show effects of laryngeal coarticulation in voice source measures taken in vowels flanking voiceless consonants. In a recent pilot study, we presented time-varying voice source measures from 5-year-old girls producing VCV sequences with varying consonants. The results suggested that, on average, the children produced laryngeal coarticulation over a duration at least as long as adults, but extensive token-to-token variability complicated interpretation of the results. The present analysis extends that work by comparing normal women with normally-developing 5-year-old and prepubertal 10-year-old children. Speakers were recorded producing multiple repetitions of intervocalic /b p h/ in simple carrier phrases such as “Poppa Hopper” while oral airflow signals were collected using a Rothenberg mask. After software-inverse filtering, pulse-by-pulse measures of DC airflow, open quotient, and f_0 are made from the transition out of the consonant into the following vowel. Results will be interpreted in terms of age effects and, for the children, possible gender differences. These data have implications for our understanding of laryngeal motor control in children and, more generally, for theories of the development of coarticulation. [Work supported by NIH.]

4pSC28. Tonal and durational variations as phonetic coding for syllable grouping. Yi Xu (Univ. College London, Wolfson House, 4 Stephenson Way, London NW1 2HE, UK) and Maolin Wang (College of Chinese Language and Culture, Jinan Univ., Guangzhou, 510610, China)

While syllables in connected speech are generally believed to be prosodically divided into groups, how such grouping is done phonetically is not fully understood. This study explores the possibility that syllable grouping is partly realized through adjusting articulatory strength and duration. We compared the degrees of tonal undershoot in Mandarin as they are related to syllable position and number of syllables in words or phrases. The sequences consisted of 1–4 syllables with R or F tone and were produced by eight speakers. The all-R and all-F sequences impose great pressure on tone production and hence would best reveal the effects of strength and duration. Results show that as the number of syllables in each sequence increased, both syllable duration and size of F_0 excursion decreased. Meanwhile, excursion size varied with syllable location in the sequence. But in each case it was the first and last syllables that had the largest excursions, and the excursion variations cannot be fully accounted for by duration. There thus appear to be both an isochrony effect and an “edge marking” effect. Taking into consideration known prosodic effects on segmental phonemes, syllable grouping as a communicative function seems to involve a rather complex encoding scheme.

4pSC29. Is speech lazy or just efficient? A control-theoretic analysis. Luis Rodrigues (Dept. of Mech. and Industrial Eng., Concordia Univ., 2160B Bishop St., B-304 Montreal, QC, Canada H3G, luisrod@me.concordia.ca) and John Kroeker (Eliza Corp., Beverly, MA 01915)

This paper introduces a control-theoretic model that allows us to address the energy dynamics of the vocal tract system. The model can be generated directly from articulatory data. The model allows computation of the energy in a state transfer, from an initial to a final articulator configuration. This method can help determine the degree of physical feasibility of various proposed articulatory trajectories. The basic assumption is that the set of articulators evolve through configurations that minimize the energy spent by the system to produce an utterance. Minimum control energy gives a measure of how hard it is to reach a target point for the

different articulators. Simulation results are presented corresponding to the computation of the minimum energy from the MOCHA database. The linear model is shown to be adequate for short, well-labeled segments. The results show the intriguing fact that minimum control energy seems to have an oscillatory (swinging) nature for the production of speech. Physical features such as time constants and natural frequencies of the articulators are derived. A control-theoretic model of the dynamics of the mechanical articulators of speech production could be a fundamental tool to understand the mechanism of speech production.

4pSC30. Effects of simultaneously presented pitch- and loudness-shifted voice auditory feedback on voice fundamental frequency.

Charles R. Larson, Jean Sun, and Hideki Takaso (Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208)

Recent studies have demonstrated that subjects respond to pitch- or loudness-shifted voice feedback with compensatory changes in voice fundamental frequency (F_0) or intensity. In the present study, subjects sustaining /u/ vowel sounds were presented with either pitch-shifted auditory feedback (50 or 100 cents) or simultaneous pitch-shifted and loudness-shifted voice feedback (3 or 6 dB SPL) of 200 ms duration. During simultaneous stimulus presentations, the stimulus directions were opposite in direction (e.g., increasing pitch and decreasing loudness feedback). Subjects ($N=24$, normal, age 18–24) responded to pitch-shifted feedback with compensatory adjustments in F_0 . Subjects responded to simultaneous stimuli with independent compensatory adjustments in voice F_0 and intensity. Latencies of F_0 responses to simultaneous stimuli ($m=211$ ms) were longer than to pitch-shifted stimuli alone ($m=145$ ms, $F=26$, $df=2306$; $p<.0001$). Results suggest auditory feedback mechanisms for stabilizing the direction of voice F_0 against perturbed pitch feedback are independent of mechanisms for stabilizing loudness feedback, but the simultaneous presence of pitch and loudness perturbations slows down the corrective mechanism for pitch-shifted feedback.

4pSC31. Phoneme clustering based on segmental lip configurations in naturally spoken sentences.

Jianxia Xue, Abeer Alwan (Dept. Elec. Eng., Univ. of California, Los Angeles, 405 Hilgard Ave., Los Angeles, CA 90095, jxue@ee.ucla.edu), Jintao Jiang, and Lynne E. Bernstein (House Ear Inst., Los Angeles, CA 90057)

It has been shown that face (lips, cheeks, and chin) information can account to a large extent for visual speech perception in isolated syllables and words. Visual speech synthesis has used small reduced sets of phonemes (“visemes”), under the theory that perceivers are limited in their ability to extract visual speech information. In this study, lip configurations from a manually segmented sentence database [L. Bernstein *et al.*, J. Acoust. Soc. Am. **107**, 2887 (2000)] were analyzed to provide phoneme clusters that are algorithmically distinguishable using mouth vertical/horizontal opening and lip protrusion from the middle position of each segment. The lip feature sample spaces for each phoneme were represented by Gaussian mixture models. Maximum posterior probability classification results were computed for each phoneme. Confusion matrices were generated from the classification results, and a set of confusions with 74% or higher within-group classification correct was judged to be a cluster. Preliminary results from 191 sentences by a single talker generated the following clusters: {/p, b, m/(77%), /f, v/(74%), /w, r/(80%), /t, d, s, z, D, k, n/(88%)}. We will present results analyzing the entire English phoneme set across different talkers and compare the results with visual perceptual clusters. [Work supported in part by the NSF.]

4pSC32. The effects of signal-to-noise ratio on auditory-visual integration: Integration and encoding are not independent. Mitchell S. Sommers (Dept. of Psych., Washington Univ., Campus Box 1125, St. Louis, MO 63130, Msommers@wustl.edu), Brent Spehar, and Nancy Tye-Murray (Washington Univ. School of Medicine, St. Louis, MO 63130)

Most current models of auditory-visual speech perception propose a two-stage process in which unimodal information is extracted independently from each sensory modality and is then combined in a separate integration stage. A central assumption of these models is that integration is a distinct perceptual ability that is separate from the ability to encode unimodal speech information. The purpose of the present study was to evaluate this assumption by measuring integration of the same speech materials across three different signal-to-noise ratios. Twelve participants were presented with 42 repetitions of 13 consonants presented in an /iCi/ environment at 3 different signal-to-noise ratios. Integration was assessed using an optimum processor model [L. Braida, *Q. J. Exp. Psych.* **43A**, 647–677 (1991)] and a new measure termed integration efficiency that is based on a simple probability metric. In contrast to predictions made by current models of auditory-visual speech perception, significant differences were observed for both measures of integration as a function of signal-to-noise ratios. These findings argue against strictly serial models of auditory-visual speech perception and instead support a more interactive architecture in which unimodal encoding interacts with integration abilities to determine overall benefits for bimodal speech perception. [Work supported by NIA.]

4pSC33. The University of South Florida audiovisual phoneme database, v 1.0. Stefan A. Frisch, Sarah Hardin, Dee Adams Nikjeh, and Adrienne M. Stearns (Dept. of Commun. Sci. and Disord., Univ. of South Florida, Tampa, FL 33620, frisch@cas.usf.edu)

An audiovisual database of English speech sounds has been developed for teaching purposes. This database contains a variety of Standard English speech sounds produced in clear speech in isolated words. Phonemes are produced in word initial, word medial, and word final position, unless not allowed by English phonotactics. There is one example of each word spoken by a male talker of Standard American English from the Midwest. The database consists of individual word files that contain simultaneous audio recording, video of the lips, flexible endoscopic image of the pharynx and larynx, and ultrasound video of the tongue in the mid-sagittal plane. The files in the database are uncompressed video avi format and are suitable for examination in the Wavesurfer freeware program (Sjolander and Beskow, KTH Stockholm). This database is intended as a multimedia reference for students in phonetics or speech science. Its coverage is relatively complete, though there are some gaps due to technical difficulties with the recording procedure. A demonstration of selected recordings from the database and suggestions for their use will be presented. Plans for further development of the database will also be discussed. [Work supported by a USF Innovative Teaching Grant.]

4pSC34. Generalization of the imitation effect within a natural class. Kuniko Nielsen (Dept. of Linguist., UCLA, 3125 Campbell Hall, Los Angeles, CA 90095)

A natural class refers to a set of segments which share acoustic or articulatory features. Support for this notion has traditionally been provided by phonological alternations and phonotactic constraints, and recently by experiments (e.g., Goldrick, 2004). This study investigates the psychological reality of natural class using the imitation paradigm (Goldinger, 1998) in which subjects speech is compared before and after they are exposed to target speech (= study phase). Although this paradigm has shown that subjects shift their production in the direction of the target, these results do not reveal the size of the linguistic unit(s) influenced by the effect. That is, when a subject shifts production of a particular sound in a word, it is uncertain whether the subject is picking up on the word, the segment, or the feature. In this study, to investigate whether phonetic

imitation is generalized across members of a natural class, the study-phase word list includes words with initial /p/ and /t/ (with extended VOT), while the pre- and post-study production list includes (1) the modeled words, replicating Shockley *et al.* (2004), (2) the modeled segments /p/ and /t/ in new words, and (3) the modeled feature [+spread glottis] (aspiration) in a new segment /k/.

4pSC35. Functional MRI reveals two distinct cerebral networks subserving speech motor control. Axel Riecker (Dept. of Psychiatry III, Univ. of Ulm, Leimgrubenweg 12-14, D-89075 Ulm, Germany), Klaus Mathiak (Univ. of Aachen, Pauwelsstr. 30, D-52074 Aachen, Germany), Wolfgang Grodd (Univ. of Tuebingen, D-72076 Tuebingen, Germany), Ingo Hertrich, and Hermann Ackermann (Univ. of Tuebingen, D-72076 Tuebingen, Germany, hermann.ackermann@uni-tuebingen.de)

To further delineate the neural basis of speech motor control, functional magnetic resonance imaging (fMRI) was performed during syllable repetitions synchronized to click trains (8 subjects, 2–6 Hz; vs. passive listening task). (a) Bilateral hemodynamic responses emerged within mesiofrontal and sensorimotor cortex, putamen / pallidum, thalamus and cerebellum (two activation spots at either side). In contrast, dorsolateral premotor cortex and anterior insula showed left-sided activation. (b) Calculation of rate / response functions revealed a negative linear relationship between repetition frequency and hemodynamic activation within the striatum whereas both cerebellar hemispheres exhibited a step-wise response increase at about 3 Hz. (c) Analysis of the temporal dynamics of hemodynamic activation revealed these cortical and subcortical brain regions to be organized into two separate networks (medial and dorsolateral premotor cortex, anterior insula, superior cerebellum versus sensorimotor cortex, basal ganglia, inferior cerebellum). These data provide evidence for two levels of speech motor control bound, most presumably, to motor preparation and executions processes. Furthermore, these findings help to explain clinical observations such as an unimpaired or even accelerated speaking rate in Parkinsons disease and slowed speech tempo which does not fall below a rate of about 3 Hz in cerebellar disorders.

4pSC36. A phonetic study of guttural laryngeals with data from Semitic. Kimary Shahin (Effat College of Al-Faisal U., P.O. Box 34689, Jeddah 21478, Saudi Arabia, kshahin@effatcollege.edu.sa)

Phonetic data from Hebrew and Arabic were examined to determine if laryngeal consonants in those languages have tongue root articulation. This was done in search of an articulatory basis for the phonological patterning of Semitic laryngeals with tongue root consonants like pharyngeals and uvulars. This issue has been problematic for phonological theory because a theoretically comfortable phonetic basis for that patterning has not yet been identified [J. J. McCarthy, *Pap. Lab. Phonol.* **III**, 191–234 (1994); F. Nolan, *ibid.* **IV**, 361–367 (1995)]. The present study is the first to address the problem with clear natural-language data. Acoustic and articulatory data are presented (digital audio and video, waveform, spectrogram and video picture) from two laryngoscopic films: Prof. A. Laufer's film of Hebrew and Arabic speech recorded at Haskins Labs in the early 1980s, and a new film of Arabic speech recorded at Speech Technology Research. The data show no tongue root articulation for the laryngeals. The implications for phonology are discussed. Note: Thanks to Prof. Laufer and Haskins Labs for permission to use the Haskins film, and to Prof. John Esling for collaboration in recording the new Arabic data. [Work supported by a SSHRCC grant to J. Esling.]

4pSC37. Quality of American English back vowels before /r/. Michael J. Clark and James M. Hillenbrand (Speech and Hearing Ctr., MS5355, Western Michigan Univ., Kalamazoo, MI 49008)

The vowels /o/ and /ɔ/ are not contrastive before /r/ in most American English dialects, and the phonetics literature is equivocal about the phonetic quality of the nucleus in words such as *board*. Most works use [ɔ] to

represent the first part of the nucleus. In this study acoustic measurements, listening tests, and discriminant analyses were used to determine the phonetic quality of such vowels. Fourteen women recorded monosyllables containing /o,ɔ,a/, with initial /b,g,h/ and final /d/ or /z/ (e.g., *bode*, *Baud*, *bod*). Additionally a set with rhotic diphthongs (*board*, *barred*, *gored*, *guard*, *hoard*, *hard*) was recorded. The central back vowel in rhotic diphthong syllables (*board*, *gored*, *hoard*) showed formant values very similar to those for /o/ and very unlike those for /ɔ/. The low back rhotic diphthong (i.e., *barred*, *guard*, *hard*) showed a range of values from /a/ to /ɔ/. Listening tests using brief excerpts from vowel onsets supported the greater similarity of *board* to *bode* than to *Baud* and the intermediate nature of *barred* between *bod* and *Baud*. Discriminant classification of the rhotic diphthong formant measures supported the same conclusions. [Work supported by NIH.]

4pSC38. Articulatory and acoustic characteristics of English /l/ in children's speech production. Sunyoung Oh and Bryan Gick (Dept. of Linguist., Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z1, oh.sun_young@courrier.uqam.ca)

English /l/ is one of the later-developing sounds in language acquisition. It has syllable-based allophones (e.g., light l in initial, dark l in final) and comprises multiple articulatory gestures (e.g., tongue tip fronting and raising, tongue dorsum backing, lateral dipping) with different coordination in timing and magnitude in syllable position (e.g., synchronicity in initial, tongue tip delay in final with greater reduction in magnitude). Using ultrasound, this study examined how articulatory characteristics of /l/ are presented in children's speech production. Replicating previous articulatory studies in adult speech production, /l/ words in isolation and combination were collected from eight monolingual children aged 3;11 to 5;9. Although some children produced more similar to adult /l/, children produced /l/ using different articulatory properties. /l/ was produced with less

detail and more variations than in the adults' speech as movements of the tongue were simplified or modified. While articulatory performance varied across subjects as well as syllable positions, acoustic analysis of formants ($F1$, $F2$, $F3$) of sample tokens showed similar patterns for all subjects. This study suggests that the tendency toward late acquisition of /l/ is due directly to the articulatory as well as motor complexity.

4pSC39. The effects of tongue shape categories on tongue segmentation in English. Melissa A. Epstein and Maureen Stone (Biomed. Sci., Univ. of Maryland Dental School, Rm. 5A12, 666 W. Baltimore St., Baltimore, MD 21201)

In our recent work, we have proposed that the tongue moves by compressing and expanding local functional segments. For any single gesture, functional segments may move in similar or opposite directions to compress and expand the tongue locally. High correlations between segments suggest biomechanical constraints. Low correlations suggest independent control of these segments. Our previous studies on English have shown a front-back division of the tongue, where adjacent segments correlate positively with each other (moving in the same direction) and distal segments correlate negatively with each other (moving in opposite directions). Individual segments aggregate with adjacent or distal segments. Furthermore, the phonemic content of the dataset influences these aggregations and the location of the front-back division of the tongue. This study will more deeply explore these phonemic effects. In particular, we will examine the effects of the transitions between consonants and vowels of the four basic tongue shape categories of English [front raising (e.g., /n,i/), back raising (e.g., /ng,o/), complete channel (e.g., /s,ae/) and two point displacement (e.g., /l/)] on tongue segmentation and the location of the pivot point for the front-back division. [Work supported in part by NIDCD/NIH Grant RO1-DC01758 and by NIH Grant T32-DE07309.]

4pUWa1. Multipath cancellation with a two-channel array. John E. Piper (NSWC-PC, Code R21, 110 Vernon Ave., Panama City, FL 32407, john.e.piper@navy.mil)

A test pool experiment with direct and multipath signals incident on a small vertical array was conducted. To separate these signals a maximum likelihood method approach was used. This approach is based on exploiting the orthogonal nature of the signals in the maximum likelihood parameter space, which leads to a theoretically complete decoupling of the desired signal from the multipath interference. This approach has no analog in conventional signal processing. Results of the test pool experiment using this maximum likelihood method cancellation and conventional beamforming methods are presented.

4pUWa2. Torpedo detection using multi-path signals and fast orthogonal search techniques. Jeff Collins, Donald McGaughey (Dept. of Phys., Royal Military College of Canada, P.O. Box 17000, Stn Forces Kingston, ON, Canada K7K 7B4, jeff.collins@rmc.ca), Jim Theriault, and Sean Pecknold (Defence Res. and Development Canada (Atlantic), Dartmouth, NS, Canada B2Y 3Z7)

Detecting a high speed torpedo by means of a passive acoustic detector is very challenging for most acoustic operators. Coupled with a very noisy environment, multiple sources in a multi-path scenario and varying environmental factors, a time-constrained assessment will prove difficult. In addition, a passive sensor cannot estimate the range of a torpedo approaching it at a constant bearing. The passive acoustic sensor will receive a direct path signal from the torpedo as well as a signal that has reflected off

4p THU. PM

the surface. Due to the different angle of arrival, the direct-path and surface-reflected signals have different Doppler shifts. The Torpedo Detection Algorithm (TDA) employs the fast orthogonal search (FOS) algorithm for high-resolution spectral analysis to detect the closely spaced direct-path and surface-reflection signals. When a direct-path and surface-reflection are found, an automatic alert of a torpedo detection is initiated. In simulation, a torpedo is detected 20 times out of 20 as it travels from 5000 to 500 m from the receiver. Simple trigonometric expressions are used to estimate the torpedos range given the two frequencies estimated by FOS and *a priori* information about the torpedo speed and depth.

4pUWa3. A comparison of mine counter measure performance models. Andrew Holden (Dstl. Winfrith, Dorchester, DT2 8WX, UK, apholden@dstl.gov.uk)

Mine counter measure (MCM) sonar systems perform the task of detection and classification of marine mines that are typically laid in shallow water environments. Currently, there are several MCM performance models in use that can predict the performance of MCM sonars. This paper gives a brief description of some these models and gives a comparison of their performance predictions for several shallow water scenarios. All the models examined are self contained packages that can model the entire problem—the sonar, the environment, and the target. They are considered to be energy models in that only the intensity of sound received from various parts of the environment is modeled while phase calculations are ignored. The results show that the models can give good agreements with each other for some scenarios. In some other scenarios the agreement is not so good and reasons are given to show why this happens.

4pUWa4. Tank experiments and model comparisons of shallow water acoustics over an elastic bottom. Jon M. Collis, William L. Siegmann (Rensselaer Polytechnic Inst., Troy, NY 12180, collisj@rpi.edu), Michael D. Collins, Erik C. Porse, Harry J. Simpson, and Raymond J. Soukup (Naval Res. Lab., Washington, DC 20375)

A series of tank experiments are being conducted in order to obtain high quality data for acoustic propagation in environments with sloping elastic bottoms. Such problems can now be solved accurately with the parabolic equation method, which is being used to model the experiment. This paper will present results of the initial experiments and discuss plans for upcoming experiments, which will include propagation onto land. The initial experiments involved a broadband source over a block of PVC that was suspended in deionized water. Time series were collected at 100 to 300 kHz on horizontal and vertical arrays for two source positions. [Work supported by the Office of Naval Research.]

4pUWa5. Adjoint-based control of nonlocal boundary conditions for Claerbout's wide-angle parabolic approximation. Matthias Meyer and Jean-Pierre Hermand (Dept. of Optics and Acoust., Univ. Libre de Bruxelles, av. F-D. Roosevelt 50 - CP 194/05, B-1050 Brussels, Belgium)

This paper applies the concept of optimal boundary control for solving inverse problems in shallow water acoustics. A continuous analytic adjoint model is derived for a wide-angle parabolic equation (WAPE) using a generalized nonlocal impedance condition at the water-bottom interface.

While the potential of adjoint methodology has been demonstrated for ocean acoustic tomography, this approach combines the advantages of exact transparent boundary conditions for the WAPE with the concept of adjoint-based optimal control. In contrast to meta-heuristic approaches the inversion procedure itself is directly controlled by the waveguide physics and, in a numerical implementation based on conjugate gradient optimization, much fewer iterations are required for assessment of environments that are supported by the underlying subbottom model. Furthermore, since regularization is important to enhance performance of full-field acoustic inversion, special attention is devoted to applying penalization methods to the adjoint formalism. Regularization incorporates additional information about the desired solution to stabilize ill-posed problems and identify useful solutions, a feature that is of particular interest for inversion of field data sampled on a vertical array in the presence of measurement noise and modeling uncertainty. Results show that the acoustic fields and the bottom properties embedded in the control parameters are efficiently retrieved.

3:15

4pUWa6. Line-integral prediction for horizontal coherence in deep-water propagation. Michael Vera (Univ. of Southern Mississippi, 730 E. Beach Blvd., Long Beach, MS 39560, michael.vera@usm.edu)

Some of the characteristics of an acoustic signal propagating to basin-scale ranges in the ocean can be estimated using line integrals along deterministic ray paths. These line-integral approximations involve the statistics of the internal-wave field. The success or failure of the integral expressions can be analyzed by comparison to parabolic-equation simulations through multiple realizations of the stochastic internal-wave field. One acoustic characteristic of interest is the length scale of acoustic horizontal (cross-range) coherence. Recent work comparing integral predictions of horizontal coherence length to values from simulations of the North Pacific Acoustic Laboratory experiment yielded mixed results. Additional comparisons will be discussed for acoustic propagation paths that are not impacted by range-dependence in the bathymetry or background sound-speed profile. These simulations will employ a single sound-speed profile and a deep, range-independent bottom. The comparisons can yield some insight into the accuracy of the integral estimate; they will not be influenced by bathymetric interaction or range dependence in the background sound speed.

3:30

4pUWa7. Decomposition method in constructing simulation models of parametric location for statistically irregular mediums. Irene Starchenko (TSURE, 347928, Taganrog, GSP-17a, Nekrasovskiy, 44, Russia, star@tsure.ru)

In using parametric arrays for the purposes of distant sounding in a water medium it is necessary to take into account the probable characteristics of acoustic signals. In this case the modeling of processes is especially important, because experiments in natural conditions are not always possible. In the case of parametric location the medium plays the very important function of formation of the parametric array. Results will be discussed.

4pUWb1. Range estimation of broadband noise sources in an ocean waveguide using the array invariant. Sunwoong Lee and Nicholas C. Makris (MIT, 77 Massachusetts Ave., Cambridge, MA 02139, makris@mit.edu)

A method is developed for range estimation of broadband noise sources in a horizontally stratified ocean waveguide without *a priori* knowledge of the environment. It has previously been shown that the range of a transient source can be estimated using the “array invariant” method by analyzing instantaneous beam-time intensity data [Lee and Makris, *J. Acoust. Soc. Am.* **116**, 2646 (2004)]. This method is now extended to range estimation of continuous, broadband noise sources in an ocean waveguide. It is shown that the cross-correlation of instantaneous beam-time intensity asymptotically reaches the array invariant. The range of the source can then be determined without knowledge of the environmental parameters. This method is applied to localize multiple uncorrelated noise sources in a horizontally stratified ocean waveguide without ambiguity.

4pUWb2. Effect of shallow water internal waves on the ambient noise notch. Daniel Rouseff, Dajun Tang, and Frank S. Henryey (Appl. Phys. Lab., College of Ocean and Fishery Sci., Univ. of Washington, Seattle, WA 98105, rouseff@apl.washington.edu)

Consider a vertical receiving array in shallow water that is recording ambient noise. If the recorded noise is beamformed, the resulting beam pattern often exhibits a notch at broadside to the array. Modeling of range-independent environments suggests that this ambient noise notch should become more pronounced as the sound speed gradient is increased. In the present work, the effect of range dependence on the ambient noise notch in the 1–5 kHz band is studied. Range dependence is introduced into the model in the form of random shallow water internal waves. Coupling between the propagating acoustic modes is calculated using the Dozier-Tappert formulation [*J. Acoust. Soc. Am.* **63**, 353–365 (1978)] extended to consider bottom loss. The model is internally consistent as the buoyancy profile determining the internal waves is dictated by the sound speed gradient. Experimental results from the 2001 East China Sea Experiment are also reported. [Work supported by ONR.]

2:30

4pUWb3. Using vertical directionality to study the ambient noise fluctuations due to internal waves in South China Sea. Hsiang-Chih Chan (Natl. Taiwan Univ., No. 1, Sec. 4, Roosevelt Rd., Taipei, 106, Taiwan, d91525003@ntu.edu.tw), Ruey-Chang Wei, Wen-Zheng Hu (Natl. Sun Yat-sen Univ., Kaohsiang, 804, Taiwan), and Chi-Fang Chen (Natl. Taiwan Univ., Taipei, 106, Taiwan)

A range-dependent acoustic propagation model is used to simulate the complex ambient noise field, which offers the key to the understanding of noise varying during the ASIAEX 2001 SCS experiment. The surface noise sources that are generated by wind/waves and ships are distributed

horizontally in the simulated model. Observed ambient noise fluctuations in South China Sea are greatly affected by prevailing internal waves in this area, the vertical directionality changes on vertical line array output were believed to be results of interaction between sound and ocean environment. The measured twin-peak beam patterns are not consistent with previous studies on flat or upslope bathymetry. Therefore, in this study the discrepancy is explained by modeling and correlation between the noise distributions and internal wave position.

2:45

4pUWb4. Acoustic spreading and boat noise within shallow Florida waterways. Richard Phillips (Dept. of Mech. and Aerosp. Eng., Univ. of Florida, Gainesville, FL 32611-6250), Christopher Niezrecki (Univ. of Massachusetts Lowell, Lowell, MA 01854-2881, Chris_Niezrecki@uml.edu), and Diedrich O. Beusse (Univ. of Florida, Gainesville, FL 32611-0126)

The West Indian manatee has become endangered partly because of watercraft collisions in Florida’s coastal waterways. Several boater warning systems, based upon manatee vocalizations, have been proposed to reduce the number of collisions. One aspect of the feasibility of an acoustically based system will rely upon the distance in which a manatee vocalization can be detected. The magnitude of environmental noise and manatee vocalizations, as well as the acoustic spreading properties of the habitat will help to estimate the detection range of a manatee. This study surveyed several shallow-water coastal areas in Florida (Crystal River, Cedar Key, and Indian River) which are likely to be inhabited by manatees. Using a chirp signal (1–10 kHz) broadcast by an underwater transducer, it was observed that the acoustic pressure data collected was best represented by the mixed and Lurton spreading models. The overall data obtained from passing a boat directly over the hydrophone was most closely represented by a spherical spreading model. However, for a boat that is approaching, a mixed spreading model is the most appropriate. The mean SPL for boat traffic was measured to be 140 dB and the background environment noise level ranged between 69 and 105 dB.

3:00

4pUWb5. One year of background underwater sound levels in Haro Strait, Puget Sound. Val Veirs (Phys. Dept., Colorado College, Colorado Springs, CO 80903, vveirs@coloradocollege.edu) and Scott Veirs (BeamReach Sustainability Sci. School, Seattle, WA 98115)

Haro Strait, on the west side of San Juan Island, WA, is the home range of the Southern Resident orca whales, a major shipping lane to and from Canada, and a center of private and commercial boating, especially in the summer. Four ITC hydrophones in a near-shore fixed array are used here to localize the underwater vocalizations of Southern Resident orca whales. The system operates 24 hours a day and has a frequency response of 100 Hz to 10 kHz. Background sound levels are automatically characterized by half-hour reports that include: statistics and graphics based on mean sound levels (2-min running arithmetic mean pressure); a histogram of mean sound levels binned by frequency; and 2-s sound samples from maximum background events. Sound levels range from ~90 dB re 1 microPa (quiet conditions) to ~130 dB re 1 microPa when loud commercial ships are passing in the nearby shipping lane or speedboats are passing

close to the hydrophone array. Complete results for one year of continuous monitoring will be presented, segmented by time (season, day of the week, hour in the day), frequency spectrum and dominant noise source class. [Work supported by 35 undergraduate researchers and the Colorado College.]

3:15

4pUWb6. An acoustic modeling study of airgun noise from seismic surveys performed offshore British Columbia. Alexander O. MacGillivray (JASCO Res. Ltd., 2101-4464 Markham St., Victoria, BC, Canada V8Z 7X8) and N. Ross Chapman (Univ. of Victoria, Victoria, BC, Canada V8W 3P6)

A recent numerical modeling study has examined the propagation of underwater noise from potential seismic survey activity in Hecate Strait and Queen Charlotte Sound, Canada. Noise level predictions from this study are based on an integrated modeling approach incorporating an airgun array source model, a broadband transmission loss model, and an environmental model based on high resolution bathymetry, historical CTD casts and geophysical data. Details of the source model, transmission loss model and environmental model are discussed. Selected noise level predictions from the modeling study are presented. Results from this study will aid in evaluating potential environmental impacts of seismic exploration activity on marine ecosystems in British Columbia's offshore region. [Work supported by BC MEM and NSERC.]

3:30

4pUWb7. An integrated acoustic modeling infrastructure for underwater noise impact assessment. David E. Hannay and Roberto G. Racca (JASCO Res. Ltd., 2101-4464 Markham St., Victoria, BC, Canada V8Z 7X8, dave@jasco.com)

When industrial activities such as underwater dredging or seismo-acoustic surveying are planned near ecologically sensitive areas, effective forecasting of the associated sound levels is often necessary to allow effective noise management planning and to satisfy permitting requirements. To this end a comprehensive software application, the Marine Operations Noise Model, was developed to enable the estimation of aggregate noise levels from complex operations involving numerous activities over extended regions. The software architecture includes a specially adapted Parabolic Equation propagation model, a database of field measured spectral source levels from a wide range of industrial vessels, a run module that coordinates modelling and summing of sound from multiple sources, and a GIS interface for the definition of operational layouts and the display of noise level contours on area maps. This application has been used in the planning and regulatory approval process for future pipeline and offshore platform installation activities to take place in the proximity of marine mammal habitats. Its accuracy in this context was validated through an extensive program of acoustic monitoring of similar activities taking place in a nearby location over the course of a prior construction season.

Session 5aAA

Architectural Acoustics: General Topics in Architectural Acoustics

8:30

5aAA1. An investigation of Columbia College Chicago reverberation chamber. Ryan P. Shannon, Kevin A. Fowler, Jeremy J. Hill, Sean D. Terry (Dept. of Audio Arts & Acoust., Columbia College Chicago, 33 E. Congress Pkwy Ste 601, Chicago, IL 60605, ryanshannon8@hotmail.com), Melinda J. Carney, and Dominique J. Cheenne (Columbia College Chicago, Chicago, IL 60605)

The Audio Arts and Acoustics department at Columbia College in Chicago acquired a new building in 2003. The facility, a former bank, contained an old steel and concrete vault that was converted to a reverberation chamber. The acoustic properties of the space, including reverberation time, modal density, and early reflection maps were analyzed and compared to a computer model. Reflectograms were predicted at various locations and compared to test data acquired with Time Delay Spectrometry (TDS). Polar Energy Time (PET) techniques were also used to identify the location of a single 4×4 sample of foam absorber and the results of the test were compared to the predicted value from the computer model. The results of the tests show that, under its current configuration, the room is usable as a reverberation chamber down to 300 Hz, and that the computer model was able to accurately predict the results from the PET methodology.

8:45

5aAA2. Chronological analysis of architectural and acoustical indices in halls for music performance. Youngmin Kwon and Gary W. Siebein (Architecture Technol. Res. Ctr., School of Architecture, Univ. of Florida, 231 Arch, P.O. Box 115702, Gainesville, FL 32611)

The objective of this study was to identify the changes in architectural and acoustical indices in halls for music performance built in the 18th through the 20th centuries. Seventy one halls were classified in five specific periods from the classical period (1750–1820) to the last two-decade contemporary period (1981–2000) based on chronology in music and architectural acoustics. Architectural indices such as room shape, seating capacity, room volume, balcony configuration, and the like as well as acoustical indices such as RT, EDT, G, C80, IACC, and the like for the halls found in the literature were chronologically tabulated and statistically analyzed to identify trends in architectural and acoustical design for each of the historical periods identified. For example, seating capacity increased from the eighteenth through the early twentieth century. It has decreased in the twentieth century while the room volume per seat has increased. This results in longer occupied reverberation times, higher G values and lower C80 values for contemporary halls compared to those built earlier in the century. Acoustical indices were in general found to be lower during the early twentieth century relative to other periods and to have increased since then.

9:00

5aAA3. Acoustic design for Teatro Sesc Pinheiros. Jose Augusto Nepomuceno and Anthony McCreery (Acustica & Sonica, Fradique Coutinho, 955 sala 01, Sao Paulo, Brasil)

Sesc is a non-governmental social organization to promote culture, sport and education in Brasil. Among its facilities there is the new Sesc-Pinheiros center with a multipurpose theater seating 1000. Due to changes

in the planned use of the theater during construction, Acustica & Sonica was hired by the contractor Mendes Junior to adjust and improve the room acoustics and noise control design of the theater. The original design was modified by adding adjustable acoustical systems, changing in the ceiling and balcony shaping, and revising the specification of all finish materials. The room acoustics modifications followed the recommendations of Akustiks, acoustical consultants from South Norwalk, Connecticut, USA. A concert shell was designed and fabricated to allow the use of orchestral music. An open shell concept was used. The new hall has received excellent critics from pianists, conductors and players, and is rated among the best in the country. Acoustical measurements were performed. The measured values have been compared with the results of a computer model carried out by Acustica & Sonica for this project and they are consistent. [The authors would like to thank Mendes Junior, Sesc, Bengt-Inge Dalenbeck and Christopher Blair of Akustiks for their support.]

5aAA4. Characterization and prediction of low frequency sound in workrooms. Galen Wong and Murray Hodgson (UBC Acoust. and Noise Res. Group, 3rd Fl., 2206 East Mall, Vancouver, BC, Canada V6T 1Z3)

Low-frequency noise is of concern in industrial settings since workers are subjected to long-term exposures of low-frequency noise caused by machinery which can adversely affect human health and well-being. Passive noise-control methods are usually not cost-effective. Active noise control, on the other hand, is most effective at low frequencies. As part of a project investigating active noise control of low-frequency noise in these settings, and how to predict its benefit, measurements were performed on the propagation of low-frequency noise in a workroom, with and without fittings the obstacles in the room to understand their effects and importance in prediction models. Measurements performed in a real-world workroom, as well as in a scale model workroom show that fittings alter the sound field in an unpredictable manner. With low-frequency octave band filtered noise output, changes in the sound pressure level of 10 dB or more were measured in both cases. Prediction of low-frequency noise in workrooms was performed using an image-phase and a modal model—which do not account for the effects of fittings. Predictions were compared to measurements in full-scale and scale-model workrooms with pure tone outputs. So far it has proven difficult to accurately model low-frequency effects in large workrooms.

5aAA5. Evaluation and optimization of acoustical environments in eating establishments. Zohreh Razavi and Murray Hodgson (UBC Acoust. & Noise Res. Group, SOEH, 3rd Fl., 2206 East Mall, Vancouver, BC, Canada V6T 1Z3)

Complaints from hard-of-hearing faculty members at UBC about communicating verbally in one of the upscale restaurants on the campus led to a study of acoustical environments in eating establishments and how to optimize them. Speech intelligibility and speech privacy are important considerations in the design of eating establishments; however, they are commonly overlooked. In this preliminary research, three bistros were considered. Physical measurements were done and associated acceptability criteria applied to evaluate the environments. The noise exposures of em-

ployees and customers were measured and compared to maximum permitted occupational limits. Worker noise exposures were in the range 80–84 dBA. Customers were often exposed to levels over 75 dBA; especially at lunchtime it exceeded 80 dBA. The CATT room-acoustical prediction model was used to study the physical and acoustical factors that affect the acoustical environments in eating establishments and how optimize them. The effect of facility modifications, including the use of sound-absorbing wall panels, lowered and improved acoustical ceilings, and partial barriers between tables were predicted.

5aAA6. A new method for measuring the speech security of meeting rooms. John S. Bradley and Bradford N. Gover (Inst. for Res. in Construction, Natl. Res. Council, Montreal Rd., Ottawa, Canada K1A 0R6)

This paper describes a proposed new method for measuring the speech security of offices and meeting rooms. It is intended to assess the risk of someone who is talking in the meeting room being overheard at points outside the room, close to the outside boundaries of the room. Previous work has derived frequency-weighted speech-to-noise type measures that are well related to the perceived intelligibility and audibility of the transmitted speech. The proposed new method measures the attenuation between average levels in the meeting room and received levels at points 0.25 m from the outside boundaries of the meeting room in adjacent spaces. The average source room levels are representative of all possible talker location. The receiving points, 0.25 m from the room boundaries, can assess expected privacy at critical listening locations with minimal effect of the acoustical properties of the adjacent spaces. New measurements in 11 meeting rooms have been used to evaluate the influence of several parameters on the accuracy of the measured degree of speech security. These include: the type and number of sound sources used, and the number and location of microphones in the meeting room and the adjacent spaces. Details of the analyses will be presented.

5aAA7. A simplified method to estimate the free path length variance. Yan Zhang, Godfried Augenbroe, Ruchi Choudhary (College of Architecture), and Brani Vidakovic (Georgia Inst. of Technol., Atlanta, GA 30332)

Kutruff derived an analytical solution for the prediction of reverberation time in spaces with arbitrary shape. It is the most popular analytical equation that contains shape factors. However, in this equation the free path length variance remains as unknown parameter. Kutruff suggested the implementation of Monte-Carlo simulation to determine this value for each unique shape. In practice this method is not significantly simpler than a full ray tracing simulation. Fortunately, using methods from the probability field, the free path length variance does have an analytical solution, but this takes such a complicated form that it is not convenient to use. This article treats the development of a simplified method to estimate the free path length variance without losing accuracy when applied to concert halls. A simplified regression model is developed for rectangular shapes based on the analytical solution. This simple model explains 99.8% variance for any rectangular shape up to 1:10:10. Secondly, for arbitrary shapes, a simplified model is proposed by including several additional simple variables. This model is validated against simulation results. It will be shown that this simplified method not only can be used in Kutruff's equation, but also reveals the significant shape-related parameters that influence the reverberation time.

10:30

5aAA8. Acoustic modeling in rectangular rooms with impedance using the finite element method with the Dirichlet-to-Neumann map. Yusuke Naka (Dept. of Aerosp. and Mech. Eng., Boston Univ., 677 Beacon St., Boston, MA 02215, ynaka@bu.edu), Assad A. Oberai and Barbara G. Shinn-Cunningham (Boston Univ., Boston, MA 02215)

Computational models of head-related transfer functions (HRTFs) are useful in investigating the effects of echoes and reverberations in enclosures. These models may be computed at relatively low cost by geometric methods, such as the image source method. However, geometric methods typically ignore several important physical effects, such as diffraction, which effect the fidelity of the resulting HRTF. On the other hand, methods based on solving the wave equation, such as the finite element method, include these effects but tend to be computationally expensive. This study represents a Dirichlet-to-Neumann (DtN) map which significantly reduces the costs associated with using the the finite element method for computing HRTFs in a rectangular room, by analytically eliminating empty regions of the room. The DtN map for rooms with realistic impedance boundary conditions is developed. This work represents an extension of our previous approach for sound-hard rooms [Y. Naka, A.A. Oberai, and B.G. Shinn-Cunningham, Proc. 18th International Congress on Acoustics, Vol. IV, pp. 2477–2480 (2004)]. [Work supported by AFOSR.]

10:45

5aAA9. Analysis of diffuse broadband sound fields in enclosures by decomposition in powers of an absorption parameter. Donald B. Bliss, Jerry W. Rouse, and Linda P. Franzoni (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708, dbb@duke.edu)

A novel analysis for steady-state or time-dependent broadband diffuse sound fields in enclosures is developed. Beginning with a formulation utilizing broadband intensity boundary sources, the strength of these wall sources is expanded in a series in powers of an absorption parameter, thereby giving a separate boundary integral problem for each power. The first problem has a uniform interior field level proportional to the reciprocal of the absorption parameter, as expected. The second problem gives a mean-square pressure distribution that is independent of the absorption parameter and is primarily responsible for the spatial variation of the reverberant field. This problem depends on the location of sources and the spatial distribution of absorption, but not absorption level. Additional problems proceed at integer powers of the absorption parameter, but are essentially higher order corrections to the spatial variation. The important second problem and the higher order problems are easily solved numerically, but closed form approximate solutions based on one iteration step are simple and accurate. Solutions obtained by retaining only the first couple of terms in the series expansion are compared to complete solutions obtained by another approach, and good agreement is shown between the two methods.

11:00

5aAA10. Finite-sized sources in the presence of boundaries. John R. MacGillivray (Red Tail Hawk Corp., 111 E. Seneca St., Ithaca, NY 14850) and Victor W. Sparrow (Penn State, University Park, PA 16802)

Many methods of auralization convolve a source signal (e.g., cello recorded in an anechoic room) with a room's impulse response (which has been computed using method of images, ray tracing, etc.). Many instruments are finite-sized sources because they produce music having frequencies where the product of the wavenumber and the instrument's characteristic length is not small. Sound produced by a finite-sized source in the presence of boundaries can include scattering and diffraction, resulting from the presence of the source in its own field. These effects are not accounted for by the auralization types mentioned above. A geometrically simple example of a finite-sized pulsating sphere in the presence of a rigid infinite boundary is solved using the translational addition theorem for spherical wave functions (TATSWF). Using TATSWF, the original problem is solved by replacing the rigid infinite wall with an image of the finite-sized sphere. This is a surprisingly complicated problem to solve,

given the simple geometry, and serves to illustrate how a source can perturb its field when near a boundary. Examples are presented for which significant changes in the pressure magnitude occur. [Work supported by the Applied Research Laboratory, Penn State.]

11:15

5aAA11. Subjective impression of differences in realism, source width, and orientation between auralizations created from multi-channel anechoic recordings. Michelle C. Vigeant, Lily M. Wang (Architectural Eng. Prog., Univ. of Nebraska–Lincoln, Peter Kiewit Inst., 1110 S. 67th St., Omaha, NE 68182-0681, mvigeant@unlnotes.unl.edu), and Jens Holger Rindel (Tech. Univ. of Denmark, DK-2800 Kgs. Lyngby, Denmark)

Auralizations can be very useful in the design of performing arts spaces. One of the fundamental modeling inputs to create auralizations is the source directivity. Standard methods involve inputting the measured source directivity, calculating the impulse response (IR) and convolving it with a single channel anechoic recording. This paper focuses on an alternative method of modeling source directivity which involves multi-channel anechoic recordings to create auralizations. Subjective tests were conducted comparing auralizations made with one, four and thirteen channels for differences in realism and source width. Auralizations were made using three different types of musical instruments: woodwinds (flute), brass (trombone) and strings (violin). Subjects were asked to rate each musical track on a seven-point scale for the degree of realism and source width. An analysis of variance (ANOVA) was carried out to determine the differences between the number of channels and the effect of instrument. A second test was conducted to assess the degree of difficulty in detecting source orientation (facing the audience or facing the stage wall) depending on the number of channels (one, four or thirteen) and the amount of absorption in the room. [Work supported by the National Science Foundation.]

11:30

5aAA12. Sampling methods for decay time evaluation in acoustically coupled spaces. Tomislav Jasa, Ning Xiang, and Mendel Kleiner (School of Architecture and Dept. of Electrical, Computer, and Systems Eng., Rensselaer Polytechnic Inst., Troy, NY 12180)

This paper applies the methods of Bayesian inference to the estimation of decay times in coupled rooms. Previous papers [N. Xiang and P. M.

Goggans, J. *Acoust. Soc. Am.* **110**, 1415–1424 (2001); **113**, 2685–2697 (2003)] developed a solution method to estimate the decay times and the number of decay modes in terms of measured Schroeder's decay functions. This paper extends the previous work by using statistical sampling methods to efficiently determine the decay times along with error estimates and evaluate the "Bayesian evidence" term used in determining the number of decay modes. This paper discusses the implemented methods together with the previous work to solve the problem of decay time estimation as well as determining the number of decay modes in acoustically coupled rooms.

11:45

5aAA13. Experimental validation of a diffusion equation-based modeling of the sound field in coupled rooms. Alexis Billon, Vincent Valeau (LEPTAB Univ. of La Rochelle, Av. M. Crepeau 17042, La Rochelle Cedex 01, France, abillon@univ-lr.fr), Judicael Picaut (LCPC Nantes ESAR Rte. de Bouaye–BP 4129 44341, Bouguenais Cedex, France), and Anas Sakout (LEPTAB, La Rochelle, France)

Sound modeling in coupled rooms (i.e., two acoustically coupled rooms separated by an open area) has attracted considerable attention in the past. However accurate and operational models are still needed, principally when three or more rooms are coupled. In recent papers, a diffusion equation-based model has been applied to unusual room shapes. For the coupled rooms geometry, this diffusion model has been validated successfully by comparison with the classical statistical theory in a parametrical study of the coupling parameters [Billon *et al.*, *J. Acoust. Soc. Am.* **116**, 2553 (2004)]. In the present work, the diffusion model results are validated by means of a comparison with experimental results, both in terms of sound attenuation and reverberation time. A comparison is also provided with results given by the statistical theory and a ray tracing program. For this purpose, experiments have been conducted in two coupled classrooms with two different sound source locations. The results show a very good agreement between the diffusion model and the experiments. Conversely, the statistical model is not valid for modeling accurately the sound field distribution and decay in both coupled rooms. At last, the diffusion model runs much faster than the ray tracing program.

Session 5aAB**Animal Bioacoustics and ASA Committee on Standards: Behavioral Audiometric Methods in Animal Bioacoustics: The Search for Standards I**

Edward J. Walsh, Cochair

Boys Town National Research Hospital, Omaha, NB 68131

Ann. E. Bowles, Cochair

*Hubbs-Sea World Research Inst., 2595 Ingraham St., San Diego, CA 92109***Chair's Introduction—8:50*****Invited Papers*****9:00****5aAB1. Common hearing functions among mammals and birds.** Richard R. Fay (Parmly Hearing Inst., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626, rfay@luc.edu)

Among many mammals and birds, frequency-place cochlear maps have a similar form and differ primarily with respect to the length of the cochlea or basilar papilla, and with respect to the frequency range of hearing. This is remarkable, especially given the differences in anatomical organization and evolutionary history between mammals and birds. This is a striking example of convergent or parallel evolution. With few exceptions, the cochleae of mammals and birds are indeed scale models of one another. One of the primary functions of the frequency-place map is in frequency analysis. Whether this function is defined by frequency discrimination thresholds, critical masking ratios, critical bands or auditory filters in general, frequency analytic performance, behaviorally-defined, can be laid out on the basilar membrane and a critical basilar membrane distance can be associated with a given performance criterion. In general, these critical distances differ according to the function (e.g., frequency delta F s versus critical bandwidths), but are remarkably similar functions of frequency within and between species (they tend to be constant). It seems likely that evolution has selected the consequences of frequency analytic mechanisms for perception rather than the mechanisms themselves. [Work supported by NIH.]

9:20**5aAB2. How do you know what an animal can hear?** Henry E. Heffner (Dept. of Psych., Univ. of Toledo, Toledo, OH 43606)

The comparative study of hearing is based on the ability to obtain valid behavioral measures of hearing in different species. This requires careful generation and measurement of sound, a behavioral task and reinforcer appropriate for the species, and a comparable definition of threshold. For audiograms, it is important to generate artifact-free pure tones and test with the animal's head fixed in a free-field sound field. For sound localization, a two-point discrimination with the animals head fixed in the sound field is commonly used. For all discriminations, it is important to obtain data for stimuli that are below threshold to ensure that an animal is not using extraneous cues. Descriptions of techniques should be sufficiently detailed to allow other researchers to replicate them; new techniques can be calibrated by replicating the results of others. Behavioral procedures that work well with one species may not elicit optimal performance from others. Although performance should be corrected for false positives, signal detection measures are difficult to interpret and cannot compensate for the failure to keep an animal under stimulus control. In general, valid results are obtained by following good scientific practice.

9:40**5aAB3. The critical band and the critical ratio.** William A. Yost and William Shofner (Parmly Hearing Inst., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626)

The critical band is arguably one of the most important psychophysical descriptors of auditory function. The critical ratio is often used in animal psychophysical research to estimate critical bandwidth because it is easier to obtain than estimates of critical bandwidth. However, in most cases the underlying assumptions required to use the critical ratio as an estimate of critical bandwidth are rarely met. The critical bandwidths for chinchilla and guinea pigs are similar to those obtained for human subjects, while the critical ratios are considerably higher, an observation that violates the use of the critical ratio as an estimate of critical bandwidth. This paper will describe the assumptions necessary for the critical ratio to estimate critical bandwidth. We will describe data on critical bands and critical ratios for chinchilla and guinea pigs, and we will provide evidence that the chinchilla appears to be a wideband processor of the signal in critical-ratio experiments. The inability of the chinchilla to process the signal in its narrow critical band in the critical-ratio psychophysical procedure leads to the large critical ratios. We recommend that the critical ratio not be used to estimate critical bandwidth. [Work supported by NIDCD grants to Dr. Yost and to Dr. Shofner.]

10:10

5aAB4. Estimating loudness in animals. Micheal L. Dent (Dept. of Psych., 361 Park Hall, Univ. at Buffalo-SUNY, Buffalo, NY 14260, mdent@buffalo.edu)

Although auditory acuity experiments in animals are valuable, this is not how animals typically encounter real world sounds. It is also important to know how animals respond to stimuli at more “realistic” intensities. The perception of above-threshold level sounds has been well documented in humans, but is much less studied in animals, where acoustic communication is important for survival. In humans, equal loudness contours are used to show that loudness does not increase with intensity equally at all frequencies. Loudness is a subjective experience, however, and much harder to measure in animals. Reaction time is one untrained response that can be used to gauge how different or similar two stimuli are: high intensities yield short and low intensities yield long reaction times. Comparing reaction times across frequencies (equal latency contours) in birds and mammals show results that are similar to equal loudness contours obtained in humans. At low SPLs equal-latency contours closely parallel threshold curves, while at high SPLs the contours flatten and all frequencies are perceived as being about the same loudness. These results in animals should be considered when thinking about aspects of acoustic communication such as sound transmission, vocal signals designs, and sound-attenuating properties of the environment.

10:30

5aAB5. Animal behavioral psychoacoustics: Issues related to methodology and interpretation. David Kastak, Ronald Schusterman, Brandon Southall, Marla Holt (UCSC Long Marine Lab., Santa Cruz, CA 95060), and Colleen Kastak (UCSC Long Marine Lab., Santa Cruz, CA 95060)

A brief survey of the literature in animal behavioral psychophysics shows that researchers use numerous methods to obtain information on sound detection, discrimination, and identification. Behavioral methodology in animal psychoacoustics includes both classical and operant conditioning, go/no-go or multiple alternative forced-choice tasks, and various methods of estimating detection and discrimination thresholds. Recent emphasis on comparing data across subjects, species, and media (e.g., hearing in air versus water), as well as investigations into the effects of age, noise, and ototoxins on auditory perception highlight the need for methodological standardization. In this paper we will discuss several important issues related to behavioral audiometrics, focusing primarily on marine mammals. These issues include variability among species, individual subjects, and laboratories; experimental concerns such as time constraints; adaptive versus non-adaptive psychophysical methodology and threshold reliability; signal detection theory versus threshold models of audition and the search for unbiased estimates of auditory performance; and measurement and interpretation of subject response bias. Standards for animal psychoacoustic methodology should be sensitive to each of these factors.

10:50

5aAB6. Body size and assessment of auditory function: A comparative conundrum. Edward J. Walsh, JoAnn McGee (Boys Town Natl. Res. Hospital, Omaha, NE 68131), John Rosowski, and William Peake (Harvard Med. School, Boston, MA 02115)

One goal of the bioacoustics community is to compare auditory function among species representing the entire animal kingdom, including terrestrial mammals. As an alternative to behavioral measures, it is frequently necessary, and/or desirable, to assess auditory function using electrophysiological approaches. Body size is an important factor that can effect the distribution and amplitude of evoked brain potentials (EP) measured from the surface of the head and the ranges of body mass and size within *Mammalia* are extensive. Consequently, the development of comparison protocols must include consideration of factors affected by size differences, e.g., the distance between EP generators and recording electrodes and the thickness of the skull. Ultimately, these factors, along with the acoustical character of the recording environment itself, affect acquired signal-to-noise ratios (SNR). In this context it is notable that the SNR associated with large animals are reduced relative to those observed in smaller animals, making the comparison of results from one species to another complex. This procedural challenge is further complicated by the requirement to acquire data efficiently and rapidly in recording environments that are non-optimal from an acoustic perspective. These issues will be addressed by considering auditory brainstem responses in tigers, bobcats, manul, sandcats and rodents.

11:10

5aAB7. Psychometric data and standards for the estimation of noise exposure for animals. Ann E. Bowles (Hubbs-SeaWorld Res. Inst., 2595 Ingraham St., San Diego, CA 92109, annb1@san.rr.com)

ASA standards are used in the estimation of noise exposure for humans. The approaches pioneered for humans can be used as a model for animal standards, but a number of differences must be considered. First, animal standards will normally be applied across multiple taxa rather than to a single, monotypic species. Thus, it will be essential to find defensible methods for generalizing across taxa. Second, samples of subjects and measurement conditions are often inadequate in animal studies (e.g., measurements on a single animal, noisy testing conditions), but may be the only data available. Therefore, standards are needed for specifying the limitations of various data sources. Third, taxa may have very different psychoacoustic capabilities (e.g., best sensitivity, temporal integration time, and loudness perception). Therefore, comparative measures will be essential. For example, while weighting functions for humans are standardized to zero at 1 kHz, there are advantages to developing weighting functions for animals with an appropriate correction for taxon-specific sensitivity. Although the differences between standards for animals and humans represent a significant challenge, the development process and research in support of animal standards will yield valuable new perspectives that could be applied to humans in the future.

Session 5aBBa

Biomedical Ultrasound/Bioresponse to Vibration: Hemostasis and Bleeding Detection

Tyrone M. Porter, Chair

Univ. of Cincinnati, Biomedical Engineering, 231 Albert Sabin Way, Cincinnati, OH 45267-0761

Contributed Papers

8:00

5aBBa1. Vector-Doppler ultrasound for the detection of internal bleeding. Bryan W. Cunitz, Peter J. Kaczkowski, and Andrew A. Brayman (Ctr. for Industrial and Med. Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

A vector Doppler (VDop) ultrasound system uses a transmitter and a spatially separated pair of receivers to measure bistatic scattering from blood. VDop has two principal advantages over color-flow Doppler in identifying internal bleeding: (1) measures flow direction, and thus absolute magnitude of flow velocity (2) does not require special orientation to detect and measure flow, thus can measure flows perpendicular to the transmitter. Our hypothesis is that real-time flow direction and magnitude can be used to detect and characterize internal bleeding. A real-time vector Doppler system has been built and tested *in vitro*. The system is capable of measuring flow magnitude and direction up to 145 cm/s at a depth of 3.6 cm at a processing rate of 10 Hz. Accuracy was measured using a calibrated moving string phantom and the system performs well within a useful range. A blood flow phantom was developed to mimic arterial flow into an open cavity as well as into tissue and replicate both pulsatile flow as well as the energy storage due to vascular elasticity. Flow signature data is gathered under conditions of normal branching flow, and vessel breach. The talk will describe the VDop system and the flow phantom and summarize results.

8:15

5aBBa2. Color-Doppler guided high intensity focused ultrasound for hemorrhage control. Vesna Zderic, Brian Rabkin, Lawrence Crum, and Shahram Vaezy (Appl. Phys. Lab. and Bioengineering, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, vesna@u.washington.edu)

To determine efficacy of high intensity focused ultrasound (HIFU) in occlusion of pelvic vessels a 3.2 MHz HIFU transducer was synchronized with color-Doppler ultrasound imaging for real-time visualization of flow within blood vessels during HIFU therapy. HIFU was applied to pig and rabbit pelvic vessels *in vivo*, both transcutaneously and with skin removed. The *in situ* focal intensity was 4000 W/cm² on average. Vessel occlusion was confirmed by color or audio Doppler, and gross and histological observations. In rabbits, five out of 10 femoral arteries (diameter of 2 mm) were occluded after 30–60 s of HIFU application. The average blood flow reduction of 40% was observed in the remaining arteries. In pigs, out of 7 treated superficial femoral arteries (2 mm in diameter), 4 were occluded, one had 80% blood flow reduction, and 2 were patent. In addition, 3 out of 4 superficial femoral arteries, punctured with 18 gauge needle, were occluded after 60–90 s of HIFU application. Larger vessels (diameter of 4 mm) were patent after HIFU treatment. Doppler-guided HIFU has potential application in occlusion of injured pelvic vessels similar to angiographic embolization.

8:30

5aBBa3. A pulsatile flow phantom for image-guided high-intensity focused ultrasound studies on blood vessels. Robyn Greaby and Shahram Vaezy (Ctr. for Medical and Industrial Ultrasound, APL, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698, rgreaby@u.washington.edu)

A pulsatile flow phantom has been developed for controlled studies of acoustic hemostasis and high intensity focused ultrasound (HIFU) effects on blood vessels. The flow phantom consists of an excised carotid artery attached to a pulsatile pump and embedded in an optically and acoustically transparent gel to create an *ex vivo* model of a human artery. The artery was punctured with a needle to simulate percutaneous vascular injury. A HIFU transducer with a focal distance of 6 cm and a frequency of 3.33 MHz was used to treat the puncture. *B*-mode and power-Doppler ultrasound were used to locate the site of the puncture, target the HIFU focus, and monitor treatment. Also, the effects of vascular flow on HIFU lesions were studied by treating vessels in the phantom for different times at a variety of flows. In both studies, histology was done on the artery. In nine trials, HIFU was able to provide complete hemostasis in 55 ± 31 s. It is feasible to use the flow phantom to study acoustic hemostasis of blood vessels. Histology shows that the flow in the phantom appears to diminish the vascular damage from HIFU.

8:45

5aBBa4. High throughput high intensity focused ultrasound (HIFU) treatment for tissue necrosis. Vesna Zderic, Jessica Foley, Sean Burgess, and Shahram Vaezy (Appl. Phys. Lab. and Bioengineering, Univ. of Washington, 1013 NE 40th St., Seattle WA 98105, vesna@u.washington.edu)

To increase HIFU throughput, a HIFU transducer (diameter of 7 cm, focal length of 6 cm, operating frequency of 3.4 MHz), coupled to an imaging probe (ICT 7-4, Sonosite), was driven by 100 W driving unit with 500 W amplifier. A water pillow connected to a circulation pump with degassed water provided transducer coupling and cooling. Input electrical power was 400 W, corresponding to focal intensity of 51 300 W/cm² (in water). HIFU was applied transcutaneously in porcine thigh muscle *in vivo*, and intraoperatively in liver hilum, for 30–60 s. After 30 s of treatment, muscle lesions had diameter of 2.1 ± 0.4 cm and length of 2.0 ± 0.4 cm. After 60 s of treatment, muscle lesions had diameter of 3.1 ± 0.9 cm and length of 3.1 ± 1.0 cm. In few cases of severe skin burns, the lesions were formed immediately under the skin and were shallow (~ 1 cm). Liver lesions had diameter of 2.1 ± 0.3 cm and length of 2.3 ± 0.6 cm. In comparison, after the 30 s treatment with our standard HIFU device (focal intensity of 27 000 W/cm², in water) the muscle lesions had diameter of 1.3 ± 0.6 cm and length of 1.1 ± 0.6 cm. High power HIFU device can quickly coagulate large tissue volumes.

5aBBa5. Image-guided high intensity focused ultrasound annular array for hemostasis and tumor treatment. Vesna Zderic, Robert Held, Thuc Nguyen, and Shahram Vaezy (Appl. Phys. Lab. and Bioengineering, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, vesna@u.washington.edu)

To develop and characterize an ultrasound-guided high intensity focused ultrasound (HIFU) array, an 11-element annular phased array (aperture of 3.5×6.0 cm, focal depth of 3.0–6.0 cm, frequency of 3 MHz) was coupled to an imaging probe (C9-5, Philips). LabView software was developed to control driving electronics and image guidance. Radiation force balance measurements, Schlieren imaging, and hydrophone field mapping were performed. Lesions were produced in gel phantoms, and *ex vivo* porcine liver and human cancerous uterus. The lesions were formed beginning at a focal depth of 6.0 cm and moving by 0.5 cm increments to 3.0 cm, and vice versa, with the overall treatment time of 2 min. The transducer had efficiency of 38%, with intensities of up to 6200 W/cm^2 at the natural focus of 5 cm, in water. The 6 dB focal area varied from 0.4 mm^2 (at 3 cm) to 1.5 mm^2 (at 6 cm). The 3 to 6 cm tissue lesions were 2.7 ± 0.5 cm in length, compared to 4.1 ± 0.3 cm for the 6 to 3 cm lesions. The average lesion width was 1 cm. Image-guided HIFU array may enable treatment of large tumor volumes and hemorrhage control at different depths inside the body.

9:15

5aBBa6. Image guided acoustic hemostasis. Sean Burgess (Dept. of Bioengineering, Univ. of Washington, Box 355640, 1013 NE 40th St., Seattle, WA 98105, sburgess@u.washington.edu), Vesna Zderic (Univ. of Washington), and Shahram Vaezy (Univ. of Washington)

Previous studies have shown that high intensity focused ultrasound (HIFU) can successfully control visible bleeding from solid organ injuries. This study investigates the ability of ultrasound image-guided HIFU to arrest occult hemorrhaging in the posterior liver parenchyma using a pig model. The image-guided HIFU device consisted of an intraoperative imaging probe and a spherically-curved HIFU transducer with focal length of 3.5 cm, frequency of 3.23 MHz, and focal acoustic intensity of 2350 W/cm^2 . A total of 19 incisions (14 HIFU-treated and 5 control incisions) were made in five pig livers. The incisions were 30 mm long and 7 mm deep with HIFU application occurring within 20 s of making an incision. Hemostasis was achieved in all treated incisions after a mean \pm SD of 65 ± 15 s of HIFU application. The mean blood loss rate of the control incisions initially and after seven minutes was 0.268 and 0.231 mL/s, respectively. Subsequent histological analysis showed coagulative necrosis of liver tissue around the incision which appeared to be responsible for hemostasis. Ultrasound image-guided HIFU offers a promising method for achieving hemostasis in surgical settings in which the hemorrhage site is not accessible.

9:45

5aBBa7. Ultrasound-guided high frequency focused ultrasound neurolysis of peripheral nerves to treat spasticity and pain. Jessica L. Foley, Frank L. Starr III, Carie Frantz, Shahram Vaezy (Ctr. for Industrial and Medical Ultrasound, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, jlf2@u.washington.edu), Jessica L. Foley, Shahram Vaezy (Univ. of Washington, Seattle, WA 98195), and James W. Little (Univ. of Washington, Seattle, WA 98195)

Spasticity, a complication of central nervous system disorders, signified by uncontrollable muscle contractions, is difficult to treat effectively. The use of ultrasound image-guided high-intensity focused ultrasound (HIFU) to target and suppress the function of the sciatic nerve of rabbits *in vivo*, as a possible treatment of spasticity and pain, will be presented. The image-guided HIFU device included a 3.2-MHz spherically-curved transducer and an intraoperative imaging probe. A focal intensity of $1480\text{--}1850 \text{ W/cm}^2$ was effective in achieving complete conduction block in 100% of 22 nerves with HIFU treatment times of 36 ± 14 s (mean \pm SD). Gross examination showed blanching of the nerve at the treatment site and lesion volumes of $2.8 \pm 1.4 \text{ cm}^3$ encompassing the nerve. Histological examination indicated axonal demyelination and necrosis of Schwann cells as probable mechanisms of nerve block. Long-term studies showed that HIFU intensity of 1930 W/cm^2 , applied to 12 nerves for an average time of 10.5 ± 4.9 s, enabled nerve blocks that remained for at least 7–14 days after HIFU treatment. Histological examination showed degeneration of axons distal to the HIFU treatment site. With accurate localization and targeting of peripheral nerves using ultrasound imaging, HIFU could become a promising tool for the suppression of spasticity and pain.

5aBBa8. Percutaneous high intensity focused ultrasound on pigs. Herman du Plessis (Surgery, 1 Military Hospital, Thaba Tshwane 0143, South Africa) and Shahram Vaezy (Univ. of Washington, Seattle, WA 98195)

Two types of HIFU Handpieces were tested on pigs under general anesthesia. The direct applicator (focal distance 4 cm) was adequate to control bleeding from a liver injury, although direct pressure was effective in a shorter time. The percutaneous application did not work at all, as the fixed focal distance (6 cm) was too deep for the size pigs available, and the diagnostic modality was difficult to integrate with the therapeutic window. We were able to create necrotic lesions in the liver substance, but not in the areas where the injury was situated. More development is needed to build a better, user-friendly application device before HIFU can be used in the clinical situation for control of hemorrhage.

8:05

5aBBb1. Audible-frequency medical diagnostic methods: Past, present and future. Armen Sarvazyan (Artann Labs., Lambertville, NJ 08530)

From time immemorial, the medical practitioners used audible-frequency diagnostic methods (percussion, pulse tone analysis, lung, heart and abdominal sound listening) for diagnosing and treatment of ailments without much help from other tests. During the last century, despite the fact that the stethoscope became the sign of the physician, auscultatory techniques are becoming outmoded and are often considered of little clinical value in comparison with many other modern diagnostic technologies. But obviously, there is rich information on the normal and diseased states of human organs in audible-frequency signals since characteristic times for many physiologic processes and resonance frequencies of anatomical structures are in that frequency range. In recent years, numerous emerging technologies started to bring new life into the ancient diagnostic approaches using low-frequency signals. Significant part of these new technologies are based on ultrasonic methods such as remote detection of tissue oscillation using the Doppler technique and especially on emerging ultrasonic technologies based on the use of acoustic radiation force. This talk presents an overview of current trends in the development of methods realizing the tremendous untapped medical diagnostic potential of sonic range acoustics.

8:30

5aBBb2. *In vivo* breast vibro-acoustography. Mostafa Fatemi, Azra Alizad, Dana H. Whaley, and James F. Greenleaf (Mayo Clinic College of Medicine, 200 First Ave. SW, Rochester, MN 55905)

Vibro-acoustography is based on audio-frequency harmonic vibrations induced in the object by the radiation force of focused ultrasound. The resulting object vibration produces a hydrophone detectable acoustic emission that is a function of regional dynamic properties of the object at the vibration frequency. The amplitude of the hydrophone signal is mapped into an image that represents the object's vibro-acoustic response to the radiation force by scanning the focused ultrasound across the object. Contrast in Vibro-acoustography images represent several properties of the object, including the dynamic characteristics at the audio frequency and scattering and absorption properties at the ultrasound frequency. A Vibro-acoustography system has been combined with a stereo-tactic x-ray mammography system for *in vivo* breast imaging and has been tested on a number of volunteers. Resulting images show soft tissue structures and microcalcifications within breast with high contrast, high resolution, and no speckles. The results have been verified using x-ray mammograms of the breast. The encouraging results from *in vitro* and *in vivo* experiments suggest further development of vibro-acoustography may lead to a new clinical breast imaging modality. [Work supported in part by a grant from the Susan G. Komen Breast Cancer Foundation. Vibro-acoustography is patented by MF and JFG.]

5aBBb3. Supersonic shear imaging. Mathias Fink, Mickael Tanter, and Jeremy Bercoff (Laboratoire Ondes et Acoustique, ESPCI, 10 rue Vauquelin, 75005, Paris, France)

There is a great interest for developing *in vivo* quantitative imaging of the shear tissue properties. This can be achieved by using an ultrafast ultrasonic imaging device able to follow in real time the propagation of low frequency transient shear wave in the body. We have developed such an ultrafast scanner that can give up to 5.000 images/s. From the spatio-temporal evolution of the elastic field a local inversion algorithm allows to recover the shear modulus and viscosity map without the limitations induced by diffraction. Transient shear sources are induced by ultrasonic radiation pressure generated by the ultrasonic probe array. The most interesting configuration that induces high amplitude shear waves used a sonic shear source that moves at supersonic velocities. *In vitro* and *in vivo* results will be presented that demonstrate the great interest of supersonic shear imaging.

5aBBb4. Shear wave interferometry, an application of sonoelastography. Clark Z. Wu and Kevin J. Parker (Hopeman 204 ECE Dept., Univ. of Rochester, Rochester, NY 14623, wuzhe@ece.rochester.edu)

Sonoelastography is an ultrasound imaging technique where low-amplitude, low-frequency (LF) vibration is detected and displayed via real-time Doppler techniques. When multiple coherent shear wave sources exist, shear wave interference patterns appear. Two shear wave sources at the same frequency create hyperbolic shaped interference patterns in homogeneous, isotropic elastic media. Shear wave speed can be estimated from the fringe separation and the source frequency. If the two sources are driven at slightly different sinusoidal frequencies, the interference patterns no longer remain stationary. It is proven that the apparent velocity of the fringes is approximately proportional to the local shear wave velocity. With this approach, local shear wave speed in elastic media can be estimated. In addition, with a single shear wave source at frequency f and the ultrasound probe externally vibrated at frequency $f - \Delta f$, a novel type of moving interference between the shear waves and the frame of reference motion is created. The moving interference fringes represent the shape of shear wave wavefronts while traveling at a much slower speed. This approach provides a real-time visualization of shear wave propagation and local wave speed estimation from which local stiffness is inferred. [Work supported by NIH.]

5aBBb5. Magnetic resonance elastography. Richard Ehman and Armando Manduca (Depts. of Radiol. and Bioengineering, Mayo Clinic, Rochester, MN 55905)

The goal of our research is to develop MRI-based methods for assessing the mechanical properties of tissues *in vivo*. We have focused on a novel MRI technique for visualizing propagating acoustic shear waves [Science **269**, 1854–1857 (1995)]. Suitable dynamic shear stress for Magnetic Resonance Elastography (MRE) can be generated by surface drivers, inertial effects, acoustic radiation pressure, or endogenous physiologic mechanisms. The MRE acquisition sequence is capable of visualizing cyclic tissue motion of less than 1 micron in displacement amplitude, with imaging times ranging from 100 ms to several minutes. Inversion algorithms based on continuum mechanics are used to process the acquired data to generate maps of mechanical properties such as depict stiffness, viscosity, attenuation, and anisotropic behavior. We have applied MRE to assess specimens of a variety of tissues, ranging in stiffness from lung to cartilage. Human studies have demonstrated that it is feasible to apply MRE to quantitatively image the mechanical properties of skeletal muscles, gray and white matter in the brain, thyroid, kidney, liver, and skin. Our preliminary clinical studies have to date applied MRE to observe changes in tissue mechanical properties in patients with breast, brain, and thyroid tumors, liver fibrosis, and diffuse diseases of skeletal muscle.

10:25

5aBBb6. Microscopic dynamic magnetic resonance elastography. Shadi F. Othman, Thomas J. Royston, and Richard L. Magin (Univ. of Illinois at Chicago, 842 W. Taylor St. MC 251, Chicago, IL 60607)

Microscopic magnetic resonance elastography (uMRE) is a high resolution imaging technique for measuring the viscoelastic properties of small synthetic and biological samples. Mechanical shear waves, typically with amplitudes of less than 100 μm and frequencies of 500–600 Hz, are induced using a piezoelectric oscillator directly coupled to the region of interest. By using multiple phase offsets and motion encoding gradients we acquire data that allows the generation of images that depict shear wave motion and the calculation of local values of the tissue viscoelastic properties. Recent MRE investigations are increasingly being conducted at higher spatial resolution to establish histological correlations between elasticity maps and tissue structures; such microscopic MRE studies require stronger static fields, stronger magnetic field gradients, higher performance RF coils, and more compact, higher frequency mechanical actuators. Microscopic MRE experiments were conducted at 11.74 T in a 54 mm diameter vertical bore magnet with a 10 mm diameter \times 25 mm length cylindrical space available for imaging. The field-of-view ranged from 4 to 14 mm. The study was conducted on agarose gel phantoms of different concentrations ranging from 0.25%–1% w. Different biological samples, including frog oocytes and tissue engineered constructs, were also tested.

10:40

5aBBb7. Coupled vibration and sound radiation from a fluid-filled and submerged or embedded vascular tube with internal turbulent flow due to a constriction. Yigit Yazicioglu, Thomas J. Royston, Todd Spohnholtz, Bryn Martin (Univ. of Illinois at Chicago, 842 W. Taylor St. MC 251, Chicago, IL 60607), Francis Loth (Univ. of Illinois at Chicago, Chicago, IL 60607), and Hisham Bassiouny (Univ. of Chicago, Chicago, IL 60637)

The vibration of a thin-walled cylindrical, compliant viscoelastic tube with internal flow and an axisymmetric constriction that results in turbulent fluid flow is studied theoretically and experimentally. Vibration of the tube is considered with internal fluid-coupling only and with coupling to internal flowing fluid and external stagnant fluid or external tissue-like viscoelastic material. The theoretical analysis includes the adaptation of a model for turbulence in the internal fluid and its vibratory excitation of and interaction with the tube wall and surrounding viscoelastic medium. Theoretical predictions are compared with experimental measurements conducted on a flow model system using laser Doppler vibrometry to measure tube vibration and the vibration of the surrounding viscoelastic medium, as well as miniature hydrophones to measure fluid pressure in the tube. Discrepancies between theory and experiment and the coupled nature of the fluid-structure interaction are highlighted. This study is relevant to and may provide further incite into vascular patency and mechanisms of

failure, as well as diagnostics via noninvasive acoustic measurements. [Work supported by NIH EB002511 and HL55296, and Whitaker Foundation BME RG 01-0198.]

10:55

5aBBb8. A multimode sonic and ultrasonic diagnostic imaging system with application to peripheral vascular characterization. Todd Spohnholtz, Thomas J. Royston, Yigit Yazicioglu, Bryn Martin (Univ. of Illinois at Chicago, 842 W. Taylor St. MC 251, Chicago, IL 60607), Francis Loth (Univ. of Illinois at Chicago, Chicago, IL 60607), and Hisham Bassiouny (Univ. of Chicago, Chicago, IL 60637)

Ultrasound (US) medical imaging technology is enhanced by integrating a simultaneous noninvasive audible frequency measurement of biological sounds that could be indicative of pathology. Measurement of naturally-occurring biological acoustic phenomena can augment conventional imaging technology by providing unique information about material structure and system function. Sonic phenomena of diagnostic value are associated with a wide range of biological functions, such as breath sounds, bowel sounds, and vascular bruits. The initial focus of this multimode technology was to provide an improved diagnostic tool for common peripheral vascular complications that result in transitional or turbulent blood flow, such as associated with arteriovenous (AV) grafts and stenoses in common carotid and other arteries due to plaque buildup. We review: (1) the development the multimode system by combining a commercial US system with a novel sonic sensor array and associated instrumentation, and (2) the evaluation of its capability via controlled phantom models of basic subsurface sound sources/structures, as well as simulations of constricted peripheral blood vessels. [Work supported by NIH EB002511 and HL55296, and Whitaker Foundation BME RG 01-0198.]

11:10

5aBBb9. Characterization of a vibro-acoustography system designed to detect kidney stones during lithotripsy. Neil R. Owen, Michael R. Bailey, and Lawrence A. Crum (Appl. Phys. Lab., University of Washington, 1013 NE 40th St., Seattle, WA 98105)

Acoustic properties of a vibro-acoustography system designed to detect kidney stones were measured. Our system was formed with two spherical transducers (10 cm diameter, 20 cm curvature) in degassed water that were confocal and separated by an angle of 30 degrees. They were driven at 1.1 MHz and 1.125 MHz to generate a difference frequency of 25 kHz. The acoustic field was characterized by scattering from a known target, the curved surface of a steel cylinder with 6.4 mm diameter. Waveforms of both the low and high frequency scattered signals were measured for different target locations, different hydrophone locations encircling the target, and different acoustic pressures. Focal dimensions of the -6 db pressure profile measured at 25 kHz and the fundamental were both 3×10 mm, in an elliptical shape, which is highly localized. Scatter amplitude was rather insensitive to hydrophone position when the target was in the focus, quite sensitive to hydrophone position when the target was out of the focus, and increased linearly with the sum of the sources. It is hoped

that this characterization will help improve the understanding of the mechanisms of the targeting technique. [Work supported by NIH grants DK43881 and DK55674, and NSBRI grant SMS00203.]

11:25

5aBBb10. 3D steady-state ultrasound-elastography. Ralph Sinkus, Jeremy Bercoff, Mickael Tanter, and Mathias Fink (Laboratoire Ondes et Acoustique, 10 rue Vauquelin, 75005 Paris, France)

One of the current main limitations of Elastography is the lack of access to the full displacement field within a volume. Standard ultrasound techniques provide good motion estimation only along the ultrasound beam. These data are subsequently used for the reconstruction of elastic parameters assuming that the missing displacement components are negligible. Although feasible under certain circumstances, these assumptions typically do not hold for in-vivo applications. Thus, there is need for a technique to assess the entire displacement field in 3D. Recently, the 1D motion estimation has been extended to the measurement of the 2D displacement field [Tanter *et al.*, IEEE Trans. Ultrason. Ferroelectr. Freq. Control **49**, 1363–1374 (2002)]. This method is utilized for the assessment of the 3D displacement field by rotating and translating the US-transducer around the object of interest. Low-frequency mechanical vibrations (approx. 80 Hz) are coupled into the object from underneath (i.e., from the direction perpendicular to the plane of rotation). The measured displacement field is used to reconstruct within a volume shear elasticity and shear viscosity by local inversion of the wave equation. Contributions from the compressional wave are removed via application of the curl-operator. In-vitro results for phantoms and excised specimen are presented.

11:40

5aBBb11. Feasibility of shear-mode transcranial ultrasound imaging. Greg T. Clement, P. Jason White, and Kullervo Hynynen (Dept. of Radiol., Harvard Med. School, Brigham and Women's Hospital, Boston, MA 02115, gclement@hms.harvard.edu)

Despite ultrasound's potential to provide a low cost method for imaging blood flow and diagnosing certain brain disorders, distortion and low signal to noise ratios caused by the skull have severely limited the use of existing clinical devices, such as transcranial Doppler sonography. Presently we investigate the potential to propagate ultrasound through the skull with reduced distortion and higher signal amplitudes by using high incident angles. In such cases the ultrasound angle of entry is set beyond Snell's critical angle for the longitudinal pressure wave, so that propagation in the bone is purely due to a shear wave. This wave then converts back to a longitudinal acoustic wave in the brain. This conversion from a longitudinal wave (skin) to a shear wave (skull) and again to a longitudinal wave (brain) does not necessarily produce a highly distorted or small-amplitude wave. Basic images and measurements of shear speed-of-sound and attenuation values for *ex vivo* human skull bone will be presented for frequencies between 0.25 MHz and 2 MHz. Similar measurements with porcine samples will also be shown, indicating the large discrepancy between shear characteristics of the two species; the porcine samples showing no detectable shear mode.

5aMU1. Acoustical considerations in the design—and re-design—of the violin. Joseph Curtin (Joseph Curtin Studios, 3493 W. Delhi, Ann Arbor, MI 48103, violins@josephcurtinstudios.com)

The violin is a highly evolved instrument which has long resisted significant changes to its design and construction. Still, acoustical research over the past several decades has shed sufficient light on the workings of the violin that makers can now consider non-traditional approaches to their craft in order to optimize the sound, playability, and consistency of their instruments. The work of researchers such as Duenwald, Haines, Hutchins, and Weinreich will be considered in terms of its usefulness as a guide to building better violins.

8:40

5aMU2. The violin octet and bowed string instrument design. George Bissinger (Phys. Dept., East Carolina Univ., Greenville, NC 27858)

Modal analyses were combined with room-averaged acoustic measurements of a complete octet to assess Schellengs fundamental scaling design assumptions: similarity of shape and flat plate scaling. The scaling employed only the two lowest strongly radiating violin resonances, the main air $A0$ and main wood comprised of the first corpus bending modes $B1^-$ and $B1^+$. $A0$ fell below the desired pitch placement ($1.5\times$ lowest string pitch), while the $B1$ complex generally straddled the desired placement at $2.25\times$. Difficulties in properly scaling $A0$ derived partly from an unreliable theory that failed to incorporate $A0$ coupling to $A1$ (first length-wise cavity mode), and partly from inability to incorporate cavity wall compliance. Wall compliance dropped $A1$ into main wood region even though larger instruments were designed successively shorter; the $A1/A0$ frequency ratio rose from ~ 1.5 to ~ 2.0 (smallest to largest). Modern models sensitive to cavity shape predict $A0$ and $A1$ within $\sim 10\%$ over the octet, ranging over $\sim 4.5:1$ in length, $\sim 10:1$ in f -hole area, $\sim 3:1$ in top plate thickness, and $\sim 128:1$ in volume. $A0$ radiates strongly over the octet, while surprisingly $A1$ is the dominant radiator in the main wood region for the large bass even though $A1$ was never included in the scaling.

9:05

5aMU3. The acoustics of hammered dulcimers. David R. Peterson (Dept. of Mathematics, Univ. of Central Arkansas, Conway, AR 72035, DavidP@uca.edu)

The hammered dulcimer, a stringed instrument played with two wooden hammers, probably originated in the Middle East, but it has become part of the musical culture of many countries. In the U. S., the folk revival in the 1970's sparked renewed interest in the hammered dulcimer as a concert instrument. Today, despite some consolidation in the retail market, there are still hundreds of builders, mostly amateurs, who experiment with the basic design. The most important design parameters will be discussed from a practical and acoustical point of view: soundboard size, shape, and composition, internal bracing, bridge shape, string arrangement and composition, hardness of bridge caps, hammer weight and stiffness, instrument resonances due to the unique string splitting and stiffness of the body, and soundboard modes.

9:30

5aMU4. Classical guitar construction: The acoustician's tale. Bernard E. Richardson (School of Phys. and Astron., Cardiff Univ., 5 The Parade, Cardiff CF24 3YB, UK, RichardsonBE@cardiff.ac.uk)

The vast majority of guitars produced today are built according to general principles laid down in the nineteenth century. Nevertheless, the devil is in the detail, and innovative makers constantly reappraise the design and construction of instruments in their endeavors to control quality or to seek "improvement." The maker's approach, necessarily, tends to be pragmatic, but it is one which can be greatly informed by the application of relatively simple acoustical models. This paper will examine various important design aspects—for example choice of materials, body size, strutting, soundboard thickness—introducing the basis for making informed decisions.

9:55

5aMU5. Normal modes of a single mandolin with different bracing patterns installed. David J. Cohen (Cohen Musical Instruments, 9402 Belfort Rd., Richmond, VA 23229) and Thomas D. Rossing (Northern Illinois Univ., DeKalb, IL 60115)

The vibrational modes and sound spectra of a single archtop mandolin constructed with a removable back plate were studied with different bracing patterns installed. The bracing patterns were (i) symmetric and (ii) asymmetric parallel “tone bars,” (iii) X-bracing, and (iv) an asymmetric pattern previously used and studied [D. Cohen and T. D. Rossing, *Can. Aeronautics Space, J.* **4**(2), 48–54 (2000), D. Cohen and T. D. Rossing, *Acoust. Sci. Tech.* **24**, 1–6 (2003)]. The results have been compared with those obtained previously for vintage mandolins [D. Cohen and T. D. Rossing, “Normal modes of different types of pre-1929 mandolins,” presented at the 147th meeting of the Acoustical Society of America, New York, NY (2004)] and for mandolins constructed more recently. As was the case for the different types of vintage mandolins, changing the bracing pattern has little effect on the shapes of the normal modes, but does affect the frequencies of the normal modes. The X- or crossed bracing pattern imparts more cross-grain stiffness than the other bracing patterns, with the result that modes involving cross-grain bending occur at higher frequencies than is the case for the other bracing patterns.

10:30

5aMU6. Design aspects of the five string banjo. James Rae (Dept. Physio. and Biomed. Eng., Mayo Clinic College of Medicine, 200 First St. SW, Rochester, MN 55905, rae.james@mayo.edu) and Thomas Rossing (Northern Illinois Univ., DeKalb, IL 60115)

The five string banjo is a stringed instrument that uses a drum head (membrane) to radiate sound. The strings couple to the head through a moveable bridge. Many have a removable resonator whose spacing from the main part of the banjo is adjustable to allow tuning of the internal air cavity. Holographic interferometry demonstrates vibrational modes of the head that have a strong dependence on head tension. Driving point acceleration measurements demonstrate that the ability of the bridge to be vibrated depends on the mass and stiffness of the materials used in its construction. Peak accelerances usually occur between 1800–2000 Hz. Power spectra measurements of the sound show that 99% of the sound is in a frequency range of 147–5200 Hz. Two substantial formants are seen in the power spectra. The first and largest occurs in about the 400–1800 Hz range, the same frequency range where the most substantial head modes are found. The second is from 2000–4000 Hz, a range where the series combination of bridge and head show increasing accelerances by driving point measurements. Measurements of the transient response following a pluck quantify the frequency content of the rising and falling phase.

10:55

5aMU7. Tuning the lower resonances of carved Baltic psalteries by adjusting the areas of the sound holes. Andres Peekna (Innovative Mech., Inc., 5908 N River Bay Rd., Waterford, WI 53185) and Thomas D. Rossing (Northern Illinois Univ., De Kalb, IL 60115)

Previous work has shown that with carved Baltic psalteries it is highly desirable to have a body-resonance with high radiating efficiency between the keynote and the tone above. In many cases, it is also desirable to have a body-resonance close to the low dominant. The frequencies of the two lowest body-resonances can be adjusted, to some extent, by adjusting the areas of the sound holes. We describe two trials. In one case, the instrument started out with no sound holes, and their areas were increased step by step, mostly according to listening trials, but the results were also verified by electronic TV holography. In the second case, the instrument started with excessive sound hole area. In this case, the listening tests first determined the extent of sound holes to be covered by sufficiently stiff material. The findings were subsequently confirmed by electronic TV holography. In both cases, a point was reached below which (smaller areas) the sound quality became less bright and more dull, and above which the sound quality was perceived as good. In each case, an optimum was reached.

11:20

5aMU8. Harp design and construction. Chris Waltham (Dept. of Phys. & Astron., Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z1, waltham@physics.ubc.ca)

The harp is an instrument with a set of plucked strings connected directly to the sound board. Thus the requirement that the sound board be very light for efficient radiation is pitted against the requirement that the strings be tight enough to maintain harmonicity. These factors have determined the evolution of the harp since Sumerian times. As materials and construction methods have improved, strings have become tighter and sound boards lighter. Large harps have total tensions in the range of ten kilonewtons. The material of choice for the sound board, usually spruce, is pushed to the limits of its strength, and even professionally built concert harps tend not to last more than a few decades. The strings themselves are made from a variety of materials, wrapped or plain, to balance the physical requirements of tension and feel, with the acoustical demands of harmonicity and tone. Historical materials such as copper and silk have given way to steel and nylon, although gut still has a niche in the mid-range of a concert harp. These physics and engineering issues will be considered in the context of practical harp construction.

11:45

5aMU9. The motion of harp strings. Gary Chan and Chris Waltham (Dept. of Phys. & Astron., Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z1)

The harp is an instrument with a set of plucked strings that excite the sound board directly, without the medium of a bridge. The strings are

positioned at an acute angle to the plane of the sound board. The quality of the sound produced depends on the motion of the string and its interaction with the resonances of the sound board. The string and sound board motions of small and large harps have been studied using small, fast position sensors. The results are compared to those of a simple non-linear model based on the measured elastic properties of the string materials, and those of the sound board. The implications for the sound production are discussed.

5aNS1. Assessing multi-source noise environments with an “equally annoying” exposure summation model. Paul Schomer (Schomer and Assoc., Inc., 2117 Robert Dr., Champaign, IL 61821)

Miedema [J. Acoust. Soc. Am. **116**, 949–957 (2004)] posits an “equally annoying” energy summation model for assessing annoyance in areas exposed to multiple differing noise sources. His “proof” is a theorem. Since his model fits the requirements of the theorem, he states that this “proves” that his model is correct. While it may be true that meeting the conditions of the theorem is a necessary condition, it is not a sufficient condition. From a psycho-acoustical standpoint, the Meidema model is very complex and not really believable. Moreover, it fails to address differences between types of aircraft, types of operation, types of motor vehicle, etc. An “equally annoying” exposure summation model, presented here, is psycho-acoustically much simpler and better satisfies the same theorem conditions because it better satisfies the independence requirement.

8:55

5aNS2. Neural network analysis of soundscape in urban open spaces. Lei Yu and Jian Kang (School of Architecture, Univ. of Sheffield, Western Bank, Sheffield S10 2TN, UK, j.kang@sheffield.ac.uk)

The physical and social environments of open spaces in a city influence people's behavior as well as their perception of the city. Soundscape is an important component of an open urban space, and key aspects for producing a good soundscape include its description, evaluation, and design. In this research, an artificial intelligent system is being developed for the analysis of soundscape evaluation in urban open spaces. The system considers acoustic factors including the level, type and spectrum of sound sources and the reflection effects of an urban space; users social and demographic factors; and other physical and environmental factors including urban morphology, microclimate conditions, and thermal and visual comfort. Since 2001 a large scale social survey has been carried out in England, Switzerland, Italy, Greece, Germany and China. Correspondingly, a database suitable for artificial neural networks (ANN) modeling has been established. Simulating biological brains, ANN are simplified models of the central nervous system, which have the ability to respond to input stimuli and to learn to adapt to the environment. The software Qnet is being used, and initial results suggest that there is a good convergence of using ANN to predict peoples perception of soundscape in urban open spaces.

9:15

5aNS3. Soundscape assessment. Osten Axelsson, Birgitta Berglund, and Mats E. Nilsson (Inst. Environ. Medicine, Karolinska Inst. and Dept. Psych., Stockholm Univ., SE-10691, Stockholm, Sweden)

In order to improve the quality of the soundscape it is necessary to know its descriptive and evaluative properties, and the relationships between these properties. This was explored in a listening experiment with 100 participants (48 women, 52 men; mean age 25.6 years). Each participant scaled 5 out of 50 soundscapes with regard to 116 single verbal attributes, using a visual analogue scale of agreeableness. In addition, acoustical properties of the soundscapes were assessed. A principal component analysis identified

two major evaluative components, labeled Hedonic Tone and Eventfulness. Furthermore, it was found the mere presence of common sound sources, regardless of sound level, correlated significantly with these evaluative components. Technological sounds (e.g., traffic noise) were negatively associated with both Hedonic Tone and Eventfulness, while a positive association was found between Hedonic Tone and sounds of nature (e.g., bird song), and a positive association was found between Eventfulness and human sounds (e.g., human voices). These relationships lead to the hypothesis that introduction of nature and human sounds, in combination with the reduction of technological sounds may improve the quality of soundscapes considerably.

9:35

5aNS4. Assessment of outdoor soundscapes in quiet areas. Mats E. Nilsson and Birgitta Berglund (Inst. of Environ. Medicine, Karolinska Inst. and Dept. of Psych., Stockholm Univ., SE-106 91, Stockholm, Sweden)

Existing quiet outdoor areas should be preserved. Appropriate indicators and limit values are needed, which are grounded in knowledge on positive aspects of soundscapes, such as perceived pleasantness and psychological restoration. For this reason, a questionnaire study was conducted in four green areas close to a major city and in four city parks. Measured equivalent sound levels (LAeq, 15 min) ranged between 42 and 50 dBA in the green areas, and between 49 and 60 dBA in the city parks. Sounds from nature, such as bird song, completely dominated the soundscape in the green areas. The city-park soundscapes were more complex, containing sounds from nature, as well as technological sounds (e.g., traffic noise), and human sounds (e.g., human voices). In general, sounds from nature were perceived as pleasant, technical sounds as annoying, and human sounds as neutral. Between 84 and 100% of the visitors in the green areas assessed the soundscapes as good or very good. The corresponding percentages for the city parks were distinctly lower, between 52 and 65%. The results indicate that the equivalent sound level should be below 50 dBA in order to secure pleasant and restorative outdoor soundscapes in urban areas.

9:55–10:15 Break

10:15

5aNS5. Techniques of analysis and their applicability in the context of community noise. Andre Fiebig and Brigitte Schulte-Fortkamp (ITA-Tech. Univ. Berlin, Einsteinufer 25, D-10587 Berlin, Germany)

There is common consent to the necessity using and combining subjective and objective data for a sufficient understanding of human perception and evaluation of noise. Moreover, a wide discussion about methodology and techniques of analysis with respect to new methods in the context of soundscape research, community noise, and annoyance evaluation is urgently needed. The presentation at hand shows a methodological discussion of qualitative data and its systematic analysis based on explorative approaches applied in two different surveys. For example, by means of the analysis a transfer from verbal evaluations based on habitual language to acoustical descriptors is possible. Furthermore, the principals and steps of the analysis of qualitative data in the context of community noise are presented. Insofar, with regard to an effective and unitized handling, options and possibilities of methods in connection with specific techniques of analysis will be discussed.

10:35

5aNS6. Correlation of airport noise complaint terminology with available noise metrics. Nancy S. Timmerman (Consultant in Acoust. and Noise Control, 25 Upton St., Boston, MA 02118-1609)

In the discussion of airport noise, there is a disconnect between the language used by complainants and the acoustical terminology available to the technical community. It will be shown in what ways the complaint terminology can be described with the available noise metrics and in what ways it cannot. The complaint terminology analyzed comes from the author's personal (previous) experience as noise control officer at Logan International Airport. Examples of some of these are (aircraft noise is): too loud, too late, too early, unending, continuous, at the wrong time, so loud it sets off car alarms, so loud I cannot hear the TV/telephone/radio, so loud it woke me up, and annoying. Terms which are not related to noise are mentioned, but not correlated. The acoustical terminology comes from the international literature and includes the standard noise metrics as well as some more recently proposed. The airport noise metrics discussed include measures of single events (maximum level, SEL, duration, signal-to-noise) and measures of noise exposure (DNL, CNEL, Leq). It is shown that while cumulative noise metrics are useful for planning and comparison, they correlate with complaint terminology less well than single event measures.

10:55

5aNS7. Explorative interviews as a tool for sound evaluation. Stephan Paul (Lab. of Vib. and Acoust., Dept. of Mech. Eng., UFSC, CxP 476 Florianopolis, 88.040-900 SC, Brazil)

Sound and noise evaluation needs to combine physical-measurements of sound with research on the interaction of the sound and the human being. For this kind of research qualitative techniques and especially explorative interviews, with the addressed people are appropriate as they consider the human being acting within this environment. The evaluation process refers to the basic concepts of qualitative research. Different forms of interviews, how to prepare and conduct an interview and not to forget about the discipline under investigation have to be considered. This clearly shows the requirement of transdisciplinarity including knowledge from disciplines like engineering sciences, social sciences and psychology. To obtain the required information on the subject under investigation within an interview the verbal ability of the addressed people has to be considered. The possibilities of transdisciplinary work, check of verbal abilities as well as approaches for basic standardization in interviews and the need for cultural adaptation will be discussed.

11:15

5aNS8. Digital identification of intrusive noise: Pilot study to digitally characterize soundscapes and intrusion. Tim Lavallee (LPES, Inc., 14053 Lawnes Creek Rd., Smithfield, VA 23430), Robert Kull (Parsons, Norfolk, VA 23502), and Brigitte Schulte-Fortkamp (ITA/TU-Berlin, Einsteinufer 25, D-10587 Berlin, Germany)

One of the difficulties with soundscape investigation and the definition of intrusion is the need for an individual to manually identify and log specific acoustical events. Event logging can be labor intensive, costly, and difficult to standardize. If information about physical setting and in situ acoustical signatures can be used to define a given soundscape, event logging could possibly be performed digitally and intrusion could be defined based on the spectral fingerprint of a given soundscape. Two soundscapes with different settings and acoustical signatures were identified. Sound time histories and periodic third octave spectra were measured over a given period. An individual manually logged acoustical events. Independently, algorithms to identify both normal and acoustically intrusive events for the given soundscape were applied to the data. The digitally identified events were compared to the manually taken event log. An evaluation of the results will be presented.

11:35

5aNS9. Evaluation of sound environment characteristics: Comparative study between objective and subjective criteria. Francoise Chartier and Catherine Semidor (GRECO, EAPBx, Domaine de Raba F-33400 Talence, France, catherine.semidor@bordeaux.archi.fr)

The evaluation of urban sound environment quality depends on quantitative information as well as the opinion of city dwellers. In order to underline the relation between objective and subjective points of view, a comparative study was carried out. The subjective survey consisted in listening to several binaural sound recordings of very short extracts from the urban scene, called "sonoscene." During these sessions, the listeners' opinions were noted. The binaural sound recordings are performed in accordance with the "soundwalk" method explained in previous papers [C. Semidor, ASA 2004, ASA 2005]. The same binaural sound recordings were analyzed in form of objective criteria such as Equivalent Sound Level, Loudness, Roughness, etc. This paper deals with the comparison between some of these objective criteria and subjective judgments such as Lack or Presence of traffic noise, Lack or Presence of human activities, Spatial Dimension, Attractiveness or Annoyance, etc. These first results point out some significant correlations between Loudness and Attractiveness for example, according to the nature of the sound sources (traffic, human activity).

Contributed Papers

8:00

5aPAa1. Long-range excitation of vibrational response in landmines with Rayleigh and Love waves. Thomas Muir (Natl. Ctr. for Physical Acoust., Univ. Mississippi, One Coliseum Dr., University, MS 38677)

An experiment was conducted in a clay soil at a range of 25 m from two types of electromagnetic shaker sources, operating in a cw pulse mode centered at 100 Hz. The sources were in co-located arrays, one vertically oriented to generate Rayleigh waves and another transversely oriented to generate Love waves. Two cylindrical landmine targets were used: an unloaded (empty) plastic shell, and a metal shell, loaded with paraffin to simulate an explosive. These target types represent extreme variations in what could conceivably be encountered. The targets were instrumented with three-axis seismometers and accelerometers, and were also viewed with a laser Doppler vibrometer (LDV). Data were acquired on both mine cases in various stages of deployment, including sitting upon the ground surface, snugged in to a tight hole in the ground, and completely buried some 5 cm beneath the surface. The responses of the mine cases to Rayleigh and Love wave excitation were measured and compared to data from a reference seismometer deployed nearby, on natural, undisturbed soil. The mine case responses to these seismic excitation fields, under a number of conditions are presented and discussed. [Work supported by the U.S. Marine Corps Systems Command.]

8:15

5aPAa2. Influence of buried objects on the dynamic nonlinearity of inhomogeneous materials. Keith Attenborough, Qin Qin (Dept. of Eng., Univ. of Hull, Hull HU6 7RX, UK), Jonathan Jefferis, and Gary Heald (DSTL, Fort Halstead, Kent, UK)

Donskoy *et al.* [J. Acoust. Soc. Am. **111**, 2705–2714 (2002)] and Korman *et al.* [J. Acoust. Soc. Am. **116**, 3354–3369 (2004)] have shown that the nearby presence of compliant buried objects results in a significant nonlinear response in the spectrum of surface vibration induced by acoustic excitation. The latter have suggested that there is a strong connection with the inherent Nonlinear Mesoscopic Elasticity (NME) of inhomogeneous materials. Laboratory experiments are reported that investigate the comparative NME of granular and fibrous materials and the variation observed between several states of a single material (sand) subject to high sound pressure levels in the frequency range 100 Hz to 2 kHz. Fiberglass and gravel are shown to have strong inherent nonlinearity whereas wet compacted sand has relatively little. In both two-tone and single tone experiments, it is shown that, the presence of buried objects may enhance or reduce the inherent NME of the embedding medium. In cases where the NME is enhanced, compliant buried objects have a greater effect than relatively stiff objects. [Work supported by DSTL, UK.]

5aPAa3. Investigation of the applicability of microphones to nonlinear acoustic mine detection. Douglas Fenneman and Brad Libbey (U.S. Army RDECOM CERDEC Night Vision and Electronic Sensors Directorate, 10221 Burbeck Rd., Fort Belvoir, VA 22060)

The feasibility of using microphones to measure intermodulation effects above a buried mine is under investigation at the U.S. Army RDECOM CERDEC Night Vision and Electronic Sensors Directorate. Acoustic mine detection techniques employ acoustic energy to excite soil and buried mines. The resultant linear and nonlinear response at the surface can then be measured using non-contacting vibrometers. Carrier signal scattering by rough surfaces, however, can limit the measurement accuracy of these vibrometers and, subsequently, successful detection of the landmine. A microphone is proposed as an alternative non-contact sensor specifically for nonlinear acoustic mine detection applications. In this scenario, distinct frequency content facilitates separation of the intermodulation effects at the surface from the acoustic excitation. Experimental results employing intermodulation effects for acoustic mine detection have been reported in the literature [Donskoy *et al.*, *J. Acoust. Soc. Am.* **111**, 2705–2714 (2002)]. Preliminary experimental results demonstrate the ability of microphones to sense pressure radiated from soil in the presence of realistic ground velocities. The applicability of these measurements to practical mine detection systems will also be addressed.

5aPAa4. Application of time-reversal focusing in elastic wave propagation to buried object detection. Pelham D. Norville and Waymond R. Scott, Jr. (School of Elec. and Comput. Eng., Georgia Inst. of Technol., 777 Atlantic Dr., Atlanta, GA 30332-0250)

Time-reversal focusing is a technique for focusing energy both spatially and temporally to a single desired point. First studied in fluid media, additional studies have demonstrated the applicability of time-reversal focusing to solid media and elastic wave propagation. A significant difference between time-reversal and other focusing methods is time-reversal focusing immunity to the variation of wave speeds and the effects of scattering objects within the medium. In the detection of buried objects, this feature is paramount where wave speed variations and clutter are common in the region to be searched. The effectiveness of time-reversal focusing is investigated for a variety of configurations of scattering objects. Fields of uniform objects are examined as well as distributions of randomly shaped clutter, and changes in the propagation medium. Both experimental and three-dimensional numerical results are presented. In previous studies, a phenomenon of super-resolution caused by high-order scattering has been observed where focusing exceeds the diffraction limits of the excitation array. The extent of super-resolution is evaluated for the various configurations of scattering objects in an elastic medium. [Work supported by ARO.]

5aPAa5. Nonlinear acoustic experiments involving landmine detection: Connections with mesoscopic elasticity and slow dynamics in geomaterials, Part II. Murray S. Korman (Phys. Dept., U.S. Naval Acad., Annapolis, MD 21402) and James M. Sabatier (Univ. of Mississippi, University, MS 38677)

In nonlinear acoustic detection, airborne sound at two primary tones, f_1, f_2 (chosen several Hz apart from resonance) insonifies the soil surface over a buried landmine, and due to soil wave interactions with the landmine, a scattered surface profile can be measured by an LDV. Profiles at $f_1, f_2, f_1 - (f_2 - f_1)$ and $f_2 + (f_2 - f_1)$ exhibit a single peak while profiles at $2f_1 - (f_2 - f_1), f_1 + f_2$ and $2f_2 + (f_2 - f_1)$ are attributed to higher order mode shapes. The lowest resonant frequency for a VS 1.6 plastic, inert, anti-tank landmine, buried at 3.6 cm deep is ~ 125 Hz. The “on target” to “off target” contrast ratio, for some of the nonlinearly generated combination tones, is roughly 15–20 dB higher compared to either primary component. Near resonance, the bending (softening) of a family of increasing amplitude tuning curves, involving the surface vibration over the landmine, exhibits a linear relationship between the peak particle velocity

and corresponding frequency. The tuning curves exhibit hysteresis effects. Landmine-soil vibrations exhibit similar characteristics to nonlinear mesoscopic/nanoscale effects that are observed in geomaterials like rocks or granular materials. Nonlinear mechanisms of soil and the soil interacting with the top-plate of the mine case are compared. [Work supported by U.S. Army RDECOM CERDEC, NVESD.]

5aPAa6. Time-dependent finite-element model for optimizing source array element position and excitation for a seismic sonar for buried mine detection. Anthony N. Johnson (CPT, U.S. Army, and Dept. of Mathematics, Naval Postgrad. School, Monterey, CA 93943), Clyde L. Scandrett (Naval Postgrad. School, Monterey, CA 93943), and Steven R. Baker (Naval Postgrad. School, Monterey, CA 93943)

A three-dimensional (3-D) continuum mechanics approach to the development of a time-dependent finite-element model for optimizing the position and excitation of source array elements for use in a seismic sonar to detect buried landmines is presented. Mathematical formulation of the problem consists of the coupling of a system of linear, second order, partial differential equations and related boundary conditions into one single wave equation, from which a composite elastic finite element is derived. The *hp*-adaptive finite-element kernel, ProPHLEX [Altair Engineering, Inc., McKinney, TX], is used to perform the numerical computations. The radiation characteristics of a discrete number of transient seismic sources are analyzed in a linear, isotropic, homogeneous half-space. Results for radial and vertical radiation fields, and for radiated Rayleigh wave strength will be presented for various source configurations. Particular attention will be paid to those configurations which maximize the radiation of unidirectional Rayleigh waves, while suppressing the radiation of unwanted body waves.

5aPAa7. Deduction of ground impedance using level difference measurements. Shahram Taherzadeh (Faculty of Technol., The Open Univ., Milton Keynes MK7 6AA, England) and Keith Attenborough (Univ. of Hull, Hull HU6 7RX, England)

Previously, a numerical method for deducing ground-surface impedance from measurements of complex excess attenuation spectra was reported [*J. Acoust. Soc. Am.* **105**, 2039–2042 (1999)]. Subsequent applications have predicted unrealistic values at low frequencies. Here, we report improved results using two-microphone, transfer-function measurements and discuss its merits as opposed to measuring excess attenuation in regards to a free field. Furthermore, effects of errors in measured parameters on the deduced impedance are discussed also.

5aPAa8. Comparison of two mapping methods for computing sound propagation over irregular terrain. Xiao Di (Appl. Res. Lab., Penn State Univ., University Park, PA 16804, xxd1@psu.edu) and Kenneth E. Gilbert (Univ. of Mississippi, University, MS 38677)

This paper compares a piecewise linear mapping and a cascaded conformal mapping for computing sound propagation over irregular terrain using the parabolic equation (PE) approximation. Although the piecewise linear mapping does not preserve the form of the underlying Helmholtz equation (i.e., it is not conformal), it does preserve the form of the narrow-angle PE. Further, it is shown that the correct impedance boundary condition at the ground surface can be closely approximated with the piecewise linear mapping. Compared to the cascaded conformal mapping, the piecewise mapping is extremely simple and easy to implement. It involves only a phase multiplication at the end of each range step. To test the accuracy of the piecewise linear mapping, it is compared with a cascaded conformal mapping for propagation over a single hill at various frequencies. Propagation predictions for more general terrain using the piecewise linear mapping are presented and discussed. [Work supported by the Federal Aviation Administration.]

10:30

5aPAb1. Clayton H. Allen's discovery of nonlinear acoustic saturation. David T. Blackstock (Appl. Res. Labs. and Dept. Mech. Eng., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029)

In 1950 Clayton H. Allen (1918–2004) discovered nonlinear acoustic saturation. His Penn State doctoral thesis, "Finite Amplitude Distortion in a Spherically Diverging Sound Wave in Air," is about experiments on intense sound produced by a 12.2-cm diameter baffled piston vibrating at 14.6 kHz. At $r=3.8$ cm (the next-to-last nearfield peak) the maximum SPL produced was 161 dB (re $20 \mu\text{Pa}$). The farfield began at about 50 cm. Measurements were made of the fundamental and 2nd–6th harmonics out to $r=200$ cm. His received level versus source level curves at $r=200$ cm show the now familiar plateau that is reached as nonlinear effects limit the achievable SPL for a given distance at a given frequency. Clay's discovery is quite remarkable because (1) it was totally unexpected and (2) it came long before any theoretical predictions of the phenomenon were developed. Alas, however, the work was never published except in the Army Signal Corps report from Penn State, "Atmospheric Physics and Sound Propagation, Final Report for Period July 1, 1945 to May 20, 1950," and in two papers presented orally at the Penn State ASA Meeting in June 1950. As a result, Clay's remarkable work has gone unappreciated for many years. This presentation is dedicated to his memory.

5aPAb2. Nonlinear enhancement and saturation phenomena in focused ultrasound beams of various geometry. Vera A. Khokhlova, Marina S. Basova (Dept. of Acoust., Faculty of Phys., Moscow State Univ., Moscow, Russia), Michael R. Bailey, and Lawrence A. Crum (Univ. of Washington, Seattle, Washington)

The effects of nonlinear enhancement of focusing gain and saturation are studied and compared for high-intensity focused ultrasound sources with an initial Gaussian shading and uniform amplitude distribution. Simulations are performed using the Khokhlov Zabolotskaya (KZ) nonlinear parabolic equation for weakly dissipative medium in a wide range of source linear focusing gains and source pressure amplitudes, including the strongly nonlinear regime with shocks. An artificial absorption proportional to the fourth power of frequency or an asymptotic frequency-domain approach is employed in the algorithm in order to reduce the number of harmonics for accurate modeling of strongly distorted waveforms with shocks. The effect of focusing gain and amplitude shading of the source on nonlinear enhancement of acoustic energy concentration and saturation levels at the focus is discussed. It is shown that nonlinear enhancement of focusing gain is different for different values of linear gain, different spatial distributions of the source amplitude, and different parameters of acoustic field. The levels of nonlinear saturation at the focus are obtained for very high source amplitudes. The results of simulations give lower enhancement and higher saturation levels compared to the known approximate analytic predictions. [Work supported in part by NIH Fogarty and NSBRI.]

5aPAb3. Numerical simulation of nonlinear phenomena using a dispersion-relation-preserving solution of the Navier-Stokes equations. Mark S. Wochner and Anthony A. Atchley (Grad. Program in Acoust., The Penn State Univ., 217 Appl. Sci. Bldg, University Park, PA 16802)

A modified Navier-Stokes equation set that includes classical absorption and molecular relaxation is solved using a fourth-order Runge-Kutta scheme in time and a fourth-order dispersion-relation-preserving algorithm in space. The algorithm is applied to examine nonlinear phenomena such as waveform evolution of a high amplitude sine wave to old age, shock coalescence, and evolution of arbitrary time waveforms. The results are compared to analytical solutions whenever possible. The drawbacks of such an approach are discussed along with possible solutions to problems associated with the numerical method.

11:15

5aPAb4. Parabolic approximation versus geometrical acoustics for describing nonlinear acoustic waves in inhomogeneous media. Vera A. Khokhlova, Mikhail V. Averianov (Dept. of Acoust., Faculty of Phys., M. V. Lomonosov Moscow State Univ., Leninskie Gory, Moscow 119992, Russia), Robin O. Cleveland (Boston Univ., Boston, MA 02215), and Philippe Blanc-Benon (Ecole Centrale de Lyon, 69134 Ecully Cedex, France)

Propagation of intense periodic acoustic waves in inhomogeneous media is studied in the nonlinear geometrical acoustics (NGA) approximation and using nonlinear parabolic equation (NPE). Various types of 2-D inhomogeneities are considered, such as a phase screen, single Gaussian inhomogeneities, and random inhomogeneous media. Distributions of acoustic rays are obtained by numerical solution of the eikonal equation. Pressure field patterns are calculated numerically with account for nonlinear effects and diffraction using a frequency-domain algorithm for the NPE. The location of caustics and shadow zones in the ray patterns are compared with the results of the parabolic model for the areas of increased and decreased sound pressure. Both linear and nonlinear propagation is investigated in order to reveal the validity of NGA in predicting the acoustic field structure and to better understand how the combined effects of inhomogeneities, diffraction, and nonlinearity determine the overall peak and average parameters of the acoustic field. It is shown that NGA does not accurately represent all the locations of enhanced or reduced acoustic pressure even for single scattering inhomogeneities, and the discrepancies become larger for smaller size inhomogeneities and at longer distances in random inhomogeneous medium. [Work supported by CNRS, RFBR, and NIH Fogarty.]

5aPAb5. Measurements of the rate of change of the power spectral density due to nonlinearity in one-dimensional propagation. Lauren E. Falco, Kent L. Gee, and Anthony A. Atchley (Grad. Program in Acoust., Penn State Univ., 217 Appl. Sci. Bldg., University Park, PA 16802-5018)

The influence of nonlinear effects in the propagation of jet noise is typically characterized by examining the change in the power spectral density (PSD) of the noise as a function of propagation distance. The rate of change of the PSD is an indicator of the importance of nonlinearity. Morfey and Howell [AIAA J. **19**, 986–992 (1981)] introduced an analysis technique that has the potential to extract this information from a measurement at a single location. They develop an ensemble-averaged Burgers equation that relates the rate of change of the PSD with distance to the quantity Q_{p^2p} , which is the imaginary part of the cross-spectral density of the pressure and the square of the pressure. Despite its potential applicability to jet noise analysis, the physical significance and utility of Q_{p^2p} have not been thoroughly studied. This work examines Q_{p^2p} for the one-dimensional propagation of plane waves in a shock tube. The use of such a simple, controlled environment allows for a better understanding of the significance of Q_{p^2p} . [Work supported by the National Science Foundation, the Office of Naval Research, and the Strategic Environmental Research and Development Program.]

5aPAb6. Nonlinear standing waves in shaped resonators driven by a piston. Cheng Luo, Xiaoyang Huang, and Nam Trung Nguyen (School of Mech. and Production Eng., Nanyang Technolog. Univ., 50 Nanyang Ave., Singapore 639798)

The nonlinear standing waves in a shaped resonator driven by a piston are investigated analytically and experimentally. In the study, the resonator is an exponentially expanded horn with a piston oscillating at its large end. The air pressure waves inside the resonator are obtained by solving a 1-D nonlinear wave equation with the Galerkins method, taking into account the moving boundary due to the piston. The simulation results, in terms of the pressure waveforms, the pressure amplitudes, and the resonance frequency shift, show that the nonlinear standing waves generated by the piston have characteristics similar to those in the same resonator but under entirely shaking condition. The experiment is also conducted on an exponentially expanded resonator. The small end of the resonator is sealed and the big end is connected to a 5-inch 40 W loudspeaker, functioned as the driving piston. The resonance frequency shift is observed, and high amplitude pressures, up to 0.3×10^5 Pa, have been detected at the small end, which is 20 times higher than that at the big end. The experimental results agree well with the simulated values.

FRIDAY MORNING, 20 MAY 2005

REGENCY C, 8:00 A.M. TO 12:00 NOON

Session 5aPP

Psychological and Physiological Acoustics: Auditory Perception and Psychophysics II (Poster Session)

Neal F. Viemeister, Chair

Dept. of Psychology, Univ. of Minnesota, 75 East River Rd., Minneapolis, MN 55455

Contributed Papers

All posters will be on display from 8:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:00 a.m. to 10:00 a.m. and contributors of even-numbered papers will be at their posters from 10:00 a.m. to 12:00 noon.

5aPP1. Sensitivity to stimulus distribution characteristics in auditory categorization. Sarah C. Sullivan (Dept. of Psych., Univ. of Texas, Austin, TX 78712-0187), Andrew J. Lotto (Boys Town Natl. Res. Hospital, Omaha, NE 68131), Elizabeth T. Newlin, and Randy L. Diehl (Univ. of Texas, Austin, TX 78712-0187)

Several experiments were performed to examine the ability of humans to categorize sounds as a function of training distribution characteristics. Participants were presented non-speech sounds randomly sampled from two overlapping distributions. The sounds consisted of 25 narrow-band noise bursts varying in center frequency from 1000–1360 Hz. Two conditions were created by varying the ratio of stimuli in each category (i.e., prior probabilities of each category), resulting in different ideal boundaries (maximizing accuracy). Participants were asked to categorize the sounds as either *A* or *B* and feedback was provided. In one experiment, prior probabilities were altered mid-session without alerting the subjects. Performance was tracked by plotting identification functions and noting boundary placement for each individual block. After only six blocks of training (~35 min), most subjects had established optimal or near-optimal boundaries. Identification function slopes were calculated and found to be steeper than training distribution slopes; suggesting that listeners established criterion-like boundaries as opposed to performing probability matching. The fact that listeners adjusted their responses in accordance to distribution changes within relatively short periods of time

demonstrates the perceptual systems effectiveness at optimizing categorization based on distribution characteristics. [Work supported by NSF and NIDCD.]

5aPP2. Hearing silent shapes: Identifying the shape of a sound occluding surface. Ryan L. Robart and Lawrence D. Rosenblum (Univ. of California, Riverside, Riverside, CA, 92521, rosenblu@citrus.ucr.edu)

While most psychoacoustics is concerned with perception of sound sources, there is evidence that surfaces which reflect or occlude sound can also be detected and can guide behavior [e.g., M. S. Gordon and L. D. Rosenblum, J. Acoust. Soc. Am. **107**, 2851 (2000)]. While there is also evidence that listeners can hear the shape of sound reflecting surfaces [e.g., C. E. Rice, Science **155**, 655–664 (1967)], it is not known whether the shape of sound occluding surfaces can be heard. In a series of experiments, blindfolded listeners were asked to judge the shape of surfaces (of equal area) which occluded a set of loudspeakers emitting white noise. Overall, listeners were successful at this task, with some listeners showing near perfect performance. Follow-up experiments examined the acoustic information supportive of this skill. The findings suggest a type of auditory sensitivity not often considered in the psychoacoustics literature.

5aPP3. Comparing linear regression models applied to psychophysical data. Zhongzhou Tang, Virginia M. Richards (Dept. of Psych., Univ. of Pennsylvania, Philadelphia, PA 19104, richards@psych.upenn.edu), and Andrew Shih (Univ. of Pennsylvania, Philadelphia, PA 19104)

Relative weights for a profile analysis task were obtained using four regression/classification models; correlation coefficients, linear regression, logistic regression and probit regression. The aim of the study was to examine the impact of the choice of model on the accuracy and the efficiency with which the relative weights were determined. A yes/no task was used with observers indicating whether or not there was an increment in level to the central component of an 11-component standard. On each presentation the amplitudes of the individual components of the complex were randomly perturbed using draws from a normal distribution. When a large number of trials (1250) were used to estimate the relative weights, the four methods generated nearly identical weight estimates. When smaller numbers of trials were used (112), the different methods generated patterns of relative weights that were largely similar, and the patterns deviated only modestly from the large-number solution. In terms of efficiency, the error boundaries of the different methods were nearly indistinguishable. All in all, the number of trials needed to obtain statistically significant weights is sufficiently large that there is no apparent advantage of using one method over the others. [Work supported by NIH/NIDCD.]

5aPP4. The difference in auditory memory between young and aged listeners with normal hearing. Bruce Schneider, James Qi (Dept. of Psych., Univ. of Toronto at Mississauga, Mississauga, ON, Canada L5L 1C6, bschneid@credit.erin.utoronto.ca), Juan Huang, Xihong Wu, and Liang Li (Peking Univ., Beijing 100871, China)

The perceptual fusion of a noise with its delayed copies implies that there is a memory for maintaining a detailed representation of an arbitrary waveform. This auditory memory would be important for perceptually grouping correlated sounds and segregating uncorrelated sounds in noisy, reverberant environments, in which older listeners find it much more difficult than younger listeners to process signals. To determine the temporal extent of the auditory memory and whether it is affected by aging, this study investigated the detection of a break in correlation between two correlated broadband noises in younger and older listeners with normal hearing. The results show that younger listeners could detect a 100-ms break in correlation up to interaural delays ranging from 6.3 to 23.0 ms, suggesting that higher-order central mechanisms beyond the brainstem delay lines are likely to be involved in maintaining a memory trace of the fine details of the acoustic waveform. Aged listeners, however, could detect the break up to interaural delays ranging only from 6.7 to 9.7 ms, indicating the age-related decline in auditory memory. This decline may be one of the main causes leading to perceptual difficulties experienced by older listeners in noisy, reverberant environments. [Work supported by NSERCC and MSTC.]

5aPP5. About the neglected auditory abilities within psychological tests of intelligence. Jenny Papenbrock, Kristin Seidel, Susanne Weis, and Heinz-Martin Suess (Dept. of Psych., Univ. of Magdeburg, Pfaelzer Platz, Geb. 24, Postfach 4120, 39016 Magdeburg, Germany, si-projekt@gse-w.uni-magdeburg.de)

Auditory abilities play an important role in human intellectual abilities. In his model of human cognitive abilities Carroll (1993) identified a separate domain of auditory ability. Despite their theoretical and practical relevance, these abilities were mainly excluded in psychological tests. In order to compensate for this lack we developed a test which is intended to complement existing intelligence tests. To measure general auditory abilities already existing materials (Stankov and Horn, 1980) were used along with newly developed auditory tasks. Our test includes nonverbal tasks containing only tones as well as auditory textual tasks using spoken words. We expect that the auditory tasks measure a separate ability and therefore can make an important contribution to complement already existing intel-

ligence tests. To demonstrate that the test is able to measure different aspects of auditory abilities pure tone tasks should be distinguishable from auditory textual tasks. 120 subjects worked on the auditory test as well as on a well-established test of intelligence (Test for the Berlin Intelligence Structure Model, BIS-4; Jger, S & Beauducel, 1997) which operates with written, numerical and figural material. Main results of our study are reported and implications for future research concerning psychological ability tests are discussed.

5aPP6. Contributions of individual components to the overall loudness of a multi-tone complex. Lori Leibold, Samar Khaddam, and Walt Jesteadt (555 North 30th St., Omaha, NE 68131, leiboldl@boystown.org)

The contributions of individual components to the overall loudness of a multi-tone complex were examined in a two-interval, loudness-matching task. Stimuli were five-tone complexes centered on 1000 Hz, with six different logarithmic frequency spacings, ranging from a frequency ratio of 1.012 to 1.586. Stimuli were presented for 300 ms (10 ms rise/fall). The overall level of the standard complex was fixed at 60 dB SPL (53 dB/component). Levels of the individual components of the comparison complex were selected at random from a rectangular distribution with a range of 20 dB. Ten 100-trial blocks were run for each frequency-spacing condition. Perceptual weights were computed by calculating the point-biserial correlation between the difference in the level of each component across the two intervals and the subjects response. When all components fell within the same critical band, weights varied little across components. In contrast, the range of weights increased with increasing frequency separation, with increasing weight given to the lowest and highest frequency components. The audibility of individual components was determined by measuring detection thresholds for each component in the presence of the remaining four components. A strong relation between component weight and audibility was observed for all but the narrowest spacing conditions.

5aPP7. Differences in loudness of tone complexes with positive and negative Schroeder phase. Manfred Mauermann and Volker Hohmann (Medizinische Physik, Institut für Physik, Fakultät V, C.v.O Universität Oldenburg, 26129 Oldenburg, Germany)

Tone complexes with positive ($m+$) and negative Schroeder phase ($m-$) have an identical long-term spectrum, the same temporal envelope but are inverted in time. They show large differences in masking efficiency most probably being related to a different cochlear representation. The current study investigates to which extent loudness perception is affected similarly by the different phase characteristic of $m+/m-$ stimuli. Therefore, the loudness of $m+/m-$ stimuli (1.6 octave bandwidth) was matched in seven normal hearing and three hearing impaired subjects. In the first experiment the fundamental frequency f_0 of the tone complexes was varied from 2–1536 Hz for different center frequencies at a soft level of the reference signal ($m-$). In normal hearing subjects the $m+$ stimuli need a 6 dB higher level to be perceived as equally loud as the respective $m-$ stimuli (for f_0 in the range of 24–96 Hz). In the second experiment the difference in loudness of $m+/m-$ was investigated as function of the of the reference-stimulus level (5–80 dB SL) at a center frequency of 2660 Hz and f_0 at 48 Hz. The largest differences in loudness were found for levels between 40–60 dB, clearly reduced for higher and lower levels of the reference stimulus.

5aPP8. Perception of combined intensity and frequency contours by normal-hearing and hearing-impaired listeners. Marjorie R. Leek, Michelle R. Molis (Army Audiol. & Speech Ctr., Walter Reed Army Medical Ctr., 6900 Georgia Ave, N.W., Washington, DC 20307-5001, Marjorie.Leek@naamedd.army.mil), and Jennifer J. Lentz (Indiana Univ., Bloomington, IN 47408)

When a speaker utters a consonant-vowel or vowel-consonant syllable, the frequency transitions are critical to identification of the sound. However, an intensity contour is also superimposed on the frequency glides, as the mouth opens or closes. In this study, the interaction of frequency and intensity contours was explored using a frequency glide discrimination task. Offset frequency difference limens (offset DLs) were measured for upward and downward frequency glides in two frequency regions, and with three intensity contours, increasing from silence, decreasing to silence, and steady-state. For both normal-hearing (NH) and hearing-impaired (HI) subjects, larger offset DLs were observed for the high frequency stimuli than for the lower frequencies, and for upward-gliding stimuli than for downward frequency glides. Amplitude contour had little effect on the NH data, but did influence offset DLs for HI subjects. These findings indicate that for these stimuli, the interaction of frequency and amplitude contours plays only a small role in the perception of transition-like glides for NH listeners, but may affect the perception of frequency transitions by HI listeners. [Work supported by NIDCD.]

5aPP9. Processing two stimuli simultaneously: Switching or sharing? Frederick J. Gallun, Christine R. Mason, and Gerald Kidd, Jr. (Hearing Res. Ctr. and Comm. Disord., Boston Univ., 635 Commonwealth Ave., Boston, MA 02215)

This study explored whether listeners can perform two auditory tasks simultaneously or whether they must switch rapidly between tasks. The stimuli were two simultaneous speech streams (sentences) processed into sets of mutually-exclusive narrow frequency bands. One was presented to each ear and listeners reported either the keywords from the sentences (Task 1, recognition) or simply whether or not a sentence had been presented (Task 2, detection). For both sentences and tasks, overlapping bands of noise were presented at a level that reduced performance to below 90% correct in a single-stream reference condition. Listeners were informed of which stream to report either before or after stimulus presentation. The two tasks were either the same (Task 1 at both ears) or different (Task 1 on the right, Task 2 on the left). The effect of having the opportunity to rapidly switch between sentences was examined by presenting full sentences or only the keywords. Interference occurred primarily when the tasks were the same in both ears and was greatest when the target ear was not specified in advance. Presenting only the keywords hurt single-stream performance but did not increase interference in the different-task case, arguing against a rapid-switching explanation. [Work supported by NIH/NIDCD.]

5aPP10. Explaining two-tone suppression and forward masking data using a compressive gammachirp auditory filterbank. Toshio Irino (Faculty of Systems Eng., Wakayama Univ., 930 Sakaedani, Wakayama 640-8510, Japan) and Roy Patterson (Univ. of Cambridge, Cambridge, CB2 3EG, UK)

The gammatone filter was imported from auditory physiology to provide a time-domain version of the roex auditory filter and enable the development of a realistic auditory filterbank for models of auditory perception. The gammachirp auditory filter was developed to extend the domain of the gammatone auditory filter and simulate the changes in filter shape that occur with changes in stimulus level. Recently, the gammachirp was extended to explain the level-independent frequency glide of the impulse response and a large volume of simultaneous masking data quantitatively. Although this could be implemented with a static filter, we used a time-varying filter whose active component is an IIR asymmetric compensation filter. In this case, it is necessary to estimate the signal level that controls the level dependency, and explain how the level measurement

produces the time course of threshold observed in forward masking experiments. In this talk, we propose a new implementation of the time-varying, compressive gammachirp auditory filterbank to explain two-tone suppression and forward masking data qualitatively. We will also show that the system can resynthesize compressed speech sounds and so provide the basis for a gammachirp analysis/synthesis filterbank. [Work supported by GASR(B)(2) No. 15300061, JSPS.]

5aPP11. Behavioral estimates of level-dependent shifts in the vibration pattern of the apical region of the basilar membrane. Luis F. Barrios, Enrique A. Lopez-Poveda, and Ana Alves-Pinto (Instituto de Neurociencias de Castilla y Leon, Univ. of Salamanca, Avda. Alfonso X El Sabio s/n, 37007 Salamanca, Spain)

The best frequency of any given site on the BM shifts to a different value as the stimulus level increases. For basal sites, the shift occurs towards lower frequencies. For apical sites, however, the direction of the shift is unclear. Auditory nerve data [e.g., Rose *et al.*, *J. Neurophysiol.* **34**, 685–699 (1971)] suggest that shifts may not occur or may occur toward higher frequencies. The present work investigates which is the case in human. To do it, psychophysical tuning curves were measured for three normal-hearing listeners using forward masking. The level of a masker tone required to just mask a fixed, low-level probe tone was measured for different masker-probe time intervals. The duration of the interval was adjusted as necessary to obtain PTCs for the widest possible range of masker levels. Probe frequencies of 125, 250, and 500 Hz were considered. Masker frequencies ranged from 0.5 to 2.0 times the probe frequency. A clear shift toward lower frequencies occurred for all probe frequencies for one listener only. For the other two listeners, shifts were not observed for any probe frequency. No clear shifts toward higher frequencies were observed. [Work supported by Spanish FIS PI020343 and G03/203.]

5aPP12. Modeling the influence of the cochlear nonlinearity on estimates of psychophysical tuning. Xuedong Zhang and Andrew J. Oxenham (Res. Lab. of Electron., MIT, Cambridge, MA 02139)

Most behavioral measures of human frequency selectivity have been made with simultaneous masking and the notched-noise technique. The resulting filter shapes may be influenced by the effects of cochlear nonlinearity, such as suppression. Forward masking may provide a measure that is more comparable to neural tuning curves, because it does not involve stimuli that interact with each other along the basilar membrane. This study investigated the extent to which cochlear nonlinearities can account for differences in results between forward and simultaneous masking. The model was constructed using a nonlinear auditory filter, a sliding temporal integrator, a logarithmic transform and a template mechanism. The effects of compression and suppression on psychophysical performance were simulated by varying the relevant parameters of the model auditory filter. The psychophysical results were simulated for both forward and simultaneous masking, using the same parameters and tracking procedure as in the behavioral studies. The results provide a detailed evaluation of the role of compression and suppression in the models predictions of psychophysical tuning and assist in the development of the refined nonlinear cochlear models for human. [Work supported by the ASA Hunt Fellowship and NIH R01DC03909.]

5aPP13. Estimating cochlear-filter shapes, temporal-window width and compression from tone-sweep detection in spectral and temporal noise gaps. Gaston Hilkhuisen, Tammo Houtgast, and Johannes Lyzenga (Dept. of Otolaryngol., VU Univ. Medical Ctr., de Boelelaan 1117, 1081 HV Amsterdam, The Netherlands, G.Hilkhuisen@vumc.nl)

A test, designed for naive listeners, measured tone-sweep detection in noise with either spectral or temporal gaps. For normal-hearing (NH) listeners, detections in spectral gaps depended on level, which can be ex-

plained from Outer-Hair-Cell (OHC) activity. At low levels, OHC activity increased frequency-selectivity by amplifying the signal in the spectral gap, improving the signal-to-noise ratio (SNR). Relative to the broad passive cochlear filter, OHC activity decreased with rising signal levels. In consequence, SNRs decreased and detection deteriorated. Similarly, decreasing OHC activity may explain the observed level dependence of detection thresholds in temporal gaps. At low and high intensities, signal and noise were equally amplified. Detection was best at intermediate levels when the low-level signal in the temporal gap was amplified more than the high-level noise. All effects are modeled using a one-parameter time window with decaying-exponential shape preceded by a simplified dual-resonance non-linear (DRNL) filter. The filter contains two parallel, one-parameter, Rounded Exponential filters: a broad filter representing passive cochlear filtering and a narrow one, combined with a level-dependent amplifier, representing OHC activity. From estimated filter and time-window widths and OHC amplification, compression curves are derived. Additionally, results for hearing-impaired listeners will be presented.

5aPP14. Speech understanding in noise: Contributions of compressive nonlinearities in the basilar-membrane response. Amy R. Horwitz, Jayne B. Ahlstrom, and Judy R. Dubno (Dept. of Otolaryngol.-HNS, Medical Univ. of South Carolina, 135 Rutledge Ave., P.O. Box 250550, Charleston, SC 29425, horwitar@musc.edu)

The contribution of compressive nonlinearities in the basilar-membrane response was assessed by measuring speech recognition in noise as a function of noise level and growth of masking for tones. Consonant recognition was measured in interrupted noise at overall masker levels of 47–77 dB SPL. Additionally, thresholds for a 10-ms, 2.0-kHz tone were measured in a masker ranging in level from 40 to 85 dB SPL and centered at 1 kHz. Subjects were younger and older adults with normal hearing. With speech at a constant level and the masker level varying, it was hypothesized that the response of the basilar membrane to the masker would be linear at lower levels and compressed at medium to higher levels, resulting in less effective masking at higher masker levels. Consistent with the hypothesis, differences between observed and predicted consonant-recognition scores, determined using AI calculations, varied as a function of masker level, especially for younger subjects. At lower masker levels, observed scores declined as predicted as masker level increased; with further increases in masker level, scores declined less than predicted. For tonal growth-of-masking functions, breakpoints were correlated with quiet thresholds: both were significantly higher for older than younger subjects. [Work supported by NIH/NIDCD.]

5aPP15. Psychometric-function slopes for forward-masked tones in listeners with cochlear hearing loss. Kim S. Schairer, Jessica Messersmith, and Walt Jesteadt (Boys Town Natl. Res. Hospital, 555 North 30th St., Omaha, NE 68131)

Slopes of psychometric functions (PF) for forward-masked tones in normal-hearing (NH) listeners decrease as a function of signal threshold in both on- and off-frequency masker conditions. This result is attributed to nonlinear cochlear response growth, and has been used to demonstrate comparable compression at 4000 and 250 Hz. The current study further tested the hypothesis that the slope effect is due to nonlinearity. In hearing-impaired (HI) listeners who presumably lack cochlear nonlinearity, PF slopes should remain steep across signal threshold levels. Four NH and six HI listeners with a range of hearing thresholds were tested in on- and off-frequency masker conditions, with signals of 4000 and 250 Hz. Otoacoustic emissions were measured to verify absent or decreased cochlear nonlinearity in the HI listeners. In general, PF slopes were steeper for the HI than NH listeners. One subject had normal hearing at 250 Hz, and hearing loss at 4000 Hz. Her PF slopes were comparable to the mean slopes across NH subjects in the 250-Hz signal conditions, but were elevated in comparison to the NH subjects in the 4000-Hz conditions. These results are consistent with predictions from a model of forward masking that incorporates cochlear nonlinearity as one of its stages.

5aPP16. Masker variability effects in backward-masked frequency discrimination. Blas Espinoza-Varas and Hyunsook Jang (Commun. Sci. and Disord., Univ. Oklahoma Health Sci. Ctr., Oklahoma City, OK 73190)

Masker variability effects have been studied mostly in detection tasks with simultaneous maskers; this paper reports variability effects in a frequency discrimination threshold (FDT) paradigm with backward maskers. FDTs for sinusoidal targets were measured unmasked (or in isolation) and in two backward-masked conditions: one included within-trial masker frequency variability, the other did not. The 1500-Hz, 40- or 80-ms targets, and 500-, 1500-, or 2500-Hz, 80-ms maskers were presented at 70-dB SPL with a 20-ms ISI. A standard and two comparisons were displayed, respectively, in the 1st, 2nd, and 3rd observation interval of a 3I/2AFC task. One comparison, chosen randomly with 0.5 probability, contained an increment in target frequency as specified by an adaptive rule that estimated 71 percent-correct FDTs. Identical increments in masker frequency were added to both comparisons in within-trial variability conditions, but not in conditions without variability. In all conditions, the task was to determine which comparison contained the target frequency increment. Masked no-variability FDTs were higher than unmasked FDTs, but training nullified this effect. Masker variability induced greater FDT elevations with 40- than with 80-ms targets, and in conditions having the same rather than different target-masker frequencies. Prolonged training nullified all masker variability effects.

5aPP17. Hearing relative phases for two harmonic components. D. Timothy Ives, Roy D. Patterson (C.N.B.H., Physio. Dept., Univ. of Cambridge, Downing St., Cambridge, CB2 3EG, UK, tim.ives@mrc-cbu.cam.ac.uk), and H. Martin Reimann (Univ. of Berne, 3012 Berne, Switzerland)

There is a new wavelet model of basilar membrane motion which predicts that existing roex and gammatone filterbanks underestimate the interaction of harmonically related components in complex tones. This interaction appears as a modulation of the basilar membrane motion associated with a higher harmonic by the presence of a lower harmonic; the period of the modulation is that of the difference frequency, or the fundamental of the implied harmonic series. The modulation depth is largest for stimuli whose spectra have a similar energy distribution as natural sounds: a high frequency roll-off of about 12-dB per octave. The strength of the modulation frequency is dependent on the relative phase of the components, which predicts that listeners will be able to hear a relative phase change. A series of experiments were undertaken to determine the threshold for a change in the relative phase of the components. The results of the experiments show that a change in the relative phase is detectable for components that are generally believed to be resolved on the basilar membrane and therefore should not interact. [Work supported by the U.K. Medical Research Council (G9901257).]

5aPP18. The fading of auditory memory. Liang Li, Juan Huang, Lingzhi Kong, Ying Huang (Dept. of Psych., Speech and Hearing Res. Ctr., Peking Univ., Beijing 100871, China liangli@pku.edu.cn), Xihong Wu, Jing Chen, Qiang Huang, Yuan Yao (Peking Univ., Beijing 100871, China), James Qi, and Bruce Schneider (Univ. of Toronto at Mississauga, Mississauga, ON, Canada)

Due to auditory memory, the auditory system is capable of maintaining a detailed representation of arbitrary waveforms for a period of time, so that a broadband noise and its delayed copies can be perceptually fused. This auditory memory would be critical for perceptually grouping correlated sounds and segregating uncorrelated sounds in noisy, reverberant environments. Its fading process over time was investigated in the present study at the behavioral level, using a break in correlation (BIC, a drop of inter-sound correlation from 1.00 to 0 and then return to 1.00) between two correlated broadband noises. The results show that with the rise of inter-sound delay from 2 to 10 ms under either headphone-stimulation or loudspeaker-stimulation conditions, the shortest BIC duration necessary

for listeners to correctly detect the occurrence of the BIC increased rapidly. This elevation in the duration threshold was faster under the headphone-stimulation condition than the loudspeaker-stimulation condition. Also, the listeners reaction time in response to the BIC but not that to a comparable silent gap elongated quickly with the increase in the inter-sound delay from 1 to 8 ms. Thus the auditory memory of fine structures fades rapidly after the sound waves are received. [Work supported by MSTC and NSERCC.]

5aPP19. Evidence for a cancellation mechanism in perceptual segregation by differences in fundamental frequency. John F. Culling, Gareth M. Linsmith, and Tracy L. Caller (School of Psych., Cardiff Univ., Tower Bldg., Park Pl. Cardiff, CF10 3AT, UK)

Identification of target speech material is better when it differs in fundamental frequency (F_0) from interfering speech material. Two experiments tested the idea that this effect is mediated by a cancellation process that perceptually removes sound on one F_0 . Expt. 1 used monotonized target speech at 112.5 Hz F_0 against two monotonized interferers. The F_0 s of the interferers were either both 112.5 Hz, both 126 Hz, or 100 and 126 Hz. Speech reception thresholds (SRTs) were about 3.5 dB lower when the two interferers shared a 126 Hz F_0 than in the other two conditions, which differed by only 0.3 dB. These results are consistent with a cancellation mechanism that is able to remove sounds at only a single F_0 . Expt. 2 replicated and extended Expt. 1, testing whether the results were affected by the allocation of the target and interferers to particular F_0 s. When all sentences shared a common F_0 , SRTs were now 1–1.5 dB higher than when they were all different. However, all 4 SRTs for interferers sharing the same F_0 (differing from that of the target by 2 or 4 semitones) were lower than all three of the SRTs for interferers with independent F_0 s.

5aPP20. Effects of high-frequency amplification and training on impaired-listeners' ability to discriminate redundant cues. Blas Espinoza-Varas, Shelagh Bowman-Edmundson, and Hyunsook Jang (Commun. Sci. and Disord., Univ. Oklahoma Health Sci. Ctr., Oklahoma City, OK 73190)

This paper examines effects of high-frequency amplification and training on the ability to discriminate redundant duration increments added simultaneously to the low (L) and high (H) frequency component of two-component complexes. The frequency of L (500 or 1000 Hz, 80 ms) and H (2000 or 3127 Hz, 60 ms) was chosen so as to stimulate simultaneously normal- and impaired-sensitivity regions of high-frequency sensorineural patients. The 3I/2AFC task displayed a standard followed by two comparisons. Duration increments in L , H , or both (tL , tH , or tLH), occurred randomly in comparison 1 or 2, and listeners had to decide which had an increment. The training stages were: (1) no H amplification, with $L=35$, $H=-5$ dB SL and tL , tH , and tLH ; (2) H amplification, same as before but with $H=35$ dB SL; (3) H amplification and tH discrimination training, same as stage 2, but with tH only and H in isolation or together with L ; and (4) retest of stage 2, post tH discrimination training. Only in stage 4 did redundancy yield a significant improvement in overall discrimination accuracy; amplification alone yielded little improvement.

5aPP21. Wideband reflectance in normal and otosclerotic ears. Navid Shahnaz and Karin Bork (Univ. of British Columbia, School of Audiol. & Speech Sci., 5804 Fairview Ave., Vancouver, BC, Canada V6T 1Z3, nshahnaz@audiospeech.ubc.ca)

For years immittance has been used in order to help diagnose middle ear pathologies. Specifically, multi-frequency tympanometry (MFT) is able to relate information regarding the mechano-acoustical characteristics of the middle ear system. In the past two decades a new method of middle ear measurement, wideband reflectance (WBR), has been introduced. WBR is the ratio of energy reflected from the surfaces of the ear canal and

middle ear on its way to the cochlea in relation to the energy that reaches the surface, or incident energy. This ratio is known as energy reflectance. This paper adds to the limited normative data available, as well as explores whether these normative data have a clinical utility in the diagnosis of otosclerosis. Descriptive statistics were gathered from 62 (115 ears) Caucasian normal hearing adults as well as in seven patients (seven ears) with otosclerosis. All of the otosclerotic patients in this study deviated from the normative values on at least one of the four WBR parameters of power absorption, admittance, susceptance, or conductance even when their MFT results were within normal limits. Although only seven patients were tested, these results provided evidence in favor of the utility of WBR for diagnosis of otosclerosis.

5aPP22. Sensitivity to combined frequency and amplitude speech cues by cochlear implant users. Eric W. Healy, Cheryl F. Rogers, and Allen A. Montgomery (Dept. of Commun. Sci. and Disord., Arnold School of Public Health, Univ. of South Carolina, Columbia, SC 29208, ewh@sc.edu)

Although a considerable amount of work has been directed toward examining the sensitivity of the cochlear implant (CI) user to various acoustic cues, less has examined the ability to combine cues. The sensitivity to concurrent cues was examined using an adaptive 3I-2AFC paradigm. Stimuli were synthesized three-syllable words having middle syllables that possessed an increase in fundamental frequency, amplitude or both. Sensitivity to increments in the individual cues was first measured for five subjects with a CI and five age-matched controls. These DLs were then used to equate sensitivity to the two cues and create stimuli having concurrent increments. It was found that the presence of the two cues reduced the mean DL to half that of either cue alone, for both groups of subjects. Thus, this combination of cues is similar across groups and simply additive. Individual differences in the ability of CI users to combine cues were more strongly predictive of performance on speech recognition tests than was sensitivity to either cue alone. These results have implications for the perception of the multiplicity of speech cues. [Work supported by NIDCD.]

5aPP23. Recognition of vowels that have been spectrally warped according to the frequency map for the spiral ganglion. Peter S. Popolo and Christopher W. Turner (Dept. of Speech Pathol. and Audiol., 119 WJSHC, The Univ. of Iowa, Iowa City, IA 52242, peter-popolo@uiowa.edu)

The purpose of this study was to explore the effect of a specific spectral warping on vowel recognition in cochlear implant users. The warping was designed to simulate the misalignment of frequency-to-place stimulation which occurs if the spiral ganglion cells are electrically stimulated instead of the eighth-nerve dendrites in the organ of Corti. Simulated CIS-processed vowel stimuli were generated in which the analysis and carrier band center frequencies were shifted according to the projection of the spiral ganglion cells onto the organ of Corti, derived from published data [A. Kawano, H. L. Seldon, and G. C. Clark, Ann. Otol. Rhinol. Laryngol. **105**, 701–709 (1996)]. Similar spectral warping was applied to unprocessed vowel stimuli. Listening experiments were conducted in which normal hearing subjects were presented with four types of stimuli: unprocessed-unwarped, processed-unwarped, unprocessed-warped, and processed-warped. For each condition, performance was allowed to stabilize over repeated trials with feedback, to allow for learning. Vowel recognition scores averaged across listeners were drastically reduced for the warped stimuli, regardless of whether the stimuli were CIS-processed or not. The combination of spectral warping and reduced spectral resolution resulted in the poorest intelligibility scores. These results may have implications for the design of frequency-to-place maps in cochlear implants.

5aPP24. Utilizing different channels for multiple inputs in cochlear implant processing. Bom Jun Kwon (Cochlear Americas, 400 Inverness Pkwy, Ste. 400, Englewood, CO 80112, bjkwon@gmail.com)

While cochlear implants successfully provide auditory sensation for deaf people, speech understanding through the device is compromised when there is a background noise or competing sounds, partly due to implant users' reduced ability in auditory grouping. The present study investigates whether providing multiple streams of input on different channels would facilitate auditory grouping, thereby assisting speech understanding in competing sounds. In acoustic hearing, presenting two streams of input (such as speech and noise) in spectrally separate channels gener-

ally facilitates grouping; however, in electric hearing it is difficult to predict and separating them could lead to a negative result, because channel interactions inferred from the excitation patterns are severe and the actual amount of electric current for the noise delivered to the cochlea would be much higher for a given SNR, therefore contaminating the target more effectively. Results from consonant identification measured in a variety of speech/noise conditions (same/different channels) indicate that speech understanding generally improves with separate channels, implying that implant users appear to extract speech information on the basis of spatial (channel) separation, easily overcoming the distracter from the adjacent channels with higher intensity. This also proposes a new measure of channel interactions based on auditory grouping.

5aSA1. Time reversal in heterogeneous flexural beams. Dany Francoeur and Alain Berry (Dept. Gen. Mecanique, Universite de Sherbrooke, 2500 boul. de l'Universite, Sherbrooke, QC, Canada J1K 2R1, Alain.Berry@USherbrooke.ca)

Time reversal of acoustic and structure-borne waves has been explored in recent years mostly for ultrasound and for nondispersive propagation, that is under frequency-independent wave velocity. In contrast, the case of time reversal in flexural beams presented here involves dispersive propagation, and is carried for frequencies below 5 kHz. The study has been started with analytical time reversal simulations in infinite homogeneous or heterogeneous beams (comprising point-mass scatterers). Experiments have also been realized on a 5 m beam with anechoic terminations and under transverse impact excitation. The time-reversal mirror was made of several thin piezoceramic elements bonded on the beam to sense the impulse response of the structure and re-emit its time-reversed image. The experimental results are in good agreement with the analytical results, and show that time spreading due to dispersive propagation of bending waves is successfully compensated by the time reversal operation. The presentation will illustrate the main results of the simulations and a comparison with the experiments.

5aSA2. Medium frequency vibration modeling of cracked plates using hierarchical trigonometric functions. Jérôme Pinonnault, Patrice Masson, Philippe Micheau (GAUS, Mech. Eng. Dept., Université de Sherbrooke, Sherbrooke, QC, Canada J1K 2R1, Patrice.Masson@USherbrooke.ca), and Nezih Mrad (Defence R&D Canada, Dept. of Natl. Defence, Ottawa, ON, Canada K1A 0K2)

A modeling tool is proposed to describe the vibration behavior of pristine and damaged plates in the medium frequency range (below 10 kHz). This tool is intended to provide a platform for the development and assessment of damage detection algorithms for aircraft structural health monitoring applications. The proposed analytical model employs a Hierarchical Trigonometric Function Set (HTFS) to characterize homogeneous plates with through cracks. This approach takes advantage of the very high order of stability of the HTFS [O. Beslin and J. Nicolas, *J. Sound Vib.* **202**, 633–655 (1997)] to approximate the effects of a small crack in a plate for all combinations of classical boundary conditions (e.g., CFSC,

CCFF, FSFS). The model is first presented and then assessed for healthy and cracked CCCC plates with eigenvalues and eigenmodes presented in the literature. For a healthy square plate, numerical results provide good agreement up to the 1000th mode while, for a cracked rectangular plate, good agreement is obtained up to the 3rd mode, corresponding to the highest mode order available in the literature. Wave propagation simulation obtained from HTFS shows the scattering around the cracks in the plates. Experimental validation of the model is conducted both in frequency and time domains for healthy and cracked plates. [Work supported by the Consortium for Research and Innovation in Aerospace in Quebec (CRIAQ) and Defence R&D Canada.]

5aSA3. An exact analytical expression of the shear coefficient in the Mindlin plate equation. Andrew Hull (Code 8212, Naval Undersea Warfare Ctr., Newport, RI 02841, hullaj@npt.nuwc.navy.mil)

This paper derives an exact analytical expression of the shear coefficient in the Mindlin plate equation for a plate of infinite extent. The equation of motion derived from the Mindlin plate equation is set equal to the equation of motion derived from the thick plate equation, and the result is a closed-form expression of the shear coefficient at all wave numbers and frequencies. A numerical example is included to illustrate the variation of the shear coefficient. It is shown that the shear coefficient is extremely dependent on wave number and only slightly dependent on frequency. Shear coefficients derived in other work are compared favorably to the values calculated by this new method at the plate flexural wave response. [Work funded by the Office of Naval Research.]

9:45

5aSA4. Structural acoustic control of plates with variable boundary conditions. Robert L. Clark, Joseph D. Sprofera (Dept. of Mech. Eng. and Mater. Sci., Duke Univ., Box 90300, Durham, NC 27708-0300), Gary P. Gibbs, and Ran H. Cabell (NASA Langley Res. Ctr., Structural Acoust. Branch)

A method for optimizing a structural acoustic control system with respect to potential variations in plate boundary conditions is provided. The assumed modes method is used to build a plate model with varying levels of rotational boundary stiffness to span a range of possible boundary conditions which can be used to capture uncertainty in the model. A trans-

ducer placement scoring process, involving Hankel singular values (HSVs), is combined with a genetic optimization routine to find spatial locations robust to boundary condition variation. Predicted frequency response characteristics are examined, and optimized results are discussed in relation to boundary condition variations. Results indicate it is possible to minimize the impact of uncertain boundary conditions in active structural acoustic control by optimizing the placement of transducers with respect to uncertainties. Both analytical and experimental results will be discussed.

10:00–10:15 Break

10:15

5aSA5. Optimal energy dissipation in a semi-active friction device. Paulin Buaka, Philippe Micheau, and Patrice Masson (GAUS, Mech. Eng. Dept., Université de Sherbrooke, Sherbrooke, QC, Canada J1K 2R1, Patrice.Masson@USherbrooke.ca)

A semi-active device is presented for vibration control using energy dissipation by dry friction at contact surfaces. Semi-active behavior is provided by two piezoelectric stack actuators driven in real time to apply a normal force on a mobile component through two friction pads. Theoretical and experimental results show that there is an optimal constant normal force to maximize the energy dissipated for the case of a harmonic disturbance. In order to improve the energy dissipation by real time control of the normal force, two nonlinear controllers are proposed: (1) the Lyapunov method leading to a nonlinear bang-bang controller law and (2) the feedback linearization approach leading to equivalent viscous friction. The implementation of both strategies is presented and both are experimentally assessed using a clamped-free beam with the semi-active device attached to the beam. It is shown that a proper choice for the parameters of the controllers leads to an increased energy dissipation with respect to the case where the normal force is constant. This dissipation is further increased by adjusting a phase shift in the nonlinear feedback loop in order to avoid a stick-slip motion of the mobile component.

10:30

5aSA6. Energy sinks: Vibration absorption by an optimal set of undamped oscillators. Ilker Koç (Mech. Eng. Dept., Carnegie Mellon Univ., Pittsburgh, PA 15213), Antonio Carcaterra (Universita Degli Studi di Roma "La Sapienza," 00184 Roma, Italy), Zhaoshun Xu, and Adnan Akay (Carnegie Mellon Univ., Pittsburgh, PA 15213)

This presentation offers the concept of energy sinks as an alternative to conventional methods of vibration absorption and damping. A prototypical energy sink envisioned here consists of a set of oscillators attached to, or an integral part of, a vibrating structure. The oscillators that make up an energy sink absorb vibratory energy from a structure and retain it in their phase-space. In principle, energy sinks do not dissipate vibratory energy as heat in the classical sense. The absorbed energy remains in an energy sink permanently so that the flow of energy from the primary structure appears to it as damping. This paper demonstrates that a set of linear oscillators can collectively absorb and retain vibratory energy with near irreversibility when they have a particular distribution of natural frequencies. The approach to obtain such a frequency response is based on an optimization that minimizes the energy retained by the structure as a function of frequency distribution of the oscillators in the set.

10:45

5aSA7. Experiments on vibration absorption using energy sinks. Adnan Akay, Zhaoshun Xu (Mech. Eng. Dept., Carnegie Mellon Univ., Pittsburgh, PA 15213), Antonio Carcaterra (Universita Degli Studi di Roma "La Sapienza," 00184 Roma, Italy), and Ilker Koç (Carnegie Mellon Univ., Pittsburgh, PA 15213)

This presentation describes experiments that demonstrate the concept of energy sinks where a set of multiple undamped linear oscillators attached to a vibrating structure can absorb most of its energy. In principle,

energy sinks do not require presence of damping in the classical sense. A set of undamped oscillators that make up an energy sink collectively absorb the vibratory energy and retain it in their phase space. Earlier optimization studies by the authors have shown the feasibility of vibration absorption and retention by energy sinks if the set of oscillators have a particular frequency distribution. Experimental results support the concept of energy sinks. Different physical realizations of energy sinks demonstrate the significance of frequency distributions and the ability of energy sinks to reduce vibration amplitude of a primary structure to which they are attached.

11:00

5aSA8. Experimental study on passive/active hybrid isolation. Zi Jun Zhang, Woo Suk Chang, Koon Meng Nyang, and Yew Wing Chan (DSO Natl. Labs., Singapore, No 20, Sci. Park Dr., Singapore 118230)

This paper discusses the control of a high stroke low stiffness nonlinear actuator which formed the key element of a smart engine mount system that provides strong support for the engine while at the same time absorbing the engine vibration energy. The actuator is made of a stacked PZT embedded in an elliptical shaped metal frame, in the horizontal direction. Due to the geometry of the frame, the displacement generated by the PZT stacks is amplified up to about 5 times in the vertical direction. However, due to the geometry of the actuator, the vertical and horizontal motions are non-linear and excite motions at multiples of the driving frequency. Feedback controllers cannot be used since the high frequency motion causes spillover problem and control becomes unstable. The filtered-X adaptive controller with sufficient high sampling rate is tested and found to be a useful and reliable controller for the actuator for suppressing the vibration to almost ambient noise level. This actuator requires relatively lower driving voltage level and delivers larger stroke range. This would be more suitable for vibration isolation application where the actuator is serially connected with passive dampers.

11:15

5aSA9. Comparison between control strategies for active constrained layer damping treatment to control the sound radiation from a vibrating structure. Hui Zheng, Chun Lu, and Heow Pueh Lee (Inst. of High Performance Computing, 1 Sci. Park Rd., #01-01 The Capricorn, Sci. Park II, Singapore 117528)

A comparative study is presented of three control strategies for active constrained layer damping (ACLD) treatments to control the sound radiation from a vibrating planar structure. The first control strategy is one commonly used in most existing studies of ACLD for structural vibration control; i.e., the error signal to be minimized for the controller is the vibration response sensed by point transducers, and a proportional derivative controller is employed where the sensor signal and the voltage output is related by real-valued feedback gains. The second control strategy is similar to the first, except that the real-valued control gains are substituted by complex-valued ones. In the third control strategy, the discrete structural acoustic sensing approach is introduced for observing the sound radiation from the structure, and the estimated sound power constitutes the controller input. The control gains aiming to reduce the sound radiation from a simply-supported beam are optimized respectively for the three control strategies, and the control performances are compared. Numerical results show that using the complex-valued control gain in the controller design is always better than using real-valued gain. Furthermore, the ACLD treatments adopting the third control strategy require lowest control efforts.

5aSA10. Vibration control of optomechanical components. Vyacheslav M. Ryaboy (Newport Corp., 1791 Deere Ave., Irvine, CA, 92606, vyacheslav.ryaboy@newport.com)

The purpose of optomechanical components is to anchor optical elements (such as light sources, lenses, mirrors, etc.) in space so that the optical paths would be unperturbed by environmental impacts, first of all by vibration. Dynamic alignment of components is a main design optimization criterion for the optomechanical systems. An optical table or breadboard is often used as a common base for the whole optomechanical assembly. It can be sufficiently isolated from the floor vibration, but its own flexural resonance vibrations may still cause misalignments. The paper estimates various ways of vibration damping of optical tables, including new methods of passive damping combined with motion transformation, as well as active damping. Optical rods and posts offset optical elements from the table. These components have their own resonance properties. The paper presents analytical estimates and optimization methods for introducing damping materials in the optical posts. Experimental results comparing dynamic properties of damped and non-damped structures will be presented.

5aSA11. Whole body vibration measurements on forklift trucks. Alberto Behar (Noise Control, 45 Meadowcliffe Dr, Scarborough, ON, Canada, M1M 2X8 behar@sympatico.ca) and Steven Libich (WESA)

Data on acceleration values on forklift trucks related to Whole Body Vibration are notably missing in the literature. Although there are several standards that provide guidance on how measurements have to be performed, they are somehow conflicting and difficult to implement since they require simultaneous measurement and processing of data in the three axes, x , y and z . Standards also provide limit values for safety of the personnel exposed to the vibrations. The development of new instruments has made these kind of measurements much easier to perform and to interpret the results, since they include filters following the standards and allow for the use of tri-axial accelerometers. This paper describes measurements done on 11 forklift trucks in a real-life situation, while performing tasks normal for their use. The trucks are of the standing-operator type. The accelerometers were mounted on the body of the truck, so that vibrations were representative for what the operators were exposed to. The three-axes orientation of the accelerometer were taken into account. The paper will present results of the measurements and their assessment following the existing ISO and BS Standards.

Session 5aSC

Speech Communication: Intelligibility and Studies of Populations with Speech and Hearing Disorders (Poster Session)

Sigfrid D. Soli, Chair

House Ear Inst., 2100 W. Third St., Los Angeles, CA 90057

Contributed Papers

All posters will be on display from 8:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:00 a.m. to 10:00 a.m. and contributors of even-numbered papers will be at their posters from 10:00 a.m. to 12:00 noon.

5aSC1. Evaluation of effect of presbycusis on speech intelligibility by several kinds of speech test in rooms. Hiroshi Sato (Inst. for Human Sci. & Biomed. Eng., Natl. Inst. of Adv. Industrial Sci. and Technol., 1-1-1 Higashi, Tsukuba, Japan) and Hayato Sato (Kobe Univ., Rokko, Nad, Kobe 657-8501, Japan)

Word recognition tests with logatom and word familiarity controlled word lists and sentence intelligibility test in simulated sound fields with noise and/or reverberation were carried out to assess the effect of hearing loss due to aging on speech communication in rooms. The result demonstrates that (1) speech recognition scores of elderly listeners are 25% lower than those of young adults for any kinds of speech test. This difference is equal to the 5 dB increase of ambient noise for elderly listeners. (2) Detailed speech recognition process in noise and/or reverberation is described with scores of various kinds of speech test. (3) Peripheral auditory functions are mainly affected by aging. On the other hand, central auditory processing functions of the aged examined with word familiarity and meanings of words shows same performance as the young. These results were expected to lead the discussion for speech communication in aged society and the standardization for sound environment.

5aSC2. Effect of training using lexically easy and hard words on speech understanding in noise. Matthew H. Burk and Larry E. Humes (Dept. of Speech and Hearing Sci., Indiana Univ., Bloomington, IN 47405, maburk@indiana.edu)

Older hearing-impaired adults often have difficulty understanding speech in noise, even with proper amplification. One reason for this difficulty may be a lack of practice or inability to make use of new auditory information, which has been absent due to a progressive, peripheral hearing loss over many years. An often overlooked aspect of the rehabilitation process, which could help to improve this deficit, is listener training. The goal of this study was to create a word-based training protocol which could improve speech understanding in noise when listeners are presented with new, novel stimuli outside the clinic. Previous work with word-based training using one talker showed a large training effect that generalized to novel talkers; however, sufficient generalization to novel words and sentences was lacking. The current study attempts to increase generalization by training listeners with multiple talkers and lexically hard words. Generalization to novel words, both lexically easy and lexically hard, novel talkers, and sentences, with the latter also constructed from lexically easy

and hard words, will be described. [Work supported, in part, by a research grant from NIA, R01-AG08293, awarded to the second author, and an NIH training grant.]

5aSC3. Comparison of speech intelligibility measures. Jacqueline S. Laures and Gary G. Weismer (Georgia State Univ., Atlanta, GA 30302) and (Univ. of Wisconsin-Madison, Madison, WI)

The speech intelligibility of dysarthric speakers is perceptually measured by one of the following four techniques: direct magnitude estimation with a modulus, free modulus magnitude estimation, interval scaling, and transcription. Weismer and Laures (2002) suggest that magnitude estimates may provide a more complete representation of speech intelligibility than other methods of measurement because it may be more sensitive to non-segmental aspects of speech, such as prosody. However, the empirical data supporting such a statement is quite limited. The purpose of the current study is to explore the relationship of the four different measurement techniques to determine if one approach may provide a more accurate determination of the speech intelligibility of dysarthric speakers. Twelve listeners measured the speech of six dysarthric speakers and two healthy control speakers using the four different measurement techniques. Each speaker produced three sentences twice. The sentences were presented via a loudspeaker in a sound attenuated booth. Listeners rated the sentences using the four techniques. The order of techniques used was counterbalanced. A correlation analysis revealed that the four techniques were highly related. Implications of this finding are discussed.

5aSC4. Effects of speech-rate and pause duration on sentence intelligibility in younger and older normal-hearing listeners. Akihiro Tanaka, Shuichi Sakamoto, and Yô-iti Suzuki (R.I.E.C., Tohoku Univ., Katahira 2-1-1, Aoba-ku, Sendai 980-8577, Japan)

Speech-rate conversion techniques aid speech comprehension by allowing more time for perceptual and cognitive processes. However, if only the speech-rate of a telecast is converted, auditory and visual information become asynchronous. One possible method to resolve the problem is to reduce the pause durations between phrases; unfortunately, this can evoke a marked negative effect. For that reason, the present study examines the effects of the speech-rate and pause duration on sentence intelligibility. We manipulated the lengths of phrases relative to the original length (0, +100, +200, +300, and +400 ms), and the pause durations between phrases in a sentence (0, 100, 200, 300, and 400 ms). Listeners were asked to write down sentences they discerned from the noise. The intelligibility score increased in younger and older listeners when the speech signal was expanded. Regarding the pause duration, intelligibility was best when the pause duration was 200 ms in younger listeners; in older listeners, the intelligibility score was highest when the pause durations were 200 ms and 400 ms. These results provide evidence that might benefit speech-rate conversion through better use of pause duration.

5aSC5. Simulation of temporal aspects of auditory aging. Ewen MacDonald (Inst. of Biomaterials and Biomed. Eng., Rm 407 Rosebrugh, Univ. of Toronto, Toronto, ON, Canada M5S 3G9, macdone@ecf.utoronto.ca), Kathy Pichora-Fuller, and Bruce Schneider (Univ. of Toronto at Mississauga (UTM), Mississauga, ON, Canada L5L 1C6)

A jittering technique to disrupt the periodicity of the signal was used to simulate the effect of the loss of temporal synchrony coding believed to characterize auditory aging. In one experiment jittering was used to distort the frequency components below 1.2 kHz and in a second experiment the components above 1.2 kHz were distorted. To control for spectral distortion introduced by jittering, comparison conditions were created using a smearing technique (Baer and Moore, 1993). In both experiments, 16 normal hearing young adult subjects were presented with SPIN sentences in three conditions (intact, jittered, and smeared) at 0 and 8 dB SNR. When the low frequencies were distorted, speech intelligibility in the jittered

conditions was significantly worse than in the intact and smeared conditions, but the smeared and intact conditions were equivalent. When the high frequencies were distorted, speech intelligibility was reduced similarly by jittering and smearing. On low-context jittered sentences, results for young adults mimicked results found previously for older listeners with good audiograms (Pichora-Fuller *et al.*, 1995). It is argued that the jittering technique could be used to simulate the loss of neural synchrony associated with age-related changes in temporal auditory processing.

5aSC6. Comparison of hearing loss compensation algorithms using speech intelligibility measures. Meena Ramani (Dept. of Elec. and Comput. Eng., Univ. of Florida, P.O. Box 116130, Bldg. 33, Ctr. Dr. Rm. NEB 444, Gainesville, FL 32611), John G. Harris (Univ. of Florida, Gainesville, FL 32611), Alice E. Holmes (Univ. of Florida, Gainesville, FL 32611), Mark Skowronski (Univ. of Florida, Gainesville, FL 32611), and Sharon E. Powell (Univ. of Florida, Gainesville, FL 32611)

Sensorineural hearing loss includes loss of high-frequency sensitivity which results in decreased speech intelligibility. The loss cannot be compensated by inverting the audiogram because of the non-linear effects of sensorineural hearing loss (frequency smearing, decreased dynamic range, decreased time-frequency resolution). Several non-linear compensation schemes exist (Half-gain, POGO, NAL-R, Fig. 6, DSL and LGOB) and this paper provides a comparison of those using the objective Perceptual Evaluation of Subjective Quality (PESQ) score and the subjective Hearing In Noise Test (HINT). The listening tests were run on 15 unaided hearing impaired listeners as well as 15 normal hearing listeners using a simulated hearing loss algorithm. These results show marked improvement in intelligibility for the compensated speech over the normal speech for both normal and hearing impaired adults.

5aSC7. A comparative study of perceived, predicted, and measured speech intelligibility. Michael E. Hermes, Melinda J. Carney, and Dominique J. Cheenne (Dept. of Audio Arts & Acoust., Columbia College Chicago, Chicago, IL 60605)

Intelligibility metrics were obtained using a variety of methods in a gymnasium that serves as a place of worship. A word list trial, a computer model, and a computer-based %Alcons test provided the data. The results were compared in order to gauge their relative accuracy. The data from the %Alcons testing were found to be unreliable, but a direct relationship was established between the mean word list test scores and the results gathered from the computer model. This relationship allowed for a translation of the scores to %Alcons.

5aSC8. A statistical model for prediction of functional hearing abilities in real-world noise environments. Sigfrid Soli (House Ear Inst., 2100 W. 3rd St., Los Angeles, CA 90057), Chantal Laroche, Christian Giguère, and Véronique Vaillancourt (Univ. of Ottawa, Ottawa, ON, Canada)

Many tasks require functional hearing abilities such as speech communication, sound localization, and sound detection, and are performed in challenging noisy environments. Individuals who must perform these tasks and whose functional hearing abilities are impaired by hearing loss may constitute safety risks to themselves and others. We have developed and validated in two languages (American English and Canadian French) statistical techniques based on Plomps (1986) speech reception threshold model of speech communication handicap. These techniques predict functional hearing ability using the statistical characteristics of the real-world noise environments where the tasks are performed together with the communication task parameters. The techniques will be used by the Department of Fisheries and Oceans Canada to screen individuals who are required to perform hearing-critical public safety tasks. This presentation will summarize the three years of field and laboratory work culminating in the implementation of the model. Emphases will be placed on the methods

for statistical characterization of noise environments, since these methods may allow generalization of the model to a wider range of real-world noise environments. [Work sponsored by Department of Fisheries and Oceans Canada.]

5aSC9. Predicting speech intelligibility in real-world noise environments from functional measures of hearing. Christian Giguère, Chantal Laroche, Véronique Vaillancourt (Univ. of Ottawa, 451 Smyth Rd., Ottawa, ON, K1H 8M5, Canada), and Sigfrid Soli (House Ear Inst., Los Angeles, CA 90057)

In everyday life situations and in many occupational settings, speech communication is often performed in noisy environments. These environments can sometimes be very challenging, particularly for individuals impaired by hearing loss. Diagnostic measures of hearing, such as the audiogram, are not adequate to make accurate predictions of speech intelligibility in real-world noise environments. Instead, a direct functional measure of hearing, the Hearing In Noise Test (HINT), has been identified and validated for use in predicting speech intelligibility in a wide range of face-to-face speech communication situations in real-world noise environments. The prediction approach takes into account the voice level of the talker in noise due to the Lombard effect, the communication distance between the talker and the listener, a statistical model of speech perception in specific noises, and the functional hearing abilities of the listener. The latter is taken as the elevation of the individual's speech reception threshold in noise above the normative value for the HINT test. This test is available in several languages, so that language-specific needs can be addressed. The detailed approach will be presented with an emphasis placed on application examples in clinical and/or occupational settings.

5aSC10. Perceptual, acoustic, and tongue shape measures during /r/ production pre- and post-treatment using visual feedback from ultrasound: case studies of two adolescents. Marcy Adler-Bock, Barbara Bernhardt, Penelope Bacsfalvi (Dept. of Audiol. and Speech Sci., Univ. of British Columbia, 5804 Fairview Ave., Vancouver, BC, V6T 1Z3), and Bryan Gick (Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z1)

This study examined the effectiveness of using visual feedback from ultrasound in remediation of persistent /r/ errors. Ultrasound provided the participants and the clinician with a dynamic sagittal or coronal image of the tongue during speech production. The participants in this study were two adolescent boys ages 12 and 14 who were not able to produce an on-target North American /r/. Both participants had received at least one year of traditional /r/ therapy without improvement. Treatment was provided over 13 one-hour sessions using visual feedback from ultrasound. Initially, /r/ was broken down and rehearsed as individual motor targets (tongue tip, body, root); these components were then practiced in combination to produce /r/ in isolation, then in syllables, words, and phrases. Post-treatment changes in /r/ production were captured through transcription, acoustic analysis, and tongue shape measurement. Both participants /r/ productions were rated as having more tokens of on-target /r/ post-treatment. Acoustic results supported these findings with the third formant lowering post-treatment. Tongue shape measures indicated that the participants tongue shapes were more similar to the modeled /r/ tongue shape post-treatment. These case studies suggest that visual feedback as provided by ultrasound may be a useful adjunct to speech (re)habilitation.

5aSC11. The influence of severity of speech involvement on acoustic measures in dysarthria. Yunjung Kim, Gary Weismer, and Ray D. Kent (Dept. of Communicative Disord. and Waisman Ctr., Univ. of Wisconsin-Madison, Madison, WI 53705)

Several different acoustic measures have described the articulatory deficit and predicted the overall speech intelligibility deficit in speakers with dysarthria. The articulatory basis of acoustic variables that predict

speech intelligibility variations across speakers have been thought to be the ones that should be manipulated clinically for maximum therapeutic effect. For example, *F2* extent and slope are known to have strong correlations with speech intelligibility measures, across dysarthric speakers. This may suggest that within-speaker manipulation of magnitude and/or speed of articulatory movements will, if successful, result in improved speech intelligibility. Some of our previous work [Weismer *et al.*, 2001, Folia Phoniat. Logopaed.] indicates, however, that these measures may not be predictive of within-speaker fluctuations in intelligibility, but rather are indices only of across-speaker variation in severity. The large data base of dysarthric speakers at UW-Madison permits us to begin to determine how much variability exists for measures like *F2* slope in a relatively large group of speakers with homogeneous speech severity. This paper will report results of *F2* extent and slope measures for speakers with relatively mild speech involvement. If the measures are primarily tied to severity, they should not vary much within a homogeneous group of speakers. [Work supported by DC00319.]

5aSC12. Variability of jaw movement in contrastive stress production of children with and without speech delay of unknown origin. Jennell C. Vick, Lakshmi Venkatesh, and Christopher A. Moore (Dept. of Speech and Hearing Sci., Univ. of Washington, Seattle, WA 98101)

This study was designed to evaluate the control of jaw movement in contrastive stress productions of children with and without speech delay. The spatiotemporal index (STI) was used to calculate variability in jaw movement trajectories in 12 children producing three different metrical forms of CVCV syllables (trochaic, iambic, and even stress; papa, mama, and baba). The children (mean age: 3;2 years) were categorized, four in each of three groups, as having Normal Speech Acquisition (NSA), Speech Delay (SD), or both (NSA/SD) using the Speech Disorder Classification System (Shriberg *et al.*, 1997). Results replicated findings in typically developing children of a similar age reported by Goffman and Malin (1999) where iambic forms were produced with greater stability than trochaic forms as measured by the STI. Analysis using a repeated measures ANOVA revealed significant effects for contrastive stress type, speech disorder classification, and syllable identity. Results are reported in the context of vowel acoustic measures of contrastive stress. [Work supported by NIDCD R01 DC 0000822-10.]

5aSC13. Articulatory movements during vowels produced by speakers with dysarthria and normal controls. Yana Yunusova, John Westbury, and Gary Weismer (Dept. of Commun. Disord. and Waisman Ctr., Univ. of Wisconsin-Madison, 1500 Highland Ave., Madison, WI 53705)

The central goal of the study was to provide a quantitative description of contributions of the jaw, lower lip, tongue blade and tongue dorsum to vowel productions, and to determine patterns of interarticulatory interactions between movements. Kinematic and acoustic signals were collected using the x-ray microbeam. Thirty-four speakers, 12 with dysarthria due to Parkinson disease, 7 with amyotrophic lateral sclerosis, and 15 normal controls, were recorded reading sentences at a comfortable speech rate. Ten CVC words, each containing one of the English vowels /i, I, u, a, ae, o/ carrying primary stress, were selected for analysis. Each fleshy point trajectory was characterized by marker positions at vowel onset and offset, and the moment when speed was lowest. Measures of distance traveled, time to and from the moment of minimum speed, and peak and average movement speed were employed. Movement characteristics, and associations between movements, were compared for different vowels, contexts, speakers and groups. Results are reported for vowels and vowel groups (e.g., lax versus tense), averaged separately by contexts for speaker groups. The data speak to previous claims that speakers with dysarthria exhibit evidence of discoordination in speech movements relative to normal performance. [Work supported by NIDCD Award R01 DC003723.]

5aSC14. Spectral contributions to intelligibility of sentences with flattened fundamental frequency. Peter J. Watson and Robert S. Schlauch (Dept. of Speech-Lang-Hearing Sci., Univ. of Minnesota, 164 Pillsbury Dr. S.E., Shevlin 115, Minneapolis, MN 55455, pjwatson@umn.edu)

Recently, the contribution of fundamental frequency (F_0) variation to speech intelligibility in background noise has been studied [J. Laures and G. Weismer, *JSLHR* **42**, 1148–1156 (1999)]. The process used for this analysis is to flatten the frequency contour at the average F_0 . Results show that sentences with flattened F_0 are less intelligible than those with natural F_0 variation. However, this technique may reduce the prominence of formant peaks because it excludes F_0 s that are below the average flattened frequency. As noted by Laures and Weismer (1999), eliminating lower F_0 s from the analysis results in wider spacing between the harmonics and the available energy to excite the vocal tract resonances is diminished. This study examined the effect of flattening at the average and lowest F_0 of each sentence to intelligibility. Twenty subjects listened to sentences in a continuous noise background. Sentences were equated for root-mean square energy. Results showed that the low-flattened condition was significantly more intelligible than the average-flattened condition. However, a condition with natural F_0 variation was more intelligible than the two flattened conditions. These findings show that the frequency of flattening does contribute to intelligibility but that natural F_0 variation appears to contribute to a greater degree.

5aSC15. Comparison of cues in auditory selective and divided attention. Jae hee Lee and Larry E. Humes (Indiana Univ. at Bloomington, Bloomington, IN 47405)

This study investigated auditory selective and divided attention in ten normal-hearing listeners. Subjects listened to two simultaneous sentence-like utterances from the Coordinate Response Measure (CRM) speech corpus at 90 dB SPL in dichotic or monotic listening conditions. This corpus has the following format, Ready (call sign), go to (color) (number), now, with all possible combinations of call signs (8), colors (4) and numbers (8). In all conditions, the listener identified the color-number coordinates spoken by the target talker. The target talker was identified by a cue provided either prior to (selective attention) or following (divided attention) the presentation of the two simultaneous utterances. In the first experiment, either the ear or the call sign served as the cue for the target talker in monotic or dichotic listening conditions. In the second experiment, talker gender served as the cue in monotic listening conditions. Across both experiments, performance for selective attention was superior to that for divided attention. Performance for ear or gender cueing was better than for call sign. Analysis showed that 80% of errors were due to intrusions from the competing utterance, supporting an informational (attention), rather than energetic, form of masking. [Work supported, in part, by NIH R01 AG08293.]

5aSC16. Effects of high intensity on recognition of low- and high-frequency speech in noise. Van Summers and Mary Cord (Army Audiol. & Speech Ctr., Walter Reed Army Medical Ctr., Washington, DC 20307-5001)

For listeners with normal hearing (NH), speech recognition scores often decrease when intensities exceed moderate levels (rollover is observed). It is currently unclear whether the factors leading to rollover in NH listeners also limit performance for hearing-impaired (HI) listeners at high sound levels. This study aimed at clarifying the stimulus conditions most clearly associated with rollover and whether rollover effects are similar for NH listeners and listeners with mild hearing impairment. In Stage 1, NH and HI listeners heard digitally-filtered sentences and adaptive procedures were used to determine high- and low-frequency bandwidths yielding 70%-correct word recognition in quiet at moderate levels. In Stage 2, broadband and band-limited stimuli (based on the high-, and low-frequency passbands measured in quiet in Stage 1) were tested at

moderate levels in background noise. Noise levels were varied adaptively to determine signal-to-noise levels supporting 30%-correct recognition. Stimulus conditions leading to criterion performance at moderate presentation levels in Stage 2 were then retested at higher levels in Stage 3. NH listeners showed larger and more consistent rollover effects for high-frequency than for low-frequency or broadband stimuli. The results for HI listeners showed greater variability but also indicated clear rollover effects for high-frequency stimuli at high levels.

5aSC17. The effect of auditory feedback alterations on the speech quality of hearing aid and cochlear implant users. Dragana Barac-Cikoja and Leslie Klein (Gallaudet Univ., 800 Florida Ave. NE, Washington, DC 20002)

The speech of seven hearing aid (HA) users with severe-profound hearing loss and six cochlear implant (CI) users was recorded as they read the Rainbow Passage while their speech feedback was either spectrally altered in real-time, completely masked by multi-talker babble noise, or unaltered. Spectral alterations were implemented by filtering the speech signal into either one or four frequency bands, extracting their respective amplitude envelope(s), and amplitude-modulating the corresponding noise band(s). While the single-band condition provided only coarse information about the speech rhythmic structure, the four-band noise signal remained intelligible. Auditory feedback was presented via insert earphones to the HA users, and via the auxiliary jack (with the headpiece microphone silenced) to the CI users, at the participants' most comfortable listening level. The quality of the recorded speech (separated into individual sentences) was assessed using a 2IFC procedure. For each combination of the experimental conditions, six judges selected the more natural-sounding utterance in a pair. Preference scores were calculated for each of the four feedback conditions and statistically tested. HA and CI group differed in how feedback intelligibility affected the speech quality. Possible acoustic correlates of the perceived differences will be discussed.

5aSC18. Articulatory and acoustic measurements of vowels in hearing impaired speakers following treatment. Penelope Bacsfalvi and Barbara Bernhardt (School of Audiol. and Speech Sci. (SASS), UBC, Vancouver, BC, Canada V6T 1Z3, Penelope@audiospeech.ubc.ca)

The purpose of this study was to examine the relationships between ultrasound tongue shapes, electropalatography (EPG) contacts, formant data, and the perceptual data in the vowels of three hard of hearing adolescents. This pilot study examines the pre- and post-therapy speech of the participants in a 6 week group therapy programme with ultrasound and EPG technologies. Before treatment, participants showed particular difficulty with high vowels and the tense-lax distinction. Recordings were made of 2 males and 1 female with ultrasound and EPG. Three types of measurements were made; formant measurements, EPG tongue palate contacts, and perceptual judgements by experienced speech-language pathology researchers. Initial analysis values showed a change in the direction of EPG contact patterns, and perceptual categories. F_1 values decreased and F_2 values increased, moving in the direction of typical formant frequencies found in hearing people. Preliminary results of this study support a lingual-articulatory approach to treatment.

5aSC19. The role of fundamental frequency (F_0) contours in the perception of speech against interfering speech. Christine Binns and John F Culling (School of Psych., Cardiff Univ., Tower Bldg., Park Pl. Cardiff, CF10 3AT, UK)

A set of experiments investigated the effect of the F_0 contour on speech intelligibility against interfering sounds. Speech Reception Thresholds (SRTs) were measured in dB for sentences with different manipulations of their F_0 contours. These manipulations involved either a scaled reduction in F_0 variation, or the complete inversion of the F_0 contour. Against speech-shaped noise, a flattened F_0 contour did not have a sig-

nificant impact on the intelligibility of speech compared to a normal *F0* contour: the SRT for the flattened *F0* contour being only 0.7 dB higher. The SRT for the inverted contour, however, was 1.6 dB higher than for the normal *F0* contour. When the sentences were played against a single-talker interferer, the overall effect was greater, with a 2.1 dB difference between the normal and flattened conditions, and 3.3 dB between the normal and inverted *F0* contours. There was found to be no effect of altering the *F0* contour of the interferer, indicating that any abnormality of the *F0* contour serves to mask the intelligibility of the target speech, but does not alter the effect of the interfering speech. Future research will investigate the impact on speech intelligibility of similar manipulations of a low-pass-filtered *F0* contour.

5aSC20. Perceptual strategies for identifying vowels produced by speakers with dysarthria. Kate Bunton (Dept. of Speech, Lang., and Hearing Sci., Univ. of Arizona, P.O. Box 210071, Tucson, AZ 85721)

It has been previously reported that changes to the fundamental frequency contour of vowels influences their identification [e.g., H. Traunmuller, *J. Acoust. Soc. Am.* **69**, 1465–1475 (1981)]. Similar changes in vowel identification have been demonstrated for some listeners when the *F0* contour of a dysarthric speaker has been modified (e.g., flattened or enhanced) [Bunton (2004)]. These listeners appear to rely on *F0*–*F1* space for identification of vowel height; this strategy is consistent with a perceptual model of vowel recognition described by A. Syrdal and H. Gopal [*J. Acoust. Soc. Am.* **79**, 1086–1100 (1986)]. Other listeners, however, appear to utilize different acoustic cues to identify a given vowel. This study focused on defining those perceptual strategies. Multi-dimensional plots of acoustic cues likely to influence vowel perception are used to illustrate perceptual strategies that may have been used by these listeners for identification of vowels in the speech of individuals with dysarthria associated with Parkinson disease. [Work supported by NIH R03 DC005902.]

5aSC21. Perception of coarticulation in gated words by dyslexic and non-dyslexic children. Patricia Keating (UCLA, Los Angeles, CA 90095-1543), Frank Manis, Jennifer Bruno, and Jonathan Nakamoto (USC, Los Angeles, CA 90089-1061)

In an auditory word gating task, listeners are presented with portions of words, and try to identify these acoustic fragments as lexical items. It has been shown that children need more acoustic information than adults to succeed, and that dyslexic children can require more information than other children. It is also known that adults can use early acoustic cues to identify features of upcoming segments. For example, in English anticipatory vowel nasalization implies that a nasal consonant will follow, and similarly anticipatory lateralization. Our study asked whether dyslexic children are impaired in their perception or use of such anticipatory coarticulatory information. Successive gates from test words that ended in a nasal (8 words) or /l/ (4 words), or control words with final oral stops, were blocked by length and presented to 26 dyslexic and 26 non-dyslexic children. Responses were audiorecorded and later transcribed; responses were scored re both the full word and the nasality/laterality of the final consonant. Dyslexics as a group required more gates to identify nasality, but not whole words. Language-impaired dyslexics required more gates to identify whole words as well as nasality. Performance on the gating task significantly predicted reading ability when age and IQ were controlled.

5aSC22. Phonetic labeling along a formant transition duration continuum in children with specific language impairment. Harvey M. Sussman, Elizabeth Burlingame, Ronald B. Gillam (Dept. of Commun. Sci. & Disord., Univ. of Texas, Austin, TX 78712), and Jessica F. Hay (Univ. of Texas, Austin, TX 78712)

Fifteen children diagnosed with specific language impairment (SLI) and fifteen typically developing (TD) children were tested for identification performance on two synthetic speech continua varying in formant transition durations (FTDs). One continuum varied from [ba]-to-[wa] and

the other varied from [da]-to-[ja]. Several dependent measures were derived based on *d'* from signal detection theory. These measures were used to assess category boundaries and to indirectly assess sensitivity to phonetic changes in labeling category tokens along each continuum. The SLI group showed less consistent identification performance along the [ba]-[wa] series relative to the TD group, as well as reduced sensitivity to phonetic changes along the continuum. On the [da]-[ja] continuum, the SLI group revealed less consistent identification performance on the short FTD end, but similar identification levels to the TD group at the long FTD end. The overall results support the view that children with SLI reveal a deficiency in the processing of speech sounds at the level of segmental identity.

5aSC23. Classification of dysarthric and non-impaired speech based on prosodic features. Greg Kochanski (Oxford Univ., 41 Wellington Square, Oxford OX1 2JF, UK, gpk@kochanski.org) and Rupal Patel (Northeastern Univ., Boston, MA 02115)

Prosodic differences between dysarthric and healthy speakers were studied. Six acoustic properties that are plausibly more influenced by suprasegmental aspects of speech (e.g., emphasis) than the segmental details of the words were measured. The time course of these properties were analyzed over each utterance by fitting Legendre Polynomials. The resultant Legendre coefficients were then fed to linear- and quadratic-discriminant classifiers. All of the six properties were individually capable of distinguishing dysarthric speech from healthy speech. Based on one acoustic property measured over a single short sentence, we could correctly classify a speaker as healthy or dysarthric 55–75% of the time, depending on the acoustic property used. More complex classifiers that used all the acoustic properties correctly classified the speaker 97% of the time based on nine utterances. The strongest difference between normal and dysarthric speech was in loudness. Dysarthric speakers did not reliably produce the loudness patterns associated with stressed syllables. They also had a wider range in amplitude, greater voicing variability, smaller excursions of fundamental frequency, and less final lengthening compared to healthy speakers. The classification we demonstrated may be extended to become a graduated measurement of severity, thereby contributing to diagnostics and intervention in dysarthria.

5aSC24. Effects of hearing impairment on the perception and neural representation of time-varying spectral cues. Ashley W. Harkrider, Patrick N. Plyler, and Mark S. Hedrick (Dept. of Audiol. and Speech Pathol., Univ. of Tennessee, 457 South Stadium Hall, Knoxville, TN 37996)

Differences in phonetic boundaries versus normal controls suggest that listeners with hearing impairment (HI) have difficulty categorizing stop consonant place of articulation based solely on the dynamic spectral information present in the second formant transition (*F2*), even when the stimuli are amplified. This may be due to a degraded ability of the central auditory nervous system to process time-varying spectral cues despite ensuring overall audibility. However, increasing the overall level of the stimuli may not result in improved audibility of *F2*. To determine if spectral shaping of *F2* improves performance of listeners with HI, psychometric functions and *N1*-*P2* cortical responses were compared in 10 older listeners with normal hearing versus 10 older listeners with HI. Stimuli were synthetic consonant-vowels along a /ba/-/da/-/ga/ place-of-articulation continuum in an unshaped and shaped condition. Generally, behavioral and *N1*-*P2* results indicate that, with shaping, categorization of /d/ and /g/ improves. These findings suggest that enhanced audibility of *F2* through spectral shaping does improve perception of stop consonant stimuli. However, categorical boundaries for the individuals with HI are shifted lower in frequency with shaping for all phonemes versus normal controls, indicating that enhancing audibility improves but does not completely normalize categorization performance.

5aSC25. Effect of two-band dichotic listening for hearing impaired listeners. Shuichi Sakamoto, Atsunobu Murase, Yōiti Suzuki (Res. Inst. of Elect. Comm./ Grad. School of Information Sci., Tohoku Univ., 2-1-1 Katahira, Aoba-ku, Sendai, Miyagi, Japan, saka@ais.riec.tohoku.ac.jp), Tetsuaki Kawase, and Toshimitsu Kobayashi (Tohoku Univ., Aoba-ku, Sendai, Miyagi, Japan)

The increase of the upward spread of masking is a phenomenon that is typically observed among sensorineural hearing-impaired listeners. To resolve this problem, dichotic listening, by which an input speech spectrum is split into two complementary parts and is presented dichotically, seems effective to reduce masking between contiguous frequency bands. This study examines effects of simple two-band dichotic listening with a cut-off frequency around and between the typical first and second formant frequencies of the preceding vowel. We measured speech intelligibilities in both quiet and noisy environments (S/N 4 and 0 dB). Three types of vowel-consonant-vowel nonsense monosyllables, of which preceding vowels were /a/, /i/, and /u/, were used as speech stimuli. Results showed that this dichotic processing was effective, especially in relatively high S/N conditions. Moreover, the best dividing frequency was dependent on the preceding vowel. When /a/-consonant-vowel was used, the best dividing frequency was 1.0 kHz (around F_1 of Japanese vowel /a/), whereas the best dividing frequency was 0.8 kHz (between F_1 and F_2 of Japanese vowel /u/) when the /u/-consonant-vowel was used.

5aSC26. Signal to noise ratio loss and consonant confusions. Yangsoo Yoon and Jont B. Allen (Univ. of Illinois, Speech and Hearing, 901 s sixth, Champaign, IL 61820, yyoons5@uiuc.edu)

Previous SNR loss (also called speech loss) studies showed that (1) SNR loss cannot be predicted from audiometric measures, (2) 40% of hearing aids wearers have 5 dB SNR loss or greater, and (3) SNR loss influences speech intelligibility significantly. These showed SNR loss to be important in speech recognition, but they do little, or no to illuminate the nature of consonant confusion, resulting from SNR loss. Thus, the goal of the current study was to investigate the effect of SNR loss on 16 consonants recognition in hearing impairment as a function of SNR. Confusion matrix data were collected and analyzed, and Fletcher's AI was calculated from the SNR. These two measures were utilized (1) to determine how SNR loss was related to the event loss, (2) to test whether clustering of syllables in terms of consonant confusions was complied with SNR loss, and (3) to compare PI functions obtained from subjects and AI model. The results show that the degree of consonant confusion varies, but members of consonants confused with target sound above chance level are similar, as a function of SNR loss and SNR. It suggests that SNR loss limits recognition for specific consonants, even in noise.

5aSC27. Driving performance and auditory distractions. Elzbieta B. Slawinski, Jane F. MacNeil, Mona Motamedi, Benjamin R. Zendel (Psych. Dept., Univ. of Calgary, 2500 Univ. Dr., Calgary, AB, Canada T2N 1N4), Kirsten Dugdale, and Michelle Johnson (Univ. of Calgary, Calgary, AB, Canada T2N 1N4)

Driving performance depends on the ability to divide attention during different tasks. In spite of the fact that driving abilities are associated with visual stimulation, driving performance depends on attention to stimulation and/or auditory distraction. Research shows that listening to the radio is a principal auditory distracter during the time of driving (Brody, 2002). In the laboratory a few experiments were conducted on the auditory distraction (e.g., music, stories) and signal processing by young and older drivers. Results show that older subjects involved in listening to the stream of information (independent of the hearing status) require higher intensity of the auditory stimulation than younger drivers. It was shown that cognition plays a role while listening to auditory stimuli. Moreover, it was demonstrated that driving performance was influenced by the type of per-

formed music. A portion of these experiments and their results were presented at the Annual Meetings of CAA in 2002 and 2003 as well as being published in the Journal of Psychomusicology **18**, 203–209. Complete results of the experiments will be discussed.

5aSC28. Speech intelligibility index calculations in light aircraft cabin during flight. Tino Bucak and Ernest Bazijanac (Dept. of Aeronautics, Faculty of Transport and Traffic Eng., Univ. of Zagreb, Croatia)

High levels of cabin noise in small general aviation aircraft significantly deteriorate the quality of speech communications and potentially endanger the safety of flight. Several ground and inflight cabin noise measurements on new generation Cessna 172R were made during various phases of flight. The results are analyzed and used for Speech Intelligibility Index (SII) calculations, in order to quantify the influence of cabin noise on speech communications between crew members.

5aSC29. A detailed study on the effects of noise on speech reception. Tammo Houtgast and Finn Dubbelboer (VU Univ. Medical Ctr., Amsterdam, The Netherlands)

The effect of adding continuous noise to a speech signal was studied by comparing, for a series of quarter octave bands, the band output for the original speech and for the speech-plus-noise. Three separate effects were identified. (a) Average envelope-modulation reduction: the original intensity-envelope is, on average, raised by the mean noise intensity, resulting in a reduction of the original modulation index. (b) Random instantaneous envelope fluctuations: on an instantaneous basis, the speech-plus-noise envelope shows random variations, caused by the stochastic nature of the noise, and by the instantaneous changes in the phase relation between the speech and the noise. (c) Perturbations of the carrier phase: in the band output carrier signal the addition of the noise causes random phase changes. By applying signal processing techniques, we were able to either include or exclude each of these three effects separately. The results of intelligibility measurements indicated the following order of importance of the three different effects: (1) the average envelope-modulation reduction, (2) the perturbation of the carrier phase, and (3) the random envelope fluctuations. The results will be discussed in the light of modeling and enhancing (noise suppression schemes) speech reception in noise.

5aSC30. Speech rate characteristics in dysarthria. Kris Tjaden, Geoff Greenman, Taslim Juma, and Roselinda Pruitt (Dept. of Communicative Disord., Univ. at Buffalo, 122 Cary Hall, 3435 Main St., Buffalo, NY 14214, tjaden@acsu.buffalo.edu)

Speech rate disturbances are pervasive in dysarthria, with some reports suggesting that up to 80% of speakers with dysarthria exhibit speech rates that differ from neurologically normal talkers. The contribution of articulation time and pause time to the overall impairment in speech rate is not well understood. Studies investigating speech rate characteristics in dysarthria also tend to focus on reading materials, yet there is reason to suspect that the higher cognitive load of conversational speech may impact speech rate characteristics differently for individuals with impaired speech motor control, and neurologically normal talkers. The current study will report speech rate characteristics for both a reading passage and conversational speech produced by individuals with dysarthria secondary to Multiple Sclerosis (MS), individuals with dysarthria secondary to Parkinson Disease (PD) and healthy controls. The manner in which speech rate, articulation rate, and pause characteristics differ for speakers with dysarthria and healthy controls will be examined. The contribution of articulation time and pause time to overall speech rate also will be studied and compared for the reading passage and conversational speech. [Work supported by NIDCD R01DC04689.]

Session 5aSP**Signal Processing in Acoustics: Smart Acoustic Sensing for Land-Based Surveillance**

Brian Ferguson, Chair

*Defense Science and Technology Organization Maritime Systems Div., Pyrmont 2009, Australia***Chair's Introduction—8:30*****Invited Papers*****8:35****5aSP1. Acoustic methods for tactical surveillance.** Brian G. Ferguson and Kam W. Lo (Defence Sci. and Technol. Organisation, P.O. Box 44, Pyrmont, NSW 2009, Australia)

Smart acoustic sensor systems can be deployed for the automatic detection, localization, classification and tracking of military activities, which are inherently noisy. Acoustic sensors are appealing because they are passive, affordable, robust, and compact. Also, the propagation of sound energy is not limited by obstacles that block or obscure the clear line of sight that is required for the effective operation of electromagnetic systems. Methods, with examples, for extracting tactical information from acoustic signals emitted by moving sources (air and ground vehicles) are provided for both single sensor and multiple sensor configurations. The methods are based on processing either the narrowband or broadband spectral components of the sources' acoustic signature. Weapon firings generate acoustic impulses and supersonic projectiles generate shock waves enabling source localization and classification by processing the signals received by spatially-distributed sensors. The methods developed for land-based acoustic surveillance using microphone data are also applied to hydrophone data for passive acoustic surveillance of the underwater environment.

9:05**5aSP2. Autonomous acoustic sensing on mobile ground and aerial platforms.** Tien Pham and Nassy Srour (US Army Res. Lab., 2800 Powder Mill Rd., Adelphi, MD 20783-1197)

Acoustic sensor systems on the ground and/or in the air can be used effectively for autonomous and remote intelligence surveillance and reconnaissance (ISR) applications. Acoustic sensors can be used as primary sensors and/or secondary sensors to cue other higher-resolution sensors for detection, tracking and classification of continuous and transient battlefield acoustic events such as ground vehicles, airborne aircraft, personnel, indirect fire, and direct fire. Current collaborative research activities at ARL in acoustic sensing from mobile ground platforms such as HMMWVs and small robotic vehicles [P. Martin and S. Young, Proc. of SPIE Defense & Security Symposium, 2004] and from aerial platforms such as UAVs and balloons [Reiff, Pham *et al.*, Proc. of the 24th Army Science Conference, 2004] demonstrate practical performance enhancements over fixed ground-based platforms for a number of ISR applications. For both mobile ground and aerial platforms, self-generated noise (flow noise and platform noise) is problematic but they can be suppressed with specialized windscreens, sensor placement, and noise cancellation technology. Typical acoustic detection and processing results for mobile platforms are compared and contrasted against fixed ground-based platforms.

9:35**5aSP3. Ferret and its applications.** Jacques Bedard (Defence R&D Canada—Valcartier, 2459 Pie XI North, Val-Belair, QC, Canada G3J 1X5)

Ferret is an acoustic system that detects, recognizes and localizes the source and direction of small arms fire. The system comprises a small array of microphones and pressure sensors connected to a standard PC-104 computer that analyzes, displays, reports and logs the parameters of a recognized shot. The system operates by detecting and recognizing the ballistic shock wave created by the supersonic bullet, combined with the muzzle blast wave propagating from the weapon. The Canadian Land Force Test and Evaluation Unit evaluated a vehicle-mounted version of the system and recommended deployment of the system during peacekeeping missions. The system is the result of a collaborative effort between Defence R&D Canada and MacDonald Dettwiler and Associates. This presentation describes the hardware and software components of the system along with the current and future applications of the system.

5aSP4. Acoustic self-localization of a wireless sensor network. Peter L. Schmidt, Stephen M. Williams, and Kenneth D. Frampton (Vanderbilt Univ., 2400 Highland Ave., Nashville, TN 37212)

One of the biggest challenges to the field of wireless sensor networks is self-localization: that is the determination of the relative and absolute coordinates of each sensor node in the network. Previous work has been done to locate hydrophone arrays. However sensor networks have some unique constraints that make this more challenging. A typical application would involve the distribution of hundreds or thousands of sensor nodes over an area either by hand, airdrop or other means. One of the primary constraints on such a system is that centralized processing of self-localization data may be prohibitively complex. Furthermore, the data may be incomplete, contain reflected path events, and may be subject to other mission specific constraints. Therefore, a distributed computational scheme has been developed to solve acoustic time-of-arrival equations. *A priori* information about some sensor locations and user triggered source localization events are used along with a regularized inversion solution. Results of this will be presented based on both small scale experiments and larger systems simulations. Limits of the types of *a priori* information required for accurate results are detailed, along with studies of the accuracies obtained using various distributed calculations parameters.

10:35

5aSP5. Distributed source localization in a wireless sensor network. Stephen M. Williams, Peter L. Schmidt, and Kenneth D. Frampton (Vanderbilt Univ., 2400 Highland Ave., Nashville, TN 37212)

This work concerns experimental implementation of distributed acoustic source localization with a wireless sensor network. The envisioned application is the distribution of hundreds or thousands of small, semi-disposable, wireless sensor nodes (possibly by airdrop). These nodes would form an ad-hoc communications network and monitor and track acoustic events within the array. Centralized processing of such data would be prohibited by the excessive communications and complexity of calculations. Furthermore, localization with a network of randomly placed sensors is not suited to use of traditional array theories due to irregular placement of sensors and the unknown sensitivity and phase relationships between sensors. Therefore, a fully distributed localization algorithm was developed in which nodes organize themselves into groups which collaborate to locate sources. Acoustic event time-of-arrival information is shared among group members and the source locations were determined using Tikhonov regularized inversion. Small scale localization experiments (with 10 sensor nodes) were conducted to validate the performance of the method. Results are discussed, along with limitations of the method discovered during conduct of the experiments. In addition, a comparison is made between this method and traditional matrix solution methods.

5aSP6. Particle filters for tracking a vehicle through a field of acoustic directional frequency and recording (DIFAR) sensors. Anton J. Haug (The MITRE Corp., 7515 Colshire Dr., McLean, VA 22102, ahaug@mitre.org)

For nonlinear/non-Gaussian processes, Bayesian approaches to tracking require integration over probability density functions, which cannot be accomplished in a closed form. Recently, numerical Monte Carlo “particle filter” integration techniques have been developed and applied to tracking problems. However, multidimensional application examples of these tech-

niques have been limited because they require an analytic expression for the likelihood function, which is usually not easy to obtain when the noise is non-Gaussian and not additive. Tracking a vehicle through a field of acoustic DIFAR sensors is such an application. Although the vehicle dynamic model can be linear with additive Gaussian noise, the observation model is inherently nonlinear with observations that contain embedded non-Gaussian noise. For the DIFAR vehicle tracking problem, we will consider large time-bandwidth signals, develop both the dynamic and observation models, and show how the Gaussian additive noise on each DIFAR channel results in non-Gaussian noise embedded in the bearing observations. The likelihood function will then be presented and the performance of several particle filter trackers will be compared with that of an Extended Kalman Filter.

5aSP7. Source localization in complex scattering environments using random amplitude and bearing information. D. Keith Wilson, Mark L. Moran, and Roy Greenfield (USACE ERDC-CRREL, 72 Lyme Rd., Hanover, NH 03755-1290, D.Keith.Wilson@erdc.usace.army.mil)

By scattering sound waves, atmospheric turbulence and other outdoor objects (such as building and trees) induce random fading and angle-of-arrival variations in signals received by small-baseline microphone arrays. This study addresses the relative utility of signal amplitude and bearing estimates when such variations are present. Source-localization simulations are performed for four idealized statistical scattering models: no scattering, weak turbulent scattering, strong turbulent scattering, and diffuse (multiple) scattering. Each of these cases is considered with low, moderate, and high SNR. It is found that bearing information provides highly accurate source localization when SNR is high and scattering is negligible. However, when the SNR is low and/or there is significant scattering, the bearing information loses its utility while the amplitude information remains relatively robust. Algorithms are considered that attempt to assess the relative reliability of the bearing and amplitude information, and subsequently weight signal features to provide the most satisfactory results. The simulations also confirm previous analyses suggesting that, for unfavorable propagation conditions and SNR, Cramer-Rao lower bounds predict substantially better performance than is obtainable in practice.

11:20

5aSP8. A method for locating nearby sources. John V. Olson, Kenneth Arnault, and Curt. A. S. Szuberla (Geophysical Inst., Univ. of Alaska, Fairbanks, AK 99775)

A fast method for locating nearby sources based solely on the time-of-flight information is described. The time delays for a signal passing between all sensor pairs is determined using cross-correlations and a vector of time delays is constructed. In the noise free case, where the speed of sound is constant, each point in the plane is associated with a unique value of the time delay vector. The method we present uses a fast, simplex-based search of the plane for a source location by minimizing the difference between the vector associated with the candidate location on the plane and the value estimated from cross-correlations. The search takes place over the three dimensional space that includes two coordinates in the plane and the propagation speed. The starting point for the search is constructed from an analytic fit of circular wave fronts to groups of sensors within the array. This method has been useful in identifying near-field sources in the 153US and 155US CTBT/IMS infrasound arrays. Examples of the locations we have determined along with a description of the statistical confidence limits associated with the method will be presented.

5aUW1. Identification of strong scatterer locations on the Malta plateau. Mark K. Prior (NATO Undersea Res. Ctr., Viale San Bartolomeo 400, 19138, La Spezia, Italy, prior@saclantc.nato.int)

Reverberation data gathered in the Malta Plateau region of the Mediterranean Sea using a Low-Frequency Active Sonar (LFAS) and a cardioid receiver array are presented. A processing strategy involving normalization, geo-referencing and averaging over pings is described and is shown to highlight the locations of strong scatterers and to provide a first-order estimate of their strength. A second process of calculating the ratio of local standard deviation and mean values is shown to reveal scatterer locations and to provide an indication of whether the probability density function of the reverberation is well-described by the Rayleigh distribution. The characteristics of the observed scatterers are revealed by comparison with independent sidescan, echo sounder and boomer data. Areas of high reverberation are identified as being associated with wrecks, oil production platforms, rock outcrops and variations in local sediment properties.

8:45

5aUW2. Range-dependent 3D scattering and reverberation in the continental shelf environment from biology, geology and oceanography. Purnima Ratilal (Northeastern Univ., 409 Dana Res. Ctr., Boston, MA 02115), Sunwoong Lee, Yisan Lai, Tianrun Chen, Deanelle Symonds (MIT, Cambridge, MA 02139), Ninos Donabed (Northeastern Univ., Boston, MA 02115), and Nicholas Makris (MIT, Cambridge, MA 02139)

Several unified scattering and reverberation models were developed in support of the ONR Acoustic Clutter Program. They include a range-dependent model based on the parabolic equation that can be used to efficiently model scattering from a random spatial distribution of random targets that obey the sonar equation in the waveguide and a similar but range-independent waveguide model based on normal modes for scattering from extended objects. Both these models are bistatic and fully 3D, and the latter model also accounts for modal coupling between propagation and scattering caused by extended objects in the waveguide. These models are applied to examine both coherent and diffuse scattering measured after beamforming and match-filtering on an array from schools of fish, plankton, volume inhomogeneities in the sea bottom, roughness on the seafloor, extended seafloor and sub-bottom features such as river channels and reflective strata, and internal and surface waves. We provide a review of the dominant sources of clutter as well as background reverberation for long range active sonar based on comparison of model predictions with measured data from the Acoustic Clutter Experiments of 2001 and 2003.

9:00

5aUW3. Dominant source of background reverberation during the Acoustic Clutter 2003 experiment. Ninos Donabed, Purnima Ratilal (Northeastern Univ., 409 Dana Res. Ctr., Boston, MA 02115), and Nicholas Makris (MIT, Cambridge, MA 02139)

Reverberation data from the Acoustic Clutter 2003 experiment on the New Jersey Continental shelf are analyzed to provide estimates of the background scattering strength over wide areas of the environment as a

function of time. We corrected the acoustic data in the 390–440 Hz range for two-way transmission loss modeled using the range-dependent parabolic equation, the spatially varying beam pattern of the receiving array, and source level to obtain estimates of the scattering strength per unit area of the environment. Data from regions of space devoid of strong clutter were statistically analyzed to provide a temporal and spatial characterization of the background scattering strength. They were then compared to scattering strength levels deduced from modeling from a variety of scatterers including schools of fish, the sea bottom, internal waves and surface waves. Analysis indicates that the dominant sources of background reverberation can be either low density fish schools or the sea bottom.

9:15

5aUW4. Higher moment estimation for shallow water reverberation. Kevin LePage (Naval Res. Lab., Code 7144, 4555 Overlook Ave. SW, Washington, DC 20375)

Shallow water reverberation is characterized by clutter which causes false alarms in sonar systems. In previous work we have estimated the non-Rayleighness of shallow water reverberation time series predictions obtained by the R-SNAP model. Here we extend the R-SNAP model to the closed form estimation of the second moment of reverberation intensity, allowing the estimation of pdf fits for the two parameter K distribution as a function of system and channel characteristics and time after shot. This work is intended to theoretically guide the selection of clutter-robust system characteristics. [Work supported by ONR.]

5aUW5. Statistical characterization of sonar-like clutter observed on the STRATAFORM during the 2003 Acoustic Clutter Experiment in the 400–1500 Hz region. John Preston and Douglas Abraham (Appl. Res. Lab., The Penn State Univ., State College, PA 16804)

In 2003 ONR sponsored the Acoustic Clutter Experiment to study shallow water scattering and clutter in the STRATAFORM area off New Jersey. Sources were bistatic coherent pulses from a vertical array. The receiver was the Five Octave Research Array (used horizontally). The STRATAFORM is known to have benign surface morphology but contains many buried river channels and other sub-surface horizons. MIT researchers have shown fish to be a primary source of the observed clutter and reverberation. The K -distribution's shape and scale parameters have been shown to be useful in describing non-Rayleigh behavior. Statistical characterization is presented as a function of location. The "bandwidth" effect is shown where the shape parameter first decreases inversely proportional to bandwidth but then increases in a trend back toward the Rayleigh distribution at higher bandwidths. The shape parameter estimates are well fit by an elongated patch model of Abraham and Lyons. Differences between the 2003 and 2001 data taken in the same area are discussed. It is believed that the sound speed profiles in 2003 lead to more bottom interaction than in 2001 producing a larger time spread in the multipaths leading to observed differences. [Work supported by ONR Code 32, Grant N00014-05-1-0156.]

5aUW6. Comparison of measured buried target backscatter levels with high-order predictions: Rippled interface effects. Raymond Lim (Naval Surface Warfare Ctr.-Panama City, Code R21, 110 Vernon Ave., Panama City, FL 32407), Joseph L. Lopes, and Gary S. Sammelmann

Controlled sonar measurements with buried spheres and cylinders have demonstrated diffraction by bottom ripple can significantly improve target detection performance with sonar operated at grazing angles shallower than the critical grazing angle. Furthermore, buried target scattering models based on low-order perturbation theory to handle sound transmission through bottom roughness confirm that a significant enhancement in detection performance can be expected. But comparisons between measurements and model predictions have not always produced good agreement. As the bottom ripple height increases, discrepancies have been noted in comparisons with the predicted backscatter levels from a buried sphere, suggesting a failure of low-order perturbation theory to properly account for high-amplitude roughness effects. Recently, a recursive algorithm to generate arbitrary-order perturbation corrections for transmission and reflection through an idealized sinusoidal ripple was formulated and incorporated into our existing buried target scattering codes. The resulting higher-order predictions indicate previous discrepancies were not necessarily due to the neglect of high-order corrections. Calculations show model inputs such as bottom attenuation can influence backscatter levels significantly and measurement of these parameters may need to be performed more carefully. We demonstrate this through a presentation of data and model comparisons. [Work supported by ONR and SERDP.]

5aUW7. Calculation of scattering from underwater targets using the equivalent source technique. Ahmad T. Abawi and Michael B. Porter (Heat, Light, and Sound Res., Inc., San Diego, CA 92130, Ahmad.Abawi@HLSResearch.com)

The equivalent source technique is a method of computing scattering and radiation from a target by replacing the target by a distribution of discrete sources, whose complex amplitudes are determined by applying the boundary condition on the total field. The advantage of using this method, particularly in underwater acoustics, is that it essentially transforms the scattering and propagation problems into just a propagation problem, where the target can be treated as a distribution of sources rather than an impedance discontinuity. In this paper the equivalent source technique and different propagation models such as the normal mode, the parabolic equation and the fast field method are used to compute scattering from various target shapes/properties placed in the ocean waveguide. The results are compared with those obtained from other numerical codes. In addition, the relationship between the equivalent source technique with boundary element method (BEM) and the method of moments (MoM) is investigated.

10:30

5aUW8. Detecting small targets in strong bottom reverberation. Jinyun Ren and John S. Bird (School of Eng. Sci., Simon Fraser Univ., Burnaby, BC, Canada V5A 1S6, jren@cs.sfu.ca)

The detection of small targets moving or appearing in heavy bottom reverberation is a challenging problem for surveillance sonars. Conventional detection techniques, such as variable thresholding, are inefficient because they require that the target return be large enough to compete with the total reverberation return. Based on a new reverberation model, this paper proposes a target detection scheme that provides target subclutter visibility in the presence of reverberation. First it is shown through experimental evidence that bottom reverberation as seen by a stationary sonar is coherent or at least partially coherent from ping to ping. Therefore reverberation for a particular range cell can be modeled as a complex signal composed of a stationary or slowly varying mean plus a rapidly varying diffuse component. This mean is easily estimated using an adaptive mean

estimator and then removed so that the target need only compete with the diffuse component. Experimental results show that the detection gain over variable thresholding as measured by the coherent-to-diffuse ratio can be as much as 40 dB.

10:45

5aUW9. Channel effects on target characteristics in very shallow water. Kevin LePage (Naval Res. Lab., Code 7144, 4555 Overlook Ave. SW, Washington, DC 20375)

Very shallow water waveguides introduce channel effects which complicate the scattered response from objects. Here we model the effects of channel time spread and dispersion on the expected value of the time series backscattered by a sphere with and without uncertainty introduced by imperfect knowledge of the channel. We also model the predictable characteristics of the bottom reverberation against which detections are made. Results are intended to guide the design of dispersion and uncertainty-robust sonar systems in very shallow water. [Work supported by ONR.]

5aUW10. Mode extraction from acoustic backscatter in a waveguide. Shane Walker, Philippe Roux, and William A. Kuperman (Scripps Inst. of Oceanogr., Marine Physical Lab., 9500 Gilman Dr., La Jolla, CA 92093-0238, shane@physics.ucsd.edu)

Recently we introduced a technique for extracting the acoustic modes in a range-independent waveguide from measured data alone without *a priori* knowledge of the environment. This method requires a Vertical Line Array (VLA) to collect data from a moving broadband point source at a single depth in order to reconstruct the frequency-wavenumber (f - k) structure of the waveguide. Our goal is to apply this technique to the more complicated case of bottom reverberation using the VLA as both a source and receiver. As a broadband signal propagates away from the VLA, inhomogeneities along the water/bottom interface scatter some of the field back toward the VLA, mimicking a moving source. However, ambiguities inherent in assigning ranges to the received signal lead to ambiguities in the f - k structure. As a preliminary step, we remove these ambiguities by applying the technique to individual point scatterers at various known ranges along the bottom. These results lay a foundation from which to approach the problem of modeling the bottom as a distribution of point scatterers at unknown locations. Theory, simulation, and laboratory measurements are presented.

5aUW11. Nonlinear scattering of acoustical waves on sphere after passing the obstacle. Nickolay Zagrai, Andrey Zagrai, and Irene Starchenko (TSURE, 347928, Taganrog, GSP-17a, Nekrasovskiy, 44, Russia, znp@tsure.ru)

The problem of nonlinear interaction of acoustical waves in the system medium-obstacle-medium-sphere was considered. The expressions for secondary field of parametric array were obtained. The contributions of components were evaluated on separated processes of non-linear interaction before and after the obstacle as for the primary signals field as for the secondary fields of combinational frequencies waves. The possible practical applications were also discussed.

5aUW12. Separability of modal back-scattering matrix in shallow-water reverberation models. Jinrong Wu, Tianfu Gao, Erchang Shang, and Li Ma (Inst. of Acoust., Chinese Acad. of Sci., Beijing, China; No. 21, West Rd., Beisihuan, Beijing, China)

Normal mode model of the reverberation in shallow-water waveguides has been presented based on Born approximation. The key component of this model is the modal back-scattering matrix. Separability is one of the most important characteristics of the modal back-scattering matrix. The

separability or quasi-separability of this matrix could make it easy for modal back-scattering matrix inversion. In this paper, the modal back-scattering matrix due to the roughness of the bottom interface in shallow-water was obtained and its separability error was analyzed. Numerical simulation shows that the separability error increases with modal grazing

angle and density ratio of the sediment to the water, while decreases with sound speed ratio of the sediment to the water. It also shows that the effect of the separability error on shallow water reverberation level prediction is negligible. [Work supported by the National Science Foundation of China under Grant No 10474111.]

5pAB1. Dependence of detection threshold estimates in rabbit on method of constant stimulus parameters. Laurel H. Carney, Yan Gai (Inst. for Sensory Res., Dept. of Biomed. and Chemical Eng., Syracuse Univ., Syracuse, NY 13244), Kristina S. Abrams (Syracuse Univ., Syracuse, NY 13244), Fabio Idrobo (Boston Univ., Boston, MA 02215), and John Michael Harrison (Boston Univ., Boston, MA 02215)

The goal of this study was to estimate behavioral detection thresholds in quiet and noise for subsequent physiological studies of responses to near-threshold stimuli. The difficulty in measuring detection thresholds is maintaining stimulus control of behavior over schedule control. Tracking paradigms are efficient, but the large proportion of trials below threshold weakens stimulus control. The Method of Constant Stimuli controls the proportion of trials below, near, and above the SPL for a given percent correct. Here, percentages of trials at different SPLs and zero intensity catch trials were varied to determine proportions that yielded satisfactory stimulus control by a 500-Hz tone in quiet. Trials were initiated by nose-poke observing responses; a nose-poke reporting response within a 3-s window after tone onset resulted in food reinforcement. Reporting responses in the absence of tones resulted in timeouts. A metric for stimulus control was the ratio of the number of correct detections to the number of responses in the absence of the tone. This ratio was highest when approximately 20% of trials were near the 50%-correct SPL and 80% of trials were 20 dB higher. The ratio was lowest when significant proportions of catch and/or below-threshold trials were included. [Work supported by NIDCD DC-001641.]

5pAB2. Manatees masked thresholds for complex sounds. Edmund Gerstein, Laura Gerstein, Joseph Blue (Leviathan Legacy Inc., 1318 SW 14th St., Boca Raton, FL 33486), and Steve Forsythe (Naval Undersea Warfare Ctr., Newport, RI)

Acoustical masked thresholds of complex real world sounds were measured with West Indian manatees. Motor boat and species-specific calls were recorded, filtered and played back in a forced-choice two-alternative test. A method of constant stimuli was used to estimate the 50% detection thresholds of peak spectral components. Both white noise and recorded wild ambient spectra were used as continuous background noise for two sets of threshold estimates. Manatee calls were detected at and

within both white noise and wild ambient levels. Thresholds for broadband boat noise ranged from 9 to 29 dB above ambient conditions. Thresholds for idling boat noise were the highest. The levels were consistent with the subjects' auditory limits for the lower frequencies with the spectra. The manatee is well adapted to hear the species specific vocalizations under noisy conditions. The integration of multiple critical bands may result in loudness summation benefits which manatees can exploit at higher frequencies, however, at lower frequencies, near the manatees' limits of sensitivity, benefits of loudness summation were not apparent.

1:35

5pAB3. Testing marine mammal hearing with a vocal response paradigm and the method of free response. James J. Finneran, Donald A. Carder (U.S. Navy Marine Mammal Program, SPAWARSYSCEN San Diego, Code 2351, 53560 Hull St., San Diego, CA 92152, james.finneran@navy.mil), Carolyn E. Schlundt (EDO Professional Services, San Diego, CA 92110), and Sam H. Ridgway (Univ. of California, La Jolla, CA 92093-0612)

Behavioral hearing tests with marine mammals often use single interval experiments with a go/no-go paradigm, where the subject pushes a response paddle or similar device to indicate the presence of a hearing test tone. This approach is widely accepted, but the time required for the subject to physically move and/or interact with the response device and the requirement of one trial per reinforcement interval limit the speed at which data can be collected (typically 20–30 minutes for a threshold). An alternative to the single interval/paddle press approach is the use of a vocal response technique and the method of free response, where multiple trials are presented within a single reinforcement interval. An acoustic or vocal response eliminates the need for the subjects to physically move, allowing for faster responses and shorter inter-trial intervals. The method of free response allows multiple tone presentations between reinforcement periods, dramatically increasing the rate at which data may be collected, especially from diving marine mammals. This talk describes the application of these techniques to hearing tests of bottlenose dolphins, white whales, and California sea lions and the advantages and disadvantages compared to the single interval experiment. [Work supported by ONR.]

5pAB4. Noise localization ability in the Mongolian gerbil (*Meriones unguiculatus*). Srijata Sarkar, Kristina S. Abrams, and Laurel H. Carney (Inst. for Sensory Res. and Dept. of Biomed. and Chemical Eng., Syracuse Univ., Syracuse, NY 13244)

Understanding localization ability is essential for comparison to physiological studies of binaural neurons. Heffner and Heffner [Beh. Neuro. **102**, 422 (1998)] reported relatively poor ability of the gerbil to localize a 100 ms noise burst (approximately 75% correct at 27° separation.) Their experimental setup required the gerbil to enter an observing response compartment, initiating a noise burst from one of two speakers separated by the test angle. The animal was required to respond by entering a reporting compartment, positioned 90° to the right or left, regardless of speaker location. This required mapping from speaker location to response location. In this study, response mapping was avoided in an effort to improve performance. After an observing response (jumping on a platform in the center of a circular cage), the animal responded by moving directly towards the active speaker. The results of this study were consistent with those of Heffner and Heffner at small angles of separation. [For 180° separation, this task resulted in poorer performance than the previous study, presumably due to lack of control of head orientation during stimulation, leading to front-back confusions.] In conclusion, the poor localiza-

tion ability of gerbils is apparently not explained by response mapping. [Work supported by NIDCD R01-DC001641.]

5pAB5. Strain differences in auditory sensitivity in canaries bred for song and plumage. Amanda Lauer, Elizabeth Brittan-Powell, Bernard Lohr, and Robert Dooling (Dept. of Psych., Univ. of Maryland, College Park, MD 20742)

Canaries have been domesticated for well over 100 years. They have been bred for specific characteristics such as song, plumage, or body shape. Here we measured audiograms in several canary strains using both behavioral (operant conditioning) and physiological (auditory brainstem responses) methods. Overall, there was a good correspondence between behavioral and ABR audiograms, but there were differences in audiogram shape and sensitivity between strains. Belgian Waterslager canaries bred for low-pitched song had elevated high frequency thresholds, while Spanish Timbrado canaries bred for high-pitched song had slightly better high frequency thresholds than canaries that were not bred for song. Other strains showed intermediate sensitivity. These results suggest there can be more variability in hearing within a species than previously thought and that these differences are correlated with other behavioral or morphological traits. 5pBB1. Monitoring changes of human airways by acoustical means. Hans Pasterkamp (Dept. of Pediatrics, Univ. of Manitoba, CS5120-840 Sherbrook St., Winnipeg, MB, Canada R3A 1S1, pasterkamp@umanitoba.ca)

The state of human airways is typically assessed by spirometry, i.e., by measuring airflow during maximum forced expiration. The required effort excludes subjects who cannot or will not perform such maneuvers. Turbulent airflow during normal breathing generates sound that can be recorded at the chest surface. Changes in airway caliber, e.g., by constriction or dilation, and concurrent changes in the tension of the airway walls affect the relation of airflow and breath sounds. This relation is complex and incompletely understood. However, the possibility to assess changes in the state of human airways by the relation of airflow and breath sounds promises an opportunity to develop auxiliary methods to spirometry. Two regions of the human airways have attracted the interest of researchers in respiratory acoustics. Breath sounds over the trachea (windpipe) increase in their airflow-specific intensity on narrowing of the upper airways, e.g., due to abnormal anatomy, infectious causes etc. Furthermore, spectral characteristics of tracheal sounds may indicate the region of abnormality. On the other hand, breath sounds over the chest change in their airflow-specific intensity with constriction of airways in the lung, e.g., due to asthma. It may therefore be possible to monitor the effectiveness of treatment by acoustical means.

5pBB2. A system to evaluate and compare transducers used for lung sound research. Steve S. Kraman, George R. Wodicka, Gary A. Pressler, and Hans Pasterkamp (Kentucky Clinic J515, Univ. of Kentucky, Lexington, KY 40536) (Purdue Univ., West Lafayette, IN 47907) (Purdue Univ., West Lafayette, IN 47907) (Univ. of Manitoba, Winnipeg, MB, Canada)

Since lung sounds were first recorded and analyzed in the 1960s, a variety of custom made or adapted transducers have been used for detecting these sounds. There is no standard lung sound transducer nor have those in use been adequately compared. To address this problem, a test platform was constructed that provides a stable and reproducible sound source coupled to a viscoelastic surface that is mechanically and acoustically similar to human skin and subcutaneous tissue as judged from comparisons with similar thicknesses of fresh meat and fat. The device was designed to be equally suitable for air-coupled microphones and for accelerometers. When driven by a broadband noise source, the acoustic amplitude at the surface of the platform was found to be relatively uniform from 100 to 1200 Hz. The system was used to evaluate a variety of lung sound transducers. They were found to vary significantly in frequency response with no device appearing to be adequate as an all-purpose lung sound sensor. It is concluded that lung sound characteristics are likely to be significantly affected by the type of sensor used to acquire the sound. This makes comparisons between differently equipped laboratories difficult.

5pBB3. Vascular sounds as an indicator of hemodialysis access patency. Hansen Mansy, Silas Hoxie, Nilesh Patel, and Richard Sandler (Rush Medical College, Chicago, IL 60607)

Background: Vascular access for renal dialysis is a lifeline for about 200 000 individuals in North America. Stethoscope auscultation of vascular sounds has some utility in the assessment of access patency, yet may be highly skill dependent. The objective of this study is to identify acoustic parameters that are related to changes in vascular access patency. Methods: Fifteen patients participated in the study. Their vascular sounds were recorded before and after angiography, which was accompanied by angioplasty in most patients. The sounds were acquired using two electronic stethoscopes and then digitized and analyzed on a personal computer. Results: Vessel stenosis changes were found to be associated with changes in acoustic amplitude and/or spectral energy distribution. Certain acoustic parameters correlated well (correlation coefficient=0.98, p less than 0.0001) with the change in the degree of stenosis, suggesting that stenosis severity may be predictable from these parameters. Parameters also appeared to be sensitive to modest diameter changes (greater than 20%), (p less than 0.005, Wilcoxon rank sum test). Conclusions: Computerized analysis of vascular sounds may have utility in vessel patency surveillance. Further testing using longitudinal studies may be warranted. 5pBB4. Computational and experimental models for sound transmission in the pulmonary system and chest to aid in medical diagnosis. Serhan Acikgoz, Thomas J. Royston, M. Bulent Ozer (Univ. of Illinois at Chicago, 842 W. Taylor St. MC 251, Chicago, IL 60607), Hansen A. Mansy, and Richard H. Sandler (Rush Univ. Medical Ctr., Chicago, IL 60612)

Acoustic wave propagation in the pulmonary system and torso is simulated by coupling a numerical acoustic boundary element model that predicts sound propagation throughout the solid tissues with a proven comprehensive analytical model for sound wave propagation in the airways of the bronchial tree that is valid up to at least 2 kHz. This approach enables modeling various pathologies that result in structural changes in the lung and/or changes in breath sound source and strength. The model may be also used to predict the resulting acoustic changes measured by acoustic sensors, e.g., stethoscopes, accelerometers, or other skin-contact sensors. Experimental studies in a novel lung phantom model are used to partially validate the computational model. This study focuses on low audible frequencies, i.e., less than 2 kHz. This range encompasses naturally generated respiratory sounds that have been shown to have diagnostic value, as well as externally-introduced vibro-acoustic stimuli used for diagnosis. [Work supported by NIH EB 003286-01.]

5pBB5. Recent developments in the characterization of anisotropic, biological media utilizing magnetic resonance elastography. Anthony J. Romano, Nicolas P. Valdivia, Philip B. Abraham, Joseph A. Bucaro (Naval Res. Lab., 4555 Overlook Ave, Washington, DC 20375-5320, romano@pa.nrl.navy.mil), Philip J. Rossman, and Richard L. Ehman (Mayo Clinic and Foundation, Rochester, MN 55905)

In this paper, we present recent developments in the characterization of anisotropic, biological media utilizing displacements measured with dynamic MRE. In one approach, a waveguide constrained analysis is applied to physical structures (such as muscle), which evaluates the velocities of wave propagation along arbitrarily oriented fibers or fiber bundles in a local fashion, utilizing a spectral filter and a sliding window, spatial Fourier transform. In a second approach, the anisotropic equations of elasticity, in variational form, are inverted for a determination of the complex moduli comprising the medium. Issues concerning ill-conditioning, the effects of boundary conditions, and multiaspect excitation requirements will be addressed, as well as a discussion concerning the models which are appropriate for various physical situations. These two complementary methods of analysis will be demonstrated utilizing both phantom as well as *in vivo* dynamic displacement measurements.

5pBB6. Local inversion of transient shear-wave propagation for elasticity and viscosity mapping in soft tissues. Jeremy Bercoff, Mickael Tanter, and Mathias Fink (Laboratoire Ondes et Acoustique, ESPCI, 10 rue Vauquelin, 75005 Paris, France)

Observation of transient shear-wave propagation in soft tissue is of great interest for the study of tissue viscoelastic properties. In previous work, we introduced a technique, called Supersonic Shear Imaging (SSI), able to generate transient shear waves using the acoustic radiation force and image their propagation in real time in soft tissues. In this work, a

local inverse problem of the shear wave propagation permitting the recovery of shear elasticity and viscosity is presented. Compressional and shear waves are decoupled by applying the curl operator to the experimental 2-D displacement field. The role of viscosity on the accuracy of the elasticity estimation is studied. The influence of out of plane shear propagation on the inversion algorithm is discussed. Finally, in media presenting shear viscoelasticity heterogeneities, finite difference simulations are used to study the spatial resolution of the algorithm and its sensitivity to the signal-to-noise ratio. Experiments on calibrated tissue-mimicking phantoms presenting different viscoelastic properties are presented validating the simulation results. First *in vivo* results on female breasts are presented.

5pNS1. Auditorium Mundi soundscape in the narration of the world. Artistic and scientific aspects in the presentation of soundscapes. Harald Brandt (Philippsbergstrasse 40, D-65195 Wiesbaden, Germany, haraldbrandt@yahoo.fr)

Auditorium Mundi is a project for the exploration and presentation of sounds and soundscapes of the whole world. The aim is an installation of a museum of audible perception in interrelation with other senses. The concept of the museum is an acoustic planetarium in which the locations of the world are put in place of the stars. Also located here are world archives for sound in which the acoustic and musical multitude of this planet will be preserved. The archives of sound are available world-wide through the internet. The museum is, at the same time, a laboratory for the development of new formats in scientific definitions and the multimedia presentation of acoustic phenomena. It is a show-place for artistic programs and an auditorium where questions from the area of acoustic as well as new developments of industry will be accessible to a wider public. A place of innovation, where concepts for other museums, promoters and scientific institutions can be developed. The leitmotif of Auditorium Mundi is the question how man influences the soundscapes in which he lives and how strongly he himself is influenced by the noise, the resonance and the dissonance between various ways of life.

5pNS2. An L_{Aeq} is not an L_{Aeq} . Dick Botteldooren, Tom De Muer, Bert De Coensel (Acoust. Group, Dept. of Information Technol., Ghent Univ., St. Pietersnieuwstraat 41, B-9000 Ghent, Belgium), Birgitta Berglund (Stockholm Univ., SE-106 91 Stockholm, Sweden), and Peter Lercher (Univ. of Innsbruck, A-6020 Innsbruck, Austria)

Classical dose response relationships for environmental noise annoyance have been based on L_{dn} or L_{den} . These exposure measures are essentially based on an energy averaging measure, L_{Aeq} . Differences between groups of sources (e.g., continuous or event based) are accounted for by using separate dose-effect relationships. In society today, one often sees that event loudness is traded for number of events which is perfectly acceptable within the L_{Aeq} based annoyance concept. Clearly a more unified theory for noise annoyance is needed to fully account for the effect of such trade-offs. In this paper a model implementing such a theory is presented. The perceptual model starts from the premises that a sound event has to be noticed for it to contribute to overall annoyance. The model accounts for the fact that noticing a noise event not only depends on the level of the event itself but also on background noise, sound insulation and acoustic characteristics of the dwelling, level of attention, etc., the severity of the effect of a noticed sound on overall annoyance is assumed to primarily depend on the signal to noise ratio. The model allows to account for modifiers such as previous exposure, noise sensitivity, and coping. The model results are compared to the findings of a recent field experiment. Conclusions based on calculated and experimental trends will be presented.

Session 5pSC

Speech Communication: Speech Production and Perception II (Poster Session)

Bryan W. Gick, Chair

*Dept. of Linguistics, Univ. of British Columbia, 1866 Main Mall E 270, Vancouver, BC V6T 1Z1, Canada**Contributed Papers*

All posters will be on display from 1:00 p.m. to 5:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 3:00 p.m. and contributors of even-numbered papers will be at their posters from 3:00 p.m. to 5:00 p.m.

5pSC1. Perceptual development of phonotactic features in Japanese infants. Ryoko Mugitani (NTT Commun. Sci. Labs., NTT Corp., 2-4 Hikari-dai, Seika-cho, Soraku-gun, Kyoto, 619-0237, Japan), Laurel Fais (Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z4), Sachiyo Kajikawa, Shigeaki Amano (NTT Corp., Seika-cho, Soraku-gun, Kyoto, 619-0237, Japan), and Janet Werker (Univ. of British Columbia, Vancouver, BC, Canada V6T 1Z4)

Acceptable phonotactics differ among languages. Japanese does not allow consonant clusters except in special contexts and this phonotactic constraint has a strong effect on adults speech perception system. When two consonants follow one another in nonsense words, adult Japanese listeners hear illusory epenthetic vowels between the consonants. The current study is aimed at investigating the influence of language-specific phonotactic rules on infants' speech perception development. Six-, 12-, and 18-month-old infants were tested on their sensitivity to phonotactic changes in words using a habituation-switch paradigm. The stimuli were three nonsense words: "keet (/ki:t/)," "keets (/ki:ts/)," and "keetsu (/ki:tsu/)." "Keetsu" perfectly follows Japanese phonotactic rules. "Keets" is also possible in devoicing contexts in fluent speech, but the acceptability of "keets" for adult native Japanese speakers is much less than "keetsu." "Keet" is phonotactically impossible as a Japanese word. The results indicate the existence of a developmental change. Twelve months and older infants detected a change from the acceptable Japanese word "keetsu" to the possible but less acceptable word "keets." However, discrimination between "keets" and the non-Japanese "keet" is seen only in 18-month infants. Implications for infants' speech perception with relation to language specific phonotactical regularities will be discussed.

5pSC2. Temporal evidence against the production of word-internal syllable structure. Melissa A. Redford (Dept. of Linguist., 1290 Univ. of Oregon, Eugene, OR 97403, redford@darkwing.uoregon.edu)

A production study examined whether the temporal pattern that cues onset cluster syllabification in English should be attributed to syllable structure per se or to coarticulatory processes that depend on segment identity and sequencing, but not on syllable structure. Experiment 1 tested for independent effects of syllable structure on intervocalic stop-liquid consonant duration. Three speakers produced stimuli in which sequence order, boundary strength, and stress were manipulated. The results showed that stimuli with word-internal sequences were produced with similar stop-liquid duration ($S:L$) ratios regardless of sequence order or stress.

When a word boundary split the consonants, $S:L$ ratios were much smaller, primarily because liquids were longer. Experiment 2 was aimed at distinguishing between alternate explanations for the pattern observed in Experiment 1. Data from three Russian speakers suggested that the English pattern was due to word-internal liquid reduction rather than to boundary lengthening. The $S:L$ ratios in Russian were not affected by sequence order or boundary strength. Further, the ratios were significantly different from the word-internal $S:L$ ratios of English, but not from the word-peripheral ones. Overall, the results argue against a causal relationship between syllable structure and articulatory timing, and for word-sized articulatory units in English.

5pSC3. Perception of coarticulated speech with contrastively enhanced spectrotemporal patterns. Travis Wade and Lori Holt (Dept. Psych., Carnegie Mellon Univ., 5000 Forbes Ave., Pittsburgh, PA 15213, twade@andrew.cmu.edu)

High-level contrastive mechanisms cause perception of auditory events to be influenced by spectral and temporal properties of surrounding acoustic context, and may play a role in perceptual compensation for coarticulation in human speech. However, it is unknown whether auditory contrast is incorporated optimally to compensate for different speakers, languages and situations or whether amplification of the processes involved would provide additional benefit, for example, in the perception of hypoarticulated speech, under adverse listening conditions, or in an incompletely acquired language. This study examines effects of artificial contrastive modification of spectrotemporal trajectories on the intelligibility of connected speech in noise by native and non-native listeners. Adopting methods known to improve automatic classification of speech sounds, we model contrast-providing context as an averaged estimated vocal tract function (LPC-derived log area ratio coefficient vector) over a Gaussian-weighted temporal window. Local coefficient values are adjusted from this context based on previously observed contrastive perceptual tendencies, and the intelligibility of the resulting speech is compared with that of unmodified trajectories across listener language backgrounds. Results are discussed with respect to implementation and applicability of general auditory processes.

5pSC4. Lip and jaw closing gesture durations in syllable final voiced and voiceless stops. Willis Warren (Univ. of Texas Dept of Linguist., Calhoun 501, 1 University Station B5100, Austin, TX 78712-0198, warisill@mail.utexas.edu) and Adam Jacks (Univ. of Texas, Austin, TX 78712)

It is generally assumed that the longer vowel durations in voiced final consonant contexts can be attributed to longer vowel steady state durations wherein the jaw remains stable for a longer period of time (see diagrams in Chen, 1970; Summers, 1987). Chen (1970) argued that the rate of closure duration was the best explanation for the vowel length effect. However, the closure durational differences he reported were very small relative to the reported differences in vowel duration with an average of 17 ms to 92 ms. Lip and jaw movements for two speakers were measured and synchronized with acoustic data in the CSD department at the University of Texas using the head-mounted lip-jaw movement transducer (HML-JMT) of Barlow *et al.* (1983). This study provides much stronger evidence for Chen's hypothesis, suggesting that there is a more dynamic arc to the jaw. While Chen (1970) gave data showing the closing gesture accounted for less than 20% of the overall difference, the data given here, shows that the duration of the closing gesture can account for 80% of the total vowel durational differences, and the remainder can be accounted for in the opening gesture and the relative timing of vocal cord cessation.

5pSC5. Assimilation context effects as cue grouping phenomena. Nicole Couture, Sarah Godbois (Dept. of Psych., Salem State College, 352 Lafayette St., Salem, MA 09170, gow@helix.mgh.harvard.edu), and David W. Gow, Jr. (Massachusetts General Hospital, Boston, MA 02114)

Listeners show bidirectional context effects in the perception of spontaneously assimilated speech. One account of these phenomena, feature cue parsing theory, suggests that both regressive and progressive context effects result from the same perceptual grouping process of aligning feature cues with assimilated word offsets and assimilating word onsets. This hypothesis was examined through two form priming experiments that explored the interpretation of spontaneously assimilated items under manipulations that either favored or disfavored the perceptual grouping of feature cues associated with assimilated and assimilating items. In both experiments, listeners heard phrases such as right berries in which a word final coronal segment (*/t/*) assimilated the non-coronal place of a subsequent word onset (labial */b/*) to form an item that sounded like one of its lexical competitors (ripe). In Experiment 1 spatial continuity was manipulated through the use of same and different side lateralized presentation of assimilated words and their contexts. In Experiment 2 continuity in speaker identity was manipulated through cross-splicing. Analyses contrasted the pattern of priming found in continuous versus non-continuous contexts. The results are discussed in the terms of competing interpretations of assimilation context effects. [Work supported by the NIH.]

5pSC6. Relationships among perceived sexual orientation, perceived height, and perceived speech clarity. Benjamin Munson and Elizabeth C. McDonald (Dept. Speech-Lang.-Hearing Sci., Univ. of Minnesota, 115 Shevlin Hall, 164 Pillsbury Dr., SE, Minneapolis, MN 55455 Munso005@umn.edu)

Previous research [B. Munson, *Linguist. Soc. Am.* (2005)] showed that listeners rate self-identified gay/lesbian/bisexual (GLB) talkers as more-GLB sounding than self-identified heterosexual talkers when listening to readings of single words in isolation. In this investigation, we examine relationships among measures of perceived sexual orientation (PSO) and two other perceptual measures made from the same talkers' speech, perceived height and perceived speech clarity. Ratings were collected from three independent groups of listeners. Regression analyses showed that approximately 80% of the variance in PSO of women's voices was predicted by measures of perceived clarity (women rated as speaking more clearly were more likely to be rated as heterosexual-sounding than women rated as speaking less clearly) and perceived height (women rated as sounding tall were more likely to be rated as GLB-sounding than women

rated to sound short). In contrast, 50% of the variance in men's sexual orientation was predicted by measures of perceived clarity (men rated as speaking more clearly were more likely to be rated as GLB-sounding than men rated as speaking less clearly). These results suggest that ratings of PSO from speech may be mediated by judgments of other parameters that are robustly coded in short samples of speech.

5pSC7. Relative contributions of feedback and editing in language production: Behavioral & articulatory evidence. Corey T. McMillan, Martin Corley (Univ. of Edinburgh, PPLS, 7 George Square, Rm. F23, Edinburgh, EH8 9JZ, UK, Corey.McMillan@ed.ac.uk), Robin J. Lickley (Queen Margaret Univ. College, Edinburgh, EH12 8TS, UK), and Robert J. Hartsuiker (Univ. of Ghent, 9000 Ghent, Belgium)

Psychologists normally attribute the surfacing of phonological speech errors to one of two factors: editing of the speech plan [Levelt (1989)] or feedback between word and phoneme levels [Dell (1986)]. This paper assesses the relative contributions of each factor, focusing on the perception and articulation of elicited speech errors. Experiments one and two measure the likelihood of phonological exchange errors as a function of phonetic similarity [Frisch (1996)], using the SLIP paradigm and a tongue-twister task. Both experiments show that error likelihood increases with phonetic similarity between intended and actual utterance, an effect easy to account for in terms of feedback but not in terms of editing. Experiment three uses EPG to analyze the tongue-twister utterances: many errors occur at the articulatory level but are not easily perceived in the speech signal. Preliminary analysis suggests three patterns of error: (1) substitution of segments, which may be the result of editing; (2) simultaneous double articulation, hypothesized to be the result of residual activation due to feedback; and (3) overlapping double articulation, representing partial execution of one articulation before substitution with another. Taking these findings together, we hope to evaluate the relative contributions of editing and feedback to phonological speech errors.

5pSC8. Acoustical study of the development of stop consonants in children. Annika K. Imbrie (Speech Commun. Group, MIT, Rm. 36-545, 77 Massachusetts Ave., Cambridge, MA 02139, imbrie@mit.edu)

This study focuses on the acoustic patterns of stop consonants and adjacent vowels as they develop in young children (ages 2;6-3;3) over a six month period. Over forty different acoustic measurements were made on each utterance, including durational, amplitude, spectral, formant, and harmonic measurements. These acoustic data are interpreted in terms of the supraglottal, laryngeal, and respiratory actions that give rise to them. Data show that some details of the child's gestures are still far from achieving the adult pattern. Significant findings include a high number of bursts in children's stop productions, possibly due to greater compliance of the active articulator. The incidence of multiple bursts decreases over the period of the study. Measurements of the burst spectra show that the production of all three places of articulation is close to normal. Finally, children's voiced stop productions display a delayed onset of voicing for all three places of articulation, indicating difficulty with coordination of closure of the glottis and release of the primary articulator. This measurement is found to decrease toward adult values over six months. Analysis of longitudinal data on young children will result in better models of the development of motor speech production. [Work supported by NIH grant DC00075.]

5pSC9. Relations between speech sensorimotor adaptation and perceptual acuity. Virgilio Villacorta, Joseph Perkell, and Frank Guenther (Res. Lab of Electron., Mass. Inst. of Tech., 50 Vassar St., Ste. 36-511, Cambridge, MA 02139)

The goal of this research is to study the auditory component of feedback control in speech production. This experiment investigates auditory sensorimotor adaptation (SA) as it relates to speech production: the pro-

cess by which speakers alter their speech production in order to compensate for perturbations of normal auditory feedback. Specifically, the first formant frequency (F_1) was shifted in the auditory feedback heard by naive adult subjects as they produced vowels in single syllable words. Results presented previously indicate that the subjects demonstrate compensatory formant shifts in their speech. The current study investigates the relationship between compensatory adaptation and speaker perceptual acuity. Subjects from the SA study were tested for their ability to discriminate vowel tokens differing in F_1 frequency. Preliminary results indicate that subjects with greater perceptual acuity also demonstrated greater ability to adapt, with a significant cross-subject correlation (p less than 0.05). The relation between these experimental findings and DIVA, a neurocomputational model of speech motor planning by the brain, will also be discussed. [Work supported by NIDCD Grant R01-DC01925.]

5pSC10. Glottal-wave and vocal-tract-area-function estimations from vowel sounds based on realistic assumptions and models. Huiqun Deng, Rabab K. Ward, Micheal P. Beddoes (Elec. and Comput. Eng. Dept., Univ. of British Columbia, Canada), Murray Hodgson, and Bryan Gick (Univ. of British Columbia, Canada)

Estimating glottal waves by inverse filtering vowel sounds and deriving vocal-tract area functions (VTAFs) from vocal-tract filter (VTF) estimates require that VTF models be realistic and that VTF estimates contain no effects of open glottises and glottal waves. In this study, VTFs are modeled to have lip reflection coefficients with low-pass frequency responses; to minimize the effects of open glottises and glottal waves on the estimates, VTFs are estimated from sustained vowel sounds over closed glottal phases, assuming that the glottal waves are periodically stationary random processes. Since incomplete glottal closures are common, VTF estimates may contain the effects of glottal loss. To eliminate the effects of glottal loss in the VTF estimates, lip-opening areas must be known. Theoretically, estimates of glottal waves and VTAFs corresponding to large-lip-opening vowel sounds are less affected by the glottal loss than those corresponding to small-lip-opening vowel sounds. The VTAFs and glottal waves estimated from vowel sounds produced by several subjects are presented. The normalized VTAFs estimated from large-lip-opening sounds are similar to that measured from an unknown subjects magnetic resonance image. Over closed glottal phases, the glottal waves are non-zero. They increase during vocal-fold colliding, and decrease or even increase during vocal-fold parting.

5pSC11. Cross-modal perception of vowels, stops, and approximants using reduced-formant stimuli. Philip Rubin (Haskins Labs., 270 Crown St., New Haven, CT 06511-6204 and Yale Univ., School of Medicine, New Haven, CT, rubin@haskins.yale.edu), Catherine Best (Haskins Labs., New Haven, CT 06511-6204), Gordon Ramsay, Stephen Frost, and Bruno Repp (Haskins Labs., New Haven, CT 06511-6204)

This paper explores the relationship between audio and video representations of speech, by examining how information in particular formants is complemented by facial information, for different classes of speech sounds. Specifically, we investigate whether acoustic information removed by deleting formant combinations that usually signal contrasts between vowels (F_1, F_2), stops (F_2) and approximants (F_3) can be replaced by optical information derived from the talking face. Simultaneous audio and video recordings were made of speakers uttering CVC nonsense syllables constructed from vowels, stops, and approximants exhibiting varying degrees of facial motion and varying dependence on individual formant cues. Synthetic stimuli were then resynthesized from combinations of one, two, and three formants using a parallel formant synthesizer. Subjects performed an auditory identification task with stimuli presented in an audio-only condition, followed by a separate block of stimuli presented in an audio-visual condition. Source effects were examined using an inverse-filtered source and a synthetic source with constant source characteristics. There were no differences between source conditions, but differences were obtained between the audio and audio+video conditions that reflect the

relationship between facial and formant dynamics. These results complement recent research on perception of reduced video information and complete audio information [L. Lachs and D. B. Pisoni, *J. Acoust. Soc. Am.* **116**, 507–518 (2004)]. [Work supported by NIH.]

5pSC12. Analysis of vowel and speaker dependencies of source harmonic magnitudes in consonant-vowel utterances. Markus Iseli, Yen-Liang Shue, and Abeer Alwan (UCLA, 405 Hilgard Ave., Los Angeles, CA 90095, iseli@ee.ucla.edu)

It is assumed that voice quality characteristics are mainly manifested in the glottal excitation signal. As [Holmberg *et al.*, *J. Speech Hear. Res.* **38**, 1212–1223 (1995)] showed, there is a correlation between low-frequency harmonic magnitudes of the glottal source spectrum and voice quality parameters. In this study, we assess the influence of vowel and speaker differences on the difference between the first and the second harmonic magnitudes, $H_1 - H_2$. The improved harmonics correction formula introduced in [Iseli *et al.*, *Proceedings of ICASSP*, Vol. 1 (2004), pp. 669–672] is used to estimate source harmonic magnitudes. $H_1 - H_2$ is estimated for consonant-vowel utterances where the vowel is one of the three vowels /a, i, u/ and the consonant is one of the six plosives in American English /b, p, d, t, g, k/. Several repetitions of each of the utterances, spoken by two male and two female talkers, are analyzed. Other measurements, such as fundamental frequency, F_0 , and energy are estimated pitch synchronously. Results are compared to current literature findings. [Work supported by NSF.]

5pSC13. Pharynx depth and tongue height in relationship to intrinsic F_0 of vowels. D. H. Whalen, Leonardo Oliveira, and Bryan Gick (Haskins Labs, 270 Crown St., New Haven, CT 06511, whalen+AEA@haskins.yale.edu)

Intrinsic F_0 (IF_0) is the tendency for high vowels to have higher F_0 s than low vowels. It is universal and apparently automatic, but the exact mechanism is still unclear. Here, ultrasound measurements of the tongue were used to determine whether vowel height is the best predictor of IF_0 . Ten native speakers of English spoke keywords for the eleven non-diphthongal vowels while the lips, jaw, and tongue were imaged with the HOCUS ultrasound/Optotrak system [D. H. Whalen *et al.*, *J. Sp. Lang. Hear. Res.* (in press)], which tracks the head and lips with optical markers while the tongue is imaged with ultrasound. The tongue edge can be extracted and rotated relative to the head, indicating changes in tongue height and pharyngeal depth. Preliminary analysis indicates that IF_0 is better correlated with the most anterior point on the tongue root (indicating pharyngeal depth) than with the highest point on the tongue. It thus seems likely that the shape of the pharynx is more of a determinant than tongue height for IF_0 . Because pharynx depth and vowel height covary in most languages (including English), the earlier description is somewhat accurate; IF_0 may be more accurately described as correlated to the tongue root.

5pSC14. Acoustically-guided articulation patterns for vowel production. Brad Story (Dept. of Speech, Lang., and Hearing Sci., Univ. of Arizona, P.O. Box 210071, Tucson, AZ 85721, bstory@u.arizona.edu)

The purpose of this study was to investigate the link between the vocal tract deformation patterns obtained from statistical analyses of articulatory data (i.e., measured area functions) and the acoustic properties of a realistic neutral vocal tract shape. The starting point was a previously reported statistical analysis (i.e., PCA) of a speaker-specific set of measured vowel area functions. It resulted in a mean area function, and two basis functions that perturb the vocal tract into vowel-like shapes. In the present study, acoustic sensitivity functions were calculated for the same mean area function. Then, four separate sum and difference combinations of the sensitivity functions were used directly to perturb the mean area function. The

results showed that these sum and difference combinations created deformation patterns with nearly the same variation along the vocal tract length as the basis functions derived from articulatory data. The procedure was then applied to other speaker-specific sets of area functions and the results were similar. [Work supported by NIH R01-DC04789.]

5pSC15. The effect of spatial frequency information in central and peripheral vision on natural gaze patterns and audiovisual speech perception. Julie N. Buchan, Amanda Wilson, Martin Paré, and Kevin G. Munhall (Queen's Univ., Kingston, ON, Canada, 2jnb@qmlink.queensu.ca)

It has been known for some time that visual information plays an important role in how we perceive speech. The present research examines how this visual information is processed in central and peripheral vision. The perception of visual images is carried out in the nervous system by a set of spatial frequency-tuned channels and the sensitivity to spatial resolution varies across the retina. The experiment was conducted using a gaze-contingent display system that records a person's eye position and then displays different information to their peripheral and central vision. The amount of high spatial frequency information presented in the central and peripheral visual fields was manipulated and the effect on both audiovisual speech perception and natural gaze patterns was measured. Preliminary results show that when peripheral information is no longer adequate, gaze patterns become altered to gather important visual information. This suggests that information across the whole visual field influences audiovisual speech behavior.

5pSC16. Perception of a Japanese moraic obstruent in an identification task. Shigeaki Amano, Ryoko Mugitani, and Tessei Kobayashi (NTT Commun. Sci. Labs., NTT Corp., 2-4 Hikari-dai, Seika-cho, Souraku-gun, Kyoto 6190237, Japan)

Native Japanese speakers perceive a moraic obstruent when the closure duration between successive moras is longer than a normal obstruent. However, it has not been well clarified how the perception of the moraic obstruent relates to the closure and neighboring moras' duration. To investigate this point, a perceptual experiment was conducted with stimuli consisting of two-mora nonsense syllables with a closure between the moras (/bipa/, /guku/, /kuku/, /kuto/, and /tapi/). The closure duration was shortened or lengthened in 10-ms steps. The duration of the first mora was modified by changing its vowel duration to 50%, 100%, and 150% by the STRAIGHT method. Forty native Japanese speakers identified whether the nonsense syllable contained a moraic obstruent with the 2AFC method. Results showed that the perceptual boundaries of the moraic obstruent were 182 ms (SD=13.2 ms), 204 ms (SD=14.7 ms), and 222 ms (SD=16.6 ms), respectively, with 50%, 100%, and 150% vowel durations in the first mora, and that a logistic function fits the identification ratio very well. The results indicated that the perception of a moraic obstruent depends on both closure duration and the duration of neighboring moras. They also suggest that the perception would be categorical.

5pSC17. Nasals and nasalization: The interplay between segmental duration and coarticulation. Samantha E. Sefton and Patrice S. Beddor (Dept. of Linguist., Univ. of Michigan, 4080 Frieze Bldg., Ann Arbor, MI 48109, beddor@umich.edu)

Two experiments were conducted on English to test the hypothesis that the temporal extent of coarticulatory nasalization is inversely related to the duration of the source of coarticulation. Experiment 1 investigated patterns of carryover (NVC) and anticipatory (CVN) vowel nasalization, and the overall timing of nasalization across the syllable. Acoustic analysis of CVN and NVC words (e.g., seen/niece, pin/nip, tame/mate, ten/net) produced by five speakers showed that, although vowel nasalization is temporally more extensive in CVN than in NVC sequences, *N* is shorter in CVN than in NVC, so that there was no significant overall difference in

total nasalization between the two syllable types. Experiment 2 tested similar timing patterns in CVNC syllables, where *N* duration varied as a function of the voicing of the following *C* (e.g., wince/wins, sent/send, can't/canned). Acoustic measures of productions of five English speakers again showed that the shorter the *N*, the temporally more extensive the vowel nasalization. Findings for selected other languages (Thai, Italian) provide further evidence of the inverse relation. These findings have implications for theories of coarticulation and theories of phonological change. [Work supported by NSF.]

5pSC18. Perception of a Japanese moraic obstruent in a discrimination task. Tessei Kobayashi, Ryoko Mugitani, and Shigeaki Amano (NTT Commun. Sci. Labs., NTT Corp., 2-4, Hikaridai, Seika-cho, Soraku-gun, Kyoto, Japan 619-0237)

Previous research with an identification task suggests that native Japanese speakers perceive a moraic obstruent categorically (Amano et al., 2005). However, it is still unclear whether the suggestion would be confirmed by other tasks. This study used an AX discrimination task to investigate whether the performance is highly sensitive around the perceptual boundaries that were obtained from the identification task. Native Japanese speakers (*N*=40) were presented with a pair of two-mora nonsense syllables (/bipa/, /guku/, /kuku/, /kuto/) and then required to judge whether the stimulus pair was acoustically identical. The stimulus set was produced by reducing or increasing the closure duration between the successive moras in 5-ms steps (-95 to 240 ms). Results showed that the participants discriminated more precisely around closures duration ranging from approximately 150 to 180 ms (/bipa/: 180 ms, /guku/: 160 ms, /kuku/: 155 ms, /kuto/: 175 ms). Although the results indicate, to some degree, the possibility of perceptual categorization of the moraic obstruent, the high sensitivity peak in each stimulus type was slightly shifted from the perceptual boundaries in the identification task.

5pSC19. Intrinsic factors of releasing motions in an articulator: On assuming segmental input in speech-production models. Victor J. Boucher (Univ. of Montreal, C.P. 6128 succ. Centre-ville, Montreal, QC, Canada J3C 3J7)

Prominent models of speech production use serial input that is assumed to be commensurate with linguistic segments. The view is that such units underlie a serial activation of aperture motions such as closing and opening motions of the lips in articulating a bilabial stop. This is incompatible with conventional EMG observations showing a single burst of activity of labial adductors at the onset of a close-open cycle. The present study examines the spring-like effects of bilabial compression and pressure on labial opening (release) following a relaxation of the orbicularis oris muscle. Using reiterative series [papapapa] produced at increasing intensities, the range and velocity of opening motions of the lower-lip were correlated with lip compression and oral-pressure. The results for three speakers show that pressure and compression are correlated and that these factors account for 45% to 66% of the variance in velocity of lower-lip opening, and for 47% to 73% of the variance in the range of lower-lip opening. These results complement earlier findings of Abbs and Eilenberg (1976) showing the intrinsic effects of muscle elasticity on opening motions of the lips. Close-open cycles in articulators may not reflect segment-by-segment serial activation.

5pSC20. Kinematic properties of stop and fricative production. Anders Lofqvist (Haskins Labs., 270 Crown St., New Haven, CT 06511, lofquist@haskins.yale.edu)

This study examined movement kinematics in stop and fricative consonants, looking for potential evidence of different movement characteristics related to precision requirements. It has often been claimed that fricatives require more precision in their production than stops due to the management of airflow. However, the empirical evidence for this claim is

very limited and mostly based on different developmental trends. Tongue movements were recorded using a magnetometer system. Speed and movement paths were used to examine movement kinematics, including different measures of stiffness. Preliminary results do not show any consistent pattern across subjects, although some subjects did have systematic differences in movement stiffness with stop consonants having stiffer movements than fricatives. These results most likely reflect that fact that speech is an over learned skill, so that any differences related to precision are very small, or nonexistent, in adults, and probably only apparent in the early stages of speech development. [Work supported by NIH.]

5pSC21. Haptic information enhances auditory speech perception.

Kristin M. Johannsdottir, Diana Gibrail, Gick Bryan, Ikegami Yoko (Dept. of Linguist., Univ. of British Columbia, Canada), and Jeff Muehlbauer (Univ. of British Columbia, Canada)

Studies of tactile enhancement effects on auditory speech perception [Reed *et al.*, JSHR, 1978, 1982, 1989] have traditionally used experienced, pre-trained subjects. These studies have left unanswered the basic questions of whether tactile enhancement of speech is a basic component of human speech perception or a learned association [Fowler, JPhon, 1986; Diehl and Kluender, *Ecol. Psych.*, 1989], and which aspects of the signal are enhanced through this modality. The present study focuses exclusively on tactile enhancement effects available to naive speakers. In a speech-masked environment, naive subjects were tasked with identifying consonants using the Tadoma method. Half of the stimuli were presented with tactile input, and half without. The results show that all subjects gained considerably from tactile information, although which part of the tactile signal was most helpful varied by subject. The features that contributed most to consonant identification were aspiration and voicing. [Work supported by NSERC.]

5pSC22. Categorization of spectrally complex non-invariant auditory stimuli in a computer game task.

Lori Holt and Travis Wade (Dept. Psych., Carnegie Mellon Univ., 5000 Forbes Ave., Pittsburgh, PA 15213, twade@andrew.cmu.edu)

This study examined perceptual learning of spectrally complex non-speech auditory categories in an interactive multi-modal training paradigm. Participants played a computer game in which they navigated through a three-dimensional space while responding to animated characters encountered along the way. Characters appearances in the game correlated with distinctive sound category distributions, exemplars of which repeated each time the characters were encountered. As the game progressed, the speed and difficulty of required tasks increased and characters became harder to identify visually, so quick identification of approaching characters by sound patterns was, although never required or encouraged, of gradually increasing benefit. After thirty minutes of play, participants performed a categorization task, matching sounds to characters. Despite not being informed of audio-visual correlations, participants exhibited reliable learning of these patterns at post-test. Categorization accuracy was related to several measures of game performance and category learning was sensitive to category distribution differences modeling acoustic structures of speech categories. Category knowledge resulting from the game was qualitatively different from that gained from an explicit unsupervised categorization task involving the same stimuli. Results are discussed with respect to information sources and mechanisms involved in acquiring complex, context-dependent auditory categories, including phonetic categories, and to multi-modal statistical learning.

5pSC23. Acoustic correlates of non-modal phonation in telephone speech. Tae-Jin Yoon (Dept. of Linguist., Univ. of Illinois, 4080 FLB, 707 S. Mathews Ave., MC-168, Urbana, IL 61801, tyoon@uiuc.edu), Jennifer Cole, Mark Hasegawa-Johnson, and Chilin Shih (Univ. of Illinois, Urbana, IL 61801)

Non-modal phonation conveys both linguistic and paralinguistic information, and is distinguished by acoustic source and filter features. Detecting non-modal phonation in speech requires reliable F_0 analysis, a problem for telephone-band speech, where F_0 analysis frequently fails. An approach is demonstrated to the detection of creaky phonation in telephone speech based on robust F_0 and spectral analysis. The F_0 analysis relies on an autocorrelation algorithm applied to the inverse-filtered speech signal and succeeds in regions of non-modal phonation where the non-filtered F_0 analysis typically fails. In addition to the extracted F_0 values, spectral amplitude is measured at the first two harmonics (H_1 , H_2) and the first three formants (A_1 , A_2 , A_3). F_0 and spectral tilt are measured from 300 samples of modal and creaky voice vowels, selected from Switchboard telephone speech using auditory and visual criteria. Results show successful F_0 detection in creaky voice regions, with distinctive low F_0 , and statistically significant differences between modal and creaky voice in measures of spectral amplitude, especially for measures based on H_1 . Our current work develops methods for the automatic detection of creaky voicing in spontaneous speech based on the analysis technique shown here. [Work supported by NSF.]

5pSC24. A consonant-vowel-consonant display as a computer-based articulation training aid for the hearing impaired.

Fansheng Meng, Eugen Rodel, and Stephen Zahorian (Dept. of Elec. and Comput. Eng., Old Dominion Univ., Norfolk, VA 23529)

Computer-based visual speech training aids are potentially useful feedback tools for hearing impaired people. In this paper, a training aid for the articulation of short Consonant-Vowel-Consonant (CVC) words is presented using an integrated real-time display of phonetic content and loudness. Although not yet extensively tested with hearing-impaired listeners, real-time signal processing has been developed, flow-mode displays have been developed, and accuracy tests have been completed with a large database of CVC short words. A combination of Hidden Markov Models and time-delay neural networks are used as the primary method for the acoustic-phonetic transformations used in the display. [Work partially supported by NSF grant BES-9977260.]

5pSC25. Stop consonant perception in silent-center syllables.

Mark DeRuiter (Univ. of Minnesota, 164 Pillsbury Dr. S.E., 115 Shevlin Hall, Minneapolis, MN 55455), Virginia S. Ramachandran, and Sheryl J. Rosen (Wayne State Univ., Detroit, MI 48202)

Silent-center (SC) syllables are consonant-vowel-consonant syllables with the steady-state vowel portion excised from them. These syllables are appealing for research of stop-consonants because they retain the complexity, brevity, and rapid changes inherent in formant transitions while presumably eliminating temporal masking by the vowel. However, questions exist as to whether or not SC syllables are processed in the same manner as their full-vowel (FV) counterparts (i.e. are they processed as speech units or as sounds?). Data is reviewed from a series of experiments which examined listeners discrimination, labeling, and response time for synthesized consonant-vowel-consonant syllables in FV and SC conditions. Results from 3 experiments with typical listeners reveal that: (1) discrimination is significantly better in the SC condition; (2) consonant labeling on a /bab/ to /dad/ continuum is poorer in the SC condition and is significantly poorer at the category boundary; (3) discrimination response-time (RT) is significantly shorter in the SC condition. Labeling and discrimination results reveal that listeners processed the stop-consonants in these SC syllables in a less-categorical manner than in the FV syllables. Taken together with significantly different response-times, these results may indicate that listeners utilize a different mode of processing for SC syllables.

5pSC26. Voice *F0* responses elicited by perturbations in pitch of auditory feedback during English speech and sustained vowels. Jay J. Bauer (Dept. of Commun. Sci. & Disord., Univ. of Wisconsin–Milwaukee, P.O. Box 413, Milwaukee, WI 53201, jbauer@uwm.edu) and Charles R. Larson (Northwestern Univ., Evanston, IL 60208)

Twenty-one native speakers of American English were asked to repeatedly inflect the pitch of either the first or second syllable of an English speech phrase or produce non-word sustained vowels while listening to amplified auditory feedback. Brief upward and downward perturbations in pitch of auditory feedback were introduced in real time shortly after vocal onset. Resultant changes in voice *F0* due to perturbations in pitch were compared across vocal conditions and perturbation direction. Data indicated that auditory feedback was used in real-time to stabilize voice *F0* during both normal English speech and sustained vowels. Incomplete compensatory corrections in voice *F0* due to the perturbations in pitch of auditory feedback were prevalent during both dynamic speech (gain: ~12.7%) and static sustained vowel phonations (gain: ~19.3%), and appear to be regulated by similar corrective mechanisms. However during dynamic speech, voice *F0* was modulated across syllable boundaries in a task-dependent manner according to syllable pitch inflection. Thus, voice *F0* responses appear to help maintain the underlying suprasegmental meaning of a speech phrase by delaying the onset of the voice *F0* response to coincide with the pitch-inflected syllable. [Work supported by NIH Grant No. F31 DC005874.]

5pSC27. The perception of speech rhythm: An investigation of inter and intra rhythmic class variability using delexicalized stimuli. Volker Dellwo (Dept. of Phonet. and Linguist., University College London, 4 Stephenson Way, London NW1 2HE, UK) and Petra Wagner (Universitaet Bonn, D-53115 Bonn, Germany)

It has been demonstrated that stress- and syllable-timed languages are differentiable in terms of parameters based on vocalic and consonantal interval durations, and that stress-timed languages are more variable in terms of these parameters. There is also significant between- and within-subject variability on these parameters, but it is unclear whether this production variability is perceptually salient in terms of rhythm. This issue was investigated in a series of experiments using delexicalized stimuli, in which the vocalic intervals were substituted by sinusoidal tones and the consonantal intervals by white noise. Subjects were asked to classify the stimuli according to the regularity of the tone sequences. The results thus far indicate that intra rhythm class variation, as measured by consonantal and vocalic interval duration variation, can be well perceived.

5pSC28. Palato-lingual contact patterns during Korean obstruent production; lax, aspirated and forced. Hirohide Yoshioka and Kim Soone (Inst. of Human Sci., Univ. of Tsukuba, Japan)

In Korean obstruents, there is a three-way distinction in manner of articulation; lax, aspirated and forced. The present study is to investigate the temporal and spatial details of tongue contacts with the hard palate during these three types of consonant production. The subject, a 30-year-old female of the Seoul dialect was instructed to read a set of various words beginning with these consonants, embedded in a frame sentence i-geo-/Cal/-ita (C=consonant). The palato-lingual contact patterns were recorded using dynamic electro-palatography. The results show that the area and duration of the palato-lingual contact are clearly different among these three types of consonants. As for stops, the palato-lingual contact is wider and longer in the forced stop production. In the affricate production, the patterns of the maximum contact area and the duration are as follows: wide and long in the forced type, middle in the aspirated, and narrow and short in the lax. These data strongly suggest that the temporal and spatial details of the palato-lingual contact may play an important role in manifesting the Korean three-way distinction, together with other articulatory adjustments, such as laryngeal and respiratory controls.

5pSC29. Vowel production and perception in French blind and sighted adults. Sophie Dupont and Lucie Menard (Universite du Province Quebec a Montreal, Departement de linguistique, CP 8888, succ. Centre-Ville, Montreal, Canada H3C 3P8, menard.lucie@uqam.ca)

It is well known that visual cues play an important role in speech perception and production. Early in life, blind speakers, who do not have access to visual information related to lip and jaw movements, show a delay in the acquisition of phonological contrasts based on these visible articulatory features [A. E. Mills, *Hearing by eye: The psychology of lip-reading*, pp. 145–161 (1987)]. It has also been claimed that blind speakers have better auditory discrimination abilities than sighted speakers. The goal of this study is to describe the production-perception relationships involved in French vowels for blind and sighted speakers. Six blind adults and six sighted adults served as subjects. The auditory abilities of each subject were evaluated by auditory discrimination tests (AXB). At the production level, ten repetitions of the ten French oral vowels were recorded. Formant values and fundamental frequency values were extracted from the acoustic signal. Measures of contrasts (Euclidean distances) and dispersion (standard deviations) were computed and compared for each feature (height, place, roundedness) and group (blind, sighted). Regression analyses between discrimination scores and produced contrasts were carried out. Despite between-speaker variability, results show an effect of speakers group (blind versus sighted) on the produced contrast distances.

5pSC30. The role of intonational phrasing in the elicitation of speech errors. Marianne Pouplier (TAAL, Univ. of Edinburgh, UK and Haskins Labs, New Haven, CT, pouplier@ling.ed.ac.uk), Mark Tiede (Haskins Labs, New Haven, CT), Stefanie Shattuck-Hufnagel (MIT R.L.E., Cambridge, MA), Man Gao, and Louis Goldstein (Yale Univ., New Haven, CT)

Recent work has proposed that some speech errors arise from an underlying coordination process in speech production in which gestures can assume grammatically illegal but dynamically stable coordination modes. The general premise is that shared gestural structure within a prosodic domain sets up the conditions under which stable coordination modes spontaneously emerge and produce errors. If certain gestures (e.g., coda consonants) recur every word but others recur less frequently (e.g., alternating initial consonants), the lower frequency gestures will increase in occurrence, resulting in gestural intrusion errors. This suggests that manipulation of the rhythmic domain through intonational phrasing should determine error patterns differentially. Since the gestural coupling which lies at the heart of the rhythmic synchronization approach takes time to establish, it is predicted that continuous repetitions of e.g. “cop tap tube cub” will lead to a maximum buildup of coupling strength and thus the most errors. If however phrasal grouping is imposed, as in “cop tap, tube cub,” fewer errors are hypothesized to occur. We test these predictions by having subjects repeat the same word string in different prosodic grouping conditions. Our initial results confirm that the more alternating consonants an intonational phrase contains, the more errors occur.

5pSC31. Effect of aspiration noise and spectral slope on perceived breathiness in vowels. Rahul Shrivastav and Maria Pinero (Dept. of Comm. Sci. & Disord., Univ. of Florida, 336 Dauer Hall, Gainesville, FL 32611)

Breathy voice quality is frequently encountered in both normal and dysphonic voices. Breathiness has been associated with an increase in the intensity of aspiration noise as well as changes in spectral slope [Childers and Ahn, 1995; Fischer-Jorgenson, 1967; Huffman, 1987; Klatt and Klatt, 1990]. Shrivastav and Sapienza (2003) found that subjective ratings of breathiness obtained from a group of listeners were highly correlated with certain measures calculated from the auditory spectrum of the vocal acoustic signal. One of these measures, the partial loudness of the harmonic energy, was related to both the aspiration noise and the spectral slope of the voices. In the present experiment, 10 young adult listeners with normal

hearing were presented with voices that varied systematically in terms of their aspiration noise and spectral slope. The stimuli, five male and five female voices, were generated using the Klatt synthesizer and were modeled after naturally occurring voices. Listeners rated breathiness for each of these stimuli using a 7-point rating scale. Results show the relative contribution of spectral slope and aspiration noise to the perception of breathiness.

5pSC32. Intensity variation in vowels across acoustic and auditory spectra. Ewa Jacewicz and Robert Allen Fox (Dept. of Speech and Hearing Sci., The Ohio State Univ., Columbus, OH 43210, jacewicz.1@osu.edu)

Changes to vowel intensity are affected primarily by an increased physiological effort of the speaker. A second source of intensity variation comes from immediate consonant environment of the vowel as a result of coarticulation [House & Fairbanks, *J. Acoust. Soc. Am.* **22**, 105–113 (1953)]. Variation in intensity distribution across the vowel spectrum was measured for eight American English vowels in ten symmetrical CVC environments (consonants included both stops and fricatives) at four different locations (at the vowels rms peak and at points corresponding to 20%, 50%, and 80% of the vowels duration). Three types of spectral intensity distribution were examined: (1) the relative amplitudes of formants $F1$ - $F4$; (2) the summed intensity in four contiguous frequency bands of 0–0.5, 0.5–1.0, 1.0–2.0 and 2.0–4.0 kHz [Sluijter and Van Heuven, *J. Acoust. Soc. Am.* **100**, 2471–2485 (1996)]; and (3) the intensity distribution following three stages of auditory processing (using an auditory filter bank consisting of 33 filters, equal loudness pre-emphasis, and intensity-loudness compression). The nature and size of the effects of spectral intensity variation as a function of consonant environment in the acoustic spectrum (formants) and in auditory pre-processing of the acoustic spectrum will be compared. [Work supported by NIDCD R03 DC005560-01.]

5pSC33. Voice onset time is shorter in high-frequency words. Mark VanDam and Robert Port (Dept. of Linguist., Indiana Univ, Bloomington, IN 47405)

Frequency of occurrence is known to have many effects on speech production [see J. Bybee, *Phonology and Language Use* (Cambridge, 2001)] including vowel quality, overall duration, rate of deletion, assimilation, coarticulation, etc. The current work addresses voice-onset time (VOT) in words with differing lexical frequency estimates from published materials and addresses whether words in a list exhibit similar effects to words in sentential context. Four talkers produced 20 low frequency words and 10 high frequency words four times each in isolation and again in non-idiomatic, sentential context. VOT was measured in monosyllabic content words with initial /t/. Results show that frequent words (e.g., *talk*, *table*) have a mean VOT roughly 10 ms shorter than less frequent words (e.g., *tal*, *taint*) ($p < 0.01$). The effect was significantly stronger for words in a sentence (e.g., *He will talk to his supervisor*) than in a list. These findings are consistent with linguistic theories that propose detailed auditory representations for words and finely controlled productions, but are in conflict with traditional, abstract phonological representations.

5pSC34. Tension asymmetries in a finite element model of the vocal folds. Greg S. Davidson (Univ. of Chicago, Chicago, IL 60637) and Fariborz Alipour (Univ. of Iowa, Iowa City, IA 52242)

Tension asymmetries in a finite element model of the vocal folds were examined as a function of lung pressure. The vocal fold model had an asymmetry in the tension ratio ranging from 1.1 to 2.0, corresponding to a 10%–100% increase in tension of the left fold compared to the right, and

lung pressure was increased over the range 5–40 cm H₂O. For tension ratios greater than 1.6, oscillation was not supported over most of this range. For tension ratios less than 1.6, the fundamental frequency was found to increase up to approximately 22 cm H₂O. Mean vocal fold contact area showed a broad maximum over the range 8–13 cm H₂O and decreased between 13 and 22–25 cm H₂O. Open quotient decreased between 7.5 and 13–15 cm H₂O and increased afterwards to reach a maximum value between 20 and 23 cm H₂O. For these three parameters, the behavior above the upper thresholds was tension ratio dependent. Mean glottal area linearly increased with lung pressure with differing slopes over different pressure ranges. Taken together, the four parameters provide evidence for different vibratory domains. [Work supported by NIDCD grant No. DC03566.]

5pSC35. Not just any contour: Intonation marking semantic domain narrowing. Karsten A. Koch (Univ. of British Columbia, Vancouver, BC, Canada)

Not just any statements (*Natalie won't drink just ANY wine from France*) carry an intonational contour. Previous studies have characterized the contour as fall-rise [D. Robert Ladd, *The structure of intonational meaning* (1980)], but more intricate acoustic analysis that considers the semantics of the construction has not been performed. Preliminary data shows that for speakers of Canadian English, the contour contains a rise-fall and stress accent on *any*, followed by a rise on the sentence-final syllable. If the stressed rise-fall on *any* indicates a topic accent, then the meaning of the construction can be calculated semantically: the presence of the topic accent indicates a disputable topic (in this case, Which wines will Natalie drink?) [following Daniel Buring, *Linguistics and Philosophy* **20**, 175–194 (1997) for German]. This operation narrows the domain of *any wine* from all wine from France to some smaller amount perhaps Natalie only drinks expensive cabernets. Furthermore, the same intonational contour occurs in other quantificational statements, like *ALL gamblers aren't addicted*. Here, the disputable topic is: How many gamblers are addicted? Again, the intonation serves to narrow the domain to a subset of all the gamblers. Thus, documenting this intonational contour identifies a more general semantic process.

5pSC36. The role of stress accent in the understanding of sentences in noise. Pierre Divenyi and Alex Brandmeyer (Speech and Hearing Res., VA Medical Ctr., 150 Muir Rd., Martinez, CA 94553)

When a target sentence is presented in noise, the stressed syllables therein will constitute epochs with a high likelihood of S/N increase. Since in spontaneous speech stressed syllables have significantly higher information content than unstressed syllables [S. Greenberg *et al.*, in *Proc. 2d Intern. Conf. Human Lang. Technol. Res.* (2002), pp. 36–43], it follows that masking the stressed syllables will negatively impact the perception of neighboring unstressed syllables. This hypothesis was tested by varying the S/N of only the stressed syllables in sentences embedded in otherwise unmodulated speech-spectrum noise. Results suggest that, compared to conditions with absent or decreased-S/N stressed syllables, increasing the S/N during stressed syllables increases intelligibility of the unstressed syllable or syllables that follow. Since the unstressed syllables are rarely masked in the classic, energetic sense, the phenomenon reported constitutes an instance of informational masking. The masking can affect perception at the phonemic as well as on higher linguistic levels, depending on the information provided by sentence context.

5pUW1. An autonomous underwater vehicle towed hydrophone array for ocean acoustic measurements. Jason D. Holmes, William M. Carey (Boston Univ., Boston, MA 02215), James F. Lynch, Arthur E. Newhall, and Amy Kukulya (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

An autonomous underwater vehicle (AUV) with a towed hydrophone array (THA) can provide the capability of mobile-single-ship operation for both short-range single path and long range synthetic aperture experiments. A low noise towed array for an AUV (REMUS) has been developed to demonstrate the feasibility and utility of such measurements. Previous measurements of AUV radiated noise indicated levels that would limit measurements by hull arrays providing a rationale for a THA. A small-diameter fluid-filled prototype hydrophone array was developed and tested to ensure adequate sensitivity and system noise levels. The digital recording system (DRS) consisted of mini-disc recorders with a band width of 20 kHz housed in a tube attached to the AUV. This combined system (REMUS, DRS, and THA) was used to conduct a proof of concept test in Dodge Pond. This paper presents the results that show, in the Sea State 0 noise field of Dodge Pond, array system self noise was less than the ambient and vehicle noise was manageable. The test included three pingers and a beacon sound source. The acoustic results were at a high signal-to-noise ratio and show the array tow stability and coherent processing capability. [Work supported by Boston University, Woods Hole, and ONR.]

5pUW2. Response pattern control in spite of failed array elements. Henry Cox and Hung Lai (Lockheed Martin Orincon, 4350 North Fairfax Dr., Ste. 470, Arlington, VA 22203)

Large arrays of many elements usually are shaded to achieve low sidelobes. However, in practice these arrays typically operate with some element failures that significantly degrade sidelobe performance. First, the effects of different numbers of failed elements on sidelobe levels are analyzed and illustrated with simulations. Statistics and bounds for sidelobe levels with failed elements are presented. The inability and limitations of conventional shading modifications to compensate for failed elements is discussed and illustrated. Missing elements give rise to large inter-element spacings that in turn result in grating effects that cannot be compensated for using modified shading weights. An adaptive compensation approach for failed elements is then presented. This involves narrowband interpolation from nearby elements to estimate the missing data prior to applying the original shading weights. Failures of both isolated and neighboring elements are considered. When there is a strong source present it is relatively easy to estimate its value on missing elements. But this is exactly the case of interest, when sidelobe levels are important. The adaptive interpolation approach provides good bearing response patterns so that strong signals are well isolated in bearing. Results are illustrated with large array simulations with different failure patterns and multiple strong sources.

5pUW3. Underwater acoustic measurements with the Liberdade/X-Ray flying wing glider. Gerald L. D'Spain, Scott A. Jenkins, Richard Zimmerman (Marine Physical Lab., Scripps Inst. of Oceanogr., La Jolla, CA 93940-0701), James C. Luby (Univ. of Washington, Seattle, WA 98105), and Aaron M. Thode (Scripps Inst. of Oceanogr., La Jolla, CA 93940-0701)

An underwater glider based on a flying wing design (Jenkins *et al.*, 2003) presently is under development by the Marine Physical Laboratory, Scripps Institution of Oceanography and the Applied Physics Laboratory, University of Washington. This design maximizes the horizontal distance between changes in buoyancy to minimize mechanical power consumed in horizontal transport. The prototype wing has a 6.1 m wing span and is 20 times larger by volume than existing gliders. Initial at-sea tests indicate that the lift-to-drag ratio is 17/1 at a horizontal speed of about 1.8 m/s for a 38-liter buoyancy engine. Beamforming results using recordings of the radiated noise from the deployment ship by two hydrophones mounted on the wing verify aspects of the prototype wing flight characteristics. The payload on the new glider will include a low-power, 32-element hydrophone array placed along the leading edge of the wing for large physical aperture at midfrequencies (above 1 kHz) and a 4-component vector sensor. Data previously collected by these types of arrays illustrate the performance of narrow-band detection and localization algorithms. Flight behaviors are being developed to maximize the arrays' detection and localization capabilities. [Work sponsored by the Office of Naval Research.]

5pUW4. Adaptive rapid environmental assessment simulation framework. Ding Wang and Henrik Schmidt (Acoust. Lab, Ocean Eng. Dept., MIT, 77 Mass Ave 5-435, Cambridge, MA 02139, prolog@mit.edu)

The coastal environment is characterized by variability on small spatial scales and short temporal scales. These environmental uncertainties translate—in a highly non-linear fashion—into uncertain acoustic propagation properties, often severely affecting the sonar performance prediction capabilities. Conventional oceanographic measurement systems cannot capture these environmental uncertainties due to their limited predictability and the lack of mobility of the traditional measurement platforms. Taking advantage of the mobility of modern autonomous underwater vehicle technology, the Adaptive Rapid Environmental Assessment (AREA) concept has been developed to optimally use the available resources to capture the acoustic uncertainty by adaptive and rapid *in situ* measurement of the environmental properties most significant to the actual sonar system. The ocean area of interest is usually fairly large, and the *in situ* measurement resources are limited, and the adaptive sampling strategy in AREA can therefore make a significant difference in capturing and mitigating the sonar performance uncertainties. To determine an optimal or sub-optimal sampling strategy and test the optimization effect before doing costly on-site experiments, an Adaptive Rapid Environmental Assessment Simulation Framework (AREASF) has been developed, based on state-of-the-art forecasting frameworks and acoustic propagation models. The simulation framework has been applied to investigate the performance of AREA under different environmental conditions, and based on these

results, the feasibility of performing real-time adaptive environmental assessment using AREA under realistic ocean conditions will be discussed. [Work supported by ONR.]

5pUW5. Optimizing multistatic sonobuoy placement. Donald R. DelBalzo, Erik R. Rike, and David N. McNeal (Neptune Sci. Div. of Planning Systems, Inc., 40201 Hwy 190 E, Slidell, LA 70461, delbalzo@neptunesci.com)

Sonobuoy patterns for monostatic sensors were developed during the Cold War for deep, uniform underwater environments, where a simple median detection range defined a fixed inter-buoy spacing (usually along staggered lines). Oceanographic and acoustic conditions in littoral environments are so complex and dynamic that spatial and temporal variability of low-frequency signal and noise fields destroys the basic homogeneous assumption associated with standard tactical search concepts. Genetic Algorithms (GAs) have been applied to this problem to produce near-optimal, non-standard search tracks for monostatic mobile sensors that maximize probability of detection in such inhomogeneous environments. The present work describes a new capability, SCOUT (Sensor Coordination for Optimal Utilization and Tactics), to simulate multistatic distributed-sensor geometries and to optimize the locations of multistatic active sonobuoys in a complex, littoral environment. This presentation reviews the GA approach, discusses the new chromosome structure, and introduces a new target-centric geometry. The results show that (a) standard patterns are not optimal even for a homogeneous environment, (b) small distributed sensor clusters are preferred, and (c) standard patterns are grossly ineffective in inhomogeneous environments where 20% improvements in detection are achieved with SCOUT. 5pUW6. Acoustic particle velocity and intensity calculations from tri-axial pressure gradient measurements. Melanie E. Austin and Alex O. MacGillivray (JASCO Res. Ltd., 2101-4464 Markham St., Victoria, BC, Canada V8Z 7X8, melanie@jasco.com)

In July 2004 Fisheries and Oceans Canada supported a study to investigate effects of seismic airgun signals on hearing organs of freshwater fish

in the Mackenzie River at Inuvik, NWT Canada. The study required particle velocity measurements for correlation with observed biological effects. JASCO Research built a pressure gradient measurement apparatus consisting of four hydrophones mounted at the vertices of a triangular-pyramid frame. The system was used to measure differential pressure from the airgun events simultaneously in three perpendicular axial directions. An attached depth-compass sensor monitored the depth and orientation of the system. Hydrophone separations were chosen to be small relative to the acoustic wavelength so that measured differential pressures correctly approximated the pressure gradients along each axis. Particle accelerations were computed directly from pressure gradients following Euler's linearized momentum equation, and particle velocities were computed by integrating particle accelerations. Acoustic intensity was computed from the product of acoustic pressure and particle velocity. The hydrophone precision imposed a limit on accuracy of particle velocity measurements at low frequencies. Likewise the fixed hydrophone spacings defined an upper frequency limit for applicability of this method.

5pUW7. Macroscopic sonic crystals in a wave guide. Dalcio K. Dacol, Gregory J. Orris, and David C. Calvo (Acoust. Div. Naval Res. Lab., Washington, DC 20375-5350)

Periodical arrays of long, parallel cylinders have been shown in the published literature to exhibit acoustical properties which are analogous to the electronic properties of certain crystalline solids. Thus there are frequency bands for which no acoustic propagation through the array is allowed, with those band gaps being directionally dependent. The properties of such arrays in wave guides are examined in this work. Particular emphasis is put in investigating the properties of those arrays in wave guides that are idealized models of shallow water oceanic wave guides. The effects of those arrays on the propagation of normal modes is investigated in detail. The possibility of using such arrays in the construction of large scale underwater devices such as filters and lenses is also discussed. [Work supported by ONR.]
